Minimally invasive techniques including video-assisted thoracoscopic (VATS) thymectomy and robotic thymectomy have come to enter use over the last decade. Video-assisted techniques are generally accepted for benign conditions of the thymus, but their appropriateness in oncologic settings is a matter of active investigation. A Japanese center reported on using this procedure to treat 35 patients with clinical stage I thymoma from 1998 to 2009.[186] The authors reported the technique to be safe, with no perioperative deaths and three minor complications. Disease in 20 of the 35 patients was upstaged to Masaoka stage II or III at the time of surgery. At an average follow-up time of 65 months, one patient had experienced recurrence in the bilateral lung.[186] Similarly, a Polish group reported on 24 patients operated on for thymoma with VATS, which resulted in no operative mortality and one bleeding complication.[187] Finally, a Chinese center reported on comparative outcomes between 15 early-stage thymoma patients with myasthenia gravis treated with VATS and 18 patients treated with transsternal technique. The VATS patients achieved similar perioperative morbidity and significantly better oncologic outcomes, although the authors noted that selection bias may have influenced the latter finding as the open sternotomy patients had, on average, more advanced

tumors.[188]

Despite this promising safety profile, it is an open question whether the oncologic outcomes will be the same as open procedures. Kimura et al. compared 45 early-stage thymoma patients who underwent VATS thymectomy with 29 patients who underwent open sternotomy.[189] They noted that all three cases of pleural recurrence occurred in the VATS group. Their conclusion was that VATS was oncologically feasible but that the technique should be favored for patients for whom en bloc resection is possible; special caution should be exercised for large or cystic tumors, for which the risk of capsular injury and tumor spillage is high.

Robotic surgical techniques have also become an accepted approach at specialized centers. The potential advantages of robotic techniques include increased rates of preserved pulmonary function, improved cosmesis, and higher rates of patient compliance because of the minimally invasive nature of the surgery.[190] The improved visualization and versatility of the robotic technique may allow for increased radicality of thymectomies by allowing surgeons to achieve resections in challenging anatomies such as patients with tumor located between the aorta and innominate vein or in those with encasement of the left phrenic nerve.[191]

Several institutions have explored the use of robotics in thymectomy, and a few studies have been published. Rückert et al. demonstrated the feasibility of this technique for patients undergoing thymectomy for myasthenia gravis.[192] That same group of investigators then published a retrospective cohort study comparing robotic and nonrobotic thoracoscopic thymectomy and found that rates of remission of myasthenia gravis were actually higher for patients who had received a robotic thymectomy; the authors attributed this finding to the potential for improved mediastinal dissection with the robotic technique.[193] A survey of the utilization of robotic techniques published in 2013 revealed that nearly 3,500 robotic thymectomy cases had been performed at approximately 100 centers worldwide.

Finally, surgeons have recently asked whether patients with early-stage thymoma and no evidence of myasthenia may be served by thymomectomy (removal of the tumor alone, akin to a wide local excision) rather than complete thymectomy. Tseng et al. reported on a cohort of 95 patients treated at a Taiwanese center between 2002 and 2011.[194] Forty-two patients underwent thymomectomy, whereas 53 underwent complete thymectomy. As expected, patients undergoing thymomectomy had lower morbidity and shorter

hospitalizations. Intriguingly, after a median follow-up of 57 months, neither the rate of tumor recurrences nor myasthenia neurologic outcomes were significantly different in the two groups. Because this was a nonrandomized retrospective study with limited patient numbers and length of follow-up, the results should be interpreted with caution. Nevertheless, minimizing not just surgical technique, but also the surgical target itself, is a compelling subject for further inquiry.

The appropriate use of these newer surgical techniques and surgical paradigms will clearly evolve as more evidence is collected on their safety and oncologic efficacy. Publication of long-term outcomes and development of clinical trials, whenever possible, will be critical for defining the role of these novel approaches in the spectrum of thymic malignancies.

Patterns of Failure After Surgical Resection

The pattern of failure in the overwhelming majority of thymomas is locoregional: 81% of recurrences are local, 9% are distant, and 11% are both.[17,18,43,48,103,104] Figure 55.4 demonstrates that, although recurrences in a radiation field are rare, a significant number of intrathoracic recurrences are observed along pleural surfaces.[195]

Most recurrences arise within 3 to 7 years,[17–19,48,49,104] but recurrence has been documented as late as 32 years after the initial resection.[43,55,172,196,197] Given the tendency for late recurrences, patients require at least 15 years of follow-up after potentially curative therapy.

If technically feasible, the traditional recommendation for recurrence has been surgery and adjuvant radiation.[75,104,198] Most recurrences (50% to 75%) are operable, and of those that are operable, the reported rates of a successful R_0 resection range from 45% to 71%.[48,75,102,104,199] Patients with a recurrence after an R_0 resection generally experience acceptable short-term and long-term results,[75,198] with 10-year actuarial survival rates ranging from 53% to 72%[75,102,104,200]; 10-year survival rates after an incomplete resection, by contrast, range from 0% to 35%.[18,75,102,104,200]

Despite the historical tendency to reresect operable recurrences, some emerging data suggest that this recommendation for reresection should be tempered by the high rate of additional recurrences. In one study from Memorial Sloan-Kettering Cancer Center, of 25 patients who experienced recurrent disease after initial resection, 11 (44%) had disease that was amenable to reresection. In that same study, 50% of patients undergoing surgery for recurrent disease had an

R_0 resection, but 82% of these patients still experienced a second recurrence. The authors concluded that "despite the historical enthusiasm for re-resection… reoperation should be considered only in selected patients."[201]

When recurrent disease is unresectable, radiation and chemotherapy have been used with modest results: 5-year overall survival rates reportedly range from 25% to 50%, with poorer longer-term survival.[19,48,102,104,199,202]

Radiation Therapy

Adjuvant Radiation After Complete Resection

Recurrence rates for stage I thymomas after an R_0 resection are so low that radiation is considered unlikely to offer improvement. More commonly, radiation therapy is offered as an adjuvant treatment for patients with resected stage II and III thymomas or those with incompletely resected tumors. However, patterns of care studies demonstrate significant controversy even around these indications; some centers recommend adjuvant radiation for all patients,[22,106] others recommend adjuvant radiation for stage II and III thymomas,[18,65,79,151,159] and still others recommend radiation only after an incomplete resection.[52,151,159] The reason for this diversity of opinions is that the evidence regarding adjuvant radiation is retrospective, and, because of the rarity of thymoma, studies span many decades. Nonetheless, because disease stage and completeness of resection are such important prognostic factors, analyses of adjuvant radiation have tended to focus on these factors.

For completely resected stage II thymoma, studies have been mixed with regard to local control benefit of adjuvant radiotherapy, with some studies showing trends toward better local control after adjuvant radiation, others finding no difference in recurrence rates, and one series reporting worse results with adjuvant radiation.[52,104,195–198] A report by Chang et al. of patients with completely resected stage II or III thymoma demonstrated similar overall survival rates but improved disease-free survival rates with adjuvant radiation therapy (93% with radiation vs. 70% without).[203] In counterpoint, Berman et al. found that the local recurrence rate among 74 patients after complete resection for stage II disease was only 3% and was not affected by receipt of adjuvant radiation.[204] Utsumi et al. reported similar findings in a study of patients with stage I or II completely resected disease.[205] Finally, a SEER analysis of 901 patients showed no clear benefit from adjuvant radiation for patients with completely resected disease.[206] Some studies have sought to fine-tune the pathologic indications for adjuvant radiotherapy in stage II disease with

additional high-risk features beyond capsular invasion. For instance, Haniuda et al. found that patients with fibrous adhesion to the mediastinal pleura without microscopic invasion benefited the most from postoperative therapy[207]: Recurrence rates among patients with such adhesion were 36.4% versus 0% among those without adhesion.

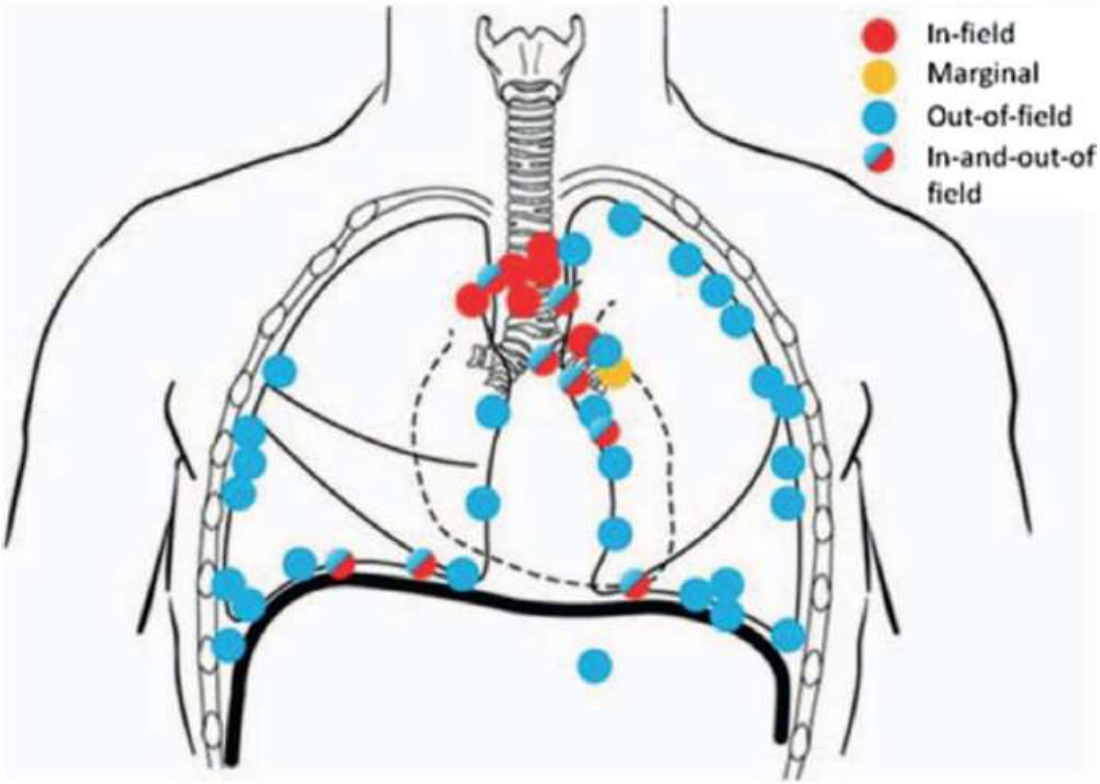

FIGURE 55.4. Graphical illustration of failure patterns following radiotherapy for stage II to IV thymoma. (Reprinted from Rimner A, Gomez DR, Wu AJ, et al. Failure patterns relative to radiation treatment fields for stage II-IV thymoma. *J Thorac Oncol* 2014;9[3]:403–409. Copyright © 2014 International Association for the Study of Lung Cancer. With permission.)

Similar to the literature for stage II disease, there are mixed findings in the literature regarding the role of adjuvant radiation after R_0 resection for stage III thymoma. Traditionally, the literature has consisted of small retrospective studies showing excellent local control after radiation but unclear survival benefit with conflicting results. An illustrative example of a positive result in terms of local control is an early study by Urgesi et al., who reported no in-field recurrences and only 3 out-of-field recurrences among a cohort of 33 stage III and IVa patients treated with surgery and radiation.[157] Similarly, Ogawa reported on 103 patients with stage I to IV thymoma treated with postoperative radiation and

found a 100% in-field control rate.[208] And yet, the impact of local control benefit on survival outcomes has not been borne out in some single-institution studies. For instance, Shen et al. reported on 83 patients with completely resected stage II and stage III thymic epithelial tumors and found no survival benefit to adjuvant radiation in these groups.[209]

More recently, large population-based databases have sought to answer the question of radiation's role, but just as in the preceding single-institution studies, these population-based studies have been inconsistent in their findings. The Japanese Association for Research on the Thymus Database Study published its findings on postoperative radiotherapy for stage II to III thymoma in 2015 using the records of 2,835 registered patients. In multivariate analysis comparing those who either did or did not receive adjuvant radiation, the study found no benefit to radiotherapy for either relapse-free survival or overall survival.[210] Furthermore, subgroup exploratory analysis failed to identify factors among the stage III patients that could reliably predict a benefit to adjuvant radiation.

In contrast to the Japanese study, three population-based analyses found an association with adjuvant radiation with improved outcomes. Weksler et al. reviewed the outcomes of 798 stage III thymoma patients in the SEER database. In multivariate analysis, postoperative radiation therapy after surgery was associated with improved disease-free survival but not overall survival.[211] Jackson et al. reported on a population cohort of 4,056 patients in the National Cancer Database with all stages of thymoma and found that adjuvant radiation was associated with improved overall survival after adjustment for other clinical factors. Subgroup analysis found that this benefit was most pronounced in patients with stage IIB to III disease and with positive margin.[212] Lastly, an analysis of 1,263 patients in the ITMIG database who had undergone complete resection of a stage II or III thymoma found a 7% improvement in the 10-year overall survival among those given postoperative radiotherapy (86% vs. 79%, $P = .002$).[213] Furthermore, the association of radiotherapy with overall survival was significant after multivariate adjustment.

The dose–response relationship is also a matter of controversy in the literature. Harnath et al. found that doses in excess of 50 Gy were associated with improved disease-free and overall survival among 27 patients diagnosed with thymic epithelial tumors and treated with adjuvant radiation. However, Fan et al. reviewed the cases of 53 patients who underwent complete resection of stage III thymoma followed by radiation (range 28 to 60 Gy) and found no clear dose–response relationship.[214]

Even if local control is achieved, it is not evident that distant or regional recurrences or overall survival are clearly impacted by adjuvant radiation.[48,52,215–217] Until a randomized controlled trial rigorously addresses the controversy around postoperative radiotherapy for completely resected tumors, we recommend that treatment for stage II or III disease should be made on an individual basis and should consider risk factors such as frank pleural or pericardial invasion, tumor grade, margin status, and comorbid conditions. We further strongly encourage that proposed treatment strategies be discussed in a multidisciplinary setting before the final recommendation is made.

In the scenario of an incomplete resection, radiotherapy is often considered to be an important adjunctive treatment for addressing residual disease. Although rigorous prospective evidence is unavailable for this clinical scenario, retrospective analyses have observed very low rates of mediastinal failure among patients with gross residual disease treated with adjuvant radiation.[38,157,218]

Radiation as Neoadjuvant Therapy

Radiation has been proposed as a neoadjuvant strategy to reduce tumor burden and improve resectability, especially for cases involving gross invasion of critical structures.[35,108,160,219–223] Response rates of up to 80% have been reported, and a theoretical decrease in the potential for tumor seeding during surgery has been proposed as well.[19,38,159,219] The rates of R_0 resections after neoadjuvant radiation for stage III thymoma can be as high as 53% to 75%,[108,223] which are favorable compared with the typical 50% rate of R_0 resections of stage III thymomas.[18,21,22,38,48,79,105,151] Ten-year survival rates do not seem to be better after preoperative radiation, but to date, the studies evaluating this approach have been small.[108,222,223]

Radiation as Definitive Therapy

Radiation therapy alone has been used for patients who cannot undergo surgery because of medical conditions, or those for whom surgical resection is not possible, with modest results. Arakawa et al. reported that 7 of 12 patients presenting with unresectable tumors treated with primary radiation therapy were still alive at follow-up times ranging from 1 to 5 years.[224] Ciernik et al. reported a 5-year survival rate of 87% for a small group of patients with stage III and IV disease who underwent radiation without resection,[218] and Jackson et al. found 10-year survival rates of 44% for patients who received radiation after biopsies or incomplete resections.[225] As for the use of radiation for recurrent disease,

Urgesi and others reported outcomes of 21 patients given radiation alone after intrathoracic recurrences of thymoma.[199] The 7-year survival rate of 70% was similar for those treated with radiation alone and for those treated with surgery and adjuvant therapy. Although these results are informative, in the era of combined modality therapy, the use of preoperative and definitive radiation therapy in the absence of chemotherapy is rarely a primary recommendation in the management of inoperable thymomas.

Chemotherapy

Thymomas are quite sensitive to chemotherapy, with approximately two-thirds of patients showing a clinical response and one-third experiencing a complete response to systemic cytotoxic agents.[68,173,226–233] The duration of response ranges from 12 to 93 months. Whether chemotherapy influences long-term survival is more difficult to assess. In one retrospective analysis of 90 patients, chemotherapy reduced the rates of metastases to the lung, pleura, or other sites by half (17% vs. 38%, $P < .05$). All of those patients were high risk with stage III or IV tumors treated with radiation and partial or no resection.[159] Another study reported a nonsignificant trend toward better disease-free survival from the addition of chemotherapy.[185]

As is true for the literature on the effects of radiation, most of the series describing the use of chemotherapy are small and retrospective. Drugs commonly used in combination chemotherapy include cisplatin, doxorubicin, and cyclophosphamide. One prospective intergroup study reported disappointing results with combined etoposide, ifosfamide, and cisplatin.[227] A more recent study of patients with advanced disease showed that the combination of carboplatin and paclitaxel produced response rates of 43%, with a median survival time of 20 months. The authors of that report concluded that the clinical activity of that combination was less than that of anthracycline-based therapy.[234]

The most promising use of chemotherapy is in the neoadjuvant setting. Like preoperative radiation, chemotherapy seems to render tumors more suitable for complete resection. An early investigation suggested that neoadjuvant chemotherapy was associated with improved survival for patients with stage III or IVa thymomas.[177] This hypothesis was more rigorously tested in a phase II prospective trial by Park et al.: 27 patients with radiographic evidence of stage III or IV thymic malignancies were enrolled (9 had thymoma and 18 had thymic carcinoma).[235] After induction therapy with docetaxel/cisplatin, 19 of the 27 patients underwent surgery and 15 among the 19 achieved a complete resection,

which represents 55.6% of the intent-to-treat population. Overall survival at 4 years was 92.9% and 62.2% among those who did and did not achieve complete resection, respectively, though statistical significance was not achieved (possibly as a result of the small numbers involved). This study serves as evidence that tumor resectability can potentially be improved with a course of systemic chemotherapy.

Aside from cytotoxic agents, somatostatin analogs (e.g., octreotide) and high-dose corticosteroids have shown promise in thymomas.[236,237] In one prospective study, two courses of glucocorticoid therapy before surgery led to a 47% response rate among 17 patients with resectable thymomas.[238] This therapy seems to work by exploiting the ability of corticosteroids to induce apoptosis in CD4+CD8+ immature thymocytes. Another prospective study by the Eastern Cooperative Oncology Group enrolled 42 patients with unresectable, advanced thymic malignancies for whom octreotide scans were positive. Patients were treated with octreotide with or without prednisone. Two patients had complete responses and ten had partial responses, which led the investigators to conclude that octreotide alone had modest activity and that prednisone improved the overall response rate.[239]

Targeted therapies, which seek to take advantage of aberrations in signaling pathways, have been investigated in small series for thymic malignancies. Early studies have focused on c-KIT, EGFR, IGF-1R, and VEGF angiogenesis and histone deacetylation pathways.[142,240,241] Phase I/II trials with agents targeting receptors in these pathways, like those with EGFR-targeted agents, have been largely disappointing,[242,243] although figitumumab, an anti–IGF-1R antibody, has shown efficacy in early clinical trials for advanced/refractory thymomas.[244,245] In addition, a phase II study evaluating the efficacy of the histone deacetylase inhibitor belinostat in patients with recurrent or refractory advanced thymic epithelial tumors showed that of 41 patients enrolled (25 with thymoma, 16 with thymic carcinoma), the response rate was 8%, with median times to progression and survival of 5.8 and 19.1 months, respectively. These investigators concluded that this agent had “modest” antitumor activity in this setting, but the prolonged duration of the response warranted further study.[246] mTOR inhibition represents a newer line of investigation with promising early results reported in a phase I trial.[247]

Although steroid receptor expression has been thoroughly studied in other malignancies such as breast cancer, less research on this topic has been done in thymic malignancies. Glucocorticoid receptors are known to be expressed in

epithelial cells, and the delivery of glucocorticoids can induce apoptosis in thymocytes.[248,249] A recent study evaluating the presence of glucocorticoid, estrogen, and progesterone receptors in thymomas and thymic carcinomas showed that glucocorticoid and estrogen receptors were overexpressed in 83% and 76% of thymic malignancies and progesterone receptors were overexpressed in <1%. Glucocorticoid receptor expression was also associated with better prognosis among patients who underwent resection.[250] Interestingly, these receptors may underpin the observation that prednisone is an active agent in this disease.

Other small investigations of agents that exploit molecular pathways—including agents such as imatinib, sorafenib, sunitinib, cetuximab, cixutumumab, and bevacizumab—have largely failed to demonstrate major activity for thymic malignancies although observations of modest response have been sporadically noted. The most compelling data for these agents comes from a phase 2 study of everolimus in a cohort of patients with advanced or recurrent thymoma or thymic carcinoma who failed cisplatinum. In this trial of 51 patients, 88% had a degree of disease control (mainly stable disease) and median survival was 25.7 months.[250a] Ultimately, better understanding of tumor biology coupled with studies involving larger numbers of patients is necessary to advance this approach.

Combined Modality Therapy

Some evidence exists to suggest that multimodality treatment can improve both resectability and long-term survival among patients with stage III or IV thymomas; typical combinations include neoadjuvant chemotherapy followed by surgery and postoperative radiation, chemotherapy, or both. Prospective trials of preoperative combination chemotherapy have been undertaken at several institutions[76,231,233,251]; the regimens in all cases included cisplatin with some combination of cyclophosphamide, doxorubicin, vincristine, prednisone, or epirubicin. Reported response rates to these regimens range from 77% to 100% (Table 55.8); R_0 resections were possible in 57% to 82% of cases; and pathologic complete response rates ranged from 4% to 31%. Overall survival rates at 5 years (57% to 95%) were quite favorable for unresectable stage III or IV thymoma.[76,231,233,251,252] In many of these studies, most if not all patients received postoperative radiation (Table 55.8), and the results seem superior to historical results from patients who underwent surgical resection alone. In summary, multimodality therapy consisting of preoperative combination

cisplatin-based chemotherapy followed by surgery and postoperative radiation can produce excellent results.

Modest results have also been obtained from the combination of chemotherapy plus definitive radiation therapy for limited-stage, unresectable thymoma. A prospective intergroup study[210] reported a 5-year survival rate of 52% for 26 patients who were treated with cisplatin, doxorubicin, and cyclophosphamide followed by radiation therapy for patients with unresectable thymomas. The median survival time was 93 months.

TABLE 55.8 OUTCOMES AFTER COMBINED MODALITY THERAPY FOR THYMOMAS

Study and Reference	Institution	*n*	Preop Chemo	Adjuvant Therapy	% Response	% R_0	% pCR	% 5-Year Survival
Lucchi et al.[177]	Pisa	36	Cisplatin, vp, epi	RT and Chemo	67	78	6	65 (est)
Venuta et al.[76]	Rome	25	Cisplatin, vp, epi	RT and Chemo	—	80	4	80

Cyclo, cyclophosphamide; doxo, doxorubicin; epi, epirubicin; pCR, pathologic complete response; pred, prednisone; R_0, complete resection; vin, vincristine; vp, etoposide.

Management of Myasthenia Gravis

Thymectomy has been used effectively to induce remission or reduce symptoms of myasthenia gravis. Removal of even normal-appearing thymuses improves symptoms in about half of patients with myasthenia gravis,[254–256] which may be related to the associated high acetylcholine receptor activity and the presence of antibodies to striated muscle within the thymus.[257]

In fact, the value of thymectomy in the management of nonthymomatous myasthenia was rigorously evaluated in the MGTX trial, which randomized 126 adult patients with myasthenia gravis in the absence of thymoma to extended transsternal thymectomy plus alternate-day prednisone with alternate-day

prednisone alone. Patients who underwent thymectomy had improved symptomatology over a 3-year period, required lower prednisone doses, had fewer episodes requiring immunosuppression with azathioprine, and had fewer hospitalizations for myasthenia exacerbations (9% vs. 37%, $P < .001$).[258] The results of this trial put the use of thymectomy in the treatment of nonthymomatous myasthenia on unequivocal footing.[259,260]

The mortality rate associated with thymectomy, at centers with experience in the preoperative and postoperative management of myasthenia gravis, is essentially the same as that associated with general anesthesia.[54] An important consideration to optimize perioperative outcomes is to ensure that the anesthesiology team is experienced in compensating for the effects of myasthenia on diaphragmatic function, which may have implications for respiratory function while under anesthesia.

Interestingly, radiation therapy to the thymus has also been reported to be effective for treating myasthenia gravis, with symptom improvement or response noted in about 50% of patients.[261–263] However, radiation treatment alone for myasthenia gravis is mostly of historical interest given the advances in surgical expertise and perioperative management of this syndrome.

Radiation Therapy Dose

Radiation doses given for thymoma have ranged from 30 to 70 Gy, most often given in standard 1.8- to 2.0-Gy fractions. Typical postoperative doses are 45 to 50 Gy, with higher doses for positive surgical margins (54 Gy) or gross disease (60 to 70 Gy). Dose–response effects have been difficult to determine owing to the retrospective nature of most published studies; one study did not identify a dose response,[264] but two others did.[185,265]

Radiation Targets

As radiation planning techniques have evolved, the trend in treating thymic tumors, like NSCLC, has been toward use of involved-field techniques. Because thymomas do not routinely spread via the lymphatic system, the draining nodal distributions do not need to be included in the radiation fields.[104] In general, neoadjuvant or definitive radiation therapy delivered a clinical tumor volume consisting of the entire extent of gross disease as visualized on imaging with a further clinical tumor margin (1 to 2 cm) to account for microscopic infiltration. Extending the clinical tumor margin into the lung parenchyma is generally unnecessary.

When radiation is to be given as adjuvant therapy, the radiation treatment fields are designed to treat any residual gross disease and the surgical bed. This region is defined based on the pretreatment images, with the field generally encompassing the surgical field, which can be defined by the placement of surgical clips, and preoperative imaging that delineates the superior–inferior extent of disease before treatment. A clinical tumor margin is added to account for infiltration beyond the area previously occupied by gross tumor.

It is highly advisable to review the treatment volumes for adjuvant radiotherapy with the operating surgeon to ensure that all areas of concern for recurrence are addressed. Likewise, the surgeon can aid the radiation oncologist by placing radiopaque clips at the time of surgery to help define the tumor bed and other areas of interest. It is especially critical to mark in this way regions known to harbor an unresected positive margin based on frozen section or wherever there is a high expectation of margin positivity on permanent section.

There is evidence that these principles of delineation lead to good interobserver consensus; an investigation by Holliday et al. sought to measure interobserver variability by comparing contours among seven radiation oncologists given a pilot dataset for a preoperative and postoperative case.[266] Their results showed exceptional agreement in the preoperative contours although lower agreement was observed in the postoperative setting, further highlighting the benefit of multidisciplinary involvement that includes the surgeon for these cases.

In theory, hemithoracic radiation could be beneficial in thymic malignancies because of their tendency to recur along the pleural surfaces. This technique has been assessed in several studies. In one such study, Sugie et al.[267] reported findings from 60 patients with stage I to IV invasive thymoma, 48 of whom had been treated with fields limited to the mediastinum to a dose of 30 to 64 Gy and the other 12 given hemithoracic radiation therapy to a dose of 11.2 to 16 Gy. Although the toxicity of the extended-field (hemithoracic) radiation was acceptable and seemed to produce modest improvements in pleural dissemination rates, no differences were found in overall survival between the two techniques.[267] Other small studies have also tested hemithoracic radiation to doses of 15 to 20 Gy, and some have had promising results.[268–270] However, these studies were small and primarily retrospective. Ultimately, the dose that can be delivered safely in hemithoracic therapy is probably not sufficient for controlling microscopic disease, which typically requires 40 to 45 Gy. However, conformal techniques such as those noted below may allow further dose

escalation in future investigations.

Radiation Modalities and Simulation Techniques

CT-based treatment planning is essential for targeting the tumor and for accurate dosimetry of critical structures. In the modern era, 4D techniques to manage respiratory are also helpful for ensuring coverage of the target as well as optimizing avoidance of organs at risk. As is true for all thoracic and mediastinal tumors, the major critical structures include the spinal cord, lung parenchyma, pericardium, heart, and esophagus. The guidelines to be followed to minimize dose to these structures are the same as those used in the treatment of lung cancer. Table 55.9 lists common dose constraints for radiation therapy, with or without chemotherapy, for mediastinal malignancies. These constraints were derived from a Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) consensus analysis published in 2010.[271–274] Any deviations from these dose constraints should be reviewed in a radiation quality assurance setting and discussed with the patient before treatment is begun.

Major advances in radiation delivery over the past decade have led to great improvements in both conformality and therapeutic ratio of radiation for thoracic malignancies. Intensity-modulated radiation therapy (IMRT) has been shown to allow the dose to normal structures to be reduced relative to that from 3D conformal radiation and to allow accurate target localization.[275–281] Indeed, a recent study of 496 patients with locally advanced, unresectable NSCLC demonstrated that the more advanced technique (4D CT with IMRT) led to lower rates of high-grade radiation pneumonitis and better overall survival compared with 3D simulation and 3D conformal therapy.[282] Although similar comparisons for thymic malignancies have not been done because of the rarity of this disease, the same principles would be expected to apply given the mediastinal location of these tumors and hence their close proximity to the lungs, heart, and esophagus.

TABLE 55.9 STANDARD DOSE CONSTRAINTS USED IN RADIATION THERAPY FOR THORACIC MALIGNANCIES

Organ at Risk	RT Alone	Chemo and RT	Chemo and RT before Surgery
Spinal cord[1]	D_{max} < 45 Gy	D_{max} < 45 Gy	D_{max} < 45 Gy
Lung[2]	Mean dose ≤ 20 Gy V_{20} ≤ 40%	Mean dose ≤ 20 Gy V_{20} ≤ 35%	Mean dose ≤ 20 Gy V_{20} ≤ 30%

		$V_{10} \leq 45\%$	$V_{10} \leq 40\%$
		$V_5 \leq 65\%$	$V_5 \leq 55\%$
Heart	$V_{30} \leq 45\%$	$V_{30} \leq 45\%$	$V_{30} \leq 45\%$
	Mean dose < 26 Gy	Mean dose < 26 Gy	Mean dose < 26 Gy
Esophagus	$D_{max} \leq 80$ Gy	$D_{max} \leq 80$ Gy	$D_{max} \leq 80$ Gy
	$V_{70} < 20\%$	$V_{70} < 20\%$	$V_{70} < 20\%$
	$V_{50} < 50\%$	$V_{50} < 40\%$	$V_{50} < 40\%$
	Mean dose < 34 Gy	Mean dose < 34 Gy	Mean dose < 34 Gy
Kidney[3]	20 Gy < 32% of bilateral kidney	20 Gy < 32% of bilateral kidney	20 Gy < 32% of bilateral kidney
Liver	$V_{30} \leq 40\%$	$V_{30} \leq 40\%$	$V_{30} \leq 40\%$
	Mean dose < 30 Gy	Mean dose < 30 Gy	Mean dose < 30 Gy

D_{max}, maximum dose; V_x, percent volume of organ receiving x dose.

Another treatment modality, proton beam therapy, has shown promise for reducing the dose to normal structures while maintaining adequate doses to the tumor target in NSCLC.[275,283–290] Indeed, the dose distribution properties of proton therapy, specifically the "Bragg peak" that minimizes dose distal to the tumor, are well suited for anteriorly located thymic tumors. Proton therapy has been shown to produce greatly reduced doses to critical structures in mediastinal lymphoma, which often presents in the same anterior location as thymic malignancies, compared with photon-based techniques.[291] Vogel et al. tested this hypothesis by comparing double-scattered proton beam plans to IMRT plans for 22 consecutive patients requiring treatment for thymic malignancies. They confirmed that proton beam therapy resulted in statistically significant reductions in dose to the heart, lungs, left ventricle, and spinal cord and that the baseline risk of major cardiac events was increased by 135% after IMRT and 74% after proton therapy ($P = .04$).[292] Further investigation via rigorous, prospective clinical trials will be essential in determining if the dosimetric benefits of proton beam therapy (Fig. 55.5) translate to clinical benefits.

Regardless of treatment modality, we recommend that all treatment simulations for patients with thymic tumors take place while the patients are supine, and well immobilized with their arms above their head, to maximize the number of potential beam arrangements. We recommend that 4D CT scans be obtained at the time of simulation to assess the motion of the tumor during respiration. If 4D CT scanning is not available, we recommend either a slow

helical scan to encompass all phases of the breathing cycle or that CT images be obtained at full inspiration and expiration to assess the extremes of respiratory motion. Full descriptions of radiation techniques for thymic malignancies are available elsewhere.[293,294]

THYMIC CARCINOMA

Natural History and Diagnosis

Thymic carcinomas are considerably less common than thymomas. Like thymomas, thymic carcinomas are thought to arise from thymic epithelium and typically appear in the anterosuperior mediastinum. The clinical behavior of thymic carcinoma is quite different from that of thymoma; they are generally more aggressive and have a higher propensity for capsular invasion and metastatic proliferation. Because of these features, thymic carcinoma often presents as advanced disease and its 5-year survival rates are much poorer than for thymomas.[52,295,296]

Clinically, thymic carcinoma can present with cough, dyspnea, pleuritic chest pain, phrenic nerve palsy, or superior vena cava syndrome.[295,297,298] Associated paraneoplastic syndromes have been observed occasionally though these are less

commonly seen compared to thymoma.[298–300] CT scans often demonstrate an irregular mass with necrotic, cystic, or calcified regions.[297,301–303] In about 80% of cases, thymic carcinoma shows radiographic evidence of invasion into adjacent structures in the mediastinum, and mediastinal lymphadenopathy is evident at presentation in about 40% of cases.[298,304–306] Distant metastases to regional lymphatics, bone, liver, kidney, and lung are also common clinical features.[298,307–309] Therefore, bone scanning, MRI, PET with ^{18}F-flourodeoxyglucose or ^{11}C-labeled methionine, and single photon emission computed tomography (SPECT) have been used for both staging and evaluation of response to therapy.[90,310–313]

Historically, thymic carcinomas have been classified as type C thymic tumors in the WHO classification, and disease staging is most often done with the Masaoka clinical staging system for thymomas.[105,314] Most thymic carcinomas are undifferentiated high-grade lesions with anaplasia and marked cellular atypia, lacking the histologic features of a normal thymus[315]; others may be of adenocarcinomatous, sarcomatous, squamous, basaloid, mucoepidermoid, or lymphoepithelial-like histology.[297,316,317] Some thymic carcinomas are associated with the multilocular thymic cysts, which are acquired lesions of the thymic gland associated with an inflammatory reaction. Recent studies have demonstrated the importance of thorough sampling of thymic cysts to rule out underlying carcinoma.[318]

Because histologic grade is one of the most significant indicators of prognosis, a revised histologic classification has been proposed that broadly divides thymic carcinomas into high-grade or low-grade lesions.[319] Tumors in the low-grade histologic group are characterized by a relatively favorable clinical course and a low incidence of local recurrence and metastasis.[320–322] High-grade variants of thymic carcinoma are more lethal, with frequent metastases to regional lymph nodes, bone, liver, and lung.[303,323]

The extent of surgical resection, Masaoka stage, TNM stage, and receipt of adjuvant therapy are also associated with improved survival[324–327]; interestingly, the specific histology of thymic carcinoma, just as in thymoma, does not appear to reliably confer an impact on survival. Stage IVb patients with lymph node–only metastases may have better outcomes than those with distant metastatic disease at presentation, a result which may be driven by the possibility of curative resection in some of these patients.[328]

General Management

Owing to the paucity of experience with this rare tumor, the ideal therapeutic regimen is unknown. Current management strategies borrow from the principles of treating non–small cell carcinoma of the lung. Thus, an aggressive multimodality approach is often employed, which includes the consideration of primary surgical resection, adjuvant cisplatin-based chemotherapy, and postoperative radiation therapy.

Although incomplete resection does not necessarily preclude long-term survival if multimodality platinum-based therapy is used,[329] complete resection is nevertheless the cornerstone of treatment.[324–327] Reflecting multiple other single-institution studies, Takeda et al. observed a median survival time of 57 months for patients with completely resected thymic carcinomas versus 13 incomplete resection.[330] A multi-institutional study of patients with thymic carcinoma showed that the 5-year survival rates of total resection, subtotal resection, and inoperable groups were 67%, 30%, and 24%, respectively.[52] Likewise, the largest modern series of 1,042 cases from the combined European Society of Thoracic Surgeons (ESTS) and ITMIG databases reported overall survival rates for R0, R1, and R2 groups were 70%, 55%, and 42%, respectively.[326] In light of this consistent finding in multiple datasets, complete resection of the primary tumor is a fundamental recommendation.

The routine addition of lymph node dissection is more controversial though it has merited attention because of the higher rate at which thymic carcinomas spread to regional lymph nodes in comparison to thymomas. Park et al. retrospectively reviewed 37 thymic carcinoma patients who were divided into 4 groups: No node dissection, N0 by limited dissection, N0 by extensive dissection, and N1 by dissection of any type.[331] Among the 29 patients who underwent node dissections, 6 (20.7%) were found to harbor nodal metastases. Furthermore, patients who underwent no dissection or node negative after limited dissection had outcomes that were inferior to those who were node negative after an extensive dissection. These results suggest that an extensive dissection may impart more accurate staging and better prognostic information. Though this study requires confirmation in larger investigations, it raises an intriguing hypothesis that routine lymph node dissection may improve outcomes either by the therapeutic effect of completely excising gross disease or by providing better guidance for necessary adjuvant therapies.

The role of radiotherapy for thymic carcinoma is not well defined, again owing to the rarity of the disease and the absence of prospective clinical trials. Although radiotherapy should be considered in all cases of thymic carcinoma,

there is limited evidence that omission in completely resected, early-stage disease may be feasible. A small investigation of four patients fitting this characterization who were treated with radical surgery alone found that all four were alive and free from relapse at a median follow-up of 72 months (range 12 to 167 months).[332]

Most single-institution retrospective studies have reported on outcomes with adjuvant radiation therapy, typically to a dose of 40 to 70 Gy delivered in standard fractionation (1.8- to 2.0-Gy fractions).[264,321,330,333–336] In one such series of 26 patients treated with surgery and postoperative radiation without chemotherapy, Hsu et al. observed a 5-year overall survival rate of 77% for all patients,[336] 82% for patients with completely resected tumors, and 66% for those with subtotally resected tumors. The 5-year local control rate was 91% with a median radiation dose of 60 Gy. In another study of 40 patients given either surgery and adjuvant radiation or definitive radiation therapy with or without chemotherapy, Ogawa et al. reported no local recurrences among the cohort of patients with complete resection who had received adjuvant radiation of at last 50 Gy.[321] Kondo and Monden observed no survival benefit from adding adjuvant radiation to surgical resection in a retrospective multi-institutional study of 186 patients, although the authors did note that the retrospective nature of the study and its small subgroup sizes precluded any definitive conclusions.[52]

Investigators of the ESTS database reported on 229 patients treated with thymic carcinoma between 1999 and 2010. Compared to patients receiving surgery alone, a significant survival advantage was observed among patients receiving surgery and postoperative radiotherapy. Ahmad et al. went further to study the combined ESTS and ITMIG databases to create a cohort of 1,042 thymic carcinomas, 60% of whom received adjuvant radiotherapy. In their multivariable analysis, attaining R0 resection and administration of radiotherapy were the only variables associated with prolonged overall survival (hazard ratio for radiotherapy, 0.45).[326]

In aggregate, these studies seem to indicate that local control is improved with radiation and that a survival benefit may also accrue. The quality of the evidence, however, is limited by its retrospective nature and vulnerability to selection bias. As is true for all mediastinal tumors, better knowledge will depend on conducting randomized clinical trials. The formation of international collaborations such as the ESTS and the ITMIG is a reassuring development as they will likely underpin the design and completion of such trials.

With regard to systemic therapy, thymic carcinoma generally is less

responsive to chemotherapy than thymoma,[337] and outcomes after chemotherapy alone are dismal. However, the use of adjuvant cisplatin-based chemotherapy has shown significantly beneficial effects in several studies.[226,338,339] In one such study, Nakamura et al. treated 10 patients with unresectable thymic carcinoma with platinum-based protocols, with or without radiation therapy, and observed a median survival time of 11 months.[339] Yoh and others reported excellent preliminary results (i.e., a 42% response rate) from the use of weekly cisplatin, vincristine, doxorubicin, and etoposide for the treatment of advanced tumors.[340] Other studies have shown favorable responses from various combinations of cisplatin, etoposide, ifosfamide, doxorubicin, nedaplatin, cyclophosphamide, and vincristine.[226,227,338–342] Finally, although data are limited, some centers advocate combined chemoradiation in select circumstances for thymic carcinoma, particularly after R1 or R2 resections.[343]

Finally, molecular pathways may provide a new avenue for treatment. Exploratory studies have shown the association of thymic carcinoma with certain mutations (VEGF,[143] IGF-1R,[144] and KIT pathways).[145,146,344] Validation of this approach, especially in combination with the other modalities, requires additional study.

Because of the rarity of thymic carcinoma, few treatment recommendations can be made; however, it seems clear that for patients with resectable disease, complete surgical resection is the preferred initial therapeutic intervention.[52,102,330,345,346] For patients with unresectable lesions, neoadjuvant chemotherapy, with or without thoracic radiotherapy, seems reasonable. Ultimately, after complete resection, the most important prognostic factors are initial disease stage and tumor grade. Five-year survival rates for patients with higher disease stage and higher-grade neoplasms range from 15% to 20%, whereas for patients with low-grade, localized disease, those rates can range from 80% to 90%.[319,323] The addition of adjuvant therapies for patients with poor prognostic factors should be made on an individual basis in the context of multidisciplinary review.

THYMIC CARCINOID

Thymic carcinoid (neuroendocrine) tumors of the thymus are very rare, accounting for <5% of all neoplasms of the anterior mediastinum. They originate from normal thymic Kulchitsky cells, which belong to the amine-precursor-uptake-and-decarboxylation group.[347] Thymic carcinoid tumors are often

confused with thymomas because of similarities in their clinical behavior. Most patients with thymic carcinoid are men aged 30 to 50 years; the male-to-female ratio is 3 to 1.[348] Roughly half of thyroid carcinoids are associated with endocrine disorders such as MEN-1 [multiple endocrine neoplasia type 1] or secondary Cushing syndrome.[349–351]

Thymic carcinoids can present with symptoms related to compression of normal structures (chest pain, dyspnea, cough, hoarseness, superior vena cava syndrome)[347,352] or with no symptoms.[351] These tumors are best evaluated by CT or MRI for visualizing local invasion of the surrounding structures (pericardium, great vessels, pleura, sternum) and metastases within or outside the thorax. Most thymic carcinoids detected on radiographic studies are already advanced, commonly metastasizing to regional lymph nodes. Metastases are present in up to 40% to 70% of patients within 8 years of the initial diagnosis,[353,354] which may explain the poor prognosis associated with these tumors.

The Masaoka staging system for thymoma has been used for staging thymic carcinoids.[105,348] The WHO system classifies the pathology of thymic carcinoids into typical carcinoid, atypical carcinoid, large-cell neuroendocrine carcinoma, or small-cell carcinoma,[115,123] and a system proposed by Klemm and Moran classifies these tumors as well-differentiated (low grade), moderately differentiated (intermediate grade), or poorly differentiated (high grade).[355] Notably, neither grading nor other histologic variables have shown a consistent association with prognosis.[348]

Complete surgical resection is the preferred method of treatment, although recurrence is common. Incomplete resections followed by adjuvant radiation, chemotherapy, or both seem to provide some benefit without increasing morbidity or mortality.[351,353,356,357] Distant metastases to the bone, liver, or skin occur in 30% to 40% of cases.[358] Despite aggressive treatment, the prognosis in most cases is poor. According to one report, the overall 5-year survival rate was 31% and all 14 patients expired within 9 years.[352] A more recent analysis of 205 patients from the combined ESTS and ITMIG databases was more reassuring with a reported 5-year survival rate of 68%, although this result should be tempered by the observation that 39% of patients experienced recurrence in this time frame.[354] Similar to the other thymic malignancies, overall survival was influenced primarily by Masaoka stage and completeness of resection. Neither chemotherapy nor radiotherapy showed statistical significance with regard to overall survival benefit. Thymic carcinoids associated with MEN-1 are

especially lethal; in one study, the 5-year survival rate for patients with thymic carcinoid without associated endocrinopathy was about 70% but was only 35% for those with an endocrinopathy.[351,352,359]

OTHER RARE TUMORS OF THE THYMUS

Thymoliposarcoma was first described by Havlicek and Rosai in 1984.[360] This rare and distinctive entity is considered the malignant counterpart of thymolipoma. Thymoliposarcomas have appeared in adults aged 36 to 77 years, with a slight female predominance. Unlike its thymolipoma counterpart, thymoliposarcoma is not associated with myasthenia gravis. It grows by expansion and has a relatively low risk of distant metastasis in the absence of histologic dedifferentiation. Complete surgical resection or subtotal resection with adjuvant radiation therapy has been used for local control.[360,361]

MALIGNANT MEDIASTINAL GERM CELL TUMORS

Epidemiology

Primary extragonadal germ cell tumors account for 2% to 5% of all germ cell tumors.[362] About two-thirds of these tumors occur in the mediastinum,[363–365] making the mediastinum the most common site of primary extragonadal germ cell tumors among young adults.[366] Germ cell tumors contribute about 10% of all malignant mediastinal tumors and about 2% of mediastinal neoplasms.[156,367] In a pooled analysis of 341 patients with mediastinal germ cell tumors treated at 11 cancer centers over a 20-year period, the median age of presentation was 33 years for seminomatous tumors and 28 years for nonseminomatous tumors.[368]

Primary extragonadal germ cell tumors have several unexplained associations. Klinefelter syndrome has been documented in patients with mediastinal germ cell tumors but not in patients with testicular germ cell tumors.[369–372] In one study, up to 20% of patients with mediastinal germ cell tumors were found to have the Klinefelter karyotype (47,XXY).[373,374] Several unusual malignant processes are associated with nonseminomatous germ cell tumors, including hematologic malignancies such as acute myeloid leukemia, acute nonlymphocytic leukemia, acute megakaryocytic leukemia, myelodysplastic syndrome, and malignant histiocytosis.[374–378] In another pooled analysis of primary extragonadal germ cell tumors, 1 in 17 patients with primary mediastinal nonseminomatous germ cell tumors developed a fatal hematologic

disorder after the diagnosis of the germ cell tumor.[379]

Natural History

Primary extragonadal germ cell tumors arise along midline structures of the body extending from the pineal gland, through the mediastinum and retroperitoneum, to the presacral areas. The origin of these primary extragonadal germ cell tumors remains controversial,[380–382] but presumably they arise from germ cells that migrate along the urogenital ridge during embryonic development.[374,383] Because the embryologic urogenital ridge extends from C-6 to L-4, malignant transformation of displaced germ cells can give rise to primary germ cell tumors outside the gonads.

Because primary gonadal germ cell tumors can spread to the retroperitoneum and mediastinum,[364,374] the diagnostic workup must be thorough and meticulous to avoid overlooking an occult gonadal primary. Although primary mediastinal germ cell tumors have the same morphologic and histologic appearance as those of the testes, primary germ cell tumors of the mediastinum are more aggressive and have a poorer prognosis.[384–386] Like testicular germ cell tumors, mediastinal germ cell tumors can be seminomatous or nonseminomatous. Benign teratomas arise from germ cell elements, but they are not included in this discussion because they are not malignant and surgical resection is often curative.

Primary mediastinal seminomatous germ cell tumors are sensitive to radiation and chemotherapy, but nonseminomatous tumors are less vulnerable to treatment and are considered poor-risk disease in all staging systems.[386] Nonseminomatous tumors are often invasive at the time of diagnosis, and approximately half of such tumors will present with distant metastases, most often to the lung.[368]

Tumor markers can aid in the diagnosis of mediastinal germ cell tumors; serum alpha-fetoprotein levels are elevated in 75% of patients (median, 2,500 ng/mL) at diagnosis, and beta-human chorionic gonadotropin and lactate dehydrogenase levels are elevated in about 50% of patients at presentation.[368] Pure seminomatous histologies are less likely to be associated with biomarker elevation, although occasionally a modest rise in beta-human chorionic gonadotropin can be observed.

Clinical Presentation

As is true for the other mediastinal tumors, local symptoms are usually caused by tumor compression or invasion of adjacent structures. Primary extragonadal germ cell tumors present with clinical symptoms in 90% to 100% of cases,[387]

with dyspnea (25%), chest pain (23%), cough (17%), fever (13%), weight loss (11%), vena cava occlusion syndrome, and fatigue/weakness (6% each) being the most common.[368,388,389] Nevertheless, these tumors are asymptomatic in many cases, and a mass is found incidentally on chest x-ray.[390,391] Roughly one-third of seminomatous mediastinal germ cell tumors present with metastases at diagnosis. The cervical lymph nodes are enlarged in about 25% of such cases, but abdominal lymphadenopathy has also been observed. Distant metastases from nonseminomatous germ cell tumors are even more common, with rates of 85% to 90% at diagnosis in prior series and 50% in more recent series.[368,392–395]

Diagnostic Workup

Mediastinal germ cell tumors are usually readily detected on chest x-rays, with most masses noted in the anterosuperior mediastinum. CT scans of the chest, abdomen, and pelvis are essential to evaluate the mass and to screen for metastases and lymphadenopathy. A careful physical examination and testicular sonography should be performed to rule out an occult primary gonadal tumor. As mentioned above, levels of tumor markers such as alpha-fetoprotein, beta-human chorionic gonadotropin, and lactate dehydrogenase can be helpful for diagnosis, for evaluating treatment efficacy, and for monitoring recurrence.[11,396–398] Thus, the determination of baseline tumor marker levels both before treatment is begun and after treatment is completed is essential.

The initial diagnosis of mediastinal germ cell tumors is usually reached through a combination of findings from CT, radiography, sonography, and tumor marker measurements. Whether PET has a place in the management of these tumors is unclear. In some instances, the tumor marker findings are sufficient to classify the lesion as an extragonadal nonseminomatous germ cell tumor without histologic confirmation, but false-positive beta-human chorionic gonadotropin levels have been reported.[399,400] Histopathologic analysis can often be done easily via fine needle aspiration and cytologic staining for tumor markers. Biopsy samples should be obtained whenever possible because both choice of treatment and prognosis depend greatly on histology.[399,400]

Prognostic Factors

The most important prognostic factor for mediastinal germ cell tumors is histologic type. Seminomas are highly curable, but nonseminomatous germ cell tumors, despite advances in therapy, are associated with poor progression-free and overall survival. The presence of metastases with tumors of either histologic

type is also associated with adverse progression-free and overall survival. In nonseminomatous tumors, elevated beta-human chorionic gonadotropin levels are associated with inferior overall survival.[368]

General Management

Seminomatous Tumors

Seminomas are quite sensitive to both radiation therapy and chemotherapy, and thus all patients with tumors of seminomatous histology should be treated with curative intent even in the presence of widely metastatic disease. The choice of treatment has evolved with the development of cisplatin-based chemotherapy regimens, and most patients should be initially treated with systemic chemotherapy.[401]

Historically, mediastinal seminomatous tumors (like all mediastinal tumors) were treated surgically.[374,402] Complete radical resection can be considered in some cases if it is technically feasible and if the patients do not want radiation or chemotherapy. Definitive radiation replaced surgical resection for localized mediastinal seminomatous germ cell tumors, with long-term survival rates of 60% to 80% achieved even for those with bulky tumors.[362,374,377,402] Before the advent of platinum-based chemotherapy, radiation therapy had the advantage of being more tolerable and less toxic, and relapses could be effectively treated with systemic chemotherapy.[362] However, cisplatin-based chemotherapy has eclipsed radiation; in an early application of this approach, Einhorn and Williams at the University of Indiana reported a complete response rate of 63% lasting a median duration of 18 months for 19 patients with disseminated seminoma treated with cisplatin-based chemotherapy.[403] In more modern series, the response to primary systemic chemotherapy is favorable for 92% of patients, and 5-year overall survival rates exceeding 90% are standard.[401]

Residual radiographic abnormalities after the completion of chemotherapy for bulky mediastinal seminomas are not uncommon, but the management strategy in such cases is still controversial. In the vast majority (80% to 90%) of such cases, the residual masses represent dense fibrosis with no viable tumor.[374,404–406] Some clinicians have advocated surgical resection or biopsy of all postchemotherapy masses larger than 3 cm,[85,405–407] and others recommend close follow-up in such cases, with early intervention if the mass enlarges on chest x-ray or CT scan and resection, radiation, or salvage chemotherapy reserved for progressive disease.[374,377,406,408] Whether ^{18}F-fluorodeoxyglucose PET is useful for predicting viable tumor is debatable and under

investigation.[409,410] Even though seminomas are extremely sensitive to radiation therapy, radiation therapy delivered to residual masses after chemotherapy has not shown a significant benefit.

Circumstances in which radiation may be appropriate include patients who refuse chemotherapy, in whom chemotherapy is contraindicated, or who likely harbor viable residual disease after chemotherapy based upon highly suspicious imaging findings or pathologic confirmation. Radiation doses and treatment techniques for mediastinal seminomatous germ cell tumors have varied.[411–416] Doses as low as 30 Gy and as high as 50 Gy have been recommended.[367,413] Given the absence of unambiguous clinical trial guidance, radiation dose should be adjusted based on the size of the lesion, the history of chemotherapy exposure, and the clinical circumstance. Because the disease is infiltrative and susceptible to nodal involvement, the entire mediastinum was traditionally encompassed with anteroposterior–posteroanterior fields with CT guidance. In the prechemotherapy era, use of smaller portals was associated with marginal relapses,[412] and in fact, the clinical target volume for definitive radiation alone often electively covered the supraclavicular, cervical, and para-aortic lymph nodes.[397,411,414,417] Extrapolating from the experience with prophylactic treatment of para-aortic nodes in testicular seminomas, one could assume that the contiguous lymphatic drainage sites for a mediastinal primary could be treated effectively with 20 Gy with minimal morbidity.[418]

In conclusion, cisplatin-based combination chemotherapy can consistently produce 5-year overall survival rates in excess of 90% for mediastinal seminomas. However, for selected patients, definitive radiation therapy has produced local tumor control rates of 89% to 100% and long-term survival rates of 60% to 80%.[367,374,412,414,419]

Nonseminomatous Germ Cell Tumors

The primary treatment for nonseminomatous germ cell tumor is intensive cisplatin-based chemotherapy, but surgical resection of all residual masses after first-line chemotherapy is recommended whenever technically possible, either as a one-stage or as a sequential procedure.[420–423] Chemotherapy regimens should include either cisplatin and etoposide or cisplatin, etoposide, and bleomycin. Patients whose tumors respond well to initial chemotherapy followed by complete resection of any residual mass can have excellent outcomes, but the outcome for patients who do not respond to primary therapy is poor, as salvage therapy is rarely effective.[386]

The role of radiation therapy in nonseminomatous germ cell tumors is not clear. Radiation may be useful for unresectable residual masses given the relatively high rate of persistent viable tumor and the poor success rates of salvage therapy. Nonseminomatous germ cell tumors are in fact radiosensitive, but they require higher doses than seminomatous tumors. Akin to other solid tumors, doses of 60 Gy or more may be necessary to achieve disease control.[424]

Before the cisplatin-based chemotherapy era, fewer than 5% of patients with mediastinal nonseminomatous germ cell tumors survived.[397] Since that time, long-term disease-free survival rates have varied from 45% to 72% in studies using cisplatin-based combination chemotherapy followed by surgery.[368,386,425] Several salvage regimens have been used for disease that progresses during or after initial chemotherapy, but unfortunately, long-term survival rates for patients with relapsed mediastinal germ cell tumors are <10%.[368,386,426,427] Thus, surgical resection and even radiation therapy may be appropriate in select cases to augment chemotherapy or as an alternative treatment modality when no further chemotherapy is available.

MEDIASTINAL MESENCHYMAL TUMORS

Epidemiology

True mediastinal mesenchymal lesions are exceedingly rare tumors. Retrospective series suggest that 2% to 8% of all mediastinal lesions are primary mesenchymal tumors; extrapolation of these values puts the estimated incidence at approximately 0.1 to 0.2 per million.[11,428–430] Approximately three-quarters of mediastinal mesenchymal tumors are of lipomatous, lymphangitic, or vascular histology, with the rest composed of unusual histologic variants.[431] The age predilection depends on the specific histologic subtype.[48,391,428–430,432]

Clinical Presentation and Workup

Mesenchymal lesions can arise in any of the three mediastinal compartments. Mesenchymal tumors that present in children seem to be more malignant than those presenting in adults.[432,433]

Mediastinal mesenchymal lesions can reach impressively large sizes before detection, typically presenting with symptoms such as chest pain and dyspnea. At least one series suggests that symptomatic presentation is a harbinger of malignant character, with 80% of patients with malignant disease presenting with symptoms versus 44% of patients with benign masses.[11] An accurate

histopathologic diagnosis is critical.[432] Tissue for these analyses can be obtained via mediastinoscopic biopsy, fine needle aspiration, or endoscopy. Disease can be staged according to the American Joint Committee on Cancer staging system for soft tissue tumors.

Tumors of Adipose Tissue

Mediastinal lipomas are the most common of the mediastinal mesenchymal lesions; they represent 1% to 5% of all lipomas.[431,434–436] Mediastinal lesions can occur in isolation or in multiples and may mimic cardiomegaly or pleural effusion on a chest x-ray. They are usually well circumscribed and encapsulated but can grow to 20 cm in diameter before detection.[437,438] Though these tumors can be quite large and cause significant compressive symptoms,[439–441] gross total resection is almost always curative.[13,442–445] Technically, lipomas are considered “benign” tumors, but those that are growing or causing symptoms should be referred for surgical resection.

In contrast to lipomas, liposarcomas consist of immature fat cells with malignant histology and behavior. Distinguishing lipomas from liposarcomas can be difficult histologically; liposarcomas are distinguished by size heterogeneity, hyperchromatic nuclei, and eosinophilic cytoplasm.[446] Primary mediastinal liposarcomas often appear in the posterior portion of the mediastinum. Anterior mediastinal liposarcomas are possible albeit rare.[447] Tumors often appear to be encapsulated and well-circumscribed, even when invasion is present (Fig. 55.6), giving rise to the term “pseudocapsule.” In one historical review, survival times for patients with well-circumscribed lesions ranged from 3 to 17 years, whereas patients with grossly invasive tumors died within 2 years.[448] As is true for all sarcomas, the prognosis depends on the histologic grade.[449,450]

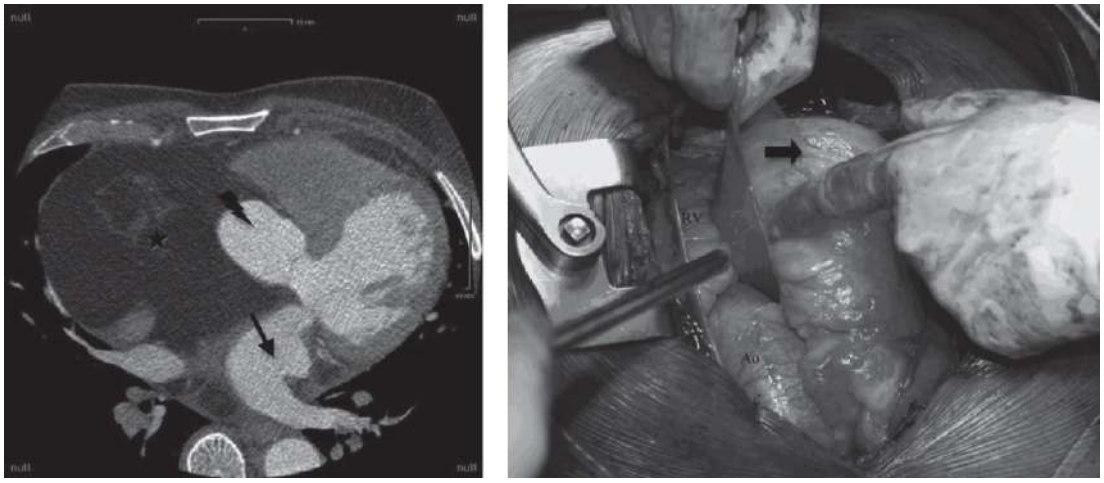

FIGURE 55.6. CT scan (*left*) and intraoperative photograph (*right*) of a primary mediastinal liposarcoma filling the right thoracic cavity. The recommended treatment for this malignancy is aggressive surgical resection with adjuvant radiation therapy and consideration of systemic therapy. (From Wiedemann D, Schistek R, Gassner E, et al. Mediastinal liposarcoma. *J Card Surg* 2011;26[2]:162–164. Copyright © 2010 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Like other sarcomas, optimal treatment consists of surgical resection and adjuvant radiation therapy.[451] Because well-differentiated tumors have little propensity for distant metastases, withholding adjuvant radiation for a trial of observation can be considered after an R_0 resection, but the significant local recurrence rates of 20% to 30% should be acknowledged during multidisciplinary discussion and with the patient.[449,450,452–455]

Tumors of Lymph Tissue

Tumors arising from the vascular or lymphatic components of the mediastinum make up the bulk of the remaining mediastinal mesenchymal lesions.[428–430] Lymphangiomas and hemangiomas are morphologically similar under light microscopy, and the presence of red blood cells or chyle within the tumor lumen often serves as a primary diagnostic aid.[442] Localized lymphangiomas are rare; more than 90% will have some degree of cervical extension.[456] A cystic lymphangioma is illustrated in Figure 55.7.[457] Lymphangiomatosis is usually seen in children and is characterized by synchronous widespread lymphangiomas.[458] Mediastinal or pulmonary involvement carries a poor prognosis.[442,459–467]

Lymphangiosarcoma seems to be a malignant variant of lymphangiomas and should probably be treated like other soft tissue sarcomas, with the optimal treatment being full extirpation.[468] In the largest reported retrospective series of

25 patients with mediastinal and cervicomediastinal lymphangiomas, survival rates were excellent after surgical resection alone, and only one patient died of a complication from lymphangioma.[469]

Adjuvant radiation has little role in most cases and may actually be detrimental for lymphangiomas. In one study, radiation was conjectured to transform a benign lymphangioma into a malignant lymphangiosarcoma.[470–472] However, radiation may be helpful for controlling symptomatic unresectable disease; Johnson et al. described a young patient with surgically refractory chylothorax and lymphangioma who experienced prompt resolution after mediastinal radiation to 20 Gy in 10 fractions.[470] In another report, radiation produced complete local control of large, unresectable lymphangiomas in three patients, findings that are consistent with other anecdotal reports of lymphangiomyomatosis.[462,471]

Tumors of Vascular Tissue

Mediastinal mesenchymal lesions of endothelial origin include hemangiomas, hemangioendotheliomas, and hemangiopericytomas. Many of these tumors have an indolent course, but hemangiopericytomas are notable for high rates of metastasis at presentation.[473–476] Hemangiomas can be capillary or cavernous; cavernous hemangiomas (i.e., angiomyomas or hamartomas) are distinguished from capillary hemangiomas by the presence of smooth muscle. Hemangiomas and hemangioendotheliomas are typically well circumscribed. Hemangioendotheliomas contain the hallmark cytoplasmic Weibel-Palade bodies.[477,478]

Hemangiopericytomas arise from the capillary contractile pericytes of Zimmerman.[473] Although most are indolent, recurrence and metastases have been observed many years after resection.[479] Retrospective studies suggest that high mitotic rates and proliferative indices may portend malignant behavior.[480,481] Nevertheless, long-term survival is still possible with aggressive treatment of metastatic disease.[482] Surgery remains the mainstay of therapy and is often curative.[483] Because of their benign nature, hemangiomas or hemangioendotheliomas should not be treated with radiation.[483] An endoscopic approach has been proposed for several types of intrathoracic tumors including benign hemangiomas and should be explored further.[484] Radiation remains an option for incompletely resected hemangiopericytomas.

Miscellaneous Mediastinal Mesenchymal Lesions

A mélange of other mediastinal mesenchymal lesions have been occasionally encountered; usually of musculoskeletal or connective tissue origin, these lesions typically appear within the posterior mediastinum.[431] These lesions have been treated with surgical excision and occasionally postoperative radiation therapy, depending on the histology and clinical presentation.[428–431,485–489]

MEDIASTINAL NEUROGENIC TUMORS

Epidemiology

Neurogenic tumors of the thorax are generally classified by their neural cell of origin, including tumors of the nerve sheath (schwannomas and neurofibromas),

autonomic ganglion (ganglioneuromas and neuroblastomas), and paraganglion (paragangliomas and pheochromocytomas). Most neurogenic lesions arise in the posterior mediastinum. Indeed, they are the most common cause of a posterior mediastinal mass and account for roughly one-quarter to one-third of all mediastinal neoplasms.[9,11,490,491]

Neurogenic neoplasms are rare, with an incidence of 0.5 per million in adults.[11] Neuroblastoma, an aggressive variant of neurogenic tumors, occurs primarily in children[492] and appears in the mediastinum in about 20% of cases. Neuroblastomas are more common in male Caucasians, whereas other malignant neurogenic tumors occur at equal rates in both sexes.[493–495]

Paragangliomas are rare tumors that arise from extra-adrenal paraganglia and can be either functional (catecholamine-secreting) or nonfunctional.[496,497] Most of these tumors are benign and surgical resection is usually curative, but some studies have suggested that the risk of the tumor being malignant is >10%.[498,499]

The most common neurogenic tumors in adults are benign schwannomas and neurofibromas, often presenting in the setting of neurofibromatosis type 1 (NF-1), an autosomal dominant neurocutaneous disorder, with an estimated birth incidence of 1 in 2,500.[500] Individuals affected with NF-1 are at increased risk of developing both benign and malignant tumors. The most common benign tumor in individuals with NF-1 is neurofibroma, a heterogeneous benign peripheral nerve sheath tumor.[501,502] Neurofibromas can occur as discrete focal cutaneous or subcutaneous growths, as intraforaminal spinal tumors, or as plexiform tumors. Plexiform neurofibromas are composed of the same cell types as dermal neurofibromas but have an expanded extracellular matrix and a rich vascular supply.[502] In one study of 125 patients with NF-1, plexiform neurofibromas were clinically visible in 30%.[503] Schwannomas often originate from the intercostal or sympathetic nerves and can become quite large before being detected.[442] Surgery is the mainstay of treatment, but the possibility of achieving a R_0 resection depends on the extent of locoregional disease. Long-term local control rates range from 90% to 100%.[491,493,504,505] In adults, most malignant mediastinal neurogenic tumors are malignant peripheral nerve sheath tumors (MPNSTs). Individuals with NF-1 carry heightened risk of developing MPNSTs, with a lifetime risk of almost 10%.[506,507] Because most NF-1–associated MPNSTs arise within pre-existing plexiform neurofibromas, individuals with NF-1 and plexiform neurofibromas warrant increased surveillance. In addition to their association with NF-1, MPNSTs have also been linked with prior radiation exposure.[508–511] In one series from the Mayo Clinic, almost 10% of the patients

treated there over a 20-year period had a history of radiation exposure.[511]

With regard to anatomical origin, one single-institution experience reported that MPNSTs were located in the trunk in half of the patients studied.[495] The authors did not distinguish between mediastinal and retroperitoneal locations, but this distinction can be difficult given the lack of an anatomical barrier. Roughly, one-third of the patients in that study had NF-1. The median age at presentation of the MPNST was 37 years overall (27 years for patients with NF-1 and 40 for patients without).

Natural History and General Management

In up to 80% of cases, mediastinal neurogenic tumors present as an asymptomatic mass on a routine chest x-ray (Figs. 55.8 and 55.9). In some cases, these masses can grow slowly enough to involve nearly the entire hemithorax before detection.[494,512,513] Large or rapidly growing lesions can cause chest pain and nerve dysfunction (including Horner syndrome) from compression.[514] Proximal organs such as the vagus or phrenic nerves, esophagus, trachea, and cardiac chambers may be involved by direct extension or via the nerve sheath.[515–522] Local invasion and bony destruction are common.[523] Distant metastases are present in up to one-third of patients at diagnosis.[510] Because MPNSTs are difficult to detect before they infiltrate nearby structures (making surgery difficult) and metastasize, they carry a poor prognosis.[524]

Management of malignant mediastinal neurogenic tumors entails a multidisciplinary approach similar to the management of adult soft tissue sarcomas. High-resolution CT (Fig. 55.10) is essential, as is MRI (Fig. 55.11), to evaluate the neural and spinal anatomy if involvement is suspected.[525] A definitive pathologic diagnosis is often reached after surgical intervention; examples of histologic slides of a schwannoma and a neurofibroma are shown in Figures 55.12 and 55.13. Histologic examination often reveals nuclear atypia, mitotic figures, cellularity, typical Antoni A and B areas, and tumor necrosis; these findings, in combination with positive immunohistochemical staining for S-100 protein and negative staining for smooth muscle markers such as desmin, are suggestive of a nerve sheath origin. Of these features, the factor most reliably correlated with malignancy is a mitotic figure of 5 or more in 50 high-power fields.

Surgical resection is the mainstay of therapy. An R_0 resection should be attempted but is often difficult for mediastinal tumors because of impingement on surrounding structures and, in the case of neurofibromas, the risk of drastic

neurologic deficits. Advances in surgical technique, including minimally invasive approaches such as video-assisted thoracoscopic surgery, are available but should be undertaken only by experienced thoracic surgeons.[526–528]

As is true for the treatment of soft tissue sarcomas, radiation appears to improve local control for MPNSTs when combined with surgery. The largest published series to date describes findings from 134 patients with NPNSTs treated at the Mayo Clinic between 1975 and 1993.[511] Only 25 of those patients had mediastinal tumors, and an R_0 operation was possible for 70%, which was an improvement over a historical series showing an R_0/R_1 rate of only 55% for mediastinal MPNSTs.[529] About half of the patients received adjuvant radiation to a mean dose of 51 Gy using a variety of radiation techniques. At 10 years, the overall survival rate was 42% and local tumor control rate was 50% for the entire group of patients.

Prognostic factors for overall survival found to be significant in multivariate analyses were surgical margin status and history of radiation. Prognostic factors for local control were surgical margin status, radiation dose, and use of intraoperative radiation or brachytherapy. The use of adjuvant radiation nearly doubled local control rates from 40% to 73% at 3 years and from 34% to 65% at 5 years ($P = .0004$), but an apparent benefit in survival (43% vs. 58% at 5 years) was not statistically significant.

Other evidence supporting the use of radiation after surgery for MPNSTs come from a review of 205 patients with localized MPNSTs at all body sites treated over a 25-year period at the Istituto Nazionale per lo Studio e la Cura dei Tumori in Milan, Italy.[495] That study reported a disease-specific mortality rate of 43% at 10 years in the context of only half of the patients receiving radiation therapy. Variables found to be significant in multivariate analyses for survival included tumor site, tumor size (>12 cm), surgical margin status, and the use of adjuvant radiation (P = .016). All of the same factors except for radiation were significantly associated with local control. Patients who received radiation seemed to have had fewer recurrences, but this was not statistically significant. About 30% of patients eventually developed distant metastases, the vast majority of which were pulmonary.

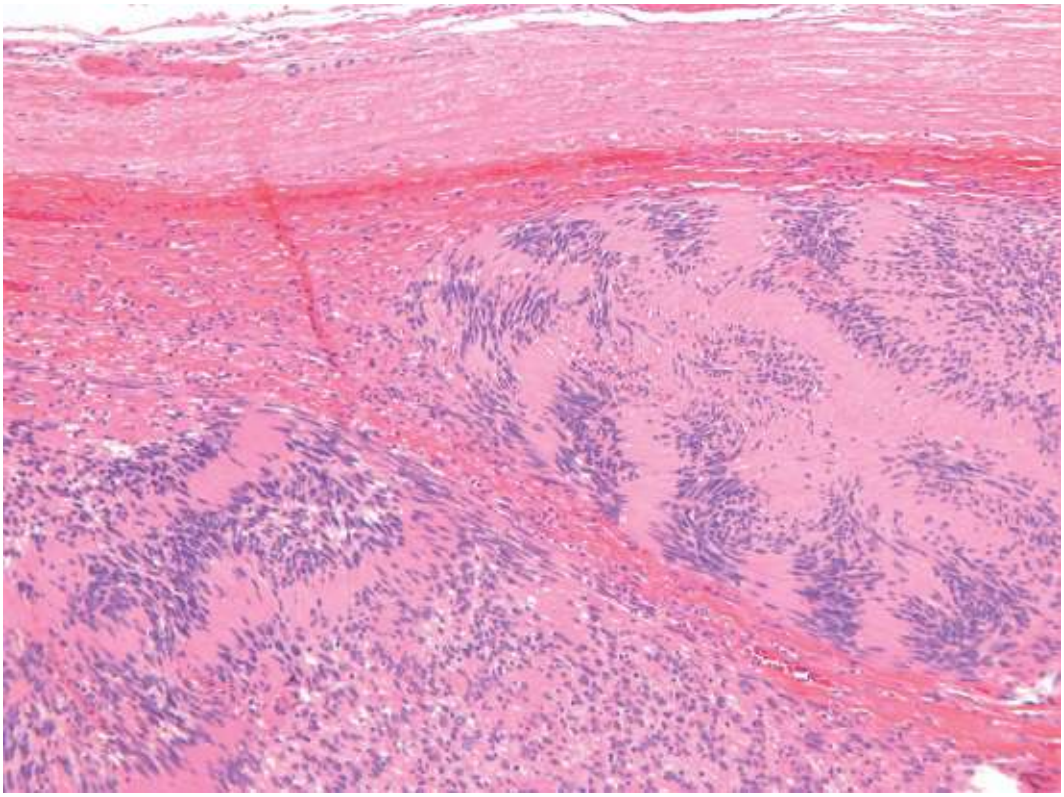

FIGURE 55.12. Hematoxylin-and-eosin–stained section of a schwannoma shows a circumscribed and encapsulated neoplasm composed of low-grade spindled and wavy Schwann cells with alternating palisaded cellular and stroma-rich areas (Verocay bodies) with nonpalisaded cellular foci (Antoni A areas) and hypocellular foci (Antoni B areas) (original magnification 100×). (Courtesy of David Sauer, MD.)

Planning and delivery of external beam radiation therapy for MPNSTs is facilitated with the use of modern approaches, including 3D conformal radiation, IMRT, and image-guided radiation using on-board imaging approaches. Patients with these tumors, which are complicated to manage, should be treated at centers with extensive multidisciplinary experience in thoracic and paraspinal neoplasms. Radiation treatment after surgery for microscopic disease should be given at a minimum dose of 60 Gy in 30 fractions, similar to the adjuvant dose given in other soft tissue sarcomas. Given the close proximity of the posterior mediastinum to the spinal cord, careful attention should be paid to immobilization and use of image guidance techniques. Although placing the patient in the prone position may reduce the distance from the localization points to the treatment volume, the patient must be able to rest comfortably in the same position throughout the treatments. Daily on-board imaging with stereoscopic guidance can ensure daily accuracy. IMRT is often necessary to provide a concave dose distribution around the spinal cord. In cases of gross residual

disease, higher doses may be beneficial but can be challenging to deliver given the constraints on exposure of normal tissues.

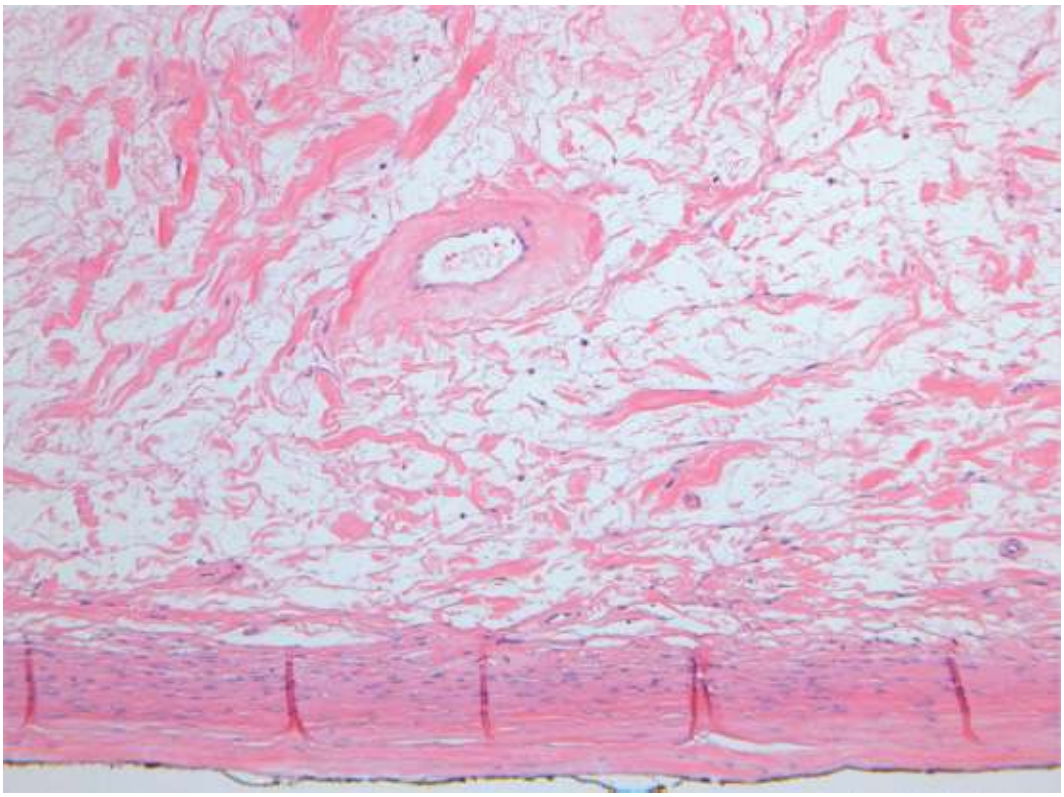

FIGURE 55.13. Hematoxylin-and-eosin–stained section of a neurofibroma shows a circumscribed and encapsulated neoplasm composed of a disorganized proliferation of low-grade spindled fibroblastic and Schwann cells within a myomatous and collagenous stroma (fibrils resembling shredded carrots). Scattered background mast cells and entrapped axons are also present (original magnification 100×). (Courtesy of David Sauer, MD.)

For patients with unresectable disease, radiation can be delivered either alone or with chemotherapeutic agents that are typically used for soft tissue sarcomas. Few agents are effective for MPNSTs, and treatment regimens usually include doxorubicin or ifosfamide.[530] Finally, significant progress has been made in recent years in elucidating the molecular genetics and biology of MPNSTs, especially in patients with NF-1. A variety of genetic alterations have been reported in MPNSTs, but it is yet unclear whether any of them are causally related to tumorigenesis or can be exploited for treatment effect.[531]

TRACHEAL CARCINOMAS

Tracheal neoplasms are quite rare, contributing to fewer than 0.5% of all

tumors.[532] Most of the information available to date is derived from pooled population-based datasets or single-institution series involving a variety of treatment regimens. Review of the largely retrospective data has revealed several patterns: First, surgical resection is the cornerstone of therapy; second, local recurrence is a major pattern of failure; and third, adjuvant radiation seems to have some positive effect on outcomes.

Demographics

Primary tracheal malignancy is exceedingly uncommon, accounting for approximately 0.1% to 0.4% of all diagnosed malignancies.[533] Epidemiologic data from the SEER project estimate an incidence of 0.2 per 100,000 persons in the United States; the true incidence of tracheal carcinomas is likely even lower.[37] Traditionally, adenoid cystic carcinomas (formerly known as cylindromas) were considered the most common tracheal neoplasms, but recent reports suggest that the most prevalent histology worldwide is squamous cell carcinoma (60% to 90%).[534]

Tracheal cancer affects roughly twice as many men as women; estimates of incidence from SEER database are 0.2 per 100,000 for men and 0.1 per 100,000 for women.[535] The male-to-female ratio is 2 to 3:1 for squamous cancer but is closer to 1:1 for adenoid cystic carcinomas.[536] Use of tobacco is associated with squamous cell carcinoma of the trachea but generally not with adenoid cystic carcinoma.[490] Squamous cell variants typically present during the sixth decade of life, whereas adenoid cystic carcinomas seem to present at younger ages. Other histologies include carcinoid, carcinosarcoma, granular cell tumor, hemangioma, neurogenic tumors, chondroma, and chondrosarcoma.[537–583]

Anatomy

The trachea is a fibrocartilaginous tube connecting the larynx superiorly and the mainstem bronchi inferiorly. The esophagus, thyroid, parathyroids, and trachea are derived from the same outpouching of the embryonic foregut; the lungs arise from terminal tracheal buds.

In adults, the trachea is 12 cm long; its diameter is slightly larger in men (2.3 cm) than in women (2.0 cm). In cross-section, the organ is “C” or “U” shaped. The upper border lies around the sixth or seventh cervical vertebra and the lower border around the fourth (full expiration) or sixth (full inspiration) thoracic vertebra. Each centimeter of trachea contains about two cartilaginous rings. The posterior aspect of the trachea is membranous and is intimately

associated with the esophagus. Three branches of the inferior thyroid artery supply blood to the upper half of the trachea and connect to the superior thyroid artery, which contributes small vessels that run from the tracheal wall adjacent to the thyroid isthmus. The bronchial arteries supply blood to the lower trachea and carina. Arterial branches interdigitate between each cartilaginous ring (see Fig. 55.2).

Natural History

Tracheal carcinomas can present with a variety of symptoms, including cough, dyspnea, dysphagia, and hemoptysis.[565,584] Yang et al. reported cough to be the most common symptom (present in 72% of patients), followed by dyspnea (66%), stridor (39%), hemoptysis (39%), and dysphonia (31%).[585] Adenoid cystic carcinomas in particular are often first mistaken for asthma, which is often treated as such until "refractory" obstructive symptoms are evaluated with bronchoscopy, typically after numerous "normal" chest radiographs.[583,584,586–595] Hemoptysis is more likely to be the presenting symptom of squamous cell carcinoma.[585,596] and dysphagia is considered an ominous sign.[597] In one study of nonadenoid cystic/nonsquamous tracheal tumors, benign tumors presented with dyspnea, whereas malignant tumors were associated with hemoptysis.[540]

In 40% to 50% of cases, adenoid cystic carcinomas are diagnosed with metastases,[598] but survival is relatively long despite the presence of such metastases.[596,599–602] In one series, the median survival time for such patients was 37 months,[536] and median reported survival from the time of diagnosis was approximately 5 years.[534,585] When these tumors spread, they almost always do so in distant nodes rather than in the locoregional paratracheal lymph nodes. Local recurrence is the predominant form of treatment failure and can appear 10 or more years after treatment.[603–605]

Unlike adenoid cystic carcinoma, squamous cell carcinoma has a much more aggressive course, with reported median survival times of only 6 to 12 months depending on resectability.[18,596,600,601,606–610] The disease often presents with local extension via paratracheal lymph nodes (in ~30% of cases) and distant metastases.[611]

The clinical course and natural history of other pathologic variants of tracheal tumors are difficult to accurately characterize because of the scarcity of reported findings. Adenocarcinomas and sarcomas are thought to have poor prognoses.[540,576,578,582,612–625] Granular cell tumor, carcinoid, lymphoma,

leiomyoma, and small cell carcinoma all have variable prognoses, yet they seem to be less aggressive than the squamous carcinomas, adenocarcinomas, or sarcomas.[540]

Staging and Prognostic Factors

No system for staging tracheal neoplasms has been universally accepted or adopted. One staging system proposed by Licht et al. does not seem to have predictable prognostic value.[46] In some studies, lymph node involvement does not seem to have a significant adverse effect on prognosis,[18,585,611] although an epidemiologic analysis showed an association between nodal status and survival outcomes.[626] The size and location of the tumor seem to be important because of the extent of surgical resection necessary to remove the tumor and higher postoperative mortality associated with carinal resection.[586,626,627]

In 2004, Bhattacharyya proposed a staging system wherein stage I is defined as T1N0 disease, stage II as T2N0, stage III as T3N0, and stage IV as T4N0 or any N1 disease (Table 55.10).[626] A similar system, with minor modifications, was used by Webb et al. in evaluating the experience at MD Anderson Cancer Center.[534] Subsequently, Macchiarini proposed a more elaborate staging model that draws from experience with other thoracic malignancies[532] (Table 55.10). However, at this time, it remains to be seen which system will be broadly implemented by clinicians or validated with large-scale clinical datasets.

TABLE 55.10 STAGING SYSTEMS FOR TRACHEAL CARCINOMA

Bhattacharyya Staging System[581]

Primary Tumor (T)

T1	Primary tumor confined to the trachea; size <2 cm
T2	Primary tumor confined to the trachea; size >2 cm
T3	Spread outside the trachea but not to adjacent organs or structures[a]
T4	Spread to adjacent organs or structures[a]
Tx	Unknown or cannot be assessed

Regional Lymph Nodes (N)

N0	No evidence of regional nodal disease
N1	Positive regional nodal disease
Nx	Unknown or cannot be assessed

[a]The MD Anderson system denotes “arising from but extending outside of trachea” as T3 disease and does not use T4.[490]

Anatomic Stage/Prognostic Groups

Stage		
I	T1	N0
II	T2	N0
III	T3	N0
IV	Any	N1
IV	T4	Any

Macchiarini Staging System[487]

Primary Tumor (T)

Tx	Cannot be assessed
Tis	Any tumor without invasion
T1a	<3 cm limited to mucosa
T1b	≥3 cm limited to mucosa
T2*	Any tumor that invades cartilage or adventitia
T3	Any tumor that invades trachea or larynx
T4a	Any tumor that invades carina or main bronchus
T4b	Any tumor that invades neighboring structures

Regional Lymph Nodes (N)

Nx	Regional lymph nodes cannot be assessed
N0	No evidence of node metastasis
N1	Local nodes positive (N1a < 3 cm; N1b ≥ 3 cm)
Upper third	Highest mediastinal nodes; upper paratracheal nodes, prevascular and retrotracheal
Middle third	Upper paratracheal nodes; prevascular and retrotracheal; lower paratracheal nodes; para-aortic nodes (ascending aorta or phrenic)
Lower third	Upper paratracheal nodes; prevascular and retrotracheal; subaortic nodes (aortopulmonalis window)
N1A	1–3 positive nodes in upper third
N1B	>3 positive nodes in upper third
N2	Regional nodes positive
Upper third	Lower paratracheal nodes; subaortic nodes (aortopulmonalis window)
Middle third	Highest mediastinal nodes; subaortic nodes (aortopulmonalis window)
Lower third	Upper paratracheal nodes; pulmonary ligament

Distant Metastasis (M)

Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Metastasis to nodes other than N1 and N2
M2	Distant metastasis (e.g., lung)

Anatomic Stage/Prognostic Groups

Stage

0	Tis	N0	M0
Ia	T1a	N0	M0
Ib	T1b–2	N0	M0
IIa	T1b–2	N1	M0
IIb	T1b–2	N2	M0
IIIa	T3	N0	M0
IIIb	T3	N1–2	M0
IVa	Any	N1–2	M1
IVb	Any	N1–2	M2

General Management

Bronchoscopy is essential for diagnosis of tracheal malignancies and for preoperative surgical planning.[584,628–630] In acute respiratory compromise, rigid bronchoscopy (see Fig. 55.2) may be indicated to "core out" the tracheal neoplasm.[586,631,632] In one series of 56 patients reported by Mathisen and Grillo, rigid bronchoscopy led to improved airway symptoms in 90% of cases, with 5% experiencing mild, easily controlled bleeding.[633] Esophagoscopy is suggested for all patients to rule out esophageal invasion. A CT scan of the chest is indicated to aid in evaluation of tumor extension, resectability, involvement of lymph nodes, and pulmonary metastases,[565,584,630,634–638] and coronal reconstruction can be helpful to evaluate tracheal wall thickening and extraluminal extension.[639]

Treatment Approaches

Resectability is universally associated with lower mortality in reported series[18,601,628,640] and as such is the initial strategy for most tracheal primaries.[532,610,611,628,635,641–643] Resection rates vary, however, by institutional and national practice, from 10% to over 65% based on the above cited studies. Historic registry data from the Netherlands demonstrated a resection rate of 12%[606]; however, a recent update[644] suggests that 24% underwent resection in 2000 to 2005 (vs. 58% who received radiotherapy). Contraindications to resection depend in large part on the preference of the surgeon; for example, Pearson recommends tracheal resection for at least some patients with adenoid cystic carcinoma with low burden pulmonary metastases, yet many would consider such cases unresectable.[536,598,645] Regardless, many tracheal carcinomas are either improperly classified (e.g., nontracheal primaries with tracheal extension) or are systematically undertreated surgically.[644]

Most patients undergoing surgery have a median sternotomy and cervical collar excision, although extensive subglottic or high tracheal disease may

require cervical exenteration with mediastinal tracheostomy.[598,604,611] Margins may of necessity be compromised to ensure a functioning airway. Technical advances in surgical procedures such as complete mobilization of the right hilar ligament, detachment/implantation of the left hilum, mobilization of the cervical trachea, and techniques for carinal resection/reconstruction and intrapericardial dissection have improved the likelihood of an R_0 resection.[338,627,640,646] Gaissert et al. reported improvements in both complete resection rates (from 68% to 82%) and in-hospital mortality (declining from 21% to 3%) with the increasing use of such techniques over a 40-year period.[600,641]

After resection, postoperative radiation is usually recommended.[534,600,601,628,629,632,641] Pathologic features such as completeness of resection, involvement of the thyroid gland, and lymphatic invasion have clearly been shown to have prognostic value,[647] and postoperative radiotherapy is routinely recommended for all patients at many institutions.[534,647] Preoperative radiotherapy has also been attempted, but fewer reports of this experience have been published. In aggregate, several small retrospective series seem to show a benefit for adjuvant radiation (Table 55.11). Chow et al. found that patients who underwent resection plus adjuvant radiation had a median survival time of 61 months versus 16 months for those who received only surgery.[648] Regnand and others found that 31 patients who had had a complete resection with adjuvant radiation had seemingly better 5-year survival rates than did 27 patients without adjuvant radiation (74% vs. 53%), but this apparent difference was not statistically significant.[18]

Postoperative radiation seems to be effective for incompletely resected disease as well, with 5-year survival rates of 45% for such patients versus 0% for patients who did not receive radiation ($P < .05$).[18] Webb et al., describing the experience at MD Anderson, demonstrated a statistically significant improvement in survival for patients given adjuvant radiotherapy rather than chemoradiation; however, no difference in survival was found between adjuvant radiotherapy and surgery alone.[534] The results of studies of definitive therapy for tracheal tumors are summarized in Table 55.12.

TABLE 55.11 RESULTS OF RESECTION WITH ADJUVANT IRRADIATION FOR PRIMARY TRACHEAL CARCINOMA

Study and Reference	Histology	Treatment	Median Survival Times or Rates

Grillo and Mathisen[601]	Squamous (n = 70)	Surgery ± RT[a]	34 mo
		RT	10 mo
	Adenoid cystic (n = 80)	Surgery ± RT[a]	118 mo
	(n = 80)	RT	28 mo
Licht et al.[46]	—	Surgery alone (n = 6)	48% (5-year actuarial)
		RT alone (n = 35)	7%
		Laser/cautery ± RT (n = 24)	28%
		RT + chemo (n = 2)	0%
Chow et al.[648]	—	Surgery alone (n = 5)	16 mo
		RT alone (n = 12)	26 mo
		Surgery + RT (n = 5)	61 mo
Regnard et al.[18]	—	R_0 + RT (n = 31)	74% (5-y actuarial)
		R_0 (n = 27)	53% (P = NS)
		$R_{1,2}$ + RT (n = 15)	47%
		$R_{1,2}$ (n = 6)	0% (P < .05)
Maziak et al.[536]	Adenoid cystic (n = 35)	R_0 ± RT (n = 14)[a]	9.8 y
		$R_{1,2}$ + RT (n = 15)	7.5 y
		RT alone (n = 6)	6.2 y

[a]A minority of these patients received surgery alone.
R_0, complete resection; $R_{1,2}$, incomplete resection; RT, radiation therapy.

Radiation has also been used as monotherapy for unresectable tumors. Results are best when doses have exceeded 60 Gy.[607,650,652] Mornex et al. found that the 5-year survival rate decreased from 12% for those receiving at least 56 Gy to 5% for those receiving lower doses.[654] However, Chow et al. caution against giving doses higher than 60 Gy, as three of six patients in their study given doses in excess of 60 Gy had severe complications requiring surgical intervention, such as tracheoesophageal fistula, esophageal stricture, and severe tracheal crusting,[648] whereas none of the six patients treated with <60 Gy in that study had late side effects. Other authors have corroborated the concern of high doses contributing to the risk of complications.[655] Still, Chow et al. noted significantly better local control among patients who received >50 Gy as adjuvant therapy and >60 Gy as definitive therapy.[603] By way of comparison, Fuwa et al. reported reasonable results with a novel endoluminal-centering catheter; the median dose delivered to the group as a whole was 91 Gy (given as external beam radiation with low–dose rate ^{192}Ir brachytherapy). Only one treatment-related death was reported 1 year after therapy in a patient who had received a total dose of

113 Gy.[653] Harms et al., using median doses of 60 Gy delivered by external beam radiation plus 15- to 18-Gy brachytherapy boosts, reported minimal rates of severe (grade 3 to 4) toxicity (8% of 25 patients).[656] Exploratory studies of fast neutrons for locally advanced adenoid cystic carcinomas have been reported; in the University of Washington experience with endoluminal brachytherapy, fast neutrons were considered feasible with acceptable toxicity.[657] A summary of the experience with radiation as monotherapy for primary tracheal neoplasms is given in Table 55.11.

Combined chemoradiotherapy without resection has been attempted at some institutions, usually for nonsquamous tumors, with mixed results.[534,596,658,659] In general, patients with squamous cell carcinoma have fared poorly, and those with small cell carcinoma or lymphoma have done better.[46,534,585,660]

Radiation Techniques

No evidence is available to suggest that adjuvant radiation therapy is not beneficial in tracheal malignancies; however, any postoperative radiation should not be begun before 30 to 45 days after surgery to allow sufficient wound healing. Modern CT-based 3D conformal or intensity-modulated radiation techniques should be used. Aggressive treatment is warranted to prevent airway obstruction even when the intent is palliative.[654] External beam doses should be about 60 Gy for fully resected disease,[534] with a boost considered for squamous cell lesions with high-risk features.[647] An intraluminal boost technique allows the dose to be increased (and, theoretically, local control to be increased as well) with minimal added acute or late side effects.[609,648,656,661–663] Standard constraints on organs at risk should be observed in all cases.[271,272,274,664]

Intraluminal brachytherapy is also useful for palliative treatment. Skowronek et al., in a study of patients treated with 10 to 30 Gy in one to three fractions, found that high-dose brachytherapy as monotherapy led to prolonged survival and improved quality of life.[663] In patients with locally extensive disease, the gravest complication of radiation therapy is the development of a tracheoesophageal fistula, which can be difficult if not impossible to avoid. For patients with emergent airway obstruction, rigid bronchoscopy should be performed instead of urgent radiotherapy.

The role of elective nodal irradiation for tracheal carcinoma is uncertain. As mentioned earlier, nodal status does not seem to have prognostic significance; even cervical adenopathy was not associated with poorer outcome.[585] Given the low proclivity for lymphatic spread of adenoid cystic carcinomas, the choice to

avoid elective nodal irradiation for this variant is certainly reasonable. Because local recurrence is the major factor influencing survival, nodal and regional failure patterns are not a main concern. Yet, if mediastinal or cervical nodes are seen on radiographic or pathologic examination, or if worrisome pathologic risk features[647] are discovered at surgery, radiation to these regions should be considered.

TABLE 55.12 RETROSPECTIVE SERIES EXAMINING RADIOTHERAPY ALONE FOR PRIMARY TRACHEAL CARCINOMA

Study and Reference	Histology	Treatment	Local Control	Survival
Schraube et al.[609]	Squamous (*n* = 11)	46–60 Gy RT + 15–20 Gy HDR	6/11	31 mo median
Cheung[649]	Squamous (*n* = 20)	40–60 Gy		5 mo median
	Adenoid cystic (*n* = 4)	40–60 Gy		12 mo median
Fields et al.[650]	Squamous (*n* = 17) Adenoid cystic (*n* = 1)	>60 Gy	5/6	25% at 5 y (*n* = 18)
		40–60 Gy	1/7	
		<40 Gy	0/4	
		>60 Gy	1/1	
Rostom and Morgan[651]	Squamous (*n* = 28)	60–70 Gy	16/24	11% (4-y actuarial)
	Adenoid cystic (*n* = 3)	<60 Gy	0/4	67% at 4 y
		50–70 Gy		
Makarewick and Mross[652]		60 Gy RT + 6–12 Gy HDR (*n* = 8)	6/8	9.5 mo median (*n* = 23)
		40–60 Gy RT (*n* = 3)	1/3	
		<40 Gy (*n* = 12)	0/12	
Fuwa et al.[653]		RT + LDR (*n* = 4)	3/4	75% at 3 y
		(80–128 Gy)[a]		

[a]One treatment-related death in patient receiving 60 Gy RT + 53 Gy LDR Ir-192.
HDR, high–dose rate brachytherapy; LDR, low–dose rate brachytherapy; RT, external beam radiotherapy.

CONCLUSION

Primary tracheal cancer is quite rare and, in most cases, is of squamous or adenoid cystic histology. The optimal management strategy for these tumors seems to be a combined modality approach incorporating surgical resection and postoperative radiation. For localized disease, the role of chemotherapy, either alone or concurrent with radiation, is unknown.

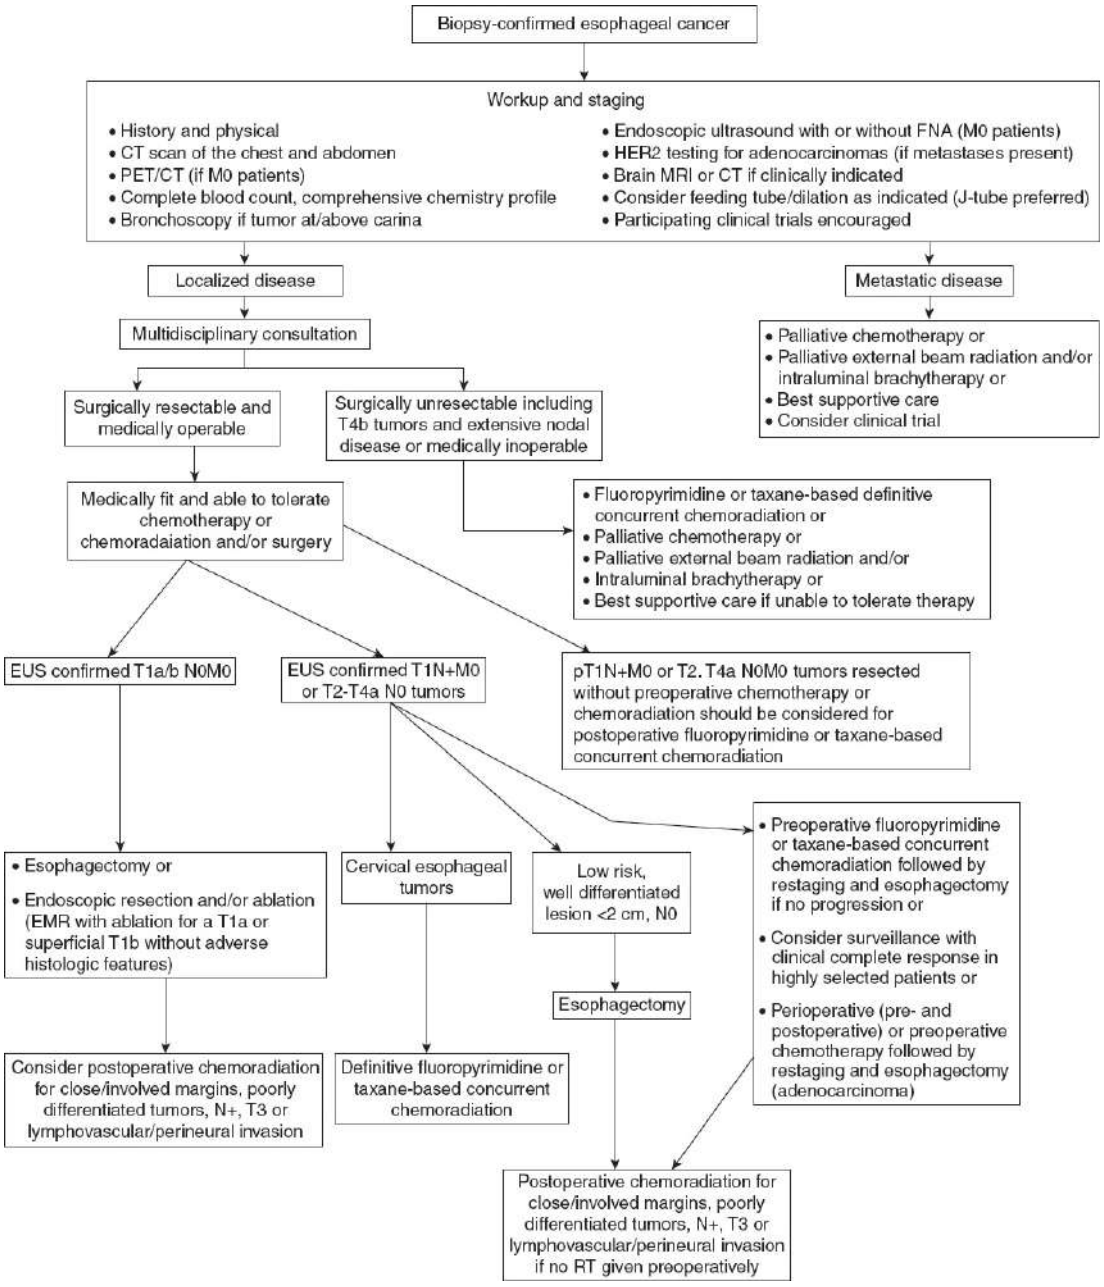
CHAPTER 56

Esophageal Cancer

Brian G. Czito, Manisha Palta, and Christopher G. Willett



Treatment algorithm for newly diagnosed esophageal cancer. Treatment approaches are based in location and stage of the tumor, as well as surgical resectability and medical comorbidities of the patient. CT, computed tomography; EUS, endoscopic ultrasound; FNA, fine-needle aspiration; MRI magnetic resonance imaging; PET, positron emission tomography.

Less than 15% of patients diagnosed with esophageal cancer are cured, with approximately half of patients presenting with unresectable or metastatic disease. This chapter reviews the natural history and treatment of esophageal cancer, including anatomy, risk factors, patterns of spread and recurrence, staging, results of current therapeutic approaches, radiation planning techniques, toxicity data, and future treatment strategies.

ANATOMY

The esophagus is a thin-walled, hollow tube approximately 25 cm in length. It is lined with stratified keratinized squamous epithelium, extending from the cricopharyngeus muscle at the level of the cricoid cartilage superiorly to the gastroesophageal junction inferiorly. The lower one-third (5 to 10 cm) of the esophagus may contain glandular elements. Replacement of the stratified squamous epithelium with columnar epithelium is referred to as Barrett esophagus, often occurring in the lower one-third. The Z line refers to the endoscopically visible junction of the squamous and glandular epithelium. The esophageal wall is composed of three layers: the mucosa, submucosa, and muscularis propria (Fig. 56.1). The mucosal layer contains the epithelium, lamina propria, and muscularis mucosae. The epithelium is separated from the lamina propria by a basement membrane. In the portion of the esophagus containing columnar-type epithelium, the muscularis mucosae may consist of two layers. The mucosa may be divided into distinct layers, including M1 (epithelium), M2 (lamina propria), and M3 (muscularis mucosae). Similarly, the submucosal layer may be divided into inner (SM1), middle (SM2), and outer (SM3) layers. The muscularis propria consists of a circular inner layer and longitudinal outer layer. The adventitia (periesophageal connective tissue) lies directly on the muscularis propria.[1] No serosa is present, facilitating extraesophageal spread of disease.

Although somewhat arbitrary, the esophagus is frequently divided into cervical and thoracic components. The most recent American Joint Committee on Cancer (AJCC) report divides the esophagus into four regions: cervical, upper thoracic, midthoracic, and lower thoracic (Fig. 56.2).[1] The cervical esophagus

lies within the neck and begins at the cricopharyngeus muscle (approximately the C7 level or 15 cm from the incisors) and extends to the thoracic inlet (at approximately the T3 level or at ~20 cm from the incisors [the level of the suprasternal notch]). The thoracic esophagus extends from approximately the level of T3 (beginning at about 20 cm) to T10 or T11.[1,2] The upper thoracic esophagus is bordered superiorly by the thoracic inlet and inferiorly by the lower border of the azygos vein, extending from approximately 20 to 25 cm. Radiographically, tumors in this location would be located between the sternal notch and azygos vein. The middle thoracic esophagus extends from the lower border of the azygos vein to the inferior pulmonary veins, extending from approximately 25 to 30 cm. The lower thoracic esophagus extends from the inferior pulmonary veins and to the stomach and is inclusive of the gastroesophageal junction, typically extending from approximately 30 to 40 cm. Endoscopically, the gastroesophageal (GE) junction is often defined as the point where the first gastric fold is encountered, although this may be a “theoretical” landmark. The location of the GE junction can be accurately defined histologically as the squamocolumnar junction. In the most recent AJCC staging system, cancers with an epicenter in the lower thoracic esophagus or gastroesophageal junction or within the proximal 2 cm of the stomach (i.e., cardia) and extending up to the GE junction or esophagus are staged as an adenocarcinoma of the esophagus. If the epicenter is >2 cm distal to the gastroesophageal junction, these are classified as stomach cancers. Useful landmarks in reference to endoscopy include the carina (∼25 cm from the incisors) and gastroesophageal junction (∼40 cm from the incisors).

Siewert et al.[3,4] characterized cancer *involving the gastroesophageal junction* according to the location of the tumor (Fig. 56.3). If the tumor center is located from >1 cm up to 5 cm above the gastroesophageal junction (Z line), the tumor is classified as a type I adenocarcinoma of the distal esophagus. If the tumor center is located within 1 cm cephalad to 2 cm caudad to the gastroesophageal

junction, it is classified as type II. If the tumor center is located >2 cm below the gastroesophageal junction, the tumor is classified as type III. Only Siewert type I/II tumors would be staged as esophageal cancer in the most recent staging AJCC staging system. However, locally advanced/bulky tumors can make it difficult to accurately distinguish where tumors originated in relationship to the GE junction.

Lymphatic Drainage

The esophagus has an extensive, longitudinal interconnecting system of

lymphatics. The esophageal lymphatic network is primarily located within the submucosa (Fig. 56.1); however, channels are also present within the lamina propria, facilitating spread of even superficial cancers of the esophagus involving the mucosa. In addition to these longitudinal lymphatics, intramural lymphatics may traverse the muscularis propria, facilitating tumor spread to regional lymphatic channels and paraesophageal nodes. Supporting this, autopsy series have demonstrated a relatively high incidence of directly draining channels extending from the submucosa lymphatics into the thoracic duct (Fig. 56.1), facilitating systemic spread. Lymph can travel the entire length of the esophagus before draining into lymph nodes,[2] and thus, the entire esophagus is at potential risk for lymphatic involvement. Up to 8 cm or more of "normal" tissue can exist between gross tumor and micrometastases "skip areas" secondary to this extensive lymphatic network.[5] In addition, as many as 71% of frozen tissue sections scored as margin negative by conventional histopathology show involvement by lymphatic micrometastases with immunohistochemistry.[6] Lymphatics of the esophagus drain into nodes that usually follow arteries, including the inferior thyroid artery, the bronchial and esophageal arteries, and the left gastric artery (celiac axis).[7]

Epidemiology and Risk Factors

Esophageal carcinoma accounts for approximately 6% of all gastrointestinal malignancies. In 2018, there will be an estimated 17,290 new patients diagnosed with esophageal cancer in the United States and 15,850 deaths. Worldwide, in 2012, an estimated 455,800 esophageal cancer cases and 400,200 deaths occurred. Most cases occur in males, at a rate of 4:1 relative to females.[8–10]

The incidence of esophageal carcinoma varies according to geography. The highest incidence occurs in Linxian, China, Russia, and the Caspian region of Iran. The incidence in these regions is 100/100,000 persons. What is often referred to as the "esophageal cancer belt" extends from northern Iran through the Central Asian republics to north-central China. In areas such as northern France, Kazakhstan, and South Africa, incidence can be as high as 50 to 99/100,000. Although the reasons for the geographic discrepancy are unknown, some reports have linked the arid climate and alkaline soil with these high-risk areas, as well as the ingestion of nitrosamines, and inversely to the consumption of riboflavin, nicotinic acid, magnesium, and zinc.[11,12] In the United States, the incidence rate among males is <5/100,000. Over the last 20 years, there has been an increase in the incidence of adenocarcinoma at a rate of 5% to 10% per

year.[13] In 1987, adenocarcinoma was reported to represent 34% and 12% of esophageal cancers in white men and women versus 3% and 1% for African American men and women, respectively.[13] As of 1998, esophageal adenocarcinoma accounted for almost 55% of all diagnosed cases in white men, and in the United States, the rates of adenocarcinoma now exceed those of squamous cell carcinoma. African American men are more frequently diagnosed with squamous cell carcinoma.[13–15]

In North America and Western Europe, alcohol use and tobacco use are the major risk factors for squamous cell carcinoma, accounting for 80% to 90% of cases.[16] Reports have described the relative risk of esophageal cancer by the amount of alcohol and tobacco consumed, including a relative risk of 155:1 when consuming >30 g/day of tobacco along with 121 g/day of alcohol.[17]

Diets low in fruits, vegetables, and animal products result in marginal deficiencies in vitamins and trace elements and are associated with development of squamous cell carcinoma.[18] Patients with Plummer-Vinson (Paterson-Kelly) syndrome, a condition characterized by iron deficiency anemia and low riboflavin levels, are at an increased risk for oral cavity, hypopharyngeal, and esophageal cancer. In addition, dietary intake of nitrosamines, nitrosamides, and *N*-nitroso compounds and exposure to polyaromatic hydrocarbons have been implicated in esophageal carcinoma. Examples of nitrate-rich foods include pickled vegetables, alcoholic beverages, cured meats, and fish. Betel quid chewing in Taiwan and India has been implicated as a potential cause as well.[19–21] Thermal irritation from consumption of hot beverages, soup, and food and physical irritation due to loss of teeth (poor oral hygiene) have been implicated in some studies. The role of HPV 16 and 18 has been linked to squamous cell carcinoma in some geographic areas although these results are inconsistent.[21]

Other risk factors associated with esophageal carcinoma include achalasia and tylosis. Achalasia of long duration (25 years) is associated with a 5% incidence of squamous cell carcinoma.[22,23] Patients with tylosis (hyperkeratosis of the palms and soles and papilloma of the esophagus) have a reported 38% risk in developing esophageal cancer at a mean age of 45 years.[24] In addition, carcinoma of the esophagus occurs in 2% to 4% of patients with head and neck cancer.

Risk factors leading to the development of adenocarcinoma of the esophagus are being increasingly understood. Most esophageal adenocarcinomas tend to arise from the metaplastic columnar-lined epithelium known as Barrett

esophagus.[25] Severe and long-standing gastroesophageal reflux disease has clearly been shown to be a significant risk factor for Barrett esophagus, which may lead to adenocarcinoma. It has been estimated that patients with long-standing severe reflux have a 44-fold risk of developing adenocarcinoma.[26] Tobacco use is a more moderate risk factor for adenocarcinoma development. Smokers appear to have a two- to threefold greater risk for developing esophageal adenocarcinoma than do nonsmokers.[27,28] The relative risk of esophageal adenocarcinoma persists even after three decades following smoking cessation, in contrast to a significant decline in similar patients with squamous cell carcinoma.[29] Obesity has also been linked to a threefold to fourfold risk of adenocarcinoma, possibly because of an increased risk of reflux.[30] It has been estimated that a middle-aged patient with Barrett esophagus has a 10% to 15% risk of developing esophageal adenocarcinoma during his or her lifetime, although other reports have suggested this risk may be overstated.[31]

Although many risk factors are associated with esophageal carcinoma, few studies have demonstrated a causal relationship leading to pathogenesis. Montesano et al.[32] reported possible genetic abnormalities involved in the genesis of esophageal cancer. In addition, possible differences in mechanisms of pathogenesis for squamous cell carcinoma and adenocarcinoma were described. Genetic abnormalities in squamous cell carcinoma include p53 mutations and multiple allelic losses at 3p and 9q, with amplification of cyclin D1 and epidermal growth factor receptor (EGFR). These mutations lead to cell hyperplasia, low- and high-grade dysplasia, and, ultimately, squamous cell carcinoma. In contrast, genetic abnormalities in adenocarcinoma include overexpression of p53; multiple allelic losses at 17p, 5q, and 13q; and amplification and overexpression of EGFR and human epidermal growth factor receptor 2 (HER-2). These abnormalities may be involved in the stepwise development of Barrett esophagus, dysplasia, and, ultimately, adenocarcinoma. These differences suggest that squamous cell carcinoma and adenocarcinoma have different series of genetic mutations as etiologies, but these abnormalities occur in 23% to 94% of tumors studied. Whole exome sequencing has identified mutations in p53 and the cyclin-dependent kinase inhibitor CDKN2, as well as multiple other known tumor-associated genes, in both adenocarcinoma and squamous cell carcinoma.[33,34]

NATURAL HISTORY AND PATTERNS OF SPREAD

Squamous cell carcinoma is characterized by extensive local growth and proclivity to lymph node metastases. Because the esophagus has no covering serosa, direct invasion of contiguous structures may occur early. Lesions in the upper esophagus can impinge on or invade the recurrent laryngeal nerves, carotid arteries, and trachea. If extraesophageal extension occurs in the mediastinum, tracheoesophageal or bronchoesophageal fistula may occur. Tumors in the lower one-third of the esophagus can invade the aorta or pericardium, resulting in mediastinitis, massive hemorrhage, or empyema.

A review correlating the incidence of lymph node metastases with depth of penetration revealed that 18% of patients with spread to the submucosa had lymph node involvement.[35] For T1 lesions, the reported incidence of nodal spread is 10% to 21%, although this may be higher or lower depending on depth of involvement; for T2 lesions, this rises to 33% to 69%.[36–39] The location of involved lymph nodes is influenced by the origin of the primary tumor. At autopsy, lymph node metastases are found in approximately 70% of patients.[40–42] In patients with cervical lesions, lymph node metastases to the abdominal lymph nodes are rare. Distant metastasis can occur at almost any site (Table 56.1).[43]

A review of 1,077 patients with squamous cell carcinoma of the thoracic esophagus undergoing esophagectomy further characterized patterns of nodal spread. Primary disease was located in the upper (5%), middle (63%), and lower (32%) thoracic esophagus. In total, 47% of patients had lymph node metastases. On multivariate analysis, T stage, tumoral length, and degree of differentiation significantly correlated with incidence of lymph node metastases. In approximately 6% of cases, skip metastasis (distant lymph node metastases without regional lymph node metastasis) occurred, usually in patients with poorly differentiated, large, and deeply invasive tumors. Of involved nodes, 37% were macroscopically involved versus 63% microscopically involved, indicating that most lymph node metastases would be below the resolution of detection using contemporary imaging tools. Lymph node involvement was grouped into five categories: cervical, thoracic upper mediastinum, thoracic middle mediastinum, thoracic lower mediastinum, and abdominal lymph nodes. Figure 56.4 shows the incidence of nodal metastases based on primary tumor location.[44] A similar study of 1,893 thoracic squamous cell carcinoma patients from China mapped patterns of lymph node metastases by primary tumor location, with similar patterns of spread. In this study, independent prognostic factors for lymph node metastases included tumor length, differentiation, and depth of

invasion. The authors recommended treating nodal basins according to clinicopathologic factors, including enlargement of fields of patients of adverse histologic features, demonstrating similar rates of spread compared to the previously described series.[45]

TABLE 56.1 DISTRIBUTION OF METASTASES BY ANATOMIC SITE

From Anderson LL, Lad TE. Autopsy findings in squamous-cell carcinoma of the esophagus. *Cancer* 1982;50(8):1587–1590. Copyright © 1982 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.

For lower esophageal and gastroesophageal junctional adenocarcinomas, approximately 70% of patients will have nodal metastases at presentation. This is influenced by tumoral depth of penetration, with nearly all T3 and T4 lesions exhibiting metastases in surgical series. Pathologic resection data demonstrated rates of lymphatic involvement for lower esophageal and GE junctional tumors of 45%, 85%, and 100% for T2, T3, and T4 tumors, respectively (Fig. 56.5).[37] In patients with lower esophageal cancer, involvement of both mediastinal and abdominal lymph nodes is common (Fig. 56.6).[37] The primary direction for lymphatic flow for the lower esophagus is toward the abdomen. According to the classification by Siewert, nodal metastases are often seen in the mediastinum and abdomen for type I tumors, whereas type III tumors metastasize almost exclusively inferiorly, toward the celiac axis. Type II tumors are intermediate, preferentially spreading inferiorly and less frequently into the mediastinum. The primary value in the Siewert classification is to the guidance of appropriate type surgery (i.e., type I tumors are generally treated with esophagectomy and

mediastinal lymph node resection, with types II and III approached through the abdomen), although it may be useful in radiation field design as well.[3] Generally speaking, the incidence of abdominal nodal involvement increases as one proceeds distally in the esophagus to the gastroesophageal junction. For patients with tumors arising from the gastroesophageal junction, mediastinal involvement is less common. Nodal metastases above the level of the carina are rare in lower esophageal and junctional tumors.[46] In addition, histologic analyses of lower esophagus and gastroesophageal junction adenocarcinoma specimens suggest that many patients without nodal involvement on conventional histopathology actually are involved when assessed by immunohistochemistry.[47]

Extensive nodal mapping has been performed by Japanese investigators, who have devised the Japanese Gastric Cancer Association Classification (Fig. 56.7).[48] Using this system of nodal classification, investigators from Erlangen evaluated 326 patients with esophagogastric junction carcinoma undergoing primary resection. Tumors were stratified as AEG type I (distal esophagus), II (gastric cardia), and III (subcardia). Note there was significant overlap in the majority of tumors for all stages, with an overall incidence of lymph node metastasis of 71%. In T1 patients, only 17% exhibited lymph node metastasis, whereas 78%, 86%, and 90% of T2, T3, and T4, respectively, had involved nodes. Figure 56.8 shows varying patterns of nodal spread based on T stage as well as AEG location. Additional generalizations from this study include the following: (a) lymph vascular invasion was highly predictive of nodal spread and (b) proximal extension of type II and III tumors into the distal esophagus (particularly beyond the Z line) predicted an increasing incidence of paraesophageal lymph node involvement.[49]

LOCAL FAILURE

In an older series at the University of Pennsylvania and Fox Chase Cancer

Center of patients with adenocarcinoma of the esophagus and gastroesophageal junction treated with surgery alone, the locoregional recurrence rate was 77%.[50] In contemporary randomized trials, local failure rates with surgery alone range from 29% to 45%.[51–54] Similarly, data from contemporary randomized trials of esophageal cancer using "definitive" chemoradiation also indicate that local failure is a major cause of failure, with approximately 50% of patients failing locally (Table 56.2). Similarly, in a study of 239 patients receiving definitive chemoradiotherapy, 50% presented with local failure, 48% distant failure, and 31% no failure. Of local failures, 90% were within the gross tumor volume (GTV), whereas clinical target volume (CTV) and planning target volume (PTV) failures were seen in only 23% and 12%, respectively.[58] In many trials, patterns of failure are reported as first site of recurrence. This fact, along with infrequent post-therapy imaging and inability to detect subclinical recurrences, likely leads to underestimates of local recurrence rates. These data clearly emphasize the need for improvements in local treatment modalities.

CLINICAL PRESENTATION

Symptoms of esophageal cancer often start 3 to 4 months before diagnosis. Location of the primary tumor in the esophagus may influence presenting symptoms. Dysphagia is seen in >90% of patients regardless of location. Odynophagia is present in up to 50% of patients.[59] Weight loss is common, with 40% to 70% of patients reporting a loss of >5% of total body weight. This extent of weight loss has been associated with a worse prognosis. Less frequent symptoms may include vague chest pain, hoarseness, cough, and glossopharyngeal neuralgia.[60]

Advanced lesions can produce signs and symptoms from tumor invasion into local structures. Hematemesis, hemoptysis, melena, dyspnea, and persistent cough secondary to tracheoesophageal or bronchoesophageal fistula may occur. Compression or invasion of the left recurrent laryngeal nerve or the phrenic nerves can cause dysphonia or hemidiaphragm paralysis. Superior vena cava syndrome and Horner syndrome can also occur for more advanced lesions. Pleural effusion and exsanguination resulting from aortic communication may also be rarely seen.[59] Abdominal and back pain may occur with celiac axis nodal involvement with lower esophageal tumors.

DIAGNOSTIC WORKUP

After a thorough history and physical examination, all patients with suspected esophageal cancer should have a workup similar to that outlined in Table 56.3. Attention should be paid to cervical and supraclavicular lymph nodes. Basic blood counts and a metabolic panel with liver function tests should be obtained.

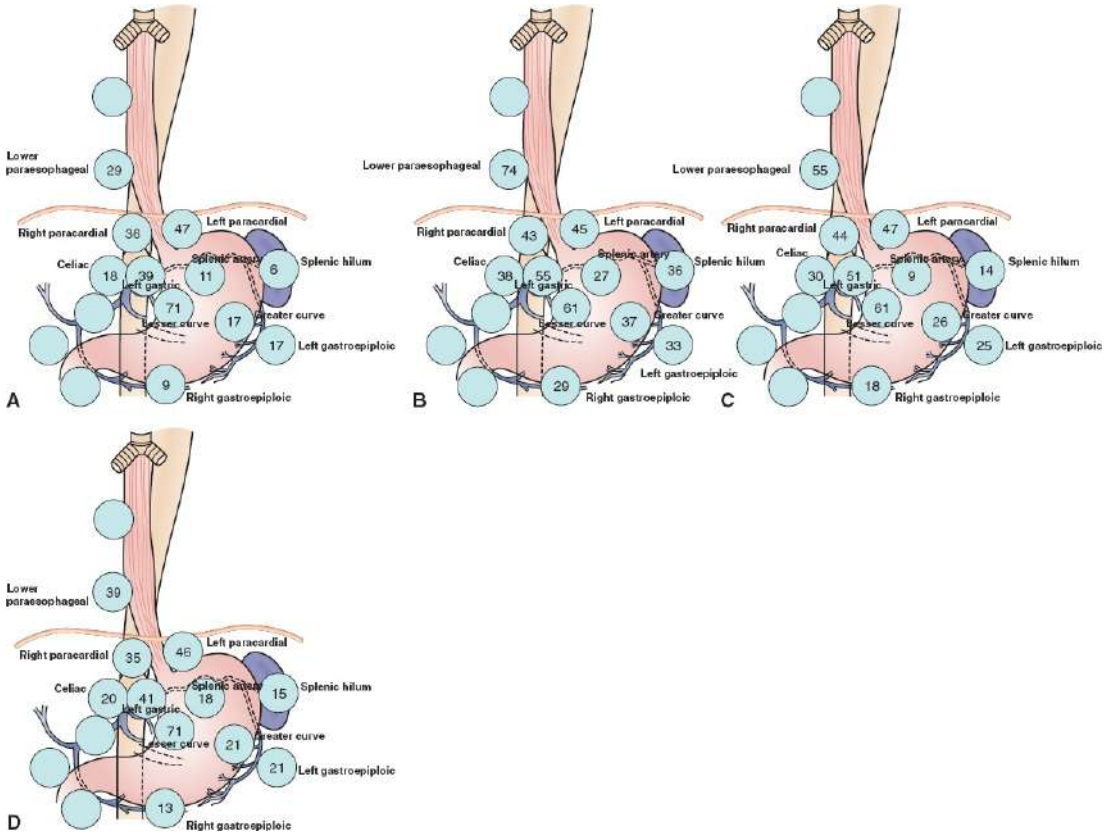

FIGURE 56.8. **A:** Frequency percent of nodal involvement for T2 tumors. **B:** Frequency percent of nodal involvement for T3-T4 tumors. **C:** Frequency percent of involvement for AEG type I tumors. **D:** Frequency percent of nodal involvement for AEG type II/III tumors. (Based on data from Meier I, Merkel S, Papadopoulos T, et al. Adenocarcinoma of the esophagogastric junction: the pattern of metastatic lymph node dissemination as a rationale for elective lymphatic target volume definition. *Int J Radiat Oncol Biol Phys* 2008;70:1408–1417.)

Although the esophagogram may be used to define lesion extent, endoscopy is the best tool to diagnose and define the extent of the lesion. During flexible endoscopy, biopsies and brushings should be taken of the primary site and suspicious areas harboring satellites or submucosal spread. In addition, accurate endoscopic measurement and characterization of tumor and gastroesophageal junction in relation to the incisors facilitate radiation treatment planning as may strategic placement of radioopaque fiducials at the superior and inferior extent of

the primary lesion. Examination with panendoscopy of the oral cavity, pharynx, larynx, and tracheobronchial tree may also be performed at the time of esophagoscopy in patients with squamous cell carcinomas, given the high incidence of second tumors in the head and neck and upper airway.[2] In addition, bronchoscopy should generally be performed in patients with proximal malignancies to evaluate for the presence of tracheal or carinal invasion, particularly for patients with tumors abutting these structures on computed tomography (CT). CT of the thorax, abdomen and pelvis is critical to identify metastases to the liver, upper abdominal nodes, or adrenals; additionally, the primary tumor can usually be appreciated as well as enlarged regional lymph nodes. However, CT may not adequately assess periesophageal lymph node involvement or accurately define the true extent of the primary tumor.[61,62] Conventional CT scan can accurately determine resectability in only 65% to 85% of cases. Furthermore, CT accurately predicts T stage in approximately 70% of cases and nodal involvement in only 50% to 70% of cases.[63–65]

TABLE 56.3 DIAGNOSTIC WORKUP FOR ESOPHAGEAL CANCER

Multidisciplinary evaluation (surgical, radiation, and medical oncology)
History and physical
Complete blood count and chemistry profile
Upper gastrointestinal endoscopy and biopsy
Chest, abdomen, and pelvic computed tomography (CT) with intravenous +/− oral contrast (combined positron emission tomography [PET]-CT optimal)
PET evaluation (combined PET-CT optimal)
Endoscopic ultrasound, with fine needle aspiration if indicated (if no evidence of distant metastases)
Bronchoscopy if tumor is located at or above the carina or there is suspected airway involvement

Nutritional assessment and consideration of feeding tube (nasogastric or feeding jejunostomy) in selected situations

To more accurately assess periesophageal and celiac lymph node involvement and transmural extent of disease, endoscopic ultrasonography (EUS) should be performed. EUS provides accuracy rates of 85% to 90% for tumor invasion (T stage) and 75% to 80% for lymph node metastases when matched to surgical pathology.[66–69] However, the accuracy of endoscopic ultrasound following neoadjuvant therapy is significantly less, ranging from 27% to 48% for T staging and 38% to 71% for N staging. This is possibly due to the failure to discriminate tumor from postradiation inflammation and fibrosis.[70–72] Illustrating the potential limitations associated with contemporary staging techniques, in one series of 102 patients with clinically staged (by PET, EUS, and/or CT) T2-3 N0 tumors receiving induction chemotherapy alone, 60% of patients were found to have metastatic nodal disease.[73]

Surgical staging procedures, including thoracoscopy, mediastinoscopy, and laparoscopy, may provide additional staging information and are considered in selected patients at some institutions.[74] Laparoscopy would primarily be used for tumors at the gastroesophageal junction.

Patients with significant obstruction and inability to maintain their weight may require placement of a feeding tube. If surgery is planned, gastric tube placement is generally avoided, given that the stomach will ultimately serve as the “neoesophagus” following resection and a feeding jejunostomy tube may be placed.

Positron emission tomography (PET) has proven to be a valuable staging tool in esophageal cancer patients. The addition of PET to standard staging studies such as CT can improve the accuracy of detecting stage III and stage IV disease by 23% and 18%, respectively.[75,76] Overall, it is estimated that PET will detect distant metastatic disease in approximately 20% of patients who are considered to have locoregional disease only by CT. However, PET also appears to have a lower accuracy in detecting local nodal disease compared to CT alone or in combination with endoscopic ultrasound. Of importance, some series suggest that PET can be used to predict response to therapy, with PET “responders” experiencing significantly improved outcomes compared to “nonresponders.”[77] In addition, PET has been used to predict response to treatment early during the treatment course. This has led to ongoing investigation of early treatment response as measured by PET as a surrogate for therapeutic efficacy and clinical outcomes, with potential subsequent therapy modification based on early

repsonse.[78,79]

STAGING SYSTEMS

Esophageal staging can be based on pathologic or clinical criteria. Pathologic staging is performed after invasive procedures, including esophagectomy, mediastinotomy, or thoracotomy. Clinical staging is often employed with "definitive" and neoadjuvant chemoradiation approaches and is less accurate. With the combination of CT, PET, and EUS, clinical staging closely correlates with pathologic stage. Note that the most recent AJCC staging system takes into consideration tumor type and grade, as well as involved number of lymph nodes (Table 56.4).

PATHOLOGIC CLASSIFICATION

Squamous cell carcinoma and adenocarcinoma constitute 95% of all esophageal tumors, although other rare histologic subtypes are occasionally seen (Table 56.5).[80] Immunohistochemical staining may be required in poorly or undifferentiated cancers to differentiate between squamous cell and adenocarcinoma.

Given that there has been a rise in adenocarcinoma compared to squamous cell carcinoma, examinations of outcomes by histology have been performed. Some series have reported that patients with squamous cell carcinomas have improved survival,[81] whereas others have suggested that patients with adenocarcinoma have an improved survival[82] and others report no survival differences. Overall, there can be no direct comparison until randomized studies are done with stratification based on histology.

Pseudosarcoma is a variant of a poorly differentiated squamous cell carcinoma with spindle-shaped cells in the stroma resembling fibroblasts. Verrucous carcinoma is a well-differentiated, papillary variant of squamous cell carcinoma.[2] Squamous cell carcinoma *in situ* is rarely seen in the United States and should be distinguished from dysplasia.[83–85]

Adenocarcinoma may arise from foci of ectopic gastric mucosa or intrinsic esophageal glands. However, as described previously, it is believed that the vast majority arise from Barrett esophagus. If a focus of squamous cell metaplasia is found in an adenocarcinoma, the tumor may be referred to as an adenoacanthoma.[86]

Adenoid cystic carcinomas are rare, with an incidence of 0.75%. Patients with this malignancy present around the sixth decade of life and have a poor median survival.[87] Mucoepidermoid tumors (adenosquamous carcinomas) are more aggressive and carry a poor prognosis.[88] The incidence of small cell carcinoma is approximately 2%. Patients with these malignancies often present in the sixth to eighth decades of life, and the lesion is usually located in the middle to lower esophagus in males.[89,90] These are believed to originate in the argyrophilic cells in the esophagus and may produce paraneoplastic syndromes, such as antidiuretic hormone secretion and hypercalcemia.[91] The clinical course of small cell carcinoma is similar to that of small cell carcinoma of the lung and may be responsive to chemotherapy and radiation therapy.[88,90]

Nonepithelial tumors of the esophagus are rare. Among these, leiomyosarcomas are the most common. Twenty-five percent of patients with this tumor present with metastases.[92–94] Histologically, these tumors have interlacing bundles of spindle-shaped cells. Less aggressive forms have fewer mitotic figures and less anaplasia. Prognosis has been reported to be more favorable than that of squamous cell carcinoma.[88] In patients with Kaposi sarcoma, gastrointestinal involvement of the esophagus can be seen.[95]

Malignant melanoma is rare and can occur as a primary esophageal tumor or as a metastasis. These lesions are usually large and often covered by intact squamous mucosa with focal areas of ulceration. Spread is usually submucosal. Mean survival is approximately 7 months.[96,97] Lymphoma constitutes approximately 1% of esophageal malignancies. It is usually associated with direct extension from other organs, although primary esophageal lymphoma has been reported.[98]

PROGNOSTIC FACTORS

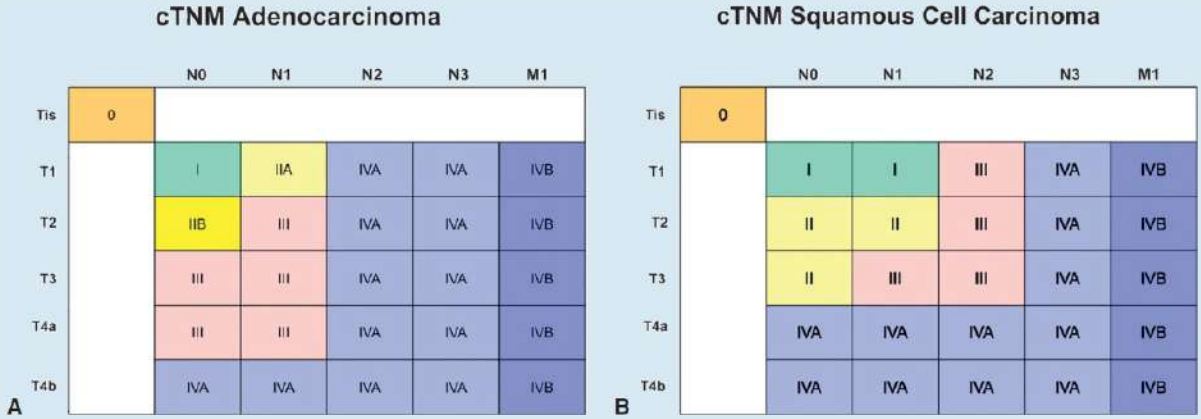
According to the Union Internationale Contre le Cancer/American Joint Cancer Committee seventh-edition staging system, R-status, age, and histologic subtype were independent prognostic factors of survival, whereas tumor grade and site were not.[99] It should be recalled that these data consider patients treated with surgery alone and as such do not apply to patients receiving chemotherapy or radiotherapy. A study published by Nomura et al.[100] evaluating 301 patients treated with chemoradiotherapy showed that T stage, M stage, and gender were prognostic factors in multivariate analysis. In addition to stage, other factors portend outcome. Tumor length/size may also impact outcome. In a study of 582

patients undergoing surgical resection as primary treatment, tumoral length adversely affected survival, with 5-year survival rates of 77%, 48%, 38%, and 23% for tumor lengths of 1, 2, 3, or >3 cm, respectively ($P < .001$).[101] Of note, length was not prognostic if patients were N+ or M+. Similarly, in adenocarcinoma patients, 5-year survival rates have been shown to be significantly higher for patients with tumors ≤2 cm compared to those >2 cm.[102] Another study of 1,553 patients with squamous cell carcinoma of the esophagus determined that tumor size, grade, lymphadenopathy, stage, and family history were prognostic following esophagectomy.[103]

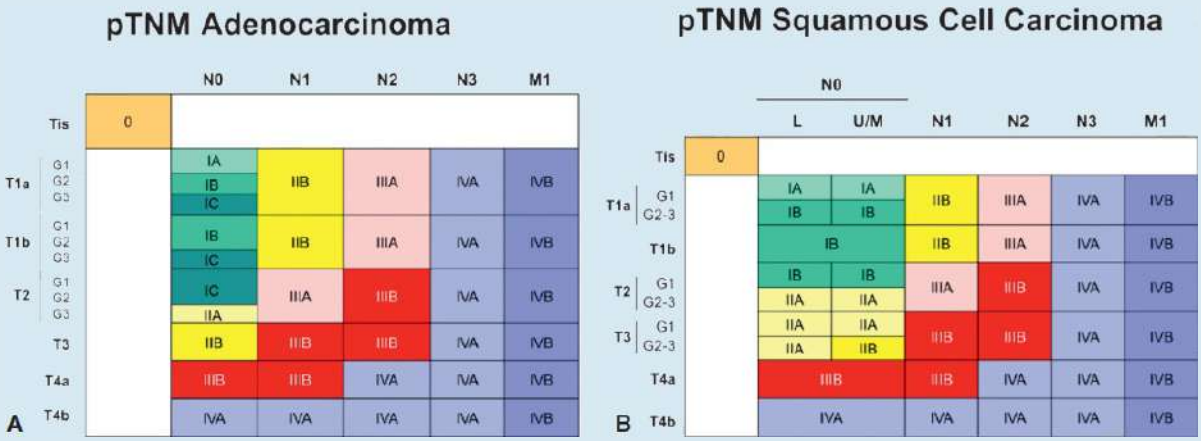
TABLE 56.4 AMERICAN JOINT COMMITTEE ON CANCER 2017 ESOPHAGEAL CANCER STAGING SYSTEM (EIGHTH EDITION)

Category	Criteria
T category	
TX	Tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined by the basement membrane
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a[a]	Tumor invades the lamina propria or muscularis mucosae
T1b[a]	Tumor invades the submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades the adventitia
T4	Tumor invades adjacent structures
T4a[a]	Tumor invades the pleura, pericardium, azygos vein, diaphragm, or peritoneum
T4b[a]	Tumor invades other adjacent structures, such as the aorta, vertebral body, or trachea
N category	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in ≥7 regional lymph nodes
M category	
M0	No distant metastasis
M1	Distant metastasis
Adenocarcinoma G category	
GX	Differentiation cannot be assessed
G1	Well differentiated, with >95% of the tumor composed of well-formed glands
G2	Moderately differentiated, with 50%–95% of the tumor showing gland formation

G3[b]	Poorly differentiated, with tumors composed of nest and sheets of cells with <50% of the tumor demonstrating glandular formation
Squamous cell carcinoma G category	
GX	Differentiation cannot be assessed
G1	Well-differentiated, with prominent keratinization with pearl formation and a minor component of nonkeratinizing basal-like cells, tumor cells arranged in sheets, and mitotic counts low
G2	Moderately differentiated, with variable histologic features ranging from parakeratotic to poorly keratinizing lesions and pearl formation generally absent
G3[c]	Poorly differentiated, consisting predominantly of basal-like cells forming large and small nests with frequent central necrosis and with the nests consisting of sheets or pavementlike arrangements of tumor cells that are occasionally punctuated by small numbers of parakeratotic or keratinizing cells
Squamous cell carcinoma L category[d]	
LX	Location unknown
Upper	Cervical esophagus to lower border of the azygos vein
Middle	Lower border of the azygos vein to lower border of the inferior pulmonary vein
Lower	Lower border of the inferior pulmonary vein to the stomach, including the esophagogastric junction



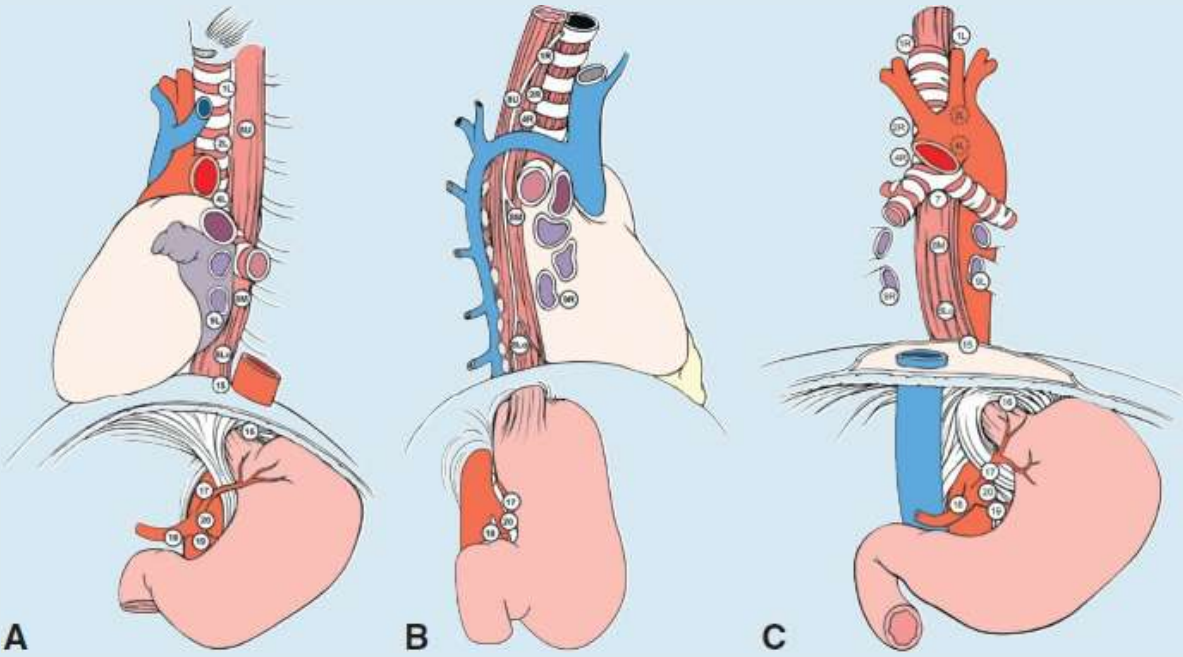
(A) Clinical stage groups (cTNM): adenocarcinoma. **(B)** Clinical stage groups (cTNM): squamous cell carcinoma.



(A) Pathologic stage groups (pTNM): adenocarcinoma. **(B)** Pathologic stage groups (pTNM): squamous cell carcinoma.

ypTNM	N0	N1	N2	N3	M1
T0	I	IIIA	IIIB	IVA	IVB
Tis	I	IIIA	IIIB	IVA	IVB
T1	I	IIIA	IIIB	IVA	IVB
T2	I	IIIA	IIIB	IVA	IVB
T3	II	IIIB	IIIB	IVA	IVB
T4a	IIIB	IVA	IVA	IVA	IVB
T4b	IVA	IVA	IVA	IVA	IVB

Postneoadjuvant pathologic stage groups (ypTNM): adenocarcinoma and squamous cell carcinoma.



Lymph node maps for esophageal cancer. Regional lymph node stations for staging esophageal cancer from the left **(A)**, right **(B)**, and anterior **(C)**. 1R, right lower cervical paratracheal nodes, between the supraclavicular paratracheal space and apex of the lung; 1L, left lower cervical paratracheal nodes, between the supraclavicular paratracheal space and apex of the lung; 2R, right upper paratracheal nodes, between the intersection of the caudal margin of the

brachiocephalic artery with the trachea and apex of the lung; 2L, left upper paratracheal nodes, between the top of the aortic arch and apex of the lung; 4R, right lower paratracheal nodes, between the intersection of the caudal margin of the brachiocephalic artery with the trachea and cephalic border of the azygos vein; 4L, left lower paratracheal nodes, between the top of the aortic arch and the carina; 7, subcarinal nodes, caudal to the carina of the trachea; 8U, upper thoracic paraesophageal lymph nodes, from the apex of the lung to the tracheal bifurcation; 8M, middle thoracic paraesophageal lymph nodes, from the tracheal bifurcation to the caudal margin of the inferior pulmonary vein; 8Lo, lower thoracic paraesophageal lymph nodes, from the caudal margin of the inferior pulmonary vein to the esophagogastric junction; 9R, pulmonary ligament nodes, within the right inferior pulmonary ligament; 9L, pulmonary ligament nodes, within the left inferior pulmonary ligament; 15, diaphragmatic nodes, lying on the dome of the diaphragm and adjacent to or behind its crura; 16, paracardial nodes, immediately adjacent to the gastroesophageal junction; 17, left gastric nodes, along the course of the left gastric artery; 18, common hepatic nodes, immediately on the proximal common hepatic artery; 19, splenic nodes, immediately on the proximal splenic artery; 20, celiac nodes, at the base of the celiac artery. Cervical periesophageal level VI and level VII lymph nodes are named as per the head and neck map.

[a]Subcategories.
[b]If further testing of “undifferentiated” cancers reveals a glandular component, categorize as adenocarcinoma G3.
[c]If further testing of “undifferentiated” cancers reveals squamous cell component or if after further testing they remain undifferentiated, categorize as squamous cell carcinoma G3.
[d]Location is defined by epicenter of esophageal tumor.

TABLE 56.5 PATHOLOGIC CLASSIFICATION OF MALIGNANT ESOPHAGEAL TUMORS

Epithelial Tumors

Squamous cell carcinoma
Variants of squamous cell carcinoma
Basaloid squamous cell carcinoma
Squamous cell carcinoma with sarcomatoid features
Undifferentiated carcinoma
Spindle cell carcinoma
Pseudosarcoma and carcinosarcoma
Verrucous carcinoma
In situ carcinoma
Adenocarcinoma
Adenoacanthoma
Adenoid cystic carcinoma (cylindroma)
Mucoepidermoid carcinoma
Adenosquamous carcinoma
Carcinoid
Small cell carcinoma

Nonepithelial Tumors

Sarcoma, 13 variants reported, most common is leiomyosarcoma.

Malignant melanoma
Myoblastoma
Choriocarcinoma
Lymphoma

In another large study from the Mayo Clinic, clinicopathologic factors that affected prognosis included T and N status, tumor grade, age > 76 years, extracapsular lymph node extension, and the absence of chemotherapy or radiotherapy; anatomic location did not influence survival.[104] In addition, weight loss and low overall performance status also indicate poor prognosis.[105] Deep ulceration of the tumor, sinus tract formation, and fistula formation are other poor prognostic factors.[59]

Obtaining uninvolved pathologic margins at resection is of significant importance with regard to long-term outcome. An Intergroup study (discussed later) evaluating chemotherapy preceding and following esophagectomy showed that outcomes were similar in patients undergoing R1 resection (positive microscopic margins) or R2 resection (gross residual disease) or patients not undergoing resection at all. Only patients undergoing R0 resection (uninvolved margins) had a substantial chance of long-term disease-free survival.[106] A meta-analysis of 17 studies found that major pathologic response following neoadjuvant therapy in gastroesophageal cancer patients was predictive of survival.[107] Another meta-analysis of 13 series showed that perineural invasion is an adverse prognostic biomarker in esophageal cancer, often associated with more advanced stage and poor differentiation.[108] A patterns-of-care survey examined the outcomes of patients with adenocarcinoma and squamous cell carcinoma of the esophagus between 1996 and 1999. Patients were treated with radiation therapy across 59 institutions. On multivariate analysis, significant improvements in survival were seen in patients treated at centers with ≥500 new cancer patients per year compared to centers seeing <500 (hazard ratio 1.32; P = .03).[109]

GENERAL MANAGEMENT

Treatment for esophageal carcinoma is characterized as either curative or palliative. According to one historical study,[110] only 20% patients present with cancer of the esophagus that is truly localized to the esophagus, indicating that at the time of diagnosis, approximately 80% patients have either locally advanced or distant disease.

Surgery with Curative Intent

Surgery of the thoracic esophagus usually requires a subtotal or total esophagectomy and is usually undertaken for lesions of the middle to lower one-third of the thoracic esophagus and gastroesophageal junction. Patients with stage I to III are often considered for potentially curative resection; however, aortic, tracheal, heart, or great vessel invasion may preclude resection. Esophagectomy may be accomplished by a number of techniques, including a transhiatal esophagectomy, right thoracotomy with laparotomy with intrathoracic anastomosis (Ivor Lewis esophagogastrectomy), right thoracotomy with laparotomy with cervical anastomosis (McKeown or "three-hole" esophagogastrectomy), and left thoracoabdominal, transhiatal, or radical esophagectomy via open or laparoscopic approaches. Each technique has its advantages and disadvantages. In general, advantages of the transthoracic approach include better visualization with access and resection of the upper two-thirds of the esophagus and mediastinal lymph nodes. One potential advantage of the McKeown approach is a cervical anastomosis, which may be easier management of anastomotic leaks. Alternatively, the transhiatal approach has less morbidity than does thoracotomy (including respiratory compromise) with easier access to anastomotic leaks. In any instance, achievement of negative margins at resection has been reported to be a significant prognostic factor and should be the goal of esophageal resection. Exemplifying this, in a study of 500 patients undergoing transthoracic resection, patients undergoing margin-negative resection had a 5-year survival rate of 29% versus no 5-year survivors in patients with involved margins.[111]

The Ivor Lewis procedure is the classic approach to expose midesophageal lesions. A left thoracotomy procedure exposes lesions of the gastroesophageal junction. Transhiatal esophagectomy is performed without a thoracotomy and is useful in lower esophageal lesions, although direct visualization and dissection of varying mediastinal lymph nodes cannot be achieved. An emerging treatment option in addition to the above techniques is the use of minimally invasive esophagectomy, which can include laparoscopic-assisted, thoracoscopic, or more limited thoracotomy. The optimal surgical approach is unknown and remains a topic of ongoing investigation.

Laparotomy or laparoscopy can be performed before neoadjuvant therapy or concurrently with esophagectomy to rule out peritoneal-based disease below the diaphragm, particularly in more advanced adenocarcinomas of the gastroesophageal junction. Multiple reconstruction options are available

following definitive surgery; esophagogastrostomy is the most widely used, using the stomach as a conduit to replace the esophagus. Patients with significant obstruction and inability to maintain their weight often require placement of feeding jejunostomy. If possible surgery is planned, gastric tube placement is generally avoided, given that the stomach will ultimately serve as the "neoesophagus" following resection, with feeding jejunostomy often preferred. Colon interposition, preferably with the left colon, can also be used; however, this approach is generally reserved for patients who have previously undergone gastric surgery or other procedures that have devascularized the stomach. Similarly, jejunal interposition may be utilized.

Squamous cell carcinoma of the cervical esophagus presents a difficult management situation. Proximal esophageal tumors <5 cm from the cricopharyngeus are generally treated with definitive chemoradiotherapy. If surgery is performed, resection of portions of the pharynx, the entire larynx, the thyroid gland, and the proximal esophagus is often required. Radical neck dissections are also carried out.[59] Because of the significant morbidity and loss of organ function with surgery, chemoradiation alone has been frequently employed. The survival probability with definitive chemoradiotherapy is similar, without the major functional impairments, morbidity, and mortality associated with surgery.[112] The optimum time to surgery following neoadjuvant therapy remains a topic of investigation, although delaying surgery from the traditional 4-6 weeks to greater than 12 weeks might improve tumor response to neoadjuvant therapy and thereby facilitate radical resection. This remains a topic of investigation.[112a]

Curative Combination Therapy

In the treatment of patients with esophageal cancer, an approach of radiation therapy with concurrent chemotherapy, with or without surgery, is frequently adopted. Multiagent chemotherapy with cisplatin and 5-fluorouracil (5-FU) has been used historically, although other combinations (e.g., paclitaxel and carboplatin; 5-FU with oxaliplatin) are now commonly utilized. Additional combinations of novel systemic agents (that also act as radiosensitizers) with radiation therapy are under investigation.

Palliative Treatment

Palliative treatment is frequently used for the relief of symptoms of esophageal carcinoma, especially dysphagia.[113] Surgical palliation involves resection and

reconstruction, if possible, removing the bulk of the disease, potentially preventing abscess and fistula formation, as well as bleeding. Substernal bypass with the colon or entire stomach has also been carried out.[113] However, given the poor prognosis in patients with advanced disease and morbidity associated with resection, a surgical approach is rarely adopted and should be avoided in patients who can be managed with nonsurgical modalities.

Endoscopic dilatation is a reasonable alternative. When the lumen of the esophagus is dilated to 15 mm, dysphagia is often no longer experienced. Repeat dilatation is often required.[59] Esophageal stenting with either conventional plastic stents or metallic self-expanding stents can also be used to maintain patency.[114]

Palliative irradiation is frequently used to control the primary disease, as well as distant metastases. Resolution of symptoms, especially pain and dysphagia, can be accomplished in up to 87% of patients. Palliative treatment regimens range from 20 Gy over 1 week[60] to 50 Gy over 5 weeks. Laser ablation with or without intraluminal brachytherapy can be used. The addition of three fractions of 7 Gy each can improve the stenosis-free interval and prevent obstruction.[114]

RADIATION THERAPY TECHNIQUES

Simulation

When patients are simulated, the radiation oncologist should know the extent of disease based on imaging (barium swallow, CT, PET), as well as on endoscopy. CT simulation is appropriate for treatment planning. During simulation, the patient is positioned, straightened, and immobilized on the simulation table. An immobilization device (e.g., wing board, alpha cradle, body fix, or Vac-Lok on indexed wing board) is used to minimize variation in daily setup. Arms are generally placed overhead and knee support placed underneath the legs. Palpable neck disease should be marked with a radiopaque wire. The administration of oral contrast to delineate the esophagus is generally used and helps to define the extent of mucosal irregularity whereas small-bowel contrast can help identify any bowel in field. For GE junctional tumors (particularly with significant gastric involvement), it may be advisable to have the patient come in with an empty stomach. Fasting prior to simulation and treatment each day may allow for greater reproducibility of treatment. In contrast, simulation without fasting and delivery of oral contrast may allow for planning in a “worst-case” scenario, with the patient is later instructed to fast prior to treatment delivery. For cervical

and upper thoracic lesions, an immobilization mask may assist in creating a reproducible position. Some authors have also advocated that midesophageal primaries be simulated in prone position to maximize distance between the target volumes and spinal cord. The patient is placed on the CT simulator in the treatment position, and a scan of the entire area of interest with margin is obtained. At minimum, 3- to 5-mm slices should be used, allowing accurate tumor characterization, as well as improved quality of digitally reconstructed radiographs. If patients lose >10% of their body weight during therapy, consideration should be given to repeat CT planning. Arterial phase intravenous contrast is generally used to delineate mediastinal and abdominal vascular nodal basins, including the celiac axis and to allow the radiation oncologist to discern normal vasculature from other adjacent normal structures, and potential adenopathy. The tumor and vital structures are then outlined on each slice on the treatment planning system. The use of respiratory gating or breath-hold techniques may help to reduce target motion with respiration and, therefore, avoid normal-tissue irradiation associated with larger margins used in free-breathing approaches, particularly for lower esophageal cancers. Additional techniques to minimize physiologic motion include abdominal compression devices. Four-dimensional CT scan may be appropriate to assess tumoral motion, facilitating appropriate margin placement on the target volumes, particularly in lower esophageal tumors and/or disease involving the stomach.

Treatment Planning

Target Design

In the design of radiation fields for esophageal cancer, it is important to define varying target volumes, including gross disease as well as potential areas of subclinical involvement (i.e., the GTVs and CTVs, respectively). Definition of GTV is based on multiple studies, including endoscopic descriptions (from both esophagogastroduodenoscopy [EGD] and EUS). The proximal and distal aspects of the tumor should be standardly defined by the gastroenterologist based on distance from the incisors, as well as relationship to varying landmarks as measured from the incisors (e.g., the GE junction). The radiation oncologist is able to use these measurements to help correlate with disease extent visualized on planning CT scan, using varying anatomic landmarks (e.g., the GE junction, which is frequently located ∼40 cm from the incisors in many patients), as well as carina (which is frequently located at ∼25 cm in most patients) to help more accurately define the GTV. Additionally, endoscopists may place radioopaque

fiducial markers at the superior and inferior extent of the primary tumor to help facilitate disease extent. Esophageal wall thickening correlating to the GTV can frequently be visualized on diagnostic and radiation planning CT. Similarly, EUS appears to be the most reliable test in detecting lymphadenopathy related to nodal spread. As in EGD, the endoscopist should be encouraged to accurately define not only the primary disease extent on EUS as measured by distances from the incisors but also depth of penetration and potential involvement of adjacent structures, which can also be used to help guide GTV delineation. Similarly, EUS may detect lymph nodes that may not be appreciated on CT or PET imaging, and the endoscopist should describe the size as well as the location (e.g., distance from incisors, relationship to adjacent mediastinal structures, etc.) of these, further facilitating accurate definition of potentially involved lymph nodes, either adjacent to or well removed from the primary tumor itself. In addition, radiographic areas of lymphadenopathy should similarly be included in the GTV.

Although the utility of PET in esophageal cancer staging primarily lies in its ability to detect distant metastases not fully appreciated on CT imaging (and thereby alter treatment approach of these patients),[115,116] diagnostic PET-CT has more recently been integrated into radiation planning of esophageal cancer patients and definition of GTV. Generally, gross disease as defined on PET is characterized by a standard uptake value of >2 to 2.5.[117] Generally speaking, PET-avid nodes should be included within the GTV volume. In a study from Fox Chase Cancer Center, the mean GTV length as determined by PET-CT closely correlated with endoscopy findings.[68] Another study from Australian investigators reported that CT-alone–based definition of GTV excluded PET-avid disease in a majority of patients, resulting in a potential geographic miss of disease in a significant minority of patients.[118] Similarly, the fusion of CT-PET has been shown to prompt GTV and PTV modification in a majority of patients.[119] Another analysis of PET-CT-based (as compared to CT alone) radiotherapy planning of esophageal cancer patients indicated a reduction of intraobserver and interobserver variability in GTV delineation.[120] However, another study compared the planning of patients with CT-alone treatment plans followed by adjustment based on PET findings. Although PET scan influenced GTV volume in half of patients, no locoregional recurrences were seen following CT-based radiotherapy that could have been prevented by the addition of PET.[121]

Finally, although the routine use of fluoroscopic barium swallow in

esophageal cancer has decreased, this study may still be useful to the radiation oncologist for field design. A study by Chinese investigators suggested that, as compared to CT, endoscopy with barium swallow more accurately defines the true length of middle and lower esophageal tumors, although CT appeared to better determine this for tumors located at the GE junction.[122]

In summary, accurate definition of primary and nodal gross disease is paramount in radiation esophageal cancer planning. It is important to rely on all diagnostic studies, including barium swallow (when available), EGD, EUS, and CT, as well as PET scan.

The identification of potential direct and nodal pathways for spread of subclinical disease (i.e., CTV definition) in esophageal cancer is also of paramount importance. These areas vary significantly, depending on site of origin of disease, making esophageal cancer planning somewhat complex. In terms of direct disease extension along the esophagus itself, varying reports have assessed the histologic findings at primary esophagectomy to determine subclinical extent of disease. One prospective analysis of 66 resection specimens showed that placement of a 3-cm margin proximally and distally on the primary tumor would cover microscopic disease extension in 94% of squamous cell carcinomas. Similarly, in GE junctional carcinomas, a 3-cm proximal margin included subclinical disease extension in 100% of patients and 5 cm distally covered 94% of subclinical spread.[122]

As described previously, the esophagus is characterized by a rich submucosal network of lymphatics that facilitates early lymph node spread of disease, even for superficial esophageal cancers. The appropriate cranial and caudal margins remain a matter of debate in the treatment of esophageal cancer. Historically, very large fields were treated, encompassing potential pathways and lymphatic spread from the thoracic inlet down to the celiac axis region; however, such fields are potentially fraught with treatment-related toxicity and may be difficult for patients to tolerate, particularly in the context of concurrent chemotherapy delivery. Most contemporary radiation trials used margins of 3 to 5 cm cranially and caudally on the GTV, along with an approximate 2-cm radial margin. With disease located at or above the carina (or middle/upper one-third of the esophagus in some instances), many of these trials recommended fields inclusive of the supraclavicular lymph node basins, whereas celiac axis nodal basin coverage was recommended for disease of the distal esophagus.[123] However, the appropriate field size for patients with esophageal cancer remains controversial, particularly the role of elective nodal irradiation.

Even the concept of what constitutes “involved-field” and “extended-field” can vary between series. Comparative series have yielded conflicting results to this effect, although recent reviews have suggested that elective nodal irradiation appears to prevent or delay regional nodal relapse. However, its impact on survival in these patients remains less clear, with a higher incidence of esophageal and lung toxicities in the latter.[124,125] This remains a topic of ongoing study and randomized studies are needed. Further description of lymph node basin coverage follows.

Field Design

Historically, the treatment of very proximal (cervical) esophageal cancers has been challenging. Because of the changing contour from the neck to the thoracic inlet, treatment of lesions in the upper one-third of the esophagus may present a difficult technical problem. Lesions in the upper cervical or postcricoid esophagus are often treated from the laryngopharynx to the carina, depending on extent of disease. Supraclavicular and superior mediastinal nodes are irradiated electively. Using older/conventional methods, this was achieved with lateral parallel opposed or oblique portals to the primary tumor and a single anterior field for the supraclavicular and superior mediastinal nodes.[105] Another historical technique treated lesions in this region by means of a four-field box approach, using a wax bolus to build up the lack of tissue above the shoulders, acting as a compensator. A high-energy beam (>15 MV) is used, and both sides of the neck are treated prophylactically. Other methods of treating lesions at the thoracic inlet include 140-degree arc rotations, anterior wedged pairs, and three- or four-field techniques using posterior oblique portals combined with a single anterior portal or anteroposterior–posteroanterior (AP/PA) fields.[105] Using three-dimensional (3D) approaches, varying techniques have been implemented, including treatment of the primary tumor and lymph nodes using an AP/PA approach to 39.6 to 41.4 Gy at 1.8 Gy/fraction, followed by a left or right opposed oblique pair to bring the total dose to 50.4 Gy, thereby limiting the spinal cord dose. This technique will generally exclude the supraclavicular fossa, and a separate electron field is often added, treating to a depth of 2 to 3 cm, depending upon individual anatomy. More recently, however, intensity-modulated radiation therapy (IMRT)-based planning has facilitated the treatment of upper esophageal lesions and is our preferred method for treating these tumors (Fig. 56.9) Strict normal-tissue constraints, including normal lung and spinal cord, are important considerations in using these techniques (discussed later).

Based on the previously described and other pathologic patterns of spread data in squamous cell carcinoma of the esophagus, general guidelines in terms of field design can be made as follows: For cervical and upper thoracic squamous cell carcinoma, the CTV should generally include nodal basins extending from the lower cervical and supraclavicular region superiorly to the subcarinal lymph node basin inferiorly, inclusive of the upper paraesophageal lymph nodes (Fig. 56.9). For lower esophageal squamous cell carcinomas, lymph node basins from the subcarinal region superiorly to the left gastric and common hepatic artery/celiac lymph nodal basins inferiorly should generally be included (described further later in this chapter). In a small series of patients without celiac radiation coverage, 6 (10%) had celiac nodal failure, portending a worse prognosis. The authors concluded that although overt celiac failure only occurred in 1 of 10 patients, the lack of effective salvage in treatments may justify treatment of this basin in distal esophageal cancer patients.[126] For tumors of the middle esophagus, we recommend individual field design according to clinical scenarios, with a more complete coverage of paraesophageal mediastinal lymph nodes, particularly in patients with a good performance status (Fig. 56.10).[43] These are general guidelines, and all plans should be individualized based on available imaging and endoscopic findings.

In field design, potential nodal involvement (and therefore target volumes) based on nodal size is problematic, given that some reports demonstrated that <15% of metastatic nodes are >1 cm and that average size differences between involved and uninvolved nodes are frequently not significantly different.[127] In addition, fluorodeoxyglucose-PET scanning has an estimated sensitivity of only 67% of detecting nodal metastases.[8] Even endoscopic ultrasound, generally considered the most sensitive test for detecting lymph node metastases, is only able to detect such disease in approximately 75% of patients.[128] Therefore, it is not appropriate to rely exclusively on varying imaging modalities to define areas

of subclinical spread for esophageal cancer, realizing that patterns-of-spread data are important in determining radiation field design.

The design of radiation fields for the treatment of adenocarcinoma of the esophagus is similar to that of lower thoracic squamous cell carcinomas but deserves special mention. Periesophageal lymph nodes are generally included in all patients. Given that lymph node involvement is clearly associated with depth of tumor penetration (T stage) and the fact that most patients in the United States and Europe presenting with GE junctional carcinoma will have more advanced disease, inclusion of celiac lymph basins for adenocarcinoma of the distal esophagus/GE junction is usually indicated, although remains an area of controversy. Based on the previously described patterns of spread data from Erlangen and others, specific considerations include the following: Lymph vascular invasion is highly predictive of nodal spread. Proximal extension of tumors (particularly beyond the Z line into the distal esophagus for type II and III tumors) predicts an increasing incidence of paraesophageal lymph node involvement. Based on an estimated nodal incidence cutoff of 20% for inclusion, specific considerations include the following: (a) The lower paraesophageal, paracardial, lesser curvature, and left gastric artery nodes should be included in the CTV. (b) The presence of lymph vascular invasion predicts a nodal positivity rate of >20% in the left and right gastroepiploic, greater curvature, celiac trunk, and splenic hilar regions. (c) In T3/4 disease, the gastroepiploic, greater curvature, celiac trunk, splenic hilar, splenic artery, and common hepatic artery should be included. (d) High-grade tumors should also include the left gastroepiploic, greater curvature, and celiac trunk nodes in CT design. (e) Larger and more deeply penetrating tumors should also include the splenic artery and splenic hilar nodes, as well as those along the greater curvature. (f) Tumors extending above the diaphragm and those extending >1.5 cm beyond the Z line should include the mid paraesophageal nodes, treating up to the carina. Of note, significant involvement of the distal esophagus by GE junctional tumors (>1.5 cm beyond the Z line) should lead to inclusion of not only lower but also middle paraesophageal nodes based on patterns of spread. However, treating these more extensive fields must be weighed against potential side effects of increased normal-tissue irradiation. In summary, middle and lower paraesophageal nodes should be included in patients with T2-T4 type I and T2-T4 type II tumors extending >1.5 cm above the Z line and T3-T4 type II patients. The splenic hilar and artery nodes are considered “spareable” in T2 tumors, notably type I.[49]

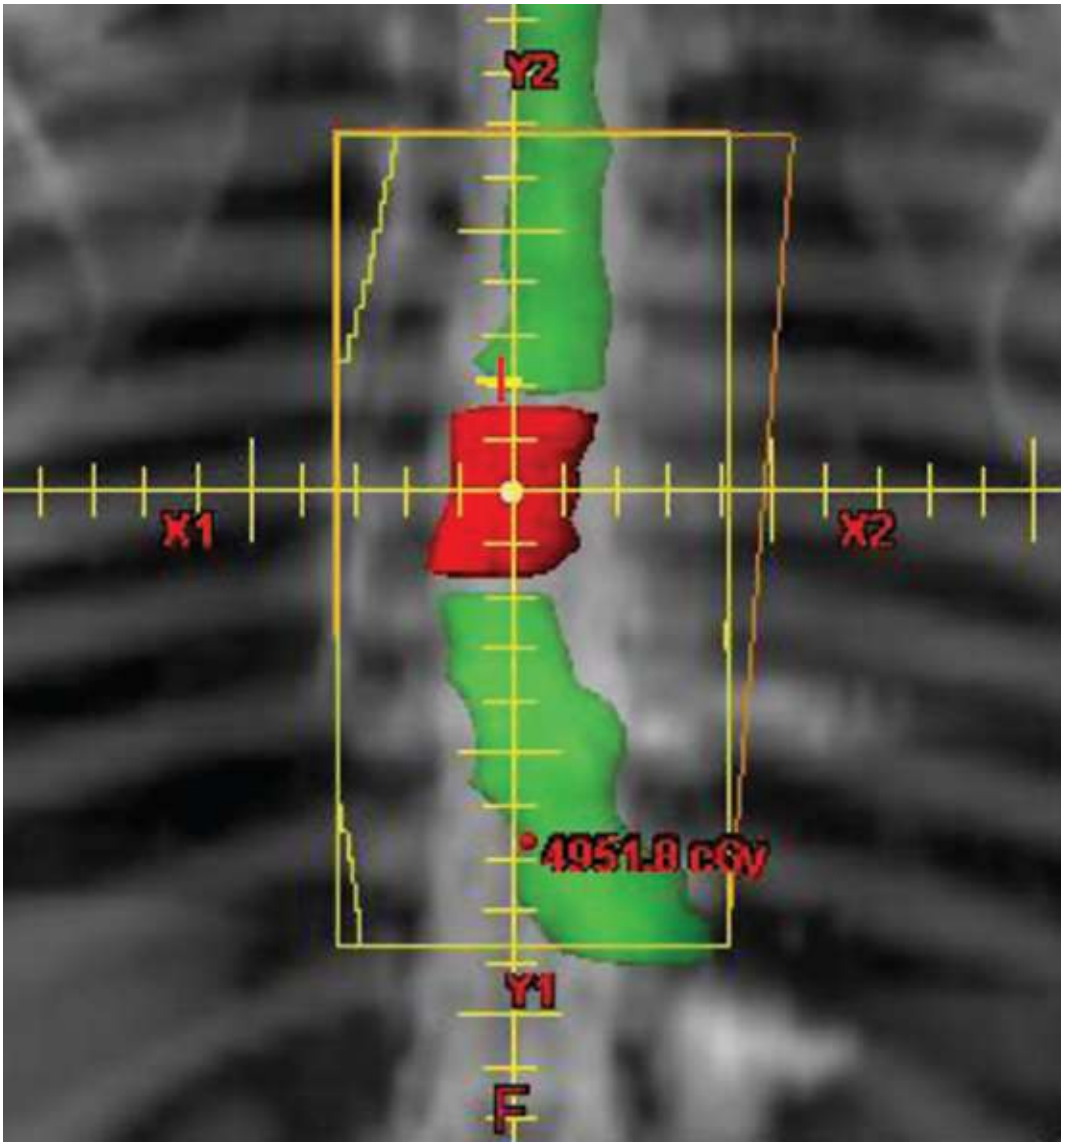

FIGURE 56.10. Example field for a midesophageal squamous cell carcinoma. Note that the field is inclusive of adjacent mediastinal/paraesophageal nodes, with approximately 5 cm margin superiorly on the gross tumor volume (GTV), as well as slightly larger margin on the inferior aspect of the GTV based on concern of previously unappreciated spread at the time of endoscopy.

Although, historically, two-dimensional–based radiation planning has been carried out primarily using anatomic landmarks such as bone and carina, as well as fluoroscopic barium swallow, to determine field borders, contemporary treatment planning using CT-based planning allows improved visualization of both target and nontarget structures, along with three-dimensional reconstruction and creation of a “beam’s-eye” view of varying fields, allowing improved conformity around target structures and improvements in normal-tissue sparing. Because volumetric data can be obtained by CT scans, dose–volume histogram

data can also be generated. A variety of three-dimensional techniques are being used and are described later.

Potential beam orientations for the treatment of thoracic esophageal and gastroesophageal junction tumors (again defined as tumors involving the gastroesophageal junction with an epicenter within 5 cm proximal or distal to the GE junction) include an initial AP/PA approach followed by AP/right posterior oblique (RPO)/left posterior oblique (LPO) fields with or without boost, an initial APPA approach followed by RAO/LPO fields with or without boost, and a three-field technique (AP/PA with left lateral or oblique field). One potential approach in lesions of the thoracic esophagus or GE junction is to use initial AP/PA/RAO/LPO fields, with boost fields using laterally oriented beams. The inferior margin of the initial fields includes the gastroesophageal junction and, for lower or middle one-third lesions, the celiac axis nodal basins (generally located at the level of T12 and identifiable on CT), as well as gastrohepatic ligament. Initial fields are often treated to a dose of 45 Gy, taking care to avoid as much of the heart as reasonably possible while continuing to minimize the kidney volume in the radiation field, inclusive of the above nodal basins. Reduced fields encompassing gross disease with an approximate 2-cm margin through oblique or lateral fields may then be used for an additional 5.4 Gy. Doses usually do not exceed 50 Gy, and lower doses (e.g., 41.4 Gy) may be appropriate (discussed later).

A margin of 5 cm above and below the GTV is generally recommended to cover subclinical submucosal/nodal disease, as well as an approximate 2.0- to 2.5-cm radial margin, although individual margins are case dependent. Because it is imperative to account for daily setup uncertainty as well as physiologic internal organ motion (secondary to respiration, peristalsis, cardiac motion, etc.), additional margin must be added to a CTV, particularly to the more mobile distal esophagus. The internal target volume (ITV) has been used to account for physiologic motion of the target volume, which is included in the PTV. Varying reports analyzing esophageal motion have shown average anterior and posterior motion ranges from 0.1 to 4 mm, lateral motion from 0.3 to 4.2 mm, and superior-to-inferior motion from 3.7 to 10 mm.[123] An analysis evaluating interfraction esophageal motion in the right–left and AP direction showed average right–left motion of 1.8 ± 5.1 mm (favoring leftward movement) and average AP motion of 0.6 ± 4.8 mm (favoring posterior movement), with an average absolute motion of 4.2 mm or less in the right–left and AP directions. The authors concluded that 12-mm left, 10-mm posterior, and 9-mm anterior

margins are appropriate.[129] Some authors have recommended defining 1-cm radial, 1.5-cm distal, and 1-cm proximal margins from CTV to ITV if target motion data are not available. Image-guided radiation therapy, including cone beam CT, may also be useful in localizing tumor and establishing physiologic variability between daily treatments.

Figure 56.11 shows general recommendations for elective target nodal station coverage in a patient with a type I GE junctional tumor with an accompanying example field. Figure 56.12 shows general recommendations for elective target nodal station coverage in a patient with a type II GE junctional tumor. Nodal basins are similar to type I tumors with the exception of inclusion of nodal basins along the splenic artery course. Figure 56.13 shows general recommendations for elective target nodal station coverage in a patient with a type III GE junctional tumor with accompanying example fields. Note that in type III tumors, there is less emphasis on more proximal (lower mediastinal) nodes and more comprehensive coverage of the splenic artery course, including splenic hilum. Figure 56.14 shows examples of varying nodal locations on axial CT images.

Another potential treatment planning approach for thoracic esophageal cancer is the use of IMRT. IMRT also uses CT-based planning, again allowing 3D reconstruction of varying structures. However, IMRT differs from 3D planning through the delivery of radiation dose by partitioning a radiation field into multiple smaller fields of varying shapes and sizes, varying the dose intensity between each area. This is carried out with either dynamic IMRT (in which

collimating leaves move in and out of the radiation beam path during treatment) or “step-and-shoot” IMRT (in which the leaves change the radiation field shape while the beam is turned off). Either method is particularly effective at conforming radiation dose to the target structures while avoiding dose to normal tissue. Radiation oncologists must determine which structures are most critical and weight their importance during the treatment planning process. Of importance, the greater the number of “avoidance” normal structures, the more difficult it is to meet all dose constraints. IMRT uses “inverse planning,” in which an intended prescription dose is placed on target volumes and dose constraints are placed on normal-tissue structures. Thereafter, computer software algorithms allow design of unconventional treatment fields that would not otherwise be possible with standard planning methods. Radiation oncologists and medical physicists critically evaluate numerous plans until dose constraints are satisfactorily met. The result should be a series of radiation doses that closely conform to the target volumes while minimizing dose to normal tissues. Similarly, volumetric arc therapy (VMAT) also utilizes IMRT delivery, although doing so while the gantry is actively rotating during treatment. Dosimetric comparisons of IMRT versus 3D conformal therapy in cervical esophageal cancer have demonstrated superior target volume coverage and conformality with decreased normal-tissue dose.[130] A potential disadvantage of IMRT is the possibility of delivering low doses of radiation therapy to normal-tissue areas that might not normally be irradiated using 2D or 3D techniques. The influence of this on toxicity (e.g., low-dose pulmonary irradiation and development of postoperative pulmonary complications) remains uncertain. Another potential disadvantage of IMRT is possible dose inhomogeneity, leading to potential hot spots in normal organs. Because IMRT requires precise target definition, the potential for marginal miss increases and careful target delineation is of paramount importance. With setup uncertainty, physiologic organ motion must be considered to ensure accurate and reproducible setup, including the use of immobilization devices, possible respiratory gating/breath-hold techniques, etc. Generally, high-energy photons (4 to 18 MV) are recommended when using 3D conformal or IMRT therapy, potentially facilitating a reduction of the integral lung dose. A multi-institutional experience of 580 patients treated across three academic centers compared patients receiving 3D versus IMRT and proton beam therapy. Advanced treatment technologies (IMRT and proton beam) were associated with significantly reduced rate of postoperative complications and length of stay. The authors indicated prospective randomized data will be needed

to validate these results.[131] Additionally, a registry-based study of patients >65 years old comparing 3D- versus IMRT-treated patients, IMRT was not associated with esophageal cancer–specific mortality or pulmonary mortality, but was with improved all-cause mortality, including cardiac and other cause mortality.[132] Similarly, in analysis of the RTOG 0617 trial randomizing patients with non–small cell lung cancer to receive concurrent carboplatin and paclitaxel with or without cetuximab with a second randomization to 60 versus 74 Gy, no benefit was seen in terms of radiation dose escalation. On secondary analysis, however, IMRT was associated with less ≥ grade 3 pneumonitis (7.9 vs. 3.5%, $P = .039$), lower heart doses ($P < .05$), and lower heart V40 doses, with the heart V40 significantly associated with overall survival ($P < .05$). Additionally, the lung V20 dose was also associated with increased ≥ grade 3 pneumonitis risk on multivariable analysis ($P = .026$), with the authors concluding IMRT was associated with lower rates of severe pneumonitis and cardiac doses.[133]

More recently, an expert panel published contouring guidelines for esophageal and gastroesophageal junction CTV volumes for IMRT planning. Examples of consensus CTV are illustrated in Figure 56.15. Delineation of the proximal border of the CTV was described as 3 to 4 cm above the proximal edge of the GTV, or 1 cm above any grossly involved periesophageal nodes, oriented along the esophageal mucosa and not a simple geometric expansion. For proximal tumors, the upper border was not extended beyond the level of the cricoid cartilage unless disease presence precludes such. For proximal or midesophageal tumors, the distal border for CTV creation was described as 3 to 4 cm below the proximal edge of the GTV, again oriented along the esophagus. For lower tumors, what is described as at least a 2-cm margin along clinically involved gastric mucosa was recommended if treating definitively, or if treating to lower, preoperative-intent doses (≤45 Gy), a 4-cm or greater gastric margin was felt appropriate, particularly with significant gastric extension. CTV radial margin was described as at least 1 cm in all direction on GTV, with a 1-cm radial margin from the outer esophageal wall to encompass periesophageal lymph nodes, with a limit of 5 mm into cardiac tissue, including the pericardium. For more distal tumors involving or approaching the GE junction, the CTV was described as being extended inferiorly to the level of the celiac axis origin, bounded by the lateral aspect of the vertebral body on the right and 0.5 to 1 cm beyond the lateral aspect of the aorta on the left, vertebral body posteriorly and pancreatic body anteriorly. Periaortic and gastrohepatic (sometimes classified as lesser curve or left gastric) lymph nodes were deemed appropriate for inclusion. Examples of CTVs are shown in Figures 56.16–56.18. Inclusion of some or all nodes in the splenic hilum and greater curvature region was felt potentially appropriate for Siewert type II gastroesophageal junction tumors depending on clinical and pathologic features. For tumors above the level of the carina, inclusion of the bilateral supraclavicular nodal basins was recommended. PTV delineation was created by adding 0.5 to 1 cm to the CTV in all directions (which is essentially equivalent to the traditional practice of placing the field border 5 cm above and below the GTV).[134]

Dose Constraints

In radiation therapy planning of esophageal cancer, normal-tissue tolerance should always be considered. The spinal cord dose is generally limited to 45 Gy using 1.8-Gy fractions (and potentially less when delivered with novel systemic agents). Efforts to minimize radiation to the heart (in particular the left ventricle in lower esophageal/gastroesophageal junction lesions) should be made. Adopting an off-heart approach using oblique orientations (including right anterior and left posterior, described earlier) is one potential way of achieving this, although multiple approaches exist, including IMRT-based techniques. Similarly, efforts to minimize dose to normal pulmonary tissues should be made, based on data suggesting that the volume of irradiated lung may correspond to postoperative complications and worsened pulmonary function (described later). Frequently, the volume of irradiated lung can be minimized using a simple AP/PA approach. However, this sometimes results in significant cardiac dose, particularly in lower esophagus and gastroesophageal junction tumors. Therefore, oblique orientations are sometimes used, resulting in increased volumes of normal lung being irradiated. When giving concurrent chemotherapy, we generally limit these fields to 13 to 15 Gy. Similarly, advanced radiation techniques including IMRT are frequently utilized.

Accurate delineation of adjacent organs, including the lungs, liver, kidneys, heart, and spinal cord, is important. Varying dose–volume normal-organ constraints have been suggested, including achieving a lung V_{20} of <20%, limiting >2,300 cm^3 of normal lung tissue to <5 Gy, and using mean lung dose of <18 Gy. Similarly, a V_{10} of ≤60% has been proposed to reduce the incidence of postoperative pulmonary complications. Historically, heart dose constraints have included maintaining one-third, two-thirds, and total heart volumes of <45, 40, and 30 Gy, respectively. Recommended heart constraints include keeping <30% of the cardiac volume to a total dose of 40 Gy and <50% receiving 25 Gy, minimizing dose to the left ventricle. In the setting of potentially significant volumes of the heart in the radiation field, consideration of respiratory gating and/or breath-hold techniques can be made. For lower esophageal and gastroesophageal cancers, it is recommended that at least 70% of one physiologically functioning kidney receive a total dose of <20 Gy and that, collectively, no more than 50% of the combined functional renal volume should receive >20 Gy.[48] One should also consider the possibility of impaired kidney function in the context of varying comorbidities, using nuclear medicine renal studies to assess individual renal function in such situations or where significant volumes of kidneys are anticipated to be within the radiation field. Generally, 70% of the liver parenchyma should be kept to a dose of <30 Gy. Many of these constraints can be achieved with three-dimensional planning with appropriate and careful design of shielding blocks/multileaf collimation and dose–volume histogram analysis, with the use of IMRT in select cases. Examples of normal tissue constraints for esophageal cancer planning are seen in Table 56.6.

Doses of Radiation

Because locoregional failure is common after conventional chemoradiation, investigators have evaluated dose escalation techniques. Varying series using doses beyond 50 Gy have shown local control rates ranging from approximately

77% to 88%.[135,136] However, Minsky et al.[56,137] reported the results of a randomized trial in which 236 patients with clinical stage T1-4, N0/1, M0 squamous cell, or adenocarcinoma of the esophagus were selected for nonsurgical therapy. Patients were randomized to receive 64.8 versus 50.4 Gy, both with concurrent 5-fluorouracil and cisplatin chemotherapy. Patients with cervical, mid, or distal esophageal cancer were eligible, with the exception of those with tumors within 2 cm of the gastroesophageal junction, with approximately 85% of patients with squamous cell histology. This study was closed after interim analysis showed no probability of superiority in the high-dose arm. No significant difference in median survival (13 vs. 18.1 months), 2-year survival (31% vs. 40%), or locoregional failure/persistence of disease (56% vs. 52%) was seen between the high-dose and standard-dose arms. Eleven treatment-related deaths occurred in the high-dose arm compared with 2 in the standard-dose arm, with 7 of the 11 high-dose arm deaths occurring in patients who received 50.4 Gy or less. The authors performed a separate survival analysis including only patients receiving the assigned radiation dose. Despite this, no survival advantage was noted in the high-dose arm. These authors concluded that higher radiation doses did not increase survival or locoregional control and that the standard radiation dose for patients treated with concurrent 5-FU and cisplatin chemotherapy is 50.4 Gy. Based on these data, standard dose of radiation therapy for esophageal cancer is usually 50 to 50.4 Gy at 1.8 to 2 Gy per fraction, including delivery of similar doses in the definitive, adjuvant (45 to 50 Gy) or neoadjuvant (41.4 to 50 Gy) settings. Nonetheless, critics of this trial argue that older radiation techniques were utilized and that dose escalation should be evaluated using modern techniques. Randomized studies are ongoing to further evaluate this concept. The French Concorde trial is currently randomizing patients to receive 66 versus 50 Gy combined with FOLFOX for using IMRT/VMAT techniques in patients receiving definitive chemoradiotherapy with an elective nodal dose to 40 Gy.[138] Similarly, the Dutch ART deco trial is evaluating radiation dose escalation in nonoperable esophageal cancer patients (50.4 vs. 61 Gy with increasing dose per fraction concomitant boost) with concurrent carboplatin and paclitaxel. The United Kingdom SCOPE 2 study is a four-arm trial comparing carboplatin/paclitaxel versus cisplatin-/capecitabine-based chemoradiation, with a second randomization to standard versus high-dose radiation therapy (50 vs. 60 Gy, both in 25 fractions). Patients will receive a lead in of chemotherapy then be further randomized based on intratreatment PET analyses. Finally, a Chinese study is comparing a regimen of

50 Gy in 25 fractions with concurrent cisplatin and 5-FU versus a simultaneous integrated boost treatment to a total of 66 Gy in 30 fractions with concurrent cisplatin and 5-FU in nonoperable squamous cell carcinoma patients.

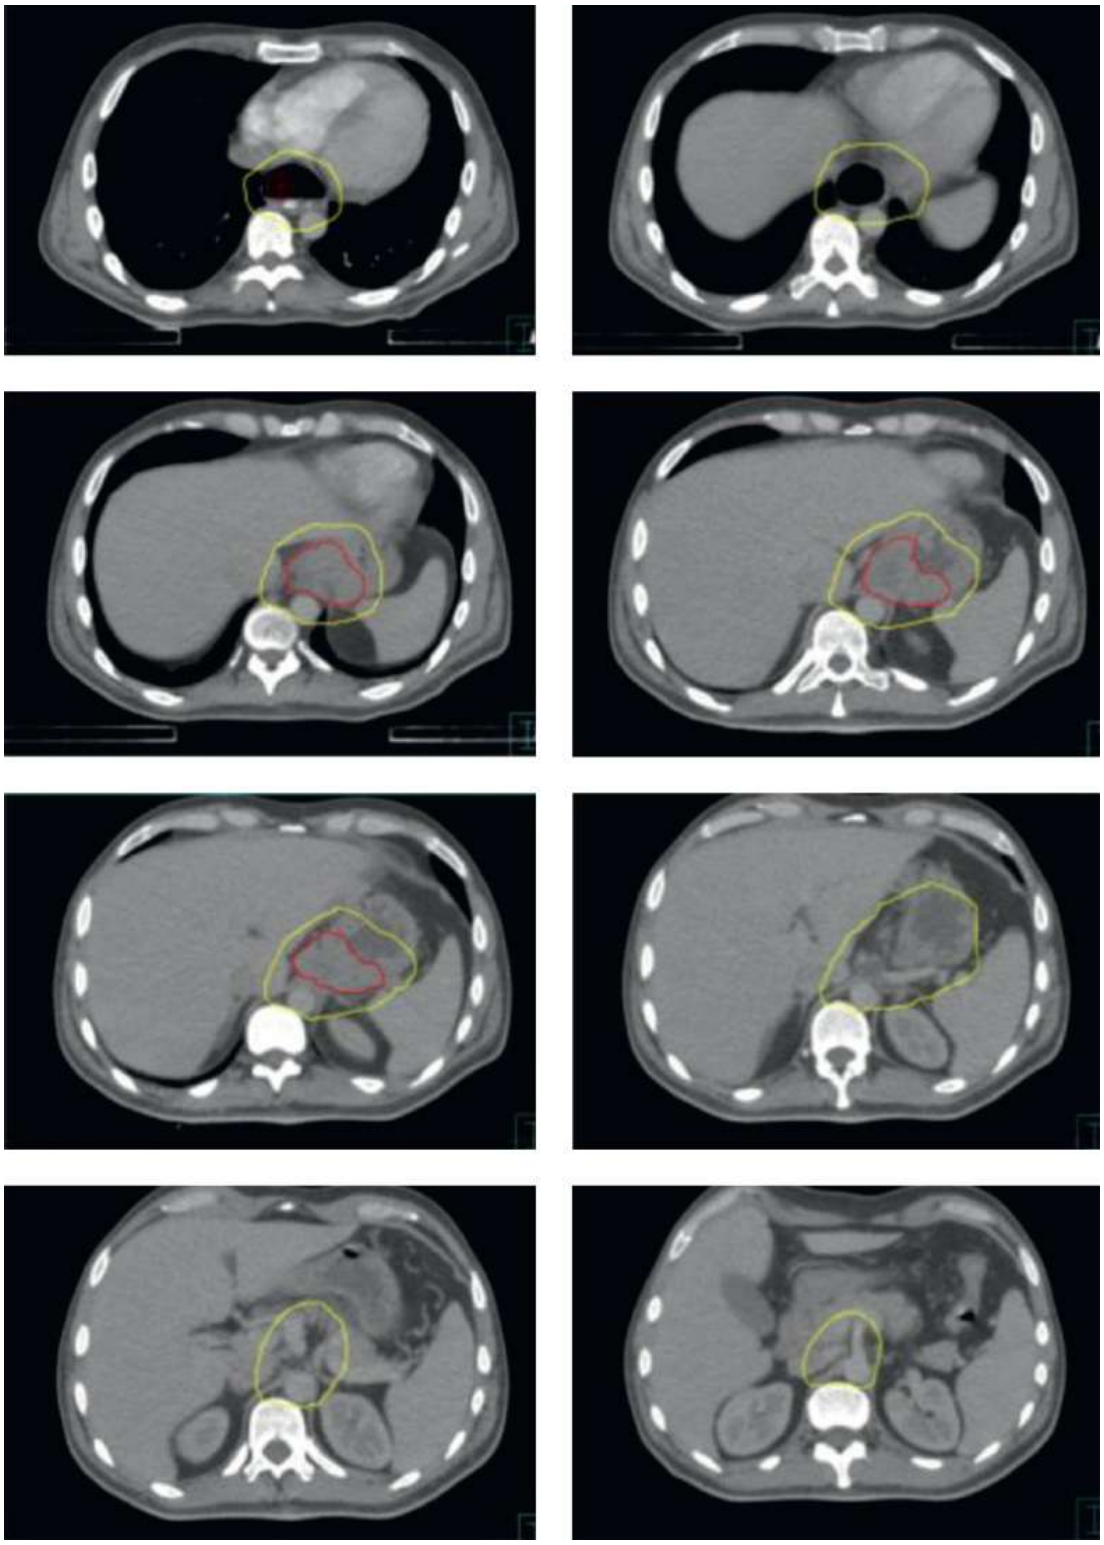

FIGURE 56.16. Consensus CTV contours for T3N0, Siewert II gastroesophageal junction cancer, gross tumor volume in *red*.

Brachytherapy

In addition to external beam radiation therapy (EBRT), intracavitary therapy can be used with curative or palliative intent. Brachytherapy has also been used as a dose escalation tool in addition to EBRT. The advantage of brachytherapy centers on exploitation of the inverse-square law and quick dose falloff, thus sparing surrounding tissues from radiation while providing focal dose escalation. The radioactive source of choice is usually ^{192}Ir. High–dose rate (HDR) techniques can deliver 100 to 400 Gy/hour, allowing treatment to be given in 5 to 10 minutes.

With brachytherapy, an afterloading catheter is introduced through the nose into the esophagus to the primary tumor site under fluoroscopic guidance. This is often performed with the patient on the simulation table. Contrast may be used to define the tumor site. CT scan can also be used to discern tumor location. After localization films are taken and dosimetry is generated, the catheter is then attached to a remote afterloader through a guide cable and the ^{192}Ir source inserted through remote control. Doses of 5 to 20 Gy are usually delivered to a depth of 1 cm from the center of the catheter. Dose can be shaped and modified through the use of dwell times.

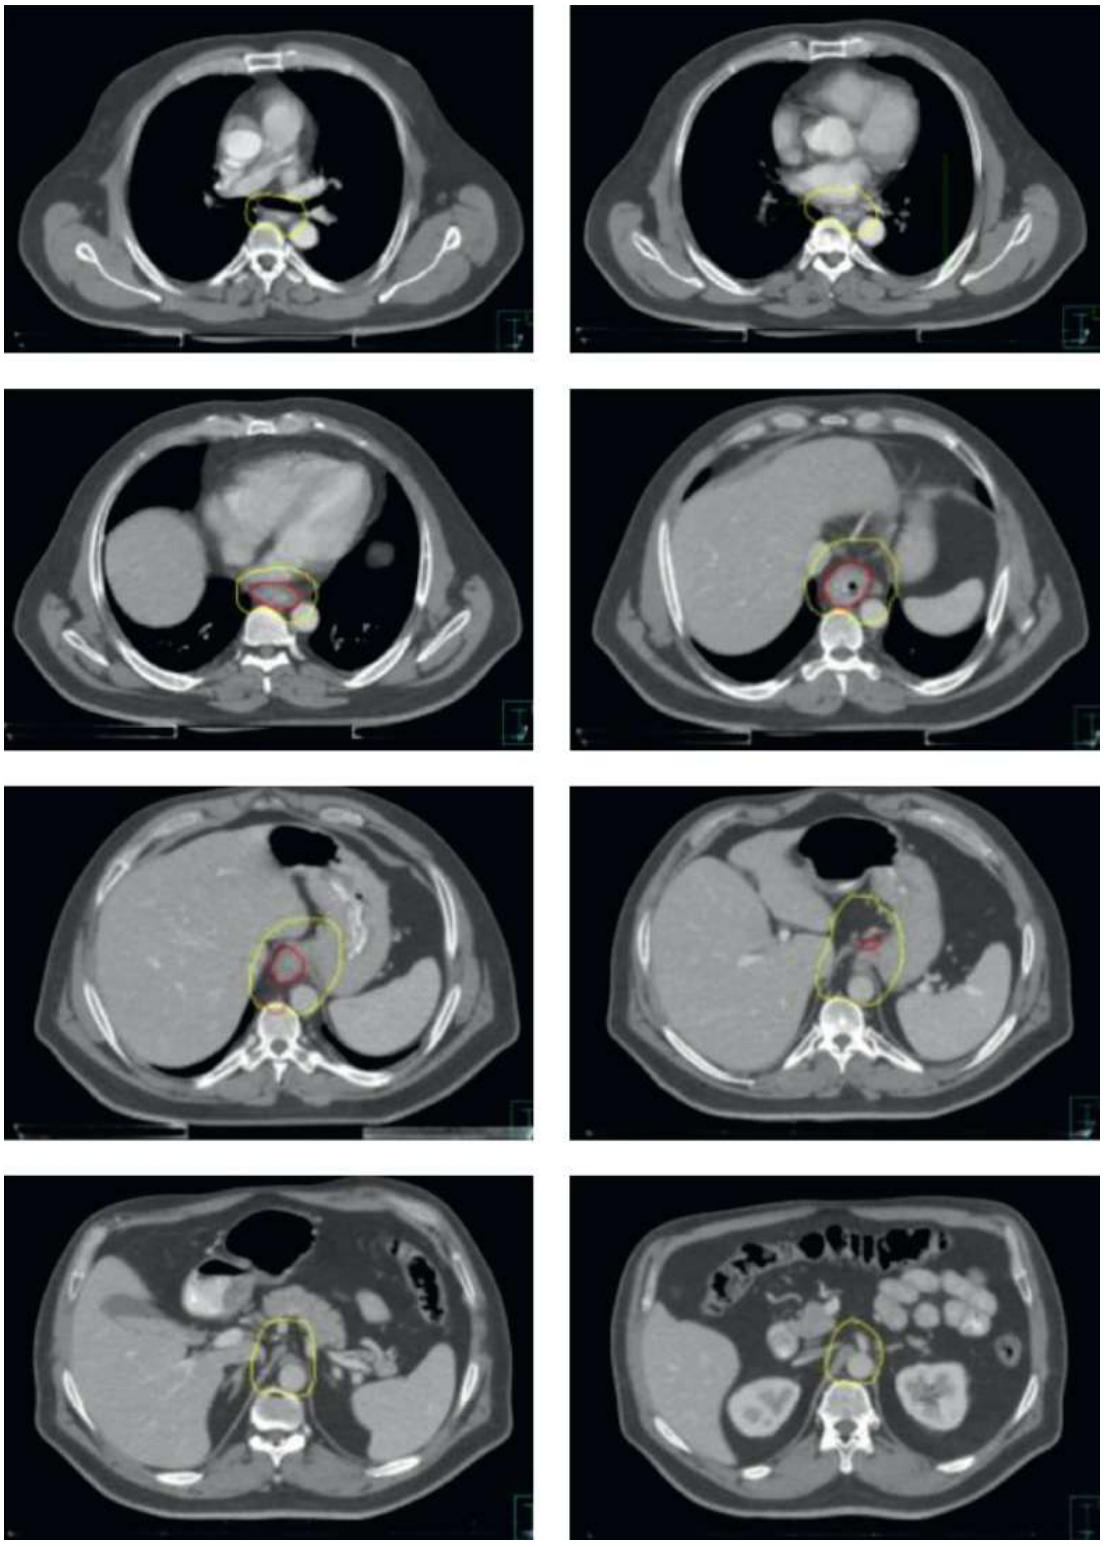

FIGURE 56.17. Consensus CTV contours for T3N1 distal esophageal cancer.

RESULTS OF THERAPY

The best survival results have been reported in patients who have esophageal tumors that are truly localized. Survival rates range from 25% to >35% at 5 years, and these results have been attained using an array of treatment approaches. Problems arise in comparisons of various modalities, however, because of patient selection factors. A historical review of the Princess Margaret Hospital data[139] supported the concept that extent of tumor, rather than therapy, is the most important factor influencing survival. They found a significant correlation between T stage and response to treatment: T1 lesions showed a 100% response rate, whereas T2 and T3 lesions had response rates of 68% and 58%, respectively. Not unexpectedly, they also found differences in survival according to T stage, M stage, and overall stage. Almost 20% of patients with stage I disease were alive at 3.5 years, whereas only 11% of stage II patients were alive after the same interval, and all patients with stage III died of disease by approximately 1.5 years following therapy.

Surgery Alone

Surgery remains a benchmark to which other modalities are compared. Surgery removes the tumor, a length of normal esophagus, and lymph nodes. Although multiple techniques exist for the resection of esophageal cancer, no one surgical approach has clearly been shown to be superior with regard to complications or outcomes. Proponents of more extended resection (including transthoracic approaches) have advocated that such procedures result in a superior nodal clearance and therefore offer a more complete “oncologic” resection. A trial from the Netherlands randomized 220 patients with esophageal adenocarcinoma to transhiatal esophagectomy alone or transthoracic esophagectomy with extended lymph node dissection. Patients undergoing transhiatal resection experienced significantly fewer pulmonary complications and chylous leaks, as well as significantly reduced ventilator dependence and intensive care unit and hospital stays. At a median 4.7-year follow-up, no significant difference in locoregional recurrence was seen between the two groups (32% transhiatal vs. 31% transthoracic). Furthermore, no significant differences were seen in median disease-free survival (1.4 vs. 1.7 years; $P = .15$) or median overall survival (1.8 vs. 2.0 years; $P = .38$). However, there did appear to be a nonsignificant trend favoring the transthoracic approach in improved disease-free survival (5-year, 27% vs. 39%) and overall survival (5-year, 29% vs. 39%). The authors concluded that a transhiatal approach was associated with less morbidity relative to transthoracic surgery, with no apparent survival advantage with either

technique, although a trend toward improved survival with a transthoracic approach was seen with longer follow-up.[51] Updated 5-year survival results were 34% versus 36%, respectively.[140] In contrast, a randomized trial from Japan comparing transhiatal to left thoracoabdominal approaches in patients with esophagogastric junction cancers. Both groups underwent total gastrectomy and splenectomy with extensive nodal dissection. Ten-year survival was 37% for the transhiatal approach versus 24% for the thoracoabdominal approach (P = .06). The authors concluded left thoracoabdominal resection should be avoided in patients of the esophagogastric junction or gastric cardia.[141]

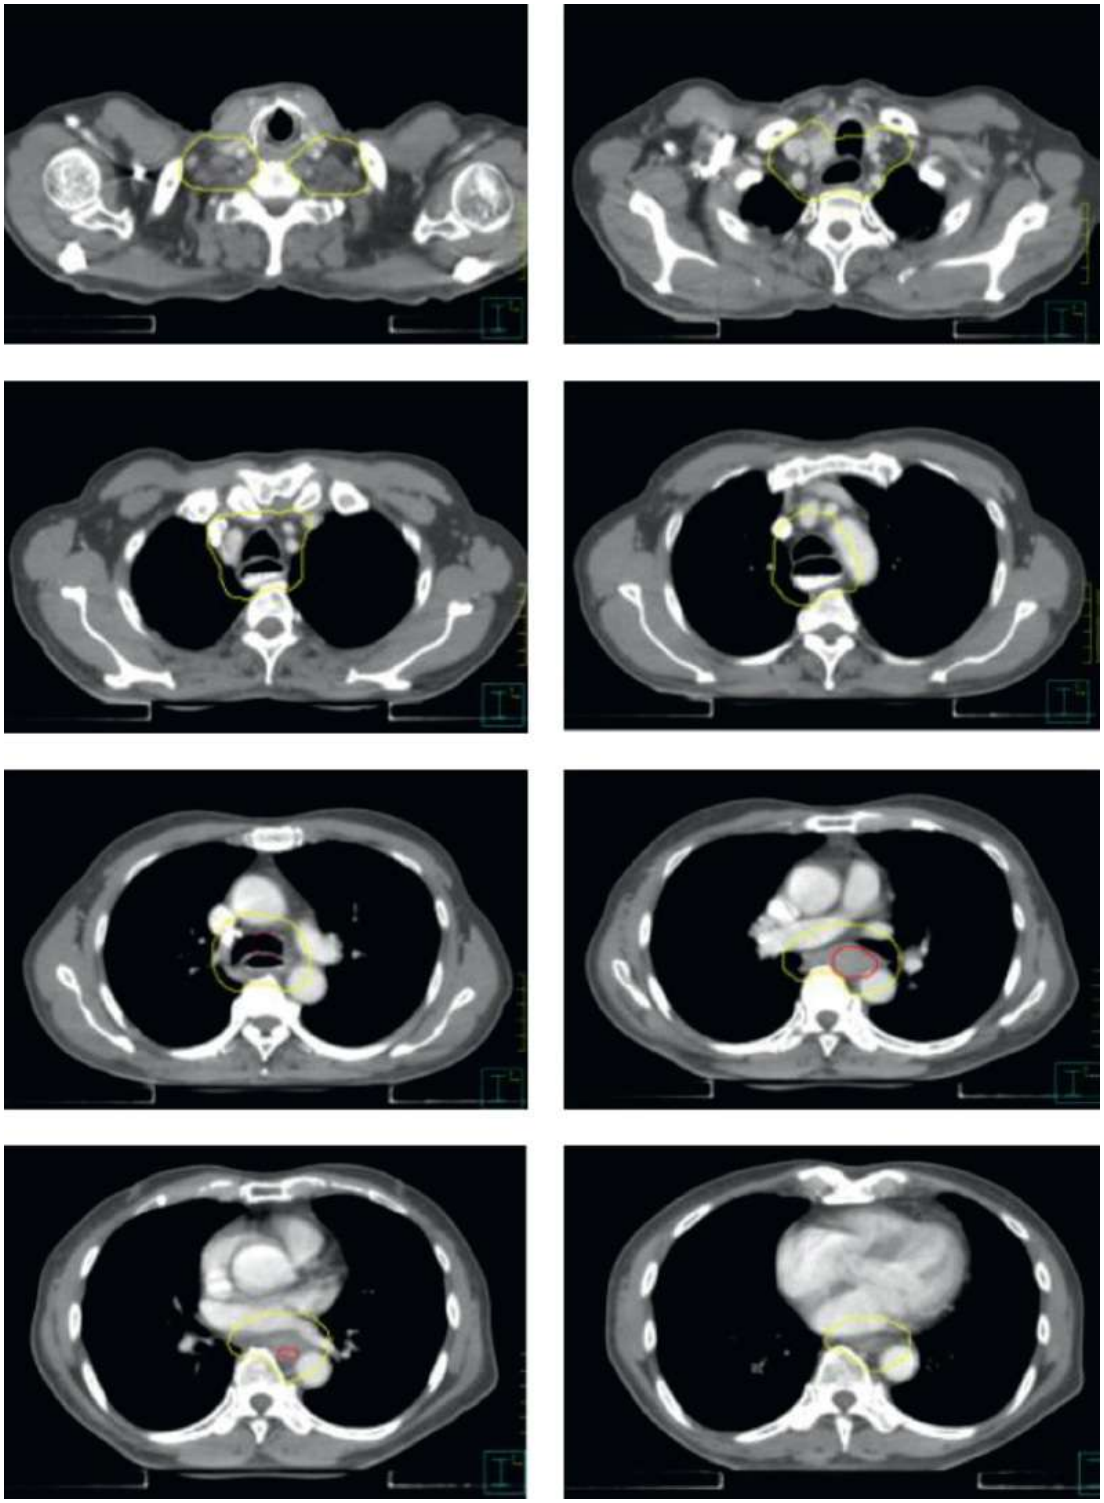

FIGURE 56.18. Consensus contours for T3N1 proximal esophageal cancer.

In summary, none of the surgical approaches to localized esophageal cancer has clearly been shown to be superior with regard to complications or outcomes, and no one standard surgical approach exists for esophageal cancer resection.

After resection alone, however, locoregional relapse is a common mode of failure. Contemporary randomized trials with surgery-alone arms have reported locoregional failure rates of 32% to 45%.[51,52,106,142] It should be remembered that patterns of failure reports often describe the first site of failure only and may include only patients undergoing R0 resection, potentially underreporting the true incidence of locoregional recurrence. These and other data suggest that even with modern surgical techniques, locoregional persistence of disease after resection remains a major problem. Prospective, randomized trials using surgery alone in the treatment of esophageal cancer have reported 3-year survival rates ranging from 6% to 48%, with more favorable rates likely reflecting inclusion of patients with earlier-stage disease[53,143–146] (Table 56.7). Given these high rates of relapse and poor long-term survival, the integration of adjuvant or neoadjuvant chemoradiation approaches into the treatment of esophageal cancer is rational and indicated.

TABLE 56.6 EXAMPLE OF NORMAL TISSUE DOSE CONSTRAINTS IN PLANNING OF ESOPHAGEAL CANCER

- Lung
  - $V_{40Gy} \leq 10\%$
  - $V_{30Gy} \leq 15\%$
  - $V_{20Gy} \leq 20\%$
  - $V_{10Gy} \leq 40\%$
  - $V_{05Gy} \leq 50\%$
  - Mean < 20 Gy
- Cord
  - Max ≤ 45 Gy
- Bowel
  - Max bowel dose < max PTV dose
  - $D_{05} \leq 45$ Gy
- Heart
  - $V_{30Gy} \leq 30\%$ (closer to 20% preferred)
  - Mean < 30 Gy
- Left Kidney, Right Kidney (evaluate each one separately):
  - No more than 33% of the volume can receive 18 Gy.
  - Mean dose < 18 Gy
- Liver
  - $V_{20Gy} \leq 30\%$
  - $V_{30Gy} \leq 20\%$
  - Mean < 25 Gy
- Stomach
  - Mean < 30 Gy (if not within PTV)
  - Max dose < 54 Gy

Radiation Therapy Alone

A trial from China randomized 269 patients to either surgery alone or radiation therapy alone. Surgery entailed esophagectomy while radiation field varied by location of primary. Patients received 50 to 50.4 Gy of daily treatment, followed by reduced fields receiving 1.5 Gy BID to a cumulative dose of 68.4 to 71 Gy. The 1-, 3-, and 5-year overall survival rates in the surgery-alone group were 93%, 62%, and 37% versus 89%, 56%, and 35%, respectively. The authors concluded survival might be equivalent between these arms.[148] However, in most series, radiation therapy alone has been usually delivered when lesions are deemed inoperable because of tumor extent or medical contraindications and/or palliative treatment is indicated. In most series, patients receiving radiation as a sole treatment modality have a median survival of 6 to 12 months and 5-year survival of <10%.

A historical review analyzing 49 series involving >8,400 patients treated primarily with radiation therapy alone found overall survival rates at 1, 2, and 5 years to be 18%, 8%, and 6%, respectively.[149] Hancock and Glatstein[112] reviewed 9,511 patients and found only 5.8% were alive at 5 years. Okawa et al.[150] reported 5-year survival rates by stage. For patients with stage I disease, the 5-year survival rate was 20%; stage II, 10%; stage III, 3%; and stage IV, 0%. Overall, the 5-year survival rate was 9%. For cervical esophageal lesions treated with radiation alone, the cure rates were comparable with those in patients treated with surgery alone. Lederman[151] treated 263 patients with radiation therapy alone and reported 3- and 5-year survival rates of 11% and 7%, respectively. In a more contemporary series, an Intergroup randomized study (discussed later) comparing combined chemotherapy with 5-FU and cisplatin with radiotherapy (50 Gy) versus radiotherapy only (64 Gy) showed that 3-year actuarial survival with radiotherapy alone was 0%. These and other data suggest that treatment with radiation therapy alone for esophageal cancer patients is palliative in the vast majority of patients.

Preoperative Radiation Therapy

The use of preoperative radiation therapy has potential biologic and physical advantages, including increased resectability of tumors, increased tumor radioresponsiveness secondary to improved tumor oxygenation, a theoretical decreased likelihood of dissemination at the time of surgery, and avoidance of surgery in patients with rapidly progressive disease.

There are multiple, largely historical randomized studies comparing preoperative irradiation followed by surgery with surgery alone. These studies demonstrate no clinical benefit to the use of preoperative radiation therapy alone (Table 56.8). Launois et al.[152] reported delivering 40 Gy over 8 to 12 days with surgery 8 days later versus surgery alone. Resection rates were similar—70% and 58% for preoperative irradiation and for surgery alone, respectively. The 5-year survival rate after resection was 11.5% for those treated with surgery alone, compared with 9.5% for those treated with irradiation and surgery. The second randomized study, published by the European Organisation for Research and Treatment of Cancer (EORTC), used 33 Gy over 12 days.[153] There was no significant difference in survival between those receiving preoperative irradiation and those receiving surgery alone. Arnott et al.[154] reported on 176 patients, 86 of whom were treated with esophagectomy alone versus 90 who

were treated with preoperative radiation therapy. Preoperative radiation therapy was delivered with 4-MV photons using opposed fields, delivering 20 Gy at 2 Gy/fraction. Resectability and local failure were not reported. Patients receiving low-dose radiation therapy did not demonstrate a benefit in 5-year overall survival rates (17% vs. 9% for surgery and preoperative radiation, respectively; $P = .4$). Wang et al.[155] randomized 206 patients to surgery alone versus 40 Gy in 2-Gy fractions delivered preoperatively. No significant survival advantage was seen for patients receiving radiation therapy (35% vs. 30%; $P > .05$).

A meta-analysis from the Oesophageal Cancer Collaborative Group updated data from five randomized trials of >1,100 patients comparing preoperative radiotherapy alone versus surgery alone. The majority of patients had squamous cell carcinoma. At a median follow-up of 9 years, the hazard ratio was 0.89, suggestive of an overall reduction in the risk of death of 11% and absolute survival benefit of 4% at 5 years with the use of preoperative radiotherapy. However, this was not statistically significant ($P = .06$). The authors concluded that there was no clear evidence that preoperative radiotherapy improves survival of patients with potentially resectable esophageal cancer.[4]

In general, there were no differences in resectability rates or survival in almost all of the individual studies. Interpretation of these varying studies is complicated by differences in radiation techniques, suboptimal radiation doses, and inadequate radiation volumes. Nonetheless, although preoperative radiation therapy alone may improve local control, there is no convincing data that it results in improved survival in esophageal cancer patients.

Postoperative Radiation Therapy

The main advantage of adjuvant versus neoadjuvant approaches is knowledge of the pathologic staging for appropriately selected patients for therapy. Postoperative therapy may allow the radiation oncologist to treat areas at risk for recurrence while sparing otherwise normal radiosensitive structures, thereby decreasing toxicity. In addition, patients with pathologic T1, N0, and M0 or metastatic disease may be spared treatment. Postoperative irradiation has historically been delivered to patients with esophageal cancer who have bulky tumors with gross residual disease or histologically proven microscopic residual disease. Potential disadvantages of postoperative radiation include limited tolerance of normal tissues after gastric pull-up or intestinal interposition and irradiation of a devascularized tumor bed, potentially larger fields compared to a preoperative approach, and potential delays in adjuvant treatment delivery.

TABLE 56.8 RANDOMIZED TRIALS OF PREOPERATIVE RADIATION THERAPY FOR ESOPHAGEAL CANCER

Author	Patients	Dose (Gy)	Fraction (Gy)	Local Failure		Survival (5-Year)

Wang et al.[155]	160	40	2	NA	NA	30	35

[a]Both squamous and adenocarcinoma.
NA, not applicable; RT, radiation therapy.

Three randomized trials have assessed surgery alone versus surgery followed by postoperative radiation therapy.[156–158] In a French trial, 221 patients with squamous cell carcinoma of the mid–lower esophagus undergoing esophagectomy were randomized to postoperative radiation therapy or no further treatment. Patients were stratified by extent of nodal involvement. Total dose was 45 to 55 Gy at 1.8 Gy/fraction, beginning within 3 months of surgery. Five-year survival in node-negative patients was 38% versus 7% with involved nodes. No significant survival difference was seen in patients receiving postoperative radiation versus surgery alone. Rates of locoregional recurrence were lower in patients receiving radiation therapy (85% vs. 70%; P = NS). However, in patients without nodal involvement, locoregional recurrence was significantly improved in patients receiving postoperative therapy (90% vs. 65%; $P < .2$). The authors concluded that postoperative radiation therapy did not improve survival after resection for squamous cell carcinoma.[156]

Investigators from the University of Hong Kong reported the results of a randomized trial of 130 patients treated with postoperative radiation therapy versus surgery alone. Patients who underwent either curative or palliative resections were included in this trial. Radiation therapy was delivered to a total dose of 49 Gy (curative patients) or 52.5 Gy (palliative patients) using 3.5-Gy fractions. Most patients had squamous cell histology. Local recurrence was noted in 15% of patients receiving radiation and 31% of patients with surgery only (P = .06). In patients with squamous cell carcinoma, the local recurrence rate was

15% with radiation therapy versus 36% with surgery alone (P = .02). Median survival in patients was worse in patients receiving postoperative radiotherapy versus control patients (8.7 vs. 15.2 months; P = .02). Ten patients undergoing surgery alone had tracheobronchial recurrence resulting in death versus three patients receiving adjuvant radiation therapy (P = .07). The authors concluded that postoperative radiation therapy was associated with increased morbidity and death caused by radiation injury, as well as with the early appearance of metastatic disease and a reduced overall survival, although patients receiving radiation therapy were less likely to have a tracheobronchial recurrence. However, it should be noted that the high rate of complications associated with radiation therapy in this study might possibly be related to the high dose per fraction and large total dose delivered.[157]

Last, a study conducted by Xiao et al.[158] randomized 549 patients to radical resection versus radical resection followed by radiation therapy. All patients had squamous cell carcinoma. The radiation dose delivered was 60 Gy in 6 weeks. Patients were classified into three groups: group 1, no lymph node involvement; group 2, one to two lymph nodes involved; and group 3, three or more lymph nodes involved. Results showed T stage, stage group, and the number of lymph nodes involved by tumor were highly predictive of survival. The 5-year survival rates for groups 1, 2, and 3 were 58.1%, 30.6%, and 14.4%, respectively. Local control and survival were improved in patients receiving postoperative irradiation. For patients with involved lymph nodes, 5-year survival rates for resection-only patients versus patients receiving resection and radiation therapy were 17.6% and 34.1%, respectively (P = .04).

In summary, postoperative radiation therapy may decrease local recurrence, particularly in the setting of involved margins, although the impact of this adjuvant treatment on overall survival remains less clear.

Postoperative Combined Chemoradiation

A large randomized Intergroup trial evaluating the role of adjuvant chemoradiation after surgery versus surgery alone for patients with adenocarcinoma of the stomach and GE junction was reported. In this study, patients with resected, margin-negative gastric or gastroesophageal junction adenocarcinoma were randomly assigned to surgery alone versus surgery with postoperative chemoradiotherapy. Approximately 20% of patients had lesions in the gastroesophageal junction. A significant survival advantage was seen in the adjuvantly treated group (median survival 27 vs. 36 months; p = .005). On subset

analysis, this benefit was detected in patients with gastroesophageal cancer.[159] Long-term results at >10-year median follow-up continued to show significant improvement in overall and disease-free survival in the chemoradiation group, benefiting all T- and N-stage patients included in the trial.[160] Therefore, in patients with resected-stage group IB to IV, nonmetastatic GE junctional carcinoma, it is appropriate to advise adjuvant chemoradiotherapy in efforts to potentially improve upon local control and survival. In squamous cell carcinoma, no adjuvant randomized data exist, although institutional series suggests a potential survival benefit in lymph node–positive disease with adjuvant chemoradiation.[161,162]

Preoperative Chemotherapy

Five randomized trials showed conflicting results with the use of neoadjuvant chemotherapy alone in the treatment of esophageal cancer, with two of these trials also including gastric cancers. Kelsen et al.[106] reported the results of an Intergroup study randomizing 440 patients with squamous cell carcinoma and adenocarcinoma to receive either combined cisplatin or 5-FU chemotherapy for three cycles followed by resection, followed by a similar regimen of adjuvant chemotherapy, versus immediate resection with no chemotherapy. No apparent survival advantage (3-year survival of 23% vs. 26%) was seen in patients receiving chemotherapy. In addition, rates of local failure (32% vs. 31%) and distant metastasis development (41% vs. 50%) were not significantly different between the two groups. The authors concluded that neoadjuvant chemotherapy with cisplatin and 5-FU did not improve survival in patients with resectable esophageal cancer. Long-term results reported that only 59% and 63% of patients undergoing preoperative chemotherapy and surgery alone, respectively, underwent R0 resection, and patients undergoing less than R0 resection had an ominous prognosis, with only 5% of patients undergoing R1 resection surviving >5 years and no difference in median survival rates for patients with R1, R2, or no resection. In this follow-up study, patients with objective tumor regression after preoperative chemotherapy experienced improved survival. An important caveat from this study is that all long-term R1 survivors received adjuvant RT, and the authors concluded that after R1 resection, postoperative chemoradiotherapy offers the possibility of long-term disease-free survival to a small percentage of patients.[163]

In contrast to the Intergroup study, a similar trial from the Medical Research Council (MRC) randomized 802 patients with squamous cell carcinoma or

adenocarcinoma of the esophagus to either two cycles of combined cisplatin/5-FU chemotherapy or surgery alone. Patients receiving neoadjuvant chemotherapy had a statistically improved 2-year survival (43% vs. 34%).[144] Follow-up analysis at a median follow-up of 6 years showed a persistent, significant survival benefit in the chemotherapy group (5-year survival 23% vs. 17%), with the effect maintained for both squamous cell carcinoma and adenocarcinoma patients.[164] The reason for outcomes differences between these trials is not clear. A follow-up trial from the MRC (OE05) randomized patients to neoadjuvant cisplatin/5-FU for 2 cycles versus 4 cycles of ECX (epirubicin, cisplatin, and capecitabine) for esophageal adenocarcinoma. No overall survival difference was seen between the arms. The authors concluded four cycles of neoadjuvant ECX compared with two cycles of CF did not increase survival, and cannot be considered standard of care.[164a]

A smaller trial of 169 patients with squamous cell carcinoma of the esophagus randomized patients to receive preoperative chemotherapy alone with two to four cycles of etoposide- and cisplatin-based chemotherapy versus surgery alone. Median and 5-year survival rates significantly favored the chemotherapy group at 16 versus 12 months and 26 versus 17%, respectively. The authors concluded that preoperative chemotherapy with a combination of etoposide and cisplatin improves survival in patients with squamous carcinoma of the esophagus.[165]

A more heterogeneous European study (the Medical Research Council Adjuvant Gastric Infusional Chemotherapy, or MAGIC, trial) randomly assigned patients with resectable adenocarcinoma of the stomach, gastroesophageal junction, or lower esophagus to preoperative and postoperative chemotherapy with epirubicin, cisplatin, and 5-FU versus surgery alone. Although originally designed to include patients with only tumors of the stomach, eligibility was later expanded to include tumors of the lower one-third of the esophagus. Approximately one-fourth of patients had adenocarcinoma involving the lower esophagus or gastroesophageal junction. No patient achieved pathologic complete response. However, patients receiving perioperative chemotherapy had a hazard ratio for death of 0.75, which was highly significant. Five-year survival in patients receiving chemotherapy was 36% versus 23% in patients undergoing surgery alone ($P = .009$). Subgroup analysis of patients with lower esophageal or gastroesophageal junction tumors showed benefit to the delivery of perioperative chemotherapy.[166]

A follow-up study to the MAGIC trial investigated the role of perioperative epirubicin, cisplatin, and capecitabine, with or without the addition of

bevacizumab. One thousand sixty-three patients with esophagogastric adenocarcinoma were randomized. No survival benefit was seen in the bevacizumab arm, whereas wound healing complications were more prevalent with higher rates of postoperative anastomotic leak rates with bevacizumab, prompting discontinuation of recruitment of patients with lower esophageal or junctional tumors planned for esophagogastric resection.[167]

French investigators reported the results of a similar randomized trial of 224 patients assigned to perioperative chemotherapy (cisplatin and 5-FU) versus surgery alone. Although originally designed to include only patients with tumors of the lower one-third of the esophagus or gastroesophageal junction, eligibility was later expanded to include gastric cancers. Most patients (75%) had disease of the lower esophagus or gastroesophageal junction. Chemotherapy consisted of planned two or three preoperative and three or four postoperative cycles. This study was prematurely terminated because of low accrual. Patients receiving chemotherapy had improved overall survival (5-year, 38% vs. 24%; $P = .02$), disease-free survival (5-year, 34% vs. 19%, $P = .003$), and R0 resection rates (84% vs. 73%; $P = .04$). Only 50% of patients received postoperative chemotherapy. T0 disease (complete pathologic response at the primary site) was seen in 3% of neoadjuvantly treated patients. Total locoregional recurrence rates were 24% and 26%, respectively, in the chemotherapy versus surgery group, with distant recurrence rates of 42% versus 56%, respectively.[168] In addition to the foregoing studies, two meta-analyses suggested that neoadjuvant chemotherapy resulted in absolute 2- and 5-year survival benefit of 7% and 4%, respectively.[169,170]

Preoperative Chemoradiation Versus Surgery Alone

Walsh et al.[143] reported a randomized study to evaluate the role of concurrent preoperative chemoradiation combined with surgery. A total of 110 patients with adenocarcinoma of the esophagus were randomized to receive cisplatin, 5-FU, and concurrent radiation therapy followed by surgery versus surgery alone. Combined-modality patients received two courses of chemotherapy at weeks 1 and 6. Patients were treated using anteroposterior–posteroanterior fields (later changed to a three-field technique) to a total dose of 4,000 cGy in 15 fractions. Surgery was performed 4 to 6 weeks later, using five separate approaches. Median survival was 16 months with preoperative chemoradiation therapy compared to 11 months for the patients treated with surgery alone ($P = .01$). The 1-, 2-, and 3-year survival rates were 52%, 37%, and 32%, respectively, for

patients who received multimodality therapy and 44%, 26%, and 6%, respectively, for those patients assigned to surgery. These results were significant at 3 years (P = .01). The authors concluded that neoadjuvant chemoradiation was superior to surgery alone in patients with resectable esophageal adenocarcinoma. A follow-up report of this study described two simultaneously conducted randomized trials in patients with (a) adenocarcinoma and (b) squamous cell carcinoma. Combined trial results suggest that neoadjuvant chemoradiotherapy conferred a significant survival advantage in both groups, with an associated 54% relative risk reduction in lymph node metastases (64% vs. 29%, P < .001). Pathologic complete response was seen in 25% and 31% of adenocarcinoma and squamous cell carcinoma patients, respectively. Patients receiving neoadjuvant therapy, achieving pathologic complete response, and those with lymph node–negative disease demonstrated superior survival.[171] This trial has been criticized for its poor surgery-alone results, short follow-up, and lack of prerandomization CT staging.

Urba et al.[52] reported the results of 100 patients with nonmetastatic esophageal carcinoma (squamous and adenocarcinoma histology) randomized to receive preoperative chemoradiation followed by surgery versus transhiatal esophagectomy alone. Chemotherapy consisted of cisplatin, 5-FU, and vinblastine. Only 69% of the patients were able to receive the intended chemotherapy dose. Radiation was delivered at 1.5 Gy twice daily for 3 weeks to a total dose of 4,500 cGy. No elective nodal irradiation was performed. Surgery was performed on day 42. Tumors >5 cm, patient age >70 years, and squamous cell histology were associated with inferior survival. At median follow-up of 8 years, no significant difference in survival was seen between treatment arms, with a median survival of 17 months. However, 3-year survival rate was 16% in the surgery-alone arm versus 30% in the combined modality arm (P = .15). A higher incidence of locoregional failure as first site of failure was seen in surgery-alone patients (42% vs. 19%, P = .02). In patients experiencing pathologic complete response, a median survival of 50 months and a 3-year survival rate of 64% were seen versus patients with residual tumor in the surgical specimen, where median survival was 12 months with a 3-year survival rate of 19% (P = .01). The investigators stated that “Although this is not statistically significant, this suggests a possible trend to the benefit of multimodality therapy, but the sample size was too small to detect a more subtle survival difference,” and that surgery should be continued as a standard of care.

Bosset et al.[145] reported an EORTC trial randomizing 282 patients with

squamous cell carcinoma of the esophagus to either immediate surgical resection or preoperative therapy using concurrent cisplatin chemotherapy with radiation therapy. Patients were treated with split-course radiotherapy with a 2-week interval, using 3.7 Gy/fraction to a total of 37 Gy. Postoperative mortality was significantly higher in patients receiving preoperative therapy (12% vs. 4%). Outcomes showed patients receiving neoadjuvant therapy experienced a significant improvement in disease-free survival, cancer-related mortality, margin-negative resection, and local control; however, no improvement in overall survival was seen versus patients undergoing surgery alone (median survival was 18.6 months for both groups). The authors concluded that neoadjuvant chemoradiation improved disease-free survival and local control in patients with squamous cell carcinoma of the esophagus but had no impact on overall survival. They judged that the increase in postoperative mortality in the combined group "could be due to deleterious effects of the high-dose of radiation per fraction," among other factors, and believed that the dose of 3.7 Gy/fraction "probably had a detrimental effect." This trial has also been criticized for the split-course treatment approach, as well as for potential delivery of suboptimal chemotherapy.

Burmeister et al.[147] reported an Australian study randomizing 257 patients with adenocarcinoma and squamous cell carcinoma of the esophagus to surgery alone versus neoadjuvant therapy using concomitant 5-FU and cisplatin. Patient received 2.33 Gy/fraction to a total dose of 35 Gy. Patients undergoing neoadjuvant therapy had a 16% pathologic complete response rate at resection. Patients receiving neoadjuvant therapy were more likely to undergo curative resection and have negative lymph nodes on histologic examination. However, no significant improvement in median survival was seen (19 vs. 22 months; hazard ratio 0.89; $P = .57$). On subset analysis, there appeared to be a trend toward improved survival in patients with squamous cell carcinoma undergoing neoadjuvant therapy versus surgery alone (progression-free survival hazard ratio, 0.47; $P = .01$; overall survival hazard ratio, 0.69; $P = .16$). The authors concluded that neoadjuvant chemoradiation as delivered in their study provided no obvious survival benefit in patients with esophageal cancer, although further study was warranted in patients with squamous cell carcinoma. Potential criticisms of this trial include delivery of a single chemotherapy cycle, as well as delivery of lower radiation doses.

Results of a Cancer and Leukemia Group B study described 56 patients (75% with adenocarcinoma) randomized to either surgery alone or neoadjuvant

chemoradiation followed by surgical resection. Patients in the neoadjuvant therapy arm received cisplatin/5-FU–based chemotherapy and 50.4 Gy of EBRT at 1.8 Gy/fraction. This trial was closed prematurely because of poor accrual. In patients undergoing neoadjuvant therapy, pathologic complete response rate was 40%. A significant improvement in local control and survival was seen in patients receiving neoadjuvant combined-modality therapy (5-year survival, 39% vs. 16%). The authors concluded that neoadjuvant chemoradiation in patients with esophageal cancer significantly improves progression-free and overall survival.[172]

Results of the largest randomized trial (the Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study, or CROSS trial) assessing neoadjuvant chemoradiotherapy in the treatment of esophageal cancer showed a significant survival benefit in patients receiving preoperative therapy, with the majority of patients included in this trial having locally advanced adenocarcinoma.[146] Patients with resectable T1N1 or T2-3 N0-1 tumors received preoperative chemoradiotherapy consisting of weekly paclitaxel and carboplatin with concurrent radiotherapy to a dose of 41.4 Gy versus surgery alone. R0 resection rates were 92% in patients receiving neoadjuvant chemoradiotherapy versus 69% for surgery alone, with a pathologic complete response rate of 29% in patients receiving preoperative therapy. No significant differences were seen in in-hospital mortality (4% vs. 4%). Median survival was 49 months in patients receiving chemoradiotherapy versus 24 months in surgery alone, with a significant improvement in 3-year survival (58% vs. 44%). An updated analysis of this trial showed that 95% of patients were able to complete the entire neoadjuvant chemoradiotherapy regimen. After a median follow-up of 84.1 months in surviving patients, median overall survival was 48.6 months in neoadjuvant arm versus 24 months with surgery alone. Most strikingly, median overall survival in squamous cell patients was 81.6 months versus 21.1 months (P = .008), whereas it was 43.2 months versus 27.1 months in adenocarcinoma patients (P = .038). Patients receiving neoadjuvant treatment had a significant decrease in both locoregional progression (22% vs. 38%) and distant progression (39% vs. 48%).[54] The authors concluded that weekly administration of carboplatin and paclitaxel with concurrent radiotherapy improves overall survival compared to surgery alone and that this regimen can be considered the standard of care for patients with resectable esophageal or esophagogastric junction cancer. A pattern of recurrence analysis of the CROSS study indicated that preoperative therapy reduced locoregional recurrence from 34% to 14% (P

< .001) as well as reduction in peritoneal carcinomatosis (14% vs. 4%, *P* < .001) and hematogenous spread (35% vs. 29%, *P* = .025). Locoregional recurrence occurred in 5% of cases within the target volume, 2% at the field border, and 6% outside the radiation target volume, whereas only 1% had an isolated in-field recurrence.[173]

In contrast, a trial from France of 195 patients with clinically staged early-stage esophageal cancer randomized patients to receive preoperative chemoradiotherapy versus surgery alone. Study outcomes showed no significant difference in survival.[53] In this study, patients with early-stage disease (stage I to II) were randomized to receive surgery alone versus neoadjuvant chemoradiotherapy using concurrent 5-FU and cisplatin with 45 Gy. Postoperative mortality rates were 3.4% in the surgery-alone group versus 11.1% in the neoadjuvant group (*P* = .049). Three-year overall survival was 53.0% versus 47.5% (*P* = .749); however, despite the higher postoperative mortality rates, 5-year survival outcomes were 41% versus 34% in favor of the combined arm (NS). Additionally, patterns of failure analysis showed a significant improvement in local control in patients who were assigned to receive neoadjuvant therapy, nearly halving the rate of locoregional recurrence (29% vs. 15%). Disease recurrence rates were also significantly reduced in patients receiving neoadjuvant treatment. A follow-up report of surgery alone patients in this trial reported recurrent disease in 47% of patients undergoing surgery alone versus 31% neoadjuvant therapy (*P* = .03); locoregional recurrence was seen in 17% versus 30% (*P* = .047) and distant recurrence 23% versus 31% (*P* = .244) in the neoadjuvant and surgery arms, respectively.[174] The authors concluded that neoadjuvant chemoradiotherapy with cisplatin and 5-FU did not improve survival but increased postoperative mortality for patients with early-stage esophageal cancer. However, the lack of survival benefit with trimodality therapy in this study seems to be a result of increased postoperative mortality, which is likely multifactorial. A report from Chinese investigators of 451 patients with Stage IIb-III squamous cell carcinoma of the thoracic esophagus randomized patients to receive neoadjuvant vinorelbine/cisplatin with 40 Gy followed by resection versus resection alone. Pathologic complete response was seen in 43% of patients in the radiation containing arm. R0 resection (98% vs. 91%, p=0.002), and overall survival rates were significantly improved in the combined modality therapy arm (70% vs. 62% 3-year survival, p=0.035). The authors concluded neoadjuvant chemoradiotherapy plus surgery improved survival among patients with locally advanced esophageal squamous cell

carcinoma.[174a]

TABLE 56.9 RESULTS OF PREOPERATIVE COMBINED CHEMORADIATION VERSUS SURGERY ALONE—PHASE III TRIALS

Study	Median Follow-up (Year)	Pathology	Regimen	Number of Patients	Pathologic Complete Response	Three-Year Survival
Urba et al.[52] (Michigan)	8.2	SCC + adeno	5-FU–CDDP–Vinb/45 Gy Surg	50 50	28 –	CMT/Surg: 30% Surg alone: 16%
Bosset et al.[145] (EORTC)	4.6	SCC	CDDP/37 Gy Surg	143 138	20 –	CMT/Surg: 33% Surg alone: 36%
Walsh et al.[143] (Ireland)	1.5	Adeno	5-FU–CDDP/40 Gy Surg	58 55	22 –	CMT/Surg: 32% Surg alone: 6%
Burmeister et al.[147] (Australia)	5.4	SCC + adeno	5-FU–CDDP/35 Gy Surg	128 128	16 –	CMT/Surg: 35% Surg alone: 31%
Tepper et al.[172] (USA)	6.0	SCC + adeno	5-FU–CDDP/50 Gy Surg	30 26	40 –	CMT/Surg: 39% (5 y) Surg alone: 16% (5 y)
van Hagen et al.[54,146] (Netherlands)	7	SCC + adeno	Pac–Carbo/41.4 Gy Surg	180 188	29 –	CMT/Surg: 58% Surg alone: 44%
Mariette et al.[53] (France)	7.8	SCC + adeno	5-FU–CDDP/45 Gy Surg	97 98	33 –	CMT/Surg: 47.5% Surg alone: 53%

adeno, adenocarcinoma; Carbo, carboplatin; CDDP, cisplatin; CMT, combined modality therapy; EORTC, European Organisation for Research and Treatment of Cancer; 5-FU, 5-fluorouracil; med OS, median overall survival; Pac, paclitaxel; SCC, squamous cell carcinoma; Surg, surgery; Vinb, vinblastine.

Outcomes of these trials are shown in Table 56.9.

Given these conflicting results of contemporary trials, multiple meta-analyses have been performed. Two of the largest and most contemporary of these

demonstrated an absolute 2- and 5-year overall survival benefit of 13% and 6.5% with the use of neoadjuvant chemoradiotherapy, respectively, when compared to surgery-alone approaches, also suggesting a larger benefit of preoperative chemoradiotherapy as compared to a chemotherapy alone.[169,170] It should be kept in mind that some of the included trials used sequential (vs. concurrent) chemotherapy, delivered what would be considered suboptimal doses of radiation therapy, used antiquated radiation therapy techniques, delivered (arguably) inadequate chemotherapy, and so on, potentially underestimating the effect of neoadjuvant combined modality therapy. That being said, an updated meta-analysis including a total of 24 randomized trials evaluating the role of neoadjuvant chemoradiotherapy, neoadjuvant chemotherapy, or comparison of the two in patients with resectable esophageal cancer was reported,[175] evaluating the outcomes of >4,000 patients. All-cause mortality for neoadjuvant chemoradiotherapy trials estimated an absolute survival benefit at 2 years of 8.7%, with survival benefits similar between squamous cell carcinoma and adenocarcinoma patients. By comparison, estimated absolute survival difference at 2 years was 5.1% in patients receiving neoadjuvant chemotherapy and was significant only for adenocarcinoma patients. The authors concluded that neoadjuvant chemoradiotherapy improves survival compared with surgery alone in operable patients, as does neoadjuvant chemotherapy, although the benefit of neoadjuvant chemotherapy was not as great as with neoadjuvant chemoradiotherapy. They also concluded that a clear advantage of one over the other is not established, and further randomized trials comparing these two strategies are warranted.

In summary, the above data suggest that neoadjuvant concurrent chemoradiation improves local control and overall survival versus surgery alone in patients with potentially resectable esophageal cancer.

Preoperative Chemoradiation Versus Preoperative Chemotherapy

A randomized trial comparing neoadjuvant chemotherapy alone versus neoadjuvant combined-modality therapy was conducted by German investigators (Preoperative Chemotherapy, or Radiochemotherapy in Esophagogastric Adenocarcinoma, or POET, trial).[176] Patients with advanced esophagogastric adenocarcinoma were randomized to receive (a) cisplatin-/5-FU–based chemotherapy alone versus (b) a similar induction chemotherapy, followed by concurrent cisplatin/etoposide with 30 Gy of radiation therapy. Both groups went on to receive surgery. Although this study was closed early because of poor

accrual, patients receiving preoperative chemoradiotherapy had significantly higher N0 rates (37% vs. 64%; *P* = .04) and pathologic complete response rates (2% vs. 16%; *P* = .03), as well as significant trends toward improved local control (59% vs. 76%; *P* = .06) and overall survival (3-year survival, 28% vs. 47%; *P* = .07; hazard ratio, .67). The authors concluded that preoperative combined modality improves overall survival as compared to chemotherapy alone in patients with locally advanced esophagogastric adenocarcinoma.

A multicenter phase II Scandinavian trial randomised 181 patients with esophageal or gastroesophageal cancer to neoadjuvant chemotherapy with cisplatin/5-FU or the same chemotherapy concurrent with 40 Gy of radiotherapy. Primary trial end point of histologic complete response was higher in the radiation containing arm (28% vs. 9%, p=0.02), as was lymph node positivity rate (62% vs. 35%, p=0.001) and R0 resection rate (74% vs. 87%, p=0.04), although no significant survival difference was seen. The authors postulated that the lack of survival benefit may be due to increased deaths related to radiation therapy.[176a] A smaller phase II study from Australian investigators randomized 75 patients to receive either preoperative chemotherapy with cisplatin and infusional 5-FU or preoperative chemoradiotherapy with the same drugs with radiation therapy commencing day 21 of chemotherapy, delivering 35 Gy in 15 fractions.[177] Histopathologic response rate and noncurative resection rates were significantly improved in the radiation-containing arm (8% vs. 31% and 11% vs. 0%, respectively). However, median overall survival was not significantly different between the groups (29 vs. 32 months). The authors concluded that despite their being no difference in survival, the potential advantage of achieving negative margins made preoperative chemoradiotherapy a reasonable option for bulky, locally advanced resectable adenocarcinoma of the esophagus. A meta-analysis analyzing 5 randomized control trials (709 patients) demonstrated that neoadjuvant chemoradiotherapy significantly increased rates of pathologic complete response/R0 resection rates in both adenocarcinoma and squamous cell carcinoma patients compared to chemotherapy alone. A significant increase in 3-year survival was seen only in squamous cell carcinoma patients (56.8% vs. 42.8%, *P* = .003), whereas in adenocarcinoma patients, no significant difference was seen (46.3% vs. 41%, *P* = .34).[178]

Ongoing trials are evaluating the optimal approach in these patients. The European MAGIC versus CROSS (NeoAEGIS) trial is comparing neoadjuvant chemotherapy to chemoradiation in esophagogastric junctional adenocarcinomas. A Japanese three-arm randomized trial (the NExT trial) is

comparing neoadjuvant cisplatin/5-FU versus docetaxel, cisplatin, and 5-FU versus radiotherapy with concurrent cisplatin/5-FU in patients with locally advanced esophageal cancer.

The Australian TOPGEAR study is currently randomizing patients to perioperative ECF versus preoperative chemoradiation plus perioperative ECF for resectable gastric cancer and resectable adenocarcinoma of the stomach and gastroesophageal junction. The ESOPEC trial from Germany is randomizing operable patients with esophageal adenocarcinoma to preoperative chemotherapy (FLOT: 5-FU, leucovorin, oxaliplatin, docetaxel) versus chemoradiation (CROSS regimen).

Radiation Therapy Alone Versus Chemoradiation

There are multiple randomized studies comparing radiation therapy alone with concurrent radiation and chemotherapy[55,179,180] as definitive therapy. However, small patient numbers, substandard chemotherapy delivery, and the use of suboptimal radiotherapy techniques handicap many of these studies. This makes treatment results difficult to interpret. The landmark trial establishing the superiority of concurrent chemoradiation to radiation therapy alone was Radiation Therapy Oncology Group (RTOG) 85-01. Herskovic et al.[181] reported results of this two-arm trial that treated 60 control patients with radiation alone to a total dose of 64 Gy versus 61 patients with 50 Gy of radiation therapy with concurrent 5-FU and cisplatin. The chemotherapy protocol consisted of four planned courses of infusional 5-FU and cisplatin. Although less radiation was delivered in the concurrent-therapy arm, the results demonstrated a significant advantage of the combined modality arm over the radiation-alone arm. The median survival in patients treated by radiation alone was 8.9 months compared with 12.5 months for those treated with combined therapy, with 2-year survival rate 10% versus 38%; the incidence of local recurrence decreased from 24% to 16%, and the 2-year distant metastasis rate decreased from 26% to 12%. Because of this highly significant survival difference, the randomization was stopped, and 69 additional patients were treated on the chemoradiation arm. Updated trial results[55,182] showed that at 5 years, survival rates were 26% and 0%, respectively, for chemoradiation and radiation therapy alone. Local recurrence rates were also decreased with the use of combined modality therapy versus radiation alone (45% vs. 69%), and distant metastases were more frequent in the radiation-alone arm at 40% versus 12% for the combined-modality group. The incidence of acute toxicity, however, was higher for the combined-modality arm

versus the radiation-alone arm (44% vs. 25%). Similarly, the incidence of life-threatening side effects, including hematologic toxicity and fistula formation, was increased from 3% to 20%. In conclusion, this study demonstrated a significant improvement in local control, median and overall survival, and distant metastasis development with the addition of chemotherapy, at the cost of increased side effects.

Comparison of outcomes data from “definitive” chemoradiation approaches suggests that survival with combined chemoradiation is similar to that achieved by surgery alone. In previously discussed studies, median survivals of 14 to 20 months and 5-year survival rates of 20% to 30% were achieved with chemoradiation alone; in comparison, in the MRC trial and Intergroup trial evaluating surgery alone, median survivals were 13 to 16 months, with 5-year survivals of approximately 20%. In addition, local failure rates appear similar. For example, in the RTOG/Intergroup studies using chemoradiation therapy alone, local failure rates as a first site of failure range from 39% to 45%. In comparison, local failure rate for the Intergroup study evaluating surgery alone was 31%. However, this analysis was limited to patients undergoing R0 resection only (59% of patients).[163] This would undoubtedly be higher if all patients were considered. Therefore, local failure and survival rates appear similar between “definitive” chemoradiation and surgical approaches.

Novel Chemoradiation Approaches

In attempts to improve outcomes in patients with nonoperable esophageal cancer, the SCOPE-1 trial was initiated in the United Kingdom. Patients were randomized to receive neoadjuvant cisplatin and capecitabine for 2 cycles, followed by initiation of radiation therapy cycles 3 and 4 (50 Gy in 25 fractions), with or without concurrent cetuximab. Two hundred fifty-eight patients were recruited (73% squamous cell). Median overall survival was 34.5 months in the non-cetuximab arm versus 24.7 months in the cetuximab-containing arm (P = .137), and 3-year overall survival 47% vs. 38%.[183] Similarly, a trial conducted through the RTOG (0436) randomized 344 patients with nonoperable esophageal cancer to weekly cisplatin, paclitaxel, and radiation therapy (50.4 Gy), with or without the addition of weekly cetuximab. Based on interim analyses, the study stopped accrual of adenocarcinoma patients and later squamous cell carcinoma patients. The 12- and 24-month survival rates for the cetuximab-containing arm were 64% and 44%, respectively, versus 65% and 42%, respectively (P = .70). Additionally, no difference in outcomes was seen when stratifying by histology.

The authors concluded the addition of cetuximab to concurrent chemoradiation did not improve overall survival.[184]

The French PRODIGE5/ACCORD17 phase III trial compared 5-FU/cisplatin with FOLFOX4-based chemoradiotherapy. After a median follow-up of 25 months, progression-free survival was 9.4 and 9.7 months, respectively, with no significant differences observed in terms of high-grade toxicities between the two arms.[185]

Based on an overall survival advantage seen in metastatic esophagogastric patients with the addition of trastuzumab (a monoclonal antibody against HER2 receptors) to fluoropyrimidine-/cisplatin-based chemotherapy,[186] the RTOG is currently conducting a trial (RTOG 1010) randomizing patients with locally advanced esophageal adenocarcinoma to receive 50.4 Gy with weekly carboplatin and paclitaxel versus the same regimen with concurrent and maintenance trastuzumab (HER-2–overexpressing patients). The PROTECT from France is comparing preoperative chemoradiation with paclitaxel/carboplatin versus a FOLFOX-based regimen in resectable esophageal and gastroesophageal junction tumors.

Chemoradiation Versus Chemoradiation Followed by Surgery

Two randomized trials examined whether surgery is necessary after combined-modality therapy. A report from French investigators randomized 445 patients with clinically resectable squamous cell or adenocarcinoma of the esophagus.[187] All patients received concurrent 5-fluorouracil and cisplatin-based chemoradiation. Patients were treated with one of two radiation regimens: 46 Gy over 4.5 weeks (continuous) or 30 Gy at 15 Gy/week (split course). Two hundred fifty-nine patients who had at least a partial response were then randomized to either surgery or additional combined-modality therapy of 5-FU and cisplatin delivered concurrent with radiation (either an additional 20 Gy at 2 Gy/day or a split course of 15 Gy). No significant difference in 2-year survival (34% vs. 40%; $P = .56$) or median survival (18 vs. 19 months) was seen between the groups, although 2-year local control results favored the surgical arm (66% vs. 57%). The death rate at 3 months following treatment was 9% in the surgery group versus 1% in the combined-modality therapy–alone group. In addition, patients undergoing surgery were found to have a worse quality of life. However, the rate of stent and dilatation requirement was higher in the nonsurgical arm. Additionally, in a separate analysis, patients who were not randomized in this trial (i.e., nonresponders) were found to have a survival benefit with surgical

resection.[188] The results of this trial suggest that surgery after chemoradiation in responding patients does not further enhance survival.

In another study, from Germany, patients with potentially resectable squamous cell carcinoma of the esophagus received induction chemotherapy with 5-FU, leucovorin, etoposide, and cisplatin for three cycles, followed by concurrent etoposide and cisplatin with 40 Gy of EBRT.[57] Patients were then randomized to receive surgery versus continuing with combined chemoradiation (total radiation dose increased to 60 to 65 Gy, with or without brachytherapy). Local control was significantly improved in patients undergoing surgery (2-year local control, 64% vs. 41%; $P < .05$). Despite this, no significant difference in survival was seen (median survival, 16 vs. 15 months; 3-year survival; 31% vs. 24%; P = NS). The "severe" postoperative complication rate (including infection, leak) was 70%, and the hospital mortality rate was 11%. Overall, treatment-related mortality was significantly higher in patients undergoing surgery (13% vs. 3.5%). In patients who did not respond to induction chemotherapy, 3-year survival was improved in patients undergoing surgery (18% vs. 9%). On regression analysis, only tumor response to induction chemotherapy was found to be a significant prognostic factor. An important caveat to this trial was that only approximately two-thirds of patients in the surgery arm actually had surgery. The authors concluded that (a) surgery after combined-modality therapy improves local control but had no impact on overall survival and (b) nonresponders to induction chemotherapy may benefit from surgery, and it may be appropriate to individualize therapy based on response to induction treatment. Although it has not been well studied, retrospective experience suggested that definitive chemoradiation in patients with adenocarcinoma of the esophagus results in median survival of 21 months and 2-, 3-, and 5-year survival rates of 44%, 33%, and 20% respectively.[189]

A large, multicenter study was conducted to assess the impact of salvage esophagectomy following definitive chemoradiotherapy on clinical outcome. Comparisons were performed between patients undergoing salvage (n = 308) versus planned (n = 540) esophagectomy. Additionally, patients were analyzed in the salvage arm by persistent versus recurrent disease. In-hospital mortality was similar in both salvage and planned resections (8.4 vs. 9.3%). Anastomotic leak rates (17.2 vs. 10.7%) and surgical site infection were both more frequent in the salvage group. Overall and disease-free survival rates were similar between the cohorts. In the salvage group, overall survival was worse in the persistent group. Of note is that doses higher than 55 Gy were linked with increased postoperative

morbidity and mortality in this analysis. The authors concluded that salvage esophagectomy can offer acceptable short- and long-term outcomes in selected patients at experienced centers and that persistent cancer following chemoradiotherapy may be more aggressive and associated with a poor survival.[190] Similarly, RTOG 0246 was a single-arm trial in which patients received induction chemotherapy with fluorouracil, cisplatin, and paclitaxel followed by concurrent chemoradiation with 5-FU/cisplatin to 50.4 Gy. In follow-up evaluation, if there was clinical suspicion of residual disease, patients were taken immediately to surgery; however, clinical completely responding patients were followed with serial endoscopy and imaging. Of 41 patients entered, 21 (52%) were deemed to have persistent disease with 17 taken immediately to surgery, all with residual disease noted. Of 15 clinical complete responders, 3 (20%) developed recurrent locoregional disease without distant metastases and underwent salvage resection at 3 to 8 months following treatment completion. Overall, 5-year survival was 37%, and 20/41 patients (49%) did not require esophagectomy. The authors concluded that selective salvage esophagectomy is a viable option in patients who are at higher risk of resection or refuse to undergo surgery.[191]

The role of salvage (versus upfront) esophagectomy following chemoradiotherapy remains a topic of investigation. The French ESOSTRATE trial is currently randomizing patients with operable esophageal cancer achieving clinical complete response following neoadjuvant chemoradiotherapy between systematic surgery and surveillance with selective salvage surgery. The nonrandomized preSANO trial from the Netherlands is investigating the feasibility of salvage surgery with endoscopic ultrasound, biopsies, and PET-CT as response assessment diagnostics, with surgical resection offered only to those patients in whom a locoregional recurrence is highly suspected or proven.

In summary, although surgery after combined chemoradiation for esophageal cancer appears to improve local control, its effect on ultimate survival remains unclear.

Brachytherapy

Gaspar et al.[192,193] reported the results of a prospective trial evaluating intraluminal brachytherapy in patients with nonoperable esophageal cancer. Patients initially received 50 Gy of external irradiation with concurrent chemotherapy, followed by a 2-week break and brachytherapy administration. Patients received either 15 Gy using HDR techniques over three consecutive

weeks (5 Gy/fraction) or a single administration of 20 Gy using low–dose rate (LDR) techniques. Dose was prescribed to 1 cm from the source axis. Treatments were accomplished by placement of a 10- to 12-French applicator inserted transnasally or transorally. The target length was defined as the pretreatment tumor length with 1-cm margin proximally and distally as determined by CT, barium swallow, and endoscopy. Both external irradiation and brachytherapy were given concurrently with 5-FU chemotherapy. After the development of fistulas in six patients, the HDR dose was reduced to 10 Gy in two fractions, and the LDR arm was ultimately closed because of poor accrual. Results showed a median survival of 11 months in all patients. Local disease persistence/recurrence was observed in 63% of 49 eligible patients receiving HDR therapy. Six patients developed esophageal fistulas, resulting in three deaths. These fistulas were deemed treatment related. The 1-year actuarial fistula development rate was 18%. The investigators concluded that esophageal brachytherapy, particularly in conjunction with chemotherapy, should be approached with caution. Chinese investigators randomized 160 patients to receive either a stent loaded with I-125 seeds or conventional stenting. Median overall survival was 177 days in the irradiation group versus 147 days in the control group (P = .0046). Major complications included severe chest pain (23 vs. 20%) and fistula formation (8 vs. 7%).[194] Review of other combined brachytherapy/EBRT series suggests that fistula formation rates range from 0% to 12%, with a possible trend toward a higher incidence in patients receiving concurrent chemotherapy with brachytherapy. The incidence of brachytherapy-related mortality varies from 0% to 8%, with most series reporting rates of 4% or less.[195] A meta-analysis of prospective studies of brachytherapy encompassing 623 patients concluded that brachytherapy was a highly effective and relatively safe treatment option that was currently underused. However, the severe adverse event rate was 23% (stenosis 12%, fistula development 8%).[196]

Other studies have suggested that HDR brachytherapy is effective for palliation of dysphagia in up to 90% of patients.[195] Danish investigators reported the results of a randomized trial of 209 patients with dysphagia due to inoperable esophageal or gastroesophageal junctional tumors.[197] Patients were randomized to either endoscopic stent placement or single-dose HDR brachytherapy. Patient exclusion criteria included tumors >12 cm, tumors within 3 cm of the upper esophageal sphincter, deeply ulcerated tumors, tracheoesophageal fistula/tracheal involvement, presence of a pacemaker, and previous radiation treatment or stent placement. Brachytherapy was delivered through a flexible 1-cm applicator

delivering a dose of 12 Gy prescribed to 1 cm from the source axis. The treatment length was defined as gross disease plus 2 cm proximally and distally. Although trial results showed a more rapid improvement in dysphagia after stent insertion, long-term dysphagia relief was significantly improved in the group receiving brachytherapy. Patients undergoing brachytherapy experienced more days with low-grade or no dysphagia versus patients with stent placement. Complication rates were higher following stent placement (33% vs. 21%), primarily because of an increased incidence of late hemorrhage in the stent group. The authors concluded that single-dose brachytherapy is preferable to stent placement as the initial treatment for patients with progressive dysphagia due to inoperable esophageal or gastroesophageal junction carcinoma. A trial from the International Atomic Energy Agency randomized 219 palliatively approached patients to HDR brachytherapy (8 Gy × 2), with or without the addition of 30 Gy of EBRT in 10 fractions. Dysphagia relief was significantly improved in the combined approach, with an absolute benefit of 18% at 200 days from randomization (P = .019).[198] In a smaller trial, 65 patients with advanced cancer of the esophagus or gastroesophageal junction were randomized to either expandable stent or HDR endoluminal brachytherapy (7 Gy × 3) delivered over 2 to 4 weeks. Although the stent-alone patients reported significantly better dysphagia scores at 1 month, other health-related quality of life scores were worse relative to brachytherapy, and at 3 months, dysphagia-related scores were improved with brachytherapy.[199]

For patients treated with curative intent (unifocal thoracic tumors <10 cm, no distant metastases, no airway involvement or cervical esophageal location), the American Brachytherapy Society recommends a brachytherapy dose of 10 Gy in two weekly fractions of 5 Gy each (HDR) or 20 Gy in a single course at 0.4 to 1 Gy/hour (LDR). The dose is prescribed to 1 cm from midsource and delivered through a 6- to 10-mm applicator. The recommended active length is the visible mucosal tumor with a 1- to 2-cm proximal and distal margin. Ideally, brachytherapy is started 2 to 3 weeks after completion of concurrent external irradiation/chemotherapy to allow mucositis resolution. Concurrent chemotherapy with brachytherapy is not recommended. In palliative cases, a similar approach is recommended, with delivery of 10 to 14 Gy in one or two fractions (HDR) or 20 to 25 Gy in a single course (LDR). In previously untreated patients with a short life expectancy (<3 months), a dose of 15 to 20 Gy in two to four fractions (HDR) or of 25 to 40 Gy (LDR) without external irradiation is recommended (Tables 56.10–56.12).[200] In summary, the use of

brachytherapy in the curative approach to esophageal cancer does not appear to significantly improve results achieved with combined EBRT with chemotherapy alone. However, in the palliative setting, brachytherapy has shown good efficacy in the relief of dysphagia.

Palliative Treatment

Although treatment advances have occurred in esophageal cancer over the last 20 years, the majority of patients diagnosed with esophageal cancer will die of their malignancy. Therefore, palliation remains an important goal. Dysphagia is a common presenting symptom and may significantly impair patient's quality of life. Many studies report a 60% to >80% rate of relief from dysphagia with radiation.[201] Coia et al.[201] reported that nearly half of patients with baseline dysphagia experienced an improvement in swallowing within 2 weeks of treatment initiation. By the completion of the 6th week, >80% experienced improvement. A median time to maximal improvement was approximately 1 month. In another series of 148 patients receiving palliative radiation therapy (most received a dose of 20 Gy in five fractions), 75% experienced an improvement in dysphagia, with 26% of these patients requiring stent placement subsequently.[202] Given the superior outcomes of patients receiving concurrent chemotherapy with radiation therapy in nonmetastatic disease, palliative chemoradiation may be preferable to radiation alone for patients with advanced-stage esophageal carcinoma who have a good performance status. However, Trans-Tasman Radiation Oncology Group (TROG) 03.01/National Cancer Institute of Canada (NCIC) CTG (ES.2) investigators enrolled 220 patients with advanced/metastatic esophageal cancer and randomized them to receive 35 Gy in 15 fractions (or alternatively 30 Gy in 10 fractions) with or without the addition of concurrent cisplatin and fluorouracil. 45% of patients in the chemoradiotherapy group and 35% in the radiotherapy group obtained dysphagia relief (p=0·13). Median dysphagia progression-free survival was 4·1 months versus 3·4 months in the chemoradiotherapy and radiotherapy groups, respectively (p=0·58), and median overall survival was 6·9 months versus 6·7 months, respectively (p=0·88). Grade 3-4 acute toxicity occurred in 36% of patients in the chemoradiotherapy group and in 16% patients in the radiotherapy group (p=0·0017). The authors concluded that a palliative chemoradiotherapy showed a modest, but not statistically significant, increase in dysphagia relief compared with radiotherapy alone, with minimal improvement in dysphagia progression-free survival and overall survival with chemoradiotherapy but at a

cost of increased toxicity, and that a short course of radiotherapy alone should be considered a safe and well tolerated treatment for malignant dysphagia in the palliative setting.[203] As described earlier, intraluminal brachytherapy has also been used for palliation of dysphagia. The previously described randomized trial from the Netherlands comparing intraluminal brachytherapy to stent placement showed that although patients undergoing stenting experienced a more rapid improvement in dysphagia, long-term palliation was significantly improved in patients treated with brachytherapy.[197]

The palliative management of patients with tracheoesophageal fistula presents a clinical dilemma. Fistulazation usually precludes surgery. These patients are often treated effectively with the placement of silicone-covered, self-expanding metal stents, often obviating palliative surgery. In addition, placement of feeding gastrostomy or jejunostomy may be appropriate. Although considered a "relative" contraindication to radiation therapy, limited data from a Mayo Clinic series suggest that radiation therapy may not increase fistula severity and can be administered safely in this setting; however, the presence of fistula is a poor prognostic factor.[204]

TABLE 56.10 SELECTION CRITERIA FOR BRACHYTHERAPY IN THE TREATMENT OF ESOPHAGEAL CANCER

Good Candidates	Poor Candidates	Contraindications
Primary tumor ≤10 cm length	Extraesophageal extension	Esophageal fistula
Tumor confined to the esophageal wall	Tumor >10 cm in length	Cervical esophageal location
Thoracic esophagus location	Regional lymphadenopathy	Stenosis that cannot be bypassed
No regional lymph node or systemic metastases	Tumor involving gastroesophageal junction or cardia	

TABLE 56.11 SUGGESTED SCHEMA FOR DEFINITIVE EXTERNAL BEAM RADIATION AND ESOPHAGEAL BRACHYTHERAPY

External Beam Radiation

From 45 to 50 Gy in 1.8- to 2.0-Gy fractions, 5 fractions/wk, wk 1 to 5

Brachytherapy

High dose rate: total dose of 10 Gy, 5 Gy/fraction, 1 fraction/wk, starting 2 to 3 wk after completion of external beam

Low dose rate: total dose of 20 Gy, single course, 0.4 to 1.0 Gy/h, starting 2 to 3 wk from completion of external beam

All doses are specified 1 cm from the midsource or mid-dwell position.

TABLE 56.12 SUGGESTED SCHEMA FOR EXTERNAL BEAM RADIATION AND BRACHYTHERAPY IN THE PALLIATIVE TREATMENT OF ESOPHAGEAL CANCER

1. Recurrent after external beam radiation and short life expectancy
   Brachytherapy:
   HDR: total dose of 10 to 14 Gy, one or two fractions
   LDR: total dose of 20 to 40 Gy, one or two fractions, 0.4 to 1.0 Gy/h
2. No previous external beam radiation
   External beam radiation:
   From 30 to 40 Gy in 2- to 3-Gy fractions
   Brachytherapy
   HDR: 10 to 14 Gy, one or two fractions
   LDR: total dose of 20 to 25 Gy, single course, 0.4 to 1.0 Gy/h
3. No previous external beam radiation, life expectancy >6 mo
   External beam radiation:
   From 45 to 50 Gy in 1.8- to 2.0-Gy fractions, 5 fractions/wk, wk 1 to 5
   Brachytherapy
   HDR: total dose of 10 Gy, 5 Gy/fraction, 1 fraction/wk, starting 2 to 3 wk after completion of external beam
   LDR: total dose of 20 Gy, single course, 0.4 to 1.0 Gy/h, starting 2 to 3 wk after completion of external beam

All doses are specified 1 cm from the midsource or mid-dwell position.
HDR, high dose rate; LDR, low dose rate.

REIRRADIATION

Although local control rates with trimodality therapy are high, the incidence of local recurrence remains common in nonoperative patients. Varying investigators have evaluated the role of reirradiation in clinical practice. In one report of 54 patients (21 previously irradiated), radiation was associated with an improvement in dysphagia in 68% and median survival of 1 year. Dose range was 30 to 68 Gy with a median of 45. No grade 5 toxicities were seen, with 1 of 21 patients previously irradiated developing a late esophageal stenosis. The authors indicated that if reirradiation of esophageal carcinoma is contemplated, three-dimensional conformal techniques and a minimum total dose of 45 Gy are recommended.[205] In a smaller series of 10 patients who were reirradiated, the total dose of primary radiotherapy was a median of 50.4 Gy (range, 50.4 to 63.0 Gy). The total dose of reirradiation was a median of 46.5 Gy (range, 44.0 to 50.4 Gy). Three patients developed a grade 5 tracheoesophageal fistula, and five

experienced progressive disease 3 months following treatment. The authors concluded that reirradiation of recurrent esophageal cancer after primary radiotherapy can cause severe toxicity.[206] A small, prospective trial of 14 patients with history of prior thoracic radiation with newly diagnosed or locally recurrent esophageal cancer explored the use of proton beam treatment. Median reirradiation prescription dose was 54 Gy and median cumulative prescription dose was 110 Gy. Four of ten symptomatic patients had complete resolution of symptoms and four decreased or stable symptoms. One grade 5 toxicity of esophageal pleural fistula was seen, possibly related to tumor progression. Median time to local failure was 10 months and median survival 14 months. The authors conclude that reirradiation is feasible with encouraging symptom control rate and with a modest toxicity profile.[207]

TREATMENT SEQUELAE

Advances in surgical technique, as well as improved preoperative and postoperative management, have decreased treatment-related mortality. Contemporary operative mortality rates are generally <10%.[54,57,208] Complication rates can exceed 75%, including pulmonary and cardiac complications, anastomotic leak, and recurrent laryngeal nerve paralysis. Stricture formation can occur in 14% to 27% of patients. The addition of preoperative radiation therapy and chemotherapy may enhance surgical complication rates, although this remains a subject of debate.[53,54]

More than 75% of patients receiving radiation experience transient esophagitis and dysphagia, sometimes requiring nutritional support. Chemotherapy-related leukopenia and thrombocytopenia are common, although this may be less common with contemporary chemotherapy regimens.[146] Additional acute toxicities of radiation therapy include esophagitis, dermatitis, fatigue, and weight loss in most patients. Nausea and vomiting are relatively common, particularly in patients with lower esophageal and gastroesophageal junction tumors. Many symptoms resolve within 1 to 2 weeks of treatment completion. A perforated esophagus is life threatening and can be characterized by substernal chest pain, a high pulse rate, fever, and hemorrhage.[105] The addition of chemotherapy can significantly increase acute complications. Moderate-to-severe and even life-threatening toxicities have been reported in 50% to 66% of patients.[82,181,209] In the previously discussed RTOG study of chemoradiation alone, patients treated with combined therapy had a higher

incidence of acute grade 3 (44% vs. 25%) and grade 4 toxicity (20% vs. 3%) compared to patients receiving radiation therapy alone.[55] Chemoradiation treatment–related mortality rates range from 0% to 3%.[57,82,143,147,181]

The most common late effects following radiation therapy are esophageal stenosis and stricture formation. Stenosis can occur in >60% of patients. Symptomatic stricture requiring dilation has been reported to occur at least 15% to 20% of the time. Dysphagia may be relieved with two to three dilations.[82] Long-term results from the RTOG study showed that late grade 3 or greater toxicity was similar in the combined versus radiation-alone arms (29% vs. 23%). However, grade 4 or greater toxicity was higher in patients receiving combined modality therapy (10% vs. 2%).[182] Other complications include clinically apparent damage to organs within the radiation therapy volume, although this is uncommon. Chemotherapy may further increase the risk of late treatment-related toxicities.

The effects of radiation on pulmonary and cardiac function deserve special mention. Pulmonary complications associated with either the definitive or neoadjuvant treatment of esophageal cancer patients can be broadly broken up into symptomatic pneumonitis following treatment completion and postoperative pulmonary complications in patients undergoing resection. Although they are still relatively ill-defined, various institutional series have described predictive factors for these complications (which are not mutually exclusive), and are described in the following.

Radiation pneumonitis is a relatively common complication in the treatment of thoracic (lung) malignancies, which can range from minimally symptomatic to fatal. Common symptoms include nonproductive cough, dyspnea, and, uncommonly, respiratory distress. Generally, this occurs 2 to 6 months after radiation therapy completion. The ability to predict radiation pneumonitis has been a significant topic of investigation. However, most data come from patients with lung cancer, who may have more underlying intrinsic pulmonary/smoking-related disease. A variety of predictive parameters have been suggested, including V_{20} of >25% to 30%, mean lung dose of >15 to 20 Gy, V_5 of >42%, and absolute V_5 of >3,000 cm.[123]

In nonoperative patients, an analysis of esophageal cancer patients from Japan treated definitively to a dose of 60 Gy with concurrent 5-FU and cisplatin showed a radiation pneumonitis incidence of 27%.[210] The authors concluded that an optimal V_{20} threshold to predict symptomatic pneumonitis was approximately 30%. In a study of 101 both operative and nonoperative patients (88% distal

esophagus/GE junction) from the MD Anderson Cancer Center undergoing a mix of 3D and IMRT radiation therapy, 59%, 5%, and 1% of patients experienced grade 2, 3, and 5 radiation pneumonitis, respectively.[211] An analysis from Japan using fields inclusive of supraclavicular, mediastinal, and celiac regions up to a dose of 60 Gy with concurrent cisplatin and 5-FU showed a 2-year cumulative incidence of late, high-grade cardiopulmonary toxicities for patients ≥75 years of 29% versus 3% in younger patients. They concluded that older patients might not tolerate extensive radiation fields.[212] Other studies have shown that significant declines in diffusion capacity and total lung capacity may occur in patients irradiated for esophageal cancer.[213] The current RTOG 1010 study recommends maintaining a V10 ≤ 40%, mean lung dose of <20 Gy, V20 ≤ 30% (ideally < 25%), and V30 ≤ 20%. For IMRT, interval dose is limited to 60% of the lungs receiving 5 Gy or less.

In operative patients, a study of 110 patients treated with preoperative chemoradiotherapy followed by resection at the MD Anderson Cancer Center showed that mean lung dose, effective dose, and absolute lung dose receiving ≤5 Gy were predictors of development of postoperative pulmonary complications.[214] In a report on patients from the same institution describing complications in patients receiving neoadjuvant combined modality therapy,[215] 18% experienced pulmonary complications, with higher rates when the V_{10} was ≥40% (35% vs. 8%) and V_{15} was ≥30% (33% vs. 10%), leading the authors to conclude that minimization of lung volume irradiation was important in the preoperative planning of these patients. This increase in postoperative pulmonary complications (pneumonia, acute respiratory distress syndrome) when the V_{10} was >40% suggests that the volume of remaining/undamaged functional lung may determine postoperative pulmonary function, that is, patients with a small lung volume initially may be at higher risk of experiencing pulmonary complications, even if the relative V_5 is low, and that patients with small lung volume with less functional reserve may be more susceptible to postoperative pulmonary complications. Therefore, it is important to consider not only the dose–volume histogram of the lung but also the total lung volume.

A study from China evaluating patients receiving chemoradiotherapy followed by resection showed that the volume of lung spared from doses of ≥5 Gy was the only independent dosimetric factor on multivariate analysis in predicting postoperative pulmonary complications.[216] Wang et al.[217] similarly described that the relative V_5 and all spared volumes from 5 to 35 Gy

significantly correlated with the incidence of postoperative pulmonary complications, although on multivariate analysis, V_5 was the only significant independent predictive factor, indicating that the volume of “unexposed” lung during induction therapy was predictive. Of note in this study was that the majority of patients were treated with induction chemotherapy alone initially (most paclitaxel), which has been shown to increase rates of pneumonitis in other disease sites. A significant association of induction chemotherapy alone prior to concurrent chemoradiotherapy was seen as a predictor of grade 2 or greater pneumonitis (49% vs. 14%; $P = .003$), leading the authors to conclude that induction chemotherapy alone may sensitize lung tissue to radiation damage. In contrast to the foregoing studies, however, another analysis of 98 patients receiving preoperative chemoradiotherapy with 5-FU and cisplatin showed no difference in pulmonary complications versus patients undergoing surgery alone, with no correlation of any lung dose–volume histogram findings with development of postoperative pulmonary complications seen, leading the authors to conclude that neoadjuvant chemoradiotherapy had no detrimental impact on postoperative course.[218] An analysis from Taiwan of neoadjuvantly, IMRT-treated esophageal cancer patients undergoing resection suggested that preoperative (not prechemoradiation) forced expiratory volume in 1 second was an independent factor associated with postoperative pulmonary complications and that reducing the absolute volume of the right lung irradiated might decrease the risk of postoperative pulmonary complications.[219] Finally, a review from Fox Chase Cancer Center of 139 patients with esophageal cancer receiving taxane-based trimodality therapy showed that 14% of patients experienced grade 2+ radiation pneumonitis. The V5, V10, V20, and V30 were associated with an increased risk of clinically significant grade 2 pneumonitis. Multivariable analysis showed that V5 and V20 remained associated with this, with V5 of ≤65% and V20 of ≤25% optimal thresholds.[220]

Radiation-induced cardiac toxicity is a broad term describing potential radiation injury to a number of cardiac structures, including the pericardium (as manifested by effusion, pericarditis), coronary arteries, the heart muscle itself/cardiomyopathy, and cardiac valves, as well as nerve/conduction injury. Radiation injury primarily consists of fibrosis and/or small-vessel injury. “Classic” radiation tolerance (TD5/5) of the heart is about 60 Gy when 25% or less of the heart is irradiated and 45 Gy if 65% of the heart is irradiated, assuming 2 Gy/fraction. The mechanism of radiation-induced cardiac injury is relatively poorly defined, particularly in the context of esophageal cancer.

Historical data from the treatment of Hodgkin disease patients suggest that a dose of >40 Gy may increase the risk of cardiac death, as well as of pericarditis.[221,222] Several studies of cardiac toxicity and esophageal cancer patient demonstrated that a V_{30} of >46% predicted a significant increase in pericardial effusion, and increasing fraction size (particularly ≥3.5 Gy) also predicted the same. In addition, some authors have shown a possible trend for decrease in ejection fraction in patients with increasing V_{20} of the left ventricle.[123] In a study of 150 esophageal cancer patients receiving chemoradiotherapy (49 neoadjuvantly), the incidence of pericardial effusion was 28%, usually developing within 15 months of radiation therapy, with median onset time of approximately 5 months. The risk of pericardial effusion was associated with mean pericardial doses over an array of dose–volume points to the pericardium from 5 to 45 Gy. A matched-pair analysis of nonradiation patients receiving surgery versus those treated neoadjuvantly was performed, with 42% of patients in the radiation group demonstrating ischemia/scarring on single-photon emission CT images versus 4% in the surgical group, with a median onset to abnormality of 3 months.[223] In a Japanese study, long-term analysis of 139 patients treated with definitive chemoradiotherapy (cisplatin/5-FU with 60 Gy EBRT) for squamous cell carcinoma revealed grade 2, 3, and 4 late pericarditis occurring in 6%, 5%, and 1% of patients, respectively; grade 4 heart failure in 2 patients; grade 2, 3, and 4 pleural effusion development in 5%, 6%, and 0% of patients, respectively; and grade 2, 3, and 4 radiation pneumonitis development in 1%, 2%, and 0% of patients, respectively.[224] A more recent retrospective review of 343 esophageal cancer patients demonstrated the rate of symptomatic cardiac disease at 5 years was 14%. Multivariable analysis revealed this increase with increasing heart dose with the lowest significant cutoff values of V45, V50, and V55 of 15%, 10%, and 5%, respectively.[225] As described previously, an analysis of esophageal cancer patients showed no difference in disease-specific or pulmonary mortality in patients treated with either conformal therapy or IMRT, but did show an improvement in all-cause cardiac mortality with IMRT.[132] In a literature search concerning cardiac toxicity in esophageal cancer patients treated with radiotherapy, with or without chemotherapy, the overall accrued incidence of symptomatic cardiac toxicity was as high as 10.8%, corresponding with several dose–volume parameters of the heart. The most frequent complications were pericardial effusion, ischemic heart disease, and heart failure. Most events occurred within 2 years following treatment. The authors concluded that normal

tissue complication probability models for esophageal cancer were not available at present.[226]

FUTURE CONSIDERATIONS

Although modest improvements in survival have been achieved by combining neoadjuvant chemoradiation and surgery, patients treated with chemoradiation alone or with surgery have unacceptably high locoregional relapse rates and mortality rates. Ultimately, approximately 75% of patients succumb to metastatic disease. As described previously, efforts at radiation dose escalation have not resulted in significant gains for this disease, although newer efforts are now underway to further define optimal dose. Current clinical trials are also evaluating new and potentially more effective chemotherapeutic agents with radiation therapy, attempting to optimize combined regimens and integrate novel systemic agents in combination with radiation.

SUMMARY

The prognosis for patients with carcinoma of the esophagus remains poor despite recent advances in combined-modality therapies. No firm recommendation can be made for managing locally advanced disease. The data suggest that neoadjuvant chemoradiation improves outcomes in patients who are candidates for surgery. Alternatively, randomized trials have also suggested that perioperative chemotherapy improves outcomes in these patients. However, many patients are not able to tolerate surgery, and combined chemoradiation may be more appropriate in selected patients because definitive chemoradiation has resulted in survival rates comparable to those from surgery alone. Locoregional failure remains a significant pattern of relapse in nonoperable patients. For patients with stage IV disease, palliation with single-modality therapy or several modalities should be used and tailored to the patient's specific symptoms. Current unresolved issues include the following:

- Which subsets of patients are more likely to benefit from the addition of surgery than others? Is a response-based surgical approach following chemoradiation appropriate for widespread use?
- Which subsets of patients are more likely to benefit from the addition of neoadjuvant and/or perioperative therapies? Is there a superiority of a neoadjuvant chemoradiation versus a perioperative chemotherapy approach,

and will some patients benefit from one particular treatment approach?

- Can introduction of newer chemotherapy/targeted agents in the neoadjuvant or concurrent setting improve the results over “standard” chemoradiation with cisplatin/5-FU or carboplatin/paclitaxel? What is the optimal “standard” regimen in combination patients?
- Will new technologies such as PET-based planning, IMRT, proton therapy, and image-guided radiation therapy decrease complication rates and influence cure rates? Is it appropriate to reduce radiation treatment volumes to “involved-field” given the high propensity for distant metastases development?
- Will PET scan allow early prediction of both response to treatment and ultimate outcomes and potentially allow avoidance of delivery of ineffective treatments early on during the course of therapy?
- Will the identification of molecular prognostic markers allow “individualization” of treatments among patients?
- Will further studies of dose escalation improve local control rates in patients treated with “definitive” chemoradiation?

CHAPTER 57

Tumors of the Heart, Pericardium, and Great Vessels

Gregory M.M. Videtic and Roger M. Macklis

ANATOMY

The heart is a hollow, conical (MB1) organ with muscular walls. In the adult, it measures approximately 12 cm in length, 8 to 9 cm in width, and 6 cm in thickness. It is located in the inferior aspect of the middle mediastinum, with two-thirds lying to the left of midline and one-third to the right. The heart lies posterior to the sternum and rib cage, and anatomic landmarks on the chest wall may be used to approximate its position. The apex is located roughly 8 cm to the left of midline in the fifth intercostal space, and the base is at the level of the third costal cartilage. It rests on the diaphragm inferiorly. The heart receives its blood supply from the coronary arteries, which are located in the space between the myocardium and epicardium. The pericardial fat provides a smooth contour and is also located in this space. The heart has four chambers: two ventricles with thick muscular walls and two atria with thin muscular walls. Although the heart is not attached to surrounding organs, it is held in position by its association with the great vessels (GVs) and the pericardium. The GVs include the aorta, superior and inferior vena cava (IVC), pulmonary artery, and pulmonary veins, which arise from (or terminate in) the left ventricle, right atrium, right ventricle, and left atrium, respectively. The roots of the GVs, along with the heart, are encompassed by the parietal pericardium. In combination with the epicardium, this fibrous layer provides a smooth cavity in which the heart can pump freely. Externally, the pericardium is adherent to, but separate from, the mediastinal pleura, creating a potential space through which the phrenic nerve traverses.[1]

INCIDENCE AND EPIDEMIOLOGY

Tumors of the heart, GVs, and pericardium are rare and include a range of disease presentations: primary neoplasms; secondary metastases from a known malignancy; or direct tumor invasion into the structures, which is seen in certain cancers such as Hodgkin or non-Hodgkin lymphoma, lung cancer, or malignant thymoma. The focus of this chapter will be to review the epidemiology, diagnosis, natural history, and management of primary tumors arising from the heart, pericardium, and GVs as well as metastatic disease to these sites.

The first described case of a primary cardiac tumor was by Albers in 1835.[2] Reynen[3] performed a compilation of autopsy series consisting of over 700,000 cases and found 157 primary cardiac tumors. The overall incidence of primary tumors is 0.021%, with a range from 0% to 0.19%. Approximately 75% of primary tumors of the heart are benign, and about half of those are atrial myxomas arising from the interatrial septum.[4–6] Lipomas, papillary fibroelastomas, and rhabdomyomas each account for approximately 10% of cases. Fibromas, hemangiomas, and teratomas are less common benign cardiac tumors.[7] Cystic atrioventricular node tumors are extremely rare but may lead to sudden death, despite their small size.[8] There is an increased incidence of cardiac myxomas among females and in patients with Carney complex, an inherited autosomal dominant disorder that also shows hyperpigmented lentigines, blue nevi, schwannomas, endocrine tumors, and endocrinopathies.[9,10] The syndrome is most commonly caused by an inactivating germ-line mutation of the *PRKAR1 A* tumor-suppressor gene on chromosome 17q23-q24.[9,11,12] Variants include the LAMB (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, and *b*lue nevi) and NAME (*n*evi, *a*trial myxoma, *m*yxoid neurofibroma, and *e*phelides) syndromes.[8] Myxomas in patients with Carney complex account for 7% of all cardiac myxomas, are typically found at a younger age, and may have higher recurrence rates.[4,13] Hamartomas, rhabdomyomas, and fibromas are diagnosed almost exclusively in children.[14] Rhabdomyomas are the most common pediatric cardiac tumor and are associated with tuberous sclerosis.

Malignant primary tumors constitute the remaining 25% of cardiac neoplasms. Primary malignancies of the myocardium constitute the bulk of the remaining cases, of which sarcomas account for the vast majority. Malignant fibrous histiocytoma, angiosarcoma, fibrosarcoma, and rhabdomyosarcoma are among the more common histologic types.[15] Table 57.1 summarizes the relative frequency of specific subtypes of sarcoma that may be diagnosed. The median age at diagnosis is 30 to 40 years, slightly younger than that for benign tumors,

and there is no sex predilection as seen in myxoma.[15] Lymphomas account for only about 2% of primary cardiac tumors, but the incidence appears to be increasing.[19] Melanoma and carcinoma may also occur infrequently.

Primary malignant tumors of the pericardium are exceedingly rare and include mesothelioma, fibrosarcoma, angiosarcoma, and malignant teratoma.[20] An American Medical Association survey of nearly 500,000 autopsies revealed a 0.0022% incidence of primary malignant pericardial neoplasms.[21] It appears that malignant mesothelioma is the most common primary malignancy of the pericardium, accounting for 50% of primary pericardial tumors. Asbestos has well-established associations with pleural and peritoneal mesothelioma, and there appears to be some correlation in pericardial mesothelioma.[22] Unfortunately, because of the low incidence, this association has been inconsistent, and no other risk factors have been identified.[23–25] There have been very few cases reported since 1994, when 140 cases had been reported in the literature.[20,21,23–29] Fibrosarcoma, angiosarcoma, synovial sarcoma, and teratoma of the pericardium have also been documented.[20,24,29]

TABLE 57.1 DISTRIBUTION OF HISTOLOGIC SUBTYPES OF CARDIAC SARCOMA

Subtype of Sarcoma	Number of Cases	Percentage of Cases
Angiosarcoma	105	28
Rhabdomyosarcoma	43	12
Undifferentiated/NOS	43	12
Fibrosarcoma	39	10
Malignant fibrous histiocytoma	33	9
Leiomyosarcoma	26	7
Liposarcoma	20	5
Other	64	17
Total	373	100

NOS, not otherwise specified.
Data compiled from references [7] and [15–18].

With advances in echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI), the postmortem diagnosis of cardiac tumors is becoming less common. Surgical series seem to demonstrate an increase in the ratio of benign to malignant tumors, with malignant tumors accounting for only 10% of cases in a narrow range of 6% to 20%.[14,16,30–34] This is likely the result of surgical management of benign myxoma, which accounts for over 80% of

patients in some series, combined with changes in patient selection.[16,30,33]

The majority of primary cardiac tumors arise in adults with a median age of 45 to 55 years, but they can be seen at any age.[14,16,30–34] Among 533 cases in the database of the Armed Forces Institute of Pathology, McAllister and Fenoglio[7] noted that 83% of patients were adults. Infants (<1 year of age) constituted 9% of the patients, and in this group, 96% of tumors were benign and only 4% were malignant. In a review of the data from the National Cancer Institute Surveillance, Epidemiology, and End Results from 1973 to 1987, Mack[15] reported no sex predilection for the incidence of sarcoma of the mediastinum and heart.

Metastatic disease to the heart and pericardium occurs at a frequency much greater than that of primary tumors.[35–41] In a review of more than 12,000 autopsies in Hong Kong, Lam et al.[39] noted that cardiac metastases were over 20 times more common than primary tumors and may be present in up to 20% of patients dying of disease. The majority of cases have involvement of the pericardium, whereas myocardial involvement is uncommon. In a review of autopsy series of patients with a known malignancy, Hanfling[37] noted the rate of reported cardiac involvement increased steadily from 1.5% in the late 1800s to 18.3% in 1960. Contemporary series indicate the rate of cardiac metastases in patients dying of cancer may be as high as 20%.[7,37–40,42,43]

The sites of origin of cardiac metastases from solid tumors are summarized in Table 57.2. Lung cancer is the most common cause of cardiac metastases and accounts for nearly one-half of all cases. Upper gastrointestinal malignancies and breast cancer are also common causes of cardiac metastases, accounting for one-fourth of all cases. The remaining one-fourth of cases arise from a wide variety of other malignancies.[35–40] Melanoma is purported to have the highest propensity for metastatic spread to the heart and tends to involve the endocardium or myocardium, with some series showing its incidence of cardiac metastases rivaling or exceeding that of lung cancers.[2,43] Cardiac metastases may also originate from lymphoma or leukemia. In 1960, Hanfling[37] reported that the proportion of cardiac metastases arising from these malignancies rivals that arising from solid tumors. However, multiple medical advances in both chemotherapy and diagnosis have occurred since then, and modern series consistently report that these histologies account for approximately 17% of cardiac metastases.[35,36,38,39]

Tumors of the GVs are extremely rare. The literature on these consists mainly of case reports, and approximately 130 cases have been documented. As a

whole, tumors of the GVs are about as common as primary malignant pericardial mesothelioma. The largest series has been reported by Burke and Virmani.[44] They evaluated 45 tumors on the files of the Armed Forces Institute of Pathology and found that all of the tumors were sarcomas, including intimal (undifferentiated) sarcoma, angiosarcoma, leiomyosarcoma, and synovial sarcoma. There appeared to be no sex predilection for tumors of the aorta or pulmonary artery, although the female-to-male ratio was 3 to 1 among patients with tumors of the IVC.

TABLE 57.2 SITE OF ORIGIN FOR CARDIAC METASTASES

Primary Tumor	Number of Patients	Percentage of Cases
Lung	271	47
Upper gastrointestinal[a]	107	19
Breast	42	7
Genitourinary (nonprostate)	37	6
Melanoma	28	5
Other	93	16
Total	578	100

[a]Includes esophagus, stomach, small bowel, pancreas, and hepatobiliary primary tumors.
Data compiled from references [35–40].

NATURAL HISTORY

Tumors of the Myocardium

Myxomas, as discussed previously, are the most common benign tumors of the heart, are seen in women twice as frequently as men, and are diagnosed at a mean age of 45 to 55 years but have been documented in infants and octogenarians.[16,30–34,45] Benign myxomas tend to be slow growing and are minimally invasive and as such may have a long duration of symptoms before diagnosis. Typically, these tumors arise from the interatrial septum and grow into the adjacent chamber. The left atrium is the most common site of involvement for myxoma, and this is six to seven times more common than myxoma of the right atrium. The tumor may also be located in the ventricles or the valves and can be bilateral. Although they are considered benign, the tumor can elicit dramatic symptoms from valvular insufficiency, congestive heart failure, and embolic phenomena. Surgical excision is the treatment of choice, with local recurrence rates ranging from 0% to 5.4%.[8]

Primary malignant tumors of the myocardium, most commonly sarcomas, do not show a predilection for developing in any particular part of the heart, except for angiosarcomas, which tend to occur more frequently in the right atrium, and often present late with advanced disease and lung metastases.[14,16,30,32,33] The duration of symptoms is on the order of months, and survival is poor. Even after attempts at curative resection, recurrences are common, and the median survival ranges from 6 to 18 months.[14,16–18,30–34] The cause of death is most often complications of locally recurrent disease with invasion of adjacent chambers, valves, or pericardium. Tamponade, hemopericardium, and distant metastases are common.[18] About 30% of primary cardiac sarcomas have distant metastases at the time of diagnosis.[2] The high incidence of hematogenous dissemination of a cardiac sarcoma may be explained by the high rate of blood flow through the heart.[46]

Tumors of the Pericardium

Mesothelioma is the most common pericardial neoplasm and may either be confined to the pericardial sac at diagnosis or extend beyond it, involving the myocardium or mediastinal structures.[23–25] Of 140 primary malignant pericardial mesotheliomas reported in the literature, only 28% of cases were diagnosed antemortem.[24] These tumors have been documented to metastasize by lymphatic and hematogenous routes to involve regional lymph nodes, lung, liver, brain, bone, and adrenal glands.[20,21,23–28] Despite the metastatic potential, pericardial tumors are more often fatal because of local complications, such as restrictive pericarditis with resultant cardiac tamponade, arrhythmia due to myocardial invasion, or vena caval obstruction. Even if the tumor can be diagnosed antemortem, survival is poor. Typically, the onset of symptoms does not occur until the tumor is well advanced, and from that time, the median survival is <6 months, with only a handful of patients surviving beyond 1 year.[26–28]

Tumors of the Great Vessels

The median age at presentation for tumors of the GVs is between 40 and 60 years.[44] The natural history and clinical presentation depend on the exact location of the primary tumor. Depending on the location, symptoms may include dyspnea, cough, hemoptysis, pain, and thromboembolic phenomena, including pulseless extremities, stroke, peripheral edema, and superior vena cava (SVC) syndrome. In the series by Burke and Virmani,[44] they found that in contrast to the tumors of the aorta and pulmonary artery that were aggressive

sarcomas arising from the vessel lumen, tumors of the IVC were mostly low-grade leiomyosarcomas originating from the medial layer of smooth muscle in the vessel wall.

DIAGNOSIS

Tumors of the heart have been referred to as the "great imitators" of the cardiovascular system, and although there are no pathognomonic signs or symptoms, cardiac tumors can often be detected through careful attention to both cardiac and extracardiac manifestations of the disease.[47,48] It is not surprising that tumors of the heart are often asymptomatic until they become advanced enough to affect blood flow or cardiac function.[37] As the tumor enlarges, disturbances in normal heart function produce different signs and symptoms depending on the location of the tumor. The scope of clinical presentation is summarized in Table 57.3. Tumors involving the right heart may result in pulmonary emboli, pulmonary hypertension, tricuspid valve disease, or SVC or IVC obstruction. Left-sided tumors can cause mitral valve disease, thromboembolic phenomena, and rapidly progressive congestive heart failure, which may be refractory to treatment. A characteristic auscultation finding referred to as a tumor plop may be heard during early diastole in 30% of patients.[49] Arrhythmias are very common and are predominantly supraventricular tachycardia or nonspecific conduction anomalies.[48] Specific presenting complaints are equally varied. Dyspnea is the most common presenting complaint and is noted in 59% to 88% of patients.[17,35,50,51] Palpitations or syncope is also seen frequently and may be positional, and if the tumor obstructs a valve orifice, sudden death may result. Chest pain can be anginal, resulting from direct myocardial invasion or obstruction of the main coronary ostia. It can also be sharp, due to invasion of the pericardium, with resulting pericarditis. Constitutional symptoms also occur, with fever, malaise, anemia, and weight loss.[17,35,37,48,50,51] Tumors of the pericardium and GVs show a similarly variable constellation of symptoms, and as such, they pose the same diagnostic difficulties as tumors of the myocardium.

TABLE 57.3 SCOPE OF CLINICAL MANIFESTATIONS OF CARDIAC TUMORS

Cardiovascular Manifestations	Extracardiac Manifestations

Electrocardiogram findings	Pulmonary
Low voltage	Rales
Atrial fibrillation or flutter	Dyspnea
Supraventricular tachycardia	Hemoptysis
Conduction anomalies	Pulmonary hypertension
Bundle branch block	Upper digestive tract
Atrioventricular block (2nd or 3rd degree)	Hematemesis
Ventricular tachycardia	Dysphagia
Ventricular fibrillation	Embolic phenomena
Pericardial signs	Right-sided tumors
Friction rub	Pulmonary emboli
Pericarditis	Left-sided tumors
Effusion	Stroke
Tamponade	Splinter hemorrhages
Congestive heart failure	Peripheral arterial occlusion
Peripheral edema	Raynaud phenomenon
Jugular venous distention	Peripheral findings
Valvular insufficiency	Clubbing
Chest pain	Ascites
Palpitations	Constitutional symptoms
Syncope	Anemia
Sudden death	Fatigue
Superior or inferior vena caval obstruction	Fever
Myalgia	Weight loss
	Arthralgia

Physical examination may reveal tachycardia, murmur (which may be positional), pericardial rub, gallops, peripheral edema, jugular venous distention, rales, and stigmata of thromboembolic disease. Electrocardiography (ECG) most often reveals nonspecific ST- and T-wave changes, although low-voltage ECG, supraventricular tachycardia, bundle-branch block, or second-degree (type II) or third-degree atrioventricular node block may also be noted. Laboratory studies may reveal anemia, erythrocytosis, thrombocytosis, thrombocytopenia, leukocytosis, and elevated erythroid sedimentation rate.[17,48,51,52]

DIAGNOSTIC WORKUP

Before the advent of echocardiography and angiography, 66% of tumors were diagnosed intraoperatively during exploration for suspected valvular disease. With current techniques, the diagnosis can be made reliably in the preoperative setting in almost 90% of cases.[16] The diagnostic evaluation of patients with

suspected cardiac tumors is presented in Table 57.4.

Physical examination and ECG findings have been described above. The imaging techniques used in the diagnosis and evaluation of cardiac tumors include chest radiography, CT, MRI, echocardiography, radionuclide scintigraphy, and cardiac catheterization. Although there is considerable overlap among these studies, each modality is unique and complements the others in evaluating the tumor. Chest radiography shows abnormalities in over 80% of patients. Unfortunately, abnormalities are usually nonspecific and therefore of limited usefulness. Findings include cardiomegaly, an abnormal cardiac contour, mediastinal widening, or evidence of congestive heart failure.[48,53,54] Calcifications are present in up to 20% of cases, perhaps relating to the presence of valvular or pericardial disease.[53,55] Calcifications on imaging may also suggest the presence of a fibroma. In the setting of a malignant tumor, chest radiography may also reveal hilar nodal, pulmonary, or osseous metastatic disease.

Echocardiography, M-mode and two-dimensional, is the diagnostic procedure of choice among patients with suspected cardiac tumors. Either transthoracic (TTE) or transesophageal (TEE) techniques can be performed, yielding valuable information regarding size, shape, location, mobility, and areas of attachment.[48] In a review of 533 primary cardiac tumors, Blondeau[16] found echocardiography provided a 98% diagnostic accuracy rate among the 437 patients for whom it was used. Bogren et al.[54] found that echocardiography detected abnormalities in 63 of 65 (97%) patients with primary cardiac tumors. With this high level of diagnostic yield, and because the use of TTE has no known side effects, it should be performed for all patients. TEE is a complementary procedure to TTE. It is a more invasive procedure and is not required in all patients, but it may be used for guidance during endomyocardial biopsy and may also provide better evaluation of the left atrial appendage and right-sided tumors.[56–58]

TABLE 57.4 DIAGNOSTIC EVALUATION FOR A SUSPECTED OR KNOWN CARDIAC TUMOR

Required Studies	Optional Studies
History	Cardiac catheterization, right or left sided
Physical examination	Pressure and output measurements
Blood work	Coronary angiography
Complete blood count	Endomyocardial biopsy
Liver function tests	Transesophageal echocardiography

Renal profile	ECG-gated MRI
Electrolytes	Radionuclide scintigraphy, including PET
ECG	Pericardiocentesis
Imaging	Staging for malignant tumors
Chest radiography	CT of the abdomen, pelvis, and brain
Transthoracic echocardiography	Bone scan
Contrast-enhanced dynamic CT	

CT, computed tomography; ECG, electrocardiography; MRI, magnetic resonance imaging; PET, positron emission tomography.

Cross-sectional imaging has also become indispensable in the evaluation of nonmyxomatous cardiac tumors. With the development of contrast-enhanced dynamic CT (Fig. 57.1B) and ECG-gated MRI (Fig. 57.1A and C), real-time imaging of the heart provides fine details of the tumor, with delineation of intraluminal, intramyocardial, and extracardiac extension.[48,59–62] The findings may be used to plan the surgical approach and, should adjuvant therapy be required, could also be used for radiotherapy treatment planning. Compared to chest radiographs, both CT and MRI are more sensitive in detecting metastatic disease. If these studies are positive, tissue diagnosis may be made without the need for endomyocardial biopsy or thoracotomy. If they have not been performed before surgery, CT of the brain, chest, and upper abdomen and a bone scan are recommended in the staging of malignant cardiac tumors.

Radionuclide imaging has been used in the evaluation of cardiac tumors. Gated cardiac blood pool scintigraphy has limited resolution, but it may be able to detect tumors when other modalities have failed. Gallium-67 and thallium-201 scans may reveal intramyocardial invasion.[48,54] Positron emission tomography (PET), with or without CT fusion (PET-CT) (Fig. 57.1D), is rapidly gaining favor in the staging of many cancers, and there are scattered case reports on its usefulness in evaluating cardiac tumors.[63,64]

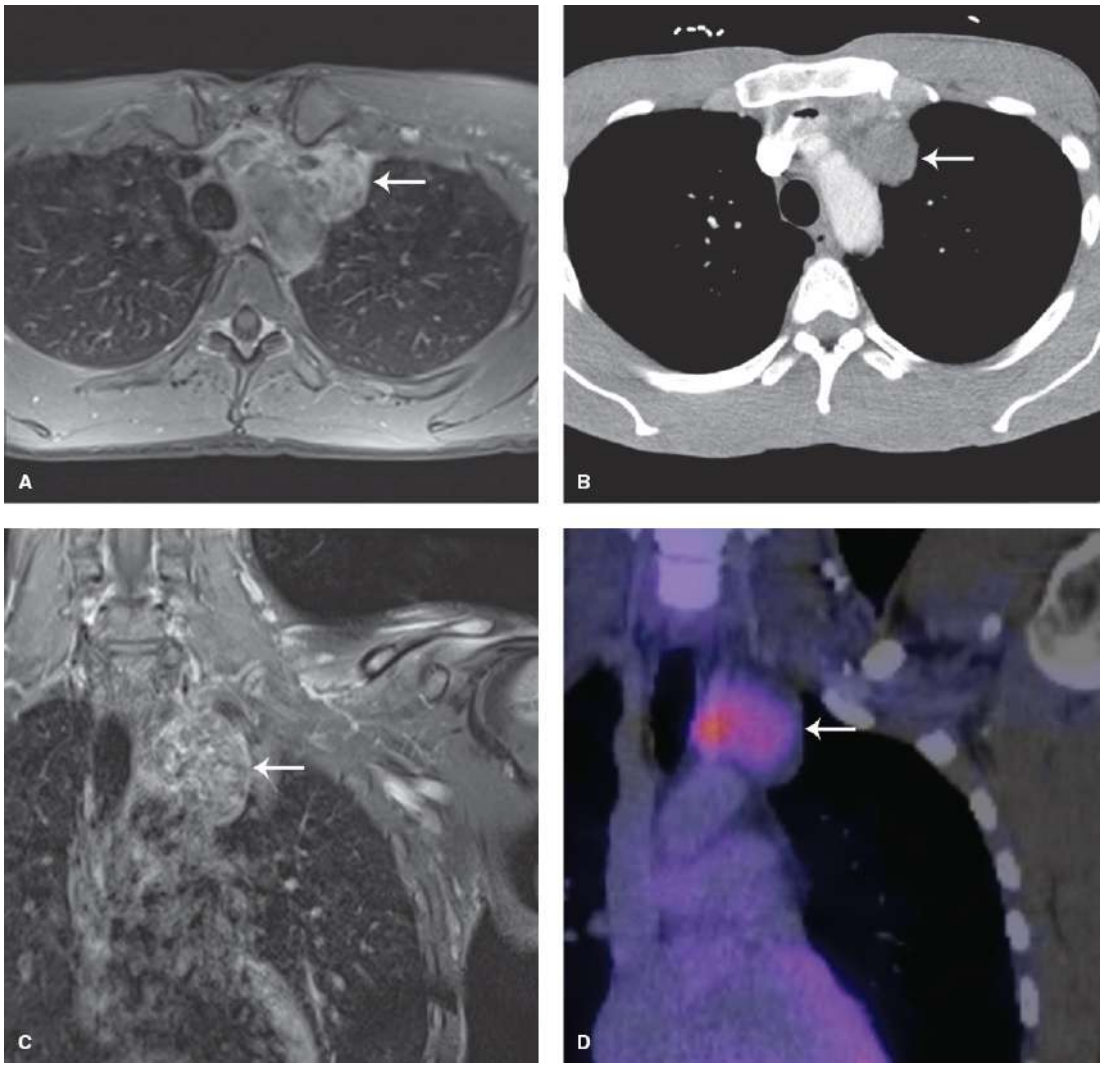

FIGURE 57.1. Axial contrast-enhanced fat-saturated T1 magnetic resonance image (MRI) of a primary cardiac neoplasm arising from the left atrium **(A)**; corresponding axial contrast-enhanced computed tomography (CT) **(B)**, coronal contrast-enhanced fat-saturated T1 MRI **(C)**, and coronal fluorodeoxyglucose positron emission tomography CT **(D)** images. Tumor indicated by *white arrows.*

Cardiac catheterization was heavily utilized in the past, but its usefulness has diminished with the emergence of the noninvasive techniques noted previously. Catheterization may reveal wall structural or motion abnormalities, intracavitary filling defects, or evidence of neovascularization of the tumor.[48,54] If a malignant tumor is suspected, endocardial biopsy may provide tissue for pathologic diagnosis. For patients who may undergo surgical resection of their tumor, catheterization is still recommended for the detection of coronary artery disease and pulmonary hypertension.

STAGING SYSTEM AND PATHOLOGIC CLASSIFICATION

There is no accepted staging system available for cardiac tumors. With respect to pathologic classification, tumors of the heart and pericardium may be classified as primary (originating from the heart) or metastatic (originating from malignancies of other organs). Primary cardiac tumors can be further subclassified by the site of origin and by malignant potential (Table 57.5).

PROGNOSTIC FACTORS

In general, the prognosis for patients with either primary or secondary malignant tumors of the heart is poor. The median survival of patients with malignant primary tumors is approximately 1 year, and both local and distant relapses are common. Blondeau[16] reported that angiosarcoma had a median survival of 2.14 years, compared with only 0.75 years for fibrosarcoma. Llombart-Cussac et al.,[65] on the other hand, noted a worse survival for angiosarcomas due to their propensity to present late with advanced disease. The series from Burke et al.[17] and Putnam et al.[18] indicate that the histologic subtype does not appear to have prognostic value, although the microscopic finding of more than 10 mitoses per high-power field does portend a worse prognosis. Tazelaar et al.[66] also noted a worse outcome for tumors with high mitotic activity and necrosis. Conversely, the ability to resect all gross tumor and a left atrial site of origin predict for longer survival.[17,18] Although the duration of symptoms is typically short, some patients have a more protracted course, and outcome may be better in those with symptoms for more than 3 months before diagnosis.[67] The use of adjuvant radiotherapy has been associated with longer median survival (22.7 vs. 9.6 months), whereas adjuvant chemotherapy has provided mixed results.[17,67] Given the retrospective nature of these studies, patient selection may be a source of bias. If a controlled, prospective study could be completed, it is unclear if it would confirm an improved prognosis with either type of adjuvant therapy.

TABLE 57.5 PATHOLOGIC CLASSIFICATION OF CARDIAC TUMORS

Pericardial Tumors	Myocardial Tumors
Benign Subtypes	**Benign Subtypes**
Teratoma	Myxoma
Pericardial cysts	Lipoma
Fibroma	Papillary fibroelastoma

Angioma	Rhabdomyoma
Lipoma	Fibroma
Malignant Subtypes	Hamartoma
Mesothelioma	Hemangioma
Angiosarcoma	Teratoma
Fibrosarcoma	**Malignant Subtypes**
Malignant teratoma	Sarcoma
	Lymphoma
	Malignant teratoma
	Melanoma
	Carcinoma

The discovery and diagnosis of metastatic disease in the myocardium is rare in the antemortem setting, and hence prognostic factors have not been elucidated. Malignant pericardial effusion, on the other hand, is more easily diagnosed in life and can be appropriately palliated with pericardiocentesis, pericardiotomy, or pericardial sclerosis. Among patients with metastases from a solid tumor, the median survival after the procedure is approximately 3 to 4 months, and it appears to be improved with better performance status.[68,69]

MANAGEMENT

Primary Pericardial Tumors

Fewer than 200 primary pericardial malignant tumors have been reported in the literature to date, and less than one-third of these were diagnosed during life.[20,21,23–28,70–73] Among those diagnosed before autopsy, locally advanced or metastatic disease is common, and palliative treatment may be the most appropriate option. Relief of pericardial tamponade can be achieved rapidly through pericardiocentesis. Palliative surgical approaches include pericardiectomy or pericardial sclerosis to alleviate the symptoms of effusion and potentially prevent its recurrence. In keeping with the contemporary data supporting the use of radiotherapy in cases of primary pleural mesothelioma, it is appropriate to consider its use in the setting of primary pericardial mesothelioma, although there are few clinical data defining its use.[74] Both external-beam radiotherapy and instillation of radiopharmaceuticals (phosphorus-32, gold-198) have been reported in the palliative setting for this disease.[6,20]

Surgical resection of all gross disease is the treatment of choice in the definitive setting. As with pleural mesothelioma, a high rate of local recurrence should be expected without adjuvant therapy, and postoperative radiotherapy and chemotherapy should be considered. The radiation treatment volume should

include the entire pericardial surface and likely should include the mediastinal lymph nodes.

Benign Cardiac Tumors

The most common benign cardiac tumors are atrial myxomas in adults and rhabdomyomas in children. These are both treated surgically with low mortality rates and local control rates in excess of 95%.[14,16,30–33,50,67] Endo et al.[31] reported a 5-year overall survival rate of 86% after resection of atrial myxoma. Bogren et al.[54] found the 5-year survival rate was 87% for patients with myxoma and 76% for all patients treated for a benign cardiac tumor. Blondeau[16] reported 444 patients had resection of a myxoma with a 4% 30-day surgical mortality rate, a 1% late tumor- or treatment-related mortality rate, and only a 2% risk of local relapse. Given the high rate of cure, with an acceptable rate of morbidity, surgical resection without adjuvant chemotherapy or radiotherapy is generally appropriate for benign primary cardiac neoplasms. Some rhabdomyomas may even regress spontaneously without the need for aggressive resection.[75]

Malignant Primary Cardiac Tumors

Surgical resection is the primary treatment of choice for patients with primary malignant cardiac tumors. Unfortunately, local resection is often incomplete because of the extent and invasiveness of the tumor and lack of experience with extended cardiac resection and partly because of uncertainty of diagnosis at the time of initial surgery.[76] In experienced hands, even tumors requiring complete reconstruction of the entire right and left atria and up to 30% of the right ventricle may be resectable and still retain adequate cardiac function.[76] Even in the presence of a complete excision, local relapse is common and accounts for as much as one-third of deaths. Sarcomas account for almost all primary malignant cardiac neoplasms, and the treatment principles should be similar to those for soft tissue sarcoma arising from other areas of the body.[77] After complete or incomplete resection of the tumor, adjuvant radiotherapy and chemotherapy may be used in an attempt to gain control of local and distant disease, respectively. There are conflicting reports on the effectiveness of chemotherapy, and given the small sample sizes, it is difficult to draw conclusions, but it seems to be less beneficial if patients are not able to obtain a complete resection.[17,18,76] Combination chemotherapy appears to have greater efficacy than single-agent therapy, with different combinations of agents such as cyclophosphamide, ifosfamide, doxorubicin, and paclitaxel in use.[18,78–81]

Anecdotal cases of orthotopic heart transplantation for patients with malignant neoplasms of the heart were first described in 1981 by Jamieson et al.[82] and in several reports in the literature since then, with some promising results in selected cases.[83–92] Although this technique should ideally achieve a complete tumor resection, the results have been mixed. There have been some case reports of long-term survivors, whereas many other patients have developed distant metastases and subsequent death within months of transplant. Some have attempted cardiac explantation, tumor removal, and autotransplantation.[81] Although orthotopic heart transplantation has promise, theoretical dangers exist, including the potential protumor effect of immune suppression and a decreased ability to tolerate adjuvant radiotherapy or chemotherapy.

Metastatic Tumors of the Heart and Pericardium

There is no known curative therapy for patients with metastatic disease to the heart. Appropriate management of the primary metastatic tumor with systemic therapy may be indicated as a first-line approach for cardiac, pericardial, or GV metastases. Surgery may have a role in both diagnosis and palliation for patients with malignant pericardial disease.[68,69] Emergency pericardiocentesis or pericardiotomy can alleviate cardiac tamponade and yield the diagnosis, and the instillation of a sclerosing agent, such as tetracycline, can often effectively prevent the reaccumulation of the pericardial effusion. Palliative radiotherapy may be used to relieve symptoms of life-threatening outflow obstruction or pericardial disease.

Tumors of the Great Vessels

Resection of the tumor with graft reconstruction of the vessel is the treatment of choice. As with sarcomas of the heart, sarcomas of the GVs are treated based on the same philosophy as used for treatment of soft tissue sarcoma.[77] Postoperative radiotherapy should be considered for all patients, even those with low-grade tumors, because local recurrence would likely not be amenable to salvage surgical resection.[17,33,44]

RADIOTHERAPY

In general, the most common indication for radiotherapy is in the postoperative setting, for example, as adjuvant therapy after resection of a primary malignant cardiac tumor. Less common is the use of radiotherapy in the definitive setting for a tumor that is not technically resectable. There are rare reports of

preoperative radiotherapy being used to render a technically unresectable cardiac tumors appropriate for surgery. Lastly, palliative radiotherapy may be considered when metastatic tumors to the heart cause clinically significant symptoms causing interference with cardiac function.

Decisions on radiation dose and target definitions for cardiac tumors will be determined by the tumor type and the particular clinical indication for treatment. Given that sarcomas are the most common primary malignant cardiac tumors, the radiotherapy model used in their management has been extrapolated from the approach used for soft tissues sarcomas arising at extracardiac sites. Thus, for completely resected tumors with negative margins, postoperative doses of 45 to 50 Gy at 1.8 to 2 Gy/fraction are recommended.[77] The initial target should include all areas known to harbor tumor before surgery, with a margin of about 2 cm. This target should be derived from diagnostic imaging and other investigations and also by the operative description of the surgeon. In the setting of incomplete resection (i.e., involved microscopic margins or gross residual disease), an additional 10 to 20 Gy boost should be added to initial dose and target the postoperative volume at risk. In definitive cases, the goal is to achieve a total dose of at least 70 Gy delivered to the unresected primary tumor, but normal tissues may impose limitations in achieving this. For GV tumors, the target volume will vary depending on the tumor origin but, as with cardiac primaries, should include a minimum expansion of 2 cm around the preoperative mass. Doses from 45 to 50 Gy are suggested for microscopic residual disease and 60 to 70 Gy for gross residual or unresectable disease, allowing for accepted normal tissue tolerances.[93–96] For patients with pericardial mesothelioma, the entire pericardium needs to be included in the initial target volume, but the total dose deliverable will be limited by the tolerance of the myocardium itself and may only be as high as 40 Gy if the whole heart is treated. Focal involvement of the pericardium may be treated to doses as high as 64 Gy.[97] For tumors with a high propensity for nodal involvement (i.e., mesothelioma, angiosarcoma, rhabdomyosarcoma, carcinoma, or lymphoma), coverage of the mediastinal lymph nodes is also recommended. With respect to altered fractionation approaches for cardiac tumors, there are few reports on dose variations to improve the efficacy of conventional radiotherapy. A rare example is a case report on the use of hyperfractionation for a cardiac sarcoma treated to a dose of 70.5 Gy at 1.5 Gy/fraction delivered twice daily with a radiosensitizer, iododeoxyuridine.[46] Regarding palliative radiotherapy, dose schedules should reflect the clinical urgency and the patient’s performance status. The origin of

the primary tumor may also have a bearing on dose schedules. A survey of palliative case reports showed wide ranges in dose/fractionation schedules with the most common ones being short-course accelerated hypofractionated approaches such as 20 to 30 Gy in 5 to 10 fractions.[98]

With respect to radiation delivery, historic practice has involved two-dimensional planning and static beam arrangements, such as anteroposterior parallel-opposed (APPA) techniques to cover the desired initial target volume. Contemporary radiotherapy should now be planned using a three-dimensional (3D) conformal approach, with careful delineation of gross tumor volumes, clinical target volumes, and planning target volumes as defined by the nature of the primary tumor, its expected natural history, and the management approach (definitive or adjuvant). When planning radiotherapy, normal tissue constraints should be observed for each case, with an emphasis on cardiac, lung, spinal cord, and esophageal tolerances. If required, advanced techniques such as intensity-modulated radiotherapy (IMRT) may be of use in the delivery of desired doses to target volumes while highly limiting dose to normal structures. IMRT techniques allow for the selective intensification or reduction of dose to areas of specific concern and may allow for greater sparing of normal tissues without sacrificing tumor coverage or dosing. A recent innovation in radiotherapy highly relevant to cardiac tumors is the use of four-dimensional (4D) CT scanning at the time of patient simulation. 4DCT allows an understanding of the effect of breathing motion on the target and normal structures within the chest. For each structure, 4DCT can generate volumetric datasets representing the various phases of the respiratory cycle. By more clearly understanding tumor motion, relevant normal structures at risk can be optimally spared by restricting treatment margins.

One of the more important advances in the field of radiotherapy has been developing technology that can deliver extremely high-dose focused radiation. Stereotactic body radiotherapy (SBRT), also known as stereotactic ablative radiotherapy-(SABR) involves the precise delivery of very high (ablative) doses of radiation to discrete targets over a small number of treatment sessions (usually five or less) by treating the target with high degree of conformality and employing rigorous pretreatment set-up verification. Given the complexity of heart tumors by virtue of their location and their relationships to a number of organs-at-risk, SBRT has proved to be of particular interest in their management. Soltys et al.[99] treated a recurrent pulmonary artery sarcoma with 33 Gy in 3 fractions. Bonomo et al. used SBRT for recurrent and metastatic cardiac tumors with doses ranging from 24 to 36 Gy in 3 to 5 fractions.[100,101] Although the total

doses used for cardiac tumors reported so far have been less than the curative doses seen in the early-stage lung cancer SBRT literature, clinicians treating heart tumors have nonetheless employed the critical organ dose constraints used in lung SBRT planning.[102–104] Mindful of the limited reported use of such high-dose, highly conformal techniques for heart tumors, it is conceivable that they may offer a means to safely escalate doses to those which would theoretically be optimal for tumor control. This is attractive given the poor outcomes seen with current nonsurgical therapies.[99] Patients who may be the best candidates for using such novel approaches may also be those who have received prior radiotherapy and suffer an isolated in-field recurrence. Because using conventional radiotherapy techniques would likely exceed critical structure dose constraints, SBRT may make high-dose therapy feasible in the setting where otherwise anything other than palliative doses might not have been possible.

Particle-based therapies are also increasingly being investigated in the management of cancers because of their physical properties, which might provide better sparing of normal tissues. A clinical report from Japan (see further below in “Results”) is an example of this modality for a heart malignancy, describing the use of carbon-ion radiotherapy for a case of cardiac sarcomas that employed 64 Gy in 16 fractions over 4 weeks.[105]

Advanced technologies must be used with caution, however, because cardiac and respiratory motions introduce considerable uncertainty in tumor localization and predictability of dose delivery. In the setting of SBRT, normal tissue and tumor motion must be therefore be effectively evaluated using 4D CT techniques. Image guidance (image-guided radiotherapy [IGRT]) at the time of delivery to further ensure targeting accuracy is also critical. Alternative delivery approaches such as gating procedures may be considered to decrease positioning uncertainty and thus decrease the necessary target expansions for daily set-up variations.[106] As a demonstration of different planning result, representative isodose distributions, and their corresponding dose–volume histogram (DVH) data, for two primary cardiac tumors are shown in Figure 57.2 for a 3D conformal radiotherapy plan and in Figure 57.3 for an SBRT plan.

As noted above, the total dose deliverable to any given cardiac tumor is primarily limited by heart and lung tolerance. Much of the available evidence on tolerance of the heart is based on patients previously treated for malignancies such as Hodgkin lymphoma or breast cancer. In general, radiation-induced heart disease (RIHD) may manifest as pericarditis, myocarditis, conduction defects, or coronary vascular disease.[107,108] Damage to the pericardium is most often

observed clinically. Risk factors for developing RIHD include total dose, dose per fraction, irradiated volume, radiation technique, age at exposure, and use of concurrent or anthracycline-based chemotherapy. Emami et al.[93] estimated the tolerance dose for the heart to be 40 Gy for the whole heart and 60 Gy for one-third of the heart based on a 5% complication rate of developing pericarditis within 5 years of treatment (TD5/5). However, current estimates of normal tissue tolerances tend to be more accurate, and administration of chemotherapeutic agents must also be taken into account as enhancing risk.[109] Most recently, Gagliardi et al.[94] reviewed all the available data on cardiac toxicities and concluded that the whole-organ dose at which toxicity occurs in 50% of cases (TD50) is on the order of 48 to 50.6 Gy, but that side-effect profiles must be considered in relation to the probability of tumor control for the specific patient. Certainly, in aggressive tumors with poor outcomes, recurrence is equally or more morbid than the potential treatment-related toxicities, and this must be balanced and discussed with the individual patient. With respect to other normal structures relevant to 3D-target planning for cardiac or GV tumors, Werner-Wasik et al.[96] have reported that doses as high as 74 Gy with concurrent chemotherapy can be delivered safely to segments of the esophagus, but that no single best threshold is identifiable for limiting esophageal toxicity. In a comprehensive literature review on lung tolerances performed by Marks et al.,[95] the authors recommended limiting the volume of lung receiving 20 Gy (V20) to ≤30% to 35%, and the mean lung dose to ≤20 to 23 Gy in order to minimize lung toxicity. All of these values are for patients receiving conventionally fractionated radiotherapy because as noted earlier, SBRT-based approaches employ a different set of normal tissue constraints.

RESULTS

Case reports and small retrospective series have been the primary means of understanding outcomes for this rare class of tumors. A classic example is the 1964 report by Sagerman et al.,[110] which included one of the earliest descriptions of adjuvant radiotherapy for attempted cure. The patient was a 55-year-old woman with a primary cardiac fibromyxosarcoma. After incomplete resection, she underwent external-beam radiotherapy to a dose up to 75 Gy to the primary site, with proper shielding of the spinal cord. As a result of the use of lateral fields, the left lung received 35 Gy to a large volume. The patient was treated with prophylactic steroids to prevent radiation pneumonitis and fibrosis.

She died 8 months later with brain and lung metastases. Autopsy revealed complete sterilization of the primary tumor.

Despite the use of aggressive treatment regimens including surgical resection, postoperative radiotherapy, and chemotherapy, the overall survival for patients with primary malignant cardiac tumors is poor, and this is true even in light of more recent reports that have suggested better outcomes with contemporary adjuvant radiotherapy or chemoradiotherapy.[17,78,79,81] Operative mortality is relatively common, at 8% to 9%, and is twice as high compared to that following resection of benign tumors.[76,111] The median survival in most surgical series is in the range of 9 to 12 months,[14,16,18,30,32,65,78,111,112] with outliers as low as 6 months[17,33,113] and as high as 23.5 months among patients who survived surgery in one of the most recent reports.[76] Putnam et al.[18] reported a median survival of 11 months and a 2-year overall survival rate of only 14%. In this series, the authors also noted the importance of complete resection. For patients in whom complete resection was possible, the median survival was 24 months, compared with only 10 months for those with incomplete resection. Llombart-Cussac et al.[65] also noted improved survival with complete resection (22 vs. 7 months). Burke et al.[17] reported significantly improved median survival of 12 months among patients who underwent adjuvant radiotherapy, chemotherapy, or both, compared with 3 months in those who did not have adjuvant therapy.

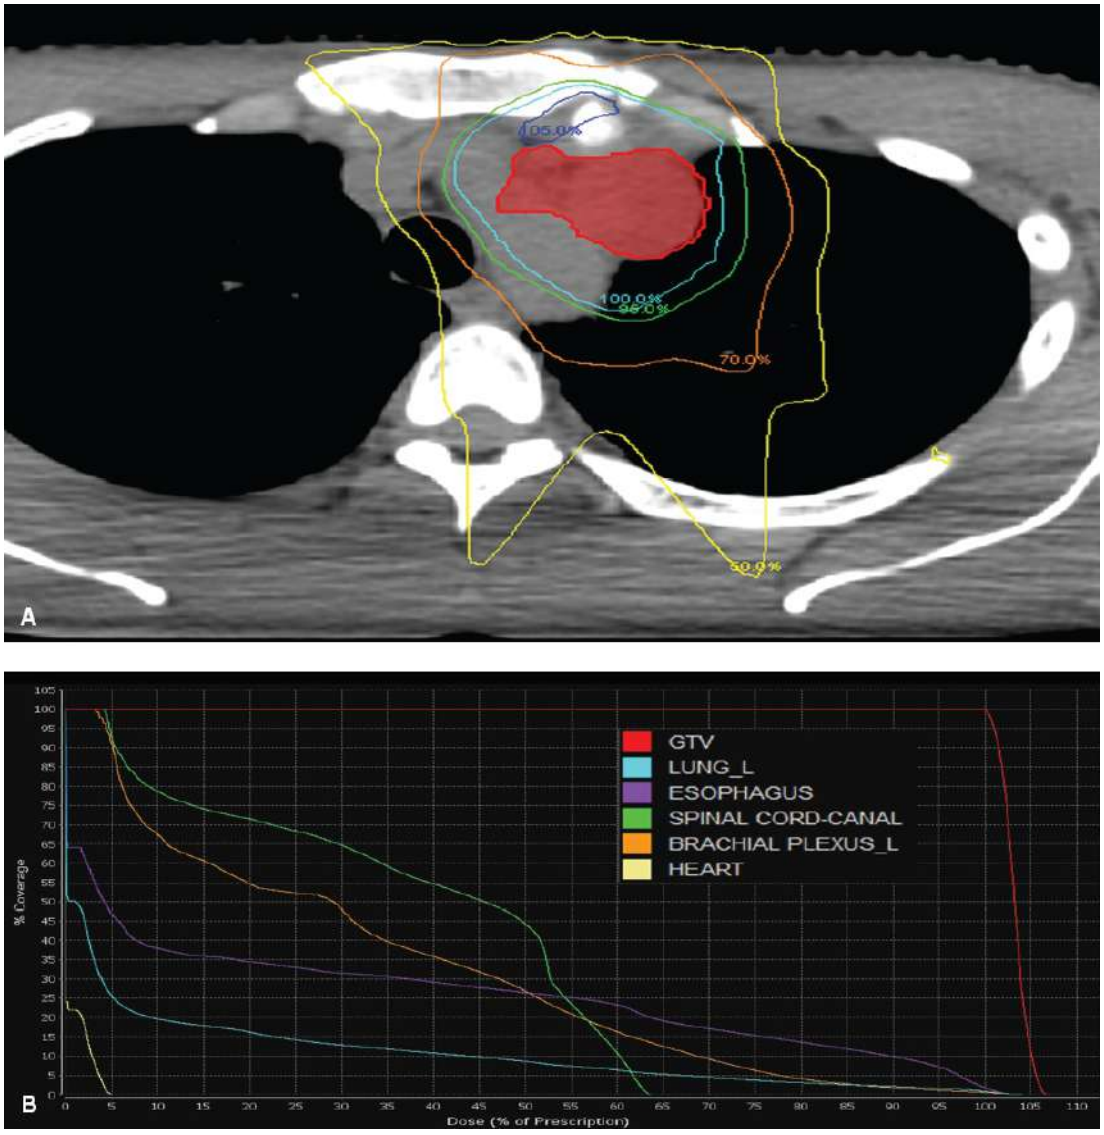

FIGURE 57.2. Sample three-dimensional conformal plan developed for a patient with an unresectable epithelioid hemangioendothelioma of the aortic arch **(A)** and corresponding dose–volume histogram data **(B)**. GTV, gross tumor volume.

With respect to the use of definitive carbon-ion radiotherapy in the treatment of a patient with cardiac angiosarcoma,[105] the tumor volume reduced by 86% following treatment and became negative on PET scan. After 18 months, the primary tumor remained controlled, but the patient had developed bilateral lung metastases 4 months after treatment.

Selected patients who develop recurrence after undergoing combined modality therapy may still benefit from aggressive management of their disease, with one author reporting an improvement in median survival from 25 months with no treatment to 47 months with resection, radiofrequency ablation, or

radiotherapy.[76] Others have shown similar benefits to this approach at the time of recurrences.[81]

The median survival for patients with metastatic disease to the heart is approximately 3 to 4 months, but rare cases of long-term survival, some as long as 3 years, have been documented and may be related to primary tumor histologic type and performance status.[68,69,114] Pericardiotomy or pericardial sclerosis appears to offer at least temporary control of tamponade and effusion in up to 90% of cases.[68,69] Palliative treatment with radiation is well tolerated and is effective in controlling cardiac tamponade in approximately 60% of patients. Cham et al.[115] reported the results of radiotherapeutic palliation for 38 patients with secondary tumors of the heart and pericardium. Thirty-seven patients were noted to have pericardial involvement, nine also had invasion of the myocardium, and one had only endocardial involvement. The radiation dose was 25 to 30 Gy in 3 to 4 weeks for 32 patients. The dose was 15 to 20 Gy in 1.5 to 2 weeks for the remaining six patients, all of whom had lymphoreticular tumors. The overall response rate was 61%, with a median duration of response of 3 to 4 months. Lymphoreticular tumors had the best response rate (6 of 7 cases) followed by breast cancer (11 of 16 cases). Only 6 of the remaining 15 cases showed a response. Although the median survival among patients with metastases to the heart and pericardium is short, palliative efforts are not in vain because tamponade appears to be effectively controlled with these measures.

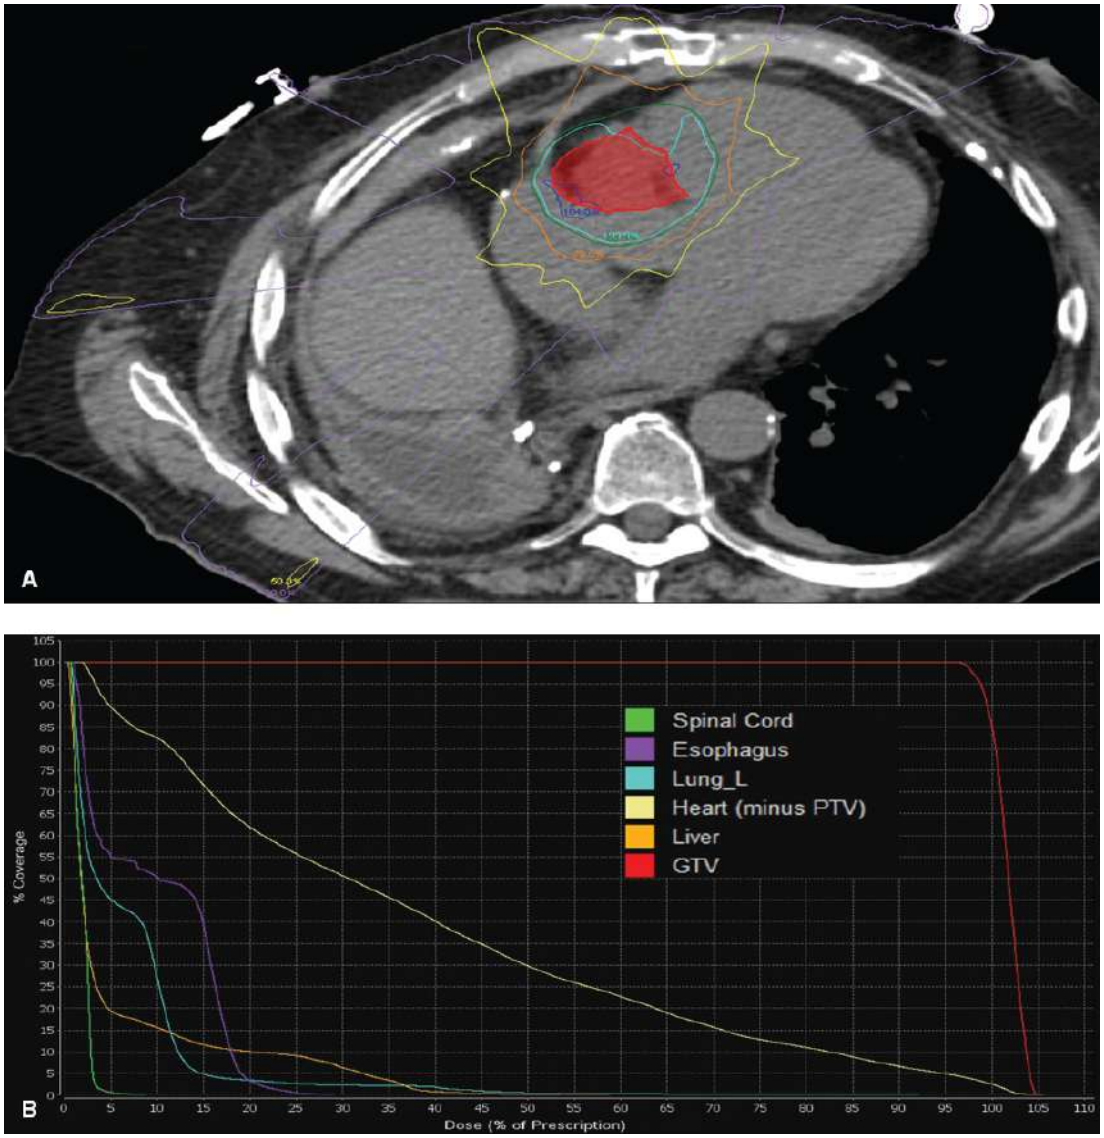

FIGURE 57.3. Sample stereotactic body radiotherapy plan developed for a patient with a local recurrence of a pleomorphic sarcoma of the pulmonary artery **(A)** and corresponding dose–volume histogram data **(B)**. GTV, gross tumor volume.

Among patients treated for GV tumors, median survival depends on the location, resectability, and grade of the primary tumor. Burke and Virmani[44] reported the median survival was 5 months for aortic sarcoma, 23 months for sarcoma of the pulmonary artery, and 37 months for sarcoma of the IVC. Two patients with sarcoma of the SVC were alive and without disease 10 and 72 months after treatment. Local relapse was documented in two patients, although metastatic disease occurred in 19 of 45 patients. The sites most commonly involved by metastases were the lung, liver, and bone. Involvement of the peritoneum, adrenals, kidneys, skin, and lymph nodes was also noted.

Treatment Sequelae

Late radiation-induced cardiac or pulmonary sequelae after the definitive treatment of cardiac tumors have not been well documented, probably as a result of the poor overall survival for these malignancies. In a recent report of 17 patients treated for different cardiac malignancies, with follow-ups ranging from 5 to 137 months, Lestuzzi et al. described late toxicities from cardiac radiotherapy in six of these cases.[116] Three patients developed recurring atrial fibrillation, two segmental hypokinesis and one constrictive pericarditis. The cardiotoxic effects of doxorubicin have been well documented, and there is evidence for increased risk when it is given in conjunction with radiotherapy[109]; therefore, concurrent therapy should be avoided to the degree possible.

PART E

Breast

CHAPTER 58

Breast Cancer: Stage TIS

Alfredo I. Urdaneta, Todd Adams, David E. Wazer, and Douglas W. Arthur

INTRODUCTION

Noninvasive carcinoma of the breast (stage Tis) includes Paget disease of the nipple and two histopathologic entities that are distinct in both their clinical presentation and biologic potential: lobular carcinoma *in situ* (LCIS) and ductal carcinoma *in situ* (DCIS). As a result of the increase in the use of mammography, these three histopathologic entities comprise a larger percentage of all breast cancer cases seen today. There remains considerable controversy regarding the optimal treatment approach and, as a consequence, treatment recommendations range from observation to breast-conservation therapy to mastectomy. It is, therefore, important to understand the distinguishing pathologic appearances, biologic characteristics, and natural history of these three noninvasive breast disease entities to appropriately formulate coherent treatment recommendations.

Lobular Carcinoma *in Situ*

LCIS is characterized by multicentric breast involvement and consists of loose, discohesive epithelial cells that are large in size, variable in shape, and contain a normal cytoplasm to nucleus ratio.[1] The extent of involvement of the lobular lumen ranges from simple filling to moderate to severe distention with extension into the adjacent extralobular ducts.[2] As such, the lines of histologic delineation can become blurred between atypical ductal hyperplasia, LCIS, and, when ductal extension is seen, DCIS. This overlap of histologic morphology may complicate the interpretation of studies from different institutions.[1–4]

LCIS has been reported to present with a multicentric distribution in up to 90% of mastectomy specimens, with bilateral involvement in 35% to 59%.[5–7]

LCIS cells are commonly estrogen receptor positive, although overexpression of c-erbB-2 and p53 are uncommon.[4,8–10] The loss of E-cadherin is often observed,[8,11,12] and the absence of this adhesion molecule may explain the growth pattern seen with LCIS.

LCIS represents <15% of all noninvasive breast cancer.[13–15] The majority of women are premenopausal at diagnosis, with an average age of 45 years.[1,3,16] Risk factors for the development of LCIS correspond to those identified for invasive carcinoma.[17] Because the male breast lacks lobular elements, this entity has not been described in men.[3] As there are no clinical or mammographic indicators that are characteristic of LCIS, it is often detected as an incidental biopsy finding.[1,4] In a minority of cases, LCIS can be detected with mammographic calcifications; however, more commonly, calcifications are in adjacent tissue and are not histologically associated with LCIS.[18–20] In excisional biopsy specimens, DCIS or invasive carcinoma are frequently identified even when LCIS is the sole histologic entity seen on core biopsy.[21–23]

LCIS is considered a marker of increased risk for the subsequent development of invasive (usually ductal) carcinoma[3,13,14,16] that may be greatest for high-grade or more extensive lesions.[1,24] This risk appears to be nearly equal for both breasts.[25]

The question as to whether LCIS can serve as a direct precursor lesion to the subsequent development of invasive lobular carcinoma is unresolved. Some studies have suggested a clonal link of synchronously detected LCIS and invasive lobular carcinoma,[26] whereas others have not.[27] In an analysis of 182 patients with LCIS who were inadvertently enrolled on the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 trial for DCIS and treated with lumpectomy only, there was a 14.4% in-breast tumor recurrence (IBTR) rate and a 7.8% contralateral breast tumor recurrence rate after a median follow-up of 12 years.[28] Nine IBTRs (5% of the total cohort) were invasive carcinoma, and 17 (9% of the total cohort) were DCIS. Although the frequency of contralateral breast tumor recurrence rate was less than that of IBTR, the frequency of invasive contralateral breast tumor recurrence rate (5.6% of total cohort) was similar to invasive IBTR (5% of total cohort). Of note, all of the IBTR were documented to be at the site of the index lesion except for one, characterized as pure LCIS, that was found at a remote site.

The evidence associating LCIS with the subsequent development of invasive disease raises the question as to whether magnetic resonance imaging (MRI) would be a useful screening tool. Limited data exist to formulate a firm

recommendation. In 2007, the American Cancer Society stated there were insufficient data; however, in 2009, the National Comprehensive Cancer Network published guidelines reflecting a panel consensus opinion that annual breast MRI should be considered in patients with LCIS. Several studies have been published evaluating the role of MRI in patients with LCIS.[29–32] Each document revealed a small but defined 3.3% to 4.5% breast cancer detection rate and a positive predictive value of 31% based on biopsies performed supporting consideration for an annual MRI in this subset of patients. Management for LCIS depends on whether it is associated with another malignancy (DCIS or invasive carcinoma) or if LCIS is the sole histologic diagnosis. Approximately 10% of early-stage breast cancers have an associated component of LCIS.[33–35] The effect that LCIS has on the outcome of conservative management of early-stage breast cancer has been evaluated. Limited studies suggest that the presence of LCIS should influence treatment approach[36]; however, the most widely accepted treatment approach is to manage the breast according to the dominant malignant histology (DCIS or invasive carcinoma) and disregard the LCIS. In such circumstances, it is not necessary to pursue additional surgery to obtain clear margins for LCIS.[27,33,34,37,38]

If LCIS is the sole histologic diagnosis, treatment recommendations range from conservative to radical. When first described as an entity, the significance of LCIS was unknown and mastectomy was often performed.[39] The high frequency of contralateral breast involvement was subsequently used to justify contralateral biopsy and even bilateral mastectomy.[16,39] Observational studies after wide local excision alone have led to a better understanding of the natural history of this condition, and a more conservative approach is now commonly practiced.[3,13,14] In patients with LCIS as the sole histologic diagnosis, the most widely accepted clinical practice is close observation with regular physical examination and mammographic surveillance.[3,13–15,28] There is no role for radiotherapy in the management of LCIS. The fact that LCIS commonly involves both breasts makes treatment with unilateral mastectomy both inadequate and illogic. Bilateral prophylactic mastectomy is likely excessive in all but those patients believed to be at highest risk: young age, diffuse high-grade lesion, and significant family history. A less radical prophylactic approach in high-risk patients is to consider the use of tamoxifen. Tamoxifen has demonstrated efficacy in the prevention of invasive carcinoma and, in the context of LCIS, has been shown to reduce risk by 56%.[40,41]

PAGET DISEASE

The clinical presentation of crusting and eczematous changes of the nipple–areola complex were first described in 1856. However, it was not until 1874 that the association with an underlying breast cancer was reported by Sir James Paget.[42] Paget disease of the nipple is characterized by the presence of Paget cells that are located throughout the epidermis.[43] Paget cells are large and have hyperchromatic, round to oval nuclei with abundant amphophilic to clear cytoplasm. Mitoses are commonly seen, and the cells can be found in clusters or individually in the basal layers. The fact that Paget disease is associated with an underlying malignancy in >95% of cases has generated discussion regarding the origin of these malignant cells. The epidermotropic theory appears to be the prevailing opinion, with the belief that the disease originates from the underlying *in situ* or invasive disease. This is supported by histologic evidence of intraepithelial extension, immunohistochemical studies, and evidence suggesting that the epidermal keratinocytes release a motility factor, heregulin-*a*, that results in the chemotaxis of Paget cells that migrate to the overlying nipple epidermis.[44,45]

Paget disease is a rare entity representing <5% of all breast cancer cases[46,47] and is typically diagnosed in the fifth or sixth decade of life. Synchronous bilateral Paget disease and male Paget disease have been reported.[44,48,49]

Patients with Paget disease describe itching and burning of the nipple and areola. There is a slow progression toward a crusting eczematoid appearance that can extend to the periareolar skin. If neglected, bleeding, pain, and ulceration can occur.[47,50] Alternatively, Paget disease can be asymptomatic and present as a pathologic finding after incidental surgical removal of the nipple–areolar complex.[51] The differential diagnosis includes superficial spreading melanoma, pagetoid squamous cell carcinoma *in situ*, and clear cells of Toker.[43,52] A palpable mass is detected in approximately 50% of patients at diagnosis; in >90% of cases, this will be an invasive carcinoma. In contrast, if no palpable mass is detected, 66% to 86% will have an underlying DCIS. These associated malignancies are usually located centrally, although they can occur elsewhere in the breast.[44,47,53] Mammographic findings are frequent in the presence of a palpable mass; however, normal mammograms are reported in as many as 50% of cases.[47,54]

At presentation, clinical evaluation includes bilateral breast examination, mammography, and biopsy to confirm the diagnosis of Paget disease and to fully evaluate the extent of the associated malignancy. The prognosis does not depend

on the diagnosis of Paget disease but rather on the associated malignancy. Therefore, local treatment, as well as systemic and regional nodal disease risk management, should be based on the associated disease.

Management of Paget disease continues to evolve. Mastectomy was employed in the past, although this has been increasingly supplanted by breast-conserving treatment.[55–58] The infrequent occurrence of this disease entity, the range of disease presentations (nipple involvement with or without an underlying mass and association with invasive vs. noninvasive disease), and the variable extent of surgical resection has made the evaluation of treatment options difficult. Small series have described results with various forms of breast-conserving treatment, including wide local surgical resection alone, radiotherapy alone, and wide excision followed by whole-breast radiotherapy. Conservative surgery alone for Paget disease appears to be inadequate, with reported local recurrence rates of 25% to 40%.[5,59–63] The use of radiotherapy alone has been reported as achieving an 85% local control rate in a small series of patients with Paget disease of the nipple who presented without an associated palpable mass.[64] However, this approach has not been widely adopted because of the undefined histologic type and extent of the underlying disease leading to uncertainty in field design and total radiation dose.

The combination of limited surgical resection and postoperative radiotherapy appears to be the most practical breast-conserving approach. Two studies have evaluated the combined use of surgery and radiotherapy in Paget disease of the nipple. The European Organization for Research and Treatment of Cancer (EORTC) Study 10873 was a multiinstitutional registry trial that reported a 5-year local recurrence rate of 5.2%.[65] In this study, a complete excision with tumor-free margins of the nipple–areolar complex and underlying breast tissue was followed by whole-breast radiotherapy. The median follow-up was 6.4 years, and the majority of these patients were found to have an underlying DCIS without a palpable mass. A separate study consisted of a seven-institution collaborative review of 36 patients with Paget disease without a palpable mass or mammographic density.[66,67] Patient follow-up was a median of 9.4 years. The extent of surgical resection varied as patients underwent complete (69%) or partial (25%) excision of the nipple–areolar complex and underlying breast tissue, with 6% reported as biopsy only. The final margin status was documented as negative in 56%, positive in 6%, and unknown in 39%. All received whole-breast irradiation, and most received an additional boost dose to the tumor bed. The actuarial rate of local failure as the only site of first recurrence was 9% at 5

years and 13% at both 10 and 15 years. Two additional patients recurred in the treated breast simultaneously with regional and distant metastasis at 69 and 122 months. Despite the differences in clinical, pathologic, and treatment factors, statistical evaluation did not identify any factors that significantly predicted for risk of local recurrence.

Current data suggest that a combined modality approach that conserves the breast is an appropriate alternative to mastectomy in properly selected patients with underlying noninvasive or invasive carcinoma of limited extent. As with any breast-conserving approach, patients with multicentric disease extension should be excluded. Surgical resection should include the nipple–areolar complex with microscopically clear margins surrounding both the Paget disease and the associated malignancy. Whole-breast radiotherapy is delivered with standard techniques. Management of regional nodes and the risk of systemic disease are dictated by the associated malignancy.

Ductal Carcinoma *in Situ*

Clinical Presentation and Epidemiology

DCIS is a neoplastic process that is confined to the ductal system of the breast and lacks histologic evidence of invasion. These cells neither disrupt the basement membrane nor involve the surrounding breast stroma. This entity lacks the ability to metastasize and is confined to the breast.[68–71] Axillary node involvement is rare (0% to 5%) and most likely is associated with an undetected focus of invasive carcinoma.[72] Risk factors for the development of DCIS are the same as those identified for invasive carcinoma,[17] including family history, reproductive events such as delayed age of first live birth and nulliparity, history of benign breast biopsy, and dietary factors such as alcohol consumption. Before the use of screening mammography, DCIS typically presented as a palpable mass or nipple discharge. An invasive component commonly was found, and pure DCIS rarely was encountered. The widespread use of mammography now routinely detects DCIS <1 cm in diameter and results in breast cancer–free survival rates that approach 100%.[72]

With the increased use of mammography and as pathologists began to recognize DCIS as a pathologic entity, the incidence of DCIS has markedly increased.[73–75] The incidence of DCIS in the United States rose from 4,800 cases in 1983 to >50,000 cases in 2004, representing a 10-fold increase in only 20 years.[76] Of the more than 250,000 new breast cancers that occur annually,

approximately 63,000 are anticipated to be noninvasive, of which 85% will be DCIS.[77] Of these, 90% are expected to be nonpalpable.[45] Studies have shown that the rate of screen-detected DCIS increases with age despite that it accounts for a progressively smaller proportion of the total breast cancers detected.[78] The rate of DCIS detection has been reported to increase from 0.56 per 1,000 mammograms among women aged 40 to 49 years to 1.07 per 1,000 mammograms among women aged 70 to 84 years.[78]

Imaging

Ninety-five percent of new cases of DCIS present with mammographic abnormalities, of which microcalcifications are most typical.[79] Noncalcified mammographic abnormalities make up the remaining findings, with asymmetric densities identified in 10%, dominant masses in 8%, and abnormal galactograms (performed for evaluation of nipple discharge) in 6%. Amorphous, coarse, fine pleomorphic, and fine linear are all forms of calcifications that can be related to DCIS. Linear and segmental calcifications are considered suspicious distribution and can be associated with DCIS in up to 80% of cases.[80] Linear and branching calcifications frequently are associated with high-grade DCIS and necrosis, whereas fine and granular calcifications are associated more commonly with low-grade DCIS[81–84] (Fig. 58.1A and B).

Initial evaluation should include magnification views that allow for complete characterization of mammographic findings and determination of the need for biopsy. The extent of the lesion as determined mammographically may be used as a guide for excision; however, the size typically is underestimated by 1 to 2 cm when compared with pathologic measurements.[82,85,86] Prior to 2000, MRI was not considered a useful imaging modality for DCIS. However, change in MRI imaging acquisition and an improved understanding of non–mass-like malignant lesion imaging characteristics now has MRI considered a valuable imaging tool for DCIS.[87] MRI now presents as the imaging modality with the highest sensitivity to detect DCIS, particularly high-grade DCIS. MRI has additionally been shown to better establish the extent of DCIS, thus aiding treatment planning.[88] In cases that present with nipple discharge and a negative mammogram, galactography may be helpful in determining the likelihood of underlying DCIS versus papilloma[89] (Fig. 58.1C).

Pathology and Biology

The histologic diversity of DCIS can lead to difficulty in distinguishing it from

other pathologic entities.[70,71] The spectrum of DCIS extends from noncomedo, low-grade DCIS that can be similar in appearance to atypical ductal hyperplasia to comedo, high-grade DCIS. In addition, DCIS can extend into lobules, making it difficult to distinguish from LCIS.[90] Traditionally, classification of DCIS has followed its architectural or morphologic appearance. The five subtypes of DCIS are comedo, solid, cribriform, micropapillary, and papillary,[70,71,91] and it is common to encounter a mixture of subtypes within the same specimen.[89] The characteristic features of each type are shown in Figure 58.2. Less common subtypes have been described and include apocrine, neuroendocrine, signet-cell cystic hypersecretory carcinoma, and clinging DCIS.[92]

In 1997, a consensus conference committee was convened to reach an agreement on the pathologic classification of DCIS and the identification of specific features that may convey prognostic significance.[69] Methods of processing and evaluating the pathologic specimen were also addressed. Rather than endorsing any specific classification system, the committee recommended and described features that should be documented for each case of DCIS, thus separating out important pathologic components and providing a comprehensive evaluation of the pathologic findings. These features include nuclear grade, presence of necrosis, polarization, and architectural pattern(s). The committee extended its recommendations to include margin status, lesion size, extent of microcalcifications, and correlation between specimen x-ray and mammographic findings. The DCIS Working Party of the EORTC arrived at similar conclusions and emphasized the importance of cytonuclear and architectural differentiation.[93]

Three-dimensional examination and reconstruction techniques have resulted in a better understanding of the enormously complex structure of the mammary duct–lobular system and the patterns by which DCIS can spread within the breast[6,85,94] (Fig. 58.3). Knowledge of the anatomy and distribution of DCIS within the mammary ductal tree can be useful in selecting patients for breast conservation and assuring maximal surgical clearance of the lesion while preserving an acceptable cosmetic result. For example, Ohtake et al.[6,85] studied the duct–lobular system with computer graphic reconstruction and found that the breast consists of 16 to 24 duct–lobular systems, each culminating in a corresponding collecting duct at the nipple. They also identified ductal anastomoses that established a connection between the various ductal–lobular units and provided a potential pathway for tumor extension and subsequent diffuse involvement.[6,85] Their proposed model for the development of

widespread intraductal tumor extension within the breast is seen in Figure 58.4.

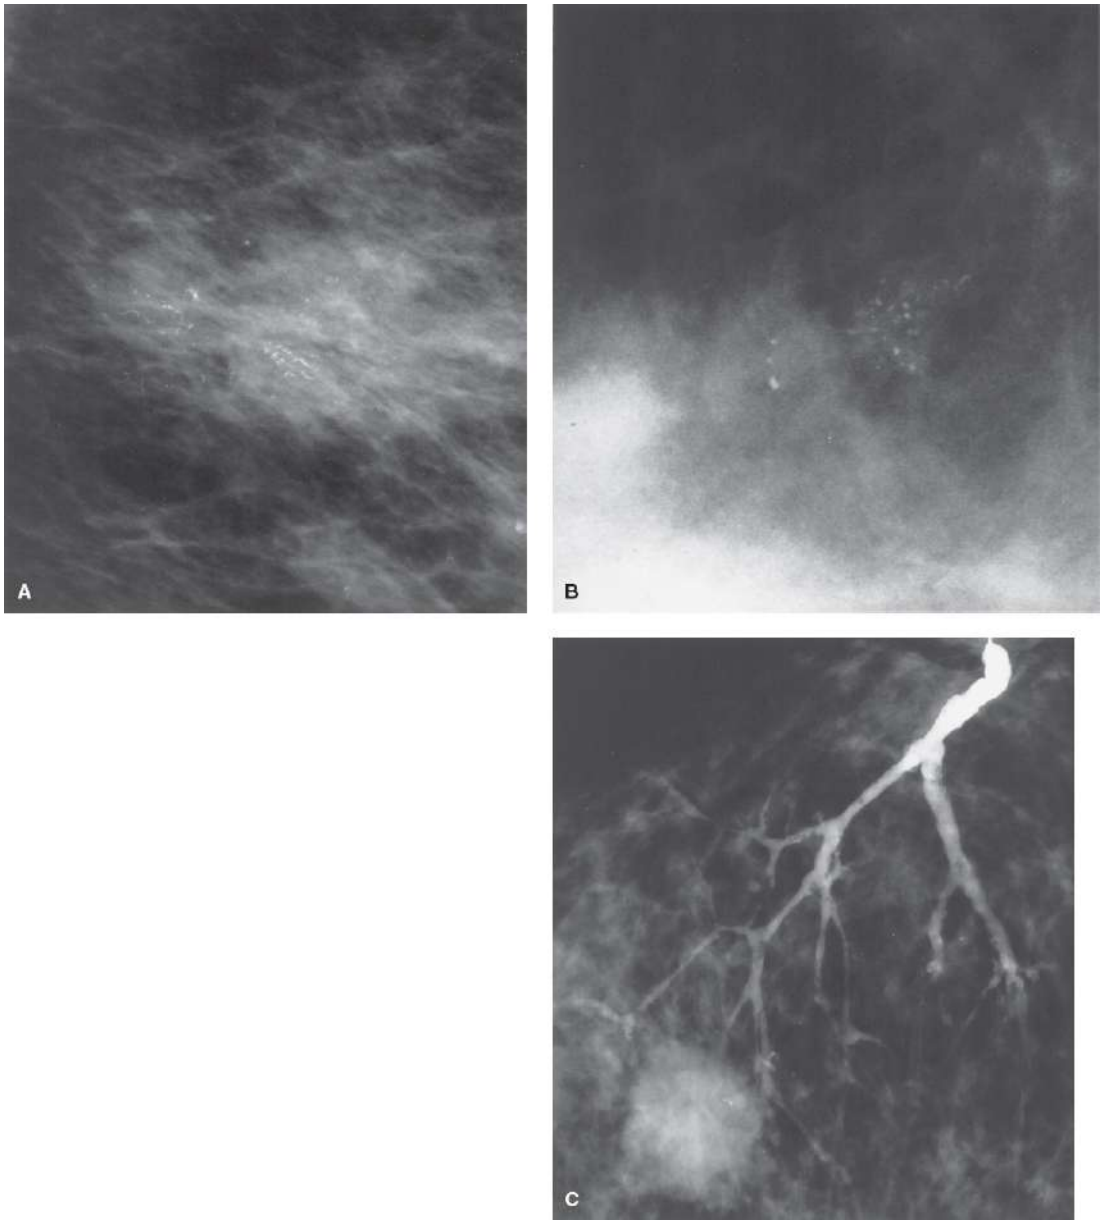

FIGURE 58.1. A: Linear and branching calcifications frequently associated with high-grade ductal carcinoma *in situ* (DCIS). **B:** Fine and granular calcifications commonly associated with low-grade DCIS. **C:** Galactogram with the multiple filling defects associated with DCIS.

Faverly et al.[95] have described the DCIS growth pattern within the ductal tree and the implications for surgical excision. The growth patterns documented include unicentric (one area only), multicentric (two distinct areas separated by >4 cm), continuous (extension along ductal system without gaps), and discontinuous or multifocal (two or more areas separated by <4 cm). They found

that in mammographically detected DCIS, a multicentric growth pattern was rare (<2%), with most cases showing an even distribution between discontinuous and continuous growth patterns. Of cases with a discontinuous growth pattern, 63% had foci separated by gaps that measured <5 mm, 83% had foci separated by <10 mm, and only 8% had foci separated by >10 mm. There was a correlation between differentiation and growth pattern such that 90% of poorly differentiated DCIS showed a continuous growth pattern, whereas 70% of well-differentiated DCIS had a discontinuous growth pattern. Based on these findings, the authors concluded that a 1-cm margin of normal tissue around the lesion would lead to complete surgical clearance of histologically evident DCIS in 90% of cases. DCIS is a precursor lesion to invasive ductal carcinoma and exists along an evolutionary continuum that starts with benign breast tissue and ends with an invasive breast carcinoma.[96] This concept has been validated in several ways. For years, pathologists have recognized and documented confirmation of a histologic progression from benign breast cells to invasive breast cancer. The evolutionary concept is supported by the recognized association between the presence of DCIS and the subsequent increased risk of developing an invasive breast cancer.[76,97,98] In some series, a 10-fold risk of developing an invasive lesion has been reported. At the biologic and molecular level, many studies have demonstrated that DCIS and invasive breast cancer are highly similar at the cellular and molecular levels.[96,99–103] These similarities have now been shown to extend to global gene expression profiles as DCIS has been classified under luminal, basal, and erbB2 intrinsic molecular subtypes.[99,104] Additionally, these shared identical genetic abnormalities between DCIS and synchronous invasive breast cancer demonstrate a clonal relationship of biologic progression.[76,97,98,105] The biologic evolution from benign breast cells to invasive breast cancer occurs through highly diverse genetic mechanisms.

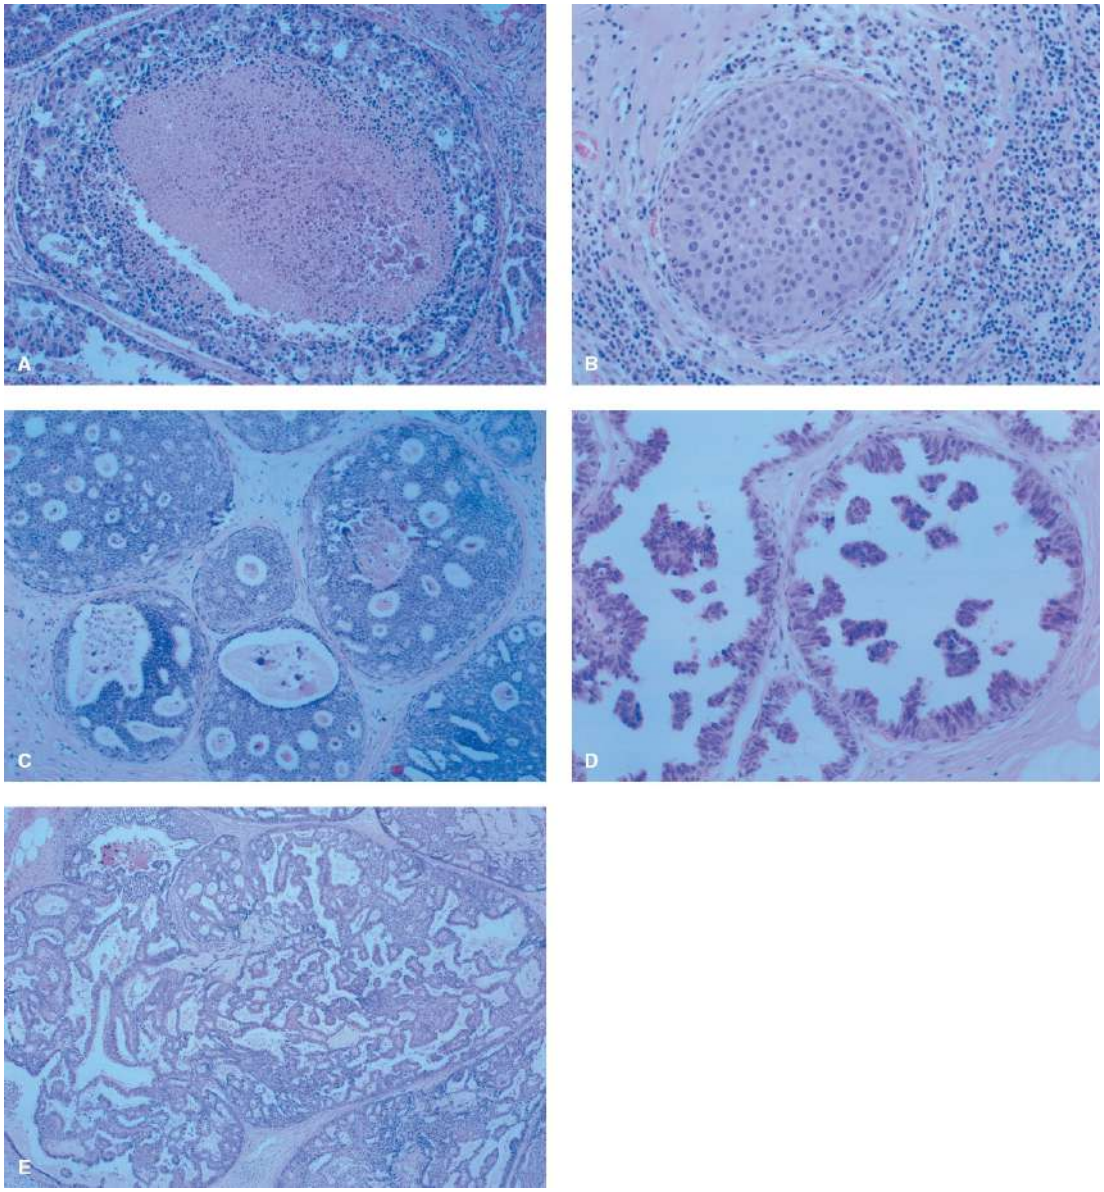

FIGURE 58.2. **A:** Comedo ductal carcinoma *in situ* (DCIS) characterized by central necrosis, large cells, and poorly differentiated nuclei. **B:** Solid DCIS characterized by ductal spaces filled with neoplastic cells with limited necrosis. **C:** Cribriform DCIS characterized by microlumens and fenestrations. **D:** Micropapillary DCIS characterized by intraluminal projections with no fibrovascular core. **E:** Papillary DCIS characterized by intraluminal projections with a fibrovascular core.

Genetic and molecular differences have been documented that differentiate DCIS from normal breast tissue. Genetic alterations have been evaluated with an analysis of loss of heterozygosity that has demonstrated gain or loss of multiple loci.[97,98,105–107] Loss of heterozygosity is not seen in normal breast tissue. The frequency of loss of heterozygosity correlates with histologic progression of breast tissue from benign to malignant. Loss of heterozygosity is seen in

approximately 50% of atypical ductal hyperplasia. Among specimens harvested from cancerous breasts, 77% of noncomedo and 80% of comedo DCIS lesions share loss of heterozygosity with the synchronous invasive lesion in at least one locus.[105]

Molecular markers have been studied in DCIS and are found to have a heterogeneous distribution of expression.[76] The estrogen receptor is present in 70% of DCIS; however, the rate of expression is higher in low-grade lesions (90%) than in high-grade lesions (25%). This association with histologic grade is

reversed for the rate of overexpression of HER2/neu protooncogene and the p53 tumor suppression gene. Approximately 50% of all DCIS lesions have overexpression of HER2/neu, and in 25%, the p53 tumor suppressor gene is also detected. Both of these molecular markers are noted in <20% of low-grade lesions but are present in approximately two-thirds of high-grade lesions.

Alterations in the surrounding breast parenchyma may also be seen with DCIS. High-grade DCIS, in particular, has been associated with the breakdown of the myoepithelial cell layer and basement membrane surrounding the ductal lumen,[108] proliferation of fibroblasts, lymphocyte infiltration, and angiogenesis in the surrounding stromal tissues.[109,110] Whether these stromal changes reflect important steps that facilitate primary tumor transformation or secondary alterations in response to ductal epithelium that is being transformed is unknown. Quantitative changes in the expression of genes related to cell motility, adhesion, and extracellular matrix composition—all of which may be related to the acquisition of invasiveness—occur as DCIS evolves into invasive carcinoma.[111]

Data suggest that DCIS represents a stage in the development of breast cancer in which most of the molecular changes that characterize invasive breast cancer are already present, although the lesion has not yet assumed a fully malignant phenotype. A final set of events, which probably includes gain of function by malignant cells and loss of function and integrity by surrounding normal tissues, is associated with the transition from a preinvasive DCIS lesion to invasive cancer. Most, if not all, clinically relevant features of breast cancer, such as hormone receptor status, the level of oncogene expression, and histologic grade, are probably determined by the time that DCIS has evolved.[112–115]

An occult microinvasive tumor (one that does not exceed 0.1 cm in diameter) may be seen with some cases of DCIS. Such cases are classified as *microinvasive breast cancer*[116] and are generally treated according to the guidelines for invasive disease. Occult microinvasive tumors are most common in patients with DCIS lesions that are >2.5 cm in diameter,[117] those presenting with palpable masses or nipple discharge, and those with high-grade DCIS or comedonecrosis.[89,118]

Natural History of Ductal Carcinoma *In Situ*

The overall incidence of DCIS in the general population is unclear. In an attempt to address this incidence, a small number of autopsy studies have been reported. One series examined 185 randomly selected breasts from 101 women in which a

subgross sampling technique was used [119] and one or more foci of DCIS were found in 6% of cases. A review of seven autopsy series of women not known to have breast cancer during life showed a median prevalence of DCIS of 8.9% (range, 0% to 14.7%).[120] The fact that some autopsy series document a greater incidence of DCIS in asymptomatic women than most clinical series suggests either the possibility that DCIS is either underdiagnosed or that many cases are not clinically significant.

A primary consideration in the natural history of DCIS is the risk of progression to invasive carcinoma. The published evidence on the clinical course of untreated DCIS is sparse because it has been recognized as a distinct entity for only a relatively brief period, having been considered rare before the widespread use of mammography and having been treated most frequently by mastectomy. Those cases for which long-term follow-up data are available were grossly palpable DCIS—a form that may not be equivalent to the mammographic DCIS that is seen more commonly today. The few published long-term follow-up studies of DCIS after only biopsy document an overall incidence of subsequent invasive carcinoma of >36%.[7,121–123] Most of these subsequent malignancies occur within 10 years, although as many as one-third may develop after 15 years.[7,121]

Women with DCIS in one breast are at risk for a second tumor (either invasive or *in situ*) in the contralateral breast [124]; the rate at which such tumors develop is similar to that among women with primary invasive breast cancer at

approximately 0.5% to 1% per year.

DCIS is a part of the breast/ovarian cancer syndromes defined by BRCA1 and BRCA2, with mutation rates similar to those found for invasive breast cancer.[125] These findings suggest that patients with DCIS with an appropriate personal or family history of breast and/or ovarian cancer should be screened and followed according to the same high-risk protocols as developed for invasive breast cancer.

Treatment Options for Ductal Carcinoma *In Situ*

Prognostic Factors and Their Interpretation

The goal of treatment with DCIS is prevention of local recurrence, with particular emphasis on the prevention of invasive breast cancer. Treatment decisions are largely based on information provided by mammography and, most especially, pathologic evaluation of the biopsy specimen. As such, in the consideration of treatment options, it is important for the clinician to be aware of some of the technical limitations associated with the clinical and histopathologic assessment of DCIS.

Studies performed during the past two decades clearly have suggested that DCIS is not a single disease. Rather, DCIS encompasses a diverse group of lesions that differ with regard to their clinical presentation, mammographic features, extent and distribution within the breast, histologic characteristics, and biologic markers. Moreover, clinical follow-up studies have indicated that these lesions vary in their propensity to recur or progress to invasive breast cancer. As a consequence, a significant proportion of patients diagnosed with DCIS can be treated adequately with breast-conserving therapy (i.e., excision with or without radiation therapy). Which patients with DCIS can be treated safely with excision alone and which patients require radiation therapy after excision are pressing clinical questions. Attempts to resolve this issue have focused on the identification of risk factors for local recurrence after breast conservation therapy for DCIS. Through multiple retrospective studies, several factors have been identified that may be important in defining local failure risk. These include symptomatic presentation,[126–128] lesion size,[128,129] histopathologic subtype,[126] nuclear/cytologic grade,[127,128,130] central necrosis,[127,128,130] margin status,[128,131,132] and patient age.[126,132–134]

The relative importance of any histopathologic factor in predicting the probability of local recurrence and in turn selecting the appropriate therapeutic option for a given patient is unclear. This is partly the result of the inherent

difficulty associated with the establishment of standardized and reproducible systems of pathologic classification, including such apparently straightforward assessments of grade, margin width, and lesion size.

Efforts to classify DCIS have been based primarily on the nuclear grade of the lesion and/or the presence or absence of necrosis. Several studies have shown that there is an association between high nuclear grade and/or necrosis and the risk of local recurrence and progression to invasion.[127,128,130] Although the criteria for histologic grading systems have been published, there are limited data regarding the ability of pathologists to apply them in a reproducible manner.

Several studies have shown that the status of the microscopic margins appears to be important in predicting the likelihood of recurrence in the breast for patients with both invasive breast cancer and DCIS treated with breast-conserving therapy.[128,131,132] In 2016, a consensus guideline was published from the Society of Surgical Oncology, the American Society for Radiation Oncology, and the American Society of Clinical Oncology on appropriate margins for breast-conserving surgery with whole breast radiation in DCIS.[135] The consensus panel recommended a 2-mm margin as the standard adequate margin and clinical judgment be used to determine the need for further surgery in patients with negative margins <2 mm. However, there are numerous technical problems in the evaluation of margins of breast excision specimens. First, if a specimen is removed in more than one fragment, the margins cannot be evaluated. Second, there is no standardized method for sampling or reporting margins, and this process is subject to sampling error. Finally, it is often difficult to provide an accurate assessment of the margin width for patients who undergo a reexcision because the initial biopsy site can be eccentrically located in the surgical specimen.

Most DCIS lesions present as a nonpalpable, grossly inapparent mammographic abnormality, which can make accurate determination of the size or extent of the lesion difficult (Fig. 58.5). The modalities available to assess the size of the lesion are mammography, MRI, and pathologic examination. Mammography frequently will underestimate the pathologic extent of DCIS, particularly for well-differentiated lesions in which substantial areas of the tumor may not contain microcalcifications. MRI has been demonstrated to more accurately estimate the disease extent; however, it should be recognized that pathologic assessment of lesion size can be difficult. Macroscopic examination of a specimen containing DCIS rarely reveals a grossly evident tumor that can be measured. Therefore, the assessment of the size of the lesion must be estimated

from histologic sections.

Mastectomy for Ductal Carcinoma In Situ

Mastectomy was the standard treatment of DCIS through the first four decades of its recognition as a distinct histopathologic entity. Mastectomy is a highly effective treatment for DCIS, with a locoregional control rate of 96% to 100% and cancer-specific mortality rates of ≤4%.[136] No randomized study has compared mastectomy with breast-conservation treatment for DCIS. Therefore, the relative outcomes for mastectomy and breast-conservation treatment can be estimated only by reviewing nonrandomized, retrospective studies. Local treatment failure after mastectomy[136] may occur because of unrecognized invasive carcinoma that results in local recurrence or distant metastasis, or it may be the result of incomplete removal of breast tissue with the subsequent formation of a new primary tumor.

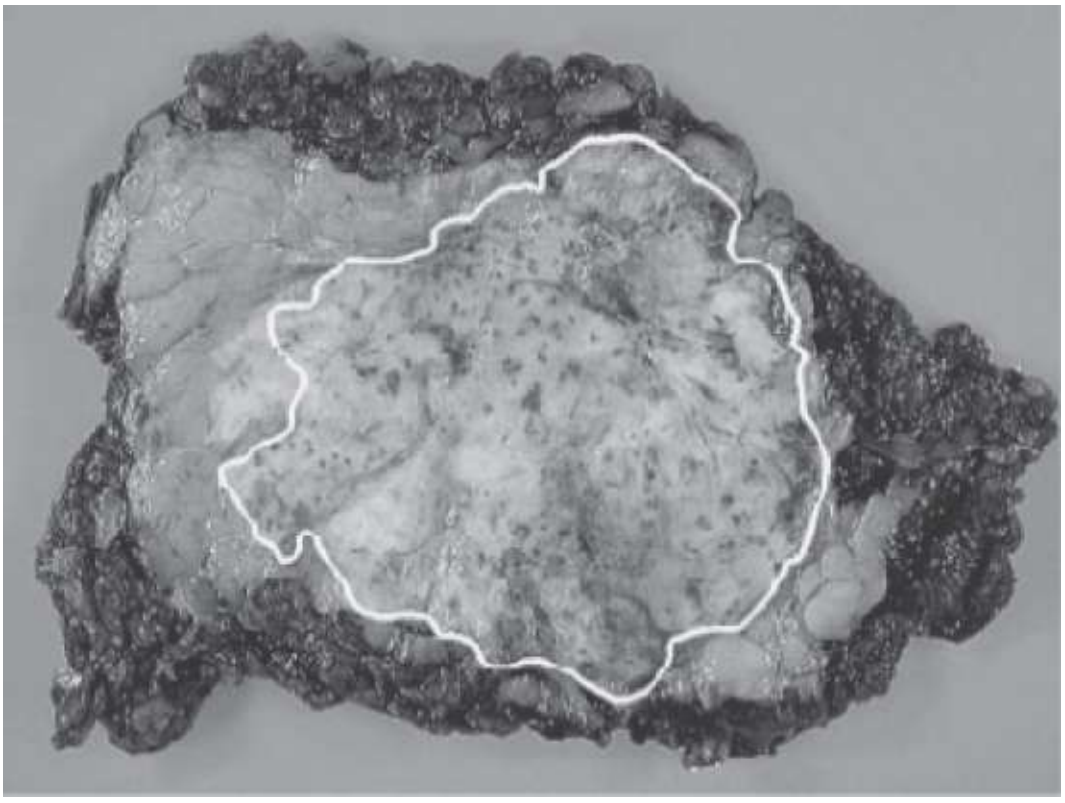

FIGURE 58.5. Extensive ductal carcinoma *in situ* (DCIS) in a mastectomy breast sectioned in the coronal plane. Every parenchymal structure (duct or lobule) within the marked perimeter is colonized by DCIS; outside that boundary there is none. (From Going JJ, Moffat DF. Escaping from flatland: clinical and biological aspects of human mammary duct anatomy in three dimensions. *J Pathol* 2004;203[1]:538–544. Data from some surgical trials[137] and large treatment registries[138] suggest that the rates of local or regional recurrence are significantly lower after mastectomy than after breast-conserving surgery, although there have been no significant differences in overall survival. Metastatic breast cancer can follow the recurrence of an invasive tumor or the development of invasive cancer in the contralateral breast. However, death related to breast cancer within 10 years after the diagnosis of DCIS occurs in only 1% to 2% of all patients, irrespective of whether mastectomy or breast-conserving surgery was performed.[138]

The role of postmastectomy chest wall radiation following mastectomy or skin-sparing mastectomy and close pathologic margins has been debated in the literature but is not presently considered the standard of care. Some studies show an increased risk of chest wall failure in selected cases of high-grade DCIS undergoing mastectomy with pathologic margins <1 mm, leading to a routine recommendation of postmastectomy radiation in these cases.[139] The empiric use of a close or positive margins as a trigger for postmastectomy radiation has been challenged, providing a strong argument against postmastectomy radiation.[140] This retrospective review evaluated the risk of chest wall recurrence following mastectomy, specifically looking at skin-sparing mastectomy and high-risk features of high-grade and close margins. In this series, the overall risk of chest wall recurrence was rare at 1.7% and only 3.3% for high-grade DCIS. Margins <5 mm were not at increased risk. It was concluded that the chest wall failure rate was sufficiently low that a routine recommendation of postmastectomy radiation DCIS with high-risk features was not warranted. Furthermore, a population-based analysis using the Ontario Cancer Registry identified >1,500 women with DCIS who underwent mastectomy without radiotherapy. With a median follow-up of 10 years, the overall rate of chest wall recurrence was 2.3% with no significant difference seen between positive, close (2 mm or less), or negative margins. Univariate and multivariate analysis failed to show a significant effect of age, nuclear grade, necrosis, or multifocality.[141]

Recent interest has surged regarding active surveillance in women with low-risk DCIS. The COMET trial is comparing guideline concordant care which includes surgery +/− radiation therapy and choice of endocrine therapy vs active surveillance with choice of endocrine therapy in women 40 years or older, with a diagnosis of grade I/II DCIS with estrogen and/or progesterone receptors present and lack of comedo necrosis. Primary end point is rate of ipsilateral invasive disease development at 2 years. Two additional trials, LORIS, of the United Kingdom, and LORD sponsored by the EORTC have recently opened for accrual

with similar randomizations.

Breast Conservation for Ductal Carcinoma In Situ

Four prospective randomized studies of excision only versus excision plus breast irradiation for DCIS have been performed with reported results, and all have shown that the rate of local recurrence was reduced with the addition of radiation (Table 58.1). The NSABP B-17 trial[142,143] consisted of 813 patients who were stratified by age (≤49 vs. >49 years), DCIS versus DCIS plus LCIS, method of detection, and whether an axillary dissection was performed. Tumor size was determined by mammogram, gross pathologic measurement, or clinical examination. Of the patients enrolled, 83% had nonpalpable tumors. The 17.5-year rate of local recurrence was 19.8% with radiation and 35.9% without radiation. The average annual incidence rates of ipsilateral noninvasive recurrences and ipsilateral invasive recurrences were reduced with breast irradiation by 47% and 52%, respectively.[144] An analysis of clinical variables showed that microcalcifications extending beyond a maximum dimension >1 cm were associated with an elevated risk of breast recurrence. A central pathology review was performed, including a multivariate analysis of histopathologic variables (Table 58.2). Comedonecrosis in patients treated on NSABP B-24 did not correlate with an increased risk of IBTR; however, comedonecrosis did relate to the risk of DCIS-IBTR. The prognostic value of margin status (free vs. unknown/involved) depended on the treatment group and was greater among those treated with lumpectomy and radiotherapy alone as compared to those that also received tamoxifen.[133,143,144]

TABLE 58.1 Lumpectomy Versus Lumpectomy and Whole-Breast Radiotherapy: Randomized Clinical Trials for Ductal Carcinoma *in Situ*

The EORTC 10853 trial[145,146] randomly allocated 1,010 patients with ≤5 cm DCIS and negative margins to excision versus excision plus breast irradiation. Lesions were nonpalpable in 79% of patients, and the mean maximal tumor diameter was approximately 2 cm. The 15-year rate of local recurrence was 18% for patients treated with radiation, as compared with 31% for patients treated without radiation (*P* <.0001). At a median follow-up of 15.7 years, radiation therapy resulted in risk reduction for both invasive and noninvasive breast relapse of 48%. As with the NSABP B-17 study, a central pathology review was performed.[126,145,146] In a multivariate analysis, factors associated with an increased risk of local recurrence were ≤40 years of age, clinically symptomatic presentation (nipple discharge or palpable mass), intermediate or poorly differentiated DCIS, solid/comedo and cribriform histologic growth pattern, involved or uncertain margins, and treatment by local excision alone. The risk of DCIS recurrence was documented to be less following treatment of clinging/micropapillary DCIS; however, in this group, breast irradiation reduced the rate of invasive recurrence in over 50%. Although early publications suggested a relationship between histologic type and risk of distant metastasis and death, with additional follow-up, no statistically significant relationship is now appreciated.

TABLE 58.2 HAZARD RATIOS FOR INVASIVE IPSILATERAL BREAST TUMOR (I-IBTR) RECURRENCE OR DUCTAL CARCINOMA *IN SITU* (DCIS-IBTR) BASED ON COMEDONECROSIS AND MARGIN STATUS ADAPTED FROM NSABP B-17 AND B-24

Histopathologic Variable	I-IBTR HR (95% CI)	DCIS-IBTR HR (95% CI)

CI, confidence interval; DCIS-IBTR, ductal carcinoma *in situ* in-breast tumor recurrence; HR, hazard ratio; I-IBTR, ipsilateral in-breast tumor recurrence; LRT, lumpectomy + radiotherapy; NSABP, National Surgical Adjuvant Breast and Bowel Project; TAM, tamoxifen.

The EORTC 10853 trial did not allow the identification of an appropriate margin width for treatment with or without radiotherapy because the eligibility criteria did not require reporting of the margin status. Nonetheless, the central review of cases did provide some information regarding the relative importance of surgical margin as related to local failure risk. A recurrence rate of 24% at 4 years was observed in cases with close/involved margins after excision alone. Radiotherapy was not adequate to compensate for involved margins because even with the application of irradiation, the recurrence rate was 20% in this group[147]. These data and others[128,129,131,132] are strongly suggestive that obtaining a microscopic complete excision is essential for optimal local control in breast-conserving therapy for DCIS. Of further note, even in the group of DCIS cases for which margins could be considered optimal (i.e., those patients who underwent a surgical reexcision in which no residual DCIS was found), a 4-year local recurrence rate of 18% was observed when these patients were treated with surgery alone.[126]

The United Kingdom, Australia, and New Zealand (UK/ANZ) DCIS trial was a randomized trial investigating the role of adjuvant radiotherapy.[148,149] With a 2 × 2 factorial protocol design, the aim of this study was to compare excision alone versus excision plus tamoxifen versus excision plus radiotherapy versus excision plus radiotherapy and tamoxifen. Tamoxifen was prescribed at 20 mg per day, and radiotherapy was delivered through whole-breast tangential fields to a total dose of 50 Gy. A boost was not recommended, and elective decision to withhold or provide one of the treatments was permitted. Data have been reported with a median follow-up of 12.7 years. The addition of radiotherapy was demonstrated to reduce the risk of IBTR. Of the 1,030 patients randomized between no radiotherapy versus radiotherapy, ipsilateral IBTR was 19.4% versus 7.1%, respectively ($P < .0001$). The addition of tamoxifen offered no benefit toward overall ipsilateral local control when administered in addition to radiotherapy; however, tamoxifen reduced the ipsilateral recurrence rate of DCIS (but not invasive carcinoma) in the absence of radiotherapy.[148,149]

The Swedish Breast Cancer Group SweDCIS study was a randomized trial

that enrolled 1,067 patients from 1987 to 1999, with 1,046 of these patients followed for a median of 17 years. Patients were randomized between lumpectomy followed by radiotherapy and lumpectomy only for treatment of DCIS.[150] Following sector resection, microscopically clear resection margins were not required, and 50 Gy in 25 fractions to the whole breast was delivered in the majority of patients. A split course, 54 Gy in 2 Gy fractions, delivered in two treatment series separated by a 2-week break was allowed. No boost dose was delivered. The in-breast failure risk reduction for the addition of radiotherapy was 12% at 20 years (95% confidence interval [CI] 6.5% to 17.7%) with a relative risk reduction of 37.5% (95% CI 0.30 to 0.54). Detailed analysis did not identify any patient or tumor characteristic subgroups, which did not benefit from the addition of postoperative radiotherapy. Additionally, despite combining factors entailing a low risk of recurrence without radiotherapy, a low-risk group without significant benefit from the addition of radiotherapy could not be identified.

A meta-analysis was completed utilizing the individual patient data from each of the four randomized trials discussed above, and an overview of results was reported by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG).[151] With a total of 3,729 women eligible for analysis, it was demonstrated that radiotherapy reduced the absolute 10-year risk of any ipsilateral breast event (recurrent DCIS or invasive disease) by 15.2% (standard error [SE] 1.6%, 12.9% vs. 28.1%, 2 $P < .00001$). This analysis further establishes strong and consistent evidence that the addition of radiotherapy following breast-conserving surgery for DCIS approximately reduces the risk of IBTR by 50%. Subgroup analyses from these randomized trials have demonstrated that the absolute benefit of radiotherapy is greater in women at increased risk for tumor recurrence, such as women with involved surgical margins (identified on retrospective pathologic review), younger women, and those with tumors that have high-grade or comedonecrotic features.[126,142,143,145,151] However, this meta-analysis confirmed that no matter what the underlying rate of ipsilateral IBTR was within subgroups evaluated, the risk reduction of approximately 50% remained. This was demonstrated across categories defined by patient age, type of excision, use of tamoxifen, method of detection, margin status, tumor focality, and histologic or nuclear grade. There was little impact of radiotherapy on contralateral or distant events, and a difference in the risk of death from breast cancer was not appreciated.

Patient age is an important prognostic variable for local recurrence after

breast conservation for DCIS.[126,132–134] In younger patients, DCIS more frequently contains adverse pathologic features and extends over a greater distance in the breast than in older patients.[134] In series with adequate follow-up, younger patients treated with lumpectomy and radiation therapy had a significantly higher rate of local recurrence than older patients, especially invasive local recurrences.[134] Some studies have suggested that careful attention to margin status and excising larger volumes of tissue can reduce this difference substantially.[132,134] No available data show that younger patients have better long-term cancer-free survival rates if treated by mastectomy rather than lumpectomy and radiation therapy. Successful treatment of younger patients with DCIS with lumpectomy and radiation therapy requires careful attention to patient evaluation, selection, and surgical technique. When this is done, age at diagnosis should not be a contraindication to breast-conserving therapy.

The randomized trials discussed were designed and conducted over a decade ago. Since then, imaging technology, surgical techniques, and pathologic evaluation have continued to advance, suggesting that the patients encountered with DCIS presently may represent a group a patients with smaller, less extensive disease that is better surgically cleared as compared to those included in the randomized trials. As a result, the value of adjuvant radiotherapy has been hypothesized to be lower than indicated in previous trials. However, it should be noted that the tumor characteristics of those included in the randomized trials represented limited and mammographically detected disease. Despite this, several recent studies have attempted to identify and treat patients with highly selected favorable tumor characteristics with excision alone (i.e., without whole-breast irradiation) and report 10-year local failure rates of 3% to 25%.[131,136] One of these studies[129] has proposed a scoring system using histopathologic features including tumor size, grade, and margin width in an attempt to stratify patients according to local failure risk after excision plus or minus whole-breast irradiation. Each variable was assigned a score of 1 to 3, and the sum total defined the Van Nuys Prognostic Index. Although appealingly simple, this schema[129] is drawn from the retrospective analysis of a patient cohort in which there existed several methodologic shortcomings, and it has not been independently validated.[152]

The Radiation Oncology Group (RTOG) published the results of a prospective randomized trial of 585 women who were defined as having good-risk DCIS (low or intermediate grade, <2.5 cm size primary, and ≥ 3 mm margins) treated with adjuvant whole breast irradiation (50.4 Gy in 28 fractions

and later amended to allow 42.5Gy in 16 fractions without a boost) or observation. The use of tamoxifen was optional. The study was closed early because of low accrual (expected accrual 1,790). With a median follow up of >7 years, the rate of local failure was 6.7% and 0.9% for the observation and radiation groups, respectively. Grade 1 to 2 acute toxicity was higher in the XRT arm, 76% versus 30%, with no difference in grade 3 to 4 toxicity in either arm. Despite the lower than expected accrual in this good-risk population, adjuvant XRT improved local failure. Additional follow up is needed to determine long term benefits.[153]

Wong et al.[154] performed a prospective study that attempted to identify patients with “low-risk” DCIS who can be spared whole-breast radiation therapy. This trial enrolled 158 patients with lesions that were mostly grade 1 or 2 and with a mammographic extent of ≤2.5 cm who were treated with wide excision, with final margins ≥1 cm or a re-excision without residual DCIS. Tamoxifen was not permitted. The median age was 51 years. The most recent data, with a median follow-up of 11 years,[155] reported an estimated annual local recurrence percentage rate of 1.9%. Of those with an IBTR, 68% had a DCIS recurrence and 32% experienced recurrence with invasive carcinoma. This data provides prospective evidence that despite margins of >1 cm, the local recurrence rate is substantial even in patients with small grade 1 or 2 DCIS following treatment with wide excision alone.

In an intergroup trial run by the Eastern Cooperative Oncology Group and North Central Cancer Treatment Group, wide excision only in a population of conservatively selected patients with DCIS was evaluated.[156,157] Eligibility included patients with low- or intermediate-grade DCIS measuring ≤2.5 cm (cohort 1, n = 561) or high-grade DCIS measuring ≤1 cm (cohort 2, n = 104). Microscopic margin width was required to be ≥3 mm with no residual calcifications on postoperative mammograms. The majority of these patients had a more favorable profile than that reflected by the eligibility criteria with median lesion size of 6 mm and 7 mm for cohorts 1 and 2, respectively, and the majority having margins >5 mm. The use of tamoxifen was optional after the year 2000, potentially impacting recurrence rates and/or time to recurrence intervals (30% and 24% for cohorts 1 and 2 respectively). With a median follow-up of 12.3 years, the 12-year rates of ipsilateral in-breast failure and invasive in-breast failure were 14.4% and 7.5%, respectively, for the low-inermediate group and 24.6% and 13.4%, respectively, for the high grade group. Whether this identifies the low-intermediate grade group as a group that could avoid radiotherapy

remains to be demonstrated, as this may represent a group with a delayed IBTR pattern, as no plateau was identified. The NSABP and Radiation Therapy Oncology Group have jointly launched a phase III accelerated partial-breast irradiation trial which randomly allocates patients between standard whole-breast irradiation following lumpectomy versus accelerated partial-breast irradiation to determine if in-breast control rates are comparable. As the in-breast failure patterns for DCIS suggest that treatment directed to the primary lesion plus a 2-cm margin should achieve local control rates that equate to whole-breast treatment approaches, patients with pure DCIS or DCIS and LCIS are eligible for stratified randomization. This trial is now closed and results are pending.

Follow-Up and Management of Recurrence

Ipsilateral tumor recurrences in patients with DCIS are usually detected on surveillance mammography, although one-quarter may be detected on the basis of changes on physical examination of the breast or chest wall.[158,159] For this reason, patients should be scheduled for a baseline mammogram 6 to 12 months after initial therapy and at least annually thereafter. Distant breast cancer metastases in the absence of regional recurrence are unusual. Local recurrences after breast-conserving surgery and radiotherapy are generally treated with mastectomy. Selected patients with local recurrences who have not previously received radiotherapy may be candidates for local excision and radiotherapy. The clinical outcome of ipsilateral tumor recurrence is governed by the nature of the recurrence. Patients with recurrent DCIS have an excellent prognosis, with <1% risk of further recurrence after salvage mastectomy. Patients with invasive recurrence after breast-conserving surgery for DCIS have a prognosis similar to those with early-stage breast cancer, with a 15% to 20% risk of metastatic recurrence at 8 years.[159]

The Role of Tamoxifen and Aromatase Inhibitors for Ductal Carcinoma In Situ

The use of tamoxifen in the treatment of DCIS has been studied; however, results have been conflicting. Therefore, its role is not yet clearly defined. The role ofHer2Neu targeted treatment is presently being investigated in the NSABP B-43 trial. In this prospective randomized trial, patients with Her2Neu-positive DCIS are treated with postlumpectomy radiotherapy and randomized between Herceptin or observation. The NSABP B-24 trial[133,144] compared excision plus radiotherapy to excision, radiotherapy, and tamoxifen. Patients who received

tamoxifen had a decreased incidence of breast cancer events (invasive or noninvasive ipsilateral or contralateral breast cancer) compared with patients who did not receive tamoxifen. With a median follow-up of 163 months, the addition of tamoxifen translated into a significant 32% reduction in invasive IBTR (9.0% vs. 6.6%, *P* = .025), a nonsignificant 16% reduction in DCIS-IBTR (7.6% vs. 6.7%, *P* = .33), and a 32% reduction in contralateral breast cancer (8.1% vs. 4.9%, *P* = .023); however, no survival benefit was found (Table 58.3). Positive tumor margins were significantly associated with breast recurrence. The 15-year cumulative incidence of invasive IBTR was reduced from 17.4% in patients with positive margins to 11.5% with the addition of tamoxifen. In those with tumor-free margins, tamoxifen did not improve in-breast disease control with a 7.4% and 7.5% incidence of invasive IBTR with and without tamoxifen, respectively.

In contrast to the findings of the NSABP B-24 trial, the UK/ANZ DCIS trial found that tamoxifen had no effect in reducing local recurrence rate when combined with whole-breast radiation therapy (Table 58.3). When used as single agent without radiation therapy after lumpectomy, tamoxifen had no effect on the incidence of invasive recurrence but did show a statistically significant reduction in the risk of DCIS recurrence (10.4% vs. 7.4%, *P* = .04).[148,149] As such, the role of tamoxifen for DCIS in the absence of whole-breast radiotherapy remains to be defined.

The role of tamoxifen versus anastrazole (an aromatase inhibitor) in the management of DCIS has been evaluated in the NSABP B-35 trial. Eligibility included postmenopausal women with DCIS, with or without associated LCIS with estrogen or progesterone positive receptors who underwent lumpectomy with clear margins and adjuvant whole breast radiation therapy. Patients were stratified by age <60 versus ≥60 years. A total of 3,104 women were enrolled with 3,084 women having a median follow up of 9 years. Breast cancer-free interval improved with the use of anastrazole, 7.8% versus 5.7%, with no significant difference in regard to the rates of in-breast recurrence, contralateral breast cancer, or distant disease. Improvement in disease-free survival was reported in women under the age of 60 years with the use of anastrazole compared to the tamoxifen arm, 89.8% versus 85.7%. Except for higher rates of thrombosis in the tamoxifen arm, no significant difference with regard to toxicity or treatment adherence was seen.[160] Because DCIS is a precursor to invasive breast cancer and shares many biologic features of invasive carcinoma, it is increasingly recognized as a target for preventive measures. In the largest trials

of the prevention of primary breast cancer among women at high risk for breast cancer by virtue of age, family history, or prior benign breast disease, tamoxifen reduced the risk of DCIS by 50% to 70%.[40,161]

TABLE 58.3 Tamoxifen Versus No Tamoxifen: Randomized Clinical Trials for Ductal Carcinoma *in Situ*

Trial Group	Number of Patients	Follow-Up	Local Recurrence (Cumulative %) DCIS + Invasive Carcinoma		
			− Tam	+ Tam	*P* Value
NSABP B-24	1,798	13.6-y median	16.6	13.2	—
UK/ANZ	1,053	12.7-y median	17.0	13.2	.04
No radiotherapy	523		2.6	2.4	.8

A Decision Tree for Ductal Carcinoma *In Situ*

The management of DCIS requires the coordinated, multidisciplinary interaction of radiologists, surgeons, pathologists, and oncologists. Patients are first assessed to determine if they are candidates for breast-conserving surgery. Women with multicentric DCIS, as defined by the presence of two or more tumors in separate quadrants of the breast, and those with extensive or diffuse DCIS or suspicious-appearing microcalcifications throughout the breast are candidates for mastectomy, as are women in whom negative margins or acceptable cosmesis cannot be achieved with the use of breast-conserving surgery. Some women may prefer mastectomy to breast conservation to minimize the chance of ipsilateral recurrence or for other reasons.

Patients deemed to be appropriate candidates for breast conservation require complete surgical excision of the affected area. The extent of DCIS in the breast and the existing margin determine the likelihood of identifying residual disease on re-excision. Nearly half of patients with margins <1 mm have residual DCIS on re-excision.[38]

Neither dissection of axillary lymph nodes nor mapping of sentinel lymph nodes is routinely warranted in patients with DCIS because of the very low incidence of axillary metastases.[162] Three to 13% of patients with DCIS, and a slightly greater percentage with DCIS and microinvasion, have isolated tumor

cells in sentinel axillary lymph nodes.[163] The prognostic significance of these cells is not clear. Clinical experience suggests that patients have a much better outcome than would be predicted by such rates of nodal metastases, and in most instances these represent micrometastases of unclear metastatic potential. However, sentinel lymph node mapping may be used in selected patients with a higher likelihood of occult invasive cancer—those with extensive, high-grade DCIS or palpable masses—and those undergoing mastectomy as sentinel node mapping cannot be performed afterward if an invasive tumor is identified.[164]

After breast-conserving surgery, radiotherapy is administered using tangential fields to the whole breast with a standard dose of 45 to 50 Gy delivered in daily fractions of 180 to 200 cGy. On the basis of extrapolation from data on the treatment of invasive breast cancer,[165] a radiation boost to the tumor bed may be added to whole-breast treatment, particularly for women with close surgical margins, although the benefit of a boost in the management of DCIS is not established. There is no role for postmastectomy or nodal irradiation in the treatment of DCIS.

It is not yet possible to prospectively identify women who are at sufficiently low risk that radiotherapy may not be of some clinical advantage in preventing recurrences. After discussing the various options, patients may elect not to receive radiation treatment; however, they must understand and accept the increased risk of recurrence that this choice probably entails.[166]

In summary, despite considerable advances in our clinical knowledge base, the answer to the question “when should radiotherapy be used for DCIS?” remains complex and surrounded by considerable controversy. Two fundamental considerations must be emphasized:

- A primary goal of breast-conserving therapy for DCIS is to achieve the best possible cosmetic outcome. Attempts to obtain wide surgical margins through deforming, large-volume breast excisions represent cosmetic failures and defeat the purpose of breast conservation.
- Breast irradiation reduces the risk of subsequent invasive or noninvasive carcinoma in the treated breast and thus reduces the risk of the ultimate cosmetic failure—mastectomy.

According to prospectively randomized trials of breast-conserving therapy for DCIS, radiotherapy reduces subsequent breast recurrence in all patient groups irrespective of prognostic risk factors. That is not to say, however, that radiotherapy must be used for all patients with DCIS. In all cases, a realistic and

balanced discussion of the relative risks and benefits of treatment options should be presented to the patient. Reasonable estimates of breast recurrence during the ensuing decade with or without radiotherapy are available based on level I evidence from prospective clinical trials.

CHAPTER 59

Breast Cancer: Early Stage

Sharad Goyal, Thomas Buchholz, and Bruce G. Haffty

Radiation therapy (RT) plays an essential and critical role in the management of breast cancer. In a general radiation oncology practice, breast cancer typically constitutes approximately 25% of total patient caseload. This chapter will provide an overview of general concepts in breast cancer and will then focus on management of early-stage invasive disease. The management of early-stage disease by breast conservation is a major focus of this chapter. Postmastectomy radiation, as well as advanced invasive disease and locoregional recurrence, will be covered in the advanced disease chapter that follows. Management of ductal carcinoma *in situ* (DCIS) and lobular carcinoma *in situ* (LCIS) are the focus of the previous chapter.

ANATOMY

The female breast lies on the anterior chest wall superficial to the pectoralis major muscle.[1] The breast can extend from the midline to near the midaxillary line and cranial caudally from the second anterior rib to the sixth anterior rib. The upper outer quadrant of the breast extends into the region of the low axilla and is frequently referred to as the axillary tail of Spence. This anatomical feature results in the upper outer quadrant of the breast containing a greater percentage of total breast tissue compared with the other quadrants, and, therefore, a greater percentage of breast cancers occur in this anatomical location.

The breast is made up of the mammary gland, fat, blood vessels, nerves, and lymphatics[2] (Fig. 59.1). The surface of the breast has deep attachments of fibrous septa, called Cooper ligaments, which run between the superficial fascia (attached to the skin) and the deep fascia (covering the pectoralis major and other muscles of the chest wall). Skin dimpling may be caused by tumors affecting these supporting structures. It is important to realize, from a staging

perspective, that the chest wall includes the ribs, intercostal muscles, and the serratus anterior muscle, but not the pectoral muscles.

The breast parenchyma is composed of lobules and ducts. The function of the lobules is to produce milk, and the function of the ducts is to transport lactation products to the nipple. The peripheral ducts converge into major lactiferous ducts, which then communicate with the nipple–areola complex. Most breast cancers develop at the interface between the ductal system and the lobules, a region called the terminal ductal lobular unit.

The breast parenchyma is intermixed with connective tissue, which has a rich vascular and lymphatic network. Mammary gland lymphatics begin in the interlobular or prelobular spaces, follow the ducts, and end in the subareolar network of lymphatics of the skin. The predominant lymphatic drainage of the breast is to axillary lymph nodes, which is commonly described in three levels, based on the relation of the lymph node regions to the pectoralis minor muscle (Fig. 59.2). The level I axilla is caudal and lateral to the muscle, level II is beneath the muscle, and level III (also known as the infraclavicular region) is cranial and medial to the muscle. A standard axillary lymph node dissection (ALND) resects the tissue and lymph nodes within levels I and II. It is very unusual to have involvement of level III of the axilla without disease in level I or II. The axillary lymph nodes continue underneath the clavicle to become the supraclavicular lymph nodes, which can be involved in locally advanced breast cancers.

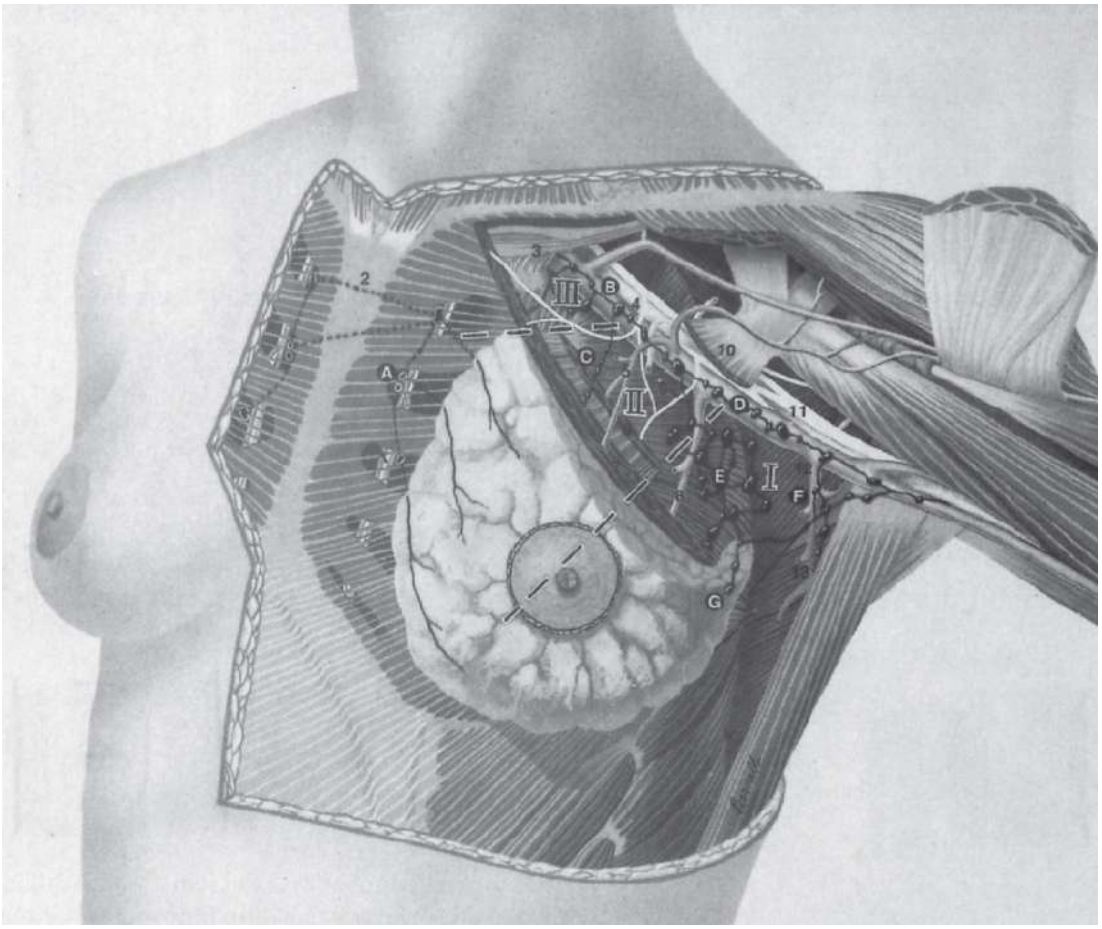

FIGURE 59.1. Anatomy of the breast and lymphatic drainage. (From Osborne MP. Breast development and anatomy. In: Harris JR, Hellman S, Henderson IC, et al., eds. *Breast diseases*. Philadelphia, PA: JB Lippincott, 1987:1–14. With permission.)

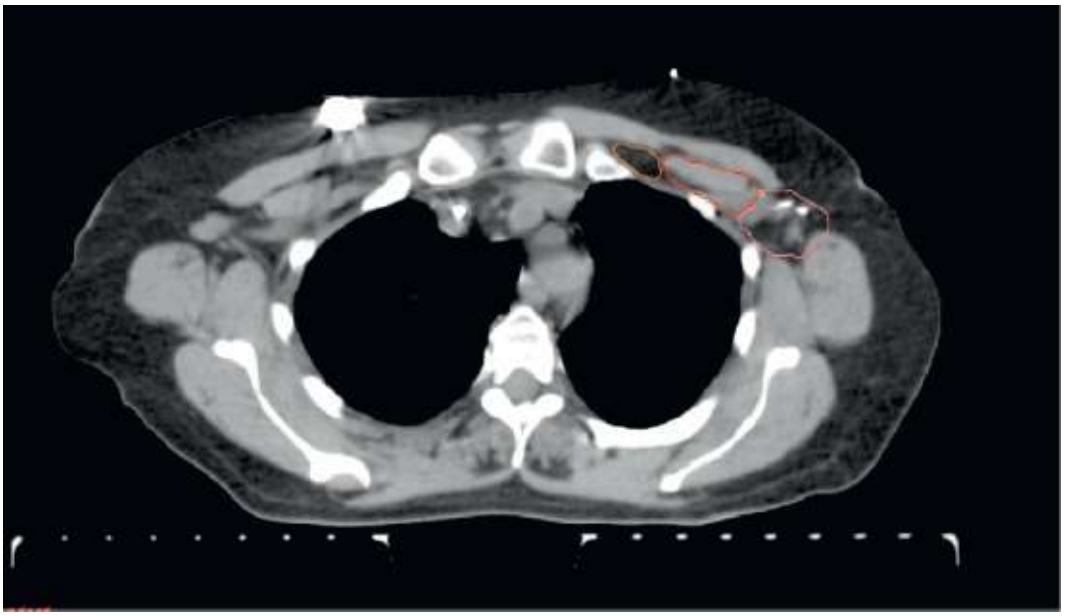

FIGURE 59.2. Location of the three levels of axillary lymph nodes (Level 1 – *pink*;

Level 2 – *red*; Level 3 – *orange*).

Lymphatics can also drain directly into the internal mammary lymph node chain (IMC), which are intrathoracic structures located in the parasternal space. Although these nodes are not usually visualized on computed tomography (CT), the anatomical region of the IMC can be determined by the internal mammary artery and vein, which are easily visualized by CT (Fig. 59.3) and usually lie 3 to 4 cm lateral to midline. When breast cancer involves the IMC, the majority of patients will have disease that is limited to lymph nodes in the first three interspaces. Regardless of location in the breast, the axilla is the most common site of lymphatic involvement. However, breast cancers that develop in the medial, central, or lower breast more commonly drain to the IMC (in addition to the axilla) than do those occurring in the lateral and upper quadrants.

The use of lymphoscintigraphy, by injecting technetium-99 radiocolloid into the peritumoral region followed by scintillation scanning, is used now for sentinel lymph node imaging. This technique has helped to delineate primary lymphatic drainage patterns of breast cancer. The distribution of axillary and internal mammary drainage is summarized in Figure 59.4.[3] Even in inner quadrant lesions, axillary drainage is more common than internal mammary drainage. However, internal mammary drainage was present in over 50% of lower inner quadrant lesions.

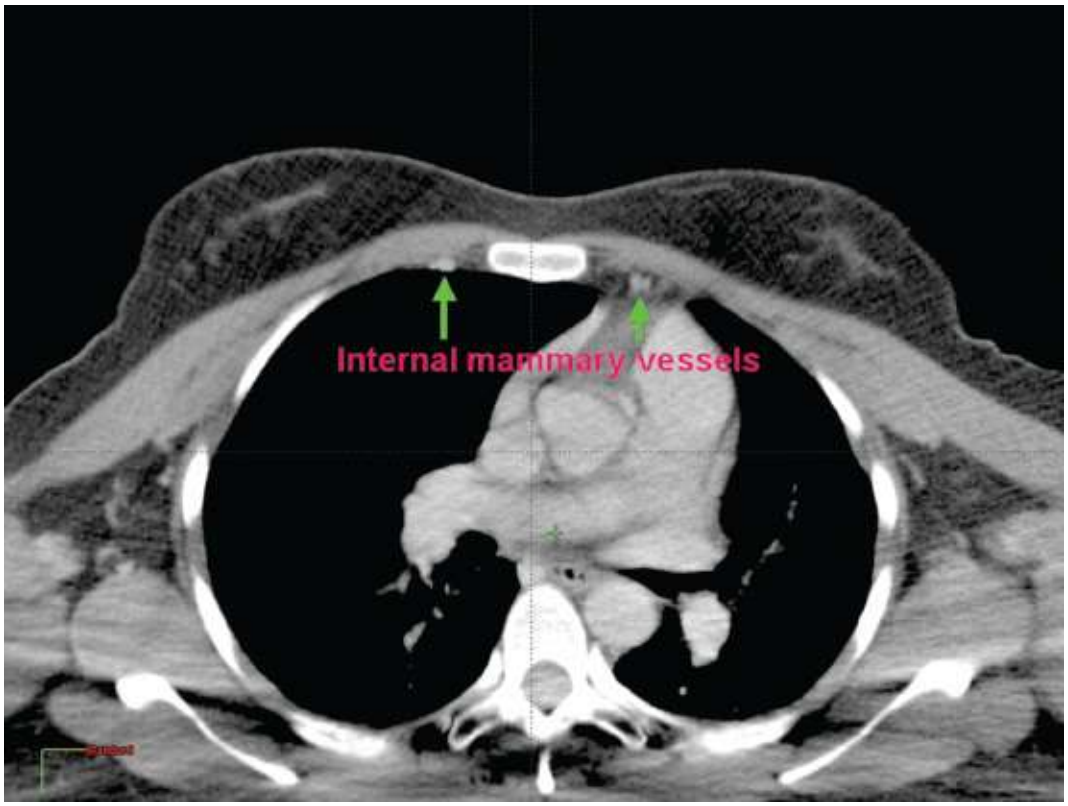

FIGURE 59.3. Treatment planning CT scan of the chest demonstrating the location of the internal mammary vessels, which are typically located approximately 3 to 4 cm lateral to midline and approximately 3 cm deep to the surface. The IMNs are in close proximity to the vessels, with the most critical nodes being located in the first three intercostal spaces.

EPIDEMIOLOGY

Breast cancer is the most frequently diagnosed cancer in women, and it is estimated that there will be 252,710 new cases of invasive breast cancer and 63,410 new cases of *in situ* breast cancers among women in the United States in 2017[4]. Primarily because of increased utilization of screening mammography, breast cancer incidence rates increased rapidly in the 1980s, and breast cancer alone is expected to account for 30% of all new cancer diagnoses in women. It is estimated that 40,610 breast cancer deaths will occur in 2017, with breast cancer ranking second among cancer deaths in women, after lung cancer. In contrast to the significant number of breast cancer cases in women, it is expected that 2,470 cases of breast cancer will be diagnosed in men in 2017, with approximately 460 breast cancer deaths in men. Because of a combination of early detection, increased awareness, and improvements in therapy, death rates from breast cancer actually declined 38% from 1989 to 2014 for female breast cancer. The

decrease in breast cancer mortality is demonstrated in Figure 59.5.

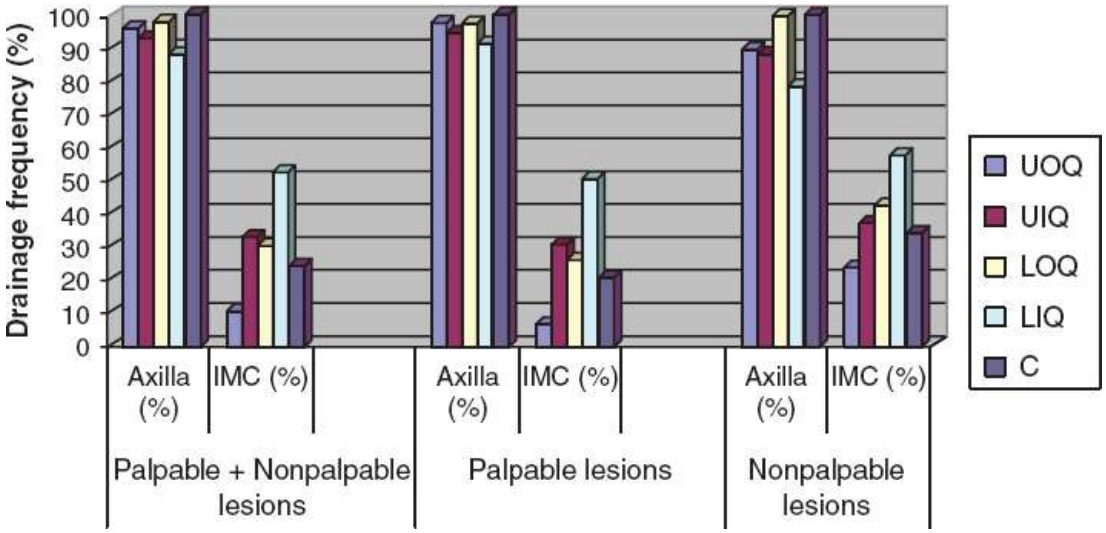

FIGURE 59.4. Distribution of lymphatic drainage of the breast to axillary and internal mammary chains according to the location within the breast. (Data extracted from study of 700 patients undergoing sentinel lymph node mapping by Estourgie SH, Nieweg OE, Olmos RA, et al. Lymphatic drainage patterns from the breast. *Ann Surg* 2004;239[2]:232–237.)

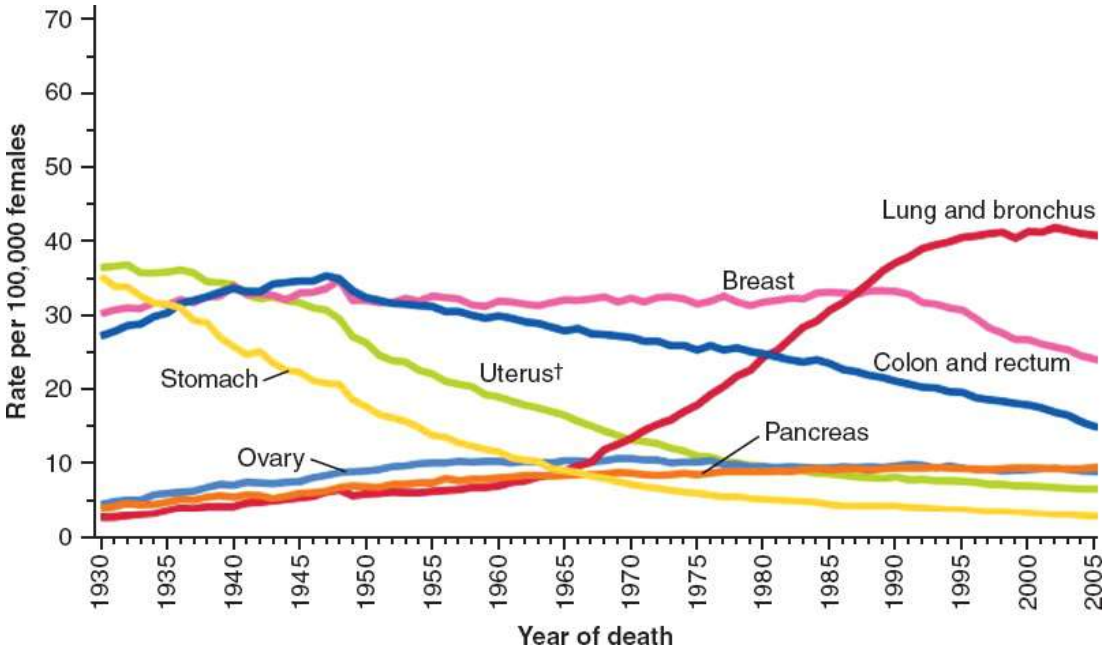

FIGURE 59.5. Age-adjusted cancer death rates for women. Statistics show a recent decrease in breast cancer mortality due to an increase in screening-detected malignancies and improvements in treatment. (From Jemal A, Siegel R, Xu J, et al. Cancer statistics, 2010. *CA Cancer J Clin* 2010;60[5]:277–300. Copyright © 2010 American Cancer Society, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

There is considerable geographic, ethnic, and racial variability in breast cancer incidence. Ethnicity and national origin rank highly as predictors of risk for breast cancer, with up to a 10-fold variation throughout the world.[5] Compared with other well-established risk factors such as age of menarche and menopause, age at first childbirth, and family history, geographic and ethnic variability is quite significant. It is likely that a complex interaction of multiple factors, including genetic, environmental, and socioeconomic, contribute to the wide variability in age-adjusted incidence across populations.

The potential contribution of environmental factors and lifestyle is clearly demonstrated in the increasing incidence of breast cancers among Japanese American women and in trends of increasing incidence of breast cancer in Japan with recent changes in lifestyle. It is well recognized that the relatively low incidence of breast cancer in Asian immigrants to the United States has gradually increased as these immigrants have adapted to Western lifestyles.[6] In Japan, incidence rates have more than doubled from 1960 to 1990. This is likely a result of adaptation of Western lifestyles, including fewer children, later marriage, increasing rates of obesity, and possibly dietary influences.[7]

In the United States, the incidence of breast cancer in white women is higher than in all other populations. Recent data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program report incidence rates of 128.3 cases per 100,000 white women, compared with 125.1 in African American, 89.3 in Asian or Pacific Islanders, 91.7 in Hispanics, and 98.1 in Native Americans or Alaskan Natives[4].

Although incidence is slightly lower in African American women, the age of onset is younger and African American women are more likely to be diagnosed at a more advanced stage. Several studies have reported an earlier onset of breast cancer in African American, compared with white women, by approximately 10 years; other studies have indicated that after correcting for stage, African American women have more aggressive biology and a poorer overall prognosis.[8,9]

Risk Factors

Table 59.1 summarizes the major risk factors associated with development of breast cancer. With the exception of female gender, increasing age is the most consistent and significant risk factor, with most populations demonstrating increasing incidence rates with age. Other risk factors include personal history and family history of breast cancer, nulliparity or late age at first childbirth, early

menarche and late menopause, prior breast biopsy with hyperplasia or atypical hyperplasia, high breast tissue density, radiation exposure at a young age, alcohol consumption, and use of postmenopausal hormone therapy. Some of the national origin or ethnicity variability discussed above may be explained in part by differences in established risk factors, such as age of menarche, parity, and age at first childbirth. However, these factors explain only part of the variability observed in national origin, indicating underlying genetic, environmental, and dietary factors are likely to contribute to the differences in the worldwide incidence of breast cancer.[10] Breast-feeding, physical activity, and maintaining a healthy body weight have been demonstrated in various studies to be associated with a lower risk of breast cancer.[10]

Age

The risk of breast cancer increases exponentially up to the age of menopause, at which time the rate of increase in the risk slows significantly. After the age of 80, the incidence of breast cancer begins to show a slight decline. For women in their late 30s, the annual increase in risk of developing breast cancer is approximately 0.07% per year. This increases to 0.44% per year for women in their late 70s. Although these percentages may seem low, they represent only the risk for a given year; the lifetime risk is a summation of the annual breast cancer risks. Because younger women have a longer life expectancy than do older women, younger women have a greater lifetime risk. Only 1.9% of women develop breast cancer before the age of 50, whereas 2.3% of women develop breast cancer between the ages of 50 and 59, 3.5% of women develop breast cancer between the ages of 60 and 69, and 6.8% of women develop breast cancer over the age of 70.[11]

Childbearing/Parity/Breast-Feeding

The protective effect of childbearing at younger ages on breast cancer risk is well established. In a worldwide case–control study, MacMahon et al.[5,12] demonstrated a nearly linear relation between relative risk (RR) of breast cancer and age at first birth, with women aged 20 to 25 having nearly a 50% reduction in the RR of breast cancer compared with nulliparous women. Interestingly, for women whose first childbirth occurred over age 35, the risk appears greater than that for nulliparous women. Data on the effect of breast-feeding are not as strong as the data on age at first childbirth, but they do suggest a protective effect. The Oxford Collaborative Group conducted an analysis of 47 studies evaluating

breast-feeding and breast cancer risk and reported a decrease in RR of breast cancer by 4.3% for each 12 months of breast-feeding.[13]

TABLE 59.1 RISK FACTORS FOR BREAST CANCER IN WOMEN

Risk Factors	Category at Risk	Comparison Category
Established Risk Factors		
Older age	Older than 50	Younger than 50
Country of residence	North America or Northern Europe	Asia or Africa
Germline mutation	With *BRCA1* or *BRCA2* mutations	Without *BRCA1* or *BRCA2* mutations
Personal history of breast cancer	With history of invasive breast carcinoma	No history of invasive breast carcinoma
High radiation exposure to chest area	With high radiation exposure to chest	Without radiation exposure
Atypical hyperplasia in breast biopsy	With atypical hyperplasia	Without hyperplasia
Cytologic findings (fine needle aspiration; nipple aspiration fluid)	Proliferation with atypia	No abnormality detected
Family history of breast cancer	With one or more close relatives with breast cancer	No close relatives with breast cancer
Early menarche	Menarche before age 12	Menarche after age 14
Late menopause	Menopause after age 55	Menopause before age 55
Older age at 1st full-term birth	Older than 30 years when first child was born	Younger than 20 years when first child was born
Not having children	Without children	With one or more children
Using menopausal hormone therapy	With hormone treatment after menopause	Without hormone treatment after menopause
Obesity after menopause	Obese after menopause	Not obese after menopause
Other Reported Risk Factors		
Using birth control pills	Current use	None
Tall height	Taller than 5 ft 9 inches	Shorter than 5 ft 3 inches
Regular alcohol consumption	Regularly consume alcoholic beverages	No alcoholic beverages consumption
Breast-feeding	None	Longer than 1 year
Postmenopausal body mass index (BMI)	Higher BMI	Lower BMI
Jewish heritage	Yes	No
Possible Risk		
High-density breasts on	With high-density	With low-density

mammograms	mammograms	mammograms
High socioeconomic position	Have high socioeconomic position	Have low socioeconomic position
Physical activity	Lower	>3 h/wk
Dietary factors	High fat, low fiber	Low fat, high fiber

Ovarian Function

The relation between ovarian function and breast cancer risk has long been recognized, with long menstrual history (early menarche and late menopause) contributing significantly to breast cancer risk. In experimental models and observational studies, removal of the ovaries reduces the risk of breast cancer.[5] Women with surgically induced menopause have been shown to have significantly reduced risks of breast cancer compared with women whose menopause occurred naturally. In comparison with women whose menopause occurs between the ages of 45 and 54 (RR = 1), women with early menopause before age 45 have a RR of breast cancer of 0.73 and women with late menopause at age 55 or older have a RR of 1.48. The data on early onset of menses and its association with breast cancer risk are also well established.[5]

Exogenous Hormone

The risk of breast cancer associated with hormonal therapy has been controversial. A collaborative meta-analysis from 51 epidemiologic studies of over 150,000 women did show an increased RR of 1.35 for current or recent users of hormonal replacement therapy.[14] The authors reported that postmenopausal hormone replacement therapy increased the annual RR of developing breast cancer by 2.3% for each year of hormonal therapy. A randomized trial of postmenopausal hormone therapy from the Women's Health Initiative Study comparing estrogen and progestin with placebo was closed prematurely, demonstrating a 24% increase in breast cancer, coronary heart disease, stroke, and pulmonary emboli. This study of 46,000 women reported that the combined use of estrogen and progesterone increased the RR of breast cancer 8% compared with the risk in nonusers, whereas the use of estrogen alone increased the RR only 1%.[15] After publication of this study, a dramatic decrease of almost 7% between 2002 and 2003 was primarily attributed to the reduction in the use of hormone replacement therapy. Since then, breast cancer incidence rates have been generally stable.[16] Other studies have also demonstrated increased risks of breast cancer with long-term use of hormonal replacement therapy.[17] However, short-term use of hormonal replacement, particularly in

women with severe menopausal symptoms, has not been consistently associated with breast cancer risk. For women who have undergone hysterectomy, it seems that hormone replacement therapy with estrogen alone rather than estrogen and progesterone has a minimal effect on breast cancer risk. For women who have not undergone hysterectomy and who elect to be treated with hormone replacement therapy, combined estrogen and progesterone remains the standard for hormone replacement therapy to avoid the risk of endometrial cancer that is associated with unopposed estrogen replacement.[17]

The use of oral contraceptives has not been consistently shown to increase the risk of breast cancer. There is some evidence that use of oral contraceptives for more than 4 years prior to first pregnancy increases the risk of breast cancer. Other studies, however, have not demonstrated increased risks of breast cancer, even with long-term exposures of more than 15 years.[18,19]

Family History

The increased risk of breast cancer as a function of family history is well established. For women with a second-degree relative (aunt, grandmother) with breast cancer, the risk is about 1.5, and for women with a history in first-degree relatives (mother or sister), the risk is 1.7 to 2.5.[20] This may be explained in part by inheritance of a genetic condition that predisposes an individual to breast cancer development (e.g., mutations in *BRCA1* or *BRCA2*); shared lifestyle; and inheritance of genes that affect risk factors, such as body habitus and age at menarche. Between 20% and 25% of women diagnosed with breast cancer have a positive family history of the disease, and approximately 10% of women with breast cancer are from families who display an autosomal dominant pattern of breast cancer inheritance.[21] The actual risk that family history conveys depends on the number of relatives affected and their age at diagnosis (having a first-degree relative with premenopausal breast cancer conveys a greater risk than does having a first-degree relative with postmenopausal cancer). Women with one first-degree relative affected by the disease have an increased RR of developing breast cancer two to three times that of women with no family history. Women with two or more first-degree relatives with a diagnosis of breast cancer have a still greater risk, four to six times that of women with no family history.[20]

Women with a strong family history, particularly those with multiple first- and second-degree relatives diagnosed with breast cancer in the premenopausal years, are at risk for carrying mutations in the breast cancer susceptibility genes,

BRCA1 or *BRCA2*. Although these mutations are present in <1% of the population and account for approximately 5% to 10% of all breast cancer cases, women carrying these mutations have a lifetime risk of developing breast cancer of up to 70% to 80%.[21] Genetic counseling or testing should be considered in women at risk for carrying these mutations. Recently, the National Comprehensive Cancer Network (NCCN) published guidelines for genetic testing.[22] In the context of pre- and posttest counseling, the NCCN recommends that genetic testing be offered when:

. The individual has a family history of a known *BRCA1/BRCA2* mutation
. Personal history of breast cancer plus one of the following:

a. Diagnosed age 45 years or younger
b. Diagnosed age ≤50 years with *one or more* close blood relatives with breast cancer at any age, *one or more* close blood relatives with pancreatic cancer, *one or more* close blood relatives with prostate cancer, or an unknown or limited family history. Diagnosed age ≤60 years with a triple negative (TN) breast cancer. Diagnosed at any age with two or more close blood relatives with breast, pancreatic, or prostate cancer at any age, ≥1 close blood relative with breast cancer ≥50 years, ≥1 close blood relative with ovarian cancer, close male blood relative with breast cancer or an individual of ethnicity associated with higher mutation frequency (e.g., Ashkenazi Jewish).

    Personal history of epithelial ovarian/fallopian tube/primary peritoneal cancer, or
c. Personal history of male breast cancer

Personal History of Breast Cancer and History of "Benign" Breast Biopsy

Women with a prior history of breast cancer are at an elevated risk to develop a second contralateral breast cancer.[1] Studies with long-term follow-up have demonstrated a risk of breast cancer in the contralateral breast of approximately 10% to 15%, depending on the patient population and length of follow-up.[23] Patients treated for invasive breast cancer or DCIS have similar risks of developing a contralateral breast cancer, which does not appear to be effected by the type of local therapy for the initial lesion. A recent analysis of the SEER database demonstrated that 4.2% of localized invasive or intraductal **breast cancer** patients surviving at least 3 months developed contralateral breast cancer with the 10- and 20-year actuarial rate of CBC being 6.1% and 12%[24]. The risk

of contralateral breast cancer as a function of prior radiation treatment is discussed in detail later.

Although women with a history of fibrocystic changes have been reported to have an elevated risk of breast cancer, recent evidence suggests that the majority of the elevated risk is due to the smaller proportion of women whose biopsy reveals atypical hyperplasia. Results from the Breast Cancer Detection Demonstration Project, which included over 280,000 women in 29 centers, demonstrated that women with atypical hyperplasia had 4.3 times the breast cancer risk of women without proliferative disease (95% confidence interval [CI], 1.7 to 11.0). In women with proliferative disease lacking atypical hyperplasia, the RR was 1.3 (95% CI, 0.77 to 2.2). In that study, the joint occurrence of family history and atypical hyperplasia had a strong synergistic effect on breast cancer risk.[25]

Radiation Exposure

Exposure to ionizing radiation during or after puberty increases the risk for development of carcinoma of the breast. Land et al.[26,27] reviewed reports on three populations of patients exposed to ionizing radiation by atomic bombings, multiple fluoroscopic examinations for tuberculosis, and multiple examinations for mastitis. They concluded that the risk of radiation-induced cancer of the breast increased approximately linearly with increasing dose and was heavily dependent on age at exposure.

In a study of 31,710 women who had tuberculosis and were examined with repeated fluoroscopic studies, a substantial proportion (26.4%) received doses to the breast of ≥0.1 Gy; the breast cancer risk was greatest among women who had radiation exposure between the ages of 10 and 14 years (RR 4.5 per 0.01 Gy and an additive risk of 6.1 per 104 person-years per 0.01 Gy); there was substantially less excess risk with increasing age at first exposure.[28]

A high risk of solid tumors, especially breast cancer, has been described in women treated with RT at a young age for Hodgkin lymphoma. In a recent study, RRs of breast cancer were defined by radiation dose to the chest (0, 20 ≤40 Gy, or ≥40 Gy). Estimates were from this case–control study conducted within an international population-based cohort of 3,817 female survivors of Hodgkin lymphoma diagnosed at age 30 years or younger. For a survivor who was treated at age 25 years with a chest radiation dose of at least 40 Gy without alkylating agents, estimated cumulative absolute risks of breast cancer by age 35, 45, and 55 years were 1.4% (95% CI, 0.9% to 2.1%), 11.1% (95% CI, 7.4% to 16.3%),

and 29.0% (95% CI, 20.2% to 40.1%), respectively.[29] A reduced volume of radiation fields has also been shown to reduce the breast cancer risk associated with treatment of Hodgkin lymphoma. The current practice of limiting radiation fields to involved nodal regions may help to further reduce the risk of radiation-related breast cancers in Hodgkin's survivors.[30]

Body Mass Index, Physical Activity, and Dietary Factors

The inherent complex interaction between body mass, physical activity, and diet complicates interpretation of epidemiologic studies correlating these factors with breast cancer risk. Body mass index (BMI) has been clearly associated with breast cancer risk in a number of studies, but it appears to influence breast cancer risk predominantly in postmenopausal women. In premenopausal women, most studies have not observed a strong relation between BMI and breast cancer risk. In postmenopausal women, a pooled analysis of prospective studies demonstrated the risk of breast cancer to be 30% higher in postmenopausal women with a BMI over 31 kg/m^2 compared with women with a BMI of 20 kg/m^2.[31] The higher risk of breast cancer with increased BMI in postmenopausal women is likely due to higher estradiol levels associated with increased adipose tissue and increased aromatase, which is involved in the conversion of androgens to estradiol. In postmenopausal women, this is the primary source of estradiol, whereas in premenopausal women, estradiol is predominantly from the ovaries so there is little association with BMI and estradiol levels.

Physical activity can have a significant impact on BMI, so it is sometimes difficult to separate these two effects in interpreting breast cancer risk. A majority of studies, however, have observed a lower risk of breast cancer among women who are more physically active compared with women who are sedentary.

Although it has been suggested that obesity and high intake of meat, dairy products, and fat may increase risk and fiber, fruits and vegetables, and phytoestrogens (soy products) may reduce risk, strong links between diet and breast cancer risk have not been clearly established.[32] Accurate data regarding nutritional factors are difficult to evaluate in most epidemiologic studies. A pooled analysis of eight prospective studies did not conclude a relation between dietary fat intake and breast cancer risk. Similarly, large prospective studies have failed to demonstrate an association between dietary fiber intake and breast cancer risk.[33] Phytoestrogens found in soy products and many cereals, tea, and vegetables may reduce the effects of estrogens. Given the lower incidence of

breast cancer in Asian countries with high soy intake, one might hypothesize a relation between this dietary factor and breast cancer risk. Although animal studies suggest that high soy intake is protective, human studies have not been as conclusive.

Alcohol Consumption

In an analysis by the Oxford Group of 53 epidemiologic studies, including 58,515 women with breast cancer and 95,067 women without breast cancer, women with daily consumption of four or more drinks a day had a 50% higher breast cancer risk.[34] The average consumption of alcohol reported was 6.0 g/day (about half a unit or drink of alcohol per day). Compared with women who reported drinking no alcohol, the RR of breast cancer was 1.32 (1.19 to 1.45; $P <$ .00001) for an intake of 35 to 44 g/day alcohol and 1.46 (1.33 to 1.61; $P <$ .00001) for ≥45 g/day or more of alcohol. The RR of breast cancer increased by 7.1% (95% CI, 5.5 to 8.7%; $P <$ .00001) for each additional drink of alcohol consumed on a daily basis. Chen et al.[35] reported on a prospective observational study of 105,986 women enrolled in the Nurses' Health Study between 1980 and 2008. With 2.4 million person-years of follow-up, 7,690 cases of invasive breast cancer were diagnosed. They found that increasing alcohol consumption was associated with increased breast cancer risk that was statistically significant at levels as low as 3 to 6 drinks per week (RR 1.15; 95% CI, 1.06 to 1.24). Moreover, binge drinking, but not frequency of drinking, was associated with breast cancer risk after controlling for cumulative alcohol intake. They concluded that low levels of alcohol consumption were associated with a small increase in breast cancer risk, with the most consistent measure being cumulative alcohol intake throughout adult life.

Although the relation among physical activity, BMI, and dietary factors may be difficult to separate, it is apparent that maintaining a sound, varied diet; limiting alcohol intake; avoiding obesity, and moderate physical activity are modifiable behaviors that can impact breast cancer risk (as well as other health-related issues) and should be encouraged.

Mammographic Density

There is a large body of evidence suggesting a correlation between mammographic breast density and breast cancer risk.[36–40] The risk of breast cancer associated with the highest category of density has been estimated to be two to six times greater than in the lowest category. Although the causal link

between mammographic density remains poorly understood, breast density is in part attributable to genetic factors.

Determining an Individual's Risk

It is important to consider the combination of risk factors when a generalized risk profile is determined. Gail et al.[41] have used these epidemiologic risk factors to derive a model for predicting an individual's annual and lifetime risks of breast cancer. In the Gail model, an individual's annual risk of breast cancer is based on her present age, number of first-degree relatives with breast cancer, age at first birth, age at menarche, number of breast biopsies, and history of atypical ductal hyperplasia. The use of exogenous hormones is not considered in this model, and many of the other risk factors discussed above are not incorporated into this specific model.

PREVENTION AND GENETIC SCREENING

Approximately 10% of breast cancer patients have familial breast cancer, typically defined as breast cancer showing an autosomal dominant inheritance pattern.[21] During the 1990s, germline mutations in three important tumor suppressor genes—*p53*, *BRCA1*, and *BRCA2*—were discovered in family members of individuals with familial breast cancer.[42–44] All three genes have been shown unequivocally to predispose to breast cancer. A number of genetic conditions associated with increased risk of breast cancer are summarized in Table 59.2.

Mutations in *p53*

Germline mutations in the *p53* gene are very rare and result in Li-Fraumeni syndrome, named after two investigators who made significant contributions to the understanding of this condition.[44] The *p53* gene is one of the most important tumor suppressor genes and has been called the "guardian of the genome" because of its critical role in cellular pathways that recognize and direct a response to DNA injury. One consequence of a germline mutation in *p53* is an increased risk for a variety of cancers, including childhood sarcomas, gynecologic tumors, and breast cancer. Breast cancer is the most common malignancy in patients with Li-Fraumeni syndrome; the lifetime risk is estimated to be 90%.[44]

Mutations in *BRCA1* and *BRCA2*

Studies of patients with familial breast cancer led to the discovery of *BRCA1* in 1995 and *BRCA2* in 1996. Similar to *p53*, both *BRCA1* and *BRCA2* are tumor suppressor genes that contribute to the stability of the genome by mediating the effects of the cellular response to DNA injury. Individuals with a germline mutation in *BRCA1* have a lifetime risk of breast cancer of 65% to 85%. In addition, these individuals have an elevated lifetime risk of ovarian cancer, which may approach 50%. Other types of cancer that develop more frequently in *BRCA1* carriers include colon and prostate cancers. The lifetime risk of breast cancer for women with germline *BRCA2* mutations mirrors that for women with *BRCA1* mutations. *BRCA2* mutation carriers are also at increased risk for ovarian cancer compared with the general population, but their risk is much less than the risk in women with *BRCA1* mutations. *BRCA2* is also associated with male breast cancer and pancreatic cancer. Genetic screening for germline mutations in *BRCA1* and *BRCA2* is now possible. Testing should be performed in centers equipped with genetic counseling programs designed to properly inform individuals of the social, economic, and legal consequences associated with genetic testing. Germline mutations in *BRCA1* and *BRCA2* are rare, occurring in fewer than 7% of patients with breast cancer. Thus, only a minority of breast cancer patients with a family history of the disease would be predicted to carry a mutation in one of these genes. Table 59.3 contains data concerning the probability of carrying a *BRCA1* mutation based on an individual's age at cancer diagnosis, personal cancer history, and family cancer history and whether the individual is of Ashkenazi Jewish descent.[45]

TABLE 59.2 GENES ASSOCIATED WITH HEREDITARY BREAST CANCER

Gene/Syndrome	Approximate Relative Breast Cancer Risk
BRCA1/BRCA2	10–20 times relative risk
P53-Li-Fraumeni	2–6 times relative risk
PTEN Cowden	2–4 times risk
STK11 Peutz-Jeghers	10–15 times risk
ATM (ataxia–telangiectasia)	3–4 times risk
CHEK2	2 times risk
BRIP1–Fanconi anemia	2 times risk
PALB2	2–3 times risk

No definitive data exist on which to base screening recommendations for individuals with a proven germline mutation in a gene predisposing to the

development of breast cancer. The NCCN has published a guideline recommending that individuals with a genetic predisposition undergo breast awareness starting at age 18, annual clinical and self-breast examination starting at age 25, and annual mammography or magnetic resonance imaging (MRI) and semiannual clinical and self-breast examination after age 25.[22] In addition, annual pelvic examinations with transvaginal sonography, color Doppler examinations of the ovaries, and measurement of serum cancer antigen (CA-125) levels can be considered beginning at age 35 to 35 years. For those women aged 35 to 40, a risk-reducing bilateral salpingo-oophorectomy is recommended, with possible short-term hormone replacement therapy.

Breast Cancer Prevention Strategies

Tamoxifen

Understanding of the role of estrogens and progesterones in breast cancer development has led to the development of pharmacologic strategies that could significantly decrease the incidence of breast cancer over the next two decades.

TABLE 59.3 PROBABILITY OF *BRCA1* GERMLINE MUTATIONS IN VARIOUS CLINICAL SCENARIOS

Scenario	Probability
Mother or father proven carrier	50%
40-year-old with breast cancer and a first-degree relative with breast cancer	
Ashkenazi	20%
Non-Ashkenazi	5%
60-year-old with bilateral breast cancer and a first-degree relative with breast cancer	
Ashkenazi	20%
Non-Ashkenazi	5%
30-year-old with breast cancer and a first-degree relative with ovarian cancer	
Ashkenazi	50%
Non-Ashkenazi	20%

Data from Shattuck-Eidens D, Oliphant A, McClure M, et al. *BRCA1* sequence analysis in women at high risk for susceptibility mutations. Risk factor analysis and implications for genetic testing. *JAMA* 1997;278:1242–1250.

Several pharmaceuticals that affect the estrogenic pathways have been studied as chemopreventive agents, but the only agent for which mature data from clinical trials are available is tamoxifen.[46–51] Interest in tamoxifen as a

chemopreventive agent arose after a number of randomized trials designed to test the efficacy of hormonal therapy for invasive breast cancer reported that tamoxifen reduced the incidence of contralateral breast cancer. On the basis of these data, in 1992, the National Surgical Adjuvant Breast and Bowel Project (NSABP) began a randomized, placebo-controlled study (the P-1 trial) to test the efficacy of 5 years of tamoxifen in the prevention of breast cancer.[51] Between 1992 and 1997, 13,388 women with a 1.67% or greater predicted risk of developing breast cancer within 5 years were enrolled in this trial. Risk was assessed using a modification of the Gail model, which permitted enrollment of any woman older than 60 years of age and selected women younger than 60 years with additional risk factors that increased their annual risk to at least that of a 60-year-old. In addition, women with a history of LCIS were included. Women were not allowed to use estrogen replacement therapy during their participation in the trial. The results of the NSABP P-1 trial indicated that tamoxifen reduced the rates of invasive and noninvasive breast cancer by 49% and 50%, respectively. The benefit of tamoxifen was seen in all age groups (≤49 years, 50 to 59 years, ≥60 years). In addition, women with a history of atypical ductal hyperplasia had an 86% risk reduction, and women with a history of LCIS had a 56% risk reduction. Finally, the benefit was seen across all subgroups specified according to family history of breast cancer. Tamoxifen selectively reduced the incidence of estrogen receptor–positive tumors; estrogen receptor–negative tumors developed at an equal rate in the tamoxifen and placebo groups. No evidence was shown of a cardioprotective effect of tamoxifen in this trial, but the number of osteoporosis-related fractures was reduced in the tamoxifen-treated cohort. Tamoxifen increased the risk of developing stage I endometrial cancer (risk ratio of 2.53).

Subsequently, a landmark study was published that compared tamoxifen to raloxifene as a preventative agent in postmenopausal women with breast cancer. Raloxifene, a drug that is primarily used in prevention of osteoporosis, had been shown in prior studies to decrease the incidence of breast cancers. The NSABP study of tamoxifen and raloxifene was a prospective, double-blind, randomized clinical trial.[52] There were 19,747 postmenopausal women of mean age 58.5 years with increased 5-year breast cancer risk. Patients were randomized to oral tamoxifen (20 mg/day) or raloxifene (60 mg/day) for 5 years. There were 163 cases of invasive breast cancer in women assigned to tamoxifen and 168 in those assigned to raloxifene, which was not significantly different between the two arms. The main benefit of raloxifene was in toxicity. There were 36 cases of

uterine cancer with tamoxifen and 23 with raloxifene. No differences were found for other invasive cancer sites, for ischemic heart disease events, or for stroke. Thromboembolic events also occurred less often in the raloxifene group. The number of osteoporotic fractures in the groups was similar, and there were fewer cataract surgeries with raloxifene. There was no difference in the total number of deaths (101 vs. 96 for tamoxifen vs. raloxifene) or in causes of death. It appears from this study that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer and has a lower risk of thromboembolic events. Of note, there were slightly more noninvasive cancers in the raloxifene group, but that was not statistically significant.

A comparison of the tamoxifen P-1, P-2, and other tamoxifen prevention trials is outlined in Table 59.4.[46–50,53,54]

Prophylactic Surgery

An alternative strategy used to prevent breast cancer development is prophylactic surgical intervention. Hartmann et al.[55] analyzed outcomes in women with a family history of breast cancer who underwent bilateral prophylactic mastectomy at the Mayo Clinic between 1960 and 1993. With a median follow-up time of 14 years, only 4 of the 639 treated patients developed breast cancer. According to the Gail model, 37.4 cases of breast cancer would have been expected to develop in this population, so the prophylactic surgery resulted in an 89.5% risk reduction ($P < .001$).[55]

Breast cancer prevention strategies will continue to be a dynamic area of preclinical and clinical research.

NATURAL HISTORY AND ORIGINS

All forms of breast cancer are believed to develop as a consequence of unregulated cell growth and the development of phenotypic changes such as the ability to invade, recruit a new blood supply, and metastasize. These changes in phenotypes are secondary to the development of aberrations in genetic pathways. Some of these aberrations are inherited (germline mutations), whereas others develop during the life of a breast cell (somatic mutations). It is currently believed that most breast cancer is a consequence of a series of somatic mutations. As previously noted, only 20% to 25% of breast cancer patients have a history of breast cancer in a first-degree relative. However, it is possible that some women without a first-degree relative with breast cancer still inherit a genetic background that predisposes to breast cancer. These mutations may be insufficient to cause breast cancer unless accompanied by other mutations and, therefore, would be predicted to have a low penetrance. Historically, it has been much more difficult to discover low-penetrance mutations than to discover germline mutations that result in an autosomal dominant pattern of breast cancer development. However, with newer molecular techniques, such as DNA-array assays, the identification of low-penetrance predisposing mutations may be more feasible.

Left untreated, breast cancer can have a variable clinical course. A classic article by Bloom et al.[56] outlined the natural history of breast cancer patients,

seen between 1805 and 1933, not treated by surgery or irradiation, 250 of whom had a pathologic diagnosis of cancer. There were no patients with stage I disease, 2.4% with stage II, 23% with stage III, and 74% with stage IV. Survival in the untreated group was 3.6% compared with an overall survival of 34% in patients treated with radical or modified radical mastectomy with or without radiation.

Concepts regarding the natural history of breast cancer have undergone great evolution over the past 100 years, with a profound impact on the management of these patients. The Halsted[57] model was based on an orderly progression to the regional lymph nodes and from there to distant metastatic sites. Later, Keynes[58] and Crile et al.[59] suggested that breast cancer is a systemic disease and that extensive surgery to achieve local tumor control was not as important as originally believed. This alternative hypothesis was fully demonstrated in both laboratory and clinical studies by Fisher,[60] who advanced the concept that breast cancer, as a systemic process involving host–tumor interactions, would not show substantial effects on survival with variations in locoregional treatment. A third hypothesis put forward by Hellman[61] considers breast cancer as a heterogeneous disease with a spectrum extending from a tumor that remains localized throughout its course to one that disseminates systemically, even when detected as a small lesion, suggesting that metastases are a function of tumor growth and progression factors.

The most common site of origin of breast cancer is the upper outer quadrant (38.5%), followed by the central area (29%), the upper inner quadrant (14.2%), the lower outer quadrant (8.8%), and the lower inner quadrant (5%).[62] These rates correlate with the amount of breast tissue in the various quadrants. Cancer is somewhat more common in the left than in the right breast and may appear in both breasts simultaneously (1% to 2%). As noted above, women with a history of breast cancer have a 10% to 15% risk of developing a new primary in the contralateral breast.

As the cancer grows, it travels along the ducts, eventually breaking through the basement membrane of the duct, invading adjacent lobules, ducts, fascial strands, and the mammary fat, spreading through the breast lymphatics and into the peripheral lymphatics. The tumor can grow through the wall of blood vessels, spread into the deep lymphatics of the dermis, and eventually produce edema of the skin (*peau d'orange*), which usually indicates that the superficial as well as the deep lymphatics are involved. Skin dimpling can be caused by involvement of Cooper ligament. Ulceration and infiltration of overlying skin, which may develop late in the course of the disease, are usually preceded by

fixation and localized redness of the skin over the tumor and are less frequently seen because of the current emphasis on screening and early diagnosis.[62]

Axillary Spread

A common route of spread of breast carcinoma is first through the axillary lymph nodes, with the incidence increasing with larger tumors. Depending on mode of detection, tumor size, histology, and other clinical or pathologic factors, between 10% and 40% of newly diagnosed stage T1 and T2 breast cancers have pathologic evidence of axillary nodal metastases. Voogd et al.[63] assessed 7,680 patients with documented invasive breast cancer; of 5,125 patients known to have clinically negative lymph nodes who underwent axillary dissection, 1,748 (34%) had positive lymph nodes at pathologic examination. Univariate analysis showed that lymph node metastases were associated with tumors larger than 1 cm ($P = .001$), moderate or poorly differentiated nuclear grade ($P = .005$), high fraction of cells in the growth phase (S phase) of the cell cycle ($P = .041$), presence of lymphatic vascular invasion ($P < .001$), and age younger than 60 years ($P = .01$).

Multiple studies have shown a strong relation between primary tumor size and axillary nodal involvement.[64–68] Even patients with T1a and T1b disease have significant nodal involvement. Mustafa et al.[69] noted an overall frequency of axillary lymph node metastases in T1a and T1b lesions of 16%; integrating age, tumor size, and grade predicted the frequency of nodal metastases. Overall, patients with all three poor prognostic indicators had a 34% incidence of nodal involvement, and those with no poor prognostic factors had a ≤7% probability of nodal metastases. Gann et al.[70] reviewed 18,025 patients with a diagnosis of breast carcinoma from the American College of Surgeons database. On multivariate analysis, the following factors were independently associated with a greater likelihood of one or more positive lymph nodes: larger tumor size, young age, African American or Hispanic race, outer-half tumor location, poor or moderate differentiation, aneuploidy, and infiltrating ductal histologic type.

Although up to 30% to 40% of T1 or T2 clinically node-negative breast cancers may have pathologically involved lymph nodes, data from NSABP-04 suggest that less than half of clinically negative but pathologically positive axilla will experience a clinical relapse in the axilla.[71] In this study, operable breast cancer patients, who were primarily diagnosed with palpable breast tumors in the premammography era, were randomized to one of three arms: simple mastectomy without axillary dissection, simple mastectomy with axillary

dissection, or simple mastectomy with comprehensive chest wall and regional nodal irradiation (RNI). In the arm undergoing axillary dissection, nodal positivity was approximately 40%. Nodal control was excellent (>97%) in this arm as well as in the arm treated with radiation. In the simple mastectomy arm, where no nodal treatment by radiation or dissection was administered, the axillary failure rate was approximately 20%. Assuming equal distribution among the arms, it is presumed the pathologic involvement was approximately 40%, indicating that less than half of those with pathologic involvement eventually failed clinically.

Internal Mammary Spread

Metastases to the internal mammary nodes (IMNs) are correlated with tumor size, are more frequent from medial half and central lesions, and occur more frequently when there is axillary node involvement (Table 59.5).[72] Veronesi et al.[73] found that, among women with tumors larger than 2 cm who were younger than 40 years of age and had positive axillary nodes, there was a 41% risk of having positive IMNs on IMN dissection; the corresponding risk for patients of that age with negative nodes was 16%. Sugg et al.[74] reviewed 286 patients with breast cancer who underwent IMN dissection. Positive IMNs were associated with primary tumor size ($P < .0001$) and the number of positive axillary nodes ($P < .0001$) but not with age or primary tumor location. Patients who had positive IMNs (25% of all patients) had a significantly worse overall 20-year disease-free survival rate than did patients with negative IMNs ($P < .0001$). Clinical failure of the IMNs is extremely rare, despite the evidence of pathologic involvement from these studies. Most studies looking at nodal failure patterns report failure in the internal mammary region of <1%.[75–79]

Supraclavicular Spread

Spread to supraclavicular lymph nodes usually follows involvement in the high axillary lymph nodes or IMNs depending on the location of the primary lesion. Chen et al.[80] reviewed 2,658 patients with invasive breast cancer who underwent surgery and adjuvant therapy. With a median follow-up period of 39 months, supraclavicular lymph node metastasis developed in 113 (4.3%). Young age (≤40 years), tumor size >3 cm, angiolymphatic invasion, negative estrogen-receptor status, and DNA synthetic phase fraction >4% were significant for predicting supraclavicular metastasis on univariate analysis. Three predictive factors were significant after multivariate analysis: high histologic grade, more than four

positive nodes, and axillary level II or III involved nodes. In patients with axillary level I involved nodes and four or fewer positive nodes, the incidence of supraclavicular lymph node metastasis was 4.4%, but if axillary level III was involved, it increased to 15.1%.

TABLE 59.5 Internal Mammary Node Involvement Related to Location of Primary Tumor and to Axillary Node Involvement[a]

	Location of Primary Tumor				
Axillary Involvement	**Upper Inner Quadrant (%)**	**Lower Inner Quadrant (%)**	**Central (%)**	**Upper Outer Quadrant (%)**	**Lower Outer Quadrant (%)**
Axilla not involved	20/143 (14)	2/36 (6)	5/76 (7)	7/170 (4)	2/40 (5)
Axilla involved	47/105 (45)	18/25 (72)	65/140 (46)	47/212 (22)	10/53 (19)
Total	67/248 (27)	20/61 (33)	70/216 (32)	54/382 (14)	12/93 (13)

Clinical failure in the supraclavicular fossa is relatively rare in patients with early-stage breast cancer and is dependent on the degree of axillary involvement. For patients with no or minimal nodal involvement (less than three involved axillary nodes), supraclavicular failure is extremely rare. In an analysis of 691 patients with zero to three nodes involved undergoing breast-conserving surgery and RT to tangential fields only without RNI, Galper et al.[76] reported failure in the supraclavicular fossa in 1.3% of patients.

Several studies have demonstrated that the failure rate in supraclavicular nodes, left untreated, may be as high as 20% in patients with advanced disease or more than four lymph nodes involved.[81–85] In a cohort of 1,031 patients with operable breast cancer treated with mastectomy and level I or II node dissection plus adriamycin-based chemotherapy, but no radiation, Strom et al.[85] reported failure in the supraclavicular fossa was 8% at 10 years. Predictors of supraclavicular failure included four or more involved nodes and gross extranodal extension. In these subgroups, supraclavicular failure ranged from 14% to 19%. Radiation to the supraclavicular fossa in these higher-risk patients results in high local control rates, with isolated supraclavicular failures occurring

in <1% of prophylactically treated nodes.

Systemic Spread

Using monoclonal antibodies to epithelial cytokeratins or tumor-associated cell membrane glycoproteins, carcinoma cells can be detected on cytologic bone marrow (or lymph node) preparations. Braun et al.[86] combined patient data from nine studies involving 4,703 patients with stage I, II, or III breast cancer. Micrometastasis was detected in 30.6% of the patients. With a median follow-up of 5.2 years, patients with bone marrow micrometastasis had larger tumors and tumors with a higher histologic grade and more often had lymph node metastases and hormone receptor–negative tumors, compared with those without bone marrow micrometastasis. The presence of micrometastasis was a significant prognostic factor for poorer overall survival (RR 2.15; $P < .001$), breast cancer–specific survival (RR 2.44; $P < .001$), disease-free survival (RR 2.13), and distant disease-free survival (RR 2.33; $P < .001$ for all outcomes measures). In multivariable analysis, micrometastasis was an independent predictor of a poor outcome.

Local Control and Systemic Metastasis

Patients treated for breast cancer are at risk for locoregional failure, as well as systemic metastasis. It is evident from the available literature that optimizing local control can impact systemic metastasis and survival, and similarly, systemic therapy can impact local control.[87–90] Integration of systemic therapy with radiation will be discussed in detail later, but numerous studies have clearly demonstrated a significant improvement in local control with the use of RT and systemic therapy (both cytotoxic and hormonal) compared with RT without the use of systemic therapy.[90–95] Appropriate integration of both local and systemic treatments through a multidisciplinary approach is thus essential to optimize outcome. Although there is some overlap, prognostic factors for locoregional control and systemic metastasis often differ.

For patients with early-stage invasive breast cancer, even with appropriate systemic therapy, development of metastasis can vary from <5% in women with T1a disease and favorable histology to >40% for women with T2 tumors and pathologically involved lymph nodes. Similarly, locoregional failure rates can vary from <5% to over 40% depending on local treatment and prognostic factors for local failure.[91–94,96–100]

The impact of local control on systemic metastasis in breast cancer as well as

other malignancies has been the subject of considerable debate and controversy. Although the benefits of local control with respect to cosmesis and quality of life are apparent, the independent effect of local control on systemic disease and survival has been questioned. Several studies have identified local control as an independent predictor of disease-free or overall survival.[9,10,12–15,17–21,23,25–97,97–100,100–109] Fisher et al.,[106] in an analysis of patients treated in NSABP protocol B-06, concluded that ipsilateral breast tumor recurrence (IBTR) was a harbinger, but not a cause, of distant metastases. Although mastectomy or breast irradiation after lumpectomy prevented expression of the marker (breast relapse), neither lowered the risk of distant metastases, which was determined by a host of prognostic factors.

More recent meta-analyses, however, have demonstrated a small but significant impact of local control on systemic metastasis and overall survival.[87,88] A meta-analysis of randomized trials by Vinh-Hung and Verschraegen[88] comparing breast-conserving surgery without radiation to breast-conserving surgery with radiation confirms an approximate threefold reduction in local relapse with RT and an 8.6% improvement in mortality in the radiated cohorts.

One of the most convincing and authoritative studies related to this subject is the recent analysis of the Early Breast Cancer Trialists' Collaborative Group (EBCTCG).[87] In this analysis, over 42,000 women were enrolled in 78 randomized trials that compared 24 types of local treatment (radiotherapy vs. no radiotherapy, more vs. less surgery, or more surgery vs. radiotherapy). The EBCTCG attempted to relate the effect on local control to breast cancer mortality by grouping studies into whether the 5-year local relapse risk difference between the two comparisons of local therapy exceeded 10%. In those comparisons in which the difference in 5-year local recurrence risk was <10%, there was no impact on 15-year breast cancer mortality. However, there were 25,000 women enrolled in trials in whom the comparisons involved >10% differences in local control. In those studies, the difference in local recurrence risks at 5 years were 7% versus 26%, and the 15-year mortality risks were 44.6% versus 49.5% ($P < .00001$). Figure 59.6 summarizes the results of this meta-analysis with respect to the impact of radiation on breast cancer mortality both in breast conservation and following mastectomy. An update from the EBCTCG focused on 10,801 women enrolled in 17 randomized trials of radiotherapy versus no radiotherapy after breast-conserving surgery and relates the absolute reduction in 15-year risk of breast cancer death to the absolute reduction in 10-

year recurrence risk.[110] Overall, radiotherapy reduced the 10-year risk of any first recurrence from 35.0% to 19.3% ($P < 00001$) and reduced the 15-year risk of breast cancer death from 25.2% to 21.4% ($P < 0001$). In women with pN+ disease ($n = 1,050$), radiotherapy reduced the 10-year recurrence risk from 63.7% to 42.5% ($P < 00001$) and the 15-year risk of breast cancer death from 51.3% to 42.8% ($P = 01$). Overall, about one breast cancer death was avoided by year 15 for every four recurrences avoided by year 10.

CLINICAL PRESENTATION

The majority of patients with T1 or T2 breast cancers present with a painless or slightly tender breast mass or have an abnormal screening mammogram. Patients with more advanced tumors may have breast tenderness, skin changes, bloody nipple discharge, or occasionally change in the shape and size of the breast. Rarely, patients may present with axillary lymphadenopathy or even distant metastasis. As noted previously, however, depending on tumor size, method of detection, and pathologic factors associated with the primary tumor, up to 30% to 40% of women with a clinically negative axilla may harbor subclinical pathologically involved axillary nodes.

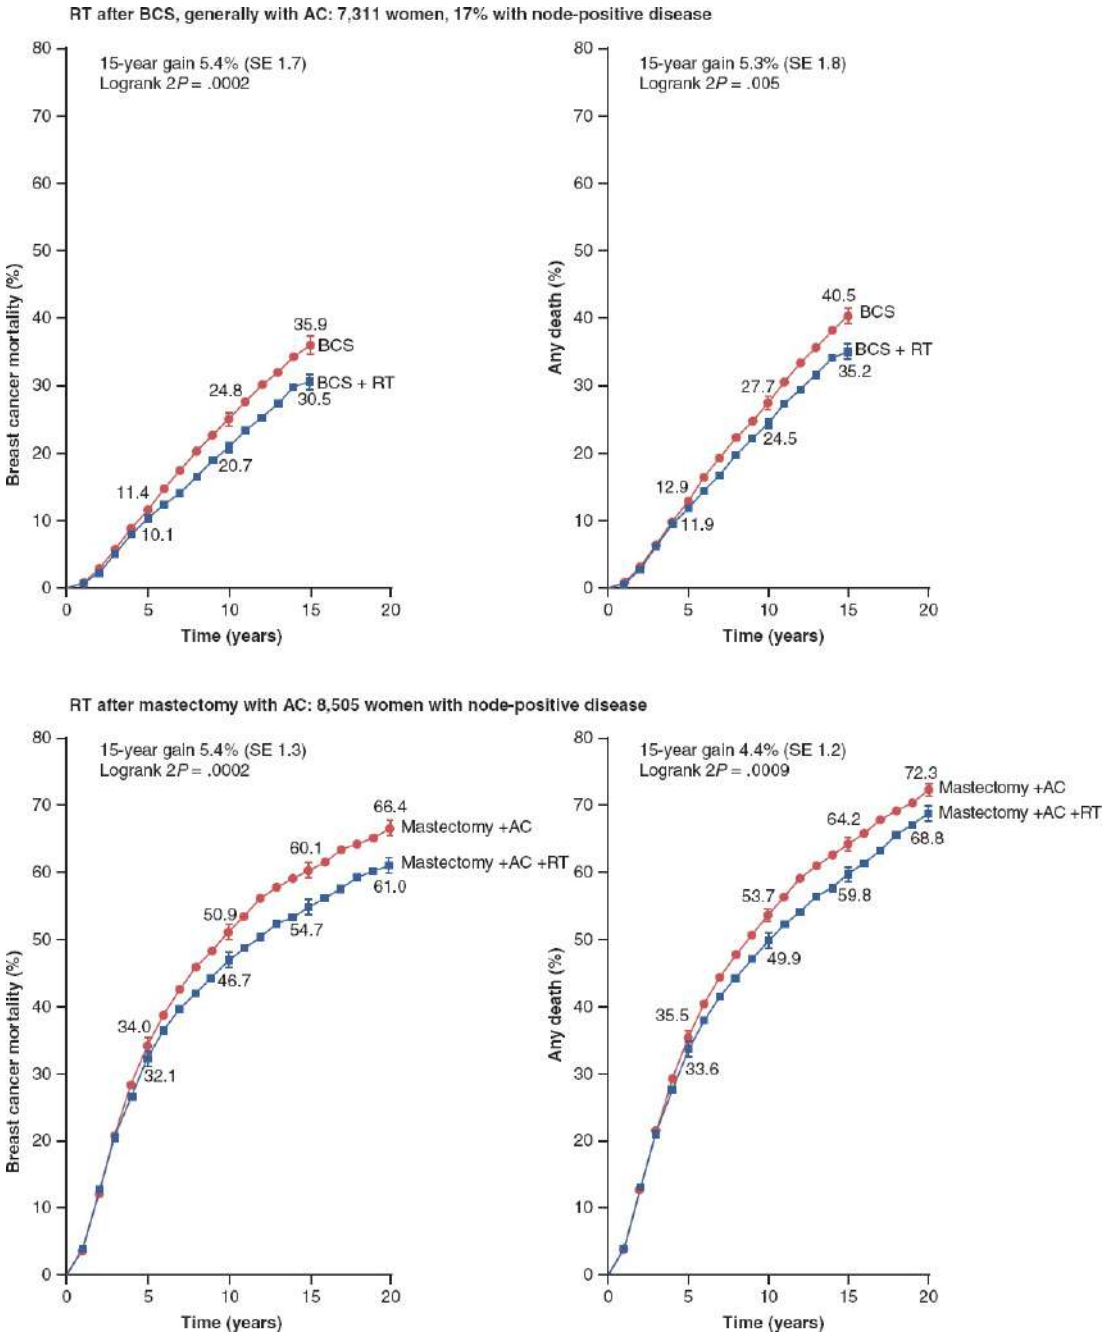

FIGURE 59.6. Effect of radiotherapy on breast cancer mortality and on all-cause mortality after breast conservation surgery or after mastectomy with axillary clearance: 15-year or 20-year probabilities. The impact of delays in evaluation or treatment on the survival of patients with breast cancer is controversial. Richards et al.,[111] in a review of 2,964

patients, found 942 (32%) who had symptoms for 12 or more weeks before their first hospital visit. Locally advanced or metastatic disease was detected in 32% of patients with delays compared with 10% of patients with intervals of <12 weeks between the onset of symptoms and hospital referral ($P < .0001$). Olivotto et al.[112] found that delays in diagnosis of 6 to 12 months led to increased risk of larger tumor size and more lymph node metastases compared with patients diagnosed within 4 to 12 weeks of an abnormal screening mammogram result.

TABLE 59.6 BREAST CANCER SCREENING GUIDELINES

Age Group	Developed by the ACS and Endorsed by the ACR, SBI
20–39	BSE optional; CBE every 3 y
40–44	Women should have the opportunity to begin annual screening between the ages of 40 and 44 y (qualified recommendation)
45-54	Women should be screened annually (qualified recommendation)
55+	Women 55 y and older should transition to biennial screening or have the opportunity to continue screening annually (qualified recommendation)
At increased risk	Consult with their doctors about the benefits and limitations of starting mammography screening earlier, having additional tests (i.e., breast ultrasound and MRI), or having more frequent exams

SCREENING IN BREAST CANCER

Mammography

Screening mammography has resulted in a shift in both the incidence and stage of patients presenting with breast cancer. In a simplified model described by Harris et al.,[113] for every 1,000 screening mammograms, 80 women (8%) will be recalled for additional diagnostic imaging, 10 (1%) will require tissue diagnosis, and of those undergoing biopsy only 3 (0.3%) will have a malignancy.

There is a large body of evidence that early detection by mammography, followed by appropriate local, regional, and systemic treatment, is associated with reduced breast cancer mortality rates for women 50 years of age and older.[114–117] Although it remains an active area of debate, several authors agree that screening mammography in women 40 to 49 years of age may reduce mortality from breast cancer,[25,115–121] and mammographic screening beginning at age 40 is encouraged in the majority of published guidelines (Table 59.6). The

reader is referred elsewhere for an extensive discussion of screening mammography studies.[115–117] Selected series will be briefly discussed here, and a summary of the classic screening mammography trials is summarized in Table 59.7.[68,123–131] Collectively, these studies demonstrate a decrease in mortality and migration of patients from later stages of disease to earlier stages of disease with the use of screening mammography.[25,115–121,123,130,131]

Sixteen-year results are available from the Health Insurance Plan study, which involved two systematically selected, randomly sampled groups of approximately 31,000 women aged 40 to 64 years who were offered screening examinations.[122,132] Compared with the control group, which was observed and monitored, the mortality rate was reduced by approximately one-third in screened women 50 to 59 years of age. The survival difference between mammography-only and clinical examination–only cases appeared in years 7 to 10 after diagnosis. Although the greatest difference in mortality between screened and control group was detected in women 50 to 59 years of age when they entered the study, the differences are in favor of the study group at all ages.

Tabár et al.[124,130,131] demonstrated the benefit from mammography screening in two Swedish counties. In the group of women 20 to 69 years of age, there were 6,807 diagnosed with breast carcinoma over a 29-year period and 1,863 breast carcinoma deaths. The mortality rate from breast carcinoma diagnosed in women 40 to 69 years of age who were screened during the screening period (1988–1996) declined by 63% (RR 0.37) compared with the breast carcinoma mortality rate during the period when no screening was available (1968–1977). The reduction in mortality rate observed during the service-screening period, adjusted for selection bias, was 48%. No significant change in breast carcinoma mortality rate was observed over the three periods in women who did not undergo screening. In a recent long-term update, there has remained a highly significant reduction in breast cancer mortality in women invited to screening (RR 0.69; 95% CI: 0.56 to 0.84; P = .001). At 29 years of follow-up, there was a reduction in 1 death for every 414 women undergoing screening for 7 years. They conclude that the group invited to screening resulted in a highly significant decrease in breast cancer specific mortality.[133]

In contrast to the above, a Canadian study revealed that in women aged 50 to 59 years, the addition of annual mammography screening to physical

examination had no effect on breast cancer mortality. Miller et al.[127] reported a study of 39,405 women (aged 50 to 59 years) randomly assigned to one of two study groups. By December 31, 1993, 622 invasive and 71 *in situ* breast cancers were observed in the mammography plus physical examination group, compared with 610 and 16, respectively, in the physical examination–only group. At 13-year follow-up, the number of deaths from breast cancer was 107 in the mammography plus physical examination group and 105 in the physical examination–only group. The results of the Canadian study may be due to the unbalanced allocation of women with advanced cancers (large tumors, four or more positive nodes) to the screened group, the poor quality of the mammography in the trial, and an insufficient sample size.[119,134]

Screening in Women under Age 50

Although the majority of studies clearly support the impact of screening mammography on mortality in women over 50 years of age, data on screening younger women are more conflicting. Frisell and Lidbrink[128] presented updated data on breast cancer mortality for women younger than age 50 years from the Stockholm Mammographic Screening Trial. Approximately 40,000 women aged 40 to 64 years (14,842 aged 40 to 49 years) were randomized to a trial of breast cancer screening by single-view mammography alone; 20,000 women (7,103 aged 40 to 49) were randomized to a control group. In the 40- to 49-year age group, 24 and 12 breast cancer deaths were found in the study and control groups, respectively, after 11.4 years of follow-up. The RR of breast cancer death in screened versus nonscreened women was 1.08 (95% CI, 0.54 to 2.17).

A large trial was conducted in the United Kingdom involving 45,841 women aged 45 to 64 years who were offered annual screening by clinical examination and mammography; 63,636 were taught breast self-examination, and 127,117, for whom no extra services were provided, constituted a control population.[135] After 16 years of follow-up, the breast cancer mortality rate was 27% lower in the two screening centers combined than in the four comparison centers. A 35% decrease in mortality rate was observed in mammographically screened women in all cohorts aged 45 to 64 years at entry. There was no evidence of less benefit in women aged 45 to 49 years at initial screening compared with a reduction of 25% in women aged 50 to 74 years.[136]

In a Swedish study evaluating women in the 40- to 49-year age group, Hellquist et al.[137] reported 803 breast cancer deaths in a screening study group compared with 1,238 deaths in a control group after 16 years of follow-up. The

estimated RR for women screened in this younger population was 0.74 (95% CI, 0.66 to 0.83), concluding that screening mammography reduced the breast cancer mortality rate in this younger population.

In the United States, screening mammography beginning at age 40 years is recommended for the general population.[138] For some women at high risk for development of breast cancer, annual screening may be started at an earlier age. These women include those with a personal history of breast cancer, those who have had therapeutic radiation to the breast area especially for Hodgkin lymphoma, *BRCA*-positive women, women with a family history of a first-degree relative with breast cancer at a young age, and women with a biopsy diagnosis of LCIS or atypical ductal hyperplasia.

Despite some conflicting data in the large randomized trials and meta-analyses summarized above, there is general agreement that screening mammography can have a significant impact on stage of presentation of disease and breast cancer mortality. Given the incidence of breast cancer, promotion of screening for breast cancer is a major public health issue. The American Cancer Society, the American College of Radiology (ACR), and Society of Breast Imaging (SBI) recommend that women with an average risk of breast cancer should undergo regular screening mammography starting at age 45 years (strong recommendation). Women aged 45 to 54 years should be screened annually (qualified recommendation). Women 55 years and older should transition to biennial screening or have the opportunity to continue screening annually (qualified recommendation). Women should have the opportunity to begin annual screening between the ages of 40 and 44 years (qualified recommendation). Women should continue screening mammography as long as their overall health is good and they have a life expectancy of 10 years or longer (qualified recommend[139]. The US Preventive Services Task Force (USPSTF) published a controversial recommendation statement on screening breast cancer in the general population.[140] For women before the age of 50 years, the decision to start regular, biennial screening mammography should be an individual one and take patient context into account, including the patient's values regarding specific benefits and harms. They recommended biennial screening mammography for women between the ages of 50 and 74 years. The group felt there was insufficient evidence to assess the additional benefits and harms of screening mammography in women 75 years or older.

This issue continues to be controversial. Even though the guidelines still differ in their recommendations on key issues, they have become more

consistent. In addition, the inconsistencies that exist may be secondary to differences in guideline member composition and evidence grading systems between the ACS and the USPSTF, as well as differences in what evidence is considered and what constitutes a favorable benefit-to-harm ratio for recommending screening.

Digital Versus Screen Film Mammography

There has been increased utilization of digital mammography for screening. This technology utilizes a special detector capable of transforming x-ray images into electronic digital image. Advantages include no film processing, faster image acquisition, and less callbacks due to the ability to manipulate the image digitally. Results of a large-scale American College of Radiology Imaging Network (ACRIN) trial of 49,000 women revealed that digital mammography overall was at least as good as screen film mammography but was superior in younger women and women with dense breasts.[141] Given the potential efficiencies and advantages of digital mammography, most centers are moving in this direction.

Magnetic Resonance Imaging Screening

The role of MRI screening is rapidly evolving. MRI is unlikely to replace mammography for screening of the general population and is not recommended by the USPSTF in their statement on breast cancer screening.[140,142,143] However, its use in screening high-risk populations has recently been supported in several studies. For women at high risk for breast cancer due to strong family history or positive *BRCA1/BRCA2* status, the standard screening techniques of breast self-examination, clinical breast examination, and mammography may be suboptimal. Nearly half of the cancers in this population are detected by physical examination between routine radiographic surveillance. In this population, increased breast density and rapid proliferative rates likely contribute to the relative insensitivity of mammography. Although MRI has not yet been shown to impact mortality, the sensitivity of MRI over mammography, clinical examination, and ultrasound in this high-risk population has been demonstrated in several prospective, nonrandomized studies[144–149].

Despite substantial differences in patient population (age, risk, etc.) and MRI technique, all reported significantly higher sensitivity for MRI compared with mammography (or any of the other modalities). All studies that included more than one round of screening reported interval cancer rates below 10%.

Participants in each of these studies had either a documented *BRCA1* or *BRCA2* mutation or a very strong family history of breast cancer. Some of the studies included women with a prior personal history of breast cancer. Overall, studies have found high sensitivity for MRI, ranging from 71% to 100% versus 16% to 40% for mammography in these high-risk populations. Three studies included ultrasound, which had sensitivity similar to mammography.

In a landmark study by Kriege et al.,[150] 1,909 eligible women (cumulative lifetime risk of breast cancer of 15% or more) at high risk for familial breast cancer, including 358 carriers of germline mutations, were screened with an annual MRI and mammography. Within a median follow-up period of 2.9 years, the screening program yielded 51 tumors. The sensitivity of clinical breast examination, mammography, and MRI for detecting invasive breast cancer was 17.9%, 33.3%, and 79.5%, respectively, and the specificity was 98.1%, 95.0%, and 89.8%, respectively. The overall discriminating capacity of MRI was significantly better than that of mammography ($P < .05$). From this study, it appears that MRI is more sensitive than mammography in detecting tumors in women at high risk for familial breast cancer.

Ultrasound Screening

Ultrasound is a complementary tool to mammography for the diagnosis of breast cancer. As with MRI, it is unlikely to replace mammography for screening the general population. The NCCN recommends ultrasound for those women presenting with a dominant mass or asymmetric thickening or nodularity.[105,151] In a randomized trial of ultrasound and mammography of 2,809 women with dense breasts from ACRIN, adding a single screening ultrasound yielded an additional 1.1 to 7.2 additional cancers found in high-risk women but substantially increased the number of false positives.[152] The role of screening ultrasound and selection of patients remains controversial and will likely continue to evolve over the next decade.

Screening by Physical Examination

Two studies have evaluated the effectiveness of screening by breast self-examination alone, the UK and the Canadian trials. Using Breast Cancer Registry data, Costanza and Foster[153,154] found fewer deaths from breast cancer (14% vs. 26%) and improved estimated 5-year survival rates (75% vs. 59%) among women who reported performing breast self-examination compared with those who did not. In the Breast Cancer Detection Demonstration Project, the

estimated overall sensitivity of breast self-examination in detecting breast cancer was 26%, compared with 75% for the combination of clinical breast examination and mammography.[155]

Clinical breast examination and self-examination may be complementary to mammography, perhaps detecting interval cancers in the 10% to 12% of cancers not visualized by mammography. Although it is evident that clinical screening is not as sensitive as mammography, the combination of clinical examination and mammography appears to yield optimal results in early detection.

TABLE 59.8 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE BREAST, STAGES T1 AND T2

General

History with emphasis on presenting symptoms, menstrual status, parity, family history of cancer, other risk factors

Physical examination with emphasis on breast, axilla, supraclavicular area, abdomen

Special Tests

Biopsy (core biopsy directed by physical examination, ultrasound, or mammography as indicated, or needle localization)

Radiologic Studies

Before biopsy

Bilateral diagnostic mammography/ultrasonography

Chest radiographs

Magnetic resonance imaging of breast (selected cases)

After positive biopsy

Bone scan (when clinically indicated, for stage II or III disease or elevated serum alkaline phosphatase levels)

Computed tomography of the chest, abdomen, and pelvis for stage II or III disease and/or abnormal liver function tests

Laboratory Studies

Complete blood cell count,

Comprehensive metabolic panel, including liver function tests and alkaline phosphatase

Other Studies

Hormone receptor status (ER, PR)*HER2/neu* status

Consider genetic counseling/*BRCA* testing in high-risk patients

Counseling for fertility if premenopausal

Assess for distress

DIAGNOSIS AND WORKUP

The workup of a patient with a breast mass, including complete clinical and family history, is summarized in Table 59.8. The patient should be examined both sitting up and lying down (to confirm masses felt on the sitting-up

examination and to detect lesions deeper in the breast or against the chest wall). Careful inspection of both breasts should be made, including size, form, and symmetry; changes in pigmentation; scaling or discharge from the nipple, and dilated veins or edema of the skin in a nonpregnant patient. The location, size, consistency, tenderness, and mobility of the palpable tumor should be recorded. It is useful to draw and photograph the projection of any suspect or palpable masses on the skin of the breast or nodal areas.

In addition to examination of the breast, careful evaluation of the axilla and supraclavicular node areas is mandatory. The number, consistency, tenderness, mobility or fixation, and size of lymph nodes should be noted. Clinically node-negative patients have pathologic involvement in 10% to 40% of cases (depending on primary tumor size), whereas no pathologic evidence of tumor is found in 25% to 30% of patients with clinically palpable axillary nodes.

Examination of the abdomen for liver enlargement and evaluation for bony pain are also essential. Finally, a complete pelvic examination should be part of the overall evaluation of the patient, if not recently performed by the patient's other physicians.

Laboratory studies include a complete blood count and chemistry profile, including liver function tests (e.g., aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, bilirubin).

Imaging in Breast Cancer Diagnosis and Workup

Routine radiographic studies include chest radiography and bilateral mammograms. As clinically indicated, these may be supplemented by CT scanning, MRI, or positron emission tomography (PET) scans, bone scans, and plain radiographs of *symptomatic* bones, if clinically warranted.

TABLE 59.9 AMERICAN COLLEGE OF RADIOLOGY BIRADS ASSESSMENT CATEGORIES: MAMMOGRAPHY

Complete Final Assessment Categories	
Category 1 Negative	There is nothing to comment on. The breasts are symmetric, and no masses, architectural disturbances, or suspect calcifications are present.
Category 2 Benign finding	This is also a negative mammogram, but the interpreter may wish to describe a finding. Involuting, calcified fibroadenomas, multiple secretory calcifications, fat-containing lesions such as oil cysts, lipomas, galactoceles, and mixed-density hamartomas all have characteristic appearances and may be labeled

	with confidence. The interpreter might wish to describe intramammary lymph nodes, implants, and the like while still concluding that there is no mammographic evidence of malignancy.
Category 3 Probably benign finding—short-interval follow-up suggested	A finding placed in this category should have a very high probability of being benign. It is not expected to change over the follow-up interval, but the radiologist would prefer to establish its stability. Data are becoming available that shed light on the efficacy of short-interval follow-up. At present, most approaches are intuitive. These will likely undergo future modification as more data accrue as to the validity of an approach, the interval required, and the type of findings that should be followed.
Category 4 Suspicious abnormality—biopsy should be considered	These are lesions that do not have the characteristic morphologies of breast cancer but have a definite probability of being malignant. The radiologist has sufficient concern to urge a biopsy. If possible, the relevant probabilities should be cited so that the patient and her physician can make the decision on the ultimate course of action.
Category 5 Highly suggestive of malignancy—appropriate action should be taken	These lesions have a high probability of being cancer.
Category 0 Need additional imaging evaluation	Finding for which additional imaging evaluation is needed. This is almost always used in a screening situation and should rarely be used after a full imaging workup. A recommendation for additional imaging evaluation includes the use of spot compression, magnification, special mammographic views, ultrasound, and so forth.

Mammography

Mammography remains the most critical component of diagnostic imaging in breast cancer patients, and bilateral mammograms should be performed routinely in the workup of the breast cancer patient. The BIRADS (Breast Imaging Reporting and Data System) classification system, outlined in Table 59.9, has been widely adopted in classifying mammograms with respect to appropriate follow-up and intervention.[156]

The radiation oncologist should be familiar with the difference between

diagnostic and screening mammography, because a majority of conservatively treated breast cancer patients will have undergone diagnostic mammography prior to treatment, as well as in follow-up. Screening mammography refers to routine mammographic images in asymptomatic women and consists of two views: craniocaudal and mediolateral oblique of each breast. Diagnostic mammography is used to characterize abnormalities detected at screening or in women with palpable masses, employs additional magnification views, and is generally done with the radiologist present to determine the need for additional views or follow-up studies. Following breast conservation, most patients will undergo diagnostic mammograms, as additional images are often needed to rule out suspicious findings in the previously radiated breast. Some mammographers recommend reverting to screening studies after several years of stable mammography in the conservatively managed breast cancer patient.

Classically, breast carcinoma is seen as an ill-defined mass that may have spiculated margins (Fig. 59.7), although rarely cancers may also be seen with a knobby, lobulated, or even a smooth contour (ultrasonography may distinguish them from cystic masses). Architectural distortion of the breast tissue may be present. The appearance of linear, radiated, or spiculated changes around a central focus should always be considered suspect for carcinoma. The tumor may be hidden by dense parenchyma; review of previous mammogram compression views and sometimes ultrasonograms is very important in detecting subtle interval changes in the appearance of the breast.[113]

Calcifications can be associated with either benign or malignant conditions of the breast. However, calcifications associated with malignant tumors are typically 100 to 300 μm in size and are rodlike, tubular, branching, or punctate. Clusters of microcalcifications (more than five) are suggestive of intraductal disease, and in nonpalpable lesions, needle localization aids in the diagnosis (Fig. 59.8). For patients undergoing biopsy of a suspicious mass or calcifications, about 30% will yield a diagnosis of malignancy.[113] The average sensitivity of mammography is approximately 90% (60% to 95%), and the specificity is 94% (50% to 98%). The positive predictive value is approximately 8% to 14% for screened patients but is significantly higher for patients with symptoms or palpable masses.[157] If microcalcifications were initially present, radiographs of the surgical specimen and postlumpectomy mammography are important to rule out residual disease for patients considering breast conservation therapy.[158]

Ultrasound

Ultrasound can be a useful tool to complement physical examination and mammography in the diagnosis and treatment of breast cancer. Its use as a screening tool is limited and is the focus of ongoing investigations, as previously noted. Ultrasonography has a reported sensitivity of 73% and specificity of 95%. It is very helpful in differentiating cysts from solid tumors, and its primary use is the identification and characterization of palpable and nonpalpable abnormalities of the breast detected by physical examination or mammography.[113,159] In the evaluation of a palpable mass in 420 patients, if both mammography and ultrasound are negative, Soo et al.[160] reported the negative predictive value to be >99%. This was confirmed in a larger study of 3,516 patients from the Netherlands reported by Flobbe et al.[161]

In addition to complementing physical examination and mammography in diagnosis, ultrasound is often used as a guide for interventional procedures. Ultrasound-guided core biopsies are routinely performed in the diagnosis of breast cancer and have been shown to be more cost-effective than stereotactic biopsy. Ultrasound can also be used for fine needle aspiration biopsies, cyst aspirations, presurgical localizations, and evaluation of breast tissue surrounding implants.

Magnetic Resonance Imaging

Although controversial for routine use, the use of MRI to supplement mammography in breast cancer diagnosis and treatment is rapidly increasing (see Fig. 59.7). In a review of MRI in the management of breast cancer, Hylton[162] summarized the potential for the current use of MRI, to complement mammography in screening; for differential diagnosis of questionable findings on physical examination, mammography, and ultrasound; and for assessment of response in the neoadjuvant treatment of breast cancers. The NCCN recommends breast MRI for staging evaluation to define the extent of cancer or presence of multifocal or multicentric cancer in the ipsilateral breast or as screening of the contralateral breast at the time of initial diagnosis. They also indicate MRI would be useful for evaluation before and after neoadjuvant chemotherapy, to identify the primary cancer in women with axillary nodal carcinoma or occult primary cancer, or in patients with invasive lobular carcinoma (ILC) poorly defined on mammography[163].

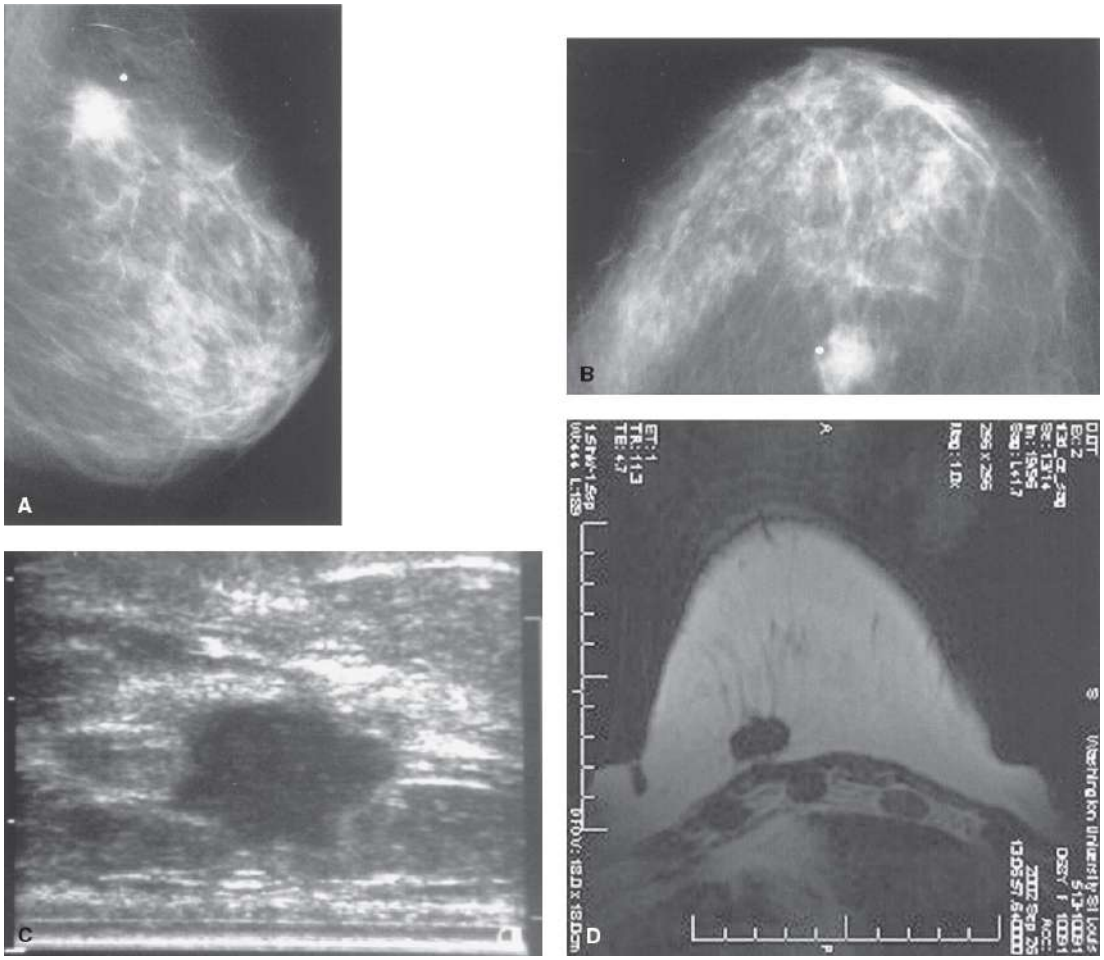

FIGURE 59.7. Mediolateral **(A)** and cephalocaudal **(B)** views of mammogram depicting a 1-cm mass with stellate margins deeply located in the upper quadrant of the left breast, histologically proven to be an IDC. Example of ultrasonogram of the breast showing a hypoechoic mass with “shadowing” deeper to the lesion, characteristic of invasive carcinoma **(C)**. T1-weighted magnetic resonance image of the breast demonstrating a mass that proved to be an invasive carcinoma **(D)**.

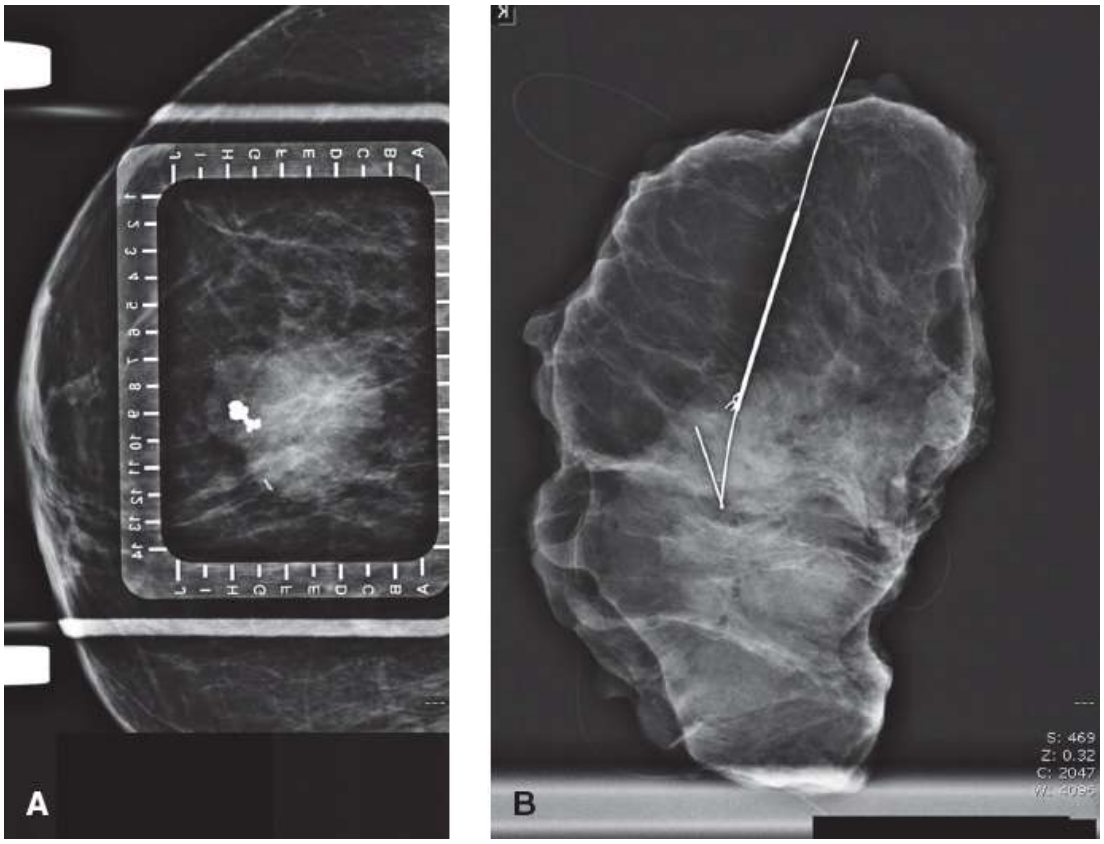

FIGURE 59.8. **A:** Mammogram demonstrating microcalcifications in the central portion of the breast with needle localization in place. **B:** Radiograph showing microcalcifications in the central portion of the wide excisional biopsy specimen. Pathologic diagnosis was intraductal carcinoma. Postlumpectomy mammogram showed no residual calcifications in the breast. The patient was treated with breast conservation surgery and irradiation years ago and remains tumor free.

In a retrospective study of MRI in the management of 441 women with breast cancer, Upponi and Warren[164] reported the indications for MRI studies were diagnostic in 176, monitoring chemotherapy in 126, and study of MRI screening for breast cancer in 139. MRI results were confusing or incorrect in 6% of the diagnostic group, 13% of the chemotherapy group, and 9% of the screening group. The authors report that MRI resulted in an increase in confidence or change in clinical plan in 46% of the diagnostic group, 72% of the chemotherapy group, and 80% of the screening group. In 44 of 283 of these, MRI caused a beneficial change in the clinical plan based on conventional radiology.

Esserman et al.[165] reported that MRI successfully detected cancer in 55 of 58 cases. There were two false-positive and two false-negative results, including a nonsignificant enhancement of one lesion. The anatomic extent of disease was correctly identified in 98% of cases by MRI but in only 55% by mammography.

MRI has a clear role in the evaluation of patients who present with axillary metastasis with no evidence of a primary tumor in the breast by physical examination or mammography. Buchanan et al.[166] reported on 55 patients who presented with axillary adenopathy without evidence of distant disease. MRI revealed suspicious lesions in 76% (42 of 55). In 62% (26 of 42), the MRI finding proved to be the occult primary tumor, of whom 58% (15 of 26) were candidates for breast conservation. MRI did not identify the primary tumor in 25 women. Of these 25, 12 underwent mastectomy, and cancer was found in 4 of these 12. The authors concluded that breast MRI detects mammographically occult cancer in half of women with axillary metastases and is a valuable tool for patients with occult primary breast cancer.

Computed Tomography

There is no established role for CT scans in routine staging of patients with early-stage breast cancer. The need for iodine contrast material to differentiate benign from malignant conditions, high radiation dose, cost per study, and inability to detect small lesions precludes the use of CT for initial evaluation, except under special circumstances. Most patients with node-negative breast cancer do not need to undergo routine CT scans for staging, because the yield is exceeding low. A small percentage of women with very high-risk node-negative disease or with node-positive disease may be upstaged by routine CT scans and, although the yield is low, it is common practice to CT stage high-risk node-negative and node-positive breast cancer patients. At present, the NCCN guidelines on breast cancer recommend an abdominopelvic CT if abnormal lab values on physical examination are present or if the patient is deemed as a stage IIIA (T3N1M0) or greater[163].

Many women undergoing breast-conserving surgery and radiation do have CT scans as part of RT treatment planning. Without the use of contrast and specific diagnostic imaging protocols, these scans should not be considered as part of a staging procedure.

Bone Scans

Routine bone scan at the time of initial treatment of stage I and II breast cancer is of limited value and should be reserved for patients with bone pain.[167] In patients with stage I disease, the incidence of abnormalities on bone scan is approximately 2%, but a greater incidence of abnormalities is found in stages II (10%) and III (>20%).[168] In a group of 7,604 patients who had bone scans, of

over 20,000 women operated for breast cancer in Denmark, approximately 5% had abnormal study results.[169] The incidence of abnormal scan results was greater in patients older than 60 years (8%) than in the younger group (3%), most likely because of the many benign bone and joint disorders frequently seen in older women.

Koizumi et al.[170] reviewed records from 5,538 patients with breast cancer. The overall incidence of metastasis to bone was 2.13% (0% in patients with stage 0, 0.08% in stage I, 1.09% in stage II, 9.96% in stage III, and 34.04% in stage IV). Bone scans are more commonly recommended in patients with stage II larger tumors (>3 cm), aggressive histopathologic features, and in stage III or IV cancer.

Positron Emission Tomography Scanning

PET using ^{18}F-labeled fluorodeoxyglucose (FDG) scanning, though not a routine component of staging, is being used more frequently in breast cancer. Its application in patients on initial presentation with early-stage disease has not been established. However, its potential role in patients with metastatic, advanced, and locoregional relapse of disease is rapidly evolving. At present, the NCCN guidelines recommend against routine PET scans in patients with stage 0 to IIIA disease but do state that it may be useful for patients with locally advanced disease or in situations where standard imaging results are equivocal or suspicious.[105,171,172]

In an analysis of PET scanning in 165 patients from British Columbia, Weir et al.[173] concluded that there are two clinical situations in which PET appears to be particularly valuable. The first is in the evaluation of patients who are suspected of having a tumor recurrence. The other is in identifying patients with multifocal or distant sites of malignancy who otherwise appear to have an isolated, potentially curable, locoregional recurrence.

Schirrmeister et al.[174] also evaluated FDG-PET scanning and compared it prospectively with standard staging procedures within 2 weeks before surgery in 117 women who had palpable breast tumors or lesions suggestive of cancer on mammography or ultrasonography. On biopsy, 89 patients were determined to have breast cancer and 28 benign tumors. For interpreting results as being breast cancer, FDG-PET had a sensitivity of 93%, a specificity of 78%, an accuracy of 89%, a positive predictive value of 92%, and a negative predictive value of 96%. In detecting multifocal lesions, FDG-PET was twice as sensitive (63%) as the combination of mammography and ultrasonography (32%). Distant metastases

in three patients were missed with the standard staging procedures but detected with FDG-PET. Because FDG-PET had a false-negative rate of 20% for detection of lymph node metastases, this imaging method cannot replace histologic evaluation of axillary nodes.

Summary of Imaging for Breast Cancer

All women should undergo history and physical examination, with mammography and liver function tests. Ultrasound or MRI may be useful in selected cases to complement mammography. For women who have operable disease with normal liver function tests, surgical staging of the breast and node sampling is performed. For low-risk patients, no further staging is required. For women with more advanced disease and those being considered for neoadjuvant chemotherapy, preoperative staging would routinely include a bone scan, chest x-ray and CT, or abdominal ultrasound. PET scanning may be considered in selected cases.

Pathologic Studies

Histopathologic diagnosis may be obtained by fine needle aspiration of cystic or solid masses or biopsies of solid masses; any fluid aspirated from the breast should be examined for malignant cells. Fine needle aspiration of the breast is a simple, low-cost, accurate diagnostic technique that has been used for many years in Europe and is gaining increasing acceptance in the United States.[175,176] A potential limitation of fine needle aspiration is that it provides cytology and no tissue architecture. Therefore, while the presence of malignant cells can be detected, cytology from fine needle aspiration cannot conclusively differentiate invasive from noninvasive disease. However, for lesions that are palpable or easily visualized on ultrasound, this method results in rapid and efficient diagnosis.

Stereotactic core needle biopsy is increasingly used to obtain a histologic diagnosis with high accuracy, particularly in small breast lesions.[177] In 6,152 lesions sampled at multiple institutions, 817 (13.3%) showed infiltrating breast cancer, 167 (2.7%) showed intermediate or high-grade DCIS, and 213 (3.5%) showed atypical hyperplasia or low-grade DCIS. Complete agreement between the core biopsy and subsequent histologic sections was reached in 89.7% of lesions and partial agreement in 9.2%. Clinically significant complications occurred in only 6 of 3,765 cases (0.2%) for which follow-up was available.

Breast biopsy of any suspicious mass is mandatory. The biopsy usually can be

done using local anesthesia; the patient should be informed of the nature of the lesion to allow for her greater participation in therapeutic decisions. There has been no evidence that delay in treatment up to 2 weeks after biopsy worsens prognosis.[178]

In nonpalpable lesions, needle localization and radiographic techniques are necessary to identify the tissue to be removed. Failure to remove the mammographic abnormality has been reported in 2% to 8% of patients undergoing needle localization.[179] The localizing wires should be left in place in the specimen and a radiograph obtained to ensure that the area of abnormality has been adequately excised. If the specimen radiograph does not document complete tumor removal, an immediate re-excision of the area at the tip of the wire should be carried out. However, specimen mammography may be of questionable benefit in the management or outcome of most patients undergoing image-guided, needle-localized breast biopsies. Bimston et al.[180] reviewed 164 patients who underwent 165 needle/dye-localized breast biopsies for suspect mammographic abnormalities. In only three (1.8%) cases did the patient clearly benefit from specimen mammography; in no patient was a malignant neoplasm missed.

If there is any question, particularly in patients with microcalcifications, a postbiopsy mammogram should be obtained to determine the completeness of tumor excision.[113] The surgeon should prepare (orient) the specimen accordingly, and the margins of the resected breast tissue should be identified and inked before processing. The pathologist should be made aware of the nature of the lesion for appropriate processing of the specimen.[181] Radiation oncologists should be familiar with the implications of the diagnostic procedures for carcinoma of the breast as active participants in a breast preservation therapeutic approach.

In the United States, estrogen-receptor (ER) and progesterone-receptor (PR) assays are routinely done for patients with breast cancer; these parameters are correlated with prognosis and tumor response to chemotherapeutic and hormonal agents.[182,183] Immunohistochemical techniques are commonly employed and correlate well with other hormonal-receptor assays. Cellular assays measure the growth fraction (S-phase fraction [SPF]) of tumors, either by thymidine-labeling index (TLI) or flow cytometry methods, and other tumor markers have prognostic implications, sometimes independent of tumor stage and hormone-receptor status.[184,185] *HER-2/neu* assay is being done routinely because overexpression is associated with poor prognosis, and these patients are

currently being offered adjuvant therapy directed at *HER2/neu*.[186,187] *HER2/neu* analysis by fluorescent *in situ* hybridization (FISH) techniques has evolved as the standard for determining response to therapy directed at the *HER2/neu* oncogene.[186,187]

Staging

Two staging systems are widely used for breast cancer: the American Joint Committee on Cancer (AJCC) (Table 59.10) and the Union Internationale Contre le Cancer systems.[188,189] Major changes made in the eighth edition of the *AJCC Cancer Staging Manual* include the following[190]:

- The inclusion of 2 stage grouping systems: The anatomic stage group table is based solely on anatomic extent of cancer as defined by the T, N, and M categories. The prognostic stage group table is based on populations of persons with breast cancer that have been offered—and mostly treated with—appropriate endocrine and/or systemic chemotherapy, which includes anatomic T, N, and M plus tumor grade and the status of the biomarkers human epidermal growth factor receptor 2 (HER2), estrogen receptor (ER), and progesterone receptor (PR).
- LCIS is removed as a pathologic tumor *in situ* (pTis) category for T categorization. LCIS is a benign entity and is removed from TNM staging.
- The general rules for rounding to the nearest millimeter do not apply for tumors between 1.0 and 1.5 mm, so that these cancers are not classified as microinvasive (T1mi) carcinomas (defined as invasive tumor foci 1.0 mm or smaller). Tumors > 1 mm and < 2 mm should be reported rounding to 2 mm.

The T categorization of multiple synchronous tumors is identified clinically and/or by macroscopic pathologic examination, and their presence is documented using the (m) modifier for the T category. The Columbia staging system is important both historically and because it clearly identifies prognostic factors affecting operability.[62] Figure 59.9 depicts the various clinical stages according to tumor and nodal characteristics.

Pathologic Classification

The World Health Organization (WHO) has classified proliferative conditions and tumors of the breast into the following categories: benign mammary dysplasias, benign or apparently benign tumors, carcinoma, sarcoma, carcinosarcoma, and unclassified tumors.[191] The AJCC has adopted the WHO classification of tumors as shown in Table 59.11.[188]

Numerous detailed reports and monographs describe the pathologic features and clinical implications of carcinoma of the breast, which are reviewed elsewhere.[113,192–195] The radiation oncologist should be familiar with the histologic characteristics of breast cancer because many of them affect prognosis and may have important therapeutic implications. Brief descriptions of several types of carcinoma of the breast follow.

Microinvasive carcinoma is defined as "the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension." Lesions that fulfill this definition are staged as T1mic, a subset of T1 breast cancer. The AJCC staging manual further states that "when there are multiple foci of microinvasion, the size of only the largest focus is used to classify the microinvasion" and that the sizes of the individual foci should not be added together. They also state that "the prognosis of microinvasive carcinoma is generally thought to be quite favorable, although the clinical impact of multifocal microinvasive disease is not well understood at this time." Widely varying definitions of microinvasion have been used, and some differ substantially from that offered here.[188]

TABLE 59.10 AMERICAN JOINT COMMITTEE ON CANCER STAGING OF BREAST CANCER

Primary Tumor (T)	
Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
Tis (DCIS)	Ductal carcinoma *in situ*
Tis (Paget's)	Paget disease of the nipple with no tumor
Note: Paget disease associated with a tumor is classified according to the size of the tumor.	
T1	Tumor ≤20 mm in greatest dimension
T1mic	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
	Tumor >20 mm but ≤50 mm in greatest dimension

T2	
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or macroscopic nodules); invasion of the dermis alone does not qualify as T4
T4a	Extension to the chest wall; invasion or adherence to pectoralis muscle in the absence of invasion of chest wall structures does not qualify as T4
T4b	Ulceration and/or ipsilateral macroscopic satellite nodules and/or edema (including peau d'orange) of the skin that does not meet the criteria for inflammatory carcinoma
T4c	Both (T4a and T4b)
T4d	Inflammatory carcinoma
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastasis to ipsilateral axillary lymph node(s) fixed or matted or in clinically apparent[a] ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N2a	Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastasis only in clinically apparent[a] ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
N3	Metastasis to ipsilateral mammary lymph node(s) with or without axillary lymph node involvement or in clinically apparent[a] ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)
Pathologic Classification (*p*N)	
*p*NX	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
*P*N0	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells (ITC)
Note: ITC are defined as single tumor cells or small cell clusters not >0.2 mm, usually detected only by immunohistochemical (IHC) or molecular methods but which may be verified on hematoxylin and eosin stains. ITCs do not usually show evidence of malignant activity (e.g., proliferation or stromal reaction).	
p N0(i–)	No regional lymph node metastasis histologically, negative IHC
p N0(i+)	No regional lymph node metastasis histologically, positive IHC, IHC cluster no >0.2 mm
p N0(mol–)	No regional lymph node metastasis histologically, negative molecular findings [reverse transcriptase polymerase chain reaction (RT-PCR)]

p N0(mol+)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)
p N1	Metastasis in 1 to 3 axillary lymph nodes and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[b]
p N1mi	Micrometastasis (approximately 200 cells, >0.2 mm, none larger than 2.0 mm)
p N1a	Metastasis in 1 to 3 axillary lymph nodes, one larger than 2.0 mm
p N1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel node dissection but not clinically apparent[c]
p N1c	pN1a and pN1b combined
p N2	Metastasis in 4–9 axillary lymph nodes or in clinically apparent[b] internal mammary lymph nodes in the absence of axillary lymph node metastasis
p N2a	Metastasis in 4 to 9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
p N2b	Metastasis in clinically apparent[b] internal mammary lymph nodes in the absence of axillary lymph node metastasis
p N3	Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent[b] ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes or in ipsilateral supraclavicular lymph nodes
p N3a	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit >2.0 mm) or metastasis to the infraclavicular lymph nodes
p N3b	Metastasis in clinically apparent[b] ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[c]
p N3c	Metastasis in ipsilateral supraclavicular lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
cM0(i+)	No clinical or radiographic evidence of distant metastases in the presence of tumor cells or and no deposits no >0.2 mm detected microscopically or by using molecular techniques in circulating blood, bone marrow, or other nonregional lymph node tissue in a patient without symptoms or signs of metastases
M1	Distant metastases detected by clinical and radiographic means (cM) and/or histologically proven metastases larger than 0.2 mm (pM)

[a]Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.
[b]Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.
[c]Not clinically apparent is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

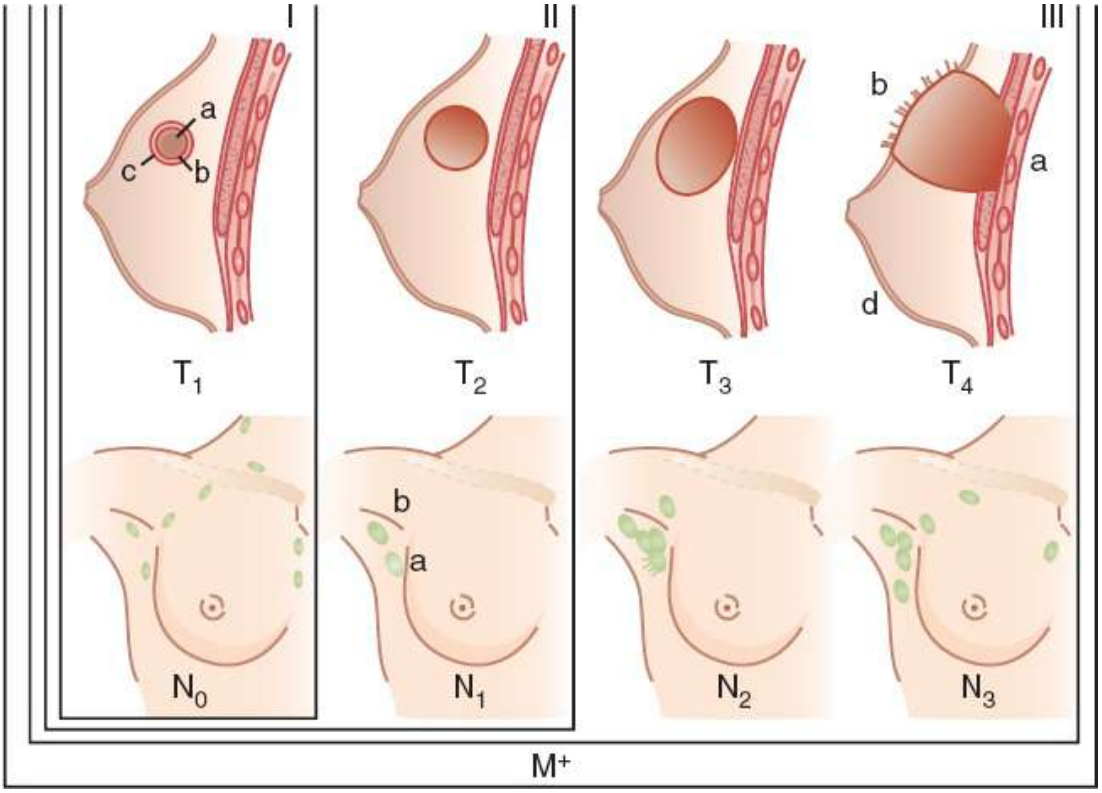

FIGURE 59.9. Clinical staging of carcinoma of the breast. Stages, in part, reflect curability by locoregional treatment modalities prognostically (surgery and radiation therapy). The equivalence of T and N categories are as follows: T2 = N1, T3 = N2, T4 = N3. The American Joint Committee on Cancer and Union Internationale Contre le Cancer classification systems use similar categories and stages. (Reprinted from Langmuir VK, Poulter CA, Qazi R, et al. Breast cancer. In: Rubin P, ed. *Clinical oncology: a multidisciplinary approach for physicians and students*. 7th ed. Philadelphia, PA: WB Saunders, 1993. Copyright © 1993 Elsevier. With permission.)

Invasive (infiltrating) ductal carcinoma is the most common type of breast cancer, constituting more than 50% of all cases. It appears as solid cords or groups of ductal tumor cells varying in size and cytoplasmic content and degree of differentiation.[196] Necrosis is rare, but lymphatic invasion may be present. An associated *in situ* component is frequently seen.

Tubular carcinoma is composed of tubular structures typically lined by a single layer of well-differentiated epithelium. The tubular cells simulate those of normal ducts or ductules, are arranged in multiglandular cribriform or adenocystic configurations, and are frequently associated with other *in situ* carcinomas of the breast.[197] Tubular carcinomas have a nonaggressive growth pattern, with an excellent prognosis. A meta-analysis of 680 women showed an overall frequency of nodal metastasis of 13.8%.[198] In view of the low incidence of axillary node metastases at presentation (7%) in low-risk tubular carcinoma of

the breast (≤1 cm), some have advocated that axillary dissection may be omitted. In a retrospective review of 73 cases of tubular carcinoma, Sullivan et al.[199] reported treatment with conservative surgery (CS) plus radiation therapy (RT) in 67%, CS without RT in 18%, and mastectomy in 15%. The published literature of 529 conservatively treated tubular carcinomas was reviewed along with the 62 conservative cases from their series. No patients developed distant metastasis or died from disease. Local failure occurred in three (4%) of the cases. The literature review showed that adjuvant RT reduces local failure following CS for tubular carcinoma.

Medullary carcinoma is composed of cords and masses of large cells with reticular pleomorphic nuclei containing prominent nucleoli. There is a scant fibrous stroma, but lymphoid infiltrate is prominent. These tumors are microscopically and grossly well circumscribed. Prognosis, in general, is better than for other tumors. These tumors are more frequently seen in younger women and are commonly associated with patients with *BRCA1* mutations.[200]

Lobular invasive carcinoma may be interspersed with; the cells appear singly or in small clusters in a targetoid or single-file pattern. Some scirrhous carcinomas probably are invasive lobular lesions; these tumors tend to be aggressive and multicentric and are prone to development of distant metastases. Du Toit et al.[201] reported five subtypes of lobular carcinomas in 171 cases and observed a 12-year actuarial survival rate of 100% for the tubulolobular subtype but only 47% for the solid variant. Two other characteristics of ILC is that it is often “mammographically silent,” meaning its detection or the full appreciation of extent of disease is often not visualized mammographically. Invasive lobular cancers are much more commonly ER positive than is invasive ductal carcinoma (IDC). Infiltrating pleomorphic lobular carcinoma, an aggressive variant of ILC, was described in 38 cases; 29% of the specimens demonstrated signet ring cells.[202]

Mucinous carcinoma, also called mucoid or colloid carcinoma, has been observed in older women with relatively long duration of symptoms.[203] It is more likely to be devoid of a cellular reaction; necrosis and lymphatic invasion are very rare. It is slowly growing with a pushing border and has a low frequency of axillary lymph node metastasis. Survival is appreciably better than with IDC.[204] Anan et al.[205] evaluated 76 patients with mucinous carcinoma (52 pure type and 24 mixed type). The incidence of lymphatic vessel invasion (4%) and nodal involvement (4%) was lower in pure mucinous carcinoma than in mixed carcinoma ($P < .05$). No nodal involvement occurred in patients with pure

mucinous carcinoma <3 cm in diameter.

Adenocystic carcinoma is rarely found in the breast. Histologic features and clinical behavior are similar to its counterpart in the salivary gland and the upper respiratory tract.[206] In 28 patients, only 1 had axillary node metastases; 22 were treated with mastectomy and 6 with local excision (with breast irradiation in 5). With a median follow-up of 7 years, there were no local recurrences; the 5-year disease-free survival rate was 95%.[207]

Invasive micropapillary carcinoma of the breast is characterized by growth of tumor cell clusters in prominent clear spaces resembling dilated angiolymphatic vessels. Nassar et al.[208] reported on 83 invasive micropapillary carcinomas; the mean tumor size was 4 cm, 22% invaded skin, 58% were poorly differentiated, and 71% were ER positive. Axillary node metastases were present in 77% of cases and were typically multiple (51% had three or more positive). Forty-six percent of the patients died from their disease (mean interval to death, 36 months). Skin involvement and nodal status were the only parameters predictive of poor survival ($P = .01$).

TABLE 59.11 AMERICAN JOINT COMMITTEE ON CANCER HISTOPATHOLOGIC CLASSIFICATION OF BREAST TUMORS

Type
Precursor lesions
Ductal carcinoma *in situ*
Lobular neoplasia
Lobular carcinoma *in situ*
Classic lobular carcinoma *in situ*
Pleomorphic lobular carcinoma *in situ*
Atypical lobular hyperplasia
Intraductal proliferative lesions
Usual ductal hyperplasia
Columnar cell lesions including flat epithelial atypia
Atypical ductal hyperplasia
Papillary lesions
Intraductal papilloma
Intraductal papilloma with atypical hyperplasia
Intraductal papilloma with ductal carcinoma *in situ*
Intraductal papilloma with lobular carcinoma *in situ*
Intraductal papillary carcinoma
Encapsulated papillary carcinoma
Encapsulated papillary carcinoma with invasion
Solid papillary carcinoma
In situ
Invasive
Invasive carcinoma of no special type (NST)

- Pleomorphic carcinoma
- Carcinoma with osteoclast-like stromal giant cells
- Carcinoma with choriocarcinomatous features
- Carcinoma with melanotic features

Invasive lobular carcinoma
- Classic lobular carcinoma
- Solid lobular carcinoma
- Alveolar lobular carcinoma
- Pleomorphic lobular carcinoma
- Tubulolobular carcinoma
- Mixed lobular carcinoma

Tubular carcinoma
Cribriform carcinoma
Mucinous carcinoma
Carcinoma with medullary features
- Medullary carcinoma
- Atypical medullary carcinoma
- Invasive carcinoma NST with medullary features

Carcinoma with apocrine differentiation
Carcinoma with signet-ring-cell differentiation
Invasive micropapillary carcinoma
Metaplastic carcinoma of no special type
- Low-grade adenosquamous carcinoma
- Fibromatosis-like metaplastic carcinoma
- Squamous cell carcinoma
- Spindle cell carcinoma
- Metaplastic carcinoma with mesenchymal differentiation
  - Chondroid differentiation
  - Osseous differentiation
  - Other types of mesenchymal differentiation
- Mixed metaplastic carcinoma
- Myoepithelial carcinoma

Epithelial–myoepithelial tumors
Adenomyoepithelioma with carcinoma
Adenoid cystic carcinoma
Rare types
Carcinoma with neuroendocrine features
- Neuroendocrine tumor, well differentiated
- Neuroendocrine carcinoma poorly differentiated (small cell carcinoma)
- Carcinoma with neuroendocrine differentiation

Secretory carcinoma
Invasive papillary carcinoma
Acinic cell carcinoma
Mucoepidermoid carcinoma
Polymorphous carcinoma
Oncocytic carcinoma
Lipid-rich carcinoma
Glycogen-rich clear cell carcinoma
Sebaceous carcinoma

Metaplastic carcinoma is relatively rare. Beatty et al.,[209] of the Swedish Cancer Institute, identified 24 cases that were compared with typical breast cancer cases matched for age; date of diagnosis; stage; and ER, PR, and *HER2* status. The mean metaplastic primary tumor diameter was 2.5 cm. The histologic or nuclear grade was high in 21 of 24 cases. ER or PR status was negative in all cases. *HER2* was negative in 10 of 11 cases tested. Epidermal growth factor receptor (EGFR; *HER1*) was positive in 7 of 7 cases tested. Five-year survival was 83% (95% CI, 66% to 100%). Comparison with matched typical breast cancer cases revealed no significant difference in multidisciplinary treatment patterns, recurrence, or survival. The increased expression of EGFR (*HER1*) provides an opportunity for targeted tumor therapy in these tumors.

In an analysis of the MD Anderson Cancer Center experience and the SEER database, Hennessy et al.[210] identified 100 patients with metaplastic sarcomatoid carcinoma and 213 patients in the SEER database with similar histology. They conclude that these are aggressive tumors with poor response to therapy and poor outcomes, also suggesting that studies evaluating novel targeted therapy are needed for these patients.

Spindle cell carcinoma of the breast, a variant of metaplastic carcinoma, includes a wide spectrum of lesions with mildly atypical features that may resemble fasciitis, fibromatosis, or myofibroblastic tumors. Unlike spindle cell carcinomas in general, they have no propensity for distant metastasis and should be termed *tumors* rather than *carcinomas*. Sneige et al.[211] studied 24 cases of fibromatosis-like spindle cell breast carcinoma. Treatment consisted of local excision (7 cases) or modified radical mastectomy (13 cases) and was not specified in 4 cases. In patients who underwent axillary nodal dissection, no lymph node metastases were found. Local recurrences developed in two of the six patients who underwent local excision only.

Primary neuroendocrine small cell carcinoma is uncommon. Francois et al.[212] reported seven cases, and Shin et al.[213] described nine cases. Immunohistochemical analysis showed consistent staining for cytokeratin markers but variable staining with neuroendocrine markers. The histologic type and prognosis are identical to those of lung cancer. It is important to distinguish these lesions from metastatic lung tumors or direct invasion of breast by Merkel cell carcinoma, lymphoma, or carcinoid tumor. It is reasonable to treat these

patients with aggressive multiagent chemotherapy, excision of the primary tumor, and breast irradiation, although no data are available on the outcome of this approach.

Paget disease describes involvement of the nipple by tumor. Most investigators agree that it represents extension of neoplasms from subjacent ducts in the nipple or metastases from an underlying carcinoma.[1] The tumor seems to travel linearly down the ducts and may appear to be multicentric. There may be an associated subareolar tumor. Breast-conserving surgery followed by radiation is effective in this disease.[214,215]

Cystosarcoma phyllodes is usually a benign lesion; in broad, fibrous beads that look "leaflike" are cystic clefts lined by a single layer of cells. These tumors are large; usually, they are encapsulated, without invasion of the adjacent breast.[62] The lesions frequently develop from preexisting fibromas and have a long initial period of slow growth followed by a sudden, rapid increase in size. The grade (mitotic rate), surgical margins, and proliferative index have prognostic importance.[216]

Primary mammary lymphomas are rare and constitute approximately 0.5% of breast malignancies and approximately 1% of all non-Hodgkin lymphomas (NHL). Diffuse large B-cell lymphoma (DLBCL) is the most common histologic subtype of PBL (50% to 80%). The indolent histologic subtypes of marginal zone lymphoma (10% to 30%) and follicular lymphoma (10% to 20%) are the next most frequent. Burkitt lymphoma (typically in pregnancy or lactation) constitutes approximately 5%, with the recently described entity of breast implant–associated anaplastic large cell lymphoma (BIA-ALCL) making up an increasing proportion of the remaining cases.[217]

Sarcoma

Primary breast sarcomas are occasionally seen. McGowan et al.[218] described 78 cases of primary breast sarcoma without metastatic disease (76 women, 2 men); 32 patients had malignant cystosarcoma phyllodes, and the others had stromal sarcomas (14 patients), angiosarcomas (8 patients), fibrosarcomas (7 patients), carcinosarcomas (5 patients), liposarcomas (4 patients), or other lesions (8 patients). The cause-specific survival rate was 48%, the relapse-free rate was 42%, and the local relapse-free rate was 75% at 10 years. No statistically significant difference in outcome was noted between those treated with conservation surgery and those undergoing mastectomy. Patients with negative margins had a significantly better local relapse-free rate than did those with

positive margins (80% vs. 33%; *P* = .009).

PROGNOSTIC FACTORS FOR SURVIVAL AND METASTASIS

Carcinoma of the breast represents a wide spectrum of tumors with a variety of clinical, biologic, and genetic characteristics resulting in a considerable variation in prognosis. It is important to understand, particularly from the radiation oncologists' perspective, that prognostic factors for systemic relapses and prognostic factors for local relapse differ significantly. Furthermore, prognostic factors for local relapse after mastectomy differ substantially from prognostic factors for local relapse after lumpectomy and radiation.[219] For example, tumor size and nodal status are clearly among the strongest predictors of overall survival and metastasis and are also strong predictors of postmastectomy chest wall relapse when radiation is not used.[113,220,221] However, these factors have not been consistently reported to be prognostic for an in-breast relapse after cancer surgery. On the other hand, margin status is a strong predictor of relapse in the conservatively treated breast but is not strongly correlated with distant metastasis.[222–224] Young age is also a very strong predictor of local relapse after breast-conserving therapy, and although it has been shown to be predictive of systemic metastasis, the effect of young age on distant metastasis as an independent factor is clearly not as significant as it is for local relapse in the conservatively managed patient.[225] Patients, as well as clinicians, often become confused regarding these issues, resulting in misconceptions regarding appropriate decision-making and treatment. Below, prognostic factors for systemic relapse (i.e., distant metastasis and disease-free and overall survival) are discussed. A more in-depth discussion of prognostic factors for local relapse following lumpectomy and radiation is included later in the section on selection factors for the conservative management of breast cancer. Prognostic factors related to postmastectomy chest wall recurrence for patients with early-stage disease are discussed in Chapter 57.

Tumor Size

The size of the primary tumor ranks among the strongest predictors of distant metastasis and disease-free and overall survival. Although tumor size correlates strongly with the presence and number of involved axillary lymph nodes, it is clearly an independent prognostic factor. Among patients with documented

node-negative disease, tumor size remains a strong and independent predictor of disease-free and overall survival. In a classic study with over 20 years of follow-up, Rosen et al.[192] reported a recurrence-free survival of 88% for tumors <1 cm, 72% for tumors 1.1 to 3.0 cm, and 59% for tumors 3.1 to 5.0 cm. In an analysis of 826 women with node-negative breast cancer treated by mastectomy at the University of Chicago with a median follow-up of 13.5 years, Quiet et al.[226] reported a 20-year disease-free survival of 79% for patients with tumors <2 cm, compared with 64% with tumors >2 cm. In multivariate analysis, the strongest predictor of outcome and time to relapse was pathologic tumor size. Survival as a function of primary tumor size in node-negative breast cancer patients is illustrated in Figure 59.10.

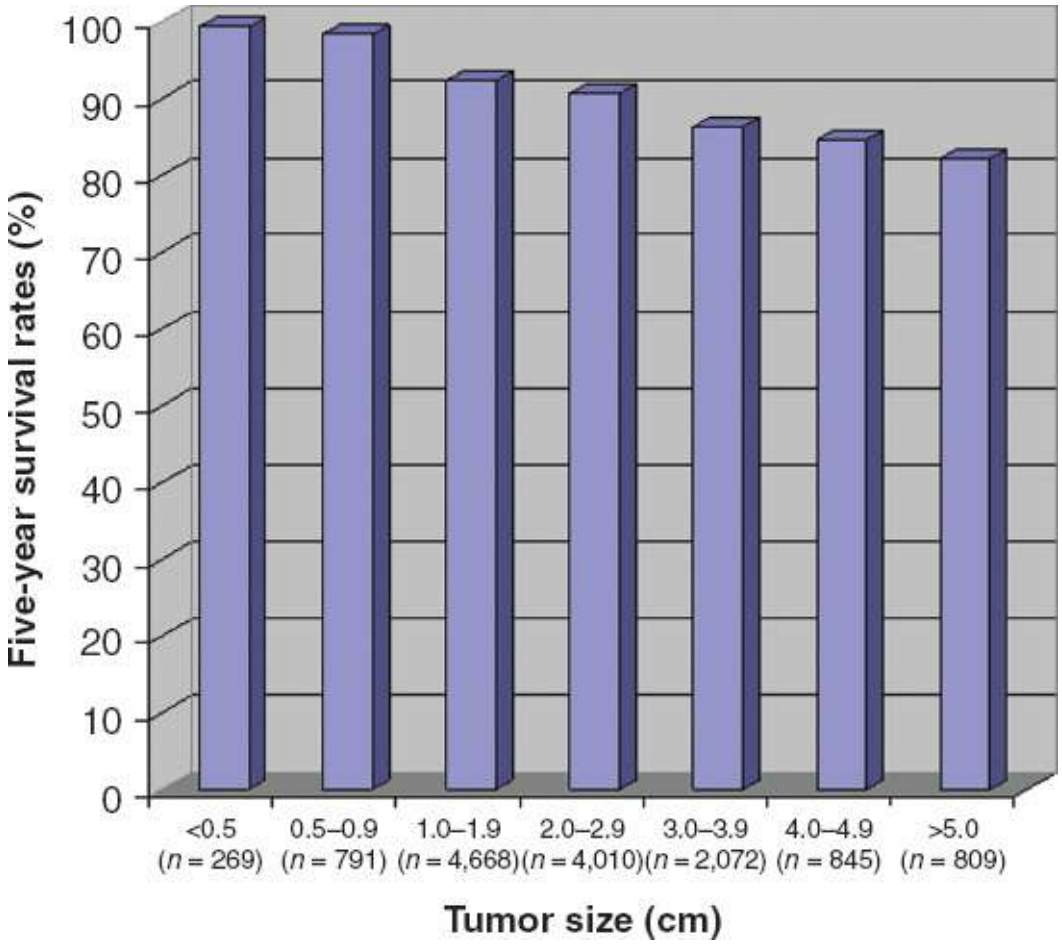

FIGURE 59.10. Five-year survival according to tumor size in node-negative breast cancers. (Data adapted from Carter CL, Allen C, Henson DE. Relation of tumor size, lymph node status and survival in 24,740 breast cancer cases. *Cancer* 1989;63:181–187.)

Axillary Nodal Status

Of all prognostic factors, nodal status continues to be the strongest predictor of disease-free and overall survival and is the primary factor that governs breast cancer staging (Fig. 59.11).[188] Although there is a direct relation between the number of axillary nodes involved and the risk of distant metastasis, the most commonly employed schema is to group patients into four prognostic categories (node negative, 1 to 3 involved nodes, 4 to 9 involved nodes, and more than 10 involved nodes). These nodal prognostic categories are employed in the N staging of the current AJCC staging system. Although outcomes will continually improve as systemic therapies advance, data from previous NSABP trials treated primarily with locoregional therapy alone revealed 5-year survival rates of 82.8% for node negative, 73% for 1 to 3 positive nodes, 45.7% for 4 to 12 positive nodes, and 28.4% for more than 13 positive nodes.[71,178,227–229]

Micrometastasis

The influence of microscopic disease in the lymph nodes has been the subject of several recent analyses because of the increased detection of micrometastasis in the era of sentinel lymph node biopsy. Most recent studies have demonstrated

that by using a combination of blue dye and radiolabeled colloid techniques, the sentinel node can be identified in >95% of cases.[230–232] In experienced hands, false-negative sentinel node rates are low (<10%), and prognosis of sentinel node–negative patients is similar to that of node-negative patients who have undergone a complete axillary dissection. Although the standard of care for sentinel node–positive patients has traditionally been completion axillary dissection, results of the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial have challenged the need for completion axillary dissection in selected sentinel node–positive patients.[233] The need for axillary dissection in node-positive patients will likely continue to be highly individualized and will be further evaluated in ongoing clinical trials.[234]

Hansen et al.[235] evaluated the sentinel node in 696 women by hematoxylin and eosin staining and immunohistochemistry. With a median follow-up of 38 months, the size of the sentinel node metastasis (<2 mm or >2 mm) was a significant prognostic factor. There was no difference in disease-free or overall survival, however, between true node-negative and immunohistochemistry-only–positive cases. Additional data from large databases will continue to emerge in the coming years to further refine the prognostic significance of micrometastasis and immunohistochemistry-only positive lymph node metastasis in breast cancer patients.

Tumor Type

The histologic subtype of invasive cancer has been shown to be of prognostic value in several studies. The tubular, mucinous, and medullary subtypes have been shown to have a more favorable prognosis, compared with invasive ductal.[192,199,236,237] Invasive lobular tumors appear to have a prognosis similar to invasive ductal tumors.[238] Poor prognostic categories include metaplastic, undifferentiated, and other rarer subtypes.[113,193] In a classic analysis of 293 T2N0 breast cancers with over 20 years of follow-up treated by mastectomy, Rosen et al.[192] reported more favorable relapse rates in medullary, mucinous, tubular, and papillary subtypes compared with invasive ductal and invasive lobular tumors.

Tumor Grade

Multiple tumor grading systems have been proposed in an effort to standardize and improve interobserver variability. The Scarff-Bloom-Richardson classification system utilizes mitotic index, differentiation, and pleomorphism,

each with scores of 1 to 3. Scores of 3 to 5 are well differentiated, 6 to 7 moderately differentiated, and 8 to 9 poorly differentiated. This system is commonly employed and has been shown to be of independent prognostic significance.[239]

Elston and Ellis[240] of the Nottingham group refined this methodology. The revised technique involves evaluation of three morphologic features—the percentage of tubule formation, the degree of nuclear pleomorphism, and an accurate mitotic count using a defined field area. A numerical scoring system is used, and the overall grade is derived from a summation of individual scores for the three variables: three grades of differentiation are used. Histologic grade, assessed in 1,831 patients, shows a very strong correlation with prognosis; patients with grade I tumors have a significantly better survival than do those with grade II and III tumors ($P < .0001$). If the protocol is followed, reproducible and consistent results regarding prognosis can be obtained.

Estrogen and Progesterone Hormonal Receptors in Tumor Cells

Several studies have indicated that patients with hormonal receptors have a significantly higher survival rate.[241,242] Crowe et al.[243] studied 1,392 patients with carcinoma of the breast treated with modified radical mastectomy. ER-positive tumors (≥3 fmol/mg cytosol protein) were found in 1,063 patients (76.4%). Their 10-year overall survival rate of 65.9% was significantly better than the 56% rate in 329 patients with ER-negative tumors ($P = .0001$). However, this correlation is not consistent, with conflicting reports regarding the prognostic significance of hormonal receptor status.[244] The apparent discrepancy in some of these reports may be explained by technical nuances. Esteban et al.[245] noted that quantitative immunohistochemistry of ERs provides results with better predictive value than the biochemically procured ones.[246]

Tumors that express both ER and PR have the greatest benefit from hormonal therapy, but those containing only ER or PR still have significant responses. Two types of ERs—ER-α and ER-β—have been identified. PR also exists in two forms, PRA and PRB.[247] Patients with tumors negative for hormonal receptors have only a small probability of responding to hormonal therapy.[183,247]

Lymphatic and Vascular Invasion

Lymphatic and vascular invasion (LVI) in the peritumoral region has been clearly demonstrated to be of independent prognostic significance in several studies.[248–252] In the study by Rosen et al.,[192] recurrence rate for LVI-positive

stage I patients was 38% compared with 22% for LVI-negative patients.

Proliferative Indices, S-Phase, and Thymidine Labeling Index

Various techniques for evaluating the proliferative rate of a tumor have been shown to correlate with distant metastasis and survival. The most common are the fraction of cells in SPF, TLI, mitotic index, or antibodies directed against proliferative markers such as Ki-67 and proliferating cell nuclear antigen.

Thymidine labeling represents the fraction of cells in S phase of the cell cycle and is based on the active incorporation of labeled thymidine into DNA; the TLI of primary breast cancers appears closely related to steroid receptor status and generally unrelated to pathologic stage. Retrospective analyses have shown that TLI is a prognostic indicator, independent of tumor size, steroid receptors, and *p53*, and Bcl-2 protein expression. Together with patient age and tumor size, TLI is able to identify patients at different levels of risk for locoregional or distant metastases.[253]

Wenger and Clark[254] concluded that despite different techniques and cut points, a higher SPF is in general associated with worse tumor grade, absence of steroid receptors, larger tumors, and positive axillary lymph nodes. Higher SPF is usually associated with worse disease-free and overall survival rates in both univariate and multivariate analyses.

Bryant et al.,[255] in over 4,000 patients from NSABP protocol B-14 who had ER-positive tumors and no axillary lymph node involvement, found a strong association between SPF and disease-free and overall survival rate.

DNA Ploidy Index

Chromosome instability (CIN) is gaining increasing interest as a central process in **cancer**. CIN, either past or present, is indicated whenever tumour cells harbor an abnormal quantity of DNA, termed “aneuploidy”.[256] At present, the most widely used approach to detecting aneuploidy is DNA cytometry—a method that involves staining of DNA in the nuclei of cells from a tissue sample, followed by analysis using quantitative flow cytometry or microscopic imaging. Most breast cancers exhibit a bimodal distribution of DNA values. DNA ploidy as measured by flow cytometry correlates with nuclear grade, with low-grade tumors being diploid and high-grade tumors being aneuploid.[257] Ploidy was found to be associated with histologic type, tumor grade, and SPF values, but not with patient age, menopausal status, tumor size, axillary nodal status, ER status, or PR status.[258] Diploid tumors tend to be ER positive, whereas aneuploid tumors

are frequently ER negative. Older patients are more likely to have hyperdiploid tumors.[259] Diploid tumors tend to have a better prognosis than do those with an aneuploid DNA distribution.[260,261] Toikkanen et al.,[262] in 351 patients monitored for a minimum of 22 years, observed a 25-year survival rate of 28% for patients with nondiploid tumors, in contrast to 48% for those with a diploid DNA pattern. In a European Organisation for Research on Treatment of Cancer (EORTC) trial evaluation of DNA, proliferative compartment was the most important predicting factor for overall survival and metastasis-free survival in 281 premenopausal, lymph node–negative patients with invasive carcinoma of the breast.[263]

Studies by Ewers et al.[264] and Fallenius et al.[265] also confirm the prognostic significance of DNA ploidy. Keyhani-Rofagha et al.[266] and Witzig et al.[267] reported no statistically significant prognostic significance of DNA ploidy.

HER2/neu

The *HER2/neu* proto-oncogene (also called c-*erbB-2*) located on chromosome 17 codes for a transmembrane glycoprotein, p185, which has tyrosine kinase activity and is homologous to the EGFR.[268] It is amplified or overexpressed in up to 30% of human breast carcinomas. Overexpression of the protein is associated with tumor aggressiveness and decreased disease-free survival in node-positive patients, with variable prognostic significance among node-negative patients. The conflicting reports regarding the prognostic significance of *HER2/neu* may be related to interobserver variability in interpretation of staining and uncertainty regarding the significance of intermediate staining.[186,187,268] Staining for overexpression of *HER2/neu* is interpreted on a 0 to 3+ scale. The available data suggest that the majority of 0 to 1 staining is clearly negative and 3+ is clearly positive, while the classification of those patients with 2+ staining remains uncertain. Amplification of the oncogene identified using FISH techniques has been found to be of more prognostic value.[186,187,268,269]

Variability in the prognostic value of *HER2/neu* may be related to variability in interpretation of protein expression levels. Birner et al.[270] correlated results of the HercepTest with *HER-2/neu* oncogene gene amplification assessed by FISH in 303 patients with lymph node–positive breast cancer.[270] Results were compared with FISH analysis performed in all 2+ and 3+ specimens (103 cases) and 104 *HER-2/neu*-negative specimens; 3+ carcinomas were found in 8.9% to 15.7% of specimens. FISH revealed that almost exclusively 3+ positive cases

had *HER-2/neu* gene amplification.

More critical than its prognostic significance, however, is its predictive value with respect to response to therapy and its value in identifying patients who may benefit from adjuvant targeted therapy directed at the protein.[271] Several studies have demonstrated that *HER-2/neu* status may be predictive of response to hormonal therapy, resistance to alkylating agent–based chemotherapy, and response to taxanes.[272,273]

p53 Gene

The *p53* tumor suppressor gene encodes a nuclear phosphoprotein that is thought to be important to cell cycle regulation and DNA repair and that also may regulate induction of apoptosis by ionizing radiation.[274,275] The *p53* gene is most frequently mutated in sporadic breast cancer; alterations of this gene were identified in 43 of 192 tumors (22%).[275] Mutations of *p53* were found more often in tumors of younger women ($P = .002$) and African American women ($P = .04$) and in tumors lacking ER ($P = .03$), PR ($P = .04$), or both ($P = .06$). In 843 cases of breast cancer, *p53* mutations were not found in low-grade carcinomas (tubular, mucinous, papillary, and invasive cribriform types) but were observed in 4.2% of ILCs (6 of 140 cases), 15.5% of high-grade IDCs (99 of 640 cases), and 50% of pure medullary carcinomas (5 of 10 cases).[276] The overall survival rates were not significantly different in patients with mutant or wild-type *p53* tumors. In another study of 156 patients with primary invasive breast cancer, overexpression of p53 protein emerged as a reliable and independent predictor for disease recurrence and reduced survival.[277] Jansen et al.,[278] in a study of 345 patients with breast cancer with a median follow-up of more than 10 years, noted that *Bcl-2* expression was not a prognostic factor, but *p53* was an independent prognostic factor for overall survival ($P = .005$) and postrelapse survival ($P = .006$). However, *p53* status was important only in the *Bcl-2*–positive subgroup.

Genetic Profiling

Recent developments in DNA microarray technologies allow for extensive profiling of tumors based on their gene expression signatures.[279] Using this technology, investigators from the Netherlands Cancer Institute screened thousands of genes to develop a 70-gene prognostic signature that in 295 women demonstrated a 10-year disease-free survival of 50.6% in 180 poor prognosis signature patients compared with 85.2% in 115 women with a favorable

signature. In a recent validation study, the profiling outperformed classic prognostic criteria, but the magnitude of the prognostic value was not as strong.[280–282]

Gene expression profiling has had a marked impact on our understanding of the biology of breast cancers and is routinely used in clinical decision-making. Categorizing breast cancer into distinct clinical subtypes of luminal A, luminal B, *HER2/neu*, and basal-like has significant prognostic value and impacts on decisions regarding systemic therapy options.[283,284] Although gene profiling forms the basis of this subtyping, most clinicians rely on common molecular markers of ER, PR, *HER2/neu*, Ki-67, and others as a surrogate to classify patients into these intrinsic subtypes of breast cancer for clinical decision making.[285]

An assay using gene profiling on paraffin-embedded specimens has been developed by Genomics Health Inc. (Redwood City, CA, USA). The Oncotype DX Breast Recurrence Score Assay measures RNA expression levels of 21 genes (16 cancer-related and 5 reference genes) using quantitative real-time reverse transcriptase polymerase chain reaction (qRT-PCR) on formalin-fixed, paraffin-embedded (FFPE) tissue samples to compute a recurrence score (RS) (0 to 100), which is used to estimate the odds of relapse over 10 years. Specimens from patients in NSABP trials with ER-positive HER2-negative tumors treated with tamoxifen alone were used to validate this scheme in which patients were categorized as low risk (<18 score), intermediate risk,[19–21,23,25–29,101–104] or high risk.[30–98,105] As shown in Figure 59.12, the likelihood of distant metastasis is low in those patients with favorable scores treated with tamoxifen alone.[286] These data can be used to determine which patients with ER-positive tumors and otherwise favorable factors may avoid chemotherapy and aid the clinician and patient in clinical decision-making. For intermediate Recurrence Score patients where chemotherapy benefit remains unclear, two phase III clinical trials (one in the node-negative and the other in the node-positive setting) are ongoing to determine whether endocrine treatment alone is noninferior to chemoendocrine treatment in this patient group[287].

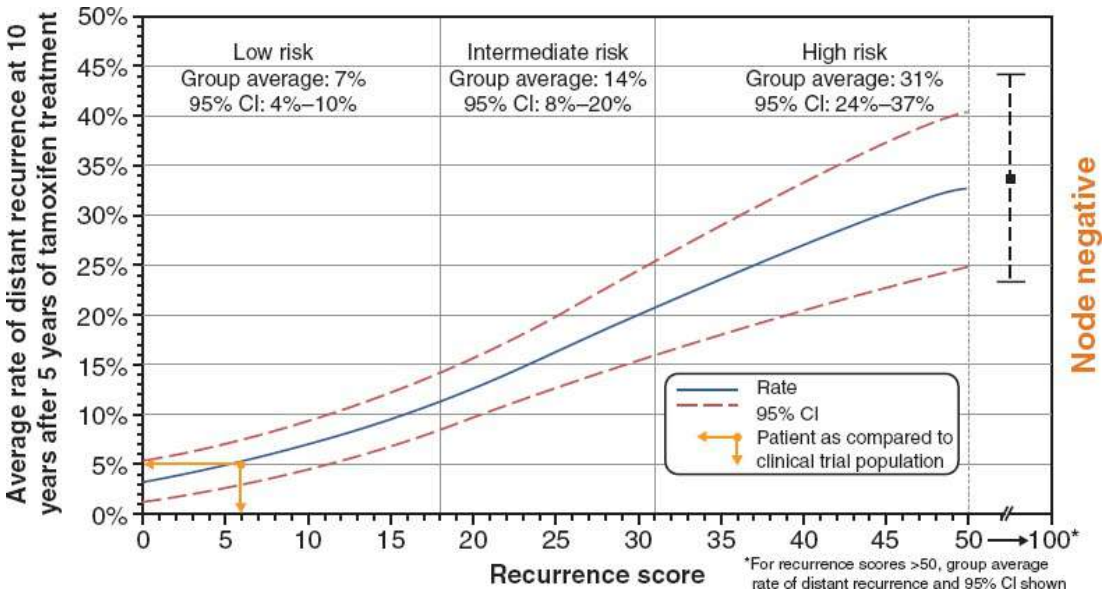

FIGURE 59.12. Risk stratification in patients with receptor positive tumors treated with hormonal therapy broken as a function of recurrence score using the Oncotype DX gene profiling scheme.

Age

Although young age has consistently been shown to be a predictor of local relapse following breast-conserving surgery, there are conflicting data regarding its prognostic significance for distant metastasis and overall survival.[11,219,225,288–291] The available data are confounded by the fact that younger women often present with palpable disease and have larger tumors with a higher percentage of positive nodes. Several studies, however, have shown that when corrected for stage, young age remains a significant prognostic factor for distant metastasis. In an analysis of 1,751 patients with nonmetastatic breast cancer, Vanlemmens et al.[292] demonstrated that younger women had a higher proportion of patients with ER-negative and high-grade tumors and lower disease-free and breast cancer–specific survival. In multivariate analysis, young age at diagnosis was an independent poor prognostic factor. Kollias et al.,[293] however, in an analysis of 2,879 patients younger than 70 years old with operable disease in the Nottingham database, demonstrated that the association of young age at diagnosis with a worse prognosis was explained by a higher proportion of poorly differentiated cancers in young women and that young age itself had no influence on the prognosis of the individual. Although clearly not as valid as tumor size and nodal status, young age may be considered in combination with other prognostic factors in clinical decision-making as a potential negative prognostic factor.

Race

African American women are commonly diagnosed with more advanced stages of breast cancer than are white women.[11] Simon and Severson,[294] in a review of 10,502 women diagnosed with breast cancer (82% white and 18% African American), observed that African American women were more likely to present with regional or distant disease (45%) than were white women (37%). White women had a better survival rate than did African American women during the first 4 years after diagnosis ($P < .0001$), but there were no significant differences in survival by race in women who lived longer than 4 years ($P = .64$). Black women are more likely than are whites to report that they have not had a mammogram within 3 years before diagnosis. However, history of mammographic screening accounted for <10% of the observed differences in stage at diagnosis.[295]

In 75 black and 615 white women with stage I and II breast cancer treated with breast conservation therapy and CMF (cyclophosphamide, methotrexate, and fluorouracil), with or without prednisone and tamoxifen, the 5-year actuarial local-only first failure rates were 5% for black women and 6% for white women ($P = .53$); regional-only failure, 9% and 1% ($P = .002$); and regional recurrence as any component of first failure, 16% and 4%, respectively ($P = .001$).[296] The 5-year overall survival rate for the black patients was 82% versus 91% for the white patients ($P = .01$); the disease-free survival rates were 64% and 83%, respectively ($P = .0002$).

Eley et al.[297] reported on a study of 612 black and 518 white women aged 20 to 79 years with primary invasive breast cancer. After controlling for geographic site and age, the risk of dying was 2.2 times greater for blacks than whites. Adjustment for stage reduced risk from 2.2 to 1.7; further adjustment for sociodemographic variables had no effect. They concluded that approximately 75% of the racial difference in survival was explained by prognostic factors. Other studies have also indicated that black women more commonly develop breast cancers that are high grade and negative for ER, PR, and *HER2/neu*.[298,299]

Obesity and Body Mass Index

In a study of 923 women treated by mastectomy and axillary dissection, those who were obese (25% or more over optimal weight for height) at the time of primary breast cancer treatment 10 years after diagnosis were at significantly greater risk for recurrence (42%), compared with nonobese patients (32%; $P < .01$).[300] On multivariate analysis, obesity remained a statistically significant

prognostic factor after controlling for tumor size, number of positive axillary lymph nodes, age at diagnosis, and adjuvant chemotherapy. Recurrent disease developed in 32% of obese patients compared with 19% of nonobese women.

Daling et al.,[301] in a study of 1,177 women 45 years of age and younger who had invasive ductal breast carcinoma, found that women with breast carcinoma who were in the highest quartile of BMI were 2.5 times more likely to die of their disease within 5 years of diagnosis compared with women in the lowest quartile of BMI.[301]

Smoking

High plasma levels of estrogens are associated with increased breast cancer risk. Manjer et al.[302] in an analysis of 792 women in a mammographic screening trial with a mean follow-up of 12.1 years observed that 145 patients died of breast cancer. The RRs for smokers and ex-smokers, compared with those who had never smoked, were 1.44 and 1.13, respectively. The association with smoking remained significant after adjustment for age and stage at diagnosis and other potential confounders.

Pregnancy

Kroman et al.[303] investigated the prognostic effect of age at first birth and total parity in 10,703 women with primary breast cancer. After adjusting for age and stage of tumor, the number of full-term pregnancies had no prognostic value. However, women with primary childbirth between 20 and 29 years experienced a significantly reduced risk of death compared with women with primary childbirth before the age of 20 years (20 to 24 years, RR 0.88; 25 to 29 years, RR 0.80). Psyrri and Burtness[304] reviewed 117 articles and three abstracts referring to breast cancer in pregnancy. They concluded the prognosis of the pregnant breast cancer patient is similar to her stage-matched nonpregnant counterparts in most series. Management of breast cancer during and after pregnancy is discussed in detail later.

Although in the past it was thought that pregnancy after the diagnosis of breast cancer was associated with a worse prognosis, recent evidence suggests the opposite.[305] Women with a history of breast cancer should be reassured that there is not strong evidence to suggest that subsequent pregnancy will increase the risk of recurrence.

Tumor Location

There is some evidence that medially located tumors have a poorer prognosis

than do laterally located tumors. An analysis of 45,880 patients from the SEER database by Gaffney et al.[306] demonstrated that the hazard ratio (HR) for inner quadrant location compared with outer quadrant was 1.27 for breast cancer–specific survival and 1.11 for overall survival. Both were significant on multivariate analysis. Lohrisch et al.,[307] in an analysis of 6,781 patients, also demonstrated a twofold risk of relapse and breast cancer death associated with high-risk medial breast tumors compared with lateral tumors. They postulate that this may be due to occult spread to IMNs.

Selected Other Prognostic Factors

A wide variety of other prognostic factors have been extensively evaluated. Although some of these have been promising in initial reports, they have not been applied in routine clinical decision-making. However, these markers may help to supplement information obtained with more established prognostic factors. Furthermore, with additional testing and validation, some of these markers may serve as targets for therapeutic interventions. Extensively evaluated and reported potentially useful prognostic factors include cathepsin-D, vascular endothelial growth factor, EGF, *Bcl-2*, carcinoembryonic antigen, prostate-specific antigen, E-cadherin, and others. The reader is referred elsewhere for an extensive review of molecular prognostic factors in breast cancer.[308,309]

MANAGEMENT OF BREAST CANCER

Management of invasive breast cancer should be based on the clinical extent and pathologic characteristics of the tumor, in addition to the age of the patient (menopausal status), some biologic prognostic factors, and the preference and psychological profile of the individual patient, optimally in a multidisciplinary setting. Although surgical, medical, and radiation oncology remain the primary therapeutic disciplines in the management of breast cancer, the patients management often is dependent on input from diagnostic radiology and pathology, the primary physician involved, and support services such as genetic counseling, social work, nursing, and others.

Surgical Management of Breast Cancer

The surgical management of patients with early-stage operable breast cancer addresses both the primary tumor and regional lymphatics. The primary tumor may be managed by mastectomy or lumpectomy, and the nodal regions may be surgically addressed by lymph node dissection or sentinel node biopsy. The

radiation oncologist should be aware of the various surgical procedures, as it may influence the radiotherapeutic management. Procedures that remove the bulk of parenchymal breast tissue include the radical mastectomy, extended radical mastectomy, modified radical mastectomy, simple mastectomy (also referred to as total mastectomy), skin-sparing mastectomy, and nipple-sparing mastectomy. Partial mastectomy, lumpectomy, tylectomy, and quadrantectomy are collectively referred to as breast-conserving surgery.

Breast-conserving approaches, as well as the skin-sparing and nipple-sparing mastectomy, used in early-stage breast cancers, are briefly discussed here as they are often used in early-stage disease. Details of the mastectomy procedures are summarized in Chapter 57.

Skin-Sparing Mastectomy

Skin-sparing mastectomy is a standard mastectomy, with minimal skin sacrifice at the mastectomy site.[113] This is often performed when immediate reconstruction is planned. This technique attempts to remove all breast tissue, but the preservation of skin provides cosmetic and reconstructive advantages. The procedure is oncologically sound, and patients undergoing skin-sparing mastectomy do not require postmastectomy radiation unless they have risk factors that place them at higher risk (i.e., positive nodes, positive margins, large primary tumors), as discussed in Chapter 57.

Nipple-Sparing Mastectomy

The nipple-sparing mastectomy is distinct from the skin-sparing mastectomy in that the nipple and/or nipple areola complex are conserved. This procedure is more controversial and is not routinely employed in cancer patients. However, there have been recent studies employing this technique in combination with intraoperative electrons in patients with operable breast cancer.[310]

Lumpectomy

Another treatment of breast cancer, initially described by Keynes in 1929 and 1937, combined breast-conserving surgery by wide local excision of the tumor followed by definitive irradiation to the intact breast.[58,311–313] Various terms have been used to describe the surgical approach, including lumpectomy, wide local excision, breast-conserving surgery, tylectomy, tumorectomy, segmental mastectomy, partial mastectomy, and quadrantectomy. This approach is extensively discussed in this chapter. The NSABP recommends specific types of incisions depending on the location of the tumor (Fig. 59.13). The radiation

oncologist may play an advisory role, as in many cases the patient may be evaluated by both the surgeon and the radiation oncologist before the definitive operation.

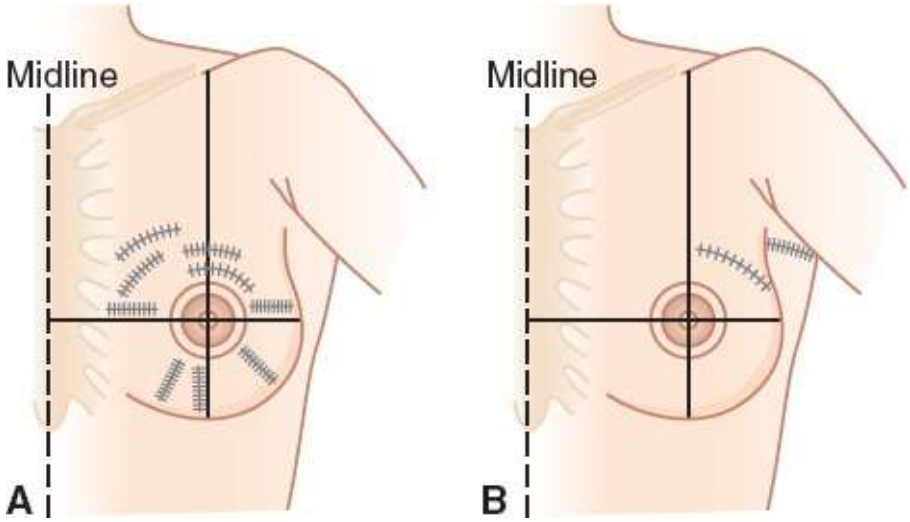

FIGURE 59.13. National Surgical Adjuvant Breast Project recommendations for the direction of incisions used for tumorectomy **(A)** and for axillary node dissection **(B)**. (Courtesy of Bernard Fisher, MD, Chairman, National Surgical Adjuvant Breast Project. From Bedwinek JM. Treatment of stage I and II adenocarcinoma of the breast by tumor excision and irradiation. *Int J Radiat Oncol Biol Phys* 1981;7[11]:1553–1559. Copyright © 1981 Elsevier. With permission.)

The optimal extent of breast resection for treatment of T1 and T2 breast cancer has not been defined. Increasing the size of the resection may lower the risk of local recurrence but also has an adverse impact on the cosmetic outcome. Because cosmesis is a critical reason for performing tumor excision and irradiation instead of mastectomy, wide local excision with microscopically negative margins is preferable to segmental mastectomy or quadrantectomy.

Surgical removal of additional breast tissue surrounding the original excision site is indicated when margins are positive and there is a substantial probability that the tumor cell burden exceeds what can be controlled by the usual doses of radiation. The percentage of patients with residual tumor at the time of re-excision varies widely (32% to 62%), depending on the criteria used for taking a patient back to the operating room for more breast surgery. If the initial margins of resection are positive, 55% to 69% of re-excision specimens contain cancer cells, compared with 49% in cases with unknown margins.[314–317] Tumor size alone is not usually considered an indication for re-excision in the absence of other factors.

Some authors have advocated re-excision of the primary site if the biopsy was performed at an outside hospital and margins of resection were unknown. Of 210 patients having surgery at the MD Anderson Cancer Center, 67 underwent re-excision after biopsies performed at other institutions, and invasive carcinoma was identified in 57%.[315] An 8.2% incidence of breast recurrence (12 of 135 patients) was noted when the tumor excision was performed before referral to the MD Anderson Cancer Center, but only 2% (4 of 210) when it was performed at that institution.

Other factors that may have an impact on the rate of positive re-excisions include extensive intraductal carcinoma (EIC) and residual calcifications on a postlumpectomy preirradiation mammogram. At Harvard University, when EIC was detected on the initial biopsy, 88% of the re-excisions were positive, compared with 48% when EIC was absent.[316] At the University of Pennsylvania, when a posttylectomy mammogram detected residual microcalcifications, 86% of the re-excisions contained tumor.[317] In a series from Yale, reported by Lally et al.,[318] of 34 patients with a postlumpectomy mammogram that showed suspicious residual calcification who underwent re-excision, 20 (59%) were found to have residual disease. Patients whose initial tumor was associated with calcifications with questionable, close, or positive margins should be evaluated with a prelumpectomy mammogram with guided re-excision if suspicious residual calcifications are present.

Based on these findings, the authors recommend re-excision at the primary tumor site (a) when the surgical procedure was less than a complete lumpectomy, such as an initial incisional biopsy or core biopsy, (b) when pathologic margins on the initial excisional biopsy are shown to be involved by tumor, and (c) when there are residual suspicious microcalcifications on a postlumpectomy mammogram. As will be discussed later, although re-excision for involved margins is indicated, selected patients with a focally involved margin may be treated with radiation therapy, without re-excision, following lumpectomy with acceptable local control rates.

Choices Between Mastectomy and Breast-Conserving Surgery in Early-Stage Disease

For the majority of patients with early-stage breast cancer, breast-conserving surgery and mastectomy are both reasonable options, and patients are often conflicted regarding the choice. Patients should be reassured that provided they meet the criteria for breast-conserving surgery, all of the available medical

evidence demonstrates equivalent long-term survival rates with both modalities.

A modified radical mastectomy may be preferable for some patients who wish to avoid radiation, for those in whom removal of clinical and radiographically apparent disease will result in a suboptimal cosmetic result, for those with diffusely positive margins which cannot be cleared with re-excision, and those with diffuse suspicious microcalcifications. Even patients who are ideally suited for breast-conserving therapy may have a personal preference for mastectomy, based on a number of factors.

Whelan et al.[319] reported on the decision-making process in 82 consecutive node-negative patients presented with a decision board of therapeutic choices. Overall, 95% of women chose lumpectomy and breast irradiation. Kelemen et al.[320] evaluated the choice between breast-conserving surgery and modified radical mastectomy in 7,815 women with early-stage breast cancer. There was a progressive increase from 16% to 47% in the use of breast-conserving therapy to treat tumors of all sizes over the 11 years of the study ($P < .0001$), and it was more frequently used for ≤2 cm tumors with an odds ratio (OR) of 2.46. Breast-conserving therapy was used at a slightly higher rate in medical centers than in community hospitals (31% vs. 28%; $P < .0001$); its use varied among geographic regions from a low of 24% in the southwestern United States to 36% in the northeast and 40% in hospitals outside the continental United States ($P < .0001$). Local availability of radiation therapy did not influence choice of treatment.

In response to a questionnaire mailed to 2,405 oncologists from all three disciplines and 60 oncology nurses in the United States, Tannock and Belanger[321] noted that more than 60% thought that modified radical mastectomy and conservation surgery plus irradiation were equivalent options for patients with stage T1 and T2 carcinoma of the breast; 31% of the surgical oncologists favored the former and 35% of the radiation oncologists favored the latter approach. Medical oncologists were equally divided between the two procedures (14% and 18%, respectively).

In an analysis from Canada, Temple et al.[322] prospectively evaluated participants with a first diagnosis of localized unilateral breast cancer who were candidates for breast-conserving therapy or mastectomy. Of 157 patients between 1992 and 1995, 71.3% anticipated having breast-conserving surgery and 28.7% anticipated modified radical mastectomy. The patient, physician, and significant other were perceived to play a role in the decision process. The two top-ranked items perceived to have influenced treatment choice were doctor’s advice and possibility of complete cure. The authors concluded that both patient

and surgeon factors are important predictors of type of planned surgery, but there is a gap between women's preferences and actual experiences with regard to information provided.

Some patients with early-stage breast cancer will choose mastectomy to avoid the course of radiation, either because of the logistics of 6 weeks of therapy or because of fears of radiation therapy. It is likely that accelerated partial breast irradiation (APBI) may further impact the choice between mastectomy and breast-conserving surgery for those women in whom the time commitment of treatment is an issue.

Patients selecting mastectomy should also be made aware that this procedure does not totally eliminate the need for radiation treatment. For patients with early-stage operable breast cancer treated by modified radical mastectomy, postoperative irradiation of the chest wall and peripheral lymphatics may be indicated in selected patients with high-risk characteristics, positive nodes, or positive resection margins. Indications for postmastectomy radiation are discussed in Chapter 54.

Surgical Management of Axillary Lymph Nodes

An axillary node dissection or sentinel node biopsy are a standard component of the staging process for a majority of women with early-stage invasive breast cancer.[188] Although the role of complete axillary dissection is evolving, there is compelling evidence that ALND is not necessary in most women with early-stage breast cancer who have only one or two sentinel lymph node metastases and who will receive whole-breast irradiation as part of breast-conserving therapy. If, however, whole-breast irradiation is not planned, then ALND is indicated for such patients. Clearly the procedure is most important for women in whom axillary nodal status will influence subsequent management with respect to adjuvant systemic therapy. Two randomized trials, the ACOSOG Z-0011 trial and the International Breast Cancer Study Group 23-01 (IBCSG 23-01) trial (discussed later), demonstrated that many of these patients with one or two metastatic sentinel nodes can safely avoid a completion axillary node dissection. It is not uncommon for clinicians to avoid axillary staging if it is not going to influence management.[66,323,324] This is relevant in elderly women with receptor-positive tumors who will receive hormonal therapy, regardless of nodal status, and who are not thought to be candidates for cytotoxic chemotherapy. The decision to omit SLNB in older women should be discussed in a multidisciplinary setting with input from the treating oncologists to ensure all

providers are in agreement as to whether or not axillary staging information is important for adjuvant-therapy decisions. As will be discussed later, axillary radiation, as with axillary dissection, results in a high rate of regional control.[66,323,324]

Axillary Node Dissection

The axillary contents are divided into three levels: level I represents tissue between the axillary vein and the latissimus dorsi muscle and the lateral border of the pectoralis minor muscle; level II is located between the lateral and medial borders of the pectoralis minor muscle; and level III is between the medial border of the pectoralis minor and Halsted ligament (the apex of the axilla).[1] Thorough dissection of levels I and II has traditionally been the most common axillary surgical procedure in patients with clinically node-negative breast cancer. Complete axillary dissection, including level III, may be performed in patients with clinically positive lymph nodes. A higher incidence of breast and arm edema has been noted with level III axillary node dissection, and the benefit of dissecting the level III lymph nodes has not been demonstrated.[325] Pigott et al.[326] reported on 146 patients treated with radical mastectomy (either modified or Halsted) for invasive ductal or lobular carcinoma of the breast. Eighty patients (55%) had histologically proven axillary lymph node metastases. If only the low (level I) axillary lymph nodes had been removed, 18 patients (25%) would have had metastases confined to levels II and III that would have gone undetected. However, only 1.4% of patients showed positive level III lymph nodes if levels I and II were negative.

Approximately 20% to 40% of patients with carcinoma of the breast and clinically negative lymph nodes have pathologic evidence of lymph node metastases.[1,113,229,327,328] Yet, in patients with stage I or II breast cancer and clinically negative axillary lymph nodes, if an axillary dissection is not performed, axillary recurrence develops in only approximately 20%.[71] In patients with clinically positive axilla, 20% to 30% have no histologic evidence of nodal metastatic disease.[71]

The necessity of axillary dissection has been questioned in selected patients with a low probability of nodal involvement by Silverstein et al.,[66] who reported positive axillary lymph nodes in only 3 (3%) of 96 patients with tumors ≤5 mm in diameter and in 27 (17%) of 156 patients with tumors 6 to 10 mm in diameter. Iwasaki et al.,[329] in a group of 823 patients with T1N0M0 invasive breast cancer, also identified a subgroup of patients who may not need to undergo ALND.

Certain tumor types (medullary, mucinous, and tubular carcinoma) had lower positive rates for lymph node involvement. With regard to the histologic grade, lymph node positivity increased significantly with high-grade tumors.

In a randomized trial, evaluating the necessity of axillary dissection in older women, Martelli et al.[330] reported on 219 women, 65 to 80 years of age, with early breast cancer and clinically negative axillary nodes who were randomized to conservative breast surgery with or without axillary dissection. Tamoxifen was prescribed to all patients for 5 years. With a follow-up of 60 months, there were no significant differences in overall or breast cancer mortality or crude cumulative incidence of breast events between the two groups. Only two patients in the no axillary dissection arm (8 and 40 months after surgery) developed overt axillary involvement during follow-up. They conclude that older patients with T1N0 breast cancer can be treated by conservative breast surgery and no axillary dissection without adversely affecting breast cancer mortality or overall survival.

In light of the increased use of primary tumor-related factors, including molecular profiling, for decision-making regarding systemic therapy, combined with sentinel node procedures and low rates of regional relapse with radiation therapy or observation in selected patients, axillary dissection has been less frequently employed in the management of early-stage breast cancer patients.

Sentinel Lymph Node Biopsies

In recent years, there has been a substantial increase in the use of sentinel lymph node biopsies to stage patients with breast cancer. Patients are injected around the tumor with technetium-99m (^{99m}Tc) sulfur colloid and vital blue dye, and a handheld γ-probe is used to identify areas of highest radioisotope uptake in the lymphatic system. The lymph nodes underlying this area (sentinel lymph nodes) are removed.[231,331–333] The sentinel node procedure has been widely embraced as an acceptable standard for women with breast cancer and has a high degree of sensitivity and specificity.[334]

Recently, the standard of care that mandated performing an ALND in node-positive patients was reexamined after the publication of IBCSG 23-01 and the ACOSOG Z11 studies[335,336]. The IBCSG 23-01 study randomized 931 patients with micrometastatic (<2 mm) deposit in the SLNB to ALND or no additional surgery[337]. The majority of the patients (97%) received adjuvant RT without RNI. In the ALND arm, additional axillary nodal involvement was detected in 13% of the patients. There was no difference in the overall survival or disease-free survival between the two study arms. Although the study closed before

meeting target accrual, the authors concluded that breast cancer patients with limited SLN involvement could be spared the morbidity of an ALND.

In contrast to the previous study, the ACOSOG Z11 study was a prospective trial examining survival of patients with sentinel node metastases detected by standard hematoxylin and eosin staining, who were randomized to undergo ALND after sentinel lymph node dissection (SLND) versus SLND alone; all patients received whole-breast irradiation. There were 446 patients randomized to SLND alone and 445 to SLND plus ALND. Patients were equally stratified according to multiple factors; those randomized to SLND plus ALND had a median of 17 axillary nodes removed compared with a median of only 2 sentinel nodes removed with SLND alone ($P < .001$). At a median follow-up time of 6.3 years, there were no statistically significant differences in local recurrence ($P = .11$) or regional recurrence ($P = .45$) between the two groups. Interestingly, ALND also removed more positive lymph nodes ($P < .001$) in 27% of the patients in this group. The patients in this trial all had whole-breast irradiation, but RNI was not allowed; however, there was no radiotherapy quality assurance and field design was not uniform. The reason for the low regional relapse rates is likely a combination of factors, including a favorable subset of patients with a low likelihood of a high residual axillary burden of disease, the use of systemic therapy, and incidental radiation to the residual nodes in level I or II from the tangential breast irradiation.

TABLE 59.12 SUGGESTED APPROACH FOR RADIATION FIELD DESIGN IN SENTINEL NODE–POSITIVE PATIENTS NOT UNDERGOING AXILLARY LYMPH NODE DISSECTION

Clinical Scenario	Sentinel Nodes +/Total Sentinel Nodes Sampled	Probability of Additional Nodes MSKCC[338] (%)	Probability of Additional Nodes MDACC[339] (%)	Probability of Four or More Nodes Involved[340] (%)	Field Design
IDC, 1.0 cm, ER+, LVI–	1 (IHC only)/3	3	8	<1	Tangents only
IDC, 1.8 cm, G3, ER+, LVI–, Unifocal	1 (macro)/2	27	24	2	High tangents
IDC, 2.0	2 (macro)/2	63	55	30	High

cm, ER–, LVI+					tangents/consider full nodal treatment
ILC, 4.0 cm ER+, multifocal, LVI–	2 (macro)/2	77	64	40	High tangents/consider full nodal treatment
IDC, 3 cm, ER–, LVI+, multifocal	3 (macro with ENE)/3	78	95	80	Full nodal treatment

ENE, extranodal extension; ER, estrogen receptor; G, grade; IDC, infiltrating ductal carcinoma; IHC, immunohistochemistry; ILC, infiltrating lobular carcinoma; LVI, lymphovascular invasion; macro, macroscopic.

Several studies describe an approach to radiation field design based on probability of additional axillary nodal involvement in patients with positive sentinel nodes (Table 59.12).[234,338–341]

The ALMANAC (Axillary Lymphatic Mapping Against Nodal Axillary Clearance) trial is a multicenter randomized trial of 1,031 patients randomly assigned to sentinel node biopsy (n = 515) or standard axillary dissection (n = 516).[332] Mansel et al.[332] reported the primary outcome measures, which were arm and shoulder morbidity and quality of life. Drain usage, length of hospital stay, and resumption of normal activities after surgery were all highly significantly better in the sentinel lymph node group. In addition, patient recorded quality of life and arm functioning scores were also significantly better, with no increase in anxiety levels in the sentinel node group. The authors conclude that sentinel node biopsy is the treatment of choice for patients who have early-stage breast cancer and clinically negative nodes.

Veronesi et al.[342] also reported on a randomized trial of 516 patients with T1 tumors, randomized to either sentinel node biopsy or total axillary dissection. Axillary dissection was performed in the sentinel node group if the sentinel node contained metastases. In the axillary dissection group, the overall accuracy of the sentinel node status was 96.9%, the sensitivity 91.2%, and the specificity 100%. There was less pain and better arm mobility in the patients who underwent sentinel node biopsy only than in those who also underwent axillary dissection. There were 15 events associated with breast cancer in the axillary dissection group and 10 such events in the sentinel node group. Among the 167 patients who did not undergo axillary dissection, there were no cases of overt axillary metastasis during follow-up.

Weaver et al.[343] evaluated 443 patients with breast cancer. After sentinel node

biopsies, a complete ALND was performed. Original pathologic material was reviewed for 431 patients enrolled in this study and for 214 patients with node-negative disease. Metastases were detected in 16% of the sentinel lymph nodes and in 4% of the nonsentinel nodes (OR 4.3; $P < .001$). Occult metastases were detected in 4% of the sentinel lymph nodes and in 0.3% of the nonsentinel nodes. The probability of detecting metastases in nonsentinel nodes was more than 13 times greater in patients with positive sentinel lymph nodes than in patients with negative sentinel lymph nodes ($P < .001$).

The role of sentinel lymph node procedures in patients undergoing neoadjuvant chemotherapy is covered in Chapter 57.

SYSTEMIC MANAGEMENT OF BREAST CANCER

Systemic therapy is an essential component of both early-stage node-negative breast cancer and advanced-stage disease. Hormonal therapy, cytotoxic chemotherapy, and the more recently introduced biologic therapies are routinely employed in the vast majority of patients with early-stage breast cancer. For patients with all stages of breast cancer, systemic therapy has been shown to decrease the RR of relapse and mortality. However, there are subsets of patients with a very favorable prognosis and extremely low rate of relapse, in whom the risk reduction results in only a very small absolute benefit. It is beyond the scope of this chapter to discuss all of the issues related to systemic management of breast cancer, and the reader is referred to comprehensive reviews on the use of chemotherapy, endocrine therapies, and biologic therapies in the systemic management of breast cancer. These issues are also discussed in more detail in Chapter 57.[344–346]

In the recent 2011 St. Galen consensus meeting, the panel adopted the approach that systemic therapy should be made based on recognition of intrinsic subtypes and that for practical reasons these intrinsic subtypes could be approximated based on more conventional parameters of estrogen receptor, progesterone receptor, *HER2/neu*, and Ki-67. Endocrine therapy alone is generally adequate for luminal A-type cancers, while chemotherapy is typically indicated for luminal B and TN cancers, and trastuzumab is generally added for *HER2*-positive disease.[347]

RADIATION THERAPY IN THE MANAGEMENT OF EARLY-STAGE INVASIVE BREAST CANCER

The radiation oncologist plays a critical role in the management of early-stage breast cancer. As noted previously, the role of radiation therapy in postmastectomy radiation and in the neoadjuvant treatment of advanced breast cancers will be discussed in Chapter 57. The remainder of this chapter will primarily be focused on the role of radiation therapy in the conservative management of early-stage invasive breast cancer.

This will include an extensive discussion of the studies establishing breast-conserving surgery and radiation as the preferred standard of care for the majority of women with early-stage invasive disease and studies evaluating the avoidance of radiation therapy in selected patients. Integration of radiation therapy with systemic therapy will be discussed, as will selection of patients for breast-conserving therapy. Risk factors for local relapse and controversies in the management of patients with special circumstances will be discussed. Technical issues in the delivery of radiation therapy for early-stage breast cancer, including dosing and fractionation, matching techniques, and newer technical approaches, will be presented. The rapidly evolving area of partial breast irradiation will also be discussed. Follow-up of the breast cancer patient and sequelae of treatment will be presented. Management of local relapse in the conservatively treated breast and postmastectomy will be covered in Chapter 57. The role of radiation therapy in the management of DCIS and LCIS was discussed Chapter 55.

Breast-Conserving Therapy and Patient Selection

Breast-conserving surgery followed by radiation therapy to the intact breast is now clearly established as the most acceptable standard of care for the majority of women with early-stage invasive breast cancer. Recommended techniques for breast conservation treatment are wide local excision of the primary tumor, preferably with clear margins, ALND, and breast irradiation (45 to 50 Gy), usually with a boost (10 to 20 Gy, depending on tumor size and status of the surgical margins). As will be discussed in detail under prognostic factors, while widely negative margins are desirable, patients with focally involved margins can be treated with radiation with excellent local control rates.

In addition to tumor control and survival, conservation of the breast with optimal cosmetic results is a crucial goal of this therapy, which is associated with improved psychoemotional adjustment of the patient to the diagnosis and treatment of carcinoma of the breast. It also enhances the acceptance by women of mammographic screening for early detection of this disease.

The widespread embracement of breast-conserving surgery followed by

radiation therapy is based on numerous mature and well-documented studies, both prospectively designed randomized trials and large retrospective series of appropriately selected patients treated with breast conservation followed by radiation therapy.

It is important to select appropriate patients and tumors for breast conservation therapy, with close consultation between the surgeon, medical oncologist, and the radiation oncologist and after thorough discussion of therapeutic alternatives with the patient. Risks and benefits of breast-conserving therapy compared with mastectomy should be discussed. Despite the clear evidence of equivalence, some patients will still prefer mastectomy, which remains an acceptable standard of care for all women with operable breast cancers. Although avoidance of radiation may be a primary rationale for some patients in choosing mastectomy, patients should realize that even with early-stage operable disease postmastectomy radiation may be indicated based on the pathologic findings at mastectomy. It is likely that over the next several years, long-term results and selection factors for APBI will become available and may further influence patient choices regarding breast-conserving surgery with more rapid radiation compared with mastectomy.[348–350]

Ideally, patients electing breast-conserving surgery and radiation will have unicentric primary tumors that are <4 to 5 cm in diameter, as cosmesis is affected by the amount of tissue that must be removed in relation to the size of the breast.[351] For patients in whom the size of the tumor, compared with the size of the breast, will result in an unacceptable cosmetic outcome, neoadjuvant chemotherapy followed by lumpectomy and radiation has been demonstrated to result excellent breast conservation rates.[352–354] This was discussed in detail in Chapter 54.

With careful attention to surgical margins, radiation technique, and the appropriate use of systemic therapy, local relapse rates in the majority of conservatively managed patients are low, and only a minority of patients with early-stage invasive breast cancer are not suitable for breast-conserving therapy. There are several perceived relative “contraindications” to breast-conserving therapy, including patients with collagen vascular disease, patients with germline mutations that predispose to breast cancer development, and those with positive margins, more advanced disease, multicentric disease, pregnancy, or who have had prior radiation. Although many of these factors require careful consideration and discussion between the treating physicians and the patient, as will be discussed in the section on special circumstances, selected patients faced with

breast cancer in the setting of these controversial circumstances can be offered breast-conserving therapy with acceptable outcomes. Although some clinicians believe that patients at higher risk for development of local recurrence should not be treated with conservation surgery, there are relatively few absolute contraindications.

Perhaps with the exception of the patients with persistently positive diffuse margins or gross multicentric disease, where removal of clinically and radiographically apparent disease would result in an unacceptable cosmetic outcome, breast-conserving therapy followed by radiation can be offered to most women with early-stage breast cancer and may be offered to a high percentage of women with advanced cancers following neoadjuvant chemo- or hormonal therapy. The decision regarding breast-conserving therapy compared with mastectomy is often based on personal preference as the available medical and scientific evidence suggests equivalent overall and disease-free survival in all subsets of patients.

Early Reports of Breast-Conserving Therapy

In 1937, Keynes[58] stated that "widespread operations based upon the permeation theory of lymphatics and fascial planes have no real justification and the idea of conservative treatment of cancer of the breast may become less repugnant to us [surgeons]." He treated 325 patients with local removal of the breast tumor and radium implantation at the site of local incision as well as in the axilla. In 250 patients, the 5-year survival rate was 71% for group 1 (disease confined to the breast), 29% for group 2 (disease apparently confined to breast and axilla), and 23.6% for group 3 (advanced disease or inoperable cancer). At the time, the results were comparable with those achieved with radical mastectomy. Other early reports[312,355–358] paved the way for the development of randomized trials that have now clearly established breast-conserving surgery followed by radiation therapy as an accepted standard of care.

Randomized Studies Comparing Breast-Conserving Surgery Plus Radiation Therapy to Mastectomy

There have been numerous randomized trials that have now clearly established breast-conserving surgery followed by radiation therapy as equivalent to mastectomy for appropriately selected patients with early-stage breast cancer. Table 59.13 summarizes these randomized trials. In all of these trials, local tumor excision (tylectomy, lumpectomy), segmental mastectomy, or

quadrantectomy combined with irradiation to the breast yielded survival and tumor control rates similar to those achieved with modified or classic radical mastectomy.[91,99,100,361–365] Each of these randomized trials, as well as meta-analyses of the trials, clearly demonstrates equivalent mortality rates in conservatively treated patients compared with mastectomy.[366–368]

The earliest prospective, randomized trial comparing breast conservation with radical mastectomy was conducted at Guy's Hospital in London. Three hundred and seventy women with stage I or II breast cancer were randomly assigned to receive either standard radical mastectomy or wide local excision plus irradiation.[369] Although the rates of survival and distant metastasis were not significantly different for stage I disease, in stage II, the recurrence rates in the breast and axilla were higher in the group treated with local excision and irradiation, and survival was significantly lower because of a higher rate of distant metastasis. Major weaknesses of this study were the low doses of irradiation used (35 to 38 Gy to the breast and 25 to 27 Gy to the axilla), probably patient selection, and surgical techniques.

TABLE 59.13 PROSPECTIVE RANDOMIZED TRIALS COMPARING CONSERVATIVE SURGERY AND RADIATION WITH MASTECTOMY FOR EARLY-STAGE BREAST CANCER

Veronesi et al.[365] reported on 701 patients with tumors <2 cm in diameter and without palpable axillary nodes of whom 352 were randomly assigned to treatment with either quadrantectomy and axillary dissection plus irradiation (50 Gy in 5 weeks to the breast and 10-Gy boost) and 349 to radical (Halsted) mastectomy. Women with positive axillary lymph nodes also received 12 cycles of adjuvant chemotherapy with CMF. Actuarial 20-year overall and disease-free survival rates were comparable in the two groups (58%). The death rates from breast cancer were 26.1% and 24.3%. The incidence of local failure was 2.3% with mastectomy and 8.8% with quadrantectomy and irradiation. There was no difference in the incidence of contralateral breast cancer (10.2% and 8.7%, respectively).[100]

Fisher et al.[91,363] updated the results of the NSABP protocol B-06 in 1,843 women with clinical stage I or II carcinoma of the breast <4 cm in diameter. Patients were randomly assigned to be treated with total mastectomy or lumpectomy (segmental mastectomy), with or without irradiation. Irradiated patients received 50 Gy to the breast through tangential fields irradiation and a boost to the operative site was not given. With 20-year follow-up, there was no significant difference in survival among patients treated with mastectomy, lumpectomy alone, or lumpectomy combined with irradiation (Fig. 59.14). For the patients treated with lumpectomy alone, the ipsilateral breast relapse rates were approximately 40% if the nodes were negative and 50% if they were positive. For patients treated with lumpectomy and irradiation, the corresponding rates were 10% for all patients and those with negative nodes and 5% for those with positive nodes, illustrating the interaction of irradiation and adjuvant chemotherapy in local tumor control. Cumulate incidence of ipsilateral breast tumor relapse in the lumpectomy alone compared with the lumpectomy and radiation arm is shown in Figure 59.15.

The Institut Gustave-Roussy conducted a prospective, randomized trial comparing mastectomy with local excision plus irradiation for women with cancers measuring ≤2 cm.[359,370] The 15-year disease-free survival rate was 55% for the tumorectomy group and 45% for the mastectomy group (P = .23). The 15-year local recurrence rate was 9% in the conservation surgery and irradiation

group and 14% in the mastectomy group.

The EORTC Breast Cancer Cooperative Group conducted a randomized trial of women with stage I or II breast cancer comparing modified radical mastectomy (420 patients) with breast conservation therapy (448 patients).[361] The actuarial 8-year local tumor control rate was similar in both arms, 91% in the mastectomy group, and 87% in the breast conservation therapy group. There was one axillary recurrence in the mastectomy group and three in the conservation therapy group.

Copyright © 2002 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

A Danish Cooperative Study carried out a similar randomized trial in 905 women (another 248 patients were treated with mastectomy or breast conservation therapy according to preference without randomization).[371] High-risk patients (tumor >5 cm, invasion to skin or deep fascia, metastatic axillary lymph nodes) who were treated with breast conservation therapy received radiation therapy to the regional lymph nodes. Those who were treated with mastectomy also received irradiation of the same target volume and all high-risk patients received adjuvant CMF. At 6 years, the recurrence-free survival rate in

430 patients treated with breast conservation therapy was 70%, compared with 66% in 429 patients treated with mastectomy. Overall survival rates were 79% and 82%, respectively. There were 12 breast relapses in the former group (3%) and 19 chest wall recurrences in the latter group (4%). In the breast conservation therapy group, 31% of patients had excellent and 41% had satisfactory cosmesis.

The US National Cancer Institute reported results of a randomized study in which 122 patients with T1-2N0M0 disease were treated with modified radical mastectomy and 125 with breast conservation therapy (45 to 50 Gy to breast plus 15- to 20-Gy boost).[372] Recently updated by Poggi et al.[360] with a median follow-up of 18.4 years, there was no detectable difference with regard to overall survival between patients treated with mastectomy and those treated with breast-conserving therapy (58% vs. 54%; $P = .67$ overall). Twenty-seven women in the breast-conserving therapy arm (22%) experienced an in-breast event. After censoring in-breast events in the breast-conserving therapy arm that were salvaged successfully by mastectomy, disease-free survival also was found to be statistically similar (67% in the mastectomy arm vs. 63% in the breast-conserving therapy arm; $P = .64$ overall). There was no statistically significant difference in the incidence of contralateral breast carcinoma between the two treatment groups.

Van Dongen et al.[99,361] reported on an EORTC trial comparing modified radical mastectomy with breast-conserving therapy (lumpectomy, axillary clearance, and irradiation to the breast, 50 Gy in 5 weeks and a 25-Gy boost with iridium implant) in 168 patients with stage I and 734 with stage II disease. Patients with microscopically incomplete excision of the tumor were included. Updated analysis from this trial with a median follow-up period of 13.4 years revealed that locoregional recurrence (LRR) rates were higher in the breast conservation therapy group (10-year rate, 19.7%) than in the mastectomy group (10-year rate, 12.2%, $P = .0097$). The overall survival rate at 10 years was 66.1% for patients undergoing mastectomies and 65.2% for patients undergoing breast conservation therapy ($P = .11$).

Additional Experiences with Breast-Conserving Surgery Plus Radiation Therapy

Although the acceptance of breast-conserving surgery plus radiation therapy as an alternative to mastectomy has been established based on the numerous randomized trials outlined above, large retrospective experiences with long-term follow-up have provided additional data regarding the selection of patients for

breast-conserving therapy and radiation, prognostic factors for locoregional end points, impact of various treatment policies and techniques, complications, cosmesis, and long-term outcomes.

Mature Retrospective Series of Breast-Conserving Surgery Plus Radiation Therapy

There have been numerous reports of breast-conserving therapy and radiation, now with follow-up exceeding 10 to 15 years. These studies have provided valuable data regarding technical issues related to treatment and have provided additional data regarding outcomes in subsets of patients, prognostic factors for local control, cosmesis, and other sequelae. Lessons learned from these retrospective series have yielded valuable insight into the conservative management of breast cancer and provide the basis for further prospective studies. Selected publications are highlighted below and in the section on prognostic factors for local control. Long-term outcome from some of these experiences are summarized in Table 59.14.[97,107,296,313,355,370,373–390] Collectively, these studies clearly show long-term outcomes that are consistent with the randomized trials noted above. Local failure rates will depend on follow-up, selection factors, and treatment, as discussed later, but in general are expected to range between 0.5% and 1% per year.

PROGNOSTIC FACTORS FOR LOCAL RELAPSE FOLLOWING BREAST-CONSERVING SURGERY PLUS RADIATION THERAPY

The retrospective experiences outlined above together with the prospective randomized trials have provided additional data confirming acceptable long-term local control, cosmesis, and toxicities and have identified prognostic factors that lead to higher local relapse rates and impact treatment policies.

Local relapse in the conservatively managed breast is an active area of investigation, with numerous studies dedicated to the evaluation of factors that identify patients at increased risk for local relapse following lumpectomy and radiation therapy. Although prognostic factors for local relapse are not as well evaluated as they have been for systemic relapse, there have been numerous studies demonstrating the prognostic value of molecular and genetic markers for local relapse. Local relapse following breast-conserving surgery and radiation can be governed by a complex array of host, primary tumor, and treatment factors.

Given the complex interaction of these factors, it is sometimes difficult to separate out the independent significance of any one factor. There have, however, been several factors that have been consistently reported in influencing local relapse in the conservatively managed breast cancer patient. Table 59.15 summarizes some of the more commonly reported prognostic factors for local relapse. The factors that most consistently have been reported to influence local relapse, namely, young age, margin status, and the use of systemic therapy, are discussed first, followed by other commonly evaluated prognostic factors.

TABLE 59.15 SUMMARY OF RISK FACTORS FOR LOCAL RELAPSE

Prognostic Factor	Effect	Strength of Data	Comment
Age	Young age increases local relapse	Multiple studies Upheld in multivariate analysis Few conflicting reports	Remains among the strongest factors
Margins	Positive margins increase local relapse	Multiple studies Upheld in multivariate analysis Few conflicting reports	Remains among the strongest factors. Data on “close” margins are less consistent.
Systemic therapy	Systemic therapy (chemo and hormonal) lowers risk of local relapse	Multiple studies support Some conflicting reports	May delay rather than counteract risk
Radiation dose	Higher doses decrease local relapse	Multiple studies support Confirmed in randomized trials (boost vs. no boost) Some conflicting data regarding doses above 50 Gy	Interaction with margins and age Necessity of “boost” in women over 50 and with widely negative margins unclear
Extensive intraductal component (EIC)	EIC positive tumors have higher rates of local relapse	Initial studies supportive Some confirmatory studies	Recent data suggest that negative margin status eliminates this as a risk factor

		Some conflicting studies	
LCIS as a component	LCIS as a component increases risk of local relapse	Conflicting data with no clear consensus	Patients with LCIS are suitable candidates for BCS. Debate remains regarding need for clear LCIS margins.
Lobular histology	Lobular histology has higher local relapse rates	Conflicting data with no clear consensus	Should be treated similar to invasive ductal cancers
BRCA1/2	Higher late local relapses in *BRCA1/2* patients	Several confirmatory studies Some conflicting data	Higher relapse rates related to late "new primaries." This may be minimized by prophylactic hormonal manipulation
Tumor size	Larger tumors result in higher local relapses	Some confirmatory studies Several conflicting studies	Data are confounded by more frequent use of systemic therapy in larger tumors
Nodal status	Higher local relapse rates in node-positive patients	Several conflicting studies	As with tumor size, data are confounded by more frequent use of systemic therapy in node-positive patients
Receptor status	Higher local relapse rates in triple-negative and *HER2*-positive patients	Some confirmatory studies Few conflicting studies Under active investigation	Would offer these patients conventional whole-breast irradiation

BCS, breast-conserving surgery; LCIS, lobular carcinoma *in situ*.

Age

Young age has been shown in numerous studies to be a risk factor for breast recurrence in conservation surgery and irradiation. These are summarized in Table 59.16.[90,291,391–400]

Different investigators have used various age cutoffs, such as 40, 35, and 30 years. Vilcoq et al.[313] found an LRR rate of 35% versus 4% in women younger or older than 30 years. Kurtz et al.[399] reported a 19% incidence of local recurrence in 210 women younger than 40 years of age, compared with 9% in 1,172 older women. This observation correlated with EIC, high tumor grade, and a major mononuclear cell reaction. The Harvard Joint Center's inferior results in younger women also correlated with the presence of EIC.[401] These findings have also been reported by other authors.[378,389,402]

One of the most significant and powerful studies correlating young age with local relapse was the large EORTC boost versus no-boost trial.[403] Overall in this study, young patient age was a significant predictor of local relapse. As shown in Figure 59.16, the use of a boost, as will be discussed later, was most effective in younger women, although the more recent update found an advantage to the boost in all age groups.[404] In a review of 3,602 women who underwent surgery (breast conservation, 55%, or mastectomy, 45%) for early breast cancer and were rolled in EORTC studies, de Bock et al.[405] clearly demonstrated the impact of young age on local relapse. The results of multivariate analysis showed that younger age and breast conservation were risk factors for isolated LRR (breast cancer under 35 years of age vs. over 50 years of age: HR 2.80; 95% CI, 1.41 to 5.60; breast cancer age 35 to 50 years vs. over 50 years: HR 1.72; 95% CI, 1.17 to 2.54; breast conservation: HR 1.82; 95% CI, 1.17 to 2.86). After perioperative chemotherapy, less isolated LRRs were observed (HR 0.63; 95% CI, 0.44 to 0.91). It is concluded that young age and breast-conserving therapy are both independent predictors for isolated LRR. The authors note that as an isolated LRR is a potentially curable condition, women treated with breast conservation

or diagnosed with breast cancer at a young age should be monitored closely to detect local recurrence at an early stage.

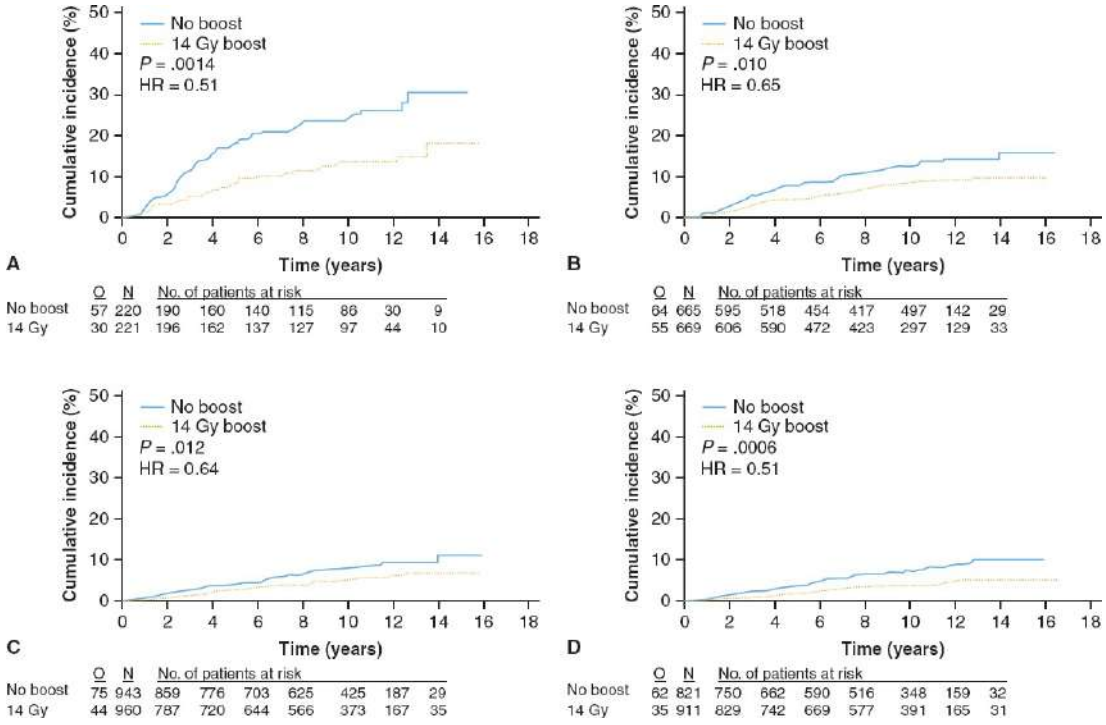

FIGURE 59.16. Cumulative incidence of recurrence of tumor in the ipsilateral breast after whole-breast irradiation at 50 Gy, with or without an additional dose to the tumor bed as a function of age group. (From Bartelink H, Horiot JC, Poortmans PM, et al. Impact of a higher radiation dose on local control and survival in breast-conserving therapy of early breast cancer: 10-year results of the randomized boost versus no boost EORTC 22881–10882 trial. *J Clin Oncol* 2007;25[22]:3259–3265. Reprinted with permission. Copyright © 2007 American Society of Clinical Oncology. All rights reserved.)

Numerous other studies have confirmed in univariate and multivariate analyses a significant correlation between younger age and local relapse rates. Although there is no apparent cutoff age where relapse rates significantly change, most of the studies have selected 35 years of age or 40 years of age to demonstrate the differences.[288,290,291,396,398,406,407] However, one study that compared the outcome of breast conservation in patients under 40 found that those under 35 had a higher risk of recurrence compared with those aged 36 to 40.[408]

Margin Status

Positive margin status has been one of the most consistently reported factors associated with higher local relapse rates. Selected studies are summarized in

Table 59.17.[222,223,374,379,391,409–415,417–420,422–426] Because of the varying definitions of margin status and the complex interaction between margin status and use of systemic therapy, radiation dose, and patient age, there are conflicting conclusions regarding the influence of margin status on local relapse.

Definition of a negative margin is variable between institutions and in national studies. Although some consider no tumor cells seen on the inked margin definitive, as defined by the NSABP, others consider negative as margins of 1 or 2 mm beyond invasive cancer; of note, many of the studies evaluating margin status utilized pathologic reports without a central re-review of the original pathology.

The degree of margin involvement (i.e., whether it is focally involved or more

diffusely involved) is also a critical issue in determining the significance of margin involvement and how it should influence management. Although there are clearly conflicting reports, it is evident that obtaining a wide negative margin is desirable. However, a focally involved margin, particularly when re-excision is not technically feasible, as may be the case with a focally involved deep margin at the pectoralis facia, is not a contraindication to breast-conserving therapy.

Recently, a multidisciplinary panel of breast experts from the Society of Surgical Oncology-American Society for Radiation Oncology examined the relationship between margin width and IBTR and developed a guideline for defining adequate margins in the setting of breast-conserving surgery and adjuvant radiation therapy[427]. The meta-analysis was based on 33 eligible studies published between 1965 and 2013 and included 28,162 patients, of whom 1,506 had an IBTR (5.3%). The median follow-up was 79.2 months. Their conclusions and recommendations are as follows:

- A positive margin, defined as ink on invasive cancer or DCIS, is associated with at least a twofold increase in IBTR. This increased risk in IBTR is not nullified by (a) delivery of a boost dose of radiation, (b) delivery of systemic therapy (endocrine therapy, chemotherapy, or biologic therapy), or (c) favorable biology.
- Negative margins (no ink on tumor) minimize the risk of IBTR. Wider margin widths do not significantly lower this risk. The routine practice to obtain negative margin widths wider than no ink on tumor is not indicated.
- The rates of IBTR are reduced with the use of systemic therapy. In the uncommon circumstance of a patient not receiving adjuvant systemic therapy, there is no evidence suggesting that margins wider than no ink on tumor are needed.
- Margins wider than no ink on tumor are not indicated based on biologic subtype.
- The choice of WBRT delivery technique, fractionation, and boost dose should not be dependent on margin width.
- Wider negative margins than no ink on tumor are not indicated for ILC. Classic LCIS at the margin is not an indication for re-excision. The significance of pleomorphic LCIS at the margin is uncertain.
- Young age (≤40 years) is associated with both increased IBTR after BCT as well as increased local relapse on the chest wall after mastectomy and is also more frequently associated with adverse biologic and pathologic features. There is no evidence that increased margin width nullifies the increased risk of

IBTR in young patients.

- A lobular carcinoma *in situ* (EIC) identifies patients who may have a large residual DCIS burden after lumpectomy. There is no evidence of an association between increased risk of IBTR and EIC when margins are negative.

Interaction between Margin Status and Other Variables

The complex interaction between margin status and other treatment-related factors is demonstrated in a recent study by Park et al.[418] They demonstrated that local relapse was significantly higher in patients with diffuse margin involvement than in patients with negative margins. Patients with focally involved margins also had a higher risk of local relapse than did patients with negative margins. However, in those women with focally involved margins who received systemic therapy, the local relapse rate was similar to those with negative margins. Whether systemic therapy delays or negates the effect of a focally involved margin is a matter of debate, but clearly, there are confounding factors that complicate interpretation of the available data.

Freedman et al.[412] studied 1,262 patients with clinical stage I or II breast cancer treated by breast-conserving surgery, axillary node dissection, and radiation therapy. The final margins were negative in 77%, positive in 12%, and close (≤2 mm) in 11%. The 5-year incidence of IBTR was not significantly different among patients with negative (4%), positive (5%), or close (7%) margins. However, by 10 years, a significant difference in IBTR became apparent (negative 7%, positive 12%, close 14%; $P = .04$). The 5-year cumulative IBTR rate in patients with close or positive margins was 1% with adjuvant systemic therapy and 13% with no adjuvant therapy. However, by 10 years, the IBTR rate was similar (18% vs. 14%), because of more late failures in the patients who received adjuvant systemic therapy.

A study by Jobsen et al.[416] demonstrates some of the difficulties associated with interpretation of studies related to margin status and local relapse as it relates to other prognostic factors. In a study of 1,752 patients with known margin status and a median follow-up of 78 months, the 10-year local relapse rate was 5.6% and 12.2% for negative and positive margins, respectively. An interaction between age category and margin status was noted in relation to local relapse-free survival. The 5-year local relapse rate for women younger than 40 years of age was 8.4% for negative margins and 36.9% for positive margins ($P = .005$). On the other hand, the 5-year local relapse rate for women over 40 years

old was 2.6% for negative and 2.2% for positive margins.

Although it is clear that margin status is a significant risk factor for local relapse, and negative margins are desirable, the available data suggest that patients with a focally involved margin are suitable candidates for breast-conserving therapy followed by radiation therapy to the intact breast.

Effect of Systemic Therapy on Local Control

The use of systemic therapy, in the form of adjuvant tamoxifen or adjuvant chemotherapy, has been clearly shown to impact local control in numerous retrospective and prospective randomized trials. Although it has been clearly demonstrated in randomized trials that chemotherapy and tamoxifen are not appropriate substitutes for radiation therapy, in patients who are treated with radiation therapy, the use of systemic therapy improves local control.[91,92,95,428] As with the other critical prognostic factors, the degree to which systemic therapy influences local control is confounded by other factors.

In the NSABP B-06 trial, patients with lymph node–positive disease who were treated with radiation therapy and chemotherapy had an 8-year local recurrence rate of 5% compared with a local recurrence rate of 12% in lymph node–negative patients treated with surgery and radiation therapy alone.[363] In the NSABP B-21 trial, tamoxifen similarly improved local control rates in patients with lymph node–negative breast tumors smaller than 1 cm. The crude rate of breast tumor recurrence was only 3% in women randomly assigned to undergo lumpectomy, radiation therapy, and tamoxifen compared with 7% in women treated with lumpectomy and radiation therapy alone.[93] A retrospective analysis from the MD Anderson Cancer Center investigating the impact of systemic therapy on local control after breast-conserving therapy in patients with lymph node–negative breast cancer further confirmed these data.[95] In this study, 277 patients treated with systemic therapy had improved 5-year (97.5% vs. 89.8%) and 10-year (95.6% vs. 85.2%) local control rates compared with 207 patients who received no systemic treatment. No statistically significant difference was evident in local control between patients treated with chemotherapy and those treated with tamoxifen alone (P = .219). In a Cox regression analysis, the use of systemic therapy was the most powerful clinical, pathologic, or treatment predictor of local control, producing a 3.3-fold reduction in the risk of local recurrence. Similar results have been reported in series from Yale as well as the Netherlands, where the risk of local relapse was lower among patients treated by breast-conserving surgery and radiation with

adjuvant chemotherapy or adjuvant tamoxifen, compared with patients treated without adjuvant systemic therapy.[428,429] Table 59.18 summarizes several of these studies that have evaluated local control as a function of systemic therapy. It is evident that both hormonal therapy as well as cytotoxic chemotherapy influence local relapse rates.[430–432]

TABLE 59.18 IPSILATERAL BREAST RECURRENCE RATES BY SYSTEMIC TREATMENT (SYSTX)

Van der Leest[428]	758	8.5	CTX	5%	12%	.002

CTX, chemotherapy; Tam, tamoxifen.

Trastuzumab (Herceptin) is a humanized monoclonal antibody against the human EGFR-2 (*HER2*), which is amplified or overexpressed in about 15% to 20% of invasive breast cancers; these tumors are known to be more aggressive and more susceptible to recurrence than *HER2*-negative tumors. Romond et al.[271] reported on a combine analysis from two large cooperative group studies investigating the utility of trastuzumab in *HER2*-positive patients with operable breast cancer and found that trastuzumab improved disease-free survival by an absolute value of 12% at 3 years and was associated with a 33% reduction in the risk of death ($P = .015$). Interestingly, they also reported that IBTR as a site of first failure was reduced from 57 patients to 27 patients with the use of trastuzumab. Recently, Kiess et al.[433] reported on a series of 197 women with early-stage breast cancer; 70 women did not receive trastuzumab while 102 did receive trastuzumab. They found that the 3-year LRR-free survival rate was 90% without trastuzumab and 99% with trastuzumab. Moreover, LRRs were reduced from 7 to 1 with the use of trastuzumab. These data lend support to the notion that systemic therapy has an impact on local control.

Tumor Size

Although tumor size is clearly a strong predictor of systemic relapse and overall survival, its prognostic value in local relapse has not been consistently reported (Table 59.19).[96,365,373–375,378,380,386,388,389,391,434–438] Differences are probably related to the treatment techniques used (e.g., completeness of tumor excision, use of irradiation boost) and the complex interaction of other prognostic factors, as noted above.

Tumor Location

Location of the primary tumor within the breast is not known to be a contraindication to breast-conserving surgery, and any specific location is not associated with a higher local relapse rate. Haffty et al.,[439] in a review of 1,014 patients with early breast cancer treated with breast conservation therapy, identified 98 patients who had a central or subareolar tumor. Ten of 98 patients had the nipple–areola complex sacrificed at the time of surgery, whereas the remaining 88 patients had the entire area included in the boost cone–down field. The 10-year actuarial breast recurrence-free survival rate was 84%, the distant disease-free survival rate was 88%, and the overall survival rate was 79%, similar to patients with tumors in other locations. The nipple–areola complex could be preserved in most patients, and there were no significant complications. Thus, a subareolar breast cancer presentation was not a contraindication to breast-conserving therapy in early-stage disease.

However, Gajdos et al.[440] reported on 95 women with tumors located within 2 cm of the border of the areola, considered to be subareolar carcinomas; 62 were treated with breast-conserving surgery and 33 with mastectomies. Radiation therapy was given to 87% of the breast-conserving surgery group and to 13% of the mastectomy group. The nipple–areola complex was removed in 11 women in the breast-conserving group. On univariate analysis, variables significantly related to pathologic involvement of the nipple–areola complex were clinical involvement of the nipple–areola complex (P = .001), mammographic calcifications or Paget disease (P < .001), pathologic tumor size (P = .019), and the presence of an EIC (P = .098). When radiation therapy was accounted for in multivariate analysis, the only variable significantly related to local recurrence in patients undergoing breast-conserving surgery was clinical involvement of the nipple–areola complex.

Extensive Intraductal Carcinoma

According to the Harvard definition of EIC, 25% or more of the primary tumor is intraductal carcinoma, and intraductal carcinoma is seen outside (adjacent to) the infiltrating tumor border.[441] Fourquet et al.[382] reported a 20% incidence of EIC in 185 women younger than 45 years of age compared with 10.4% in 279 older women. EIC involving the primary tumor and adjacent tissues has been reported by some groups, particularly Harvard University and Marseilles, to be associated with a higher incidence of breast recurrences.[399,442,443] In contrast, others have found no significant impact on local tumor control with EIC.[194,228,377,389] This difference may be related to the definition of EIC, adequacy of tumor excision, doses of irradiation delivered to the boost volume, as well as interactions with other factors. It has been reported by some that a somewhat higher breast relapse rate in EIC-positive patients was seen only in women younger than 40 years of age. Table 59.20 summarizes reports of breast relapse correlated with presence of EIC in selected studies.[96,194,196,374,397,401,434,443–445]

Holland et al.[446] stated that an EIC component is associated with subsequent

breast recurrence because of the presence of residual intraductal carcinoma in these patients. In a series of 214 women who underwent mastectomy, 71% of those with EIC had residual intraductal carcinoma, compared with 28% of those without that pathologic feature. In particular, 44% of the EIC-positive patients had prominent residual tumor compared with 3% of those who were EIC negative ($P < .00001$).

EIC, extensive intraductal carcinoma.

The impact of EIC on local relapse, however, appears to be minimized if negative margins are achieved. Although negative margins are desirable in all patients undergoing breast-conserving surgery, attention to margins in patients with EIC is particularly relevant, as a negative margin may decrease or eliminate the significance of EIC with respect to local failure. In a study from the Harvard group, Gage et al.[447] evaluated clinical stage I or II breast carcinoma treated with radiation therapy as part of breast-conserving therapy, of whom 343 had invasive ductal histology evaluable for an extensive intraductal component, had inked margins that were evaluable for an review of their pathology slides, and received ≥60 Gy to the tumor bed. The 5-year rate of ipsilateral breast recurrence (IBR) for patients with negative margins was 2%; for patients with positive margins,

the rate was 16%. Among patients with negative margins, the 5-year rate of IBR was 2% for all patients with close margins (negative ≤1 mm) and 3% for those with negative margins >1 mm. For patients with close margins, the rates were 2% and 0% for EIC-negative and EIC-positive tumors, respectively; the corresponding rates for patients with negative margins >1 mm were 1% and 14%. The 5-year rate of IBR for patients with focally positive margins was 9% (9% for EIC-negative and 7% for EIC-positive patients). The 5-year crude rate of IBR for patients with greater than focally positive margins was 28% (19% for EIC-negative and 42% for EIC-positive patients). The authors conclude that patients with negative margins of excision have a low rate of recurrence in the treated breast, whether the margin is >1 mm or ≤1 mm and whether the carcinoma is EIC negative or EIC positive. It appears from this study that although EIC may be a poor prognostic factor for local relapse, achievement of a negative margin eliminates EIC as a risk factor.

From a group of 885 patients treated for clinical stage I or II invasive breast cancer, Schnitt et al.[421] limited their study to 181 patients with IDC who received a radiation dose to the surgical site of 60 Gy or greater, whose final microscopic margins of resection were evaluable, and who had at least 5 years of follow-up. In 157 patients (87%), the tumor was evaluable for the presence or absence of EIC. The 5-year rates of recurrence among patients with negative, close, focally positive, and more than focally positive margins were 0%, 4%, 6%, and 21%, respectively. Among the 127 patients with EIC-negative tumors, the 5-year recurrence rate was <10% in all margin groups. Among the 30 patients with EIC-positive tumors, the 5-year recurrence rate was 0% when margins were negative or close but 50% when margins were more than focally positive. These results provide support for the use of breast-conserving therapy (including an irradiation boost to the primary site) for patients with EIC-positive tumors and negative margins.

NR, no results; NS, not significant.

Histology

In general, studies that have evaluated local relapse in relation to histologic subtypes of breast cancer have not demonstrated higher relapse rates associated with specific histologic patterns. Weiss et al.[236] reported on 879 patients with stage I and II breast cancer treated with conservation surgery and irradiation. The patients were divided into 7 groups based on histologic subtype: 368 patients with infiltrating and intraductal ductal carcinoma, 389 with IDC, 41 with ILC, 23 with combined infiltrating ductal and lobular carcinoma, 28 with medullary carcinoma, 12 with colloid carcinoma, and 18 with tubular carcinoma. There were no significant differences in 5-year actuarial overall survival, cause-specific survival, or relapse-free survival rates among the histologic categories. There was, however, a difference among the seven groups in distant metastasis only at first failure, with IDCs having the highest rate.

Thurman et al.,[237] in an analysis of the Harvard series, identified twenty clinical stage I and II patients with mucinous carcinoma, 27 with medullary carcinoma, 28 with tubular carcinoma, and 1,055 with IDC. No significant difference was seen in the site of first failure among the four histologic types within the first 10 years after treatment. Local failure was significantly associated with age <50 years ($P = .04$), positive surgical margins ($P = .007$), lymphovascular invasion ($P = .04$), and presence of an extensive intraductal component ($P < .001$).

An analysis of medullary carcinomas treated conservatively was performed by the Yale group, who identified 46 cases of conservatively treated patients with medullary histology who were compared with 1,444 patients with infiltrating ductal carcinoma.[200] The medullary cohort presented at a younger age with a higher percentage of patients in the 35 years or younger age group (26.1% vs. 6.6%; $P < .00001$). Twelve patients with medullary histology underwent genetic screening, and six patients were identified with deleterious mutations. This group showed greater association with *BRCA1/2* mutations

compared with screened patients in the control group (50.0% vs. 15.8%; *P* = .0035). The medullary cohort was also significantly associated with greater T stage and tumor size (37.0% vs. 17.2%; T2 mean size 3.2 vs. 2.5 cm; *P* = .00097) as well as negative ER (84.9% vs. 37.6%; *P* < .00001) and PR (87.5% vs. 48.1%; *P* = .00001) status. Breast relapse-free rates were not significantly different from the invasive ductal cancers (76.7% vs. 85.2%); however, 10-year distant relapse-free survival in the medullary cohort was significantly better than in the control group (94.9% vs. 77.5%; *P* = .028).

Tubular carcinomas treated with CS and radiation were reviewed by Sullivan et al.[199] They reviewed 62 of their own cases from the Massachusetts General as well as 529 cases from the literature. They conclude that tubular carcinoma is associated with an excellent prognosis, but long-term follow-up is essential for detecting local failures. Adjuvant RT reduces the incidence of local failure following CS for tubular carcinoma. However, elderly women treated by CS may have a very low risk of local recurrence without adjuvant RT.

Infiltrating Lobular Carcinoma

A review of the literature strongly supports local tumor resection and breast irradiation as appropriate therapy for invasive lobular breast cancer, following the same guidelines used for invasive ductal tumors. Breast tumor control and survival after breast-conserving therapy are equivalent in patients with invasive ductal or lobular carcinoma. Because of the presumed multicentric nature of lobular carcinomas, several groups have attempted to assess whether these subtypes are more prone to local failure with breast-conserving approaches.[238,448–453] Table 59.21 summarizes results of several selected series of patients treated with breast-conserving surgery and radiation comparing outcomes in lobular carcinoma to IDCs. Although some of the studies show higher contralateral rates in lobular carcinomas, local relapse, disease-free, and overall survival appear to be comparable to IDCs. The majority of studies show locoregional control, disease-free, and overall survival rates in lobular carcinomas that are comparable to patients with IDCs.

Lobular Carcinoma *in Situ* as a Component of Invasive Cancers

Several groups have evaluated whether patients with LCIS as a component of invasive cancer or DCIS were associated with higher local relapse rates. Conflicting results from these studies, as outlined in Table 59.22, preclude firm conclusions.[454–458] Sasson et al.[458] noted that LCIS was present in 65 of 1,274

patients (5%) with stage I or II breast cancer. LCIS was more likely to be associated with an ILC (30 of 59 patients; 51%) than with IDC (26 of 1,125 patients; 2%). The 10-year cumulative incidence rate of IBTR was 6% in women without LCIS compared with 29% in women with LCIS (P = .0003). In both groups, the majority of recurrences were invasive. The 10-year cumulative incidence rate of IBTR in patients who received tamoxifen was 8% when LCIS was present compared with 6% when LCIS was absent (P = .46). In a series of 56 patients with an LCIS component, Jolly et al.[457] reported a higher risk of local relapse at 10 years (14%) compared with a rate of 7% in cases without an LCIS component. In multivariate analysis, a component of LCIS was associated with a higher risk of local relapse.

TABLE 59.22 STUDIES EVALUATING LCIS AS A COMPONENT OF BREAST CANCER LOCAL RELAPSE IN BREAST-CONSERVING THERAPY PLUS RADIATION THERAPY

Study (Reference)	Number of Patients and Controls		Follow-Up (Median, Year)	Local Relapse		*P*
	With LCIS	Without LCIS		With LCIS (%)	Without LCIS (%)	
Moran and Haffty[454]	51	1,045	10.6	5	7	NS
Abner et al.[455]	119	1,062	13.4	13	12	NS
Ben-David et al.[456]	64	121	3.9	100	99.1	NS
Jolly et al.[457]	46	551	8.7	14	7	.04
Sasson et al.[458]	65	1,209	6.3	15	5	.001
Ciocca et al.[459]	290	2,604	6.0	4.5	3.8	NS

LCIS, lobular carcinoma *in situ*; NS, not significant.

However, studies from Yale, Harvard, and Michigan and a more recent study from Fox Chase failed to show a higher local relapse rate in patients with a component of LCIS. Abner et al.[455] reviewed 1,181 patients with stage I or II infiltrating ductal, infiltrating lobular, or infiltrating carcinoma with mixed features who had received at least 60 Gy to the tumor bed and had a minimum follow-up of 8 years. Of the 1,181 patients, 137 had detectable LCIS in or adjacent to the tumor. The 8-year local recurrence rate was not significantly

increased for patients with LCIS overall or for the subgroup of patients with LCIS in or adjacent to the tumor. The risk of contralateral disease and of distant treatment failure also was unaffected by the presence or extent of LCIS (5% to 10% in all groups). Similar results were reported by Moran and Haffty[454] in an analysis of the Yale series where there was no statistically significant difference between patients with or without a component of LCIS in the 10-year overall survival (67% vs. 72%), distant disease-free survival (62% vs. 79%), or IBTR-free survival (77% LCIS vs. 84% control). Ben-David et al.[456] reported the results on 64 cases treated at the University of Michigan and also found no association between local failure and presence of LCIS. The presence of LCIS at the margins and the size and presence of multifocal LCIS did not alter the rate of local control. Ciocca et al.,[459] in an analysis of 290 patients with LCIS as a component compared with 2,604 without LCIS as a component, showed no difference in local control, even if LCIS was present at the final margin.

Other Histologic Features

Clemente et al.,[460] in 506 cases of infiltrating ductal carcinoma (T1-2N0M0), described peritumoral lymphatic infiltration in 6.9% of routinely evaluated specimens, whereas in a randomly selected group of 234 cases, the frequency was 20%. Patients with peritumoral lymphatic infiltration had worse disease-free and total survival rates than did those without this feature ($P = .0001$ for each), as well as more local recurrences ($P = .0001$) and a higher incidence of distant metastases ($P = .0576$).

Wong et al.,[461] in a study of 234 patients with clinical T1N0 breast cancer treated with breast conservation surgery and radiation therapy, scored 180 patients as lymphatic vessel invasion negative and 54 as invasion positive (23 focal and 31 extensive). The local first failure rates were 14% and 22%, respectively. The percentages of regional distant failure (without local failure) were 12% and 21%, respectively. At 10 years, 60% of the lymphatic vessel invasion–negative patients remained free of any failure, compared with 50% of the lymphatic vessel invasion–positive patients.

Nodal Status

Although nodal status is the strongest predictor of distant metastasis and overall survival, most studies have not clearly demonstrated an effect of nodal status on local control in the conservatively managed breast cancer patient. This may be because a majority of node-positive patients receive chemotherapy or hormonal

therapy, which may counteract any adverse effects on local relapse. There are some data, however, that suggest an effect of nodal status on local relapse in conservatively managed patients. The Primary Therapy of Breast Cancer Study Group and others noted lower survival and a greater incidence of local recurrences in patients with positive axillary nodes after partial mastectomy.[229,462–464] At the Institut Gustave-Roussy, among 356 patients, local recurrence was noted in 26% of those with and 6.5% of those without nodal involvement; the greater the number of nodes involved, the more likely the occurrence of local failure and the lower the survival rate.[238,465] Increased incidence of breast relapse was also observed by van Limbergen et al.[389] in patients with N1b metastasis (8 of 42 patients, or 19%) and in those in whom three or more lymph nodes (4 of 14 patients, or 28.6%) compared with patients with N0 or N1a lymph nodes (14 of 187; 7.5%). However, more recent reports by several investigators noted lower survival rates but fewer breast relapses after breast conservation therapy in patients with positive nodes. Again, this is likely a result of the interaction of irradiation to the breast with adjuvant chemotherapy. Because most node-positive patients receive chemotherapy, which is synergistic with radiation in lowering the local relapse rate, any potential adverse effect of positive nodes on local relapse may be lost.

Molecular Factors and Local Relapse

In comparison with an explosion of data regarding molecular markers as risk factors for overall survival and distant metastasis in breast cancer, there are relatively few data relating molecular markers to local relapse in the conservatively managed breast. There have been several studies, however, that demonstrate the potential application of molecular markers in predicting locoregional relapse in breast cancer patients.[466–468] Particularly exciting is the potential not only to use these markers to identify patients at risk for relapse but also to consider the molecular markers as potential targets for therapeutic intervention and increasing radiation sensitivity. Several molecular markers have been shown in bench studies to be associated with radiation resistance, including *p53*, *HER2/neu*, insulin-like growth factor-1 receptor, and other markers associated with hypoxia.[467–490] In general, molecular subtypes of breast cancer may be organized into the following general categories: luminal A (ER positive or PR positive and Ki-67 <14%), luminal B (ER positive or PR positive and Ki-67 ≥14%), luminal-*HER2* (ER positive or PR positive and *HER2* positive), *HER2* enriched (ER negative, PR negative, and *HER2* positive), and basal-like

(ER negative, PR negative, *HER2* negative, and EFGR positive or CK5/6 positive).

Haffty et al.[491] examined patients treated with breast-conserving therapy plus radiation and identified 482 patients with ER, PR, and *HER2* available for analysis. Patients were then stratified into TN and non-TN status. They found that at 5 years, the TN cohort had a poorer distant metastasis-free rate compared with the other subtypes (67% vs. 82%, respectively; $P = .002$). TN subtype was an independent predictor of distant metastasis (HR 2.14; 95% CI, 1.31 to 3.53; $P = .002$) and cause-specific survival (HR 1.79; 95% CI, 1.03 to 3.22; $P = .047$). However, there was no significant difference in local control between the TN and other subtypes (83% vs. 83%, respectively). The authors concluded that although patients classified as TN have a poor prognosis, there was no evidence that these patients are at higher risk for local relapse after CS and radiation.

Nguyen et al.[492] reported on 793 patients with invasive breast cancer who received breast-conserving therapy and radiation. With a median follow-up of 70 months, the 5-year rate of local recurrence was 1.8%; 0.8% (0.3, 2.2) for luminal A, 1.5% (0.2, 10) for luminal B, 8.4% (2.2, 30) for *HER2*, and 7.1% (3.0, 16) for basal. In addition, on multivariate analysis, *HER2* and basal subtypes were associated with increased local recurrence as compared with luminal A ($P < .01$). Luminal B and basal subtypes were associated with increased distant metastases as compared with luminal A ($P < .04$).

Voduc et al.[493] investigated the rate of local and regional relapse in 2,985 patients stratified by molecular subtype. With a median follow-up of 12 years, they found that after breast-conserving therapy and radiation, patients with luminal A tumors had the most favorable prognosis, with local relapse and regional relapse rates of only 8% and 3% at 10 years, respectively. *HER2*-enriched and basal-like groups exhibited the highest rates of LR (21% and 14%, respectively) and regional relapse (16% and 14%, respectively). After mastectomy, patients with luminal A tumors again had the best prognosis, with rates of local relapse and regional relapse (8% and 4%, respectively, at 10 years). All non–luminal A subtypes exhibited a greater risk of local relapse and regional relapse.

A recent analysis of TN breast cancers from a large Canadian database revealed an interesting observation. Abdulkarim et al.[494] reported a higher rate of local relapse among T1/T2 node-negative mastectomy patients treated without radiation who had TN disease compared with a similar node-negative cohort treated with breast-conserving surgery and radiation. These results emphasize

the point that TN breast cancers do not necessarily fare better with mastectomy, possibly because of the incidental irradiation of lymphatics in the low axilla.[495] Wang et al. conducted a prospective trial where patients with stage I to II TN breast cancer were treated with mastectomy and randomized to chemotherapy +/− PMRT. With 86.5 months' follow-up, the 5-year DFS rates were 88.3% and 74.6% for adjuvant chemotherapy plus radiation and adjuvant chemotherapy alone, respectively (P = 0.02). The 5-year OS was significantly improved in adjuvant chemotherapy plus radiation group compared with chemotherapy alone (90.4% and 78.7%, P = 0.03)[496].

Mamounas et al.[497] investigated the risk of LRR in patients with early-stage, node-negative ER-positive breast cancer treated on the NSABP B14 and B20 based on the Oncotype DX recurrence score (RS). The RS was available in 355 placebo-treated patients (B14), 424 chemotherapy plus tamoxifen patients (B20), and 895 tamoxifen patients (B14 and B20). In the tamoxifen-treated patients, the risk of LRR was 4.3% for patients with low RS (<18), 7.2% for those with intermediate RS (18 to 30) and 15.8% for those with high RS (>30). In placebo-treated patients, the risk of LRR was 10.8% for patients with low RS, 20.0% for those with intermediate RS, and 18.4% for those with high RS. In chemotherapy-treated patients, the risk of LRR was 1.6% for patients with low RS, 2.7% for those with intermediate RS, and 7.8% for those with high RS. The authors concluded that the Oncotype DX recurrence score was a significant predictor of LRR.

These analyses, while showing a consistent trend, should be considered exploratory and are not significant enough to base clinical decision-making on. This is clearly an area that is an active area of investigation, ideally with molecular studies linked to large clinical trials, to help identify molecular markers predictive of locoregional outcomes and hopefully identify potential targets for improving outcomes. Table 59.23 summarizes selected studies evaluating molecular markers for locoregional relapse in conservatively managed breast cancers.[490,498,499]

TABLE 59.23 MOLECULAR MARKERS IN THE LOCAL MANAGEMENT OF EARLY BREAST CANCER TREATED WITH BREAST CONSERVATION SURGERY PLUS RADIATION THERAPY

Markers	Study (Reference)	Patient Population	Local Relapse
ER/PR	Silvestrini,	970 node	No correlation for either ER or PR

	1995[485]	negative	
	Elkhuizen et al., 1999[472]	195 case–control IBC	Higher frequency of PR-negative tumors in locally recurrent population (75% vs. 60%; *P* = .03)
	Vrieling et al., 2003[498]	5,569 cases	Higher recurrence rate was observed in ER-negative or PR-negative tumors
	Grills et al., 2003[499]	1,500 IBC	Regional nodal failure was associated with ER status on univariate analysis
	Choi et al., 2005[483]	103 IBC	Neither ER nor PR correlated with local relapse rate. PR negativity was related with distant metastasis
	Santiago et al., 2004[477]	937 IBC	Negative PR status was related to local relapse rate
HER2/neu	Haffty et al., 1996[469]	20 case–control IBC	Higher expression of *HER2/neu* in patients experiencing local relapse (19% vs. 10%; *P* = .10)
	Pierce et al., 1994[474]	137 IBC	*HER2/neu* correlated with extensive intraductal component but did not correlate to local relapse.
	Kim et al., 2003[484]	611 IBC	*HER2/neu* correlated with overall survival but not local relapse
	Choi et al., 2005[483]	103 IBC	*HER2/neu* was not related with local or distant failure
	Harris et al., 2006[488]	356 IBC	*HER2/neu* was not related to local failure
Triple negative (TN)	Haffty et al., 2006[491]	482 IDC	TN was not related to local control
	Nguyen et al., 2008[492]	793 IDC	Increased local failure with TN or *HER2*+ subtypes
	Voduc et al., 2010[493]	2,985 IDC	Increased local failure with TN or *HER2*+ subtypes
	Mamounas et al., 2010[497]	1,674 IDC	Increased local failure with higher Oncotype DX score
p53	Silvestrini et al., 1997[482]	496 IBC	No correlation with p53 and local relapse
	Turner et al., 2000[470]	94 IBC	p53 overexpression more common in locally recurrent group compared to locally controlled group (26% vs. 9%; *P* = .02)
	Elkhuizen et al., 1999[472]	195 case–control IBC	p53 expression similar in locally recurrent and locally controlled group (21% vs. 23%; *P* = .61)
	Amornmarn et al., 2000[487]	112 IBC	p53 expression associated with all local recurrence cases (only four local relapses in series)
	Choi et al., 2005[483]	103 IBC	p53 was not related with local or distant failure

Proliferative markers	Choi et al., 2005[483]	103 IBC	Ki-67 positivity was related with distant but not local failure
	Silvestrini et al., 1997[481]	496 IBC	Thymidine-labeling index was not related with local failure
ATM mutation	Meyer et al., 2004[489]	135 IBC	ATM gene alterations were not related to patient outcomes

ATM, ataxia telangiectasis mutations; ER, estrogen receptor; IBC, inflammatory breast cancer; IDC, invasive ductal carcinoma; PR, progesterone receptor.

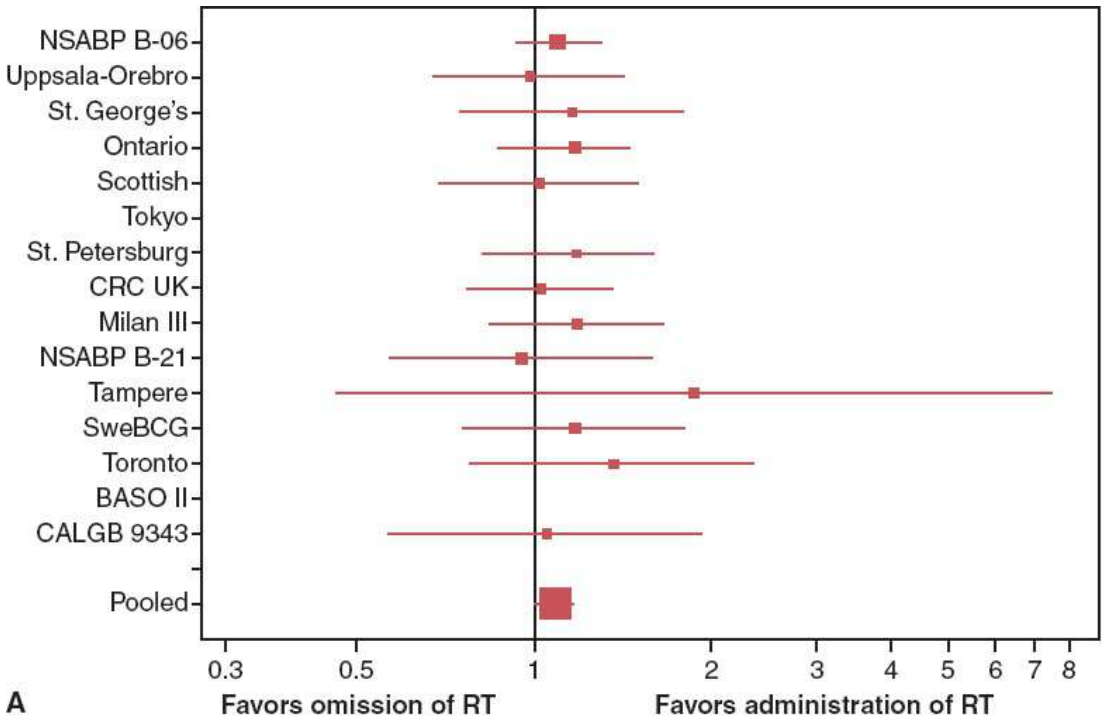
BREAST-CONSERVING SURGERY WITHOUT RADIATION

Based on the mature data from the well-conducted randomized trials outlined above and on long-term follow-up from the several large retrospective series, it is apparent that breast-conserving surgery followed by radiation therapy is a safe and effective modality for the majority of women with early-stage invasive breast cancer.[113] Whether subsets of patients can be treated with breast-conserving surgery alone without irradiation has been the subject of considerable debate and several randomized trials. With the possible exception of selected elderly women, which will be discussed in a later section, subsets of patients in whom radiation therapy can be safely avoided have yet to be clearly identified. Collectively, the randomized studies to date consistently demonstrate an approximately threefold greater local relapse rate in the unirradiated cohorts.[88] Although the majority of these trials did not demonstrate an impact on survival, recent pooled analysis of these randomized trials demonstrates a small but statistically significant impact on mortality as a result of the omission of radiation.

Vinh-Hung and Verschraegen[88] conducted a pooled analysis of published randomized clinical trials that compared radiotherapy versus no radiotherapy after breast-conserving surgery. The outcomes studied were IBTR and patient death from any cause. A search of the literature identified 15 trials with a pooled total of 9,422 patients available for analysis. The RR of ipsilateral breast tumor recurrence after breast-conserving surgery, comparing patients treated with no radiotherapy or radiotherapy, was 3.00 (95% CI, 2.65 to 3.40). Mortality data were available for 13 trials with a pooled total of 8,206 patients. The RR of mortality was 1.086 (95% CI, 1.003 to 1.175), corresponding to an estimated 8.6% (95% CI, 0.3% to 17.5%) relative excess mortality if radiotherapy was omitted (Fig. 59.17A and B).

In an analysis from the EBCTCG, similar conclusions were reached

evaluating various forms of local therapy.[87,110] Within this meta-analysis were 10,801 women treated with breast-conserving surgery in trials randomizing patients to radiation therapy versus no radiation therapy. The majority included patients with axillary clearance of node-negative disease and generally were treated with radiation to the conserved breast alone. The reduction in local recurrence (mainly in the conserved breast) in patients treated with radiotherapy was highly significant ($P < .00001$) in every separate trial. As seen in Figure 59.18, the recurrence rate ratio, comparing those allocated radiotherapy with those not, is about 0.3 in every trial, corresponding to a proportional reduction of 70%. Considering all 17 trials together, the 10-year risk of local recurrence is 19% among those allocated radiotherapy and 35% among those not, corresponding to an absolute reduction of 16% in this 10-year risk. The proportional risk reduction for breast cancer mortality is much less than that for local recurrence, and none of the trial-specific breast cancer mortality results are clearly significant on their own. However, collectively, there is a significant impact on breast cancer mortality (breast cancer death rate ratio 0.83, standard error [SE] 0.05; 95% CI, 0.75 to 0.912; $P = .0002$), indicating a reduction of about one-sixth in the annual breast cancer mortality rate. The 15-year risk of death from breast cancer (in the hypothetical absence of other causes) is 30·5% among those allocated post–breast-conserving surgery radiotherapy and 35.9% among those not (corresponding to an absolute reduction of 5.4%; SE 1.7). Figure 59.19 highlights a recent update of the EBCTCG, demonstrating the impact of radiation therapy on outcome in early-stage breast cancer.[110]



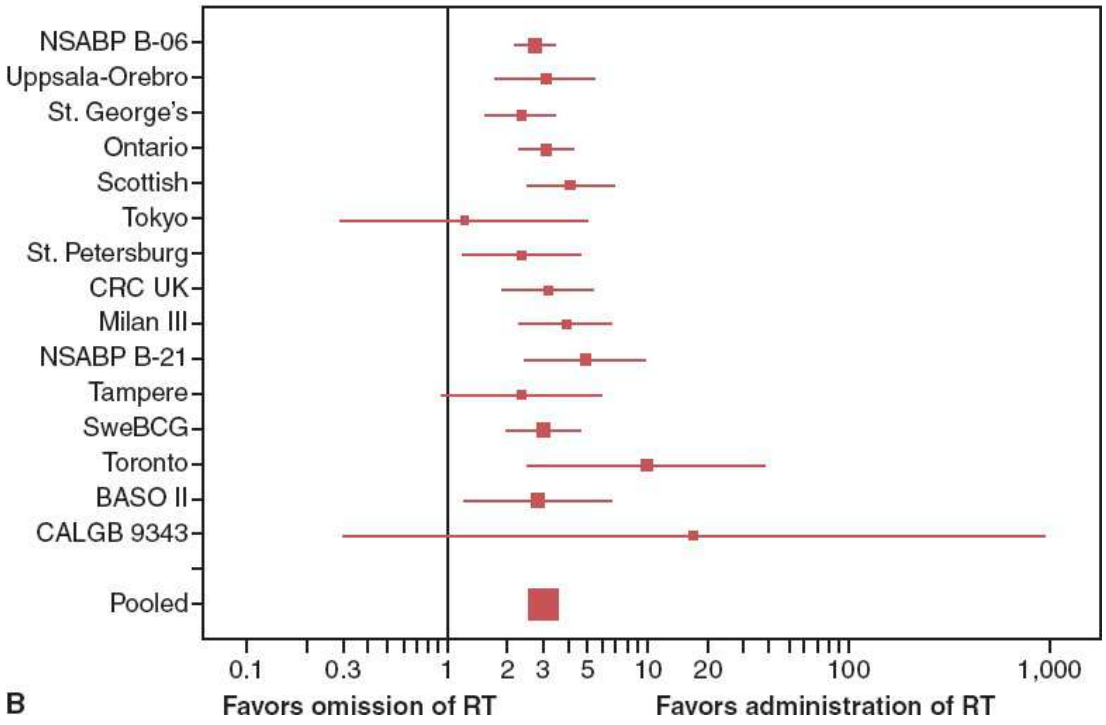


FIGURE 59.17. Meta-analysis of survival **(A)** and local control **(B)** in randomized trials comparing breast-conserving surgery with or without radiation. This meta-analysis demonstrated a threefold reduction in local relapse and a small but significant increase in survival with the use of radiation therapy following lumpectomy. Randomized Trials

Selected trials comparing breast-conserving surgery alone to breast-conserving surgery with radiation are summarized in Table 59.24.[91,93,500–503] The Uppsala-Orebro Breast Cancer Study group reported on a trial in which women with stage I breast carcinoma were randomly assigned to be treated with either sector resection and axillary dissection plus 54 Gy breast irradiation (184 patients) or the same surgical procedure alone (197 patients).[500] The actuarial local recurrence rates after a median follow-up of 63 to 65 months were 2.3% in the irradiated group and 18.4% with surgery only. The 5-year disease-free survival rates were 91% and 87%, and the 5-year overall survival rates were 91% and 90%, respectively.

Winzer et al.[503]	<2 cm node negative	347	5.9	3.2	27.8	.001

Whelan et al.[504] reported on a randomized study of women with stage I or II node-negative breast cancer; 403 had lumpectomy, axillary dissection, and breast irradiation, and 396 had the same surgical procedure without irradiation. A dose of 40 Gy was given in 16 fractions to the whole breast, followed by a boost of 12.5 Gy in 5 fractions to the primary site. No patient received adjuvant systemic therapy. The 5-year ipsilateral breast relapse rate was 8% in patients receiving irradiation and 30% in the surgery-alone group ($P < .0001$). Survival rates at 5 years were 88% and 86%, respectively. Ipsilateral breast relapse correlated with increased incidence of distant metastases and greater mortality from cancer.

Clark et al.[502] reported on a randomized study of 421 patients with tumors 4 cm or smaller and negative nodes who were treated with wide local excision and axillary dissection alone and 416 patients who were treated with the same surgery plus breast irradiation (40 Gy in 3 weeks, 16 fractions, and 12.5-Gy boost in 5 fractions). With 7.6 years' median follow-up, breast recurrences were seen in 148 (35%) of the nonirradiated patients and in 147 (11%) of the irradiated patients ($P < .0001$); 99 patients (24%) in the former group and 87 (21%) in the latter group died during the study period.

Forrest et al.,[505] after local excision of breast tumors <4 cm in diameter and axillary dissection, randomly assigned 291 patients to receive irradiation of 50 Gy to the breast plus a 10- to 15-Gy boost and 294 to receive no irradiation. Patients received either tamoxifen or 6 cycles of CMF. Overall survival was equivalent in the two groups. The rates of locoregional relapse were 6.1% (18 patients) in the irradiated group and 28.6% (84 patients) in the excision-alone group.

Renton et al.[506] analyzed 418 patients treated by wide local excision and adjuvant chemotherapy (tamoxifen if ER positive and CMF chemotherapy if ER negative) who were randomized to have radiation therapy to the breast or not. At

a minimum 5-year follow-up, the local recurrence rate in patients receiving irradiation was 13% compared with 35% in those not so treated. When histologically local excision was incomplete and patients received radiation therapy, the local recurrence rate was 17%.

One of the most significant trials addressing the issue of local relapse following lumpectomy alone was from the NSABP-06.[91] This trial included three arms—modified radical mastectomy, lumpectomy with radiation, and lumpectomy without radiation—and included both node-positive and node-negative patients. In this trial, breast irradiation decreased the likelihood of a recurrence in the ipsilateral breast in the group of 1,137 lumpectomy-treated women whose surgical specimens had tumor-free margins. The cumulative incidence of a recurrence in the ipsilateral breast 20 years after surgery was 14.3% among the women who underwent irradiation after lumpectomy and 39.2% among those who underwent lumpectomy without irradiation ($P < .001$). The benefit of radiation therapy was independent of the nodal status. Among the women with negative nodes, 36.2% of those who did not receive radiation therapy and 17.0% of those who did had a recurrence in the ipsilateral breast within 20 years ($P < .001$). Among the women with positive nodes, 44.2% of those who did not undergo irradiation and 8.8% of those who did had a recurrence in the ipsilateral breast ($P < .001$). Among the lumpectomy-treated women whose surgical specimens had tumor-free margins, the HR for death among the women who underwent postoperative breast irradiation, as compared with those who did not, was 0.91 (95% CI, 0.77 to 1.06; $P = .23$). Radiation therapy was associated with a marginally significant decrease in deaths due to breast cancer. This decrease was partially offset by an increase in deaths from other causes.

Because of continued uncertainty regarding the need for radiation in more favorable tumors, the NSABP continued to investigate this issue of elimination of irradiation. In the B-21 trial, 1,009 women treated by lumpectomy were randomly assigned to tamoxifen ($n = 336$), radiation therapy and placebo ($n = 336$), or radiation therapy and tamoxifen ($n = 337$).[92] Endpoints were divided rates of breast relapse, distant recurrence, and contralateral breast cancer. Radiation and placebo resulted in a 49% lower hazard rate of local relapse as opposed to tamoxifen alone; radiation and tamoxifen resulted in a 63% lower rate as opposed to radiation and placebo. When compared with tamoxifen alone, radiation plus tamoxifen resulted in an 81% reduction in hazard rate of IBTR. Cumulative incidences of local relapse through 8 years were 16.5% with

tamoxifen, 9.3% with radiation and placebo, and 2.8% with radiation and tamoxifen. The authors concluded that in women with tumors ≤1 cm, local relapse occurs with enough frequency after lumpectomy to justify considering radiation therapy regardless of ER status.

In another landmark trial, Veronesi et al.[397,501] randomly assigned 567 women with small cancers of the breast (<2.5 cm in diameter) to quadrantectomy followed by radiation therapy or to quadrantectomy alone. All patients underwent total axillary dissection. The number of IBTRs was significantly higher in patients treated with surgery alone (59 cases of 273; 10-year crude cumulative incidence of 23.5%) than in patients treated with surgery plus radiotherapy (16 cases of 294; 10-year crude cumulative incidence of 5.8%). The difference in IBTR frequency between the two treatments was high in women up to 45 years of age, tending to decrease with increasing age up to no apparent difference in women older than 65 years. Overall survival curves for the two groups did not differ significantly (P = .326). However, a limited survival advantage was evident after radiotherapy for node-positive women.

Other Nonrandomized Studies of Lumpectomy Alone

Lim et al.[507] recently updated a prospective single-arm trial addressing omission of radiation for highly selected favorable patients from the Harvard group. Eighty-seven (of 90 planned) patients enrolled from 1986 until closure in 1992, when a predefined stopping boundary was crossed. Patients were required to have a unicentric, T1, pathologic node-negative invasive ductal, mucinous, or tubular carcinoma without an extensive intraductal component or lymphatic vessel invasion. Surgery included local excision with margins of at least 1 cm or a negative re-excision. No RT or systemic therapy was given. Nineteen patients (23%) had local recurrence as a first site of failure (average annual local recurrence: 3.5 per 100 patient-years of follow-up). The authors concluded that even in this highly selected cohort, a substantial risk of local recurrence occurred after breast-conserving therapy alone with margins of ≥1.0 cm.

McCready et al.[508] reported on a postmenopausal group of 244 patients with breast cancer treated with lumpectomy alone. With a median follow-up of 9.1 years, the overall breast relapse rate was 24% (59 of 244). On univariate analysis, smaller tumor size, negative nodes, positive ER status, and no lymphovascular or perineural invasion were associated with significantly lower relapse rates (P < .05). On multivariate analyses, lymphovascular or perineural invasion, age, and amount of DCIS were all significantly associated with greater

risk of local relapse. The authors defined a low-risk subgroup (node negative, younger than 65 years of age, no comedo, ER positive, no emboli) with a crude 10-year local recurrence rate of 9%.

Conservative Surgery Alone in Elderly Women

The available evidence clearly establishes lumpectomy followed by radiation as the standard of care for the majority of women with early-stage invasive breast cancer. As noted in the numerous randomized trials reported above, lumpectomy alone results in a threefold increase in local relapse and compromised breast cancer–related survival to a lesser degree.[88] Given the lower reported local relapse rates in elderly women, however, the absolute benefit of radiation therapy following breast-conserving surgery, however, may be less. The question of whether radiation can be eliminated following breast-conserving therapy has been addressed in both retrospective and, more recently, carefully designed prospective randomized trials.

There is evidence from several retrospective and prospective series that elderly women may be spared radiation. Cooke et al.[509] identified 44 women treated with partial mastectomy, breast irradiation, and tamoxifen and compared them with 53 women treated in a similar fashion but without breast irradiation. At 39 months, the breast tumor recurrence rate was 5% with breast irradiation and 21% when irradiation was omitted. Of those not receiving irradiation, no breast relapses were seen in 22 patients older than 70 years of age at diagnosis, in contrast to 8 breast recurrences in 31 patients younger than 70 years.

In the trial of quadrantectomy versus quadrantectomy plus radiation reported by Veronesi et al.,[501] although there was a clear benefit in local control overall, the benefit was significant and apparent only in younger women; for patients over age 65, there was no significant benefit.

Gajdos et al.[510] noted that reported rates of local and distant recurrence for elderly patients were comparable with those for younger patients after both mastectomy and breast conservation. Ninety-eight of 920 patients older than 70 years of age were undertreated by conventional criteria. Undertreated elderly patients were significantly older (78 vs. 76 years; $P = .003$), were diagnosed with excisional biopsy more often (69% vs. 57%; $P = .069$) and had fine needle aspiration less frequently (22% vs. 38%; $P = .069$), and were more likely to have breast conservation therapy (90% vs. 73%; $P = .004$). Local and distant disease-free survival rates for both groups were comparable. Tamoxifen treatment significantly reduced the chances for development of distant metastasis in node-

negative elderly patients with invasive tumors (P = .028). Omission of chemotherapy had no impact on disease control in the elderly. Therefore, elderly women with favorable prognostic factors may be candidates for treatment with tumor resection and tamoxifen without irradiation or chemotherapy and with close follow-up.

Given the apparent biologic differences in breast cancers in the elderly, as well as the logistic issues in daily radiation treatment, two randomized trials have addressed the issue of the need for radiation therapy in elderly women with early-stage breast cancer.[173,511] The first trial from the Cancer and Leukemia Group B (CALGB), published by Hughes et al.,[511] randomly assigned 636 women with clinical stage I, ER-positive breast carcinoma treated by lumpectomy to receive tamoxifen plus radiation therapy (317 women) or tamoxifen alone (319 women). The only significant difference between the two groups was the rate of local or regional recurrence at 5 years (1% in the group given tamoxifen plus irradiation and 4% in the group given tamoxifen alone; P < .001). There were no significant differences between the two groups with regard to the rates of mastectomy for local recurrence, distant metastases, or 5-year rates of overall survival. The authors concluded that lumpectomy plus adjuvant therapy with tamoxifen alone is a reasonable choice for the treatment of women 70 years of age or older who have early, ER-positive breast cancer. An update of this trial revealed that at 10 years, 98% of patients receiving tamoxifen plus irradiation compared with 90% of those receiving tamoxifen alone were free from local and regional recurrences. There were no significant differences in mastectomy rates, distant metastases, or 10-year rates of OS[512].

The second trial was a Canadian study published by Fyles et al.[513] of women 50 years of age or older who had T1 or T2 node-negative breast cancer. In this trial, 769 women with early breast cancer with a tumor diameter of ≤5 cm were randomly assigned to receive breast irradiation plus tamoxifen (386 women) or tamoxifen alone (383 women). With a median follow-up of 5.6 years, the rate of local relapse at 5 years was 7.7% in the tamoxifen group and 0.6% in the group given tamoxifen plus irradiation (HR 8.3; 95% CI, 3.3 to 21.2; P < .001). The corresponding 5-year disease-free survival rates were 84% and 91% (P = .004). A subgroup analysis of 611 women with T1, receptor-positive tumors, similar to the CALGB cohorts, also indicated a benefit from radiotherapy, with the 5-year rates of local relapse of 0.4% with tamoxifen plus radiotherapy and 5.9% with tamoxifen alone (P < .001). There was also a significant difference in the rate of axillary relapse at 5 years (2.5% in the tamoxifen group and 0.5% in the group

given tamoxifen plus irradiation; $P = .049$), but there were no significant difference in the rates of distant relapse or overall survival. In both of these trials, women were not required to have surgical staging of the axilla, but they did have clinically negative axilla in both, and follow-up remains relatively short. Both studies show that even this favorable subgroup benefits from radiation with respect to local control, but the absolute benefit is small.

As a follow-up to the CALGB study, Smith et al.[513] conducted a detailed analysis of women over age 70 from the SEER-Medicare database. They identified 8,724 women aged 70 years or older treated with CS for small, lymph node-negative, ER-positive (or unknown receptor status) breast cancer. Using a proportional hazards model, they tested whether radiation therapy was associated with a lower risk of a combined outcome, defined as a second ipsilateral breast cancer reported by SEER, or a subsequent mastectomy reported by Medicare claims. The results, summarized in Figure 59.20, were similar to those reported by the randomized studies above in that radiation therapy, compared with no radiation therapy, was associated with a lower risk of the combined outcome (HR 0.19; 95% CI, 0.14 to 0.28). Radiation therapy was associated with an absolute risk reduction of 4.0 events per 100 women at 5 years (from 5.1 events without radiation therapy to 1.1 with radiation therapy) and 5.7 events per 100 women at 8 years (from 8.0 events without radiation therapy to 2.3 with radiation therapy; $P < .001$).

Using a comorbidity analysis, radiation therapy was most likely to benefit those aged 70 to 79 years without comorbidity (number needed to treat to prevent one event, 21 to 22 patients) and was least likely to benefit those aged 80 years or older with moderate to severe comorbidity (number needed to treat, 61 to 125 patients). The authors conclude that for older women with early breast cancer, radiation therapy was associated with a lower risk of a second ipsilateral breast cancer and subsequent mastectomy. Patients aged 70 to 79 years with minimal comorbidity were the most likely to benefit and older patients with substantial comorbidity were least likely to benefit.

Collectively, these studies indicate that the benefit of radiation therapy for elderly women is significant in terms of local control, but this absolute benefit is relatively small and must be weighed against comorbidities and other competing risks. The two randomized trials and the SEER-Medicare analysis are summarized in Table 59.25. For women with favorable T1N0 receptor-positive breast cancers, tamoxifen alone is a reasonable option that should be discussed. For patients with multiple comorbidities and shorter life expectancies, this

option is often chosen. The author's own preference in patients with low comorbidity and long life expectancy is to offer radiation, even in those over age 70 with ER-positive tumors.

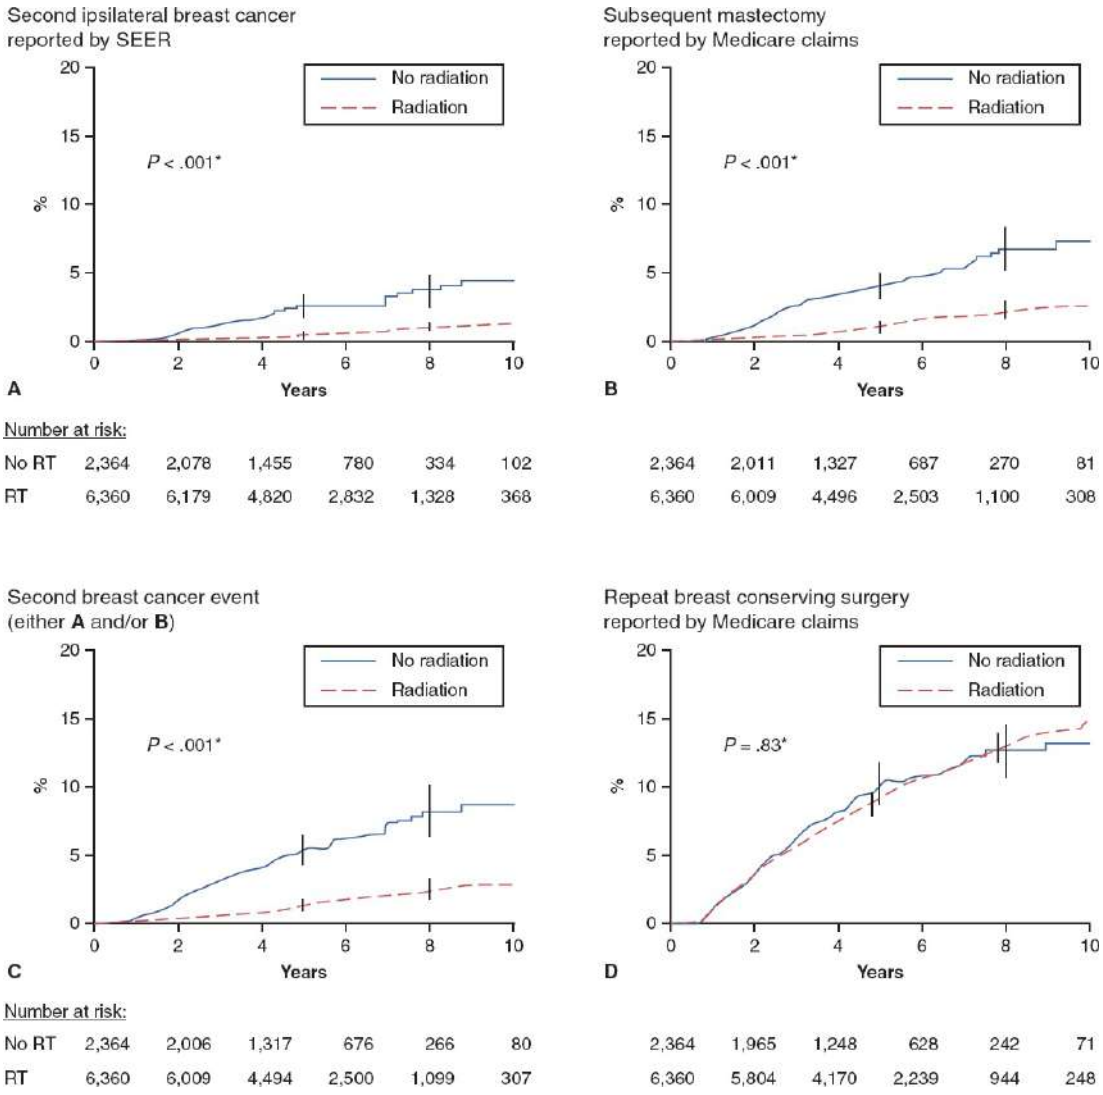

FIGURE 59.20. Association of radiation therapy with outcomes in elderly women. Patients were at risk for all outcomes beginning 9 months after diagnosis. **A:** Second ipsilateral breast cancer reported by Surveillance, Epidemiology, and End Results (SEER). This outcome was defined as a second ipsilateral, pathologically confirmed, invasive breast cancer. **B:** Subsequent mastectomy reported by Medicare claims. **C:** Second breast cancer event defined as a second ipsilateral, pathologically confirmed, invasive breast cancer reported by SEER data or as a subsequent mastectomy reported by Medicare claims. **D:** Repeat breast-conserving surgery as reported by Medicare claims. RT, radiation therapy. Error bars equal 95% CIs. *P* values were calculated from a two-sided logrank test. (From Smith BD, Gross CP, Smith GL, et al. Effectiveness of radiation therapy for older women with early breast cancer. *J Natl Cancer Inst* 2006;98[10]:681–690. Reproduced by permission of Oxford University Press.)

HYPOFRACTIONATED WHOLE-BREAST IRRADIATION

In breast cancer, the standard radiation therapy schedule treatment delivers 1.8 to 2.0 Gy/day for 25 to 28 days for a total dose of 45 to 50.4 Gy followed by a 5 to 8 fraction boost (10 to 16 Gy) for a total dose of 60 to 66 Gy delivered for 6 to 7.5 weeks. There has been a growing trend toward hypofractionation, which involves delivering a higher dose per fraction for a shorter number of fractions for a biologically equivalent dose. This has been shown to be safe and effective as a standard treatment schedule in multiple randomized trials and will be discussed below.

The UK Standardisation of Breast Radiotherapy (START) Trial A randomized patients with early breast cancer (pT1-3a pN0-1 M0); these patients received either 50 Gy in 25 fractions of 2.0 Gy versus 41.6 Gy or 39 Gy in 13 fractions of 3.2 Gy or 3.0 Gy over 5 weeks after surgery.[515] Thus, the overall treatment time was kept constant in all three arms. The trial did allow treatment of regional lymph nodes (supraclavicular and axillary) with additional radiation fields, and these were used in 20% of the patients. With the primary endpoint of locoregional tumor relapse, 749 women were assigned to the 50 Gy group, 750 to the 41.6 Gy group, and 737 to the 39 Gy group. With a median follow-up of 5.1 years, the rate of locoregional tumor relapse at 5 years was 3.6% (95% CI, 2.2 to 5.1) after 50 Gy, 3.5% (95% CI, 2.1 to 4.3) after 41.6 Gy, and 5.2% (95% CI, 3.5 to 6.9) after 39 Gy. The authors concluded that a lower total dose in a smaller number of fractions could offer similar rates of tumor control as standard

fractionation. A major limitation of the study is the use of a conventionally fractionated boost of 14 Gy in 7 fractions. How this boost interacted with the altered fractionation effects is unclear.

The UK START Trial B randomized patients with early breast cancer (pT1-3a pN0-1 M0) at 23 centers in the United Kingdom who were assigned after primary surgery to receive 50 Gy in 25 fractions of 2.0 Gy over 5 weeks or 40 Gy in 15 fractions of 2.67 Gy over 3 weeks.[516] In contrast to the START A trial, the overall treatment time was not consistent in both arms. With the primary endpoint of locoregional tumor relapse, 1,105 women were assigned to the 50 Gy group and 1,110 to the 40 Gy group. With a median follow-up of 6.0 years (interquartile range 5.0 to 6.2), the rate of locoregional tumor relapse at 5 years was 2.2% (95% CI, 1.3 to 3.1) in the 40 Gy group and 3.3% (95% CI, 2.2 to 4.5) in the 50 Gy group, representing an absolute difference of −0.7% (95% CI, −1.7% to 0.9%).

Whelan et al.[517] reported on a study of women with invasive breast cancer who had undergone breast-conserving surgery and were randomized to whole-breast irradiation either at a standard dose of 50.0 Gy in 25 fractions over a period of 35 days (the control group) or at a dose of 42.5 Gy in 16 fractions over a period of 22 days (the hypofractionated radiation group). Notably, women with breast separations >25 cm were excluded. The risk of local recurrence at 10 years was 6.7% among the 612 women assigned to standard irradiation as compared with 6.2% among the 622 women assigned to the hypofractionated regimen (95% CI, −2.5 to 3.5). At 10 years, 71.3% of women in the control group as compared with 69.8% of the women in the hypofractionated radiation group had a good or excellent cosmetic outcome. The authors concluded that hypofractionated whole-breast irradiation was not inferior to standard radiation treatment in women who had undergone breast-conserving surgery for invasive breast cancer with clear surgical margins and negative axillary nodes.

A randomized trial from Hospital Necker in Paris compared 45 Gy in 25 fractions delivered in 5 weeks to 23 Gy delivered as 5 Gy on days 1 and 3 and 6.5 Gy on days 15 and 17. In patients treated by lumpectomy (56 in the conventional arm and 45 in the hypofractionation arm), the locoregional recurrence rate was similar (7% vs. 4%).[518]

In 2011, a task force authorized by the American Society for Radiation Oncology (ASTRO) weighed evidence from a systematic literature review and produced recommendations regarding the use of hypofractionated radiotherapy in patients with breast cancer.[519] They stated that hypofractionated whole-breast

irradiation was likely equivalent to conventional fractionation in patients who meet all of the following criteria: (a) age over 50 years, (b) pathologic state T1–2N0 treated with lumpectomy, (c) patient has not received systemic chemotherapy, and (d) the minimum and maximum dose along the central axis is not <93% and not >107% of the prescription dose, respectively. For patients not receiving a radiation boost, the task force favored a dose schedule of 42.5 Gy in 16 fractions when hypofractionated radiotherapy is planned; there was no conclusion regarding the use of a tumor bed boost in patients treated with hypofractionation. Lastly, the task force also recommended that the heart should be excluded from the primary treatment fields when hypofractionated whole-breast irradiation is used because of lingering uncertainty regarding late effects of this treatment on cardiac function. An update to this evidence-based guideline on whole-breast irradiation (WBI) is currently in progress and anticipated to be published by 2018.

In the author's institution, every effort is made to follow the ASTRO consensus guidelines. However, patient factors such as distance from the radiotherapy facility, age, and comorbidities all play a role in offering a patient hypofractionated whole-breast radiotherapy. The RTOG-1005 is a phase III randomized trial comparing two fractionation schemes for whole-breast irradiation: hypofractionated radiation with concurrent boost versus standard whole-breast irradiation plus sequential boost for patients with early-stage breast cancer. This trial closed for accrual in 2014 and the data has not yet been reported.

TABLE 59.26 TREATMENT POLICY FOR CONSERVATIVE MANAGEMENT OF EARLY-STAGE INVASIVE BREAST CANCER

Treatment Volume	Indication	Fraction Size/Technique	Total Dose	Comment
Whole breast	Routinely following BCS	2 (prefer) or 1.8 Gy/ tangents with wedges or dynamic wedges to optimize homogeneity	45—50.4 Gy	Consider omission of RT in elderly with stage I disease and comorbidities
Boost	Routinely following whole breast	2 or 1.8 Gy (prefer 2 Gy)/*en face* electrons	10—16 Gy to bring total dose to >60 Gy	Consider no boost for widely negative margins in women over 60
Accelerated whole	On protocol or ASTRO	2.66 Gy tangents with no nodal fields/no boost	42.5 Gy	

breast	consensus guidelines		
Accelerated partial breast	On protocol or ASTRO consensus guidelines	3.4–3.8 Gy/external beam conformal, interstitial, or MammoSite	34—38.5 Gy

RADIATION MANAGEMENT OF THE REGIONAL LYMPHATICS

Radiation therapy of the regional lymphatics remains one of the most variable aspects of breast-conserving therapy.[324,520,521] The role of radiation therapy in management of the regional lymphatics is influenced by the risk of subclinical microscopic disease in regional nodal basins and patterns of failure. This risk is in part determined by disease characteristics and in part determined by the extent of surgical evaluation of the axilla, which has become increasingly relevant as a result of increased use of sentinel node, and whether completion axillary dissections are performed for those patients with sentinel node–positive disease. Furthermore, clinicians differ significantly regarding their philosophy with respect to the treatment of subclinical microscopic disease, particularly as it relates to the internal mammary chain.

The issue of whether one treats the “axilla” in conservatively managed patients is further complicated by both uncertainty and misconceptions about the degree to which the axilla receives radiation from a standard tangential field. Although this will vary considerably, as will be discussed in the section on radiation techniques, tangential radiation ports will likely treat most level I nodes and a portion of level II nodes.[522]

All of this uncertainty, debate, and controversy is well founded as there are little in the way of randomized data to establish a clear standard. Studies are under way randomizing high-risk node-negative and node-positive patients to treatment to the breast or chest wall only compared with the breast or chest wall and regional lymphatics. In the interim, reliance on available retrospective data, calculated risks of subclinical disease, and patterns of failure form the basis for various treatment policies. Current treatment policies and guidelines at the authors institutions are outlined in Tables 59.26 and 59.27.

Although in the earlier years of breast conservation therapy, node-negative as well as node-positive patients often received regional nodal treatment, most

authors currently agree that it is not necessary to irradiate the regional lymphatics if the nodes are pathologically negative and an adequate axillary dissection has been performed.[77,324,523] This general practice has now been extended to those patients with a negative sentinel node, because available studies have demonstrated a low rate of pathologically involved nodes after a negative sentinel node procedure performed by an experienced surgeon.[230,332,524] However, several recently published studies have swung the pendulum toward treating the regional nodes, even in node-negative patients. They demonstrated a survival benefit to chest wall or WBI with RNI by addressing postsurgical axillary residual microscopic disease subclinical disease in the supraclavicular (SCV) and internal mammary nodes (IMN) not accessible to surgery.[525,526]

However, as noted previously, the clinically negative axilla harbors subclinical microscopic disease in up to 40% of patients with early-stage operable breast cancer,[328] and both axillary dissection and axillary radiation result in high rates of regional nodal control.[77,113,324,328,523]

Radiation Compared with Axillary Surgery

Sentinel node sampling, with or without full axillary dissection, is now the most common method of axillary management in women with early-stage breast cancer. For patients in whom full axillary staging will not affect subsequent systemic management, who have not undergone any axillary staging procedure, or who have a positive sentinel node and did not undergo further axillary staging, axillary radiation has been shown to result in high rates of regional nodal control.[77,113,324,523,527] Selected series demonstrating nodal control rates with radiation therapy in breast-conserving therapy are summarized in Table 59.28.[79,378,385,436,528–532] Table 59.29 summarizes results of randomized trials comparing axillary surgery to radiation or observation.[71,330,533–542]

TABLE 59.27 TREATMENT POLICY FOR REGIONAL NODES

Treatment Volume	Indication	Fraction Size/Technique	Total Dose	Comment
Supraclav	• Clinical N2 or N3 disease • >4 +LN after axillary dissection • 1–3 + LN with high-risk features • Node + sentinel lymph	1.8–2.0 Gy (prefer 200)/AP or AP-PA	45–50.4 Gy	May omit with 1–3 positive nodes in select cases

	node with no dissection unless risk of additional axillary disease is very small • High risk[a] no dissection			
Axilla	• N+ with extensive ECE • SN+ with no dissection • Inadequate axillary dissection • High risk[a] with no dissection	1.8–2.0 Gy/AP—Consider posterior axillary boost if suboptimal coverage with AP only	45–50.4 Gy	Axilla may be intentionally included with use of high tangents.
Internal mammary	Individualized but consider for: • Positive axillary nodes • Central and medial lesions with high risk[a] • Stage III breast cancer • +SLN in the IM chain • +SLN in axilla with drainage to IM on lymphosintigraphy	1.8–2.0 Gy/Partially wide tangents or separate IM electron/photon	45–50.4 Gy	

[a]High risk is defined as estimated probability of nodal involvement >10% to 15%.

Retrospective Experiences

Haffty et al.[77] reported actuarial nodal control rates of 97% and 96% at 10 years for two groups of patients, 245 receiving irradiation alone without axillary dissection and 187 treated with irradiation to the supraclavicular lymph nodes and IMNs after axillary dissection. Minimal morbidity was associated with this treatment policy. Recently Pejavar et al.[543] updated the Yale experience, demonstrating a 98% 5-year regional nodal control rate in 582 patients with invasive breast cancer treated by RNI without dissection compared with 98% 5-year nodal control rate in 1,440 patients treated by axillary dissection. Within this experience were 16 patients with positive sentinel nodes who did not undergo completion axillary dissection and were treated with radiation therapy. None of those sentinel node–positive patients recurred.

Galper et al.[532] estimated the efficacy of axillary radiation therapy after a positive sentinel node biopsy and evaluated the risk of regional nodal failure for patients with clinical stage I or II, clinically node-negative invasive breast cancer treated with either no dissection or a limited dissection (removal of five nodes or less) followed by axillary radiation therapy. Two hundred ninety-two patients had axillary radiation therapy instead of axillary dissection; 126 underwent axillary radiation therapy following limited node dissection. The median dose to the axilla was 46 Gy and to the supraclavicular fossa 45 Gy. Among patients found to have positive nodes on limited dissection, adjuvant chemotherapy and tamoxifen were administered to 81% and 7% of subjects, respectively. All patients had an 8-year follow-up. Six of the 418 patients (1.4%) had regional nodal failure within 8 years; four had simultaneous regional and distant recurrences; and two had isolated axillary failures. Three of the 292 patients (1%) with no axillary dissection, 0 of 84 patients with pathologically negative nodes, and 3 of 42 patients (7%) with pathologically involved nodes had regional node failure as a first site of failure.

A group of 511 patients with 519 stage I and II breast cancers treated with lumpectomy, with or without axillary dissection, and irradiation were reviewed

by Halverson et al.[544] Management of the axilla consisted of irradiation after axillary dissection in 74, irradiation alone in 75, and observation in 21 patients; the extent of nodal irradiation was at the discretion of the attending radiation oncologist. Overall, axillary recurrence was uncommon (1.2%) but was slightly more frequent after irradiation alone (2.7%) than after surgery alone (0.3%; P = .14). There was no benefit for supplemental axillary irradiation after an axillary dissection yielding negative nodes or one to three positive nodes. Among the 21 patients in whom the axilla was not treated, axillary recurrence was not observed. Supraclavicular failures were rare in women with negative or one to three positive axillary lymph nodes (0.5%) and were not significantly affected by elective irradiation. IMN recurrence was seen in only one patient and was not influenced by elective internal mammary irradiation.

Randomized Studies

Randomized studies evaluating axillary treatment (dissection vs. observation vs. radiation) are summarized in Table 59.29. One of the largest and earliest comparisons of axillary surgery to radiation was the NSABP-04 study, in which operable clinically node-negative patients were randomly assigned to radical mastectomy, simple mastectomy, or simple mastectomy with radiation to the chest wall and regional lymphatics.[71] The nodal relapse rate approached 20% in those assigned to simple mastectomy without radiation. The nodal control rates in the radical mastectomy arm and simple mastectomy plus radiation arm were comparable, with <3% relapse rate in each of these arms.

A direct comparison of axillary treatment by dissection compared with radiation was recently reported by Louis-Sylvestre et al.,[533] in which 658 patients with a breast carcinoma <3 cm in diameter and clinically uninvolved lymph nodes were randomly assigned to axillary dissection or axillary radiotherapy after breast-conserving surgery with radiation to the breast. Of the group undergoing dissection, 21% of the patients in the axillary dissection group were node positive. At 10 and 15 years, survival rates were identical in both groups (73.8% vs. 75.5% at 15 years). Recurrences in the axilla were less frequent in the axillary dissection group at 15 years (1% vs. 3%; $P = .04$). There was no difference in recurrence rates in the breast or supraclavicular region or distant metastases between the two groups.

Veronesi et al.[539] carried out a study in which women older than 45 years of age with breast cancer up to 1.2 cm were randomized, 214 of whom were treated with breast conservation surgery and irradiation without axillary treatment and 221 with conservation surgery plus breast and axillary radiation therapy (50 Gy in 5 weeks).After a median follow-up of 63 months, overt axillary metastases were fewer than expected: three cases in the no axillary treatment group (1.5%) and one in the RT group (0.5%). This study suggests that occult axillary metastases might never become clinically overt and axillary dissection might be avoided in patients with small carcinomas and a clinically negative axilla. Axillary RT seems to protect the patients from axillary recurrence almost

completely. It is possible that systemic therapy, the undamaged immunocompetent tissue in the axillary lymph nodes, and axillary irradiation may all be factors contributing to the low incidence of axillary failures in these patients. Also, in the patients receiving no axillary irradiation, it is highly likely that the level I lymph nodes were included in the standard tangential fields.[324,522,545]

Irradiation of Lymphatics in Patients with Positive Axillary Lymph Nodes

Although there is general consensus that radiation to the regional lymph nodes is not necessary in patients with pathologically node-negative disease, there is considerable variability in radiation to the regional lymphatics in patients with pathologically node-positive disease.[75–77,324,527,546] Many radiation oncologists favor irradiation of the regional lymphatics in addition to the breast in node-positive women, while others favor no nodal irradiation, particularly in women with one to three positive nodes. Based on the potential disease-free and overall survival advantage, as well as the risk of failure in the supraclavicular region, most radiation oncologists favor at least supraclavicular nodal irradiation in patients with four or more nodes. The recent presentation of preliminary results of the National Cancer Institute of Canada's MA.20 trial demonstrates a distant metastasis, disease-free survival, and potential survival advantage to regional nodal irradiaton.[547] The majority of patients in this trial had one to three positive nodes and were randomized after breast-conserving surgery to tangential breast irradiation alone or breast irradiation with RNI to the supraclavicular and internal mammary regions. Full publication of this trial is eagerly awaited. A similar trial of the EORTC, randomizing high-risk node-negative and node-positive patients to treatment to the breast or chest wall alone or breast or chest wall and regional lymphatics, may help to further clarify this important issue.

The Canadian MA.20 intergroup study showed the benefit for RNI in node-positive or high-risk node-negative disease[525]. One thousand eight hundred thirty-two women were randomized after lumpectomy, ALND, and adjuvant therapy (91% of patients received adjuvant chemotherapy and 71% received hormonal therapy) to either WBI with or without regional nodal coverage (axillary, SCV, and ipsilateral IMN in the upper 3 intercostal spaces). Eighty-five percent of patients had 1 to 3 positive nodes. RNI improved 10-year DFS (82% vs. 77%, HR 0.76, $P = .01$), distant DFS (86.3% vs. 82.4%, HR 0.76, $P = .03$), and isolated locoregional DFS (95.2% vs. 92.2%, HR .59, $P = .009$). Certain

high-risk patient population on subgroup analysis (especially those with negative estrogen and progesterone receptor statuses) benefited from RNI. Overall survival was not significant.

Similarly, the EORTC 22922/10925 study randomized 4004 node-positive or node-negative breast cancer with central or medial tumors after lumpectomy or mastectomy and adjuvant therapy (85% of patients received either chemotherapy, hormonal therapy, or both) to either RNI or observation[526]. At a median follow-up of 11 years, RNI improved DFS (72.1% vs. 69.1%, HR 0.89, *P* = .04), distant DFS (78% vs. 75%, HR 0.86, *P* = .02), and breast cancer mortality (12.5% vs. 14.4%, HR 0.82, *P* = .02).

The relative reduction of 24% of distant metastasis seen in the MA.20 study was substantiated in the EORTC study and is probably due to the reduction in regional nodal recurrence and subclinical regional nodal disease[548,549]. Interestingly, OS was nonsignificant in either study. However, a meta-analysis of both studies showed a significant improvement of OS (HR 0.88, CI 0.78–0.99) with absolute benefits at 10 years of 1% in the MA.20 trial and 1.6% in the EORTC trial[550]. Subgroup analysis suggests that patients with N0 disease and a complete ALND (>10 nodes) have a larger OS advantage from RNI than do those with N1-N3 disease or an incomplete ALND. Further investigation remains necessary to identify patients who benefit the most from RNI.

The European After Mapping of the Axilla Radiation or Surgery (AMAROS) Trial randomized patients after positive sentinel nodes to axillary dissection or axillary radiation and will help to address issues of locoregional control, survival, and morbidity using these two approaches.[551] Between 2001 and 2010, 4,806 patients were enrolled in this phase III noninferiority trial and randomized for their axillary treatment if their sentinel node biopsy was positive (*n* = 1,425). Of these patients, ALND was performed in 744 patients and axillary radiotherapy in 681 patients. With a median follow-up of 6.1 years, the 5-year axillary recurrence rate was 0.54% after ALND and 1.03% after axillary radiotherapy (*P* = NS). There was no difference in DFS or OS. Interestingly, lymphedema occurred more often following ALND (40% at 1 year and 28% at 5 year) than after axillary radiotherapy (22% at 1 year and 14% at 5 years (*P* < .0001)). There was a nonsignificant trend toward more impairment of shoulder movement in the first year after axillary radiotherapy.

Acknowledging the lack of definitive data and clear consensus and allowing for flexibility depending on patient and physician preferences, the guidelines that the authors advocate are summarized in Tables 59.26 and 59.27. In general, the

authors favor treatment of the supraclavicular fossa in patients with positive nodes. Treatment of the axilla and internal mammary will vary, with attention to the indications outlined in the table.

Sarrazin et al.[359] carried out a randomized study comparing 88 patients treated with tumorectomy and irradiation and 91 patients treated with mastectomy. In a second randomization in the study, the patients with positive axillary lymph nodes in the first randomization were randomly assigned to receive or not receive nodal irradiation. There was no significant difference in overall survival between the two groups. Nevertheless, Yarnold[523] advised elective irradiation of the axilla and the supraclavicular fossa in selected patients, such as those with four or more metastatic axillary lymph nodes, involvement of the apex of the axilla, or gross extracapsular tumor extension, even if the patients are to receive adjuvant chemotherapy. These recommendations are supported by reports that document the benefit of postmastectomy irradiation in patients receiving chemotherapy, which are reviewed in more detail in Chapter 54.

Treatment of the axilla varies significantly in patients with positive nodes. For those patients with negative nodes or with one to three positive nodes without extracapsular extension (ECE) who undergo adequate axillary dissection, there does not appear to be a benefit to targeting the full axilla.[75–78,324,544] There is considerable variability regarding treatment of the full axilla, even in patients with multiple positive nodes.[75,79,522,546] The risk of axillary recurrence after full dissection is low in patients with ECE, even without axillary lymph node irradiation. Whether to treat the full axilla following dissection for patients with multiple positive nodes or ECE generally includes consideration of the extent of dissection, the degree of nodal involvement and ECE, and the degree to which the patient and physician are willing to accept some increased risk of lymphedema with full axillary radiation following dissection.[113,324]

Hetelekidis et al.[251] evaluated 368 patients with T1 or T2 breast cancer and pathologically positive lymph nodes treated with breast-conserving therapy. The median number of sampled lymph nodes was 10. Twenty percent of the patients were treated with supraclavicular radiation therapy, and 64% received both axillary and supraclavicular radiation therapy (45 Gy). One hundred twenty-two patients (33%) had ECE. There was no significant correlation of either disease-free or overall survival or local, regional nodal, or distant failure rates in patients with ECE compared with those without it.

Pierce et al.,[552] in a review of 72 women with breast cancer treated with conservation surgery and irradiation, identified 27 patients (37.5%) who had

evidence of ECE in the axilla. With a median follow-up of 14 months, 1 of 27 (4%) patients with ECE experienced an axillary failure, compared with 0 of 45 patients without ECE. Several authors concluded that ECE is associated with decreased survival but not with increased axillary failures and that radiation therapy may be omitted in a dissected axilla if the sole indication is extracapsular disease.

Internal Mammary Node Irradiation

The role of internal mammary nodal irradiation in node-positive breast cancer patients remains a controversial issue. Although, recently reported trials from the National Cancer Institute of Canada and EORTC help to address this, currently, there is no clear consensus on the role of internal mammary irradiation.[520,521,553–555] The EORTC 22922-10925 randomized patients with an involved axilla and/or medial primary tumor to WBI +/− internal mammary and medial supraclavicular LN (IM-MS) after lumpectomy and ALND. After enrolling over 4,000 women with a follow-up of 10.9 years, it was reported that IM-MS irradiation improved overall, disease-free and metastases-free survival without an increase in non–breast cancer-related mortality[526]. Similarly, the NCIC MA-20 randomized 1832 women with high-risk node-negative or node-positive breast cancer to WBI +/− RNI (internal mammary, supraclavicular, and high axillary lymph nodes) and lumpectomy and ALND[548,549]. With a median follow-up of 9.5 years, the authors reported that RNI offered women a statistically significant benefit in terms of locoregional DFS and distant DFS but not OS with acceptable rates of toxicities. These studies lend credence to the notion of RNI in patients with a positive axilla.

Recently, a prospective Danish study reported the results 3,089 early-stage breast cancer patients treated according national guidelines that directed RNI (including IM nodes) of all right-sided disease but RNI (excluding IM nodes) of all left-sided disease[556]. RT was given 48 Gy in 24 fractions regardless of cancer laterality. With a median follow up of 8.9 years, the overall survival rates (75.9% vs. 72.2%, HR 0.82, P = .005), breast cancer mortality (20.9% vs. 23.4%, HR 0.85, P = .03), and risk of distant recurrence (27.4% vs. 29.7%, HR 0.89, P = .07) all favored internal mammary irradiation. Subgroup analysis suggested that tumor size ≥51 mm and ≥4 axillary nodes positive (especially if the primary cancer was in the lateral quadrants) predicted an overall survival benefit for internal mammary irradiation.

The Danish study suggested that the effect of treating the IMNs depended on

risk of IM node metastasis. In contrast, a French randomized trial of patients with node-positive breast cancer treated with postmastectomy radiation, randomized to internal mammary radiation or no internal mammary radiation, with two-dimensional radiotherapy techniques[557]. After a median follow-up of 11.3 years among the survivors, no benefit of IMN irradiation on the overall survival was demonstrated. In addition, an older study examining the dissection of IMNs in T1-T3, N0-N1 invasive breast cancer patients who underwent either Halsted mastectomy or extended mastectomy with regional node dissection without postoperative RT showed that in 30 years, the dissection of IMNs does not improve the survival of patients. However, the prognostic value of axillary and internal mammary nodal positivity is high as it impacts overall survival. Annual death rates were 0.163 with both sites positive, 0.077 with axillary LNs positive, 0.055 with IMNs positive, and 0.031 with neither site positive for disease[558].

Several surgical series comparing extended radical mastectomy and radical mastectomy, without adjuvant systemic therapy, have shown that extended radical mastectomy was associated with improved survival rates in patients with medial T1 or T2 tumors and positive axillary nodes.[559,560] These surgical series and selected series evaluating internal mammary irradiation are summarized in Table 59.30.[553–555,559,560] The majority of randomized trials evaluating postoperative radiation therapy did include radiation to the internal mammary chain. However, it is difficult to distinguish whether the benefit derived from such treatment related specifically to radiation of the internal mammary chain or to the breast or chest wall, supraclavicular, or axillary treatment administered.

Freedman et al.[561] examined data regarding patterns of failure after elective IMN treatment. Although controversial, data from the prospective, randomized trials of IMN treatment did not seem to support elective dissection or irradiation. IMN irradiation did not contribute to survival, yet it raised the risk of cardiac toxic effects. Sentinel lymph node mapping provided an opportunity to examine the IMN chain in early breast cancer. It is possible that biopsy of the “hot” nodes could be used to select patients who are most likely to benefit from additional regional therapy to these nodes.

Fowble et al.[553] compared the outcome in 1,383 women with stage I or II breast cancer who underwent wide excision, axillary node dissection with 10 or more nodes removed, and breast irradiation. A total of 114 women had radiation to the IMNs with deep tangents and 1,269 did not. All axillary node-positive women received adjuvant chemotherapy or tamoxifen or both. There were no

significant differences in IBTR, regional node recurrence, and initial or total distant metastases for the two groups. No IMN failures were observed among the 114 patients whose IMNs were treated, and only 4 IMN failures were found in the 1,269 other patients (2 of whom had distant metastases). Similarly, 5- and 10-year actuarial overall and cause-specific survival rates were not significantly different.

[a]Survival data documented at the end point of follow-up.
IMN, internal mammary lymph nodes; NS, not significant.

In a series from Yale, Obedian and Haffty[554] found no difference in the 10-year disease-free survival rate after breast irradiation and excision, regardless of whether IMNs were irradiated. Of 984 patients with invasive breast cancer who were treated with CS and radiotherapy, patients were divided into two groups: those treated by intentionally targeting the IMNs (n = 535) and without intentionally targeting the IMNs (n = 411). The decision not to use a separate internal mammary field was a result of a change in treatment policy over time

and generally not based on number of nodes or tumor location. There were no significant differences between the groups with respect to age, ER or PR status, or use of adjuvant chemotherapy or hormone therapy. There were more patients with T2 tumors, positive nodes, medial lesions, indeterminate margins, and slightly longer follow-up in the group treated to the internal mammary chain. There were no significant differences between the groups with respect to overall survival or distant metastasis-free survival.

In a study by Stemmer et al.[555] of 100 node-positive patients scheduled to receive radiation to the internal mammary chain, 67 received the radiation and 33 did not because of technical difficulties. At a median follow-up of 77 months, disease-free survival was significantly prolonged in patients receiving internal mammary radiation compared with those without internal mammary radiation (73% vs. 52%; $P = .02$). A trend was seen for overall survival (78% vs. 64%; $P = .08$). Cox regression multivariate analysis found IMN radiotherapy to be significant both for disease-free and overall survival. There was no treatment-related mortality.

It is evident that data are conflicting, and opinions regarding the role of internal mammary radiation remain unresolved. Until more definitive data become available, it is likely that patient and physician biases will dictate practice. The authors' approach is summarized in Tables 59.26 and 59.27, acknowledging that uncertainties in the available data allow for substantial flexibility. The radiation oncologist, however, must be familiar with the various techniques to treat IMNs, which are summarized later in the section on techniques.

SEQUENCING CHEMOTHERAPY AND HORMONAL THERAPY

Sequencing Chemoradiation in the Conservative Management of Breast Cancer

With the increasing use of systemic therapy in patients with early-stage breast cancer, the integration of this treatment with surgery and radiation therapy has become an important clinical question. Initial retrospective series evaluating treatment sequencing suggested that a delay in the onset of radiation therapy to permit delivery of chemotherapy increased local recurrence rates.[89,562,563] These data are summarized in a pooled analysis by Huang et al.[89] Ten retrospective studies involving 7,401 patients investigated the association between delay in

initiating postoperative RT and local control in breast cancer (after lumpectomy in nine studies and lumpectomy or mastectomy in one study). Eight of these studies compared local control between patients who were treated more than 8 weeks after surgery and those treated within 8 weeks of surgery. The pooled random-effects OR from the combined analysis was 1.62 (95% CI, 1.21 to 2.16), corresponding to an increase in the 5-year LRR from 5.8% in those patients treated within 8 weeks to 9.1% in those patients treated between 9 and 16 weeks after surgery. In a separate analysis exploring the optimum sequencing of adjuvant RT and systemic chemotherapy after surgery for breast cancer from 11 retrospective series, the pooled random-effects OR in these 11 studies was 2.28 (95% CI, 1.45 to 3.57), corresponding to an increase in the 5-year LRR from 6.0% in the RT-first group to 16.0% in the chemotherapy-first group (Fig. 59.21).

Most of these data are subject to criticism because of their retrospective nature, the fact that patients were treated in an earlier era with different surgical techniques and lack of attention to margins, and inclusion of heterogenous groups of patients with these caveats, but there appears to be a trend toward higher local relapse rates with delays in radiation therapy, which appears to have been an appropriate concern with respect to integration of radiation therapy and chemotherapy in the conservatively managed patients.

Initial data regarding these concerns related to the delay in radiation while chemotherapy was being delivered led the Harvard group at Joint Center for Radiation Therapy (JCRT) to investigate the sequencing of radiation therapy and chemotherapy in a randomized prospective clinical trial.[562,563] In this trial, women treated with breast-conserving surgery were randomly assigned to 4 cycles of doxorubicin-based combination chemotherapy, followed by radiation therapy or radiation therapy followed by 4 cycles of the same chemotherapy. In an update of this trial, Bellon et al.[564] reported no statistically significant treatment difference in the rates of freedom from any event, including breast cancer recurrence, contralateral breast cancer, second malignancy, or death (Fig. 59.22). The 10-year rate of any event was 46% for patients in the chemotherapy-first arm compared with 51% in the radiation-first arm. The 10-year rates of distant metastasis were 35% and 36% in the two arms, respectively, and the 10-year rates of death were 28% and 33%, respectively. For the 123 patients with negative margins, the crude local recurrence rates for chemotherapy-first and radiation-first patients were 6% and 13%, respectively. Corresponding rates of distant and regional recurrences were 18% and 26%. Among women with close

margins (n = 47), crude local recurrence rates were 32% and 4%, respectively; distant or regional recurrences were 37% and 43%. In the group with positive margins (n = 51), local recurrences occurred in 23% of chemotherapy-first and 20% of radiation-first patients.

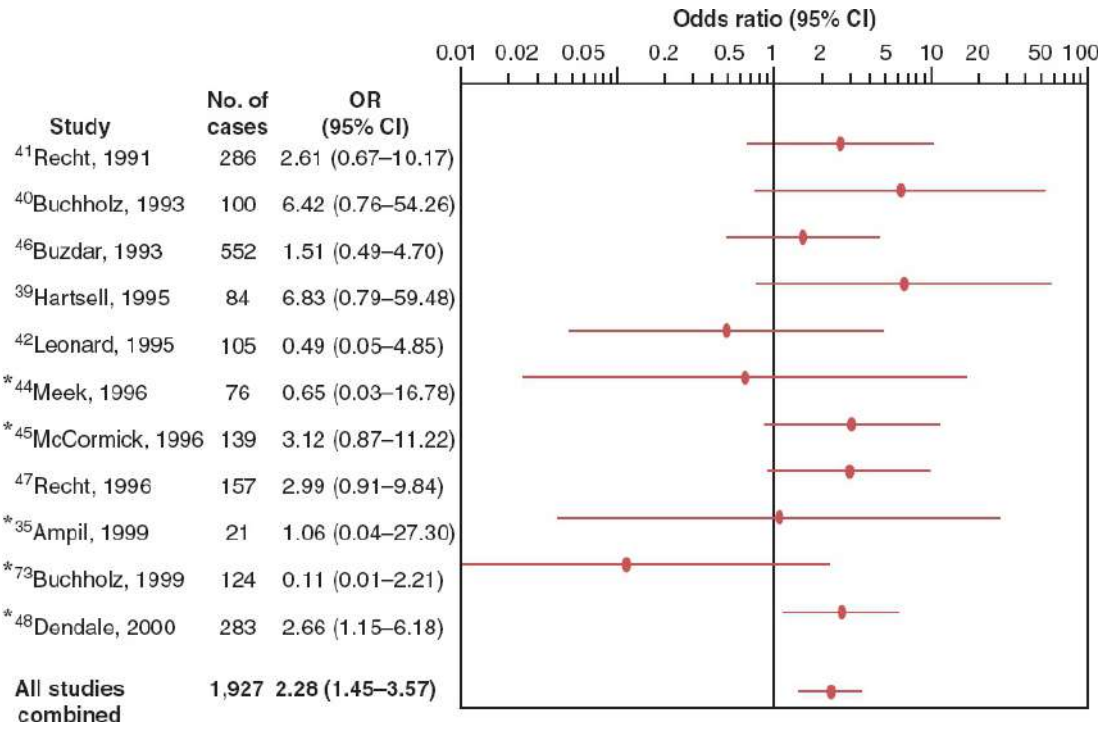

FIGURE 59.21. Associations between delay in postoperative radiotherapy (RT) and local recurrence rates (LRRs) in studies of the sequencing of adjuvant RT and chemotherapy for breast cancer. LRRs in patients who received delayed RT following initial chemotherapy are compared with the rates observed in those patients who received early RT by chemotherapy. Low-quality studies are indicated by an asterisk. (From Huang J, Barbera L, Brouwers M, et al. Does delay in starting treatment affect the outcomes of radiotherapy? A systematic review. *J Clin Oncol* 2003;21[3]:555–563. Reprinted with permission. Copyright © 2003 American Society of Clinical Oncology. All rights reserved.)

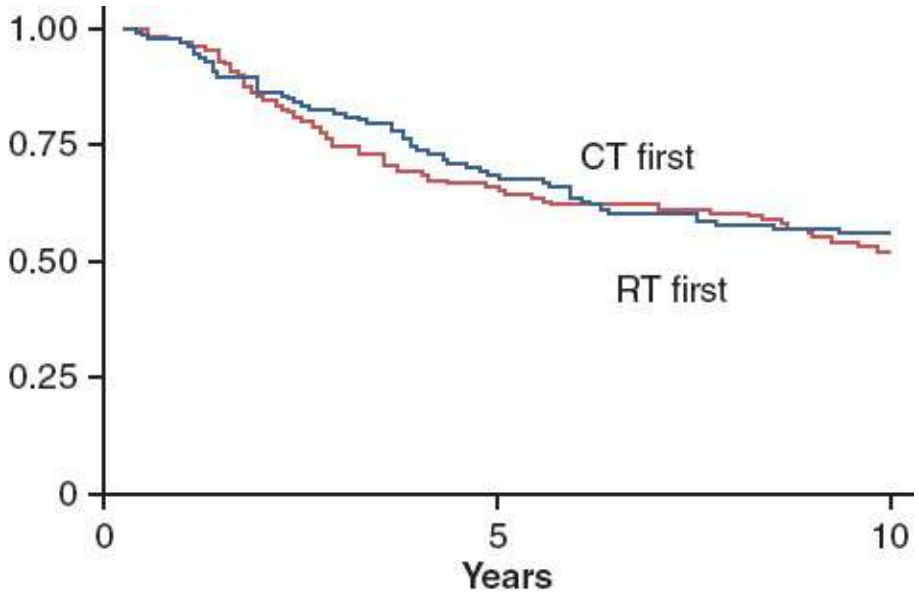

FIGURE 59.22. Event-free survival (including breast cancer recurrence, contralateral breast cancer, second malignancy, or death) by sequencing of chemotherapy and radiation following breast-conserving therapy, from the Harvard randomized trial. (From Bellon JR, Come SE, Gelman RS, et al. Sequencing of chemotherapy and radiation therapy in early-stage breast cancer: updated results of a prospective randomized trial. *J Clin Oncol* 2005;23[9]:1934–1940. Reprinted with permission. Although the JCRT study provided important data concerning treatment sequencing, this study predominantly focused on patients with lymph node–positive disease. Investigators from the MD Anderson Cancer Center performed a retrospective analysis of sequencing of chemotherapy and radiation in 124 patients with lymph node–negative disease treated with breast-conserving therapy.[565] In this series, 79% of the patients had negative margins. The 5-year actuarial rates of local control were 100% for the chemotherapy-first group (most commonly 6 cycles of doxorubicin-based chemotherapy) and 94% for the radiation-first group (P = .351). The 5-year recurrence-free survival rates for the chemotherapy-first and radiation-first groups were 92% and 77% (P = .083), respectively. These data again support an adjuvant-therapy schedule in which chemotherapy is delivered first. The median delays in radiation delivery were 6.7 months in the MD Anderson Cancer Center series and 16 weeks in the JCRT series.

More recently, with the addition of taxane-based chemotherapy to adriamycin-based regimens, concerns have arisen regarding the additional delays

in initiating radiation therapy in conservatively managed patients. This was addressed in a study by Sartor et al.[566] In this randomized CALGB study evaluating adriamycin and cytoxan versus adriamycin and cytoxan, followed by taxane, there were 345 conservatively managed patients. Although the sequencing of radiation was not randomized, patients in the adriamycin plus taxane arm had radiation delayed by an additional 84 days (4 21-day cycles of taxol). Despite this added delay, locoregional relapses were lower in the adriamycin plus taxane compared with the adriamycin arm (9.7% vs. 3.7%; P = .04). (The majority of patients in this randomized trial presumably had negative surgical margins.)

For the majority of patients undergoing breast-conserving surgery with negative margins, these data collectively indicate that administration of chemotherapy prior to radiation therapy does not result in excessive rates of local relapse, provided all modalities are given in a timely fashion without excessive delays. Whether patients with positive or close margins or other risk factors for local relapse would benefit from earlier administration of radiation remains an unresolved issue.

Concurrent Chemoradiation in Breast-Conserving Therapy

Although the concurrent use of chemoradiation therapy in conservatively managed breast cancer has fallen out of favor, there are data that suggest a high rate of local control in patients treated concurrently. These studies are summarized in Table 59.31.[567–570,572] The chemotherapy regimens used in these studies are no longer routinely employed because they are less effective.

A randomized trial of concurrent versus sequential CMF chemotherapy was reported by Arcangeli et al.[572] A total of 206 patients who had quadrantectomy and axillary dissection for breast cancer and were planned to receive adjuvant CMF chemotherapy were randomized to concurrent or sequential radiotherapy. Radiotherapy was delivered only to the whole breast through tangential fields to a dose of 50 Gy in 20 fractions over 4 weeks, followed by an electron boost of 10 to 15 Gy in 4 to 6 fractions to the tumor bed. No differences in 5-year breast recurrence-free, metastasis-free, disease-free, and overall survival were observed in the two treatment groups. All patients completed the planned radiotherapy. No evidence of an increased risk of toxicity was observed between the two arms. No difference in radiotherapy and in the chemotherapy dose intensity was observed in the two groups. The authors concluded that in patients with negative surgical margins receiving adjuvant chemotherapy, radiotherapy can be delayed to up to

7 months. However, concurrent administration of CMF chemotherapy and radiotherapy was safe, and the authors suggest that such an approach might be reserved for patients at high risk of local recurrence.

Another randomized study of concurrent versus sequential radiation therapy was reported by Rouesse et al.[570] This study supports the concept that concurrent use of chemotherapy with radiation therapy improves local control in breast cancer. This trial compared concurrent chemoradiotherapy with FNC (5-fluorouracil [5-FU] 500 mg/m^2, mitoxantrone 12 mg/m^2, and cyclophosphamide 500 mg/m^2 to sequential FEC (5-fluorouracil 500 mg/m^2, epirubicin 60 mg/m^2, and cyclophosphamide 500 mg/m^2 followed by radiation in node-positive breast cancer in 650 women with operable breast cancer. All patients had node-positive disease and were randomized to sequential or concurrent chemoradiotherapy. Although there were no differences in disease-free or overall survival, local recurrences were significantly lower with concurrent therapy (3% vs. 7%). Of patients undergoing breast conservation, there were 6 locoregional relapses in the concurrent arm compared with 18 locoregional relapses in the sequential arm (P = .01). In multivariate Cox analysis, the sequential group had an increased risk of locoregional relapse compared with those in the concurrent group (RR 2.8; 95% CI, 1.1 to 7.2).

Toledano et al.[571] recently reported the results of the ARCOSEIN sequential versus concurrent adjuvant chemotherapy with radiation therapy after breast-conserving surgery. After breast-conserving surgery, patients were treated either with sequential treatment with chemotherapy first followed by RT (arm A) or chemotherapy administered concurrently with RT (arm B). In all patients, the chemotherapy regimen consisted of mitoxantrone (12 mg/m^2), 5-FU (500 mg/m^2), and cyclophosphamide (500 mg/m^2, 6 cycles [day 1 to day 21]). Among the 214 evaluable patients, 107 were treated in each arm. Although local control was slightly superior in the concurrent arm, subcutaneous fibrosis, telangiectasia, skin pigmentation, and breast atrophy were significantly increased in arm B. No statistical difference was observed between the two arms of the study concerning grade 2 or greater pain, breast edema, or lymphedema.

Another randomized trial recently reported by Calais et al.,[573] which is similar to the Rouesse et al.[570] study, compared concurrent radiotherapy with mitoxantrone, 5-FU, and cyclophosphamide to the same regimen followed by radiation therapy. Although toxicities were higher in the concurrent group, those patients with positive nodes had a significantly lower local relapse rate in the concurrent arm.

The concurrent use of chemotherapy and radiation following breast-conserving therapy has been reported in several nonrandomized studies. A prospective single-arm study by Bellon et al.[568] also demonstrated favorable local control in a high-risk group of patients treated with concurrent CMF chemotherapy and reduced-dose radiation. Several other retrospective series, including one conducted from Yale, have demonstrated favorable local control rates and acceptable toxicity in patients at high risk for local relapse using concurrent chemoradiotherapy.[429] In the Yale retrospective series, which compared 109 patients treated with concurrent chemoradiation to 426 patients treated with sequential chemoradiation, the concurrent group had a lower rate of local relapse, despite overall poorer prognostic factors for local control. However, the majority of these studies did not employ the most commonly used current chemotherapy agents such as adriamycin and taxanes. Therefore, it is difficult to extrapolate these results to current practice.

More recently, monoclonal antibodies such as trastuzumab and bevacizumab (Avastin) are being used commonly in the management of breast cancer patients. Romond et al.[271] reported on a combine analysis from two large cooperative group studies investigating the utility of trastuzumab in *HER2*-positive patients with operable breast cancer and found that trastuzumab improved patient outcomes. There was no difference in acute locoregional toxicities, but it should be noted that the use of trastuzumab was associated with an increased risk of congestive heart failure or death from cardiac causes (4.1% vs. 0.8%). Goyal et al.[574] reported on a series of 14 patients receiving bevacizumab in combination with whole-breast irradiation who were then matched to a group of patients who received whole-breast irradiation alone. No patient receiving bevacizumab plus RT experienced grade 3 or higher toxicity; however, three matched control patients experienced a grade 3 skin reaction. Five patients (35%) developed reduction in ejection fraction in the bevacizumab arm: two with right-sided and three with left-sided treatment. Patients with left-sided treatment experienced a persistent reduction in ejection fraction compared with those receiving right-sided treatment. Thus, when treating patients with left-sided breast cancer, exclusion of the heart from the beam's eye view should be undertaken such that no unnecessary radiation dose is delivered to the heart. One challenge moving forward is determining the toxicities of these novel therapies in combination with conventionally fractionated and hypofractionated radiotherapy regimens.

The critical issue that arises with conservatively managed breast cancer is whether the modest gain in local control outweighs the added toxicities and risks of concurrent chemoradiotherapy, using currently available agents. The benefit

in locoregional control obtained in the Rouesse et al.[570] study was statistically significant, but it remains debatable whether the added toxicity of the concurrent program is worth the added risk. Potential issues with concurrent chemoradiation, as pointed out in a study by Burstein et al.,[575] include high rates of radiation pneumonitis in patients treated with radiation given in combination with weekly paclitaxel. Although they observed more favorable results with less frequent dosing, this study highlights the importance of prospective evaluation of radiation in combination with newer chemotherapeutic agents. Furthermore, this study highlights the importance of the dosing and scheduling of the chemotherapy agents given in combination with radiation.

The challenge over the next few years will be to identify those patients, who when treated by the traditional approach of surgery followed by chemotherapy followed by radiation therapy remain at elevated risk of local relapse. Also at risk may be subsets of patients treated with neoadjuvant chemotherapy followed by surgery followed by radiation. Those patients who, when treated by these traditional sequencing approaches, are at high risk of local relapse are ideally suited for prospective evaluation of novel approaches using concurrent chemoradiation strategies. From such trials, we can hopefully minimize locoregional relapse and optimize disease-free and overall survival, with acceptable treatment-related morbidity.

Sequencing Tamoxifen/Hormonal Therapy and Radiation Therapy in Conservatively Managed Patients

The question of optimal scheduling of hormonal therapy and radiation has been raised because of theoretical concerns that tamoxifen may decrease the radiation sensitivity of tumors. In cell culture studies, tamoxifen causes arrest of breast cancer cells in culture in the relatively radioresistant G_0/G_1 phases of the cell cycle. Although there are conflicting data, suggesting both no effect and increased radiation sensitivity, clinicians and patients have been in a quandary as to whether it is reasonable to begin tamoxifen during radiation. In addition, clinical studies have suggested increased pulmonary and breast fibrosis, possibly related to increased concentrations of transforming growth factor-β with the concurrent use of tamoxifen.[576] In a retrospective case series, Wazer et al.[577] reported a trend for an adverse cosmetic outcome associated with breast fibrosis in patients treated with tamoxifen and breast irradiation given either concurrently or sequentially ($P = .06$), although this was not confirmed in other series.[578–580]

A series of three separate retrospective series, however, performed

independently but published simultaneously, reached similar conclusions that sequential or concurrent use of tamoxifen were both acceptable.[578–581] These studies are summarized in Table 59.32. The largest study by Ahn et al.[578] from the Yale group compared 254 patients treated with concurrent tamoxifen and radiation therapy to 241 treated by radiation therapy followed by tamoxifen (*n* = 241). There were no significant differences in the risk of IBTR, disease-free survival, or overall survival. The HR for ipsilateral breast tumor recurrence comparing sequential with concurrent tamoxifen and radiation therapy was 0.93 (95% CI, 0.42 to 2.05; *P* = .86). In this study, morbidity outcomes were not reported.

CON-TAM, concurrent tamoxifen; SEQ-TAM, sequential tamoxifen.

The second study, by Harris et al.,[579] from the group at the University of Pennsylvania compared 174 patients treated with concurrent tamoxifen and radiation therapy with 104 patients treated with radiation therapy followed sequentially by tamoxifen. Similar to the Yale study, patients were accrued throughout a long period between 1980 and 1995, and again no significant differences in IBTR, disease-free survival, or overall survival were observed between groups. The HR for ipsilateral breast tumor recurrence (sequential vs. concurrent) was 1.23 (95% CI, 0.33 to 4.49; $P = .78$). In this study, breast edema and arm edema as well as cosmetic outcome and pneumonitis were analyzed and no significant differences were observed.

The third study, by Pierce et al.,[581] evaluated results from a randomized trial, in which patients were randomly assigned to cyclophosphamide, doxorubicin, and fluorouracil (CAF) followed by tamoxifen, CMF, or CMF followed by tamoxifen. Although the sequencing of tamoxifen was not randomized, 202 patients received concurrent tamoxifen and radiation therapy and 107 received radiation therapy followed sequentially by tamoxifen. In this study, no differences were noted in the risk of IBTR, disease-free survival, or survival between radiation therapy followed sequentially by tamoxifen and concurrent tamoxifen and radiation therapy group. Patients who received concurrent tamoxifen and radiation therapy were more likely to receive radiation after chemotherapy, with less delay. The HR for risk of IBTR (radiation therapy followed sequentially by tamoxifen vs. concurrent tamoxifen and radiation therapy) was 0.73 (95% CI, 0.26 to 2.04; $P = .54$).

Although these studies are limited by their retrospective design, they do offer some reassurance that the concurrent use of hormonal therapy with radiation therapy does not result in excessive rates of local relapse. Although a large randomized trial would be the appropriate next step in addressing this issue, it is unclear whether this issue will be addressed by such a trial in the near future. Given the lack of more definitive data, it appears that either the concurrent or the sequential use of tamoxifen is acceptable in the conservatively managed breast cancer patient. The majority of available data on the use of hormonal therapy and radiation are with tamoxifen. In a prospective phase II randomized trial evaluating concurrent or sequential letrozole, Azria et al.[582] reported no difference in local relapse (one in each arm) at 26 months of follow-up. In addition, only two patients in each group had grade 2 or worse late effects. These authors conclude that letrozole can be safely delivered concomitantly with radiation, but longer follow-up is awaited from this trial.

BREAST-CONSERVING THERAPY: CONTROVERSIES AND SPECIAL CIRCUMSTANCES

The available evidence from all of the retrospective and prospective trials above suggests that although there are clearly cohorts of patients who are at increased risk of local relapse, there are relatively few contraindications to breast-conserving therapy and there is little evidence that treatment of patients at higher risk for local relapse with breast-conserving therapy compromises overall survival. Careful attention to patient selection, surgical technique, and radiation technique, with the appropriate integration of systemic therapy, should minimize the probability of local relapse. There are several areas of controversy and special circumstances in the selection of patients for breast-conserving therapy that warrant specific discussion.

Breast-Conserving Surgery and Radiation in Familial Breast Cancer and Carriers of *BRCA1/2* Mutations

There is considerable controversy and uncertainty regarding the role of breast-conserving surgery and radiation in carriers of *BRCA1/2* mutations.[466,583,584] It has been just over two decades since these two major breast cancer predisposition genes were identified. Genetic linkage studies from families at high risk for predisposing germline mutations have led to the identification of the *BRCA1/2* genes, and these two genes are thought to account for 5% to 10% of breast cancers.[21,43,585–588] Patients with either mutation have up to an 80% lifetime risk of developing breast cancer depending on variable penetrance of the gene. Inherited mutation of *BRCA1* also confers a 20% to 40% lifetime risk of ovarian cancer. Typical patient characteristics of *BRCA*-associated breast cancer include young age at onset and bilateral involvement. The median age at breast cancer diagnosis is 40 for *BRCA1* carriers and 45 for *BRCA2* carriers.[21,585–588] Tumor characteristics of *BRCA1* carriers have been well described. Histopathologic features are often more aggressive, with high nuclear grade, aneuploidy, and high proliferation indices; tumors with a medullary component are more common. Estrogen and progesterone receptors are more likely to be negative when compared with *BRCA2* or sporadic counterparts. Although there are some conflicting data, *BRCA1/2* carriers with breast cancer appear to have equivalent survival when compared with age and staged matched patients with sporadic disease.[21,43,589–591]

The loci for *BRCA1* and *BRCA2* are chromosome 17q21 and chromosome 13q12-13, respectively.[21,585–588] Both function as tumor suppressor genes and

are involved in DNA double-strand break repair. The role of *BRCA1/2* in DNA repair suggests the possibility of hypersensitivity to radiation, as well as the potential for radiation-induced complications including second cancers. DNA double-strand breaks caused by ionizing radiation in *BRCA1/2* carriers could theoretically result in increased cell kill secondary to deficient repair mechanisms.[21,45,592–594]

The risk of both contralateral primary breast cancer and ovarian cancer is substantially higher in patients with *BRCA1/2* mutations than sporadic counterparts. An early publication by the Breast Cancer Linkage Consortium estimated a 64% risk of contralateral breast cancer by the age of 70 years in patients who have had *BRCA1*-associated breast cancer.[43,595] The cumulative risk of ovarian cancer in these patients was 44% by age 70 years. Women with *BRCA2* mutations have a risk of breast cancer similar to patients with *BRCA1* mutations. There is a lesser risk of ovarian cancer, with a cumulative risk of <10% by age 70 years. These results have been interpreted with caution, as linkage studies are likely to overestimate the cancer risk associated with *BRCA1/2* mutations. Several studies of known germline *BRCA1/2* carriers have demonstrated a less pronounced increase in the rate of contralateral breast cancer compared with sporadic controls.[21,43,595]

Early study of familiar breast cancer used positive family history as a surrogate for genetic predisposition. Many of the patients included likely did not harbor germline mutations of the *BRCA1/2* genes. Seynaeve et al.[591] for the Dutch Cancer Society investigated local recurrence after breast conservation therapy in patients with *three or more* first-degree relatives with breast or ovarian cancer or *BRCA1/2* families. Local recurrence rates were initially similar, but with longer follow-up, there was a higher rate of recurrence in the hereditary group when compared with age-matched sporadic patients. Other studies of breast conservation therapy in patients with a family history of breast cancer have not shown an increase in IBR.[406,407,596] Disparate results are expected, as family history is not the sole factor in genetic predisposition.

Garcia-Etienne et al.[597]	54	162	5	4	15	.03	

HR, hazard ratio; IBTR, ipsilateral breast tumor recurrence.

The risk of local and contralateral breast cancers as a function of *BRCA1* and *BRCA2* status has been evaluated by numerous groups over the past 10 years.[285,584,590,591,597–608] These are summarized in Table 59.33.

Robson et al.[584] studied breast conservation therapy in Ashkenazi women with the *BRCA* gene founder mutations (*BRCA1* 185delAG, *BRCA1* 5382insC, and *BRCA2* 617delT). Archival tissue samples were retrieved from 305 women, and 28 *BRCA* gene founder mutations were detected. *BRCA1/2* carriers had a nonsignificant trend toward increased ipsilateral breast cancer recurrence and decreased overall survival at 5 and 10 years. This trend may be related to the greater likelihood of young age and axillary lymph node involvement in women with *BRCA* founder mutations. On univariate analysis, age but not *BRCA* mutation status was associated with IBTR. The significance of age was maintained on multivariate analysis, with a RR of 2.5. The risk of contralateral breast cancer at 5 and 10 years was 14.8% and 27.0%, respectively.

This series from Memorial Hospital was later combined with data from

McGill University, yielding a total of 56 women with founder mutations. Again, *BRCA1/2* carriers had an increased risk of contralateral breast cancer at a median follow-up of 9.7 years (27% vs. 8%; $P < .001$). Ipsilateral breast cancer recurrence for *BRCA1/2* carriers was similar to noncarriers, and age <50 at diagnosis was the only significant predictor of metachronous ipsilateral disease ($P = .002$).[590] *BRCA1* mutations were an independent predictor of breast cancer mortality on multivariate analysis but only for women who did not receive chemotherapy. *BRCA2* mutations had no impact on breast cancer-specific survival.

Haffty et al.[598] studied breast conservation therapy in germline carriers with early-onset breast cancer. One hundred and twenty-seven women diagnosed with breast cancer at age 42 years or younger agreed to undergo genetic testing, and 22 were found to have *BRCA1/2* mutations. Adjuvant tamoxifen or oophorectomy was not used in any of the carriers of *BRCA1/2* mutations. Patients in the genetic group were younger than sporadic patients, and this difference was significant on multivariate analysis. Treatment outcomes were compared with results from patients with sporadic disease. With a median follow-up of 12.7 years, the genetic group had a higher rate of ipsilateral (49% vs. 21%; $P = .007$) and contralateral breast events (42% vs. 9%; $P = .001$). Nine of the 11 IBRs were classified as second primary tumors, based on a difference in tumor location ($n = 7$) or histology ($n = 8$). The rate of ipsilateral and contralateral events was much higher than those reported in earlier series and may be attributable to both the young age of the patients at diagnosis and longer duration of follow-up. The proportion of relapse-free *BRCA1/2* carriers was similar to noncarriers at 5 years and then progressively declined with time (Fig. 59.23). It is promising that all of the second events in *BRCA1/2* carriers were successfully salvaged and remained disease-free. Steinmann et al.[609] confirmed the increased risk of developing ipsilateral second primaries in *BRCA1/2* carriers and extended this concern to patients with bilateral breast cancer. Although the high rate of local relapses and contralateral events in these studies might be considered unacceptable, it is likely that the use of risk reduction strategies, such as tamoxifen or oophorectomy, would reduce these events to an acceptable level. Recent similar case–control-type studies were undertaken by and Garcia-Etienne et al.[597] and Kirova et al.[599] The study by Kirova et al. did not show a statistically higher local relapse rate in *BRCA1/2* carriers. However, the study by Garcia-Etienne et al., comparing 54 genetic cases to 162 sporadic cases, reported a 15% local relapse rate in the genetic group compared with a 4% local relapse

rate in the sporadic group (P = .03).

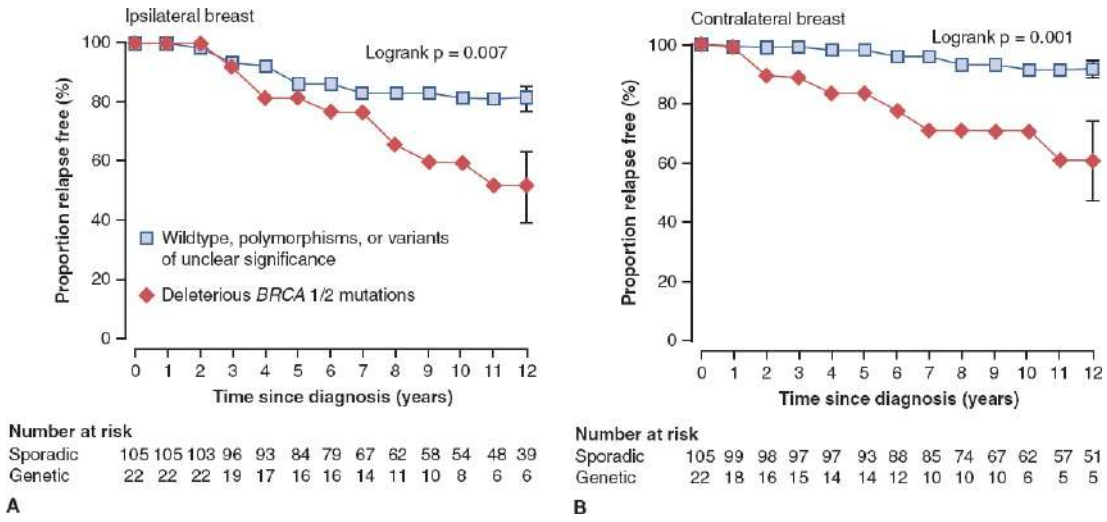

FIGURE 59.23. Risk of ipsilateral **(A)** and contralateral breast tumor relapse **(B)** as a function of *BRCA1/BRCA2* mutation status in a cohort of conservatively managed breast cancer patients. (Reprinted from Haffty BG, Harrold E, Khan AJ, et al. Outcome of conservatively managed early-onset breast cancer by BRCA1/2 status. *Lancet* 2002;359[9316]:1471–1477. Copyright © 2002 Elsevier. With permission.)

Although the data presented above have some apparent conflicting conclusions, a study by Pierce et al.[601] helps to resolve some of these issues. In a large collaborative study, these authors evaluated a total of 160 *BRCA1/2* mutation carriers with breast cancer matched to 445 controls with sporadic breast cancer (Fig. 59.24). Median follow-up was 7.9 years for mutation carriers and 6.7 years for controls. Although there was no significant difference in IBTR overall between carriers and controls (15-year estimates were 24% for carriers and 17% for controls; HR 1.37; P = .19), a subset analysis revealed higher rates of local relapse in those carriers who had not undergone prophylactic oophorectomy. Multivariate analyses for IBTR found *BRCA1/2* mutation status to be an independent predictor of IBTR when carriers who had undergone oophorectomy were removed from analysis (HR 1.99; P = .04); the incidence of IBTR in carriers who had undergone oophorectomy was not significantly different from that in sporadic controls (P = .37). Contralateral breast cancers were significantly more frequent in carriers versus controls, with 10- and 15-year estimates of 26% and 39% for carriers and 3% and 7% for controls, respectively (HR 10.43; P < .0001). Tamoxifen use significantly reduced the risk of contralateral breast cancers in mutation carriers (HR 0.31; P = .05). Thus, it appears that this study confirms the findings of Haffty et al.[598] that *BRCA1/2*

carriers have a high rate of both contralateral and ipsilateral breast events if they do not undergo specific measures to reduce the risk of subsequent breast cancers by undergoing oophorectomy or tamoxifen. Prophylactic mastectomy has been shown to significantly reduce the incidence of breast cancer in women with a family history of breast cancer and specifically women with *BRCA1/2* mutations.[55] This risk reduction strategy has complex emotional and psychological implications, and there are no data to suggest an improvement in survival when compared with close surveillance. Most preventative strategies have focused on primary prevention, but prophylactic strategies should also be considered at the time of breast cancer diagnosis. Oophorectomy and tamoxifen offer similar risk reduction for breast cancer patients with germline mutations. These agents have not been widely used in studies of conservatively managed breast cancer patients with *BRCA1/2* mutations. Their potential benefits must be weighed against the possible complications of premature menopause following oophorectomy and the side effects of tamoxifen.

In a study of 655 women with *BRCA1/2* mutations diagnosed with breast cancer and treated with breast-conserving therapy (n = 302) or mastectomy (n = 353) from a multicenter collaborative group, Pierce et al.[605] reported on local failure, as first failure was significantly more likely in those treated with breast conservation (23.5% vs. 5.5%, respectively), at 15 years (P < .0001). Of note, the in-breast relapse rate appeared to be reduced in the breast conservation group by chemotherapy, whereas the 15-year estimate in carriers treated with breast-conserving therapy and chemotherapy was 11.9% and did not significantly differ from those treated with mastectomy. There were no differences seen in regional or systemic recurrences between the breast-conserving therapy and mastectomy groups and no difference in overall survival, but contralateral breast cancers were common in both cohorts.

Women with *BRCA1/2* mutations who underwent prophylactic oophorectomy to reduce the risk of ovarian cancer were found to have a decreased incidence of breast cancer. Rebbeck[610] studied the risk of breast cancer in 43 *BRCA1* carriers with no history of breast or ovarian cancer who underwent prophylactic bilateral oophorectomy. When these patients were compared with *BRCA1* controls who did not undergo oophorectomy, there was a significant reduction in breast cancer risk (HR 0.53). A follow-up report from this author identified 551 women with *BRCA1/2* germline mutations and reported the incidence of ovarian and breast cancer in women who had undergone prophylactic oophorectomy and matched controls.[611,612] Six women who underwent prophylactic oophorectomy were

diagnosed with stage I ovarian cancer at the time of the procedure. With a median follow-up of 8 years, two women developed papillary serous peritoneal carcinoma after oophorectomy and 58 controls were diagnosed with ovarian cancer. After the exclusion of women who were diagnosed with cancer at surgery, oophorectomy reduced the risk of ovarian cancer by 96%. Oophorectomy also reduced the incidence of breast cancer in the subgroup of 241 women with no history of breast cancer or prophylactic mastectomy. Twenty-one of the 99 (21.2%) women who underwent prophylactic oophorectomy developed breast cancer versus 60 of the 142 (42.3%) women in the control group (HR 0.47).

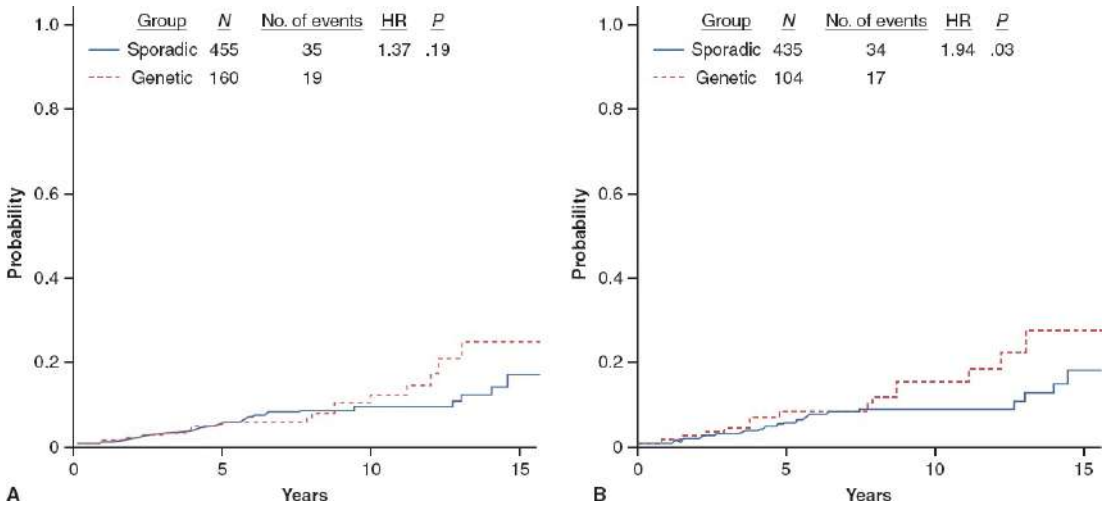

FIGURE 59.24. A: Risk of ipsilateral breast tumor relapse in *BRCA* carriers as a function of whether carriers had undergone prophylactic oophorectomy. In *BRCA* carriers who did not undergo oophorectomy **(B)**, the risk of late local relapses was significantly greater than in sporadic controls. (From Pierce L, Levin AM, Rebbeck TR, et al. Ten-year multi-institutional results of breast-conserving surgery and radiotherapy in BRCA1/2-associated stage I/II breast cancer. *J Clin Oncol* 2006;24[16]:2437–2443. Reprinted with permission. Copyright © 2006 American Society of Clinical Oncology. All rights reserved.)

Kauff et al.[613] conducted a prospective study of the risk of gynecologic cancer and breast cancer in 170 *BRCA1/2* carriers who chose to undergo surveillance or prophylactic oophorectomy. In the 98 women who chose prophylactic oophorectomy, 3 were later diagnosed with breast cancer and peritoneal cancer was diagnosed in 1 patient. The surveillance group of 72 patients yielded 8 breast cancers, 4 ovarian cancers, and 1 peritoneal cancer. With a median follow-up of only 24 months, this prospective study supports an early reduction in breast and ovarian cancer risk with prophylactic

oophorectomy.

In prospective trials, tamoxifen has been shown to reduce both the risk of breast cancer in high-risk women and the risk of contralateral breast cancer in patients with breast cancer.[51,614] An analysis of the NSABP-P1 data from the tamoxifen versus placebo prevention trial identified 19 *BRCA1/2* mutations in the 288 women who developed breast cancer.[94] Five of the 8 women with *BRCA1* mutations had taken tamoxifen versus 3 of 11 women with *BRCA2* mutations. This represented a 62% reduction in breast cancer incidence for *BRCA2* carriers, but no benefit for tamoxifen in *BRCA1* carriers. The dataset was small, however, with low power to detect a protective effect.

Narod et al.[594] studied tamoxifen and the risk of contralateral breast cancer in *BRCA1/2* carriers. This collaborative effort compared women with bilateral breast cancer and women with unilateral breast cancer in a case–control study. Sixty-four (13%) *BRCA1* mutation carriers used tamoxifen versus 39 (33%) *BRCA2* carriers. This difference is expected as breast cancers associated with *BRCA1* mutations are typically ER-negative and *BRCA2*-associated breast cancers are commonly ER positive. Tamoxifen protected against contralateral breast cancer, with an OR of 0.38 for *BRCA1* carriers and 0.63 for *BRCA2* carriers. The combined risk reduction for *BRCA1* and *BRCA2* carriers was 50%. The benefit of tamoxifen in *BRCA1* carriers was possibly detected because of the larger sample size. This study also noted a reduction in contralateral breast cancer in patients who received oophorectomy. The OR was 0.42, which is similar to the reduction in contralateral breast cancer noted with tamoxifen.

Although the conservative management of breast cancer in patients with *BRCA1/2* germline mutations warrants further study, the available evidence indicates that breast-conserving therapy followed by radiation therapy is an appropriate alternative to bilateral mastectomy in early-stage breast cancer in these women. Theoretical concerns for radiation-induced complications have not been demonstrated.[615] Although development of second primary tumors in the ipsilateral and contralateral breast remains a concern, prophylactic oophorectomy and tamoxifen appear to significantly reduce the probability of these secondary events.[21,594,601,610] Prophylactic oophorectomy is even more critical in the risk-reduction strategy for the development of primary tumors of the ovary. For those women considering breast-conserving surgery and radiation therapy, strategies to reduce secondary events, including prophylactic oophorectomy as soon as childbearing issues have been addressed and resolved, with or without tamoxifen or other hormonal agents as indicated, appear to be

rational and viable options. Despite some evidence that tamoxifen reduces the risk of secondary breast cancers in patients who are carriers of *BRCA1/2* mutations, the use of tamoxifen in *BRCA1* breast cancer patients who are ER-negative remains unresolved and controversial.

Collagen Vascular Disease

Increased acute and late effects of irradiation have been reported in patients with pre-existing collagen vascular disease (CVD). Selected studies addressing this issue are summarized in Table 59.34.[616–623]

Fleck et al.[617] reported on five women in whom CVD developed 3 months to 10 years after radiation therapy and who had no complications. However, in three of four women with pre-existing CVD, severe complications developed, characterized by persistent moist desquamation, paresthesias in the ipsilateral arm, chest wall necrosis requiring surgical resection, and osteonecrosis of the clavicle, sternum, and rib cage. These authors concluded that a history of active CVD appeared to be a contraindication to breast conservation surgery and irradiation.

On the other hand, Ross et al.[621] evaluated a group of 61 patients with CVD who were compared with a matched control group of 61 patients without CVD. The CVD group included 39 patients with rheumatoid arthritis, 13 with systemic lupus erythematosus, 4 with scleroderma, 4 with dermatomyositis, and 4 with polymyositis. Overall, there was no significant difference between the CVD and control groups in terms of postirradiation acute complications (11% and 7%, respectively) or late complications (10% and 7%, respectively). This was also true when only patients who were treated definitively were considered. Three patients in the CVD group had fatal complications, compared with none in the control group. Rheumatoid arthritis was associated with a slight increase in late complications in definitively treated patients, whereas systemic lupus erythematosus was associated with a slight increase in acute reactions. No significant acute or late reactions were observed in the patients with scleroderma, dermatomyositis, or polymyositis.

TABLE 59.34 STUDIES EVALUATING COLLAGEN VASCULAR DISEASE IN BREAST-CONSERVING THERAPY

Study (Reference)	CVD		Design	Findings
	Total	Number with Breast		

	Number	Cancer		
De Naeyer et al.[616]	3	1	Case report	Necrosis and progressive fibrosis
Fleck et al.[617]	9	4	Case report	Necrosis, brachial plexopathy, and severe moist desquamation
Robertson et al.[618]	2	2	Case report	Severe breast fibrosis, erythema, and pain
Chen et al.[619]	36	36	Case control	Late complication rates higher only in scleroderma
Morris and Powell[620]	209	19	Retrospective	Increased radiation late effects appear in nonrheumatoid arthritis cases
Ross et al.[621]	61	61	Case control	No differences in acute/chronic complications
Phan et al.[622]	38	38	Case control	No difference was observed in the incidence of acute or late complications between the two groups
Rakfal and Deutsch[623]	6	4	Case report	No severe acute or late radiation complications

CVD, collagen vascular disease.

Morris and Powell[620] treated 96 patients with documented CVD with breast conservation therapy (127 sites irradiated). Grade 3 or higher acute complications were seen in 15 of the 127 (11.8%) sites, and the actuarial rate of significant late complications was 24% at 10 years. There was a single in-field sarcoma. Patients with rheumatoid arthritis had less severe late effects than did those with other CVD (6% vs. 37% at 5 years; $P = .0001$).

In a study specifically evaluating conservatively treated breast cancer patients, Chen et al.[619] from the Yale group identified 36 patients with documented CVD conservatively treated for early-stage breast cancer between 1975 and 1998. All of these patients were treated with conventional radiation therapy to a median total dose of 64 Gy. Seventeen had rheumatoid arthritis; four, scleroderma; four, Raynaud phenomenon; five, lupus erythematosus; two, Sjögren disease; and four, polymyositis. Each of these patients was matched to two control patients without a history of CVD. Acute and late complications were assessed using a six-point scale from the toxicity criteria of the RTOG and the EORTC. No significant difference was detected between the CVD and control groups with respect to acute complications (14% vs. 8%). With respect to late complications, a significant difference was observed (17% vs. 3%) between the two groups. However, when patients in the CVD group were analyzed by

specific disease, this significance disappeared in all but the scleroderma group.

Collectively, these data suggest that with the exception of patients with scleroderma, there does not appear to be a significantly greater late complication rate associated with CVD. Nevertheless, when patients with CVD are irradiated, it is prudent to limit the whole-breast dose to 45 Gy with 1.8-Gy fractions, use 6-MV photons, optimize homogeneity of dose distribution, avoid concurrent chemoirradiation, and discuss with patients the potential increased risks of radiation sequelae. There are small, limited case series of treating breast cancer in patients with CVD with hypofractioned whole-breast or partial-breast radiotherapy.

Pregnancy

Breast Cancer during Pregnancy

Breast cancer is the most common cancer diagnosed during pregnancy and represents a significant therapeutic challenge. Recently, an expert international panel met and published general recommendations for breast cancer developing during pregnancy.[624] The panel noted that the goal for the pregnant women with breast cancer is the same as that of the nonpregnant women: local control of disease and prevention of systemic metastasis. However, because of adverse effects on the fetus, certain treatment modalities, including radiation, must be avoided.

The incidence of breast cancer associated with pregnancy is estimated to be 1.5 to 2 in 10,000 pregnancies. Albrektsen et al.,[625] in a study of 802,457 women from the Cancer Registry of Norway, observed a RR of 1.24 for breast cancer in the 3 to 4 years immediately after a pregnancy, followed by a decreased risk thereafter.

The prognosis of patients developing breast cancer during pregnancy, stage for stage, appears to be similar to age-matched controls, although delays in diagnosis may result in higher stages in pregnant women. Several studies have stated that poorer prognosis in breast cancer associated with pregnancy may be related to delay in diagnosis because pregnancy impedes early detection and possibly to the biology of the tumor.[626] Zemlickis et al.[627] compared 118 women with breast cancer (119 pregnancies) with 269 nonpregnant control patients. The distribution of breast cancer stages among the 118 pregnant women was compared with that among 5,115 cases of breast cancer in nonpregnant women of reproductive age. Women having breast cancer in pregnancy were 2.5 times more likely to have metastatic disease (95% CI, 1.1 to 5.3) and had a

significantly lower chance of having stage I disease (P = .015). However, stage for stage survival of pregnant women did not differ from that of the control patients. A number of authors have commented on the high percentage of pregnant patients with lymph node involvement, compared with nonpregnant patients. Others have also suggested that the poorer outcome relates to the young age of the patient and not necessarily to the pregnancy.[304,628,629] A single-institution retrospective chart review was performed on 99 patients identified with pregnancy-associated breast cancer (PABC), where non-PABC controls were matched 2 to 1 to PABC cases by year of diagnosis and age.[630] They found that PABC cases were more likely than controls to be negative for estrogen receptor (59% vs. 31%; P < .0001) and negative for progesterone receptor (72% vs. 40%; P < .0001). Cases were also more likely to have advanced T class (P = .03) and N class (P = .01) and higher grade tumors (P = .0115). With a median follow-up of 6.3 years for cases and 4.7 years for controls, overall survival did not differ between cases and controls (P = .08).

As will be discussed below, selected chemotherapy agents can be administered during the second and third trimesters. Although therapeutic abortion is not necessary, women with high-risk disease may find this preferable. They also note that in women with known deleterious mutations in *BRCA1/2*, early pregnancy is not known to decrease subsequent breast cancer risk. In addition, the available evidence suggests that in women with a history of breast cancer, subsequent pregnancy does not increase the risk of recurrence.

In addition to requiring close coordination among multidisciplinary cancer care givers, management of breast cancer during pregnancy also benefits from having obstetricians and pediatricians closely involved in therapeutic decision making. It is likely that as pregnancy in Western society is delayed to older ages, the incidence of breast cancer developing during pregnancy will increase.

Breast cancers during pregnancy are almost universally diagnosed after an abnormal physical examination finding.[304] There frequently may be a delay in diagnosis because the breast mass is thought to represent obstructed milk ducts and inflammatory changes of the breast may be misdiagnosed as cellulitis. For patients who present with a breast mass, a careful history and physical examination should be performed. The overall goal of managing breast cancer during pregnancy requires attention to both the mother and the fetus. Certain diagnostic and therapeutic interventions are known to be teratogenic and therefore are best avoided. Although theoretically a chest radiograph may be safely performed because the maximum dose to the fetus is <0.005 Gy,

radiographic and scintigraphic imaging for staging should be minimized or deferred.[290] Mammography is somewhat controversial, although the irradiation dose to the fetus is minimal (<0.5 mrem).[631] Ultrasound evaluations of the breast and lymph nodes can provide diagnostic information and serve as a method of guidance for core biopsy. Pathology of breast cancer during pregnancy is most frequently invasive ductal with high nuclear grade and lower rates of ER and PR positivity.[304]

The management of the patient and the risks of certain interventions are also highly dependent on the week of gestation. In general, potentially harmful interventions carry the greatest risk during the period of organogenesis (first trimester) and are safest during the final trimester. For patients with operable disease, data suggest that surgery can be safely performed after the 12th week of pregnancy. The type of surgical procedure is dependent on the extent of disease and the trimester of the pregnancy.[304,625,627,628] Few data exist concerning the safety and efficacy of sentinel lymph node biopsy. Although the blue dye used in sentinel lymph node surgery is not approved for use in pregnant patients, the estimated radiation dose to the fetus from the radiocolloid tracer is low. Except for radiation, treatment should not be altered or delayed because of pregnancy. Either a modified radical mastectomy or lumpectomy with axillary dissection is acceptable local treatment. Immediate breast reconstruction should not be performed.

Systemic chemotherapy with FAC (5-fluorouracil, doxorubicin, cyclophosphamide) has been used in pregnancy. Investigators from MD Anderson Cancer Center reported a prospective series of 57 pregnant breast cancer patients who were treated on a single-arm, multidisciplinary, protocol with FAC in the adjuvant (n = 32) or neoadjuvant (n = 25) setting.[632] Parents and guardians were surveyed by mail or telephone regarding outcomes of children exposed to chemotherapy *in utero*. All women who delivered had live births. One child has Down syndrome and two have congenital anomalies (club foot; congenital bilateral ureteral reflux). They conclude that breast cancer can be treated with FAC chemotherapy during the second and third trimesters without significant short-term complications for the majority of children exposed to chemotherapy *in utero*. Longer follow-up of the children is needed to evaluate possible late side effects such as impaired cardiac function and fertility. Administration of chemotherapy in the first trimester is associated with a high risk of birth defects (17%, 24 of 139), in terms of probability of intrauterine growth retardation, prematurity, fetal malformation, or death; this risk is less in

the second and third trimesters (1.3%, 2 of 150).[633]

As a general principle, hormonal therapy and radiation therapy should be avoided until after delivery. In one study, the estimated dose to the fetus from breast or chest wall radiation to a dose of 0.5 Gy is 0.02 Gy in the first trimester, 0.022 to 0.246 Gy during the second trimester, and 0.02 to 0.586 Gy during the third trimester. Dose to the fetus in the range of 0.1 to 0.9 Gy during the first trimester have been associated with mental retardation.[634]

When the patient chooses breast-conserving therapy, irradiation should be deferred until the fetus is delivered because 50 Gy delivered to the breast, even with external shielding, exposes the fetus to 0.1 to 0.15 Gy if it is small and contained in the true pelvis. During later gestation, when the fetus is larger and high in the abdomen, some fetal areas may receive as much as 2 Gy.[634] In another study using a phantom (film dosimetry), doses to the pelvis ranged from 0.043 Gy with 4-MV x-rays to 0.158 Gy with cobalt-60 (^{60}Co) to the midpelvis.[635]

Although there is some question whether there is any safe dose of irradiation to the fetus, Brent,[636] in an extensive review of the literature, defined 0.05 Gy as a relatively safe upper limit of fetal exposure. Hall[637] suggested that 0.1 Gy *in utero* exposure be used as a dose beyond which a therapeutic abortion should be considered.

Some authors have suggested therapeutic abortion based on a study by Adair,[638] who reported in the early 1950s a better outcome in patients who terminated their pregnancies. However, in 63 patients treated at Mayo Clinic, the 5-year survival rate was 59% in the women who carried to term and 43% in those who underwent a therapeutic abortion. The latter group had more advanced tumors.[639] Petrek[626] also noted that therapeutic abortion does not alter the outcome in patients with breast cancer. Contrary to popular belief, pregnancy does not appear to stimulate the growth of breast cancer. Therefore, no justification exists for therapeutic abortion, which may be relevant only in the patient who has rapidly progressing disease, such as inflammatory breast cancer (IBC) or metastatic disease.

Pregnancy after Breast Cancer

Almost one-third of women of reproductive age in whom breast cancer later develops have one or more pregnancies, and 70% of these occur within 5 years of treatment.[640] No data are available to suggest that subsequent pregnancy hastens or induces breast cancer recurrence. When matched by age and stage

with nonpregnant patients, pregnant women with breast cancer do not have a worse outcome than nonpregnant patients with comparable stages. However, in patients receiving adjuvant chemotherapy, a minimum of 12 months between treatment and conception is advised. Breast-feeding is contraindicated in patients receiving chemotherapy because antineoplastic agents are excreted in the milk.[304,626,628]

Sutton et al.[641] reviewed 227 women 35 years of age or younger at diagnosis who became pregnant after treatment with CAF adjuvant chemotherapy. Twenty-five patients had 33 pregnancies. The median interval between completion of chemotherapy and pregnancy was 12 months (range, 0 to 87 months). Ten pregnancies were terminated, 2 ended in spontaneous abortion, 2 patients were still pregnant at the time of the report, and 19 produced normal full-term infants. The incidence of recurrence was 46% in patients without pregnancy, compared with 28% in those who had subsequent pregnancies. Similarly, 38% of patients without subsequent pregnancy were dead at the time of the report, compared with 12% of patients who became pregnant after chemotherapy treatment for breast cancer.

A population-based matched survival study assessed the risk of death for patients with breast cancer in relation to whether they delivered a live child subsequent to their cancer diagnosis.[642] Among 2,548 women younger than 40 years of age diagnosed with carcinoma of the breast, 91 experienced subsequent deliveries (10 months or longer after the diagnosis) and 471 control patients were matched for stage, age, and year of breast cancer diagnosis. The control subjects had to survive at least the interval between the cancer diagnosis and the delivery of their matched counterparts. The control subjects had a 4.8-fold greater risk of death compared with those who delivered after the diagnosis of breast cancer. These authors' interpretation of this result was that there was a "healthy mother effect" (only women who felt healthy gave birth, and those who were affected by the disease did not). Nevertheless, 6 of 8 deaths among the 91 patients who did give birth were related to breast cancer.

It may be helpful to suggest a waiting time (2 to 3 years) for the patient to regain health before attempting the physical stress of pregnancy and deferral of childbearing until after the period of greatest risk of recurrence of the tumor.[640] The individual woman's prognosis, well-being, desire for children, support from spouse or significant other, and other sociodemographic factors must be carefully considered in this difficult decision-making process.

Lactation after Breast Conservation Therapy

Successful breast-feeding, from the untreated as well as the treated breast, is possible after conservation surgery and irradiation. Higgins and Haffty[643] reviewed the records of 890 patients treated with radiation therapy for early-stage (stage I or II) breast cancer. This series was recently updated by Moran et al.[644] Of over 3,000 patients treated from 1965 to 2003, a cohort of 21 premenopausal women who underwent breast-conserving therapy and subsequently sustained full-term pregnancies were identified. Lactation outcome parameters (breast swelling, ability to lactate, and volume of lactation in the treated and untreated breasts) were the main outcome measures. There were 28 pregnancies in 21 patients. One patient underwent bilateral breast treatment; therefore, a total of 22 breasts were irradiated. All patients interviewed reported little or no swelling of the treated breast during pregnancy. Of the patients studied, 4 (18.2%) elected pharmacologic suppression of lactation. Of the remaining 18 breasts, lactation occurred in 10 (55.6%), did not occur in 7 (38.9%), and was unknown for 1 (5.5%). The volume was reported as significantly diminished in 80% of breasts treated. Lactation in the contralateral breast occurred in all patients who did not undergo pharmacologic suppression. The authors confirm that successful lactation in the contralateral, untreated breast after breast-conserving therapy is expressed. In the treated breast, functional lactation is possible but is significantly diminished in the majority of patients. Tralins[645] reported results of a survey describing 53 women who became pregnant after conservation therapy and breast irradiation. Eighteen exhibited some lactation and 13 (24.5%) were able to breast-feed from the involved breast. Pregnancy or lactation had no impact on prognosis; with a 5.4-year mean follow-up, the tumor-free survival rate was 82%.

Breast Irradiation in Patients Previously Irradiated for Hodgkin Lymphoma

There is an increased incidence of breast cancer in female patients who have previously undergone mantle irradiation for Hodgkin lymphoma. Numerous studies have demonstrated a significantly increased RR of breast cancer in women treated for Hodgkin lymphoma, with the risk significantly increasing with decreasing age of exposure. Table 59.35 summarizes the findings of several series.[29,104,646–664]

Travis et al.[29] estimated that for a female Hodgkin lymphoma survivor who was treated at age 25 years with a chest radiation dose of at least 40 Gy without

alkylating agents, the cumulative absolute risks of breast cancer by age 35, 45, and 55 years were 1.4% (95% CI, 0.9% to 2.1%), 11.1% (95% CI, 7.4% to 16.3%), and 29.0% (95% CI, 20.2% to 40.1%), respectively. In addition to radiation dose, treatment volumes may also play a role in determining a woman's risk of developing breast cancer after radiotherapy for Hodgkin lymphoma. A study by De Bruin et al.[665] reported on a cohort of 1,122 female patients with Hodgkin lymphoma treated between 1965 and 1995. The overall cumulative incidence 30 years after treatment was 19%; for those treated before age 21 years, it was 26%. Moreover, mantle field irradiation was associated with a 2.7-fold increased risk in developing breast cancer compared with similarly dosed (36 to 44 Gy) mediastinal irradiation alone.

Mastectomy has been recommended as the preferred treatment option in these women. Lumpectomy followed by breast irradiation has been considered by some to be contraindicated because of the cumulative radiation dose to the breast. However, in selected patients using careful breast irradiation techniques that avoid significant overlap with the previous mantle port, anecdotal and retrospective reports in small numbers of patients suggest that it is possible to offer breast conservation therapy. Therapeutic options and the potential increased risk of reirradiation sequelae should be thoroughly discussed with the patient. A second issue that should also be considered is the risk of the development of new primary. Similar to patients with *BRCA* mutations, patients who have a history of breast cancer development after irradiation for Hodgkin lymphoma are at risk in the development of subsequent new primaries and may benefit from prevention strategies such as mastectomy.

Elkin et al.[666] reported on a retrospective multicenter, cohort study of 253 patients treated for Hodgkin lymphoma with radiation therapy who developed breast cancer and matched 3 to 1 with 741 patients with sporadic breast cancer. They found that patients had a median time from diagnosis of Hodgkin's to breast cancer of 18 years, with a median age at breast cancer diagnosis of 42 years. Breast cancer after RT for Hodgkin lymphoma was more likely to be detected by screening, was more likely to be diagnosed at an earlier stage, and was more likely to be bilateral at diagnosis. Hodgkin lymphoma survivors had an increased risk of metachronous contralateral breast cancer (HR 4.3; 95% CI, 1.7 to 11.0) and death as a result of any cause (HR 1.9; 95% CI, 1.1 to 3.3).

Cutuli et al.[667] reported on a retrospective multicenter analysis in which 117 women and 2 men treated for Hodgkin lymphoma subsequently developed 133 breast cancers. Hodgkin lymphoma treatment was radiation therapy alone in 74 patients and combined modality with chemotherapy in 43 patients. Breast cancer occurred after a median interval of 16 years. Tumors were treated by mastectomy without (n = 67) or with (n = 10) irradiation. Forty-four tumors were treated with lumpectomy without (n = 12) or with (n = 32) radiation therapy. Sixteen patients had isolated breast relapses, 39 had metastases, and 34 died. Young women treated for Hodgkin lymphoma should be carefully monitored in the long term by clinical examination, mammography, and ultrasonography. The authors suggested that a baseline mammography be performed 5 to 8 years after supradiaphragmatic irradiation (complete mantle or involved field) in patients treated before 30 years of age. Subsequently, mammography should be performed every 2 years or each year, depending on the characteristics of the breast tissue (e.g., density) and especially in the case of an association with other breast cancer risk factors.

Wolden et al.[668] described 71 cases of breast cancer in 65 survivors of Hodgkin lymphoma. Median age at diagnosis was 24.6 years for Hodgkin lymphoma and 42.6 years for breast cancer; the RR for invasive breast cancer after Hodgkin lymphoma was 4.7 compared with an age-matched cohort. Cancers were detected by self-examination in 63%, by mammography in 30%, and by physical examination alone in 7%. The majority were of invasive ductal histology and 27% had positive axillary nodes. The tumor was ER positive in 63% of the cases, and 25% of patients had an associated family history. The majority of tumors were smaller than 4 cm. Ninety-five percent of cases were managed by mastectomy because of prior irradiation, and two women underwent excisional biopsy with breast irradiation. One of these patients had tissue

necrosis in the region of overlap with the prior mantle field. The incidence of bilateral breast cancer was 10%. The 10-year disease-specific survival rate for DCIS was 100%; stage I, 88%; stage II, 55%; stage III, 60%; and stage IV, 0%.

One of the largest series using breast-conserving therapy plus radiation in patients previously treated for Hodgkin lymphoma is from Deutsch et al.[669] In this retrospective review, 12 women treated with radiotherapy with or without chemotherapy for Hodgkin lymphoma (11 patients) and non-Hodgkin lymphoma (1 patient) in whom breast cancer developed 10 to 29 years later were treated with lumpectomy and breast irradiation. Patients were treated with whole-breast daily irradiation with a fractionation of 2 Gy to 50 Gy with boost to the operative area. Six also received adjuvant chemotherapy for breast cancer. Breast irradiation was well tolerated without any unusual acute or chronic sequelae. They conclude that this may be an option for previously radiated Hodgkin's survivors who develop early-stage breast cancer.

This controversial area will continue to evolve. Given the development of partial breast irradiation programs over the past several years, it is likely that data regarding reirradiation with partial breast irradiation or proton therapy will be reported.[670,671] Clearly, however, Hodgkin's survivors and others who receive radiotherapy to breast at a young age are at high risk for developing breast cancers and should be carefully monitored. Women who develop breast cancer should be advised that mastectomy remains the treatment of choice. However, for patients highly motivated for breast preservation, anecdotal experiences using a variety of approaches have revealed acceptable toxicity and cosmesis.

Patients with More than One Invasive Carcinoma (Multicentric Disease)

Multicentricity of breast cancer has been considered by some a contraindication to breast-conserving surgery and suggest mastectomy as the preferred option.[672] Conservation surgery and breast radiation therapy as an alternative to mastectomy is controversial in patients with two or more lesions in the same breast. Several studies have addressed this issue, and it appears that the risk of relapse in the conservatively treated patient is slightly higher than if there is one lesion, but the risk may be acceptable in patients with two or perhaps three lesions provided these lesions are surgically excised with negative margins and there are no residual areas of suspicion on physical examination, mammogram, or imaging studies. Selected studies evaluating the conservative management of breast cancer in patients with multicentric disease are summarized in Table

59.36.[673–677]

Kurtz et al.,[677] in an analysis of 586 patients with unilateral stage I or II breast cancer treated with breast-conserving surgery and irradiation, found 61 patients who had two or more microscopic tumor nodules. After a median follow-up of 71 months, 15 patients (25%) had a recurrence in the treated breast, compared with 56 of 525 (11%) patients with single tumors ($P < .005$). Recurrence was noted more often in patients with multiple tumors diagnosed clinically or mammographically (8 of 22, 36%) than when multicentricity was apparent only on pathologic examination (7 of 39, 18%).

[a]All are SIBC treated with mastectomy.
SIBC, synchronous ipsilateral breast cancer.

Wilson et al.[673] reviewed their experience in 1,060 patients treated with conservation surgery and breast irradiation of whom 13 (1.2%) presented with synchronous multicentric ipsilateral breast cancer. With a median follow-up of 71 months, 3 of the 13 (23%) had an IBR (72-month actuarial rate of 25%) compared with 12% in the single-lesion population. The use of conservation therapy in patients with more than one primary lesion should be considered with caution, and patients should be forewarned of the need for more extensive resections and the increased risk of breast relapse. Because resection of a larger volume of breast is required, cosmetic results may be compromised, and expectations may not be met. In such instances, a mastectomy may be the preferred approach.

Conservation Surgery and Irradiation after Breast Augmentation

A growing number of breast cancers occur in women with prior augmentation mammoplasty. The stage of breast cancer at diagnosis in women who have undergone augmentation mammoplasty has been examined with conflicting results. In a retrospective review, Clark et al.[678] reported that 24% of 33 patients with augmented breasts and 42% of 1,735 patients with nonaugmented breasts had mammographically detected cancers (*P* = not significant). The incidence of DCIS in the two groups was similar (18% vs. 15%, respectively). Sizes of the mammographically detected tumors in the two groups were comparable. However, palpable tumors in the augmented group were significantly smaller than those in the nonaugmented group. Axillary lymph node involvement was detected in 19% of the augmented group and 41% of the nonaugmented group. Among those with mammographically detected tumors, there was no significant difference in axillary lymph node metastases between patients with augmented versus nonaugmented breasts (13% vs. 15%, respectively).

Patients with augmentations who have breast cancer are currently being treated with conservation therapy, but no study has investigated the complications and cosmetic results of radiation therapy specifically in this group of women.

Breast conservation therapy in 17 augmented patients with breast cancer was reported by Handel et al.,[679] where 15 patients were available for follow-up. In 10 patients (67%), significant capsular contracture occurred in the irradiated breast an average of 12 weeks after completion of treatment. Four patients underwent revision surgery to correct symptoms arising from contracture. These authors concluded that irradiation of the breast for cancer in augmented women results in a high incidence of scar tissue contracture and poor cosmetic results.

In contrast, Guenther et al.[680] evaluated 20 women in whom breast cancer developed after augmentation mammoplasty (14 subcutaneous implants and 6 retromuscular implants). Patients were treated with wide local tumor excision and level I and II ALND. Irradiation was delivered to the breast (45 to 50 Gy), and a boost (14 to 21 Gy) was given to the tumor excision site with either photons, electrons, or iridium-192 (^{192}Ir) implant. With a median follow-up of 3.8 years (range, 6 months to 9.3 years), there were no local recurrences, although distant metastases developed in two patients. Seventeen patients (85%) had good or excellent cosmetic results.

Breast Conservation and Mammoplasty

Women with large, pendulous breasts have been documented to have poorer cosmetic outcomes when undergoing irradiation after breast conservation surgery (thought to be caused by dose inhomogeneity) compared with women who have small or medium-size breasts. Smith et al.[681] evaluated 10 women who had undergone bilateral reduction mammoplasty for breast malignancy followed by radiation therapy. A variety of reduction techniques were used to include the malignant lesions. Patients received 50 Gy in 25 fractions in 5 weeks after surgery. Radiation therapy was usually initiated within 4 weeks after surgery. With a follow-up of 37 months, no patients have had complications from the surgery or radiation therapy. No local recurrent malignancies have been detected. Cosmesis has been good to excellent in all patients.

Bilateral Carcinoma of the Breast

Among factors reported to be associated with an increased risk of bilateral breast carcinoma are younger age, family history of breast cancer, lobular carcinoma, multicentric disease, histologic differentiation of the primary tumor, parity, and PR-positive status.[682–687] The appearance may be synchronous (1% to 2%) or metachronous (5% to 8%). Synchronous breast carcinoma was defined as a contralateral cancer diagnosed within 1 year of initial diagnosis.

Patients with bilateral carcinoma have been treated with total or modified radical mastectomy. However, the available evidence clearly supports lumpectomy followed by breast irradiation as an acceptable alternative for appropriately selected women. Solin et al.[688] reported on 30 treated with breast conservation therapy (11 with concurrent and 19 with metachronous carcinoma). A dose of 45 to 50 Gy was delivered to both breasts with tangential fields, in addition to a boost of 10 to 15 Gy with either iridium implant or electrons. The tangential fields were matched in the midline in 17 patients and overlapped by up to 3 cm in 10 patients. In the 60 treated breasts, the 5-year actuarial local failure rate was 6%. In 25 treated breasts with a minimum of 2 years of follow-up, 68% had excellent and 24% had good cosmetic results. The incidence of arm edema was 6%, similar to that reported in patients with unilateral disease.

Hungness et al.[689] reviewed their experience with 51 patients with bilateral synchronous breast cancer (2.1% of 2,382 treated for breast cancer during the same period). The first cancer was detected by palpation in 81% and by mammography in 14%. The corresponding figures for the contralateral cancer were 24% and 54%, respectively. The histologic type of cancer was identical in

the two breasts in 29 patients (57%) and was different in 22 patients (43%). The overall 10-year survival rate was 66%.

Heron et al.[690] compared the outcomes in 1,315 patients (89.9%) with unilateral, 103 (7.1%) with metachronous, and 47 (3.0%) with synchronous breast carcinoma treated with either mastectomy or breast conservation therapy. Patients with synchronous and metachronous bilateral carcinoma had a worse 8-year disease-free survival rate compared with patients who had unilateral breast carcinoma, as well as increased risk of distant metastasis. In multivariate analysis, differences in local tumor control and overall survival were not statistically significant for patients who had bilateral or metachronous cancer compared with those who had unilateral disease.

Kollias et al.,[691] in 3,210 women age 70 years or younger treated for primary operable breast cancer, identified 106 who had bilateral breast cancer; in 26 (0.8%), the disease was synchronous, and in 80 (24%), a contralateral breast cancer developed after treatment for an initial primary breast cancer. There was a significant difference in survival between women with unilateral breast cancer, synchronous bilateral breast cancers, and metachronous contralateral breast cancer, with survival rates at 16 years of 53.8%, 42.4%, and 60.1%, respectively ($P < .0001$), from the date of the diagnosis of the first primary tumor. There was no difference in survival among the three groups from the date of diagnosis of the second primary in cases of metachronous contralateral breast cancer ($P = .31$).

Ninety-five patients with bilateral carcinoma of the breast treated with mastectomy (60 patients), conservation of the breast (17 patients), or both (18 patients) were studied by Gustafsson et al.[692] Cumulative 5-year local tumor control rates were 94% for the 138 mastectomy patients and 90% for the 52 patients treated with breast conservation therapy. Twenty-eight percent of the first carcinomas were stage I, compared with 43% of second carcinomas ($P < .05$), probably reflecting the close follow-up after initial treatment. The 5-year distant disease-free survival rate from treatment for the second carcinoma was 74%. The 5-year distant recurrence-free survival rate when second carcinomas were diagnosed within 5 years was 58%, compared with 95% for patients diagnosed more than 5 years after the first carcinoma.

de la Rochefordiere et al.[693] reported on 149 patients with simultaneous bilateral breast cancer (diagnosed within 6 months). Of 298 tumors, 40% were T0 or T1, 45% were T2, and 15% were T3 or T4. The majority (83%) were clinically node negative. Treatments were bilateral mastectomy in 43%,

irradiation in 16%, and both in 41% of the patients. Fifty-one patients had bilateral breast-conserving therapy and 24 were treated exclusively with irradiation. The 5-year disease-free survival rates were 70% to 86%, respectively, similar to those observed at the same institution in patients with unilateral tumors. Cosmesis was assessed in 48 patients and was acceptable in 37 (77%). These authors advised special attention should be paid to any possible overlap of the supraclavicular and internal mammary fields over the spinal cord; in one patient, spinal cord myelopathy developed at T6.

Freedman et al.[596] reviewed records of 116 patients with bilateral breast cancer and a breast cancer family history. The primary treatment was a breast-conserving procedure in 55 and a mastectomy in 61. LRRs occurred in 4 of 46 cases treated with breast-conserving therapy, resulting in a 10-year actuarial locoregional tumor control rate of 83%. Of nine patients who did not receive radiation as a component of their breast-conserving therapy, LRRs developed in four patients (10-year locoregional control rate of 49%). The 10-year actuarial rates of locoregional control after mastectomy with and without radiation were 91% and 89%, respectively.

Fung et al.[694] reported on 55 women with stage 0, I, or II concurrent (n = 12) or sequential (n = 43) bilateral breast cancers treated with irradiation after breast-conserving surgery. The tangential fields were matched with no overlap in 40 patients (73%); there was overlap on skin of up to 4 cm in 14 patients (25%). For the 110 treated breast cancers, the 10-year actuarial local failure rate was 15%. Complications included breast edema (28%), arm edema (8%), pneumonitis (4%), cellulitis (3%), rib fracture (1%), and brachial plexopathy (1%). No patient had match line fibrosis. For patients with a minimum of 3 years of relapse-free follow-up, the rate of excellent or good cosmetic outcome for 104 treated breasts was 85%.

TECHNICAL ISSUES IN RADIATION MANAGEMENT OF EARLY-STAGE DISEASE

Treatment Position

Most patients are treated in the supine position, with the arm abducted (90 degrees or greater). Commercially available or custom-made breast tilt boards with armrests that maintain the patient's daily position with the slope of the chest wall parallel to the table, often in combination with immobilization devices (e.g., Alpha cradle, plastic molds), are typically used to reproduce daily positioning

and minimize day-to-day setup errors (Fig. 59.25).

Other treatment positions have been used to improve the dosimetry in patients with large, pendulous breasts. A lateral decubitus position has been suggested by investigators at the Institut Curie.[695,696]

Irradiation in the prone position has been proposed by Merchant and McCormick,[697] with reduction of dose in the high-dose region to 102% to 103% of the dose to the irradiated breast, as well as reduction of volume and dose to the underlying lung and heart and reduction of scattered dose to the contralateral breast. This technique is being increasingly employed and follow-up data appear to be promising with respect to toxicity and early outcomes.[698] Patient positioning and a corresponding CT image are shown in Figures 59.26 and 59.27.

Treatment Volume

The entire breast and chest wall are included in the irradiated volume as shown in Figures 59.28 and 59.29. Radiopaque surgical clips placed at the margin of the tumor bed may assist in defining the target volume.[699] The upper margin of the portals should be placed at the head of the clavicle to include the entire breast. The medial margin, if no internal mammary portal is used, should be at or 1 cm over the midline. If an internal mammary field is used, the medial tangential portal is located at the lateral margin of the internal mammary field. (See discussion later on regional nodal irradiation.) The lateral–posterior margin should be placed 2 cm beyond all palpable breast tissue, which is usually near the midaxillary line. The inferior margin is drawn 2 to 3 cm below the inframammary fold. The RTOG published their consensus definitions for breast cancer radiation therapy planning, which are listed in Table 59.37. An illustration of nodal volumes drawn on an axial planning CT scan is shown in Figure 59.30.

In patients treated with 6-MV or lower-energy photons with wide tangential fields in whom separation is >22 cm, there may be significant dose inhomogeneity in the breast; this may correlate with less satisfactory cosmetic results.[351,700] This problem can be minimized by using higher-energy photons (10 to 18 MV) to deliver a portion of the breast radiation (approximately 50%) as determined with treatment planning to maintain the inhomogeneity throughout the entire breast to between 93% and 105%. If desired, the buildup of the beam may be modified with a “degrader.” “Simple intensity-modulated radiation therapy” techniques such as field-in-field or dynamic multileaf collimators (MLCs) to achieve electronic tissue compensation may be utilized to

reduce dose inhomogeneity as well. Bolus should be avoided in conservatively managed patients. A variety of immobilizing devices or molds may be constructed to support the breast in the treatment position (Fig. 59.31). A polyvinyl chloride, ring-shaped device, held by a strap, has been used around the breast to aid in positioning of patients with large, pendulous or flaccid breasts. Skin reactions where material is in contact with the skin should be closely monitored.[701]

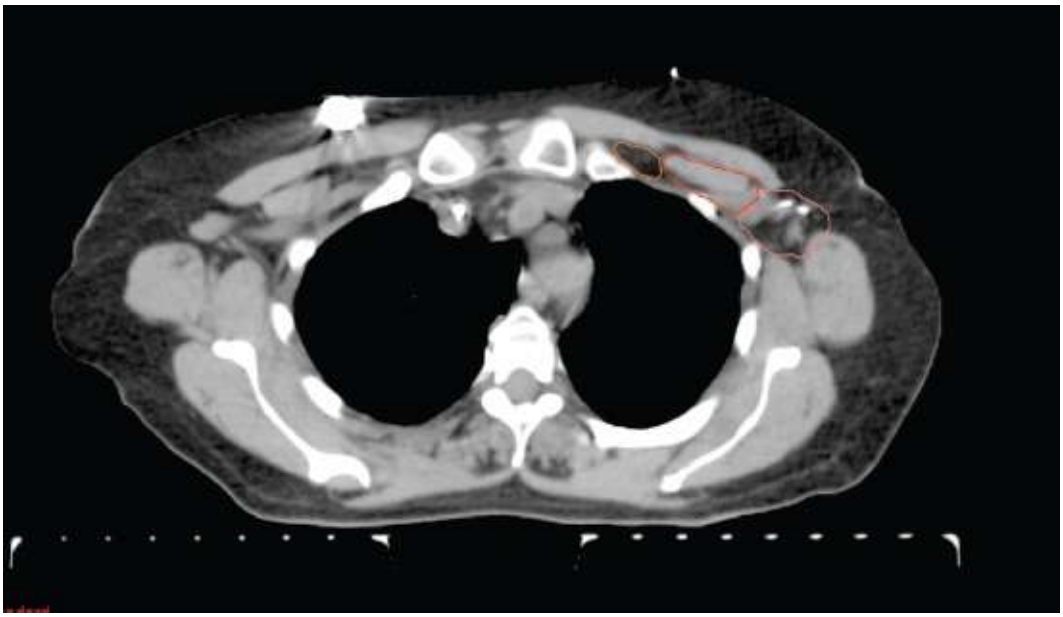

FIGURE 59.30. Nodal volumes drawn on axial planning CT scan.

Alignment of the Tangential Beam with the Chest Wall Contour

The anterior chest wall slopes downward from the midchest to the neck. To make the posterior edge of the tangential beam follow this downward-sloping contour, the collimator of the tangential beam may be rotated, or the patient may be placed on a slant so that the slope of the chest wall is parallel to the table. An alternative is to make the deep posterior edge of the tangential beam follow the chest wall contour by means of a rotating beam splitter mounted on a tray without rotation of the collimator or using multileaf collimation. In this way, the superior edge of the tangential beam remains in the true vertical and matches perfectly the vertical inferior edge of the supraclavicular field if used.

Usually up to 2 to 3 cm of underlying lung may be included in the tangential portals. The amount of lung included in the irradiated volume is greatly influenced by the portals used. Bornstein et al.[702] determined the amount of lung irradiated in 40 patients with breast cancer using CT scans for treatment

planning in the treatment position. Parameters measured from simulator films included the perpendicular distance from the posterior tangential field edge to the posterior part of the anterior chest wall at the center of the field (central lung distance [CLD]), the maximum perpendicular distance from the posterior tangential field edge to the posterior part of the anterior chest wall (maximum lung distance [MLD]), and the length of lung as measured at the posterior tangential field edge on the simulator film (Fig. 59.32). The best predictor of the percentage of ipsilateral lung volume treated by the tangential fields was the CLD. A CLD of 1.5 cm predicted that approximately 6% of the ipsilateral lung would be included in the tangential field; a CLD of 2.5 cm, approximately 16%; and a CLD of 3.5 cm, approximately 26% of the ipsilateral lung. A typical acceptable dose–volume histogram of a left-sided breast cancer treated with external beam radiation is given in Figure 59.33.

FIGURE 59.31. Immobilization material placed over breast tissue to help maintain day-to-day positioning of the breast.

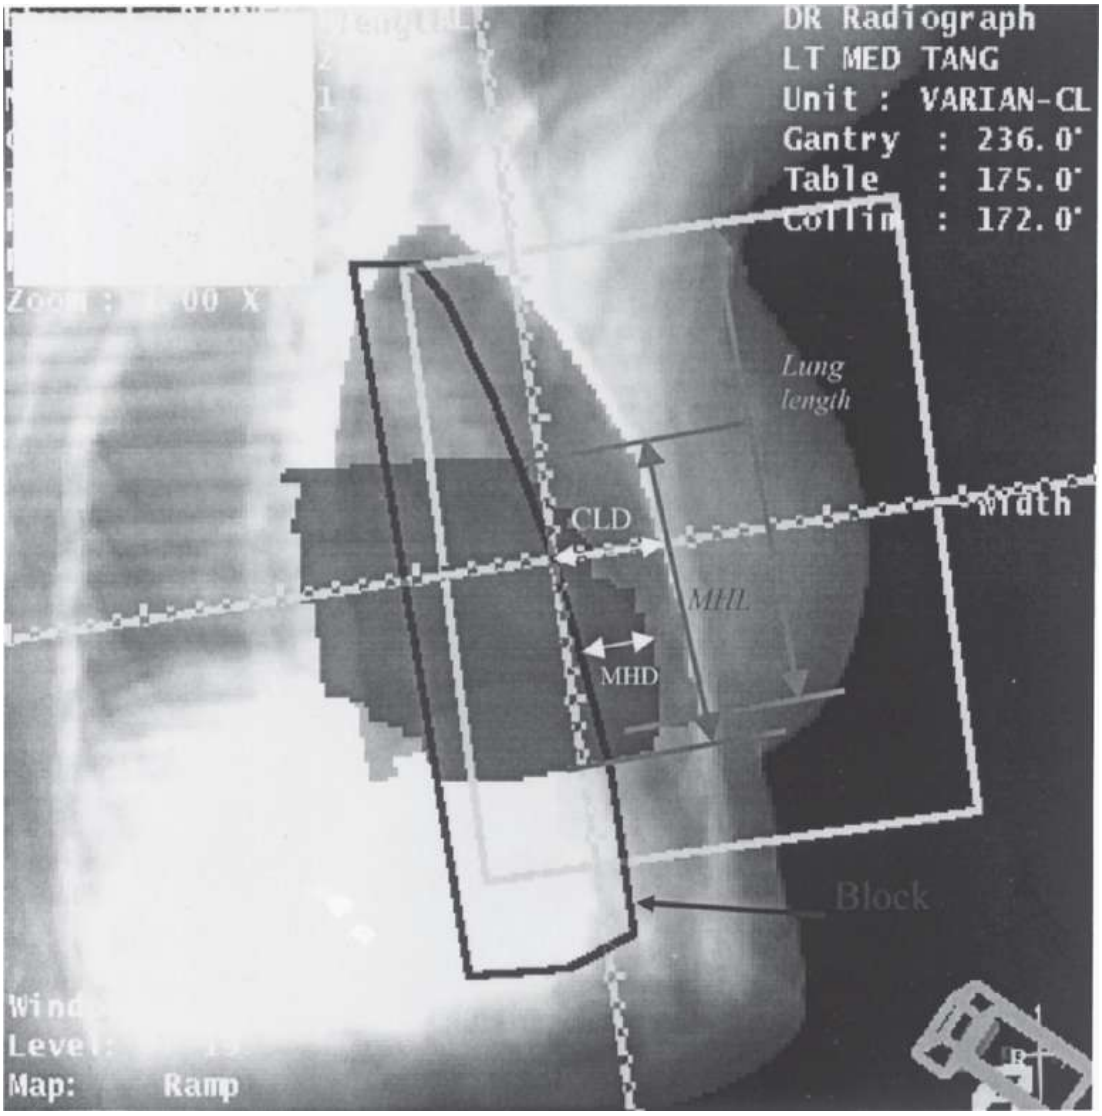

FIGURE 59.32. Measurement of the radiographic parameters using virtual simulator. The contoured heart is shown in *black*, the lung in *gray.* The central lung distance (CLD) is the lung distance in the projection of the tangential fields at the level of the central axis. Lung length is the vertical lung distance included in the radiation port. The maximal heart distance (MHD) is the width of heart in the tangent fields at its maximal level, whereas the maximal heart length (MHL) is the maximal length in tangential fields referring to the heart contour in a digitally reconstructed radiograph (DRR). (Reprinted from Kong F-M, Klein EE, Bradley JD, et al. The impact of central lung distance, maximal heart distance, and radiation technique on the volumetric dose of the lung and heart for intact breast radiation. *Int J Radiat Oncol Biol Phys* 2002;54[3]:963–971. Copyright © 2002 Elsevier. With permission.)

When the CLD is >3 cm, in treatment of the left breast, a significant volume of heart will also be irradiated. To avoid this, a medial tangential breast port (3- to 5-cm wide), somewhat similar to an internal mammary port, may be designed. The beam is angled 10 to 15 degrees laterally to conform to the angle of the

medial breast port. The dose is prescribed to the posterior border of the chest wall as determined by CT scanning.

Special attention should be paid to minimizing the volume of heart irradiated.[703] As will be discussed later in the section on cardiac sequelae, even small amounts of heart in the field can affect cardiac function. Marks et al.[704] have suggested the use of a cardiac block if the heart is in the tangential field, which can be supplemented by an electron field as shown in Figure 59.34. Use of short (10- to 15-second) treatments while the patient holds her breath is also feasible as a way of reducing cardiac radiation during left-sided breast cancer treatment.[705]

Doses of Radiation and Fractionation

Whole-Breast Dose

With whole-breast irradiation, tumor doses of approximately 45 to 50 Gy are delivered to the entire breast over 5 to 6 weeks (1.8- to 2-Gy tumor dose daily, 5 weekly fractions). Some authors have suggested daily fractions of 1.8 Gy for patients with large, pendulous breasts or when irradiation is combined with chemotherapy.[568,569,706] The authors' preference is to use 2 Gy fractions to 50 Gy because this is the scheme used in the vast majority of randomized trials using whole-breast radiation therapy following CS.

Alternative fractionation schemes have been employed and have been shown to be acceptable. These are discussed in greater detail in the hypofractionation section.

Radiation Beams

X-ray energies of 4 to 6 MV are preferred to treat the breast. Photon energies >6 MV underdose superficial tissues beneath the skin surface, but higher-energy photons may be helpful in large breasts to decrease the integral breast dose. In these patients, the high-energy photon beam may be "degraded" to bring the maximum dose to more superficial tissues. It is not necessary to apply bolus to the breast because the skin is usually not at risk for recurrence after complete excision of a T1 or T2 lesion, as is the skin of the chest wall after a mastectomy. Use of bolus results in impaired cosmetic results.[351]

Wedges or compensating filters must be used for a portion of the treatment to achieve a uniform dose distribution in the breast (5% to 8% dose variance from the chest wall to the apex). Although conventional wedges improve dose homogeneity at the central axis of the breast, significant inhomogeneity can

occur in the superior and inferior portions of the breast. Currently, with the use of MLCs and more sophisticated treatment planning techniques, optimization of homogeneity throughout the breast can be achieved through the use of a variety of techniques. Dose homogeneity in a breast plan uncompensated (without wedges), with standard wedges, and with electronic dynamic wedge technique to improve homogeneity in the superior–inferior plane is outlined in Figure 59.35. These techniques are discussed in more detail later.

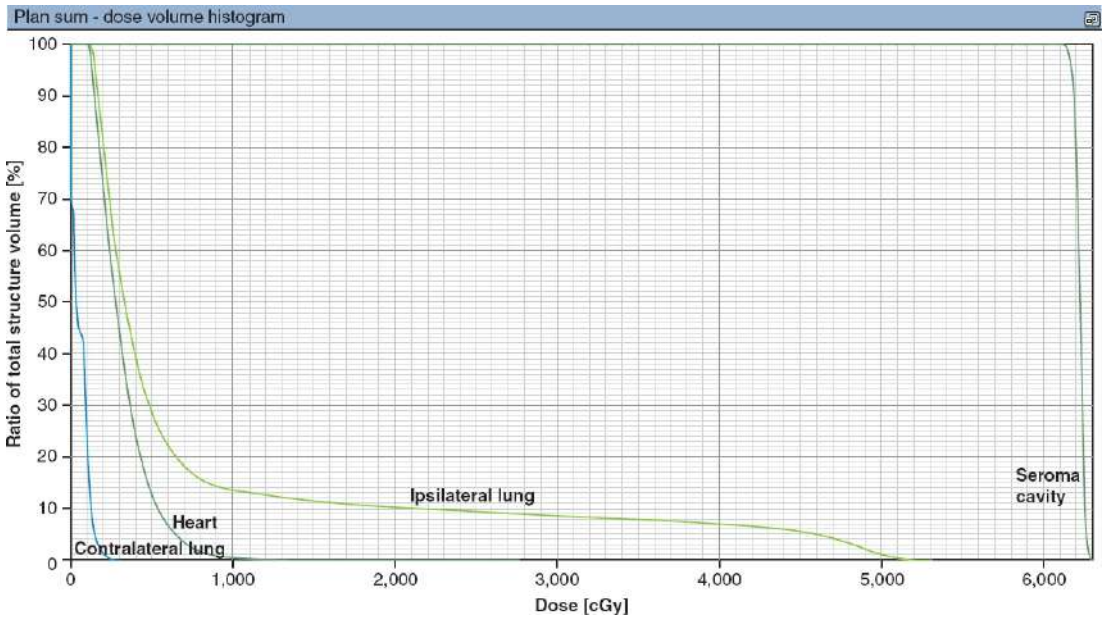

FIGURE 59.33. Dose–volume histogram of left-sided breast cancer treated with external beam radiation.

Boost to Tumor Site

The need for a boost to the tumor bed following lumpectomy and whole-breast radiation remains an area of debate. In the earlier years of breast-conserving surgery, status of the surgical margins was not always assessed. Recent retrospective data suggest that patients with known negative margins have high local control rates with no boost following whole-breast irradiation.[707] Fisher et al.[708] have all raised the question of the need for a radiation dose boost at the excision site.

Most authors report that 65% to 80% of breast recurrences after conservation surgery and irradiation occur around the primary tumor site.[107,109,194,296,375,387,679–711] These data provide a strong rationale for a tumor bed boost. Various series suggest that patients treated with higher doses have a greater probability of tumor control. Clark et al.[376] noted in 1,504 patients a

greater incidence of failures at 10 years of 17% in those to whom no boost was delivered, compared with 11% in those who received doses of 5 to 15 Gy at the primary excision site (P = .03). In other series of patients with unknown surgical margins, patients receiving a boost had roughly half the breast failure rate (6% to 11%) compared with those with no boost (9% to 20%).[113,387,403,712]

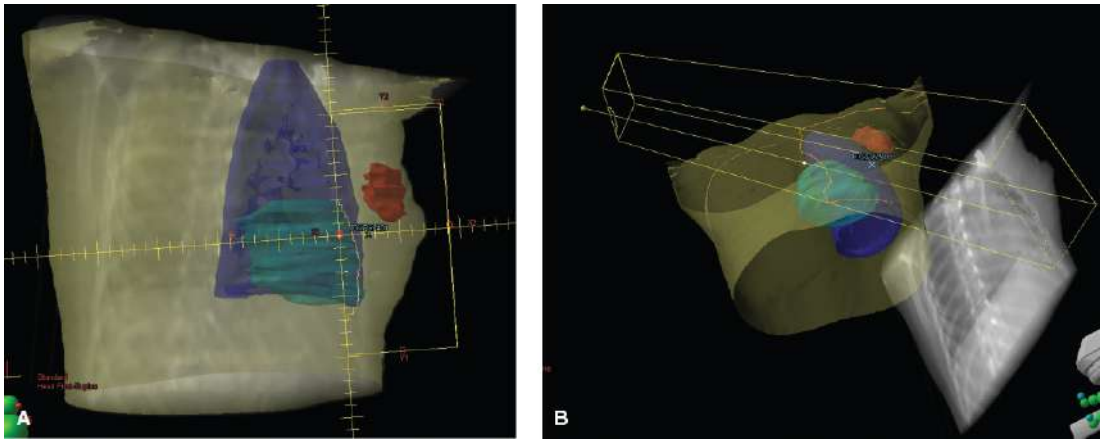

FIGURE 59.34. **A** and **B:** Left tangential breast field with heart block to shield left ventricle from radiation port. Projection of heart block on breast shields minimal amount of breast tissue. If necessary, a shadow electron field may be added to cover the portion of breast tissue shielded by heart block.

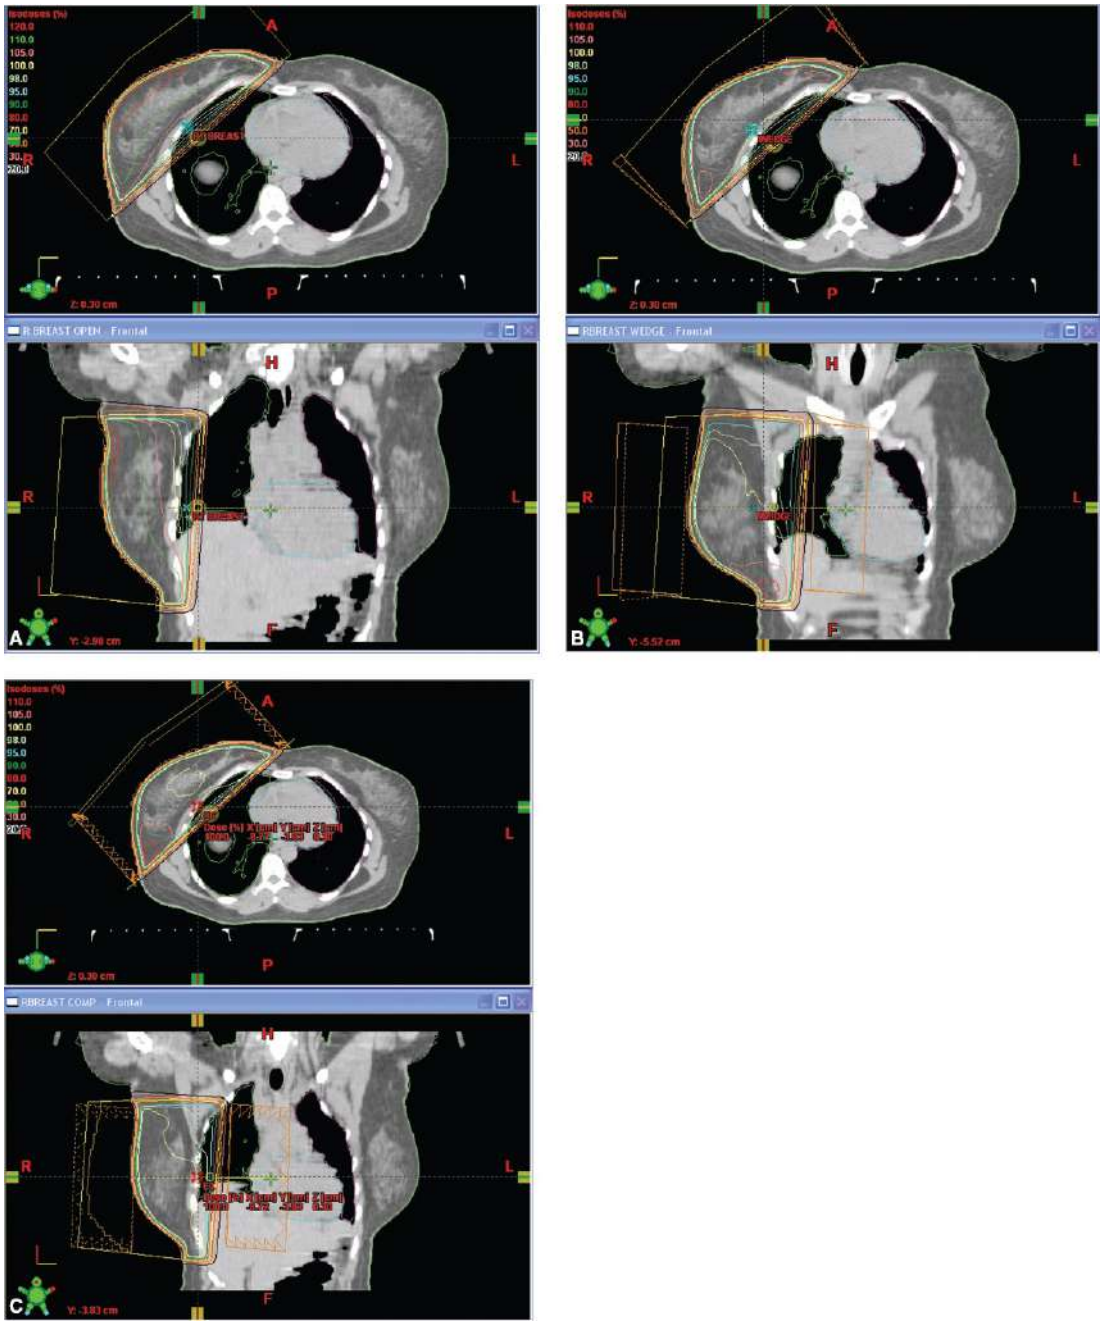

FIGURE 59.35. Isodose distributions from three breast plans. **A:** Open fields demonstrating inhomogeneity. **B:** Standard wedges demonstrating improvement in central axis, but with a hot spot in the superior inferior plane. **C:** Dynamic wedge plan showing improved homogeneity in both the central axis as well as the superior–inferior plane.

Others have advocated tailoring the need for a boost depending on margins. Arthur et al.[707] reported on 205 patients who underwent re-excision prior to radiation. All patients in this cohort had no tumor on re-excision and were treated with whole-breast irradiation to a dose of 50 Gy without a boost. Five

failures were documented, resulting in a 15-year local control rate of 92.4%. The authors advocate selective avoidance of the boost in these patients.

Randomized Data

The Lyon Breast Cancer Trial conducted a randomized study to assess the role of the boost in breast-conserving therapy in patients with stage I and II breast cancer (≤3 cm) who were treated with complete local tumor excision, axillary dissection, and 50 Gy to the breast in 20 fractions over 5 weeks and randomly assigned to receive or not a boost of 10 Gy with electrons to the tumor bed.[713] With a median follow-up of 3.3 years, at 5 years 10 of 521 women who received a boost (3.6%) and 20 of 503 (4.5%) who received no further treatment experienced a local breast relapse (P = .044). Time to local recurrence is shown in Figure 59.52, with more patients failing after 7 years in the no-boost arm.

Bartelink et al.[403] reported the results of the EORTC trial in which, after complete lumpectomy and axillary dissection, patients with stage I or II breast cancer received 50 Gy of radiation to the whole breast in 2-Gy fractions over a 5-week period and were randomly assigned to receive either no further local treatment (2,657 patients) or a boost of 16 Gy, usually given in 8 fractions by electron beam (2,661 patients). In the initial report, with a median follow-up of 5.1 years, local recurrences were observed in 182 of the 2,657 patients in the standard-treatment group and 109 of the 2,661 patients in the additional-radiation group. The 5-year actuarial rates of local recurrence were 7.3% and 4.3%, respectively (P < .001). Patients 40 years of age or younger benefited most; at 5 years, their rate of local recurrence was 19.5% with standard treatment and 10.2% with additional radiation (RR 0.46; 99% CI, 0.23 to 0.89; P = .002). In an update of this study published in 2007, with a median follow-up of 10.8 years, a significant benefit to the boost was noted in all age groups, with an overall HR of 0.59 in favor of the boost[404] (see Fig. 59.16).

If a decision is made not to use a boost, careful assessment of lumpectomy margins is critical, as discussed in the following section.

Electron Versus Interstitial Boosts

Before the widespread availability of electron beam therapy, interstitial brachytherapy or cone-down photon boost was popular. Experiences with interstitial boosts have been reported by several groups, using both high-dose rate after loading and low–dose rate temporary implants.[714–723] The reader is referred to these studies and the chapter on brachytherapy for a more extensive

discussion of techniques related to interstitial tumor bed boosts. Currently, most institutions prefer electron beam boost because of its relative ease in setup, outpatient setting, lower cost, decreased time demands on the physician, and excellent results compared with ^{192}Ir implants. The introduction of single lumen or multilumen balloon catheters, used primarily in partial breast irradiation, can also be considered an interstitial boost technique. Cosmetic results with either boost technique at various institutions are summarized in Table 59.38.

Electron Boosts

The patient is positioned with the arm toward the head to flatten the breast contour and may be rolled so the tumor bed is parallel to the table and the accelerator head can point straight down onto the target volume. An electron energy is selected that covers the target volume depth (usual range is 9 to 16 MeV electrons), based on review of the physical examination, mammogram, ultrasound, CT, or other imaging used to ascertain the location and depth of the tumor or metallic surgical clips. The 90% prescription isodose line is limited to the chest wall to decrease dose to the lung. The clinical setup for electron boost involves marking the projection of the postlumpectomy volume on the skin and adding 2 to 3 cm in all directions.

TABLE 59.38 EXCELLENT OR GOOD COSMETIC RESULTS WITH ELECTRON BEAM OR INTERSTITIAL BRACHYTHERAPY BOOST IN BREAST CONSERVATION THERAPY

Study (Reference)	Electron Beam	Brachytherapy	Follow-Up
Fourquet et al.[718]	39/52 (75%)	48/68 (71%)	3–7.3 yr
Mansfield et al.[712]	357/376 (95%)	575/629 (91%)	1 mo to 12 yr
Olivotto et al.[719]	36/36 (100%)	298/497 (60%)	5 yr
Perez et al.[720]	366/449 (81%)	97/129 (75%)	3–20 yr
Ray and Fish[721]	97/107 (91%)	12/23 (52%)	6–120 mo
Touboul et al.[715]	104/126 (82%)	91/148 (61%)	29–1 39 mo
Vicini et al.[716]	(90%)	(88%)	59.3 mo (median)

Accurate target volume definition is critical with any boost technique. Methods vary from simple and unsophisticated (as described in the previous paragraph) to complex and expensive, such as ultrasound and CT definition of the target volume.[724,725] The accuracy of using the scar to define the lumpectomy cavity has been questioned. In a study by Oh et al.,[724] 30 women

consecutively treated for 31 breast cancers had simulation CT scans performed before and after whole-breast irradiation. CT breast volumes were delineated using clinically defined borders, and excision cavity volumes were contoured based on surgical clips, the presence of a hematoma, or other surgical changes. Hypothetical electron boost plans were generated using the surgical scar with a 3-cm margin and analyzed for coverage. The volume reduction (R) in the excision cavity was inversely correlated with time elapsed since surgery (R = 0.46; $P < .01$) and body weight (R = 0.50; $P < .01$). The scar-guided hypothetical plans failed to cover the excision cavity adequately in 62% and 53.8% of cases using the pretreatment and postradiation CTs, respectively.

Surgical clips are ideal for the localization of the tumor bed.[699,725,726] The surgical clip method requires the cooperation of the surgical team. Despite the fact that it would theoretically take an infinite number of clips to define every extension of a typical tylectomy cavity, in practice six clips suffice (superficial, deep, medial, lateral, cephalad, and caudal). In a study reported by Denham et al.,[727] surgical hemoclips were left *in situ* in 27 patients to demarcate the limits of the excision cavity. The position of these clips varied widely in relation to the patient's recollection of the position of the original lump, the surgical notes, and the surgical scar. Incomplete coverage of the excision cavity in the "coronal" (*en face*) plane using an electron field could have occurred in an estimated 10 of 24 (42%) cases had surgical clips not been left *in situ*. Depth of the surgical clips below the skin surface also varied markedly; in 19 of 26 (73%) cases, the clips were observed to be ≥3 cm below the skin surface, whereas in only 5 of 26 (19.2%) cases were the clips found to be ≤2 cm deep to the surface. Had a 9-MeV electron beam been used to treat all of the patients, a major underdose of the excision cavity would have been likely in 21 of 26 (81%) evaluable cases. Coverage would have improved to 11 of the 26 (42%) had a 12-MeV beam been used.

Fein et al.[726] described a study in patients with stage I or II breast cancer treated with breast conservation therapy; surgical clips were placed in the excision cavity in 556 patients, and no clips were placed in 808. After breast irradiation with tangential fields, the primary tumor incision site was boosted with electron beam (14 to 20 Gy). The actuarial breast recurrence rates at 10 years were 11% in patients with clips and 5% in patients without clips ($P = .01$). Increased rates of breast recurrence were noted for patients with clips who had some of the following: no adjuvant treatment, unknown surgical margins, no re-excision, pathologic negative nodes, and outer location of primary tumor. The

higher incidence of breast relapse may be related to a specific surgeon who had a breast recurrence rate of 21%, compared with 6% for the remainder of the surgeons (P = .01); the status of the margins was unknown in 48% of these patients, compared with 10% overall (P = .001). The authors concluded that failure to ink the surgical specimen and inadequate assessment of margins cannot be compensated by placement of surgical clips or treatment planning using CT to delineate the surgical bed. On the other hand, this study failed to show any benefit from use of surgical clips at the tumor excision margins to design the boost volume.

Ultrasonography can provide the depth of the biopsy cavity, as well as the other dimensions, for use in designing electron portal borders and selection of electron energy.[725,728] Ultrasonography was used in 30 patients to measure breast thickness for determination of the most appropriate electron beam energy for the boost. In most patients, the depth was ≤4 cm, but in eight patients (32%), energy higher than 12 MeV should have been used to cover adequately the depth of the target volume.

CT-guided portal design should be done in the treatment position. This technique gives good definition of the depth of the chest wall and has been shown to be similar to ultrasound in delineating the lumpectomy cavity.[725,728] Delineation of the biopsy cavity becomes more difficult with increased interval from surgery. The combination of surgical clips with a treatment planning CT scan to define the lumpectomy site for electron boost is most ideal. In the absence of surgical clips, the CT scan evaluation of the biopsy cavity or postsurgical changes, in combination with clinical information including mammography findings, scar location, operative reports, and patient input, will provide accurate information regarding placement of the field and energy of the electron boost.

A recent multi-institutional study reported interobserver variabilities in the delineation of the seroma cavity and organs at risk in breast cancer patients undergoing breast-conserving surgery and whole-breast irradiation.[729] Nine radiation oncologists specializing in breast radiotherapy from eight institutions independently delineated target volumes on the same three breast cancer patients. They concluded that “variations in delineating the targets and OARs [organs at risk] for breast RT by well-experienced observers from different institutions are substantial for all relevant structures.”

To reduce these variations, guidelines for contouring the seroma cavity have been established; the Seroma Clarity Scale (SCS), developed by the British

Columbia Cancer Agency and the Cavity Visualization Score (CVS), developed by a Stanford group.[725,730] Both scoring systems are remarkably similar with the distinction being the SCS is a scale from 0 to 5, with 0 being no visible seroma cavity and 1 being a scar or shadow; the CVS is a scale from 1 to 5, with 1 being no visible seroma cavity, and omits the presence of a scar or shadow on the scale. The scores of 2 to 5 are relatively consistent between the two classification methods.

It is pertinent to note that each of these classification systems was developed without noting the presence of surgical clips or fiducial markers with respect to the seroma cavity. However, the authors, along with other investigators, have previously published that the presence of surgical clips or fiducial markers in the surgical bed improve the interphysician accuracy in the delineation of the seroma cavity in early-stage breast cancer patients.[731,732] In a study by Shaikh et al.,[733] the presence of fiducial markers improved the mean CVS score (from 2.5 to 3.5) and accuracy of physician contours compared with patients without fiducial markers. The use of titanium clips in patients treated with APBI is a focus of the United Kingdom IMPORT LOW (Intensity Modulated and Partial Organ Radiotherapy) trial.[734] An audit of the trial was performed to determine inter- and intraphysician variation for tumor bed localization for radiotherapy planning. Although no control group was used, clips were essential for the localization of the surgical cavity in 22 of 30 (73%) patients and led to modifications in radiotherapy field borders in 18 of 30 (60%) patients. A recent study by Dzhugashvili et al.[732] found that the visualization of the lumpectomy cavity was greatly improved in treatment-planning CT scans when clips were present; this was found to be even more pronounced in patients with very dense mammary glands, regardless of the physician reading the CT image.

Irradiation of Regional Lymphatics

Radiation therapy to the breast or chest wall and regional lymphatics can be technically challenging and, as previously discussed, remains one of the more variable and controversial aspects in management. A wide variety of available techniques, in combination with difficulties associated with matching fields, anatomic variability between patients, and lack of clear evidence regarding the superiority of any single approach, has resulted in a lack of consensus in regional nodal management.

Anatomic variation was highlighted in a study by Mansur et al.[735] They reported on 65 patients with breast cancer who had volumetric CT scanning in

the treatment position. The IMNs and axillary lymph node regions were delineated according to a cross-sectional nodal atlas. The variable depths of IMNs at different intercostal spaces result in dose variations if the internal mammary port is treated with a single or inadequate electron beam energy. Axillary lymph nodes frequently overlapped the head of the humerus anteriorly when the arm was angled more than 90 degrees, but did not when the arm was angled 90 degrees or less. The larger the angle, the less head of the humerus could be spared in the supraclavicular port.

Arthur et al.[736] evaluated treatment techniques for coverage of the intact breast and ipsilateral lymph node regions. Anatomic outlines were obtained from five randomly selected patients with CT scanning in treatment position (three with cancer of the left breast and two of the right). Three techniques used to treat ipsilateral breast and internal mammary and supraclavicular nodes (extended tangents, five-field, partially wide tangents) were configured and compared with a supraclavicular field matched to standard tangential fields. All of the treatment techniques covering IMNs included at least 10% more lung and heart volume than that covered by standard tangential fields. Because of increased chest wall thickness and depth of IMNs superiorly, complete coverage was not achieved with any technique if the IMN target extended superiorly into the medial supraclavicular field.

Goodman et al.[737] examined the relation between tangential, anterior, and posterior radiation fields and regional lymph nodes, including level I to III axillary and supraclavicular lymph nodes in 55 patients who underwent CT scanning in the supine position. The mean depths of the level I to III axillary nodes were 4.6, 5.1, and 3.6 cm, respectively. The mean depth of the supraclavicular nodes was 3.9 cm. With the treatment using two tangential fields, level I axillary nodes appeared in the tangential portals in nine of nine patients, either alone or with other lymph node groups. In the three-field group, level I axillary nodes were in 16 of 16 tangential fields either alone or with level II nodes (8 patients). In eight patients, level III and the supraclavicular nodes were included in the anterior field, and in the other eight, levels II and III and the supraclavicular nodes were in the anterior field. There was considerable variation in the depth of supraclavicular and axillary lymph nodes in the fields in which these nodal groups appear and in the nodal group present in the posterior axillary boost field. To be certain that nodal groups to be treated are actually treated, as well as to minimize tissue irradiated, these authors recommended that before the placement of radiation fields, the nodal groups be outlined on a CT

scan. From a practical standpoint, whether this results in better tumor control than standard techniques has not been demonstrated.

Supraclavicular Lymph Nodes

The inferior border of the supraclavicular field is matched to the tangential field usually just below the clavicular head. The medial border is 1 cm across the midline, extending upward, following the medial border of the sternocleidomastoid muscle to the thyrocricoid groove. The lateral border is a vertical line at the level of the coracoid process, just medial to the humeral head. This field is angled approximately 10 to 15 degrees laterally to spare the cervical spine (Fig. 59.36). The typical width of the supraclavicular field is 7 to 9 cm. The supraclavicular field is extended laterally to treat the full axilla, as clinically indicated. Figure 59.36 demonstrates a supraclavicular field with the supraclavicular and level I, II, and III nodes outlined. Level I as well as a portion of level II nodes will often be included in the tangential field; level III and supraclavicular nodes are covered in the supraclavicular field.

The total dose delivered to the supraclavicular field is 46 to 50.4 Gy at 1.8 to 2 Gy/day (calculated at a depth of 3 cm) in 5 fractions per week. For obese patients, an assessment of the depth of lymph nodes with ultrasound or CT treatment planning is useful to ensure adequate dose is delivered to the target. For patients in whom the target is deeper than 3 cm, higher-energy photons should be considered.

Axillary Lymph Nodes

When the axilla is treated in patients with positive nodes, or in patients with inadequate or undissected axillae, the supraclavicular field is extended laterally to cover at least two-thirds of the humeral head, as demonstrated in Figure 59.36. The dose to the midplane of the axilla from the supraclavicular field is calculated at a point approximately 2 cm inferior to the midportion of the clavicle. Depending on the dose distribution and patient's anatomy, a posterior axillary boost may be considered or anterior axillary boost, as suggested by Wang et al.,[738] may be considered.

Posterior Axillary Boost

There is considerable debate regarding the necessity of a posterior axillary boost. Bentel et al.[739] questioned its necessity in a majority of patients. In 49 patients undergoing treatment-planning CT scanning in the treatment position, the maximum depth of the supraclavicular and axillary lymph nodes was measured

on CT images, and the relation between the supraclavicular and axillary lymph node depth and patient diameter was determined. For an anterior field, the relative dose to the supraclavicular and axillary lymph nodes were calculated for a 6-MV photon beam. If an anterior 6-MV beam only is used to treat both supraclavicular and axillary lymph nodes, the dose to the axilla is within ±5% of the supraclavicular dose in 53% (26 of 49) patients and is 90% or more of the dose delivered to the supraclavicular nodes in 90% (44 of 49) of patients. These authors concluded that higher-energy beams or anterior–posterior/posterior–anterior supraclavicular axillary fields may be reasonable when the axillary and supraclavicular nodes are deep.

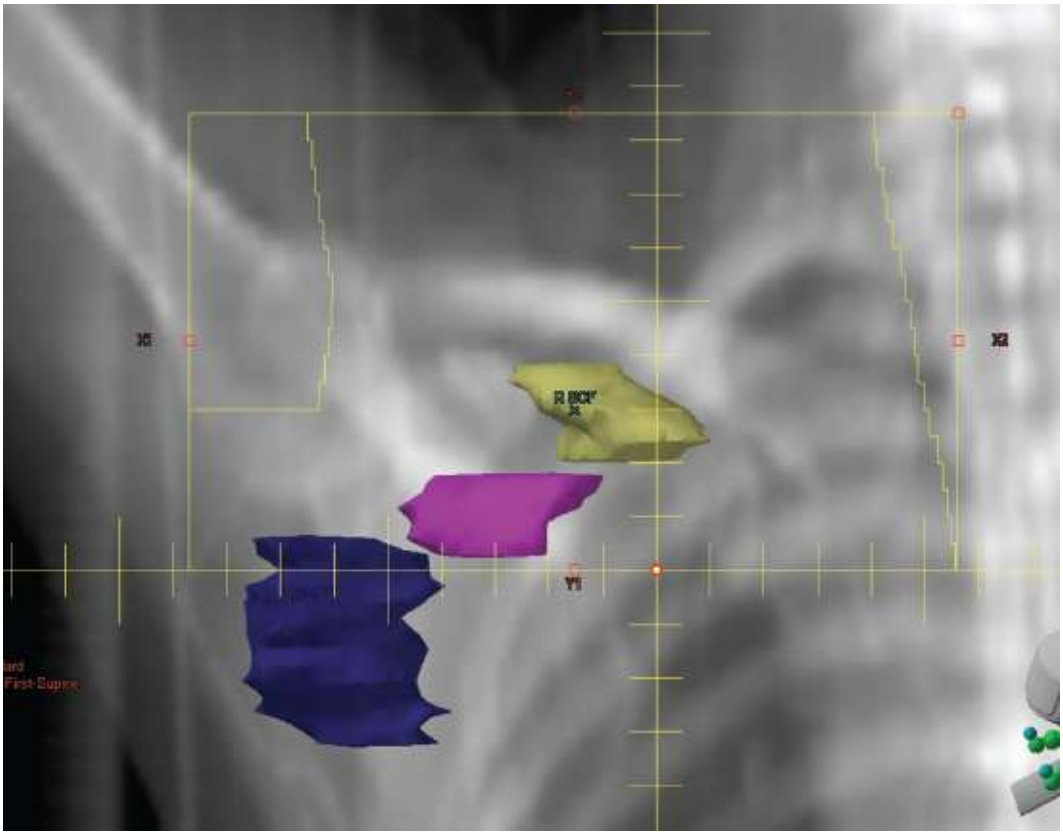

FIGURE 59.36. Supraclavicular and axillary field and field borders. Level I, II, and III nodes are demonstrated on the film. Note that level I nodes are included primarily in the tangential field in this case.

The posterior axillary boost has been employed to supplement axillary dose. At the end of the treatments to the supraclavicular field, the dose to the midplane of the axilla may be supplemented by a posterior axillary field, as shown in Figure 59.37. Alternatively, the axilla should be contoured in CT-treatment planning as variation of the depth of the axilla from the anterior-posterior skin

surface varies from patient to patient and the supplement prescription point can be adjusted accordingly. If the dose is determined to be inadequate, a posterior boost or anterior boost, as suggested by Wang et al.,[738] may be employed. When a posterior axillary boost is used, the borders are as follows: medially, the border is drawn to allow 1.5 to 2 cm of lung to show on the portal film; inferiorly, the border is at the same level as the inferior border of the supraclavicular field; laterally, the border just blocks fall-off across the posterior axillary fold; lastly, the superior border splits the clavicle and the superolateral border shields or splits the humeral head. Additional dose to the axilla midplane is usually administered to complete 46 to 50 Gy (2 Gy daily). When indicated, a boost of 10 to 15 Gy is delivered with reduced portals.

If the supraclavicular nodes are not felt to be at risk, a separate axillary field may not always be necessary to treat the axilla. In a study of 39 women with surgical clips in the axilla, Schlembach et al.[522] demonstrated that with tangential fields, placing the caudal border of the field within 2 cm of the humeral head and 2 cm deep to the chest wall–lung interface includes the majority of level I and level II lymph nodes (Fig. 59.38).

Internal Mammary Lymph Nodes

The benefit of irradiation of the IMNs is an unresolved issue because clinical failures at this site are very rare and the majority of patients at risk receive adjuvant therapy.[554,561] However, the IMNs are difficult to treat because their exact location is often uncertain and the radiation fields that include them irradiate more normal tissue.[740,741] Several techniques are used, the most common of which is a direct anterior field matched to tangential fields, which was developed for postmastectomy radiation therapy and increases the volume of heart and lung tissue in the field. With this technique, the rising contour of the intact breast interferes with dosimetry, which may affect the traditional dose prescription point at depths of 4 to 5 cm and may prevent an easy match to the breast tangential fields. Including the IMNs in the tangential fields (wide or deep tangents) may significantly increase the volume of irradiated lung and heart tissue and often includes a portion of the contralateral breast as well.

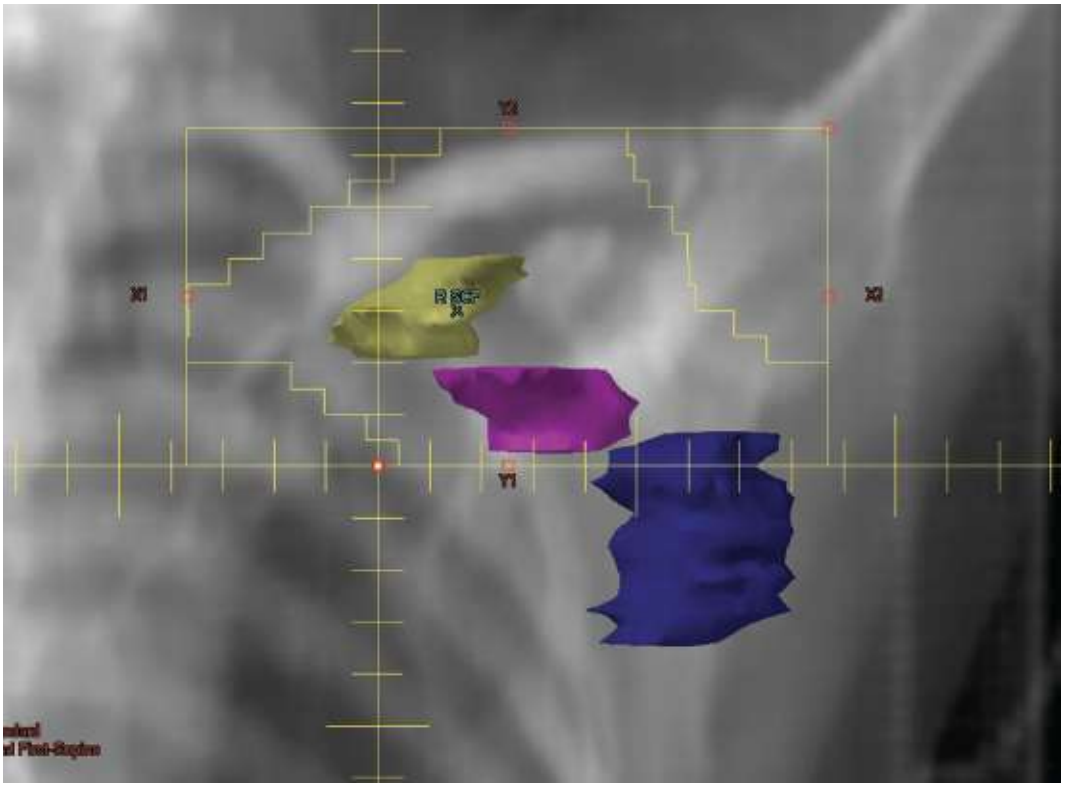

FIGURE 59.37. Posterior axillary field used to supplement the dose at midplane of the axilla. Note the small amount of lung included and the shielding of the humeral head (whenever possible).

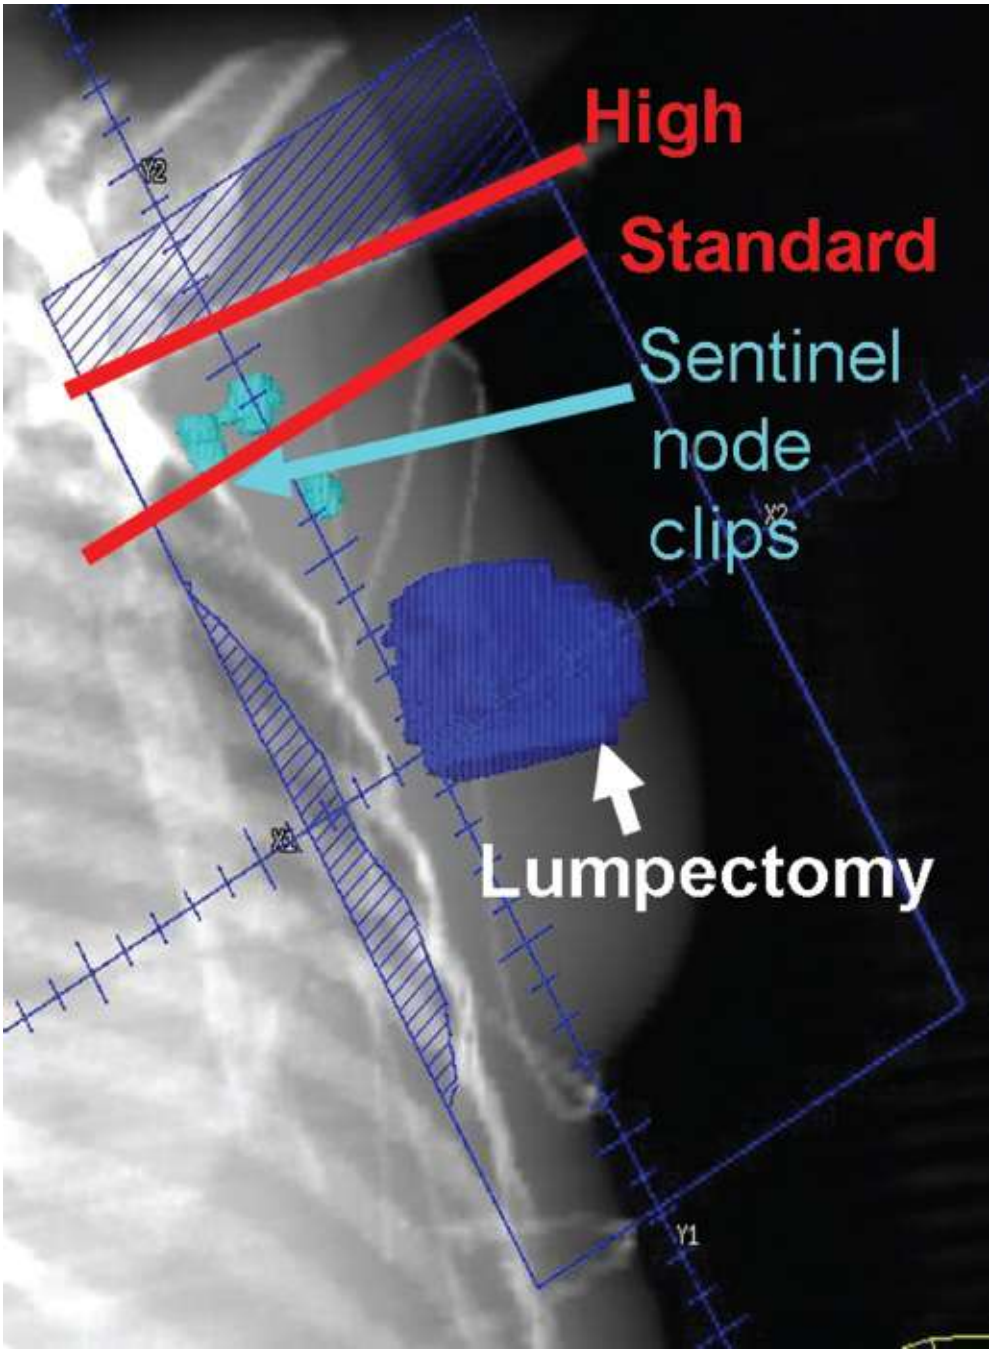

FIGURE 59.38. “High” tangential field shown coverage of level I and portion of level II nodes. With caudal edge of the field within 2 cm of the humeral head and leading edge approximately 2 cm from lung–chest wall interface, the majority of nodes in level I and level II will be covered by this technique.

The medial border of the IMN field is the midline. The lateral border is usually 5 to 6 cm lateral to the midline. The superior border abuts the inferior border of the supraclavicular field and the inferior border is at the xiphoid or higher. If only the IMNs are to be treated, the superior border of the field is at

the first intercostal space (superior border of the head of the clavicle). The field is set, as described previously, with an oblique incidence to match the medial tangential portal (Fig. 59.39).

The dose to the IMN field (45 to 50 Gy at 1.8 to 2 Gy/day) is calculated at a point 4 to 5 cm beneath the skin surface (depending on the thickness of anterior chest wall and ideally based on CT localization). Careful individualized planning and use of electrons of appropriate energy for all or a major portion of the IMN irradiation are necessary to minimize dose to the lung. To spare underlying lung, mediastinum, and spinal cord, electrons in the range of 12 to 16 MeV are preferred for a portion of the treatment, for example, 14.4 to 16.2 Gy delivered with 4- to 6-MV photons and 30.6 to 32.4 Gy with electrons.

A solution that avoids matching of fields is the use of partially wide tangential fields to treat the internal mammary chain.[742] Although IMNs can be imaged more clearly by radionuclide techniques, the nodes are typically located by identification of the internal mammary vessels, which can be seen on the CT simulator. The nodes in the first three intercostal spaces are thought to be most clinically significant. The medial border of the tangential field is moved 3 to 5 cm across the midline to cover the IMNs in the first three intercostal spaces. To minimize lung and cardiac exposure, a block is drawn in, as demonstrated in Figure 59.40, to block the inferior mediastinal nodes. The portal films should be inspected carefully to ensure that an excessive amount of lung or heart is not being irradiated. It is important to verify on the clinical setup that targeted breast tissue is not covered by the block.

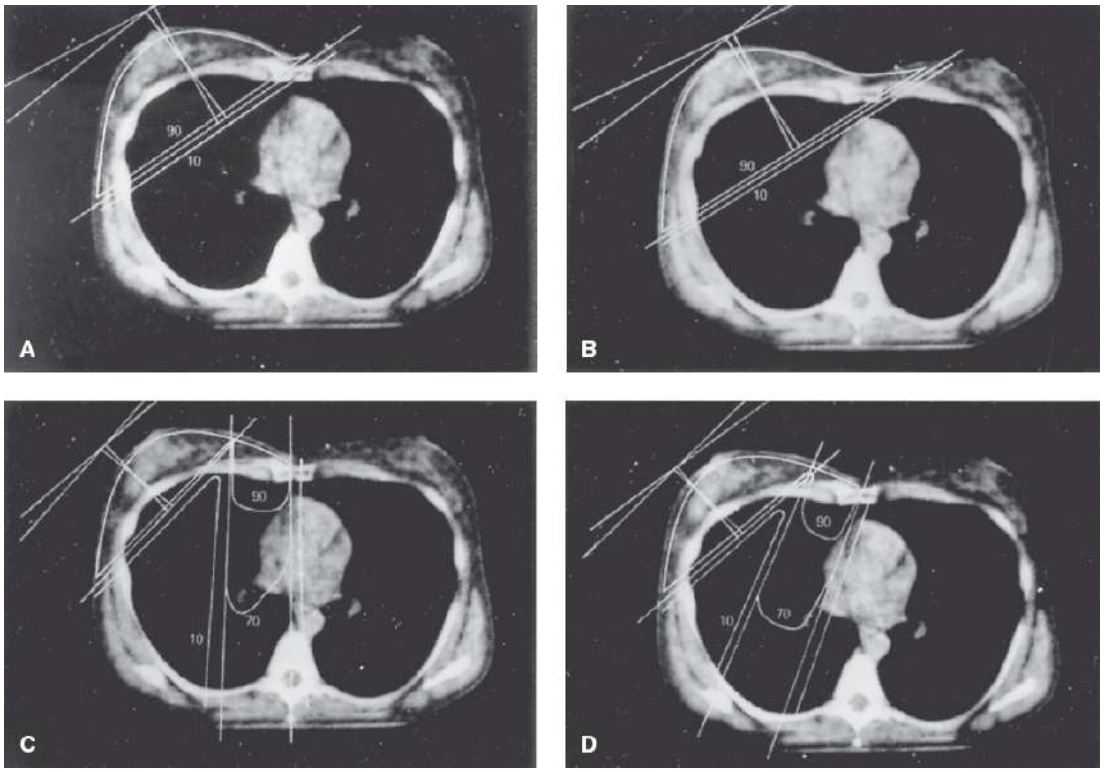

FIGURE 59.39. Irradiation of the breast: field configurations and isodose lines for 6-MV photons. **A:** "Standard tangents" technique. **B:** Deep tangents technique. **C:** *En face* internal mammary field (IMF) technique. **D:** Twenty-degree IMF technique. (Reprinted from Roberson PL, Lichter AS, Bodner A, et al. Dose to lung in primary breast irradiation. *Int J Radiat Oncol Biol Phys* 1982;9[1]:97–102. Copyright © 1982 Elsevier. With permission.)

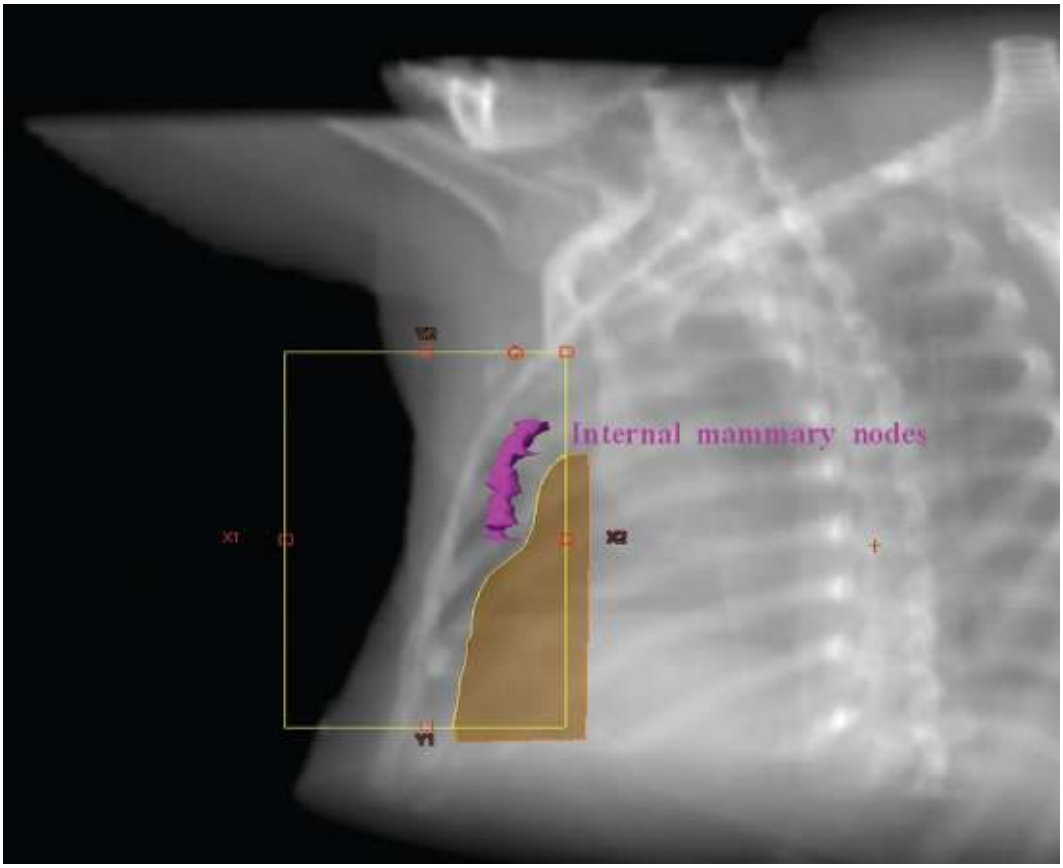

FIGURE 59.40. Partially wide tangential field covering internal mammary chain. The medial border of the tangential field is set 2 to 3 cm to the contralateral side to include the internal mammary chain. Below the fourth intercostal space, the field is blocked to minimize dose to the lungs and heart. Projection of the field on the patient's surface demonstrates adequate coverage of the involved breast–chest wall with this technique. With this technique, there may be a small amount of overlap onto the superior contralateral breast.

Severin et al.[742] compared the partially wide tangent technique (PWT) of breast and internal mammary chain irradiation with photon/electron (P/E) and standard tangent (ST) techniques in terms of dose homogeneity within the breast and the dose to critical structures such as the heart and lung in 16 patients who underwent CT simulation for left-sided breast cancers. The mean dose to the left breast with the ST, P/E, and PWT techniques was 94.7%, 98.4%, and 96.5%, respectively (P = .029). The left lung received the lowest mean dose with the ST technique (13.9%) compared with PWT (22.8%) and P/E (24.3%). The internal mammary chain volume was most consistently treated with the PWT (mean dose 99%) versus P/E (86%) and ST (38.4%) techniques, although this technique was associated with the greatest amount of contralateral breast (mean dose 5.8%) versus ST (3.2%) versus P/E (2.8%). The heart received the least dose with ST

(mean dose 6.7%) versus PWT (10.3%) and P/E (19%). Pierce et al.,[741] evaluating seven techniques of treating postmastectomy chest wall and lymphatics, also reported that the PWT technique was the most appropriate balance of target coverage and normal tissue sparing when irradiating the chest wall and internal mammary chain.

CT treatment planning is useful for irradiation of the IMN. Although the lymph nodes are most often not visible, the internal mammary vessels can be clearly seen and contoured on axial CT slices. This anatomic region can then be visualized in treatment field design and in dosimetry planning.

Matching the Tangential Fields with the Supraclavicular Field

A hot spot caused by divergence of the tangential beams into the supraclavicular field and of the supraclavicular beam into the tangential fields can exist just beneath the skin surface at the junction of the inferior border of the supraclavicular field and the superior border of the tangential fields.[743] The sharp beam of a linear accelerator and the “horns” at the edge of this beam produce a marked increase in dose beneath the match line if these divergences are not corrected. This increased dose may result in severe match line fibrosis or even rib fracture.

There are numerous methods to adjust for divergence of the beams and minimize match line fibrosis. The divergence of the tangential fields can be eliminated by angling the foot of the treatment couch away from the radiation source to direct the tangential beams inferiorly so that the superior edges of these beams line up perfectly with the inferior border of the supraclavicular field (Fig. 59.41).[744] In addition, the collimator may be rotated to geometrically eliminate overlap at this junction. Alternatively, the “hanging block” technique, in which a vertical block is affixed to the superior portion of the collimator to block off the nonvertical portion of the tangential beam, can be used (Fig. 59.42).

The inferior divergence of the supraclavicular beam can be eliminated by blocking the inferior half of the beam. This can be accomplished with a beam splitter or with multileaf collimation so that the central, nondiverging portion of the beam becomes the inferior border of this field (see Fig. 59.43B). The combination of the half-beam block supraclavicular field and the couch kick technique for the tangential field results in minimal overlap and has essentially eliminated the problem of match line fibrosis.

The Single Isocenter Technique for Matching Supraclavicular and Tangential Fields

An alternative and attractive method for minimizing field matching problems between the supraclavicular and tangential fields is to use a technique that employs a single isocenter placed at the junction of the supraclavicular and tangential fields, as demonstrated in Figure 59.44. This single isocenter serves as the isocenter for both the supraclavicular/axillary axillary field and the tangential field, such that the nondivergent central axis single isocenter results in a perfect match of the supraclavicular and tangential fields.[745] As demonstrated, when treating the supraclavicular field, the beam below the isocenter is completely blocked. The supraclavicular field is typically angled 5% to 10% away from the spinal cord. Without moving the isocenter or patient, the tangential field is treated by closing the field above the isocenter and angling the beam to treat the tangential fields. Using this technique, there is not an option for rotating the collimator. If the patient's anatomy and positioning is ideal, the tangential field is closed down to the central axis, an acceptable amount of lung is exposed (<3 cm), and no block may be required. In some cases, the tangential field needs to be opened up beyond the central axis and a block drawn to minimize lung exposure while maintaining coverage of the breast. Because much of the setup is performed on the CT simulator, it is critical when using this technique to clinically view the medial and lateral setups on the patient to ensure that the entire breast is covered, the medial border is not extending to the contralateral breast, and the blocks are not covering any of the targeted breast tissue.

Matching the Tangential Fields with the Internal Mammary Field

When an internal mammary field is required, the match between it and the

medial tangential field can be a problem if there is a significant amount of breast tissue beneath the match line. In this situation, a cold spot can exist (Fig. 59.43). The effect may be negligible if the breast tissue beneath this match line is thin (see Fig. 59.43B), or it can be avoided by including the IMNs in the tangential field, as described above (see Fig. 59.43C). Woudstra and van der Werf[746] described a technique using an oblique incidence of the internal mammary portal to match the orientation of the adjacent medial tangential portal; this results in a more homogeneous dose distribution at the junction of the two fields (Fig. 59.45). One potential advantage of the partially wide tangential field in the conservatively managed patient is that it avoids the problem of matching over breast tissue.

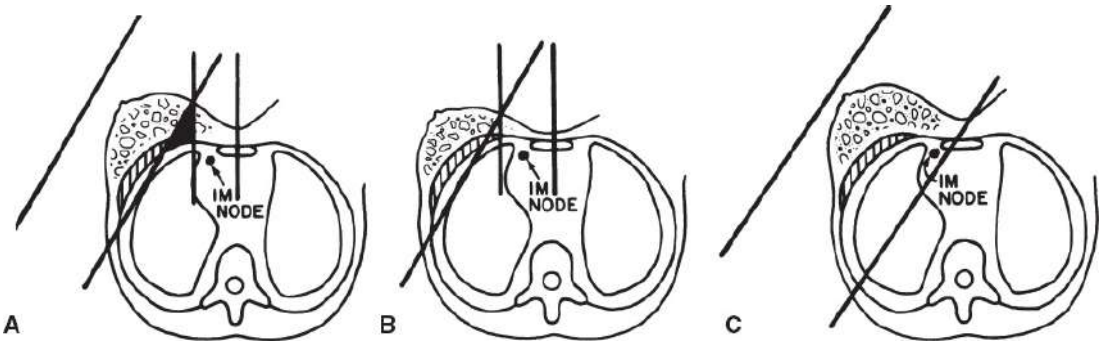

FIGURE 59.43. Diagrams showing several relationships between internal mammary and tangential fields. **A:** A significant cold region exists if the internal mammary (IM) tangential matchline overlies a large amount of breast tissue. **B:** The cold area may be negligible if the breast tissue beneath the matchline is thin. **C:** The lack of a separate IM field can result in irradiation of an excessive volume of lung, particularly in large-chested patients. (Reprinted from Bedwinek JM. Treatment of stage I and II adenocarcinoma of the breast by tumor excision and irradiation. *Int J Radiat Oncol Biol Phys* 1981;7[11]:1553–1559. FIGURE 59.44. A–C: Monoisocentric matching technique. Single isocenter is set at the match between the supraclavicular and tangential fields. The inferior portion of the beam is blocked for the supraclavicular treatment and the superior blocked for the tangential field, with no movement of the isocenter, resulting in an ideal match. Blocks are drawn as indicated to shield lung and heart. The field should be viewed clinically to ensure that the blocks drawn to shield the heart and lungs to not block target tissue on the breast–chest wall. Projection of fields onto patient surface demonstrates perfect match of the supraclavicular and tangential fields.

Irradiation Dose to the Contralateral Breast

Irradiation dose to the contralateral breast is of concern because of the potential long-term carcinogenic effect of scattered radiation. The data on risk of the contralateral breast are extensively discussed later. Although this risk appears to be minimal with modern techniques, the goal must be to expose all normal tissues not within the target volume to as low a dose as is reasonably achievable. Fraass et al.[747] measured the radiation dose to the contralateral breast in 16

women treated with 6-MV photon tangential fields and performed phantom measurements. For a typical treatment of 50 Gy, the contralateral breast received 0.5 to 2 Gy. Use of tangential fields only resulted in more dose delivered to the surface of the opposite breast, whereas use of the internal mammary field in addition to the tangential portals gave more dose deeper in the breast. Use of a 2.5-cm-thick lead shield over the contralateral breast during treatment with a medial tangential field reduced the dose to 35% of its original value. Similar shields used on the lateral tangential field had no protective effect. These authors recommended that wedges be used whenever possible on the lateral tangential fields rather than on the medial to decrease the dose to the contralateral breast.

A dosimetric study demonstrated that most of the scatter dose received by the opposite breast originates in the collimator and accessories of the accelerator, and it can be significantly decreased by increasing the distance between the source and the patient's skin.[748] Therefore, an isocentric source–skin distance technique may be desirable. The use of half-field blocks (beam splitter) or, even better, independent jaws combined with tailored beam splitters or a MLC following the contour of the chest wall of the patient is very helpful in decreasing the dose to the contralateral breast.

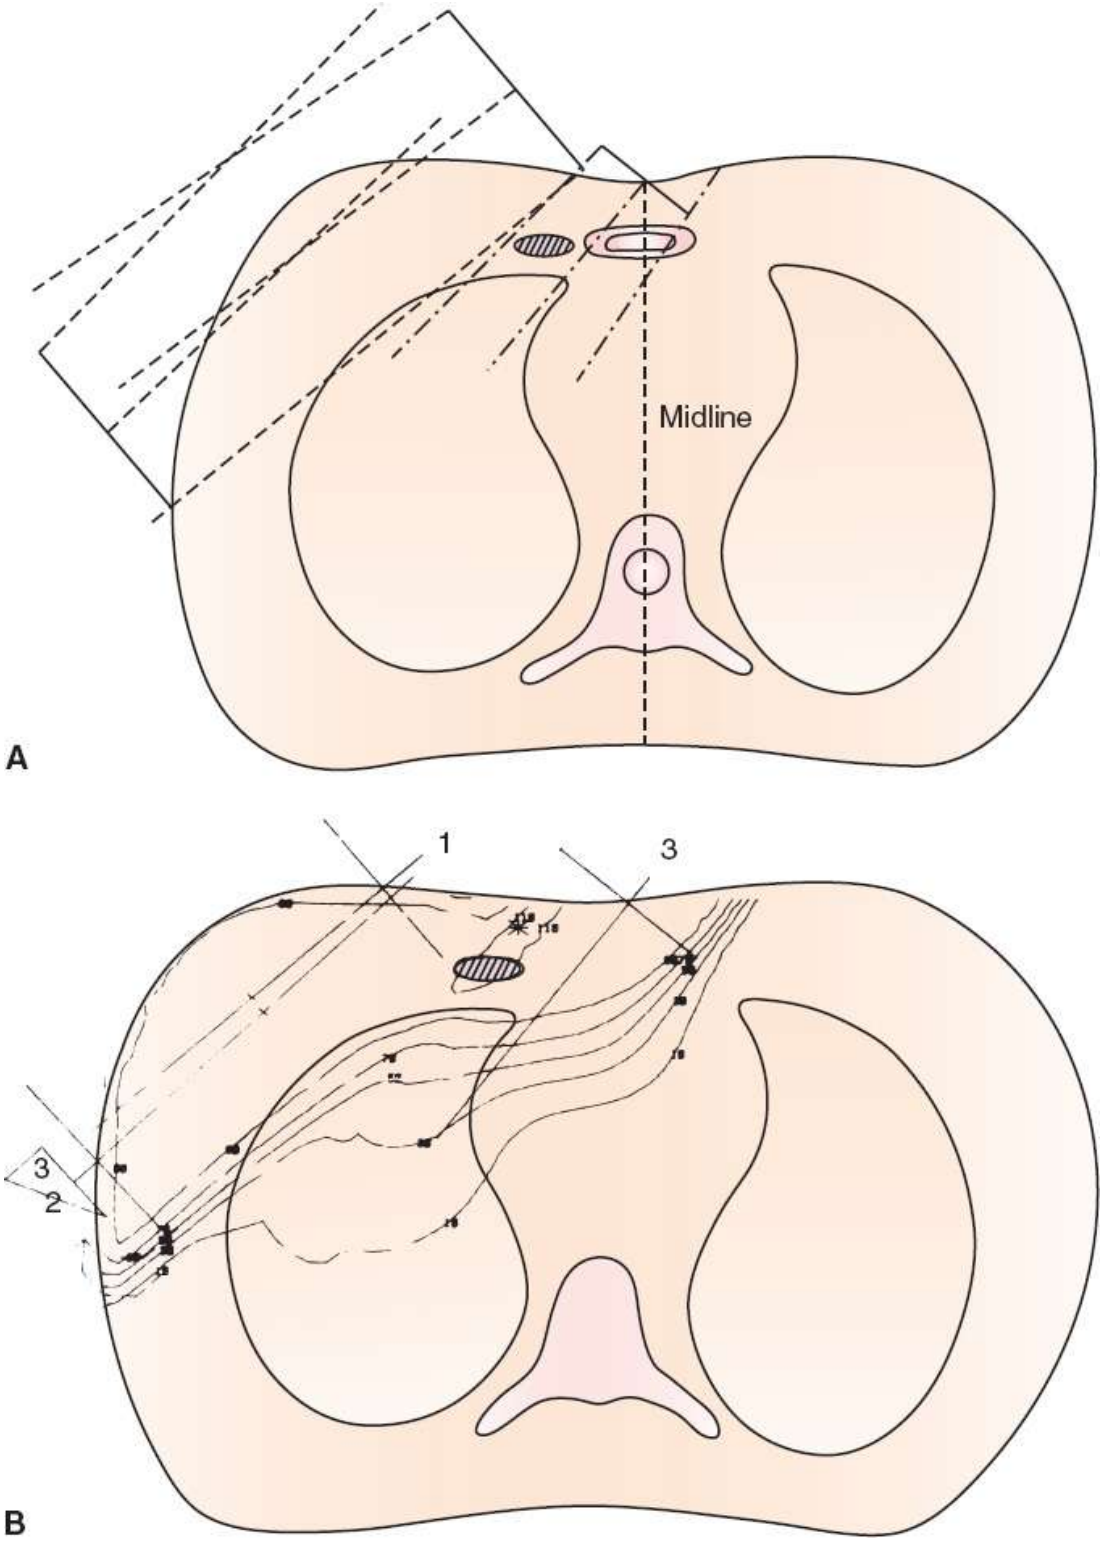

FIGURE 59.45. **A:** An obliquely incident electron beam matched to the usual tangential beams. **B:** Isodose presentation of optimal matching of an obliquely incident electron beam to the tangential beams. The target volume is enclosed by the 90% isodose line (= 40.5 Gy). Electron beam, 16 MeV; photon beam, 6 MV. (Reprinted from Woudstra E, van der Werf H. Obliquely incident electron beams for

irradiation of the internal mammary lymph nodes. *Radiother Oncol* 1987;10[3]:209–215. Copyright © 1987 Elsevier Ireland Ltd. With permission.)

Kelly et al.[749] reviewed the dose to the contralateral breast from breast irradiation with tangential fields using four different techniques. The highest dose was delivered with the use of Cerrobend half-beam blocks (regardless of the proportion of wedge used). Remaining techniques gave similar dose ranges, with the lowest total dose produced by the asymmetric jaw with no medial wedge.

The clinical significance of this inadvertent radiation dose to the opposite breast is uncertain, as various investigators have shown no increased risk of contralateral breast malignancy after treatment of the original breast by radiation therapy.[23,91,686,750]

Three-Dimensional Conformal or Intensity-Modulated Radiation Therapy

Standard opposed tangential fields with appropriate use of wedges to optimize dose homogeneity remains the most commonly employed method for delivery of whole-breast irradiation. A number of publications have explored the potential advantages of three-dimensional conformal radiation therapy (3D-CRT) or intensity-modulated radiation therapy (IMRT) to treat patients with breast cancer. Theoretically, 3D-CRT involves a reduction in the volume of normal tissues receiving a high dose, with an increase in dose to the target volume that includes the tumor and a limited amount of normal tissue. IMRT potentially can further improve the dose distribution between the target and nontarget tissue but may also increase the volume of tissue exposed to lower doses of radiation. As suggested in a review by Hall and Wuu,[637] this may increase the risk of second malignancies; the potential gains and limitations of advanced planning techniques must be weighed carefully.

Solin et al.[751] devised 38 3D treatment plans in two patients using multiple CT scan sections and compared various dose distributions. Breast inhomogeneity doses ranged from 5% to 10%. Cobalt-60 produced greater inhomogeneities than did 6-MV photons, with minimal improvement in tumor dose coverage. In contrast, 15-MV photons had significantly worse tumor coverage at shallow depths, although there was a slight reduction in hot spots. These authors were unable to identify any beam arrangement that improved dose distributions compared with standard tangential fields.

Vicini et al.[752] reported on 281 patients treated with whole-breast IMRT using

multiple static MLC segments. Figure 59.46 shows a representative dose distribution. The median volume of breast receiving 105% of the prescribed dose was 11% (range, 0% to 67.6%). The median breast volume receiving 110% of the prescribed dose was 0% (range, 0% to 39%), and the median breast volume receiving 115% of the prescribed dose was also 0%. Only three (1%) experienced grade III toxicity. The cosmetic results at 12 months (95 patients analyzable) were rated as excellent or good in 94 patients (99%). No skin telangiectasias, significant fibrosis, or persistent breast pain was noted. These authors concluded that the use of intensity modulation with a static MLC technique for tangential whole-breast RT is an efficient method for achieving a uniform and standardized dose throughout the whole breast, and widespread implementation of this technology can be achieved with minimal imposition on clinic resources and time constraints. As demonstrated in Figure 59.47, Dunst et al.[753] compared optimized IMRT with 3D-CRT and reported a small reduction in does to the heart, lungs, and contralateral breast with IMRT.

In a trial of patients undergoing breast-conserving therapy, 358 patients undergoing whole-breast irradiation were randomized to radiation to the breast with standard wedges or with IMRT. Those randomized to IMRT experienced significantly lower degrees of moist desquamation due to the improved homogeneity with the IMRT techniques employed.[754,755] In another randomized trial of IMRT in breast cancer, 306 women were randomized to standard treatment with tangential fields with wedge compensators compared with IMRT. The standard control patients were 1.7 times more likely to have a change in photographic appearance compared with those in the IMRT arm.[756] Further follow-up and additional studies relating to the technical delivery of radiation therapy in early-stage breast cancer will evolve rapidly in the next several years because of the rapid advances in technology.

It is important to recognize that the term IMRT has been used in various ways to describe breast cancer treatment. In some studies, IMRT is described as a method of 3D dose compensation without a change in the gantry angles of predesigned tangential fields. In such instances, dose distribution has been improved but the fields are not more conformal. Accordingly, low dose to other organs is not an issue. For others, IMRT attempts to improve conformality of the high-dose region by using multiple field angles that increase the volume of normal tissues that receive low radiation doses.

ACCELERATED PARTIAL BREAST IRRADIATION

The current standard of care for women with invasive breast cancer remains whole-breast irradiation following breast-conserving surgery.[757] With the notable exception of selected elderly women, omission of radiation therapy has now been proven in numerous randomized trials and meta-analysis to compromise local control and to a lesser extent breast cancer–related mortality. For some women, the 6-week course of daily radiation with its associated time and travel issues is not feasible. In response to this, a wide variety of accelerated forms of treatment have been developed and have been proven safe and effective in short-term studies.[671] These approaches include multicatheter interstitial implants placed around the excision cavity, a single balloon catheter that can be after loaded with a central radiation source (MammoSite) that is placed into the excision cavity, external beam conformal partial breast irradiation, and intraoperative single-dose irradiation. Although these techniques vary considerably, they share the common strategy of delivering the radiation to a smaller volume of breast tissue around the lumpectomy site, using fewer larger fractions delivered over a shorter time. The rationale behind this approach is that the majority of breast relapses occur at or near the lumpectomy site. Pathologic studies from mastectomy specimens have demonstrated a lower probability of subclinical microscopic disease with increasing distance from the primary tumor.[100,106,219,296,390,671,758–760] Although the early results clearly demonstrate the feasibility and acceptable toxicity of APBI, this approach has not yet been demonstrated in a randomized trial to be equivalent to whole-breast irradiation. There are several randomized ongoing trials that will attempt to answer the question of whether this approach is equivalent to whole-breast irradiation for selected patients. The current NSABP-39/RTOG-0413 is well under way with high enrollment.[761] Although the mature results of this trial will not be available

for several years, it should help to identify appropriate patients for this approach. Ongoing randomized trials investigating partial breast irradiation are summarized in Table 59.39. The NSABP-RTOG trial randomized 4,300 women with early-stage breast cancer (including DCIS) to whole-breast versus APBI. This trial allows for any one of the three techniques of partial breast irradiation, namely, interstitial brachytherapy, MammoSite, or 3D-CRT.[671] The techniques were selected based on physician or patient preference prior to randomization. Fraction size is slightly higher for the external beam conformal (3.85 Gy vs. 3.4 Gy), but all three employ twice daily radiation for a total of 10 treatments for a total dose of 38.5 or 34 Gy, respectively, over 5 days. Each of the various techniques of partial breast irradiation is discussed below.

Multicatheter Interstitial Techniques

Experience is greatest with the multicatherter interstitial technique, as it was initially developed (and is still employed) as a boost technique following whole-breast irradiation.[762–764] As demonstrated in Figure 59.48, multiple catheters are generally position at 1.0- to 1.5-cm intervals, with the total number of catheters and planes employed dependent on the size, extent, and shape of the target. With refinements in image-guided techniques, this approach is generally quite adaptable to most cavities and locations within the breast. Because of its complexity, user dependence, and logistics, however, the use of this technique has been less widely embraced, compared with the MammoSite (described below) and external beam techniques.

Kuske et al.[765] recently reported the results of RTOG-95-17, a phase I and II study employing APBI using multiplane interstitial catheters in 99 women with early-stage breast cancer. The inclusion criteria for this study included invasive nonlobular tumors ≤3 cm after lumpectomy with negative surgical margins and axillary dissection with zero to three positive axillary nodes without ECE. The patients were treated with either low-dose-rate (LDR) APBI (45 Gy in 3.5 to 5 days) or high-dose-rate (HDR) APBI (34 Gy in 10 twice-daily fractions within 5 days). Chemotherapy and/or tamoxifen was administered at the discretion of the

treating physicians. Of the 99 women, 33 were treated with LDR and 66 with HDR APBI. Of the 66 patients treated with HDR APBI, 2 (3%) had grade 3 or 4 toxicity. Of the 33 patients treated with LDR, 3 (9%) had grade 3 or 4 toxicity during brachytherapy. No patient experienced late grade 4 toxicity; the rate of grade 3 toxicity was 18% for the LDR and 4% for the HDR groups.

Vicini et al.[224] reported on 133 cases of early-stage breast cancer managed with lumpectomy and ALND followed by interstitial implant alone (99 cases using LDR and 34 with HDR implant) to the tumor bed, matched to a control group treated with external beam from the same institution. The number of catheters per patient ranged from 11 to 18 (median, 16). Tumor size ranged from 0.1 to 3 cm (median, 1.1 cm), with margins of excision >2 mm. Patients treated with LDR implants received 50 Gy over 96 hours as an inpatient procedure and those treated with HDR implants received 32 Gy in 8 fractions over 4 days (twice daily) as an outpatient procedure. The median follow-up for the external beam radiation therapy group was 5.7 years versus 3.2 years for brachytherapy. No local or regional failures have been detected and only one patient failed distantly in the HDR group. No significant adverse sequelae were noted, and cosmetic results were judged to be good or excellent in 98% of patients. No statistically significant differences were noted in the 5-year actuarial rates of ipsilateral breast (3% vs. 0%; P = .17) or locoregional failure (4% vs. 0%; P = .37) between patients treated with external beam radiation therapy and those treated with brachytherapy alone. In a recent update of this study with 12 years follow-up, there was no difference in the rate of local recurrence (3.8% vs. 5.0%; P = .40), regional recurrence (0% vs. 1.1%; P = .15), disease-free survival (87% vs. 91%; P = .30), cause-specific survival (93% vs. 95%; P = .28), or overall survival (78% vs. 71%; P = .06) between the WBI and APBI groups, respectively.[766]

Arthur et al.[767] used HDR brachytherapy (34 Gy in 10 fractions twice a day over 5 days) in 26 patients or LDR (45 Gy given at a dose rate of 0.45 to 0.50 Gy/hour) in 18 patients. After a median follow-up of 31 months (range, 11 to 61 months), all patients remain locally controlled. Among patients receiving doxorubicin after brachytherapy, at a median follow-up of 12 months, recall reactions involving the skin overlying the implant site were observed in 42% of patients (6 of 14). On multivariate analysis, a recall reaction (P = .0007) and LDR brachytherapy (P = .04) were significant predictors of fibrosis and telangiectasis.

Wazer et al.[768] reported the results of APBI using high-dose-rate interstitial

brachytherapy in a phase I or II single multi-institutional study in 33 women with early-stage breast cancer. Eligible patients included those with T1, T2, N0, N1 (≤3 nodes positive), and M0 tumors of nonlobular histologic features with negative surgical margins, no extracapsular lymph node extension, and a negative postexcision mammogram. High-activity ^{192}Ir (3 to 10 Ci) was used to deliver 3.4 Gy per fraction, 2 fractions per day, for 5 consecutive days, to a total dose of 34 Gy to the target volume. The mean tumor size was 1.3 cm, and 55% had an extensive intraductal component. Three patients had positive axillary nodes. The RTOG late radiation morbidity scoring scheme was applied. Clinically evident fat necrosis occurred in eight patients at a median of 7.5 months after HDR brachytherapy completion. The only variables significantly associated with grade 3 or 4 toxicity were the number of source dwell positions and the volume of tissue encompassed by the prescription isodose shell. The global cosmetic scores after a minimum of 18 months' follow-up were 0 cases with poor, 4 with fair, 5 with good, and 24 with excellent scores. One case of IBTR was diagnosed.

MAMMOSITE

MammoSite as an alternative method of delivering APBI has been widely embraced because of its simplicity and less dependence on user experience.[350,671,769,770] The technique employs a single balloon catheter introduced into the lumpectomy site either at the time of lumpectomy or percutaneously after the procedure. In the current NSABP/RTOG clinical trial, patients cannot be randomized until after the lumpectomy procedure when final margins and nodal status are known, and hence, the device must be placed after the lumpectomy procedure. As shown in Figure 59.48, the catheter is located centrally within a distal balloon, which is inflated once the catheter is placed in the lumpectomy cavity. Adequacy of placement requires symmetry of the balloon, conformance of the balloon surface to the lumpectomy cavity, and a minimum distance between the surface of the balloon and skin of >5 mm (ideally >7 mm). Treatment is delivered via a HDR remote afterloading system to a circumferential 1-cm distance from the balloon surface. This technique is one of the three methods employed in the ongoing randomized trial, with a dose prescription of 3.4 Gy delivered at 1 cm twice daily to a total dose of 34 Gy over 5 days.

Although early experiences with this technique are promising, the results of

the ongoing randomized trial will help to identify suitable patients. The most extensive experience with this technique has been reported by the American Society of Breast Surgeons MammoSite Registry Trial, which included 1,419 patients treated in 87 institutions.[350,771,772] This was a nonrandomized single-arm registration trial in which data were collected prospectively on clinical use of the MammoSite breast brachytherapy catheter for delivering breast irradiation. They reported on 1,237 patients (87% of enrolled patients) who received APBI (34 Gy to 1.0 cm in 10 fractions; 91% of the patients with invasive carcinoma (977 of 1,068 patients) had negative lymph node status, and 99% of all patients had negative margins. The median patient age was 65 years. Five hundred fifty-four catheters (45%) were placed with an open cavity at the time of lumpectomy, and 683 catheters (55%) were placed after lumpectomy. Skin spacing ranged from 2 to 75 mm (median, 10 mm). At 5 years, 37 cases (2.6%) developed an IBTR, for a 5-year actuarial rate of 3.80% (3.86% for IBC and 3.39% for DCIS). Negative ER status (P = .0011) was the only clinical, pathologic, or treatment-related variable associated with IBTR for patients with IBC and young age (<50 years; P = .0096) and positive margin status (P = .0126) in those with DCIS. The percentage of breasts with good or excellent cosmetic results at 60 months (n = 371) was 90.6%.The authors concluded that treatment efficacy, cosmesis, and toxicity 5 years after treatment with APBI using the MammoSite device are good and similar to those reported with other forms of APBI with similar follow-up.

External Beam Conformal Radiation

Although external beam conformal radiation has been developed only recently, it is the one that is most widely employed in the ongoing randomized trial.[214,773,774] Recent data suggest that over 70% of patients in the randomized trial are opting for the 3D-CRT. Its widespread acceptance is likely because it is totally noninvasive and delivers a homogenous dose distribution. Although the ongoing trial mandates supine position, some authors have advocated prone accelerated breast irradiation.[214,773,774]

Three-dimensional-CRT, as shown in Figure 59.49, generally employs multiple conformal fields, although plans as simple as two opposing small conformal fields may be adequate. Challenges with this technique include daily positioning of the target, movement with breathing, and delivery of higher doses to surrounding normal breast tissue than with the brachytherapy. Nonetheless, this approach has been widely embraced and has been shown to be reproducible.

In the phase I and II RTOG-0319 trial of external beam conformal radiation, Vicini et al.[774] examined the use of 3D-CRT to deliver APBI. Reproducibility, as measured by technical feasibility, was the primary endpoint. This study was designed such that if fewer than 5 cases in the first 42 patients evaluable were scored as unacceptable, the treatment would be considered reproducible. Patients received 38.5 Gy in 3.85 Gy per fraction delivered twice daily. The clinical target volume included the lumpectomy cavity plus a 10- to 15-mm margin bounded by 5 mm within the skin surface and the lung–chest wall interface. The planning target volume included the clinical target volume plus a 10-mm margin. A total of 58 patients were enrolled on this study over an 8-month period, 5 of whom were ineligible or did not receive protocol treatment. There were 4 cases with major variations and a total of 32 cases with minor variations in treatment plans. Based on this analysis, the authors concluded that APBI using 3D conformal external beam radiation therapy was technically feasible and reproducible in a multi-institutional trial using exceptionally strict dosimetric criteria. An update of this study found that the ipsilateral breast failure rate was 6%, in-field failure rate was 2%, and contralateral breast failure rate was 0%.[775] Only two (4%) grade 3 toxicities were observed. There have, however, been some reports of increased toxicity with external beam radiation using the fractionation schedule of 3.85 Gy per fraction, twice daily for 10 fractions.[776,777] Longer follow-up and detailed outcomes from the NSABP/RTOG randomized trial will help to shed further light on this issue.

Olivotto et al. published a report of the RAPID (Randomized Trial of Accelerated Partial Breast Irradiation Using Three-Dimensional Conformal External Beam Radiation Therapy) trial where 2,135 women age >40 years with invasive or *in situ* breast cancer ≤3 cm were randomly assigned after breast-conserving surgery to 3D-CRT APBI (38.5 Gy in 10 fractions twice daily) or WBI (42.5 Gy in 16 or 50 Gy in 25 daily fractions ± boost irradiation)[778]. With a secondary endpoint of cosmesis, they reported adverse cosmesis at 3 years was increased among those treated with APBI compared with WBI as assessed by trained nurses (29% vs. 17%; $P < .001$), by patients (26% vs. 18%; $P = .0022$), and by physicians reviewing digital photographs (35% vs. 17%; $P < .001$). They found that there was an adverse effect of the fractionation from APBI and boost irradiation from WBI on cosmesis.

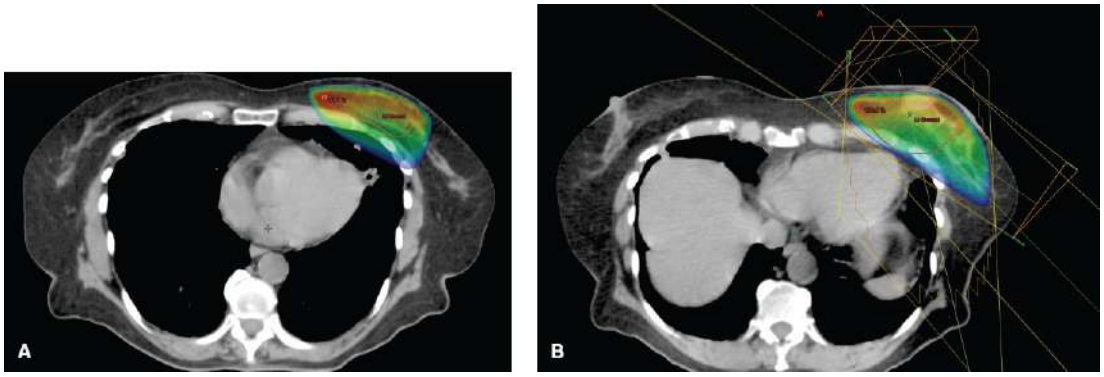

FIGURE 59.49. A and **B:** Partial breast irradiation demonstrating the external beam conformal radiation technique.

Again, the NSABP/RTOG randomized trial will help to further define acceptability and reproducibility of 3D conformal external beam radiation as an option for women with early-stage invasive breast cancer.

Intraoperative Accelerated Partial Breast Irradiation

APBI using intraoperative therapy has been most widely employed outside of the United States.[779,780] The radiation is delivered in a single intraoperative dose to the lumpectomy site at the time of surgery, using intraoperative electrons or intraoperative photons (Fig. 59.50). Vaidya et al.[781] describe a preliminary report using a 50 kV spherical source to deliver a dose of 20 Gy at a depth of 1 cm, with acceptable toxicity. This group recently published the results of a phase III study that randomized 3,451 women to either targeted intraoperative radiation therapy (IORT) or whole-breast irradiation.[782] The 5-year risks for local recurrence in the conserved breast for IORT versus EBRT were 3·3% (95% CI 2.1–5.1) versus 1·3% (0.7–2.5; P = 0·042).Veronesi et al.[779] developed an IORT technique for a breast quadrant after the removal of the primary carcinoma using a mobile linear accelerator with a robotic arm to deliver electron beams with energies from 3 to 9 MeV. Through a Perspex applicator, the radiation is delivered directly to the mammary gland, and to spare the skin from radiation, the skin margins are stretched out of the radiation field (Fig. 59.51A and B). To protect the thoracic wall, an aluminum–lead disc is placed between the gland and the pectoralis muscle (see Fig. 59.50C). Different dose levels were tested from 10 to 21 Gy without important side effects. They estimated that a single fraction of 21 Gy is equivalent to 60 Gy delivered in 30 fractions at 2 Gy per fraction. Seventeen patients received an IORT dose of 10 to 15 Gy as a boost to external radiation therapy, whereas 86 patients received 17, 19, or 21 Gy intraoperatively as their whole treatment. The follow-up time of the 101 patients ranged from 1

to 17 months (mean, 8 months). The IORT treatment was very well accepted by all patients. The authors believe that single-dose IORT after breast resection for small mammary carcinomas may be an excellent alternative to the traditional postoperative radiation therapy. Based on these data, the European Institute of Oncology has conducted a randomized trial comparing this option to whole-breast irradiation for selected patients, and results of this trial are eagerly awaited.[780]

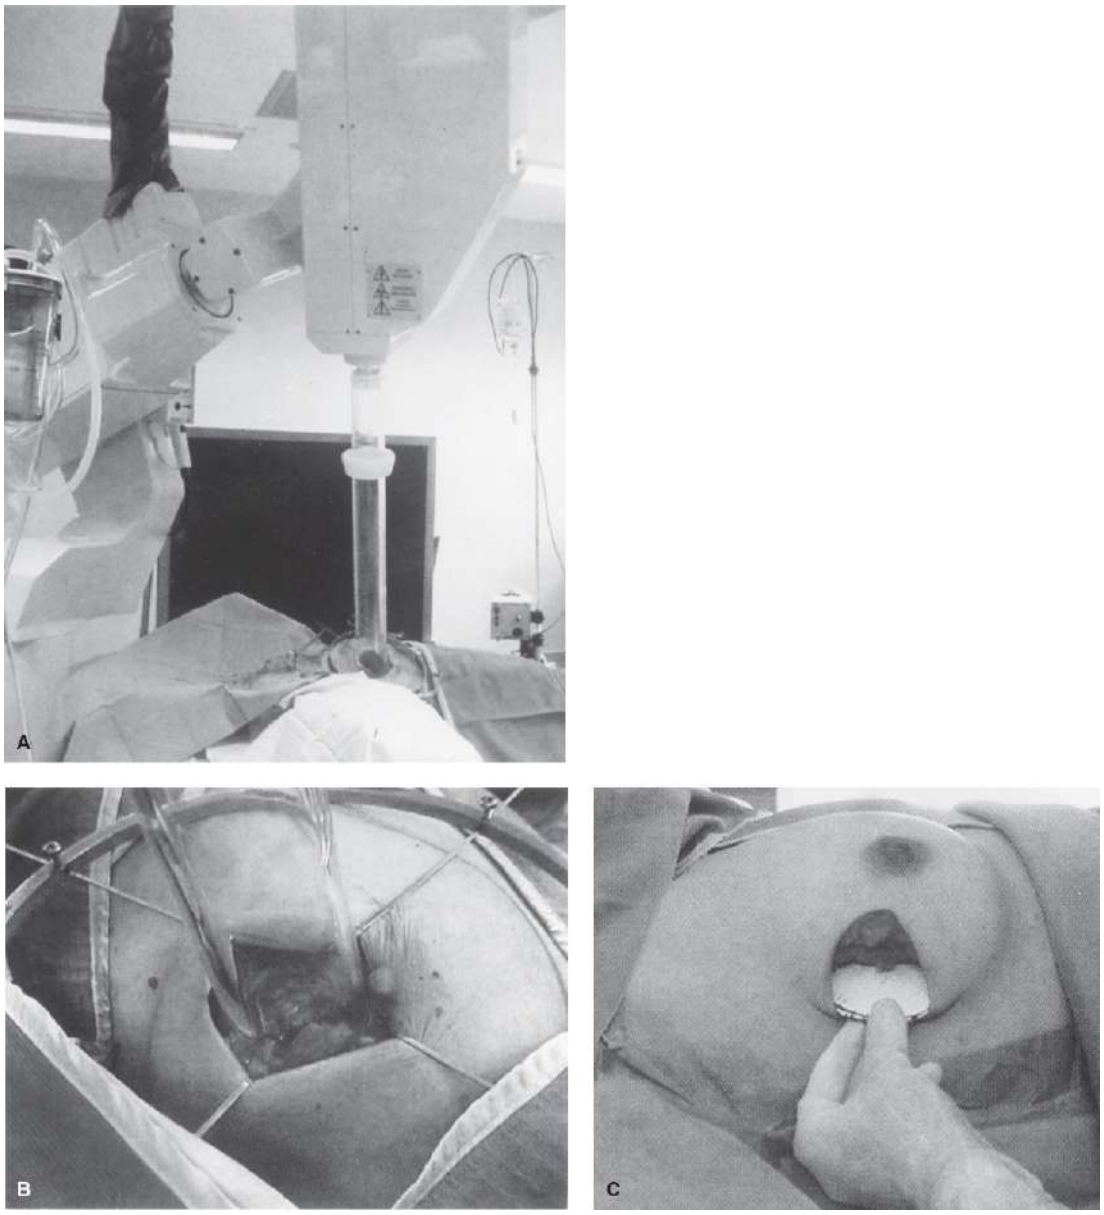

FIGURE 59.50. **A:** Linear electron beam accelerator in operating room during intraoperative radiation therapy. **B:** Proper placement of applicator in the breast. **C:** Before intraoperative radiation therapy delivery, an aluminum-lead disc (4 mm Al and 5 mm Pb thick) is placed between the deep face of residual breast and pectoralis

muscle. (Reprinted from Veronesi U, Oreechia R, Luini A, et al. A preliminary report on intraoperative radiotherapy (IORT) in limited-stage breast cancers that are conservatively treated. *Eur J Cancer* 2001;37[17]:2178–2183. Copyright © 2001 Elsevier. With permission.)

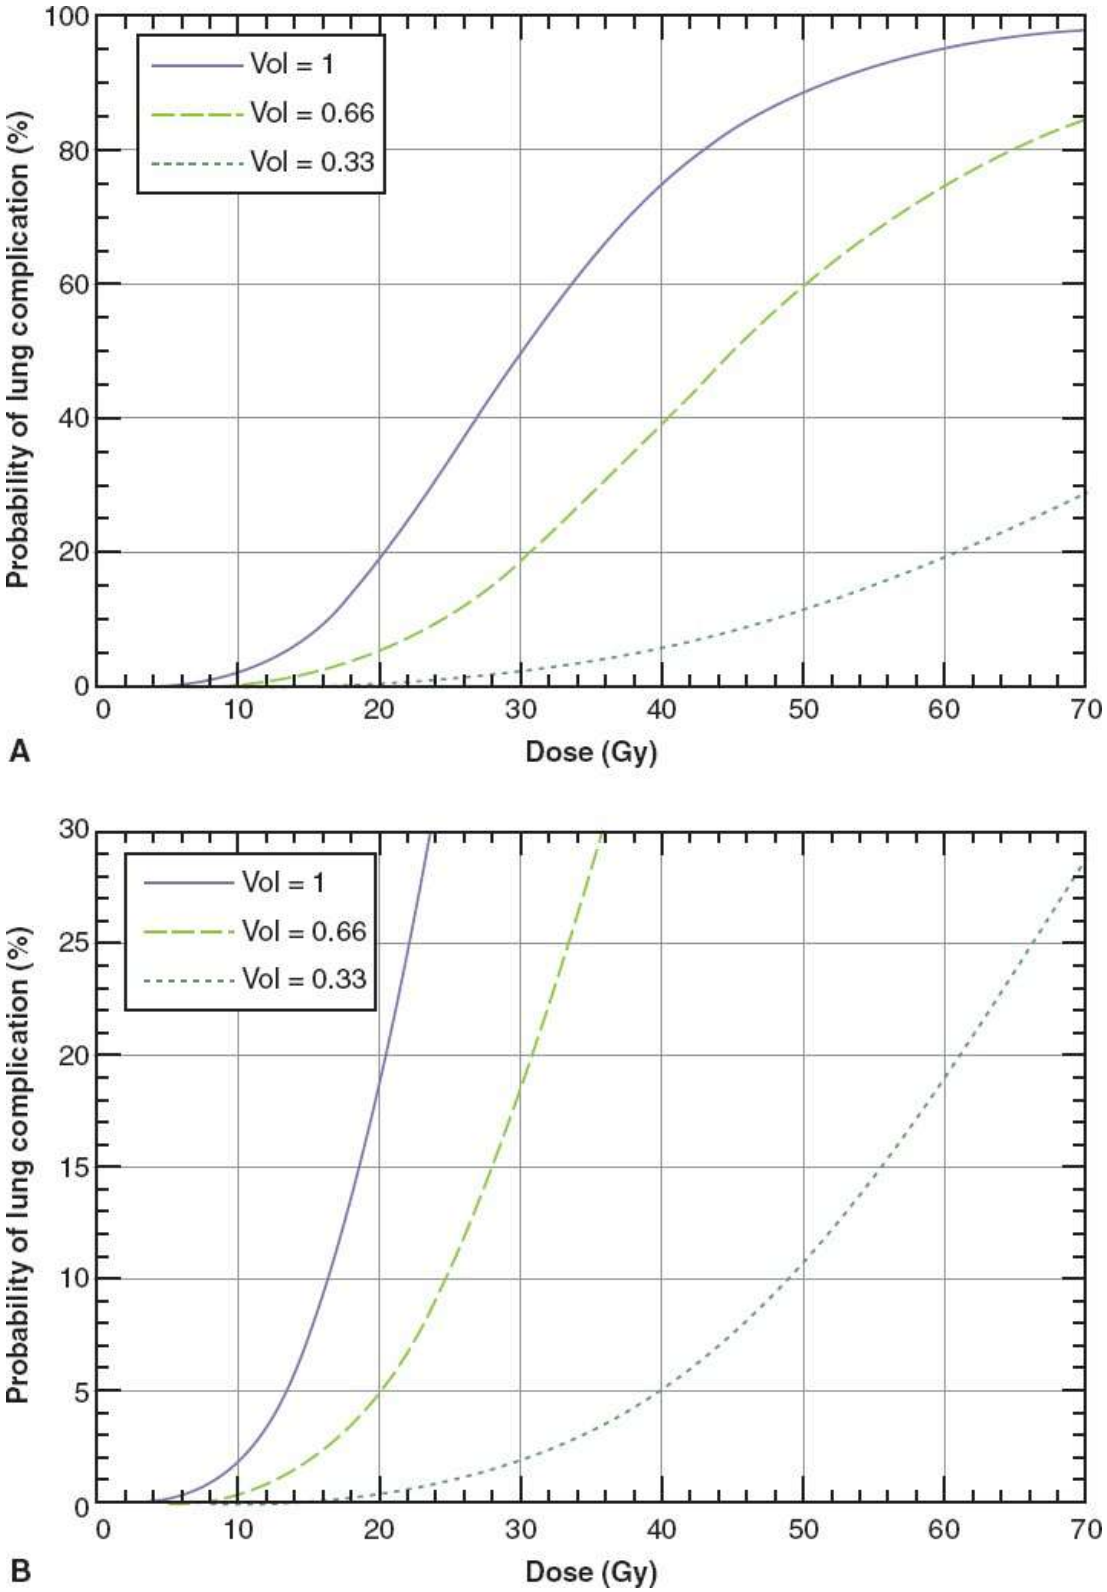

FIGURE 59.51. Probability of radiation pneumonitis versus dose. The relative lung volumes are 100%, 66%, and 33%. The curve parameters are D_{50} = 30 Gy, y = 1.01, s = 0.01. The curve covers the probability range up to 100% **(A)**, and up to 30% (i.e., within the interval of the clinical data) **(B)**. (Reprinted from Gagliardi G, Bjohle J, Lax I,

et al. Radiation pneumonitis after breast cancer irradiation: analysis of the complication probability using the relative seriality model. *Int J Radiat Oncol Biol Phys* 2000;46[2]:373–381. Copyright © 2000 Elsevier. With permission.)

In 2009, a task force of experts in the field of breast cancer developed a consensus statement on behalf of ASTRO on the use of APBI. These guidelines have since been updated in 2016. They reported their recommendations on the suitability of patients receiving APBI outside the context of a clinical trial and divided patients into three categories: suitable, cautionary, and unsuitable (Table 59.40).[783–785] In general, patients ≥50 years, with node-negative, invasive ductal or DCIS tumors ≤2 cm and with negative margins, ER positivity, and no lymphovascular space involvement were deemed suitable for use of APBI off trial. The task force hoped their recommendations would provide guidance regarding the use of APBI outside a clinical trial and serve as a framework to promote additional research into the optimal role of APBI in the treatment of breast cancer.

COSMETIC OUTCOMES AND SEQUELAE

Cosmesis

Surgical, radiotherapeutic, chemotherapeutic, and host factors may influence cosmetic outcome.[351] Surgical factors to be considered include extent of surgical resection, re-excision, orientation and length of the scar, closure or not of the tylectomy cavity, separate or continuous axilla–tylectomy scars, extent of the axillary dissection, and whether an ellipse of skin over the tumor was removed. Radiation therapy factors are doses to the whole breast with tangential portals, homogeneity of dose throughout the breast (use of wedge or compensating filters), use of bolus, fractionation, overall duration of therapy including breaks, type and dose of boost, beam energy, and volume treated (whether peripheral lymphatic irradiation is administered). Chemotherapy issues include cytotoxic agents used, timing and sequence relative to radiation therapy, and doses and combinations of drugs. Host factors include size and shape of the breast, age, race, compliance with care and hygiene, concurrent medical illnesses (e.g., hypertension, diabetes, CVD), and intrinsic sensitivity to radiation.

TABLE 59.40 ASTRO CONSENSUS GUIDELINES FOR SUITABILITY OF PATIENTS TO RECEIVE ACCELERATED PARTIAL BREAST IRRADIATION (APBI) OFF TRIAL

Patient Group	Risk Factor	Factor
Suitability	Age	≥50 y
	Margins	Negative by at least 2 mm
	T stage	Tis or T1
	DCIS	If all of the below: Screen-detected • Low to intermediate nuclear grade • Size ≤2.5 cm • Resected with margins negative at ≥3 mm
Cautionary	Age	• 40–49 y if all other criteria for “suitable” are met • ≥50 y if patient has at least 1 of the pathologic factors below and does not have any “unsuitable” factors
		• *Pathologic factors:* • Size 2.1–3.0 cm[a] • T2 • Close margins (<2 mm) • Limited/focal LVSI • ER(-) • Clinically unifocal with total size 2.1-3.0 cm[b] • Invasive lobular histology • Pure DCIS ≤3 cm if criteria for “suitable” not fully met • EIC ≤3 cm
	Margins	Close (<2 mm)
	DCIS	≤3 cm and does not meet criteria for “suitable”
Unsuitable	Age	• <40 y • 40–49 y and do not meet the criteria for cautionary
	Margins	Positive
	DCIS	>3 cm

APBI, accelertated partial breast irradiation; DCIS, ductal carcinoma *in situ*; EIC, extensive intraductal carcinoma; ER, estrogen receptor; LVSI, lymphovascular space involvement; T, tumor stage.

Different methods have been used to evaluate breast cosmesis after breast conservation therapy. Some are flawed because they do not establish strict guidelines or criteria for objectively judging cosmetic outcome. Pezner et al.[786] used scales and standard procedures for obtaining color slides to assess the cosmetic results of breast conservation therapy and other scales designed by various investigators were given to patients for comparison. The study demonstrated that observer-based consensus of cosmetic results is difficult to obtain with two commonly used scales, but by changing the scale gradations from four to two (zero to one vs. two to three satisfactory results), consensus exceeding 85% of observers can be obtained.

A commonly employed simple scale, developed by the Harvard group,

employs a 4-point scale: excellent, good, fair, and poor.[787] At Washington University, questionnaires were completed by 458 patients and their radiation oncologists at regular 6-month intervals after treatment. Cosmetic outcome analysis of these patients was done for clinical and treatment-related factors.[351] Approximately 80% of patients had excellent or good cosmesis (Fig. 59.52). Clinical factors at presentation were analyzed by age, menopausal status, race, and tumor-related parameters of size, palpable status, and location. Patients older than 60 years of age had lower excellent cosmetic scores compared with patients 60 years of age or younger. Tumor size significantly influenced cosmetic outcome, most likely related to the volume of breast removed and perhaps boost dose. Cosmetic outcome by race indicated 40% of whites had an excellent cosmetic rating, compared with only 18% for African Americans. Thirty percent of African American patients received concurrent chemotherapy or hormonal therapy with irradiation, compared with 23% of white patients. Of African American patients, 14% were obese, 17% were hypertensive, 25% had both obesity and hypertension, and 4% had diabetes.

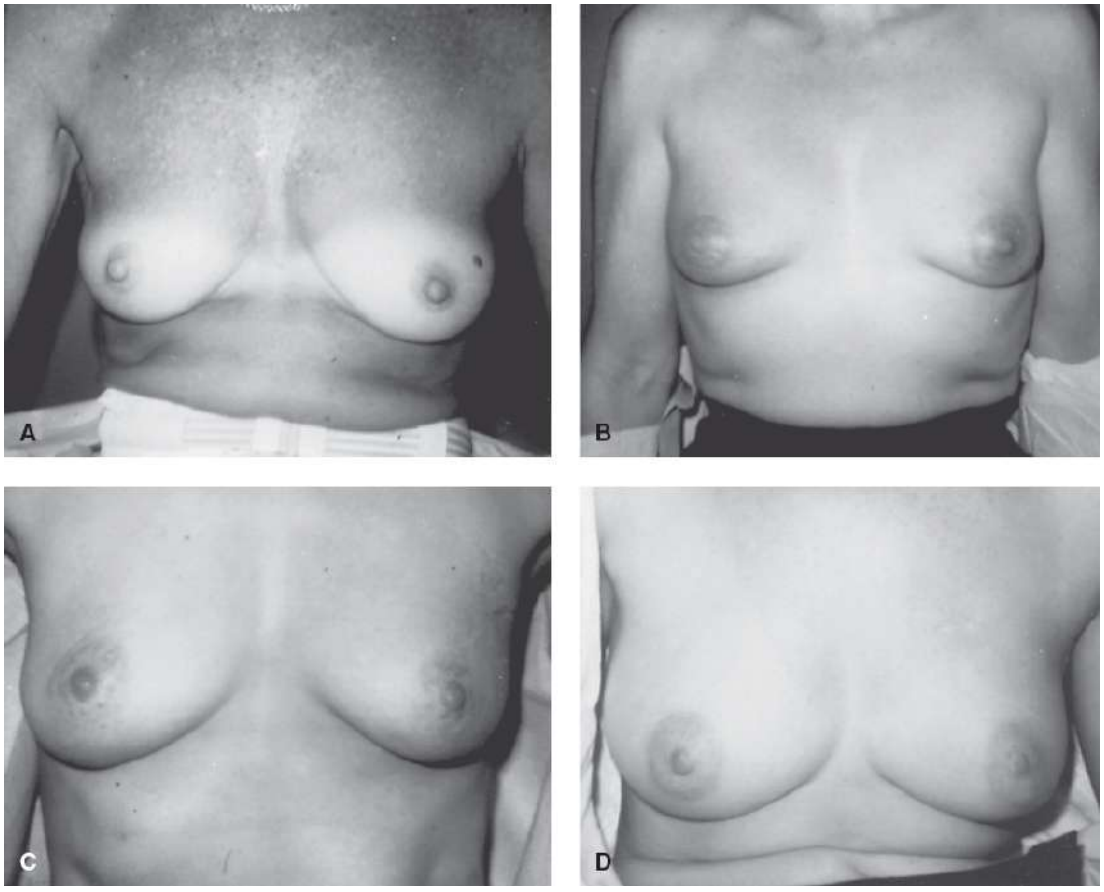

FIGURE 59.52. A–D: Photographs of patients showing excellent cosmetic results

obtained with conservation surgery and irradiation for patients with T1 and T2 carcinomas of the breast. The patient in **C** has minimal telangiectasia in the area treated with a boost (upper region of left breast).

Poorer cosmetic outcomes in African American women have also been reported by Pierce et al.[490] and Tuomokumo and Haffty.[299] In the study by Tuomokomo and Haffty,[299] a detailed cosmetic analysis was performed on a subset of 20 African American patients and 20 white patients from the Yale database. The two groups were intentionally matched by age, follow-up, adjuvant therapy, and breast size and were asked to participate in a detailed cosmetic evaluation. With respect to overall cosmetic outcome and all specific cosmetic measures (edema, fibrosis, and pigmentation), African American patients fared more poorly than did white patients. Overall cosmesis was good to excellent in 55% of African Americans, compared with 90% of whites.

Cosmesis may be affected by multiple breast and axillary surgical factors.[351] The type of breast surgery is important, with patients undergoing excisional biopsy having the highest rate of excellent cosmesis (56%) compared with wide excision (35%) or quadrantectomy (13%; P = .0001). Scar orientation compliance with NSABP guidelines was a significant factor, with a 44% excellent cosmetic rating compared with 27% for patients with noncompliant scar orientations (P = .0034). Re-excision of the primary site also resulted in a lower rate of excellent cosmesis (P = .0002). Breast tissue resection of >100 cm^3 was associated with lower rates of excellent or good cosmesis, independent of breast size (P = .0001). Similarly, a resected skin area of >20 cm^2 was correlated with a lower excellent cosmetic result (P = .045). Extent of axillary surgery did not significantly affect breast cosmesis.

Radiation factors affecting cosmesis included treatment volume (tangential breast fields only vs. three fields or more; P = .034), whole-breast dose >50 Gy (P = .024), total dose to the tumor site >65 Gy (P = .06), and optimum dose distribution created with use of compensating filters. Daily fraction size of 1.8 Gy versus 2 Gy, boost versus no boost, type of boost (brachytherapy vs. electrons), total irradiation dose, and use of bolus were not significant factors. Vrieling et al.[486] published a report of the randomized EORTC trial in which 5,318 women with early-stage breast cancer after tumorectomy were randomized to a boost of 16 Gy to the tumor bed or no further treatment. Patients with microscopically incomplete excision were randomized to receive a boost of 10 Gy or 25 or 26 Gy with interstitial implant or external beam radiation. Cosmetic results at 3 years were assessed in 731 women (364 with boost, 367 without

boost) using digitizer measurements, and displacement of the nipple cosmesis in the boost group was excellent in 33%, good in 38%, fair in 26%, and poor in 3%. In the no-boost group, the results were 42%, 44%, 13%, and 1%, respectively. The position of the nipple was the only moderately representative parameter of the overall cosmetic outcome. Other measurements had no significant correlation with cosmesis. A global assessment of the appearance of the breast was thought to be a reliable method to assess cosmetic results. Factors associated with worse cosmesis were inferior tumor location, large excision volume, presence of postoperative complications, and radiation therapy boost.

TABLE 59.41 IMPACT OF ADJUVANT CHEMOTHERAPY ON COSMESIS IN BREAST CONSERVATION THERAPY

Institution (Reference)	Chemotherapy	Good to Excellent Cosmesis (%)	
		Radiation Therapy without Chemotherapy	Radiation Therapy with Chemotherapy
Harvard University[788]	CMF, A	92	67
Palo Alto[325]	CMF	88	73
National Cancer Institute[789]	AC	80	70
University of Pennsylvania[569]	CMF ± P	89	81
Washington University[351]	CMF	81	78

A, doxorubicin; AC, doxorubicin, cyclophosphamide; CMF, cyclophosphamide, methotrexate, 5-fluorouracil; P, prednisone.

Impact of Adjuvant Chemotherapy on Cosmesis

Adjuvant chemotherapy may have a deleterious influence on excellent to good cosmetic results (Table 59.41).[325,351,787,788,790] In several studies, the main effect was a switch from “excellent” results to the “good” category. In particular, concomitant administration of chemotherapy and irradiation appears to have a more pronounced affect on cosmesis. The majority of studies using concurrent chemotherapy, however, employed agents that are no longer routinely employed.

Rose et al.,[787] reported on the Harvard cosmesis data and found that 68% of women not receiving chemotherapy had an excellent result at 3 years, compared with 37% who did receive chemotherapy. Conversely, 9% of patients who did not receive chemotherapy were judged to have fair or poor cosmetic results,

compared with 24% of those who received chemotherapy. These differences were mostly the result of an increase in breast retraction and, to a lesser extent, development of telangiectasia.

Taylor et al.[351] also reported impaired cosmetic outcome with concurrent administration of chemoirradiation. Excellent cosmetic outcome was observed in 43% of patients receiving sequential chemotherapy, in 25% receiving concomitant chemoirradiation, and in 41% receiving no adjuvant therapy (P = .02). The specific effect of methotrexate on cosmetic outcome was evaluated, and the proportion of excellent cosmetic outcomes with methotrexate omitted was 41% versus 16% with methotrexate included. Good results were obtained in 23% versus 58%, fair results in 23% versus 26%, and poor results in 12% versus 0%, respectively (P = .14). Similarly, studies by Markiewicz et al.[569,790] and Danoff et al.[789] report no compromise of cosmesis in patients receiving concurrent chemoradiation if methotrexate was held during the radiation.

In a randomized trial of concurrent versus sequential radiation therapy, using fluorouracil, Cytoxan, and mitoxantrone, Rouesse et al.[570] also reported comparable and acceptable cosmetic outcomes, whether patients were treated with sequential or concurrent chemotherapy.

Breast Cosmetic Surgery after Irradiation

Breast deformities after conservation therapy may represent difficult reconstructive problems.[791] Correction of a locally damaged breast is a surgical challenge that can result in a fully restored breast if selection of the surgical procedure is properly carried out. In 37 patients who underwent correction of deformities after breast conservation surgery, which included simple submuscular placement of traditional or expandable implants, breast reshaping, transposition of a latissimus dorsi muscle or musculocutaneous flap, transverse rectus abdominis muscle flap, and reverse abdominoplasty, aesthetic outcome was judged to be good or excellent in 78% of patients.

When partial mastectomy, a term that encompasses a diversity of excisional techniques, follows radiation therapy, breast defects characterized by parenchymal loss, nipple–areola complex distortion, and cutaneous abnormalities can occur. Slavin et al.[792] reported on eight patients who had reconstructive correction of an irradiated partial mastectomy deformity. Mammograms were obtained before and after the myocutaneous flap procedure. Six patients had reconstructions with latissimus dorsi flaps and two with rectus flaps. No patient underwent reconstruction sooner than 1 year after completion

of radiation therapy for the entire group; a mean of 2.6 years elapsed from completion of radiation therapy to flap reconstruction of the breast. An aesthetic improvement of the partial mastectomy deformity was achieved in all eight patients. Complications consisted only of seroma formation in two patients after latissimus flap reconstruction. Mammographic evaluation revealed degeneration of the soft tissues of both types of flaps, a change that occurs as early as 6 months after operation and appears as a radiolucent area.

In a review of the MD Anderson Cancer Center experience, Kronowitz et al.[793] evaluated results of 69 patients who underwent repair of a partial mastectomy defect after radiation. They concluded that immediate repair of partial mastectomy defects with local tissues results in a lower risk of complications and better aesthetic outcomes than does immediate repair of partial mastectomy defects with a latissimus dorsi flap.

Follow-Up of Patients Treated with Breast Conservation Surgery and Irradiation

It is important to closely monitor patients treated with conservation surgery and irradiation because early detection of a local recurrence may allow for another wide local excision or a total mastectomy, without significantly compromising the overall survival of the patient.[106,219,758,794–797] Although the optimal interval for follow-up mammography has not been determined, a postradiation bilateral diagnostic mammogram should be obtained within the first year following radiation therapy.[158,798–800]

A careful history and physical examination are indicated every 3 to 6 months for 3 years and every 6 months for the following 2 years and annually thereafter. In patients who underwent breast conservation therapy, a diagnostic mammogram within 3 to 6 months postradiation therapy and then annually thereafter is sufficient unless the radiologist recommends more frequent examinations.[158,799,800] Monthly breast self-examination should be emphasized to every patient, including demonstration of the examination in the upright and supine positions. At least yearly evaluation is mandatory even 10 years after therapy because of the possibility of late breast relapses and occasional distant metastases. According to the American Society of Clinical Oncology's surveillance guidelines, intensive follow-up should be limited to high-risk patients with breast cancer, especially those who enter randomized clinical trials.[801]

If there is strong evidence of suspect microcalcifications, masses, or

architectural distortions of the breast after conservation surgery and irradiation, a biopsy should be obtained to rule out a recurrence. At times, these patients are difficult to evaluate. Posttreatment hematomas, fat necrosis, seromas, cysts, and scar tissue pose frequent dilemmas. Consultation with an experienced mammographer is essential.

Kollias et al.[802] in the United Kingdom evaluated 5,102 contralateral screening mammograms performed biennially on 2,511 women aged ≤70 years after treatment for primary operable breast cancer. Sixty-five metachronous contralateral breast cancers were identified: 21 (32%) at routine clinical examination, 24 (37%) at mammography, and 20 (31%) by patients between routine follow-up appointments. The prognostic features of metachronous cancers were better than or similar to those of the first cancer in 59 of 65 (91%) cases. Mammography may have contributed to the long-term survival of 16 of 26 women in whom the histologic characteristics of the first cancer predicted a good prognosis. The cancer detection rate with mammography for these women was 6.5 per 1,000 contralateral mammograms at a cost of 3,852 pounds sterling (6,108 dollars) per cancer detected, suggesting that surveillance mammography of the contralateral breast is of value in women whose first cancer predicted a favorable prognosis.

Kramer et al.[803] assessed the efficacy of contrast-enhanced dynamic MRI compared with palpation, mammography, and ultrasonography in 33 patients after breast conservation therapy. The sensitivities for the diagnosis of local recurrences were 51% for palpation, 67% for mammography, 85% for ultrasonography, and 91% for MRI. All multicentric local recurrences were diagnosed by MRI. Mammography did not diagnose 11 local recurrences in radiodense breast, and ultrasonography was able to diagnose 8 of the 11, whereas MRI diagnosed 10 of the 11 recurrences. MRI may be useful as a complement to mammography and ultrasonography in the radiodense breast.[799]

It is important to define the cost–benefit ratio of follow-up procedures. In a controlled trial in Italy, 655 women were randomly assigned to be monitored with an intensive surveillance program including physician visits, bone scan, liver ultrasonography, chest radiography, and laboratory tests after initial treatment for breast cancer.[804] A control group of 665 women was monitored by their physicians with physical examination and only the clinically indicated tests. Both groups received a yearly mammogram. Compliance in both protocols was more than 80%. With a median follow-up of 71 months, there was no difference in overall survival between the two groups. There were 132 deaths (20%) in the

intensive surveillance group and 122 deaths (18%) in the control group. Time to detection of recurrence and parameters related to quality of life were similar in both groups. Therefore, unnecessary tests are discouraged in the follow-up of patients treated for breast cancer.

Radiographic Findings after Breast Conservation Therapy

Dershaw[158] summarized the most frequent mammographic findings: parenchymal distortion and fibrosis at the tumor excision site (secondary to surgical scar and irradiation); skin thickening, seen in 90% of patients, which may be diffuse or more prominent at the surgical excision site; and calcifications, due to fat necrosis, which are coarse and round and have radiolucent centers. Dershaw et al.[800] retrospectively reviewed the mammograms of 22 patients with local tumor recurrence that were usually associated with 10 or more calcifications (17 patients, 77%). Recurrences commonly contained very suspect patterns of calcification, with linear forms in 15 cases (68%) and pleomorphic forms in 17 cases (77%). The distribution of calcifications was usually clustered (73%, 16 of 22) or segmental (18%, 4 of 22). Recurrences were characterized as obviously malignant in 77% of cases. The remainder were indeterminate, requiring biopsy. Therefore, women without worrisome mammographic patterns need not undergo breast biopsy. If the findings are stable, mammographic follow-up is sufficient. However, a change in number or characteristic pattern warrants a biopsy to rule out recurrent tumor. Mammographic findings were correlated with clinical observations in several studies.[387,709,712,758,796,799,805–807] Most changes are observed in the first 12 months after therapy, with stabilization achieved at 12 to 36 months after completion of therapy. Breast edema is mammographically present in virtually all patients at completion of therapy, with a steady increase over 36 months and stabilization by 42 months.

Tian et al. longitudinally compare the incidence of common mammographic sequelae seen after breast-conserving surgery and RT in patients treated with APBI, hypofractionated whole-breast irradiation (HWBI), and conventionally fractionated WBI[808]. In their cohort of 89 patients, 29 had received APBI, 30 had received HWBI, and 30 had received WBI. A total of 605 mammograms were evaluated, with a median follow-up of 48 months. The fractionation scheme did not affect the severity of architectural distortion when the groups were evaluated longitudinally. The likelihood of finding skin thickening decreased with increasing follow-up duration (OR 0.6; $P < .001$) adjusted for

fractionation schemes. No differences were seen with respect to changes in skin thickening, fluid collections, or calcifications among the treatment groups, after adjustment for the follow-up time. The clinical characteristics, including age, race, T stage, and chemotherapy use, were not linked to the likelihood of finding several mammographic phenomena over time. The authors concluded that fractionation did not alter the relative incidence or severity of architectural distortion, skin thickening, fluid collections, or calcifications.

Pretreatment and posttreatment mammograms were reviewed in 103 patients undergoing conservation therapy.[809] The main posttreatment findings were a diffuse increase in parenchymal density with coarse stromal pattern, some parenchymal distortion, and thickening of the skin. Changes reached a peak at 9 months and slowly resolved over the next 2 years. At 31 to 33 months, 3 of 15 patients still had dense parenchyma and 6 had skin thickening. Sixty-nine patients had fibroadenosis. Scar with retraction in the surgical area was observed on the mammograms of 71 patients. Fat necrosis was noted in two patients. During the 3-year follow-up, recurrent cancer was noted in two treated breasts, and contralateral breast cancer developed in three women.

Orel et al.[810] reported on 1,145 women with early breast cancer treated with lumpectomy and irradiation. One hundred two women with various mammographic and clinical findings later required biopsy at the treated site, and 58 had two sets of mammograms available for review (one within 3 months of the biopsy). Recurring cancer was documented in 38 (66%) of 58 patients. Thirteen (34%) of the recurrences were detected solely with mammography, and eight others were detected both mammographically and clinically. The positive predictive value for mammographic abnormalities was 72% (76% for soft tissue microcalcifications and 62% for other findings). Twenty-one recurrences (55%) were within the lumpectomy quadrant. Within the lumpectomy site, sensitivity was substantially better for physical examination (71%) than for mammography (43%). In the remaining breast outside the lumpectomy quadrant, mammography had a significantly higher sensitivity (71%) and positive predictive value (86%). The most common posttreatment findings reported by Orel et al.[810,811] and Stomper et al.[812] were calcifications alone (48%) or with a mass (29%), distortion of the breast parenchyma (20%), and inflammatory thickening of the breast skin.

Stomper et al.[812] reported on 50 of 1,600 patients with stage I or II invasive breast cancer treated with conservation surgery and irradiation on whom biopsies were performed within 4 months of a mammogram for suspected recurrence in

the irradiated breast. The tumor was suspected based on mammography in only eight patients (35%), on physical examination in nine (39%), and on both in six (26%). The most common radiographic findings were calcifications with or without a mass. Histologic evidence of recurrent cancer was found in 23 of 45 (51%) biopsy specimens. Sixty-five percent of patients had recurrences at the primary site and 22% in other sites; 13% were multifocal.

MRI is increasingly used in the evaluation of patients with equivocal mammographic findings. Viehweg et al.[813] followed 207 patients with breast cancer treated with breast conservation therapy; 40 patients were examined 0 to 12 months and 167 patients later than 12 months after radiation therapy. Suspect or indeterminate findings were suggested by clinical examination or conventional imaging in 80 studies. In 127 women, MRI was performed in breast tissue that was difficult to assess because of scarring or dense breast tissue. Recurrent carcinoma was confirmed in 27 patients by surgical biopsy. All 27 carcinomas, except for one with a slow signal increase, demonstrated early rise of signal intensity on dynamic T1-weighted, contrast-enhanced images. During the first year after therapy, the diagnostic accuracy was not improved by additional use of contrast-enhanced MRI because of strong and sometimes early and ill-circumscribed enhancement. Later than 12 months after therapy, enhancement decreased significantly and the false-positive calls could be reduced from 49 (conventional imaging) to 12 (conventional imaging plus MRI). A total of 12 of 26 recurrences and multifocality in four of five cases were diagnosed by MRI alone at this time.

Dao et al.[814] evaluated 35 women with breast carcinoma treated with conservation therapy who underwent posttreatment MRI. Nine patients had recurrent tumors, and 26 had a benign fibrotic mass confirmed at biopsy. In all cases, a localized hypointense area was present on plain spin-echo T1-weighted images. In all recurrent tumors, dynamic gadolinium-enhanced T1-weighted images demonstrated early increased signal intensity of the lesion within 3 minutes after bolus injection.

Drew et al.[815] also investigated MRI for screening for local recurrence after breast-conserving therapy. One hundred five patients were recruited for the study. Sixteen biopsies were performed and nine recurrences were confirmed histologically. The sensitivity for clinical examination, mammography, examination combined with mammography, and MRI alone for the detection of recurrent cancer were 89%, 67%, 100%, and 100%, respectively, and the specificity was 76%, 85%, 67%, and 93%. The authors concluded that when

combined, clinical examination and mammography are as sensitive as MRI of the breast for the detection of LRR, but MRI has greater specificity.

SEQUELAE OF IRRADIATION IN BREAST CANCER

The most frequent complications associated with conservation surgery plus irradiation are arm or breast edema, breast fibrosis, painful mastitis or myositis, pneumonitis, and rib fracture. Apical pulmonary fibrosis is occasionally noted when the regional lymph nodes are irradiated.[1,113,314,351,816,817]

Lymphedema and Breast Edema

Complications from axillary surgery, regardless of breast surgical procedure, have been reported by several authors. It should be emphasized that before the treatment of arm lymphedema after breast carcinoma, it is mandatory to differentiate between treatment-associated complications and tumor recurrence in the regional lymphatics.

An extensive review of the literature related to arm edema following breast surgery was conducted by Erickson et al.[818] They found that arm edema is a common complication of breast cancer therapy that can result in substantial functional impairment and psychological morbidity. The risk of arm edema increases when axillary dissection and axillary radiation therapy are used. Preventive measures have not been well studied. Nonpharmacologic treatments, such as massage and exercise, have been shown to be effective therapies for lymphedema, but the effect of pharmacologic interventions remains uncertain. They conclude that as arm edema becomes more prevalent with the increasing survival of breast cancer patients, further research is needed to evaluate the efficacy of preventive strategies and therapeutic interventions.[43]

Maunsell et al.[819] evaluated frequency of upper extremity problems from axillary surgery in 223 patients. At 3 months after surgery, 82% of patients reported at least one arm problem: swelling (24%), weakness (26%), some limitation in range of movement (32%), stiffness (40%), pain (55%), and numbness (58%). The severity of these problems changed little 15 months later. Regardless of the type of mastectomy, women who underwent axillary dissection had more problems.

Clarke et al.[402] observed breast edema in approximately 20% of patients not undergoing axillary dissection, compared with 80% of those in whom this procedure was performed. The extent of the axillary dissection (medial or lateral

to the tendon of the pectoralis minor) influences the incidence of breast or arm edema, with this complication being more frequent when more extensive axillary dissections are carried out (beyond level II—middle). On the other hand, Dewar et al.[820] reported a greater incidence of upper limb sequelae in patients undergoing axillary surgery and irradiation (33.7%) or irradiation alone (26%) than in patients treated with axillary dissection only (7.2%). The most frequently noted complications were edema, impaired shoulder mobility, pain on movement, sensory or motor deficit, and pectoral muscle fibrosis.

Pain and discomfort after ALND were significantly related to quality of life. Hack et al.,[821] in 220 women with breast cancer who had undergone ALND, noted that 73% had sensation of pain or discomfort or the point of maximum arm–shoulder movement was different between the affected and nonaffected side. Although more than half of the patients experienced pain-related discomfort and disability, patients in general reported a good quality of life and mental health. Younger women had significantly greater pain than did older women. Patients with more than 13 lymph nodes dissected and patients receiving chemotherapy reported more pain.

Sentinel node sampling appears to be associated with a much lower degree of lymphedema.[332] Sener et al.[822] reported that 9 of 303 patients (3%) who underwent only sentinel lymphadenectomy had lymphedema, compared with 20 of 117 patients (17%) who underwent sentinel lymphadenectomy combined with axillary dissection ($P < .0001$). Among 303 patients who underwent sentinel lymphadenectomy only, lymphedema developed in 8 of 155 patients (5%) who had tumors in the upper outer quadrant and in 1 of 148 patients (0.7%) whose tumors were in other locations. The ALMANAC randomized trial also confirms lower morbidity and improved quality of life following sentinel node biopsy compared with axillary dissection.[332]

Various treatment regimens have been used to treat lymphedema.[823] The compression pump, along with skin care, exercise, and compression garments, is one. A second treatment is known as *complex decongestive physiotherapy* or *complex physical therapy*. Arm care, therapeutic exercises, manual lymph node drainage, and compression bandages or garments constitute this treatment regimen. Decreases in lymphedema are noted if women are compliant with the prescribed treatment program.

Brorson et al.[824] reported on 20 patients with arm lymphedema after breast cancer treatment who underwent liposuction combined with controlled compression therapy or controlled compression therapy alone. Liposuction

combined with controlled compression therapy reduced arm edema volume by (median) 115% (range, 92% to 179%), whereas controlled compression therapy alone decreased arm edema volume by only 54% (range, 7% to 81%; *P* = .008).

In general, the incidence of breast or arm edema after conservation therapy varies, and it is related to performance and technique of axillary dissection, whether the axillary lymph nodes were irradiated, and the dose of radiation delivered.

Skin and Breast Complications

A wide variety of symptoms may occur following radiation treatment to the conservatively treated breast. McCormick et al.[314] showed that breast swelling was the most frequently noted symptom (31% of patients), followed by muscle pain (on motion), incision site pain, and general breast discomfort (approximately 20%). Rib pain was noted by 13%. Forty-eight percent of patients reported more breast discomfort in the treated breast compared with the untreated breast during sexual activity (64 sexually active patients).

In addition to host factors such as such as CVS and diabetes, underlying genetic factors may play a role in radiation complications. Iannuzzi et al.[825] evaluated 46 patients with early-stage breast carcinoma who underwent limited surgery and breast irradiation. DNA was isolated from blood lymphocytes. Nine ataxia telangiectasis mutations were identified in six patients (eight novel and one rare). The median follow-up was 3.2 years (range, 1.3 to 19.3 years). All three of the patients (100%) who manifested grade 3 or 4 subcutaneous late sequelae possessed ataxia telangiectasis mutations, whereas only 3 of the 43 patients (7%) who did not have this form of severe toxicity harbored an ataxia telangiectasis mutation (*P* = .001).

Skin effects after postlumpectomy radiation therapy may be affected more significantly by the increase in the dose of radiation per fraction than by the total dose. Gorodetsky et al.[826] studied 110 women with breast cancer who had been treated with lumpectomies and radiation therapy and normal controls using a viscoelasticity skin analyzer. With increasing age, the viscoelasticity of the skin decreased and anisotropy increased significantly. A small but significant increase in skin stiffness was noted with radiation therapy in the range of 45 to 50 Gy given in fractions of 1.8 Gy. A dose of 50 Gy given in fractions of 2.5 Gy produced a more pronounced effect.

Pseudosclerodermatosus panniculitis is an unusual variant of panniculitis seen as a complication of radiation therapy. Carrasco et al.[827] described four women

in whom this unusual entity developed on the anterior chest and abdominal skin after they received radiation therapy for either breast carcinoma or painful bone metastases from breast carcinoma. Histopathologically, the epidermis and dermis of the involved area showed little or no evidence of radiodermatitis. The main findings were in subcutaneous tissue and consisted of thickened sclerotic septa, composed of both thick and thin collagen bundles, and a lobular panniculitis characterized by lipophagic granulomas and scattered lymphocytes and plasma cells. This sequela should be distinguished from subcutaneous metastatic disease, cellulitis, or connective tissue diseases involving the subcutaneous fat.

Rayan et al.[828] reported on a randomized clinical trial of breast-conserving surgery and tamoxifen with or without radiation therapy in women 50 years of age and older treated for stage T1 or T2, node-negative breast cancer. A companion study to assess breast pain was carried out during the past 2 years of accrual to the trial, in which 86 patients participated. Forty-one received radiation therapy and tamoxifen and 45 tamoxifen alone. The median age was 70 years. Baseline pain and quality-of-life scores were similar for the two groups. At 3 months, patients receiving radiation therapy experienced more breast pain compared with those receiving tamoxifen alone, but this did not reach statistical significance. At 3 months, the pain scores for the radiation therapy and tamoxifen and tamoxifen alone groups were 2.39 and 1.83, respectively (P = .47). At 12 months, pain scores were lower and fairly similar in both groups, with a difference of 0.20 (P = .71).

Tamoxifen has been shown to induce secretion of tumor growth factor-β, which has been implicated in pathogenesis of radiation fibrosis. Li et al.,[729] in a study of 91 patients with T1 or T2 breast cancer, noted that tumor growth factor-β and the receptor–ligand complex appeared to be of clinical value in identifying patients at risk for development of postirradiation fibrosis of the breast. Wazer et al.[577] showed a trend toward decreased cosmesis in patients receiving tamoxifen. In a randomized study, pulmonary fibrosis developed in 15 of 24 (63%) women treated with 36.6 Gy in 12 fractions and tamoxifen, compared with 10 of 30 (33%) receiving irradiation alone. Also, 5 of 14 (36%) women treated with 40.9 Gy in 22 fractions and tamoxifen had lung fibrosis, compared with 2 of 16 (13%) receiving irradiation alone.[576] In contrast, Fowble et al.[829] observed no difference in cosmetic results or complications in 154 patients who received tamoxifen in combination with breast conservation therapy compared with 337 patients who did not receive tamoxifen. The incidences of radiation pneumonitis were 0.2% and 0.3%, respectively. The sequence of tamoxifen, given

concurrently or following radiation, has not been clearly shown to correlate with complications or cosmesis.[578–580]

Markiewicz et al.[790] analyzed complications in 1,053 women with stage I or II breast cancer treated with breast-conserving therapy. Of this group, 206 received chemotherapy alone, 141 had hormonal therapy alone, 94 had both, and 612 received no adjuvant therapy. The incidence of grade 4 or 5 arm edema (≥2 cm difference in arm circumference) was 2% without chemotherapy and 8% with chemotherapy (P = .00002). However, the incidence of arm edema was not affected by sequencing or type of chemotherapy; it occurred in 10% and 7% of patients with sequential or concurrent treatment, respectively, and in 8% and 18% of patients treated with CMF or CAF, respectively. The incidence of clinical pneumonitis and rib fracture was not influenced by use of chemotherapy, sequencing of drugs, or use of hormonal therapy. These authors concluded that some chemotherapy could be given concurrently with radiation therapy to the breast without significant compromise of cosmetic results or sequelae of treatment.

Hyperbaric oxygen therapy has been shown to be effective in the treatment of some late radiation sequelae. Carl et al.[830] reported on 44 patients with persistent local symptoms after breast-conserving therapy. Hyperbaric oxygen therapy (100% oxygen at 240 kPa for 90-minute sessions) was administered to 32 patients for a median of 25 sessions (range, 7 to 60 sessions). The remaining 12 patients declined hyperbaric treatment and acted as control subjects. The patients given hyperbaric oxygen therapy demonstrated a significant reduction in pain, edema, and erythema scores compared with untreated control subjects (P < .001). Seven of the 32 women who were treated with hyperbaric oxygen therapy were free of symptoms after treatment, whereas all 12 patients in the control group had persistent complaints. However, hyperbaric oxygen therapy did not have a significant effect on fibrosis and telangiectasia in the irradiated breast.

Brachial Plexopathy

Brachial plexus dysfunction is a possible complication of regional nodal radiation therapy. In a review of 1,624 patients, brachial plexus sequelae were observed in 1.8% of patients.[831] Pierce et al.[831] found that the incidence of brachial plexopathy was significantly higher when the axillary dose was >50 Gy (P = .004). However, dose alone did not determine whether radiation damage would develop in a given patient. Treatment technique (two vs. three fields; P = .0009) and concomitant chemotherapy were also risk factors. Other investigators

have found the incidence of this complication to be ≤1%.[96,378] It is very important but difficult to distinguish between metastatic and radiation-induced brachial plexopathy.

Treatment for radiation brachial plexopathy consists of transdermal electrical nerve stimulation, dorsal column stimulators, neurolysis, and neurolysis with omentoplasty. Physical therapy, tricyclics, antiarrhythmics, anticonvulsives, nonsteroidal anti-inflammatory drugs, and steroids are helpful in therapy of both radiation-induced and metastatic brachial plexopathies.[832]

Pritchard et al.[833] used hyperbaric oxygen in 34 volunteers with radiation-induced brachial plexopathy who were randomized to hyperbaric oxygen or a control group. The hyperbaric oxygen group breathed 100% oxygen for 100 minutes in a hyperbaric chamber (30 sessions over 6 weeks). The control group breathed a gas mixture equivalent to breathing 100% oxygen at surface pressure. Normalization of the warm sensory threshold was seen in two of the patients receiving hyperbaric oxygen therapy. Two cases with marked chronic arm lymphedema reported major improvement in arm volume. These authors concluded that there is no reliable evidence to support hyperbaric oxygen therapy to slow or reverse radiation-induced brachial plexopathy, although improvements in warm sensory threshold suggest a therapeutic effect improvement in long-standing arm lymphedema and justify further investigation.

Pulmonary Sequelae

Symptomatic pneumonitis is infrequent. This clinical syndrome is noted one to several months after irradiation.[834] Patients present with dry cough (88%), shortness of breath (35%), or fever (53%), and on radiographic studies, a pulmonary infiltrate is observed in the irradiated volume.[816] The risk for development of radiation pneumonitis may be related to the volume of lung irradiated.[816,835]

The addition of regional nodal radiation therapy to breast irradiation significantly increase the incidence of symptomatic pneumonitis (1% without and 4% with regional node radiation therapy; $P < .001$). Combined axillary dissection and nodal irradiation result in a significantly higher incidence of arm edema compared with either alone (9.5% with axillary dissection, 6.1% with radiation therapy to the axilla and supraclavicular fossa, and 31% with combined modality therapy; $P < .001$).[835]

Lingos et al.[816] reported on radiation pneumonitis in a retrospective review of 1,624 patients treated with conservation surgery and irradiation. Overall,

pneumonitis developed in 1% of patients. No patient had late or persisting pulmonary symptoms. The incidence of radiation pneumonitis was correlated with the combined use of chemotherapy and a supraclavicular field ($P = .0001$). Fourteen of 17 patients who had radiation pneumonitis also had IMNs treated. When patients treated with the three-field technique received chemotherapy concurrently with irradiation, the incidence of radiation pneumonitis was 8.8% (8 of 92) compared with 1.3% (3 of 236) for those who received sequential chemotherapy and irradiation to the breast only and 0.5% (6 of 1,296) for those treated with irradiation to the breast only without chemotherapy ($P = .002$). In this study, the volume of lung irradiated did not correlate with the risk for development of radiation pneumonitis.

Taghian et al.,[836] in 41 patients treated with radiation therapy and paclitaxel (21 concurrent, 20 sequential), also described a higher incidence of pneumonitis (14.6%) compared with control patients irradiated and not receiving chemotherapy (1.1%; $P < .0001$). Burstein et al.[575] also recently reported that the concurrent use of weekly paclitaxel with radiation result in high rates of pneumonitis. However, an analysis of patients treated with radiation as a component of a randomized trial, in which 50% of the patients were treated with paclitaxel and 50% were treated with a nontaxane regimen, found that the rates of pneumonitis were very low and not significantly different between the two arms.[837]

The effect of tangential field technique on pulmonary function was reported by Lund et al.[838] in 25 patients treated with conservation surgery and irradiation. Dynamic and static lung volumes, distribution of ventilation, and gas transfer were measured before irradiation and at varying intervals up to 1 year after completion of therapy. There was a small but statistically significant decrease in the forced vital capacity and forced expired volume in 1 second 3 months after irradiation ($P < .05$). These changes normalized within 1 year. The reduction in total lung capacity after 3 months almost achieved statistical significance ($P = .06$). These slight restrictive ventilatory changes are reversible and have no clinical importance.

Radiation pneumonitis was retrospectively assessed on the basis of clinical symptoms and radiologic findings using a serial organ model by Gagliardi et al.[839] As demonstrated in Figure 59.52, a lung volume effect was relevant in the description of radiation pneumonitis. Lind et al.[840] measured pulmonary function 5 months after radiation therapy in 144 patients with node-positive stage II breast cancer. No deterioration of pulmonary function was detected among the

patients who were treated with local radiation therapy. Patients undergoing locoregional radiation therapy showed a 5% mean reduction in diffusion capacity ($P < .001$) and a 3% mean reduction in vital capacity ($P = .001$).

Cardiac Sequelae

The potential for excess cardiac morbidity associated with the use of radiation therapy in breast cancer has been extensively evaluated. It has been clearly demonstrated, based on data from randomized trials, overview, and meta-analyses, that when using older techniques, excess cardiac mortality from radiation offsets some of the benefits that radiation therapy clearly produced with respect to breast cancer mortality.[68,366,841] Although the evidence from more modern trials, using techniques that minimize exposure to the normal cardiac and pulmonary structures, have reduced cardiac toxicity, the radiation oncologist must be cognizant of the potential for adverse cardiac effects of incidental irradiation, particularly in the setting of left-sided breast cancers in patients receiving other cardiotoxic therapies, including adriamycin, epirubicin, and trastuzumab.[842,843]

Earlier techniques of radiation therapy from large pools of randomized data have clearly been implicated in excess cardiac mortality. In an analysis of over 90,000 Swedish women, comparing left- to right-sided cancers, Darby et al.[844] from the Oxford group reported excess ischemic heart disease mortality more than 10 years after initial treatment in the left-sided cancer group (HR 1.13; 95% CI, 1.03 to 1.25; $P = .01$). The majority of cardiovascular deaths were from earlier studies using techniques that are no longer used. However, for patients treated after 1980, although the ratio was still 1.11, the CIs were much larger (0.95 to 1.29), so the hazard remains uncertain for the more modern techniques.

In a separate report, Darby et al. conducted a population-based case–control study of major coronary events (i.e., myocardial infarction, coronary revascularization, or death from ischemic heart disease) in 2168 women who underwent radiotherapy for breast cancer between 1958 and 2001 in Sweden and Denmark[845]. They found that rates of major coronary events increased linearly with the mean dose to the heart by 7.4% per gray (95% CI, 2.9 to 14.5; $P < .001$), with no apparent threshold. The increase started within the first 5 years after radiotherapy and continued into the third decade after radiotherapy.

Gyenes et al.[846] reported on the incidence of ischemic heart disease 15 to 20 years after adjuvant radiation therapy in 960 patients with breast cancer enrolled in the Stockholm Breast Cancer Trial. Of 37 long-term survivors, 20 received

left-sided therapy and 17 received right-sided therapy or no therapy. Radiation therapy consisted of tangential fields for preoperative treatment and electron beam portals, which included the IMNs, for postoperative therapy (45 to 50 Gy). Evaluation consisted of echocardiography, exercise stress tests with ^{99m}Tc myocardial perfusion scan, and careful history for cardiac risk factors. Results showed that 5 of 20 (25%) patients treated with left-sided radiation had defects on ^{99m}Tc scan, compared with 0 of 17 control patients (P = .05).

Paszat et al.[847] conducted a study of 25,570 cases of invasive female breast cancer that were linked to radiation therapy records from Ontario cancer centers. Postlumpectomy radiation therapy was administered to 1,555 patients on the left side and to 1,451 on the right side. Two percent of women with left-sided radiation therapy had a fatal myocardial infarction compared with 1% of women with right-sided radiation therapy (P = .02). Adjusting for age at diagnosis, the RR for fatal myocardial infarction with left-sided postlumpectomy radiation therapy was 2.10.

Rutqvist et al.[848] followed 684 patients with breast cancer treated with breast-conserving surgery and radiation therapy using tangential photon fields (48 to 52 Gy in 4.5 to 5.5 weeks). The median follow-up was 9 years. In 88% of patients, the target volume involved the breast only; in the remaining patients, regional nodes were irradiated. A control group included 4,996 patients with breast cancer who underwent mastectomies without postoperative radiation therapy. Twelve patients (1.8%) in the irradiated group had myocardial infarctions and five patients (0.7%) died as a result of myocardial infarctions. The RR for a myocardial infarction between the irradiated group and the control group was 0.6, and the RR for death was 0.4. The study presents no evidence that the risk for myocardial infarction is increased with radiation therapy after breast-conserving surgery regardless of which side the tumor was located. However, because the number of myocardial infarctions in the study was small, there is no way to rule out the possibility of cardiac problems in patients with left breast carcinomas.

Shapiro et al.[842] assessed the cardiac effects in 299 patients with breast cancer prospectively randomized to receive either 5 cycles or 10 cycles of cyclophosphamide and a doxorubicin intravenous bolus every 21 days. Of the 299 patients, 122 received radiation therapy. The risk of major cardiac events (congestive heart failure, acute myocardial infarction) was assessable in 276 patients, with a median follow-up of 6 years (range, 0.5 to 19.4 years). The estimated risk of cardiac events per 100 patient-years was significantly higher

for 10 cycles than for 5 cycles of chemotherapy (1.7 vs. 0.5; $P = .02$). The risk of cardiac events in the 5-cycle patients, regardless of the cardiac radiation therapy dose volume, did not differ significantly from rates of cardiac events predicted for a general female population. For patients receiving 10 cycles, the incidence of cardiac events was significantly increased (RR 3.6; $P < .00003$) compared with the general population, particularly in groups that also received moderate- and high–dose-volume cardiac radiation therapy.

Cuzick et al.[841] updated cardiac toxicity data from eight randomized trials initiated before 1975 in which radiotherapy was the randomized option and surgery was the same for both treatment arms. An initial analysis of these trials demonstrated an increased all-cause mortality rate in 10-year survivors associated with radiation, but in the update this was no longer present. The initial increase in mortality in the radiation arms was strongly influenced by the earliest trials, and more recent trials have found a nonsignificant net benefit in overall mortality associated with radiation therapy. However, an excess of cardiac deaths was apparent in both early and more recent trials ($P < .001$), but this was offset by a reduced number of deaths due to breast cancer, especially in more recent trials. Based on this, it is clearly prudent to use techniques that minimize cardiac dose.

Although clinical evidence of cardiac morbidity has decreased with modern techniques, care should be taken to exclude heart from the tangential radiation field. In an analysis of 114 patients, Marks et al.[704] assessed RT-induced left ventricular perfusion defects and whether these perfusion defects are related to changes in cardiac wall motion or alterations in ejection fraction. Patients were imaged 30 to 60 minutes after injection of ^{99m}Tc sestamibi or tetrofosmin. Post-RT perfusion scans were compared with the pre-RT studies to assess for RT-induced perfusion defects as well as functional changes in wall motion and ejection fraction. The incidence of new perfusion defects 6, 12, 18, and 24 months after RT was 27%, 29%, 38%, and 42%, respectively. New defects occurred in approximately 10% to 20% and 50% to 60% of patients with <5% and >5% of their left ventricle included within the RT fields, respectively. The rates of wall motion abnormalities in patients with and without perfusion defects were 12% to 40% versus 0% to 9%. These authors note that RT causes volume-dependent perfusion defects in approximately 40% of patients within 2 years of RT, and that these perfusion defects are associated with corresponding wall-motion abnormalities. However, additional study is necessary to determine if these defects are associated with functional consequences.

Given these findings, the authors suggest the use of a heart block if needed to reduce or eliminate cardiac irradiation. CT-based 3D treatment planning is used to design such cardiac blocks and select the optimal gantry angle to minimize the need for a heart block. There may be a small amount of breast tissue underdosed if the block overlies the medial inferior breast, but this tissue is typically <5%. In situations where the heart block may underdose the high-risk volume of the breast or chest wall, an "electron patch" can be used to treat the target tissue in the shadow of the heart block. A tangential field with a heart block is demonstrated in Figure 59.33.

Although it is clearly prudent to minimize exposure of the heart during radiation therapy, using modern techniques, the available evidence does not suggest a higher incidence of cardiac mortality in left-sided radiation therapy.

Analysis of the randomized postmastectomy Danish trials, with over 10 years of follow-up, showed no excess cardiac mortality with the use of postmastectomy radiation. Hojris et al.[274] reported that the relative hazard of morbidity from ischemic heart disease among patients in the radiotherapy compared with the no-radiotherapy group was 0.86 (95% CI, 0.6 to 1.3), and that for death from ischemic heart disease was 0.84 (0.4 to 1.8). The hazard rate of morbidity from ischemic heart disease in the radiotherapy group compared with the no-radiotherapy group did not increase with time from treatment.

Patt et al.[849] analyzed data from the SEER-Medicare database for women who were diagnosed with nonmetastatic breast cancer from 1986 to 1993, had known disease laterality, underwent breast surgery, and received adjuvant radiotherapy; 8,363 patients had left-sided breast cancer and 7,907 had right-sided breast cancer. With a mean follow-up of 9.5 years (range, 0 to 15 years), there were no significant differences in patients with left- versus right-sided cancers for hospitalization for ischemic heart disease (9.9% vs. 9.7%), valvular heart disease (2.9% vs. 2.8%), conduction abnormalities (9.7% vs. 9.6%), or heart failure (9.7% vs. 9.7%). The adjusted HR for left- versus right-sided breast cancer was 1.05 (95% CI, 0.94 to 1.16) for ischemic heart disease, 1.07 (95% CI, 0.89 to 1.30) for valvular heart disease, 1.07 (95% CI, 0.96 to 1.19) for conduction abnormalities, and 1.05 (95% CI, 0.95 to 1.17) for heart failure.

Similar conclusions were reached by Nixon et al.[850] who reviewed 365 patients with 12-year follow-up who received irradiation to the left breast and 380 who received irradiation to the right breast as part of conservation therapy. Equivalent proportions from each group died of non–breast cancer causes (11%), including nine patients (2%) from each group who died from cardiac causes.

Also, Vallis et al.,[851] in a retrospective review of 2,128 women treated with lumpectomy and breast irradiation with a median follow-up of 10.2 years, noted that the incidence of myocardial infarction in the study cohort was comparable with that in an age-matched general population of women in Ontario.

The potential for cardiac vessel injury from radiation was recently explored in an elegant study by Nilsson et al.[852] who analyzed radiation fields and subsequent coronary angiograms in a Swedish breast cancer cohort study. For right-sided compared with left-sided breast cancers, the OR for grade 3 to 5 stenosis in arteries likely to be within the tangential radiation port was 4.38 (95% CI, 1.64 to 11.7) and was 7.22 (95% CI, 1.64 to 31.8) for grade 4 or 5 stenosis. They conclude there is an increased risk and direct link between radiation and the location of the coronary stenosis. In a related editorial Zagar and Marks[853] emphasize the potential effects of radiation on the heart but point out that improved radiation techniques, including custom blocking of the heart and other techniques to manipulate the radiation dose, are likely to minimize these risks and improve the therapeutic ratio.

Collectively, these data suggest that although there may be excess cardiac morbidity using tangential fields to treat left-sided breast cancers, these effects can be minimized through careful treatment planning. It remains prudent to minimize cardiac exposure in all patients and particularly in those receiving left-sided radiation in combination with other potentially cardiotoxic drugs.

Risk of Stroke with Supraclavicular Radiation

For patients with node-positive disease undergoing supraclavicular radiation, there is a theoretical concern regarding the potential for development of accelerated carotid artery stenosis. In a study by Jagsi et al.,[854] rates of stroke in 820 eligible early-stage breast cancer patients treated with radiation therapy were compared with expected rates. The relation between potential risk factors and actuarial rate of first stroke was analyzed. On multivariate analysis, only age ($P < .001$) and hypertension ($P = .003$) remained significant predictors of cardiovascular accident or transient ischemic attack. Age was the only significant predictor of cardiovascular accident alone ($P < .001$). This study found no significant association between supraclavicular RT and stroke after controlling for other factors. This study is in agreement with the findings of the EBCTCG who reported the causes of nonbreast cancer death in 32,800 patients treated in trials of surgery with and without RT. Although the incidence of heart disease was found to be significantly greater in those women who received RT,

no significant excess mortality from RT was observed because of stroke. However, a recent nested case–control study by Nilsson et al.[855] showed a significant increase in stroke (OR 1.8; 95% CI, 1.1 to 2.8) when comparing patients treated to the supraclavicular and internal mammary regions with those not treated to these regions. In addition, a study by Woodward et al.[856] of the SEER database comparing 5,281 women presumably without supraclavicular radiation with negative nodes to 482 women presumably treated to the supraclavicular region with more than four nodes did not find any increased rate of hospitalization for stroke in the treated population.

Contralateral Breast Cancer and Irradiation

Although all patients with a diagnosis of breast cancer are at increased risk for developing a contralateral breast cancer, the additional risk contributed by radiation treatment appears to be minimal, particularly when one uses modern techniques and maintains a dose to the contralateral breast that is as low as is reasonably achievable. Although this issue is often a concern raised by patients, the available data using modern radiation techniques do not suggest a significant increase of risk for contralateral breast cancers in breast cancer patients who have been irradiated, in comparison to similar cohorts of breast cancer patients who have not undergone radiation.[1,23,91,113,686,750,857–860] Although there is some evidence suggesting a slight excess risk in women who are irradiated at a relatively young age (i.e., <45 years at diagnosis), the risk is extremely small and may be related to use of older techniques, and most experts would agree that the benefit of radiation far outweighs the risk.[857] Nonetheless, it appears prudent to be aware of these potential risks and employ techniques that minimize scattered dose to the contralateral breast. As demonstrated in Table 59.42, the reported incidence of contralateral cancer in the majority of these studies of patients treated with CS and radiation do not appear to be elevated compared with those treated by mastectomy without radiation.

However, the EBCTCG overview analysis does suggest an elevated incidence of contralateral breast cancer in patients receiving radiation compared with those who did not receive radiation.[87] This overview analysis of all randomized trials comparing radiation to surgery demonstrated an increased RR of contralateral breast cancers of 1.18 (=.002). Although the excess risk appears to be driven primarily by older trials using antiquated techniques, these data do demonstrate the potential long-term effects of radiation-related secondary cancers and highlight the need to maintain dose to the contralateral breast as low as possible.

A report by Hankey et al.,[862] involving 27,175 women treated for breast cancer between 1960 and 1975, disclosed a RR of 1.2 to 1.4 for development of cancer in the contralateral breast in irradiated patients compared with those who did not receive irradiation. These authors, however, concluded that the data did not indicate a pattern of RR consistent with an increased incidence of carcinoma in the opposite breast.

Boice et al.[857] evaluated the risk of second cancers associated with radiation therapy to the breast in 41,109 women with breast cancer who were registered in the Connecticut Tumor Registry between 1935 and 1982. They reviewed the records of 655 women in whom a second breast cancer developed 5 years or longer after initial treatment and compared the radiation exposure in these patients with the exposure in 1,189 matched control patients who did not have a second cancer. The average dose to the contralateral breast in women exposed to radiation was 2.82 Gy. The RR for development of a second breast cancer was 1.9 in the women who received radiation therapy, and among patients who survived for 10 years or longer, the RR was 1.33. Women <45 years of age had a RR of 1.59 for development of a second breast cancer, compared with 1.01 for older women. According to these authors, younger patients should be informed that, based on the results of this study, after 10 years the risk for development of a second cancer increases from 14% if they do not receive irradiation to 22% if they choose treatment involving irradiation.

TABLE 59.42 INCIDENCE OF CONTRALATERAL BREAST CANCER IN CARCINOMA OF THE BREAST TREATED WITH CONSERVATION SURGERY AND IRRADIATION OR MASTECTOMY

*h*Relative risk of tangential fields increased compared to mastectomy with electron fields.
RT, radiation therapy.

On the other hand, Levitt and Mandell[863] estimated the dose delivered to the contralateral breast to be between 1 and 4 Gy. Assuming that 20,000 women undergo radiation therapy after conservation surgery and using data on the risk for development of breast cancer after various doses of ionizing radiation, they concluded that fewer than one additional case of breast cancer would occur after 10 years. Storm et al.,[864] in a case-controlled study of a registry-based cohort of patients with breast cancer in Denmark, also concluded there was little, if any, risk of radiation-induced breast cancer associated with exposure of adult breast tissue to low-dose irradiation.

Obedian et al.[23] compared 1,029 breast cancer patients treated with CS and radiation to a cohort of 1,387 breast cancer patients who underwent surgical treatment by mastectomy and who did not receive postoperative radiation during the same time period. The median follow-up was 14.6 years for the conservatively treated group and 16 years for the mastectomy group. The 15-year risk of any second malignancy was nearly identical for both cohorts (17.5% vs. 19%, respectively). The second breast malignancy rate at 15 years was 10% for both groups. In the subset of patients ≤45 years of age at the time of treatment, the second breast and nonbreast malignancy rates at 15 years were 10% and 5% for patients undergoing breast-conserving therapy versus 7% and 4%, respectively, for patients undergoing mastectomy (probability not statistically significant).

To address whether the radiation administered may influence the development of breast cancers on the contralateral side, Khan and Haffty[865] evaluated the location of contralateral breast cancers developing after radiation. There was not a preponderance of medial lesions developing in the contralateral group (where

radiation dose would be higher), suggesting that there was no cause–effect relation with respect to the prior radiation. In a study by Hill-Kayser et al.[861] the 20-year risk of contralateral breast cancer in 1,801 patients treated with breast-conserving surgery and radiation was 15.4%. They also demonstrated that the distribution of location of the contralateral tumors did not appear to be influenced by the prior irradiation.

In a recent update of the Danish randomized trials of postmastectomy radiation, Nielsen et al.[750] also reported no excess risk of second malignancies in the contralateral breast in patients randomized to receive radiation. In this long-term follow-up performed among the 3,083 patients from the Danish Breast Cancer Cooperative Group 82B and 82C, randomized to postmastectomy radiation or not, there was no significant difference in the risk of contralateral breast cancers (6% RT vs. 5% no RT) between the two groups.

Hooning et al.,[859] in a study from Amsterdam of over 7,000 predominantly young women treated with or without radiation, did note an increase in contralateral breast cancer with decreasing age with tangential breast irradiation, particularly in young women with a strong family history. Of note, patients treated with mastectomy and chest wall electrons, where scattered dose to the contralateral breast was less, did not experience an increased contralateral breast cancer risk. The joint effects of tangential breast irradiation following lumpectomy and strong family history on contralateral breast cancer resulted in a HR of 3.52 (95% CI, 2.07 to 6.02; $P = .043$).

With modern technology scattered dose to the contralateral breast is lower and should minimize this issue, but care should be taken, particularly in younger women, to ensure that the dose to the contralateral breast is as low as possible.

Incidence of Other Second Malignancies

The incidence of secondary malignancies, as with the issue of contralateral breast cancer, appears to be very low, and it is evident that the appropriate use of radiation therapy far outweighs the risk of radiation-induced malignancy. Nonetheless, there is some evidence, with very long-term follow-up, of higher rates of secondary cancers. Although this may be more prevalent with older techniques, it is an important component of treatment planning to minimize dose to nontarget normal tissues. In addition to the excess risk of contralateral breast cancers discussed previously, the EBCTCG overview analysis did demonstrate an excess risk of secondary cancers of the lung and esophagus as well as leukemia and sarcoma in all randomized trials of breast cancer that compared

patients treated with and without radiation. The increased RR for each of these secondary malignancies as a function of radiation treatment for breast cancer was lung cancer, 1.61 (±0.18; *P* = .007); esophageal cancer, 2.06 (±0.53; *P* = .05); leukemia, 1.71 (±0.36; *P* = .03); and sarcoma, 2.34 (±0.62; *P* = .03). The total RR for all secondary nonbreast malignancies was 1.20 (±0.06; *P* = .001). Although the increased risk of secondary malignancies may be driven primarily by trials using older techniques, they highlight the importance of limiting dose to nontarget tissues.

Huang and Mackillop,[866] in an analysis of 194,798 women from the SEER database who were diagnosed with invasive breast carcinoma (exclusive of those with distant metastasis) between 1973 and 1995, identified 54 women in a radiation therapy cohort and 81 women in a non–radiation therapy cohort in whom soft tissue sarcoma subsequently developed. In the radiation therapy cohort, the standardized incidence ratio was 26.2 for angiosarcoma and 2.5 for other sarcomas; in the non–radiation therapy cohort, the standardized incidence ratios were 2.1 and 1.3 (95% CI, 1.0 to 1.7), respectively. The largest increase was observed in the chest wall breast. The elevated RR was significant even within 5 years of radiation therapy, but it reached a maximum between 5 and 10 years.

Karlsson et al.[867] quantified the risk of posttreatment sarcoma in 122,991 women with breast cancer in the Swedish Cancer Register. One-hundred and sixteen cases were found, giving a standardized incidence ratio of 1.9 per 10^4 women. The absolute risk was 1.3 per 10^4 person-years. There were 40 angiosarcomas and 76 sarcomas of other types. The sarcomas were located in the breast region or on the ipsilateral arm in 63% (67 of 106). In a case–control study, angiosarcoma correlated significantly with lymphedema of the arm (OR 0.5), but no correlation with previous irradiation was observed. However, for other histologic types of sarcomas, the risk increased linearly with the integral dose to 150 to 200 J and stabilized at higher energies. The risk was 2.4 for an energy of 50 J, approximately corresponding to the radiation of the breast after breast-conserving surgery.

More contemporary retrospective series have not reported an excess risk of secondary malignancies. However, interpretation of these series is limited by follow-up periods of <20 years, which may not be adequate. A study by Fowble et al.[868] evaluated nonbreast malignancies with approximately 9 years of follow-up and reported the 10-year risk of second malignancy was 16% for all cancers, 7% for contralateral breast cancer, and 8% for all second non–breast cancer

malignancies. Obedian et al.[23] also reported no increased risk of second non-breast malignancies in patients treated with CS and radiation compared with a cohort treated with mastectomy without radiation during the same time interval. The 15-year risk of a second nonbreast malignancy was 11% for the radiation group and 10% for the mastectomy group.

Galper et al.[869] analyzed the risk for development of second nonbreast malignancies in 1,884 patients with clinical stage I or II breast cancer treated with excision and radiation therapy. By 8 years of follow-up, 147 (8%) had a second nonbreast malignancy compared with the 127.7 expected from SEER. This corresponds to an absolute excess of 1% of the study population and a relative increase of 15% greater than expected from SEER (P = .05). Lung as a second nonbreast malignancy was observed in 33 women, 50% more than the 21.67 predicted by SEER (P = .01), although most of the lung malignancies occurred <5 years after treatment. Of seven sarcomas, three developed in the radiation field. Second nonbreast malignancies occurred in a substantial minority (8%) of patients treated with conservation surgery and radiation therapy. However, the absolute excess risk compared with the general population was very small (1%) and only evident after 5 years.

Ahsan and Neugut[870] reviewed SEER data in 220,806 women in whom breast cancer was diagnosed between January 1, 1973 and December 31, 1993. In women who had received radiation therapy for breast cancer, the RR for esophageal squamous cell carcinoma increased to 5.42 and the RR for esophageal adenocarcinoma increased to 4.22 10 years or more after radiation therapy. No increased risk was seen for either type of carcinoma among patients with breast cancer who did not receive radiation therapy.

The available evidence of the risk of lung cancer in patients undergoing radiation suggests that smoking and radiation may be synergistic in contributing to the risk of lung cancer. Ford et al.[871] analyzed smoking, radiation, and both exposures on lung carcinoma development in women who were treated previously for breast carcinoma in a case–control study of 280 female patients with a diagnosis of breast cancer prior to lung cancer. Smoking increased the odds of lung carcinoma in women without radiation (OR 6.0; 95% CI, 3.6 to 10.1), but radiation did not increase lung carcinoma risk in nonsmoking women (OR 0.5; 95% CI, 0.3 to 1.1). Overall, the OR for both radiation and smoking, compared with no radiation or smoking, was 9.0 (95% CI, 5.1 to 15.9). The authors conclude that smoking is a significant independent risk factor for lung carcinoma after breast carcinoma, but radiation alone was not. Smoking and

radiation combined enhanced the effect of either alone.

Deutsch et al.,[872] in a long-term analysis of the NSABP-04 and NSABP-06 trials, suggest an excess risk of lung cancers associated with the extent of radiation. The records of all patients who developed a recurrence in the lung or a new primary lung tumor were reviewed to determine the incidence and laterality of confirmed and probable primary lung carcinoma. For the NSABP-04 trial, which employed more comprehensive radiation with larger lung volumes, there were a total of 23 subsequent confirmed and probable ipsilateral or contralateral primary lung carcinomas. In those patients who had received comprehensive postmastectomy radiotherapy, there was a statistically significant increase in the incidence of these new primary tumors (P = .029). With regard to the development of confirmed new primary ipsilateral lung carcinoma alone, the incidence was statistically significantly increased (P = .013) in those patients who had received radiotherapy as part of their treatment, and when confirmed and probable ipsilateral lung carcinomas were analyzed, there was a strong trend toward a statistically significant increase in those patients who had received radiotherapy (P = .066). For the NSABP-06 (mean follow-up of 19.0 years), there was a total of 30 second primary lung carcinomas but no increase in either ipsilateral or contralateral primary tumors of the lung in those patients who had received radiotherapy. They conclude that extensive postmastectomy irradiation of the chest wall and regional lymphatic node areas, with consequent exposure of a greater volume of lung to higher doses as administered in the NSABP-04 trial, compared with postlumpectomy breast irradiation in the NSABP-06 trial, was associated with an increased incidence of subsequent primary lung tumors, both ipsilateral and contralateral. Unfortunately, data regarding smoking were not available in this analysis.

Postirradiation Angiosarcoma of the Breast

Special attention should be paid to uncommon skin changes of the treated breast because clinical suspicion is the main clue to the diagnosis of postirradiation angiosarcoma. The primary therapy is simple mastectomy if wide tumor-free margins can be achieved. At this time, there is no clear indication for standard adjuvant chemotherapy or irradiation. Angiosarcomas arising in the field of radiation therapy are rare. Unlike other radiation-induced sarcomas, cutaneous angiosarcoma often occurs within a short time after irradiation. It is important to differentiate atypical vascular lesions from angiosarcoma, but currently, there is no evidence that they represent a precursor to radiation-induced angiosarcoma.

Deutsch and Rosenstein[873] reported an angiosarcoma arising in the breast more than 7 years after lumpectomy and breast irradiation. The initial appearance was very similar to late radiation dermatitis, and the true nature of the malignant lesion was not known for 23 months. Fineberg and Rosen[874] studied three patients with cutaneous angiosarcoma and four patients with atypical vascular lesions. All had breast-conserving surgery and ALND, and six patients received conventional high-energy postoperative doses of external beam radiation to the breast. Angiosarcoma was diagnosed 3.5, 3.7, and 5.25 years after radiation therapy. The three angiosarcomas were multifocal or diffuse and high grade, with solid cellular foci located mainly in the dermis. Two patients with angiosarcoma underwent mastectomy; one died 10 months after diagnosis with recurrent local angiosarcoma, and the other was alive and tumor free 2 months after diagnosis.

Feigenberg et al.[875] reported results of hyperfractionated radiation therapy in conjunction with surgery for angiosarcoma occurring after breast-conserving therapy in three patients. All three patients were treated initially with radical surgery for the angiosarcoma, but extensive recurrences were noted within 1 to 2 months of surgery. Because of the extremely rapid growth before and after surgery, hyperfractionated radiation therapy was used. Two of the patients underwent resection of the recurrence after radiation therapy, and neither specimen demonstrated any evidence of high-grade angiosarcoma. All three patients were alive without any recurrent disease 22, 38, and 39 months, respectively, after treatment. For previously untreated angiosarcoma, the authors recommend hyperfractionated radiation therapy followed by surgery to enhance disease control and, in recurring tumors, removing as much reirradiated tissue as possible.

Thirty-six cases of angiosarcoma after irradiation had been reported in the literature, and Edeiken et al.[876] presented two additional patients treated with breast-conserving treatment in whom angiosarcoma developed in the field of prior irradiation. Seven cases of angiosarcoma after radiation therapy for breast-conserving treatment of breast carcinoma had been reported, and the average time between the administration of radiation therapy and development of angiosarcoma was 8.6 years.

Marchal et al.[877] reported on nine breast angiosarcomas identified in a review of 18,115 patients who underwent breast-conserving treatment for carcinomas at 11 French cancer centers over a 20-year period ending in 1997. The estimated prevalence of angiosarcomas after breast-conserving therapy for carcinomas was

5 per 10,000, which is approximately the same as for primary angiosarcomas in healthy breasts. The patients had a mean age of 62.5 years when the primary breast cancer was treated and 69 years when the angiosarcoma was diagnosed. Most angiosarcomas were stage T1N0M0 and were treated with radical mastectomy; two patients underwent reirradiation, and two patients were given adjuvant chemotherapy. The median time to the median survival after diagnosis of an angiosarcoma was 15.5 months. One patient was alive without progression of disease 32 months after a salvage mastectomy and the rest had died.

In a series of 3,295 patients treated with CS and irradiation for breast cancer, Zucali et al.[878] observed three cases of soft tissue sarcoma in irradiated breasts. It appears from these collective experiences that the risk of a second primary tumor in the irradiated breast is too low to justify modification of current policies of conservation therapy of breast cancer.

A rare complication after radical mastectomy is development of lymphangiosarcoma. It is associated with the development of lymphedema in the affected extremity and occurs in approximately 5 of 1,000 patients who had radical mastectomy and survived 5 years.[879]

Cost Versus Benefit in Breast Cancer Treatment

Barlow et al.[880] compared the total medical care costs from a regional nonprofit health management organization of breast conservation therapy versus a mastectomy 5 years after diagnosis in 1,675 women with early-stage breast cancer who had initial diagnoses between 1990 and 1997 and were 35 years of age or older. These women were classified into four groups according to treatment: mastectomy only (group 1, $n = 183$), mastectomy plus adjuvant therapy (group 2, $n = 417$), breast conservation therapy plus radiation therapy (group 3, $n = 405$), and breast conservation therapy plus radiation therapy and adjuvant therapy (group 4, $n = 670$). At 6 months, the costs of the treatments differed significantly ($P < .001$). Breast conservation therapy was more expensive than mastectomy. At 1 year, costs still differed significantly ($P < .001$) but were influenced more by the use of adjuvant therapy. By 5 years, the overall cost for breast conservation therapy was lower than for a mastectomy, presumably because of costs of reconstruction or complications of mastectomy.

Warren et al.[881] linked data of women with breast cancer from the SEER cancer registries with their Medicare claims from 1990 through 1998. Initial care costs for the 6 months after diagnosis for women who underwent breast conservation therapy and irradiation were approximately $450 per month higher

than for women with modified radical mastectomy in the continuing-care phase; costs for women undergoing breast-conserving surgery with radiation therapy were significantly less than for modified radical mastectomy cases. The two groups had similar costs in the terminal-care phase. Long-term costs for women undergoing breast-conserving therapy with radiation therapy were not statistically different from those for women undergoing modified radical mastectomy.

Liljegren et al.[882] evaluated the cost-effectiveness of radiation therapy in a prospective, randomized trial of 381 women treated with sector resection plus axillary dissection with or without radiation therapy in stage I breast cancer. After a median follow-up of 5 years, 43 local recurrences, 6 of them in the radiation therapy group, had occurred ($P < .0001$). No differences in regional and distant metastases or survival rate were observed. Direct medical costs as well as indirect costs, in terms of production lost during the treatment period and travel expenses, were estimated from data in the medical records and the Swedish National Insurance Registry of each patient. Taking into account the cost of primary treatment, follow-up, cost of treatment of a local recurrence, travel expenses, and indirect costs (production lost) and excluding costs for treatment of regional and distant recurrence, the cost per avoided local recurrence at 5 years was $44,438. Adjustment of quality of life showed a cost for every gained quality-adjusted life-year (QALY) to be approximately $210,526. These results stress the importance of identifying risk factors for local recurrence, a better understanding of the impact on quality of life of a local recurrence, and adding cost evaluations to clinical trials in early breast cancer.

Hayman et al.[883] performed a cost-utility analysis of electron beam boost using a Markov model. From a societal perspective, outcomes were measured in QALYs. On the basis of the Lyon trial, the electron-beam boost was assumed to reduce local recurrences by approximately 2% at 10 years but to have no impact on survival. Direct medical, time, and travel costs were considered. The electron-beam boost led to an additional cost of $2,008, an increase of 0.0065 QALY, and an incremental cost-effectiveness ratio of over $300,000 QALY. Even if patients do value a small cancer risk reduction, the mean cost-effectiveness ratio remains high, at $70,859 QALY, which is well above the commonly cited threshold for cost-effectiveness care ($50,000 QALY). The electron beam boost is cost-effective only if patients place an unexpectedly high value on the small absolute reduction in local tumor recurrences achievable with it.

The usage of hypofractionation, with its associated reduced number of treatments, has recently been evaluated with respect to its costs by Bekelman et al.[884] in a retrospective, observational cohort study, using administrative claims data from 14 commercial health care plans covering 7.4% of US adult women. They classified patients with incident early-stage breast cancer treated with lumpectomy and WBI into 2 cohorts: (a) the hypofractionation-endorsed cohort (*n* = 8,924) included patients aged 50 years or older without prior chemotherapy or axillary lymph node involvement and (b) the hypofractionation-permitted cohort (*n* = 6,719) included patients younger than 50 years or those with prior chemotherapy or axillary lymph node involvement. They published that hypofractionated WBI increased from 10.6% in 2008 to 34.5% in the hypofractionation-endorsed cohort and from 8.1% in 2008 to 21.2% in the hypofractionation-permitted cohort. Adjusted mean total health care expenditures in the 1 year after diagnosis were $28 747 for hypofractionated and $31 641 for conventional WBI in the hypofractionation-endorsed cohort. Hypofractionated WBI was associated with savings of 9.1% and 11.8% in the hypofractionation-endorsed cohort and hypofractionation-permitted cohort, respectively. The adjusted mean total 1-year patient out-of-pocket expenses were not significantly different between hypofractionated vs conventional WBI in either cohort.

Psychoemotional Aspects and Quality of Life in Patients with Breast Cancer

Approximately 25% to 35% of patients diagnosed with breast cancer have significant psychosocial distress manifested by anxiety or depression and some level of sexual dysfunction. These disruptive consequences of treatment remain bothersome for at least 2 years after initial therapy. Jensen,[885] in a review of the literature studying psychosocial factors and their relation to breast cancer, revealed major methodologic problems in evaluation of the data, including small sample size, retrospective design, lack of cross-referencing for other important factors, cross-referencing studies instead of longitudinal studies, and insufficient statistical analysis. Regarding psychosocial factors, some of the most valid studies indicate that the risk of getting breast cancer may be connected with difficulties in expressing feelings, especially ones of aggression-coping strategy, amount of stress, and level of activity, which seem to be of possible influence on the prognosis. A possible connection between psyche and the immunologic system has been proposed, but there have been few data to support it.

The specific types, magnitude, and duration of emotional dysfunction of women undergoing breast conservation therapy compared with those treated with mastectomy are highly variable, and although somewhat different, they require the attention and psychotherapeutic support of the treating physicians.[886,887] Radical surgery produces more psychoemotional disruption in terms of feelings about body image, physical attractiveness, and sexuality, whereas lumpectomy and irradiation may interfere temporarily with the patient's lifestyle and may cause worries about cancer and the perceived adverse effects of irradiation. However, at present, this assumption is not supported by research findings; the fear of recurrence has been reported to be similar in women undergoing mastectomy or breast conservation therapy.

A clinical decision analysis on the quality-adjusted life expectancy of patients with breast cancer, comparing a group treated with mastectomy and one treated with breast conservation therapy, showed that breast conservation therapy yields better quality-adjusted life expectancy than mastectomy. However, there are selected subgroups of patients who should preferably undergo mastectomy.[888] Lasry and Margolese,[889] in a comparison of psychological effects on some patients randomly assigned to NSABP protocol B-06, noted that patients who underwent more radical surgery did not express less fear of cancer recurrence than those treated with lumpectomy. The expected tradeoff between breast conservation and increased fear of cancer recurrence did not occur.

Body image, as a component of self-concept, was compared through mailed questionnaires sent to 257 patients treated with mastectomy, mastectomy with delayed reconstruction, mastectomy with immediate reconstruction, or conservation therapy.[890] When analysis of covariance with age was used, body image in the conservation therapy group was significantly more positive than in either the mastectomy group or the mastectomy with immediate reconstruction group. No differences in self-concept were evident among the four groups.

The advantage of breast conservation therapy is psychological because preservation of the configuration of the body maintains the sensation of female identity and body image to a better extent than mastectomy.[371] Breast conservation therapy does not, however, reduce the high frequency of anxiety phenomena, mental instability, and depression. Psychosocial adjustment, body image, and sexual function were retrospectively assessed in 72 women who had partial and 147 women who had total mastectomy and immediate breast reconstruction.[891,892] Questionnaires completed at a mean of 4 years after surgery (44% of questionnaires returned) showed that fewer than 20% of women

reported good adjustment in the areas measured. There was no significant difference between the two groups with regard to body image, sexual attractiveness, or marital happiness. Of 184 women who answered the question, 109 (59%) believed that cancer had brought them closer to their partner, 44 (24%) saw no significant impact, and 31 (17%) believed that cancer had interfered with their relationships. There was no significant differences between the two surgery groups with regard to frequency of sexual expression, desire for sex, or actual sexual activity. Pleasure with breast caressing had decreased since cancer treatment for 44% of women with partial mastectomy and for 83% of those with mastectomy and breast reconstruction. With regard to satisfaction with appearance of the breast, there was no significant difference between the surgical groups.

Schain et al.[887] prospectively studied 142 women participating in clinical trials who were randomly assigned to undergo mastectomy or lumpectomy and radiation therapy. Baseline assessments were made before randomization and at 6, 12, and 24 months after treatment. At 6 months, patients receiving mastectomy reported significantly less control of events in their lives ($P = .003$) and more problems with sexual relations ($P = .021$) than did their conservatively treated counterparts. In addition, there were marked differences between patients receiving mastectomy and those undergoing lumpectomy or irradiation in the degree of distress over body image ($P = .059$ at 24 months). This study concluded that breast conservation therapy protects a woman's perception of her body but does not, over time, contribute to more positive sexual adjustment.

Despite numerous studies of partial mastectomy and psychological morbidity in the first 24 months after surgery, little is known about the long-term psychosocial repercussions. Dorval et al.[893] assessed the effect of the type of mastectomy on psychological adjustment in 124 breast carcinoma survivors, 47 of whom underwent partial mastectomy and 77 total mastectomy, 8 years after initial treatment. Interviews were also conducted 3 and 18 months after surgery. Psychological distress was assessed using the Psychiatric Symptom Index. No statistically significant differences between partial and total mastectomy were observed with respect to long-term quality of life. Among women younger than 50 years of age, partial mastectomy appeared to be protective against distress compared with total mastectomy ($P = .04$). In contrast, among women 50 years of age or older, partial mastectomy was associated with higher psychological distress.

With the increasing use of adjuvant chemotherapy in younger women with

early-stage breast cancer, the long-term impact on quality of life, effects of premature menopause, and changes in perceived sexual attractiveness must be given a high priority for research to improve posttreatment adjustment and satisfaction in these patients.[891,894,895] Women who received chemotherapy were more likely to worry about breast cancer recurrence ($P = .001$), had sex less frequently ($P = .013$), tended to desire sex less frequently ($P = .032$), and had more vaginal dryness ($P < .001$) and dyspareunia ($P < .001$). Their ability to reach orgasm through intercourse tended to be reduced ($P = .043$), and their sexual satisfaction was significantly poorer ($P = .001$). The ability to have orgasm through noncoital caressing did not differ from that of other women. There was a significant correlation between the age of the patient and the frequency of sexual desire and activity.

In two large-scale clinical trials in Switzerland, adjuvant chemotherapy had a measurable effect on health-related quality of life, but this effect was transient and minor compared with the effect of patients' adjustment and coping after diagnosis and surgery.[896]

Ganz et al.[894] conducted a survey of 864 breast cancer survivors. RAND Health Survey scores were as good or better than those of healthy, age-matched women, and the frequency of depression was similar to general population samples. Marital or partner adjustment was similar to that in normal healthy samples, and sexual functioning mirrored that of healthy, age-matched postmenopausal women. However, these breast cancer survivors reported higher rates of physical symptom (e.g., joint pains, headaches, and hot flashes) than healthy women. Sexual dysfunction occurred more frequently in women who had received chemotherapy (all ages) and in younger women who were no longer menstruating. In women 50 years of age and older, tamoxifen therapy was unrelated to sexual functioning. Clinicians should inquire about common symptoms to provide symptomatic management or counseling for these women.

Ganz et al.[895] also surveyed 1,096 women diagnosed with early-stage breast cancer between 1 and 5 years earlier in two large metropolitan centers in the United States; 356 had received tamoxifen alone, 180 chemotherapy alone, 395 chemotherapy and tamoxifen, and 265 received no adjuvant therapy. No significant differences in global quality-of-life or in depression scores were observed among the four treatment groups. The group receiving no adjuvant therapy had a physical functioning composite score that was at the mean for a normal population of healthy women, whereas those in the adjuvant treatment groups scored slightly lower. The mental health score was not significantly

different among the four treatment groups and approximated scores from the normal population of healthy women. Overall, breast cancer survivors function at a high level, similar to healthy women without cancer. However, compared with survivors with no adjuvant therapy, those who received chemotherapy have significantly more sexual problems, and those treated with tamoxifen experience more vasomotor symptoms.

Nissen et al.[897] carried out a quality-of-life study in women 30 to 85 years of age with newly diagnosed breast carcinoma who underwent breast-conserving surgery (n = 103), mastectomy alone (n = 55), or mastectomy with reconstruction (n = 40). Quality of life was assessed after diagnosis (baseline) and at 1, 3, 6, 12, 18, and 24 months. Women who underwent mastectomy with reconstruction had greater mood disturbance (P = .002) and poorer well-being (P = .002) after baseline than women who had mastectomy alone, and these differences remained 18 months after surgery. The breast-conserving surgery and mastectomy-only groups did not differ significantly regarding well-being.

CONCLUSION

Radiation therapy plays an essential and critical role in the management of breast cancer, the most common cancer diagnosed in women. Early detection by mammography, followed by appropriate oncologic therapy, may be associated with reduced breast cancer mortality rates for women aged 50 years and older. After breast-conserving surgery, WBI improves local control and survival rates in appropriately selected patients and therefore should be considered for all patients. The development of molecular signatures predictive for LRR may revolutionize how we select patients for radiotherapy; significant progress has been made in this area with systemic therapy but similar work is needed with regard to locoregional therapies. Accelerated forms of treatment including HWBI and APBI may increase the utilization rate of radiotherapy after breast-conserving surgery. Ongoing research will help to further define the safety and acceptability of these techniques in women with early-stage breast cancer.

CHAPTER 60

Breast Cancer: Locally Advanced, Part 1

Ron Y. Shiloh, Brandon A. Mahal, Serena Wong, Atif J. Khan, and Jennifer R. Bellon

BACKGROUND

This chapter focuses on the management of locally advanced breast cancer as well as locally recurrent breast cancer and selected unusual presentations of breast cancer. The emphasis is on locoregional control and radiation therapy, though systemic treatments are also reviewed.

Locally advanced breast cancer is not clearly defined, though it commonly refers to stage III disease, which includes advanced primary or nodal disease without evidence of systemic metastases. Patients who present with locally advanced breast cancer require care from a multidisciplinary team that includes radiologists, pathologists, surgical oncologists, medical oncologists, and radiation oncologists. Incorporating and coordinating the input of each specialty is of utmost importance in the management of patients with locally advanced disease, as these patients are at high risk of disease recurrence and require complex decision-making.

Fortunately, the outcome for patients who present with locally advanced breast cancer has improved substantially in recent decades. Prior to the routine use of chemotherapy, patients treated with mastectomy, radiation, or both had high rates of distant metastases and death.[1–3] Chemotherapy and hormone therapy regimens in both the neoadjuvant and adjuvant settings have significantly improved the prognosis. By decreasing the burden of distant metastases, modern chemotherapy and biologic therapies have also resulted in increased importance of local disease control.

EPIDEMIOLOGY

Between 1980 and 1987, the incidence of breast cancer increased by approximately 4% each year, due in large part to the increase in the use of screening mammography.[4] Between 1987 and 1994, the incidence remained constant and then increased again at a 1.6% rate from 1994 to 1999. Since 1999, there has been a steady decrease in incidence by 2% a year. There was a

particularly sharp drop of 7% between 2002 and 2003, likely because of the decreased use of menopausal hormones after the 2002 publication of clinical trial results that demonstrated an association between hormone replacement and increased rates of breast cancer and cardiovascular disease.[4] Between 1988 and 2000, there was a steady increase in tumors diagnosed at a size of 2.0 cm or less, but since 2000, this incidence rate has decreased by 3.3% per year, and the rate of tumors of >5.0 cm has increased by 2% per year since 1992.[4] A few reasons have likely contributed to the decline in the percentage of cases of locally advanced disease at diagnosis during the late 1980s. First, mammographic screening resulted in a larger proportion of patients being diagnosed with breast cancer at earlier stages. Second, an increase in women's health initiatives and public education efforts prompted women to seek medical care at the first sign of a breast mass. Finally, the medical community has become better educated about appropriate standards for evaluating a breast mass.

An estimated 252,710 new cases of breast cancer will be diagnosed in women in 2017, and an estimated 40,610 breast cancer deaths will occur, according to the American Cancer Society.[4] As illustrated in Figure 60.1, the incidence of breast cancer is highest in the non-Hispanic White population and lowest in the Asian/Pacific Islander population. However, mortality is highest in the non-Hispanic Black population; it is 1.4 times higher than mortality in the non-Hispanic White population and 2.7 times higher than mortality in the Asian/Pacific Islander population, the population with the lowest mortality.

This significant difference in mortality has been attributed to both biologic and socioeconomic factors. Black women have been noted to be diagnosed more frequently with breast cancers of higher nuclear grade and estrogen receptor–negative disease compared with white women. Differences in access to medical care and screening mammography have also contributed to this disparity.[5,6]

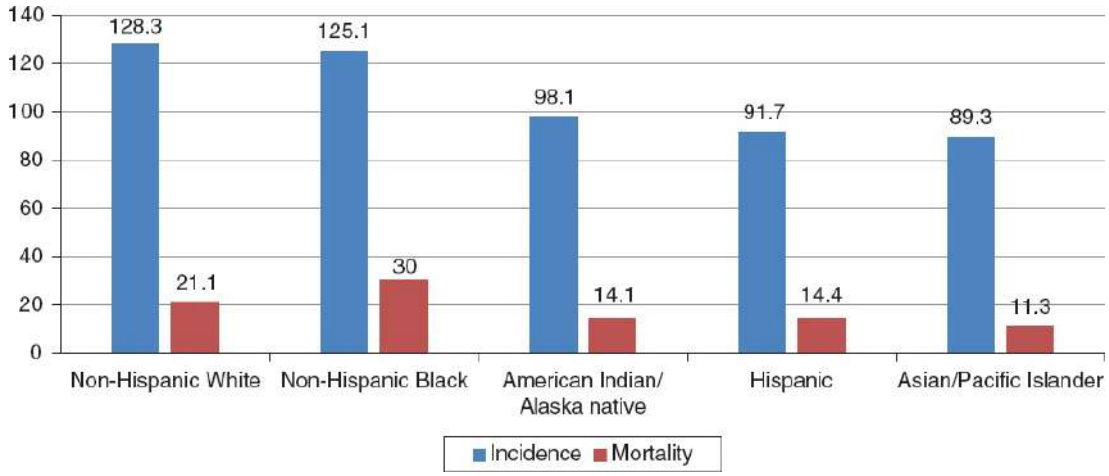

FIGURE 60.1. Female breast cancer incidence and mortality rates per 100,000 by race and ethnicity in the United States in 2008 to 2012. (From Copeland G, Lake A, Firth R, et al., eds. *Cancer in North America: 2008–2012. Volume one: combined cancer incidence for the United States, Canada and North America*. Springfield, IL: North American Association of Central Cancer Registries, Inc., 2012).

NATURAL HISTORY

Prior to recent decades, a diagnosis with locally advanced breast cancer portended a poor prognosis. However, treatment advances have allowed many individuals with locally advanced disease to be cured. The clinical course of locally advanced breast cancer may vary based on several factors, including the specific disease characteristics at presentation, the biologic features of the cancer, and the treatment given.

Locally, as disease grows within the breast, the tumor may infiltrate or invade the dermis or chest wall. Invasion of Cooper ligaments may lead to skin retraction; this can also occur in early-stage disease but is more likely as the tumor grows. When lymphatic drainage of the breast or skin occurs, edema may occur, leading to dilated dermal hair follicles appearing like the skin of an orange; this peau d'orange appearance is sometimes associated with inflammatory breast cancer (IBC).

Because of the propensity of larger tumors to invade the lymphatic system, most advanced primary tumors have spread to the axillary lymph nodes at the time of diagnosis. The axillary lymph node region is divided into three levels, each defined in relationship to the pectoralis minor muscle. Level I lymph nodes are inferolateral to the muscle, level II lymph nodes are beneath the muscle, and level III lymph nodes are superomedial to the muscle. Level III lymph nodes are also known as infraclavicular lymph nodes. Other lymph nodes that may be

involved include the supraclavicular nodes, internal mammary (IM) nodes, and Rotter nodes, located between the pectoralis minor and major muscles. Figure 60.2 shows computed tomography (CT) scans from patients with locally advanced breast cancer presenting with involvement of the level II axilla (Fig. 60.2A), an infraclavicular lymph node (Fig. 60.2B), a Rotter lymph node (Fig. 60.2C), and an IM lymph node (Fig. 60.2D).

Local disease progression can lead to ulceration of the breast skin, pain, bleeding, and infection. In addition to these sequelae, arm edema, brachial plexopathy, and obstruction and thrombosis of the brachial vasculature may also occur due to progression of regional lymphatic disease. Primary tumor growth also increases the risk of spread through the lymphatic system to regional lymph nodes or hematogenous spread to distant sites like the liver, lung, bone, and brain. Without treatment, almost all locally advanced breast cancers will metastasize to visceral organs and eventually become life threatening.[1,2]

Survival rates for women with locally advanced breast cancer have improved due to treatment advances. Before the use of systemic treatment became a standard of care, individuals with advanced disease treated with mastectomy, radiation therapy, or both had 5-year survival rates of only 25% to 45%.[1–3] After the introduction of combined modality treatments including surgery, radiation therapy, and chemotherapy, the 5-year survival rates have approached 80% for patients with stage IIA disease and 45% for patients with stage IIIB disease.[7] Continued improvement has been observed with the addition of even more effective systemic regimens.

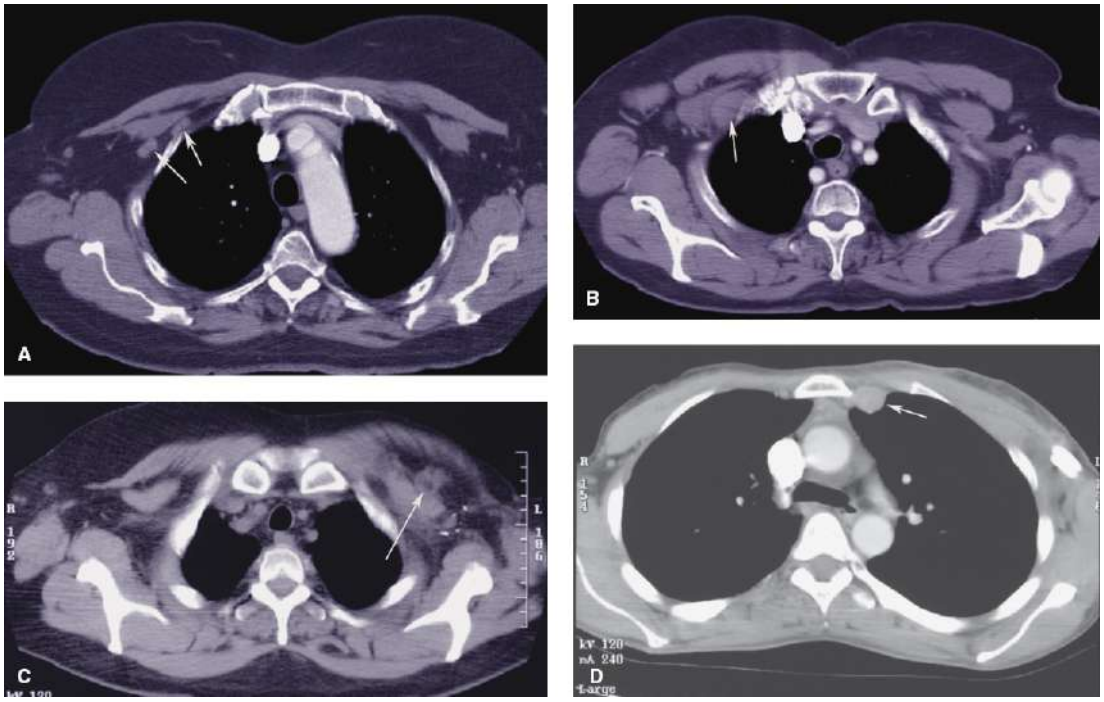

FIGURE 60.2. CT images of patients with lymph node involvement at the time of diagnosis. **A:** Image from a patient with involvement of axillary lymph nodes in the level II axilla. The *white arrows* show the involved lymph nodes, which are just beneath the pectoralis minor muscle. **B:** An involved level III axillary lymph node (*white arrow*) that extends superomedially to the pectoralis minor muscle. **C:** An involved Rotter lymph node (*white arrow*), which is anterior to the pectoralis minor and beneath the pectoralis major muscle. **D:** Image from a patient with an involved IM lymph node (*white arrow*).

Although treatment advances may be credited for much of the improvement in prognosis for individuals with stage III disease in recent decades, it is important to recognize how stage migration has affected the statistics as well. Diagnostic imaging has improved over the same time period, increasing the likelihood of detecting metastatic disease. As a result, some cases that would have been classified as stage III historically may now be classified as stage IV. The reclassification of patients with a relatively low burden of metastatic disease from stage III to stage IV may improve the outcome statistics for both stage III and stage IV diseases. A similar effect was introduced by the 2003 change in the American Joint Committee on Cancer (AJCC) breast cancer staging system, which incorporated the number of positive lymph nodes in the pathologic disease stage. Specifically, many patients with four or more positive lymph nodes in the past would have had stage II disease but are classified as having stage III disease in the 2003 staging system. Indeed, a study that compared the stage-specific survival of 1,350 patients staged according to the 1988 AJCC

staging system to the stage-specific survival of the same patients restaged according to the 2003 AJCC system found that the 10-year overall survival (OS) rates were significantly higher when the 2003 system was used, both for patients with stage II disease (76% [2003] vs. 65% [1988], $P < .0001$) and for those with stage IIIA disease (59% [2003] vs. 45% [1988], $P < .0001$).[8] The reason for the better stage-specific outcome was that restaging into the 2003 system led to most of the patients with four or more positive lymph nodes being moved from stage II to the stage III category.

PATHOLOGY AND BIOLOGY OF LOCALLY ADVANCED BREAST CANCER

The histopathology of locally advanced disease is similar to that of early-stage disease. Both of the most common subtypes, infiltrating ductal carcinoma and lobular carcinoma, can present as early-stage or locally advanced disease. However, those subtypes considered to behave less aggressively (e.g., tubular carcinoma, mucinous carcinoma, and medullary carcinoma) are unlikely to present at advanced clinical stages unless the breast mass has been present for a long time.

The term “locally advanced breast cancer” encompasses a biologic spectrum of diseases. Locally advanced disease that has developed between annual interval screening mammograms is most often ER-negative with a high nuclear grade and a high proliferative index. These cancers may be of the luminal B, nonluminal Her-2–positive, or triple-negative subtypes. In contrast, patients who present with extensive locoregional disease after years of medical neglect more often are found to have ER-positive disease with a low nuclear grade and a low proliferative index (luminal A subtype). IBC also has biologic characteristics that differ from those of non-IBC; these will be discussed further in the section on IBC later in this chapter.

CLINICAL PRESENTATION OF LOCALLY ADVANCED BREAST CANCER

Locally advanced breast cancer most commonly is diagnosed after a palpable mass is detected within the breast. Advanced disease can cause symptoms such as local or regional pain, bleeding, paresthesia, and paresis. As previously indicated, it is critically important to determine the onset of symptoms and the

rate of disease progression to reach an accurate diagnosis as to whether an advanced breast cancer should more accurately be designated an inflammatory carcinoma.

Diagnostic Workup

For patients with locally advanced breast cancer, the workup should start with a careful history and physical examination. The breast examination should include note of the breast symmetry, as well as careful inspection for involvement or edema of the skin. Peau d'orange and skin erythema can sometimes be subtle, particularly in non-Caucasian women; comparison with the contralateral side can often be helpful.

Other times, physical examination findings are more obvious. Figure 60.3 shows a photograph of a patient with a neglected locally advanced breast cancer presenting with peau d'orange, breast retraction and involution, and effacement of the nipple–areola complex. Medical photographs are highly helpful to document the extent of visible abnormalities before treatment is begun and can also be used to assess disease response.

The extent of palpable disease should also be measured and documented. Fixation of a breast mass to the pectoralis muscle or chest wall should be determined by assessing the mobility of the mass with the pectoralis muscle relaxed and contracted. Regional lymph nodes should be thoroughly evaluated by careful clinical examination with the patient in both supine and sitting positions. Clinical nodal evaluation may be supplemented with ultrasonographic imaging coupled with fine needle aspiration of suspicious lymph nodes.[9]

All cases of locally advanced disease require complete staging before initiation of therapy. Laboratory studies should include a complete blood cell count and serum chemistry profile with liver function tests. Radiographic studies should include a CT scan of the chest, abdomen, and pelvis, a bone scan, and plain radiographs of symptomatic regions or areas of increased uptake on bone scans. If any neurologic symptoms suggestive of cerebral metastases are present, a contrast-enhanced CT scan or gadolinium-enhanced magnetic resonance imaging (MRI) scan of the brain should be obtained. Gadolinium-enhanced MRI is the preferred imaging technique if leptomeningeal carcinomatosis is suspected. There are early data suggesting that subsets of women with breast cancer may have a higher risk of brain disease and may be appropriately screened with MRI. These include women with HER2-positive and triple-negative subtypes who present with extracranial metastatic disease[10] and women

with IBC who present with extracranial metastases.[11]

There is increasing interest in the use of [^{18}F]fluorodeoxyglucose positron emission tomography (PET)/CT for disease staging of patients with locally advanced breast cancer, particularly those with IBC. Several small retrospective studies have shown that PET/CT increases detection of both previously unsuspected sites of metastatic disease as well as additional sites of extra-axillary nodal disease when compared to conventional imaging.[12,13] Researchers from MD Anderson showed that the addition of PET/CT in the staging of 41 women with IBC not only detected new sites of disease in 44% of patients when compared to standard imaging but also resulted in a change in radiation doses or fields in 18%.[14]

FIGURE 60.3. Photograph of a patient with a neglected locally advanced breast cancer presenting with peau d'orange, breast retraction and involution, and effacement of the nipple–areola complex.

Staging of Locally Advanced Breast Cancer

A comprehensive discussion of disease staging systems for breast cancer is provided in the previous chapter. Some staging considerations are particularly relevant to patients with stage III disease. Stage III breast cancer can represent either T3 disease (tumors >5.0 cm) with involved lymph nodes, N2 or N3 disease, or T4 disease.[15]

Specific aspects of both primary tumor and nodal staging in locally advanced breast cancer warrant additional consideration. Specifically, T4 disease may represent invasion into the chest wall (T4a), tumors associated with breast edema or skin ulceration or satellite nodules (T4b), both invasion and T4b characteristics (T4c), or IBC (T4d). Invasion of disease into the pectoralis major muscle without chest wall invasion and dimpling or fixation of the overlying skin does not qualify as T4 disease. Both clinical and pathologic staging systems have been established for N2 and N3 disease. Clinical N2 disease signifies either involved axillary lymph nodes that are fixed to one another or to surrounding structures (N2a) or involved IM lymph nodes without concurrent disease in the axilla (N2b), as determined by physical examination or imaging studies. Clinical N3 disease is a disease that involves the infraclavicular region (N3a), both the axilla and IM lymph nodes (N3b), or the supraclavicular region (N3c). Pathologic N2 disease represents involvement of 4 to 9 axillary lymph nodes with at least 1 focus measuring >2.0 mm (N2a) or clinical involvement of IM lymph nodes with pathologically negative axillary lymph nodes (N2b). Pathologic N3 disease represents involvement of an infraclavicular lymph node or 10 or more involved lymph nodes with at least 1 focus measuring >2.0 mm (N3a), clinical involvement of IM lymph nodes with 1 to 9 axillary lymph nodes involved, pathologic involvement of a sentinel IM lymph node with 4 or more axillary lymph nodes involved (N3b), or a metastasis in the supraclavicular region (N3c).[15]

Neoadjuvant chemotherapy is recommended for most patients with locally advanced breast cancer. The initial extent of disease is an important factor for later locoregional treatment decisions and for future research. It is therefore imperative that disease in all patients be carefully assigned a clinical stage before any treatment is begun.

OVERVIEW OF TREATMENT

Combined Modality Therapy

Locally advanced breast cancer is most appropriately treated with multimodality therapy aimed at eradicating all disease in the locoregional area and preventing distant disease recurrence. These goals are best achieved through the use of systemic therapy (generally chemotherapy and, when appropriate, endocrine and HER2-directed therapy), surgery, and radiation.

Locally advanced breast cancer can present as either operable or inoperable

disease. In general, the disease is considered to be inoperable if an initial surgical procedure is unlikely to completely resect all gross disease with achievement of negative surgical margins. Most patients with T4 disease and all patients with IBC are considered to be inoperable at presentation. Inoperable disease requires the administration of upfront systemic therapy to reduce tumor volume in order to facilitate definitive local therapy. Neoadjuvant therapy (also known as preoperative or primary systemic therapy) usually takes the form of chemotherapy, although, in certain situations as discussed later on, endocrine therapy may also be an option. In addition to downstaging the tumor, systemic therapy also reduces the risk of recurrence and breast cancer mortality by eradicating occult micrometastatic disease and aiding radiation in obtaining long-term local control.

Patients who have operable disease at the time of presentation have the option of either receiving neoadjuvant chemotherapy or proceeding directly with definitive surgery followed by adjuvant systemic therapy at a later date. Multiple studies have demonstrated equivalent survival and distant disease recurrence rates between the two approaches,[16,17] and each approach has its own merits.

Neoadjuvant Chemotherapy

The landmark NSABP B-18 trial randomized 1,523 patients with operable breast cancer to receive neoadjuvant doxorubicin and cyclophosphamide (AC) for 4 cycles followed by surgery versus surgery followed by 4 cycles of AC. Although this trial included only patients with operable breast cancer, the results demonstrated the feasibility of preoperative chemotherapy. The planned surgical approach was determined prior to randomization, with approximately two-thirds of patients in each group deemed initially eligible for lumpectomy. There was no difference in OS or disease-free survival (DFS) between the two groups, but a larger proportion of patients who received neoadjuvant chemotherapy were able to undergo breast-conserving surgery (BCS) compared to those who received adjuvant chemotherapy (68% vs. 60%).[18,19] This increase was largely due to a higher percentage of patients with T3 disease being offered breast conservation after responding to neoadjuvant chemotherapy. The percentage of patients with pathologically negative nodes was also higher in the neoadjuvant group compared to the adjuvant group (59% vs. 43%, $P < .001$). Results from another pivotal neoadjuvant trial EORTC 10902 also demonstrated an increase in the percentage of patients eligible for BCS, with 23% of patients initially requiring mastectomy being able to undergo lumpectomy after the receipt of

chemotherapy. OS and recurrence rates were equivalent between the preoperative and postoperative chemotherapy groups.[20]

Patients with locally advanced breast cancer who have complete clinical resolution of skin changes and chest wall involvement may also be offered breast conservation therapy. This has been demonstrated in a study reviewing outcomes of 340 patients treated with neoadjuvant chemotherapy followed by BCS and radiation therapy. In that study, patients with T3 or T4 disease were found to have acceptably low rates of locoregional recurrence and ipsilateral breast tumor recurrence. Those with T4 disease and those with N2–N3 disease had a 5-year IBTR-free survival rate of 92% and 89%, respectively, and both had a 5-year LRR-free survival rate of 84%.[21]

A key finding that emerged from the early neoadjuvant trials was the correlation between response to therapy and long-term outcome. In B-18, patients who achieved a pathologic complete response (pCR) in the breast after neoadjuvant chemotherapy had improved DFS (hazard ratio [HR] 0.47, $P = .0001$) and OS (HR 0.32, $P = .0001$) compared to those who did not.[22] This finding has been replicated in several other studies, though the definition of pCR varied, with some studies using the definition of absence of invasive tumor in the breast and nodes and others the absence of invasive disease in the breast. The currently accepted definition of pCR is the lack of residual invasive cancer in the breast and nodes. Patients who achieve a pCR consistently demonstrate improved long-term outcomes compared to those with significant residual disease.[23,24]

In addition to downstaging the tumor to improve surgical outcomes and providing valuable prognostic information, neoadjuvant chemotherapy also allows an *in vivo* assessment of the tumor's response to chemotherapy. Patients whose tumors demonstrate resistance to initial therapy should be offered a non–cross-resistant regimen or proceed directly to local therapy. It should be noted, however, that the benefit of transitioning to an alternate chemotherapy regimen in nonresponding patients is unclear. In the GeparTrio trial, patients who did not respond to two cycles of docetaxel/doxorubicin/cyclophosphamide (TAC) were randomized to four additional cycles of the same regimen or to four cycles of vinorelbine/capecitabine (NX). pCR rates were similarly low in both groups of these nonresponders (5.3% in the TAC group vs. 6.0% in the NX group). In contrast, patients who responded initially achieved a pCR rate of 21% after 6 additional cycles of TAC and 23.5% after 8 additional cycles.[25] It appears that tumors that are resistant to one chemotherapy regimen tend to be broadly

chemoresistant, posing a significant management challenge.

For patients with locally advanced but operable disease at presentation, primary surgery followed by adjuvant therapy may be a consideration. A potential advantage of this approach is a shorter time interval between diagnosis and effective treatment for patients with disease that is resistant to chemotherapy. Primary surgery also allows for more accurate pathologic staging of the tumor and axillary nodes, which is important to guide prognosis and selection of appropriate adjuvant treatment. However, the amount of residual disease after neoadjuvant chemotherapy may ultimately provide a more individualized assessment of prognosis. Furthermore, tumor biology has become a driving force in the selection of appropriate systemic therapy, and appropriate treatment decisions can often be made at the time of diagnosis based on the clinical stage and molecular subtype of the tumor. Given equivalent DFS and OS between the two approaches, there has been a paradigm shift in the treatment of locally advanced breast cancer, with increased use of neoadjuvant chemotherapy.

As discussed above, pathologic evaluation of the tumor bed and lymph nodes after neoadjuvant chemotherapy provides important prognostic information. However, the value of pCR as a prognostic tool is highly dependent on the molecular subtype of the tumor. Tumors that are highly proliferative (luminal B, nonluminal/HER2-positive, and triple-negative) tend to demonstrate increased chemosensitivity and are associated with higher rates of pCR compared to low proliferative subtypes with high expression of hormone receptors (luminal A).[26] pCR appears to be most predictive of DFS and OS in nonluminal/HER2-positive (treated with trastuzumab) and triple-negative subtypes, with those achieving a pCR having an excellent prognosis and those with significant residual disease having a high risk of recurrence and overall worse survival. pCR in patients with luminal A tumors does not appear to be a good predictor of long-term outcome, whereas the utility of pCR as a predictive tool in patients with luminal B (HER2-negative or HER2-positive) tumors seems to be better than for luminal A tumors but worse than for nonluminal/Her2-positive or triple-negative tumors.[24,26]

Neoadjuvant Endocrine Therapy

Given the lower response rates to neoadjuvant chemotherapy in patients with tumors having high hormone receptor expression, there has been interest in evaluating the role of neoadjuvant endocrine therapy in this population. The IMPACT trial randomized 330 postmenopausal patients with clinical stage II or III HR+ breast cancer to receive tamoxifen versus anastrozole versus tamoxifen

plus anastrozole for 12 weeks. There was no difference in clinical and radiographic response rates among the three groups, but a higher percentage of women receiving anastrozole were eligible for BCS compared with those receiving tamoxifen (44% vs. 22%, *P* = .022). The authors also found that higher expression of ER was associated with increased response rates.[27] P024 compared the efficacy of letrozole to tamoxifen in the neoadjuvant setting in 324 postmenopausal women with hormone receptor–positive breast cancer. After 16 weeks, treatment with letrozole resulted in improved clinical response rates compared to treatment with tamoxifen.[28]

Neoadjuvant endocrine therapy may therefore be considered for postmenopausal patients whose tumors are of low- to intermediate-grade and express high levels of ER. Treatment with an aromatase inhibitor appears to be superior to tamoxifen, and the recommended duration is at least 4 to 6 months. The choice of aromatase inhibitor is a matter of personal preference, as all 3 third-generation aromatase inhibitors have demonstrated similar response rates, reductions in Ki67 levels, and rates of conversion to BCS when compared head-to-head.[29] The use of neoadjuvant endocrine therapy in the premenopausal population has not been established.

Choice of Systemic Agents in the Neoadjuvant Setting

Neoadjuvant Chemotherapy for HER2-Negative Disease

The optimal neoadjuvant chemotherapy regimen for patients with HER2-negative disease has not been established, but it is generally accepted that regimens with proven effectiveness in the adjuvant setting may also be used in the neoadjuvant setting. Because patients with locally advanced breast cancer are considered to have high-risk disease, a regimen containing an anthracycline and taxane is generally preferred.

These recommendations are based on results from the Early Breast Cancer Trialists' Collaborative Group meta-analyses, which demonstrated that adjuvant polychemotherapy reduced the risk of recurrence and breast cancer mortality in patients with node-positive and node-negative disease.[30] Anthracycline-based regimens were found to be superior to CMF (cyclophosphamide, methotrexate, fluorouracil) regimens, and the addition of taxanes to anthracyclines further improved outcomes.[31] Overall, taxane-plus-anthracycline–based regimens reduced 10-year breast cancer mortality by one-third.

NSABP B-27 established the role of adding a taxane after an anthracycline-based regimen in the neoadjuvant setting. In this study, 2,411 patients were

randomized to one of three groups: 4 cycles of AC followed by surgery versus AC followed by 4 cycles of docetaxel followed by surgery versus AC followed by surgery and then 4 cycles of docetaxel in the postoperative setting. The addition of docetaxel to AC prior to surgery resulted in a doubling of pCR rate (26% vs. 13%; $P < .001$). There was no significant improvement in DFS or OS with either preoperative or postoperative docetaxel for the overall study population. However, achievement of pCR was a significant predictor of OS regardless of treatment (HR 0.33; 95% CI, 0.23 to 0.47; $P = .0001$).[32] In a subset analysis, patients who achieved a clinical partial response after AC had improved DFS with preoperative, but not postoperative, docetaxel (HR 0.71; 95% CI, 0.55 to 0.91; $P = .007$). Based on these findings, outside of a clinical trial, it is preferable to administer the entire chemotherapy regimen prior to surgery if possible.

For patients with contraindications to anthracyclines or taxanes, alternate regimens are available (Table 60.1). A non–anthracycline-containing regimen may be preferred in patients who have cardiac disease or who have other risk factors for anthracycline-associated congestive heart failure such as hypertension, diabetes, or advanced age. For patients with a hypersensitivity reaction to solvent-based paclitaxel, nanoparticle albumin–bound paclitaxel (nab-paclitaxel) may be used. In GeparSepto, patients were randomized to 12 weeks of weekly paclitaxel (80 mg/m^2) versus weekly nab-paclitaxel (initially 150 mg/m^2 but later reduced to 125 mg/m^2 because of toxicities) and followed by epirubicin plus cyclophosphamide in the neoadjuvant setting. There was a higher pCR rate in the group receiving nab-paclitaxel (38% vs. 29%, $P = .00065$), but there was also a higher rate of grade 3 to 4 sensory neuropathy and anemia. It is not yet known whether the improvement in pCR will translate into a survival benefit.[33]

TABLE 60.1 RECOMMENDED NEOADJUVANT/ADJUVANT CHEMOTHERAPY REGIMENS FOR HER2-NEGATIVE BREAST CANCER (PER NCCN GUIDELINES VERSION 1.2018)

Preferred Regimens

Dose-dense AC (every 2 wk with filgrastim support) × 4 followed by dose-dense paclitaxel (every 2 wk with filgrastim support) × 4

Dose-dense AC × 4 followed by weekly paclitaxel × 12 wk

TC every 3 wk × 4

Other Regimens

Dose-dense AC × 4

AC every 3 wk × 4
CMF every 28 d × 6
AC × 4 followed by docetaxel every 3 wk × 4
AC followed by weekly paclitaxel
EC every 3 wk × 8
TAC every 3 wk × 6

AC, doxorubicin/cyclophosphamide; CMF, cyclophosphamide/methotrexate/fluorouracil; EC, epirubicin/cyclophosphamide; TAC, docetaxel/doxorubicin/cyclophosphamide; TC, docetaxel/cyclophosphamide.

Several studies have examined the role of adding additional cytotoxic agents such as capecitabine and gemcitabine to anthracycline-plus-taxane–based regimens. However, incorporation of these agents has been associated with added toxicities without improvements in pCR or survival.[34,35] Some studies have demonstrated an improvement in pCR rates in subsets of patients with the addition of the angiogenesis inhibitor bevacizumab, but use of the drug has also been associated with increased toxicities (hypertension, bleeding, thromboembolic events, surgical complications), and it remains unclear which patients are most likely to derive benefit. Furthermore, studies in the adjuvant setting have not demonstrated an improvement in survival with bevacizumab. Given the above, antiangiogenic agents should not be routinely used outside of a clinical trial setting.

The role of adding carboplatin in the treatment of triple-negative breast cancer has garnered particular interest. Results from two randomized trials demonstrated significantly higher pCR rates with the incorporation of platinum to an anthracycline-plus-taxane–based regimen in this population. In CALGB 40603, every-3-week carboplatin added to weekly paclitaxel followed by dose-dense AC-x 4 resulted in an increased pCR rate in the breast and axilla (54% vs. 41%; $P = .0029$) but did not result in an improved 3-year EFS or OS.[36,37] Patients who achieved a pCR had significantly lower event rates and mortality, but these improved outcomes were not specifically associated with receipt of carboplatin. On the other hand, in GeparSixto, patients were randomized to weekly paclitaxel and liposomal doxorubicin, with or without weekly carboplatin. In the subset of patients with TNBC, pCR rates improved from 37% to 53% ($P = .005$) with the addition of carboplatin. In addition, a significant improvement in DFS in these patients was also observed (85.8% vs. 76.1%, HR 0.56, $P = .035$).[38,39] Given the conflicting results from these two trials and the added toxicities associated with carboplatin, the routine incorporation of carboplatin in the neoadjuvant setting is not generally recommended. It can, however, be considered in patients who need a rapid response or greater

cytoreduction for optimal locoregional management.

Neoadjuvant Chemotherapy for HER2-Positive Disease

One of the most significant advances in breast cancer treatment has been the introduction of trastuzumab, a monoclonal antibody directed against the HER2 protein, into the adjuvant treatment for patients with HER2-overexpressing cancer. Several prospective randomized trials have demonstrated that the addition of trastuzumab to chemotherapy in the adjuvant setting confers an approximate 50% improvement in DFS and 35% improvement in OS in this population.[40,41] Subsequent studies in the neoadjuvant setting have confirmed an important role for trastuzumab in the neoadjuvant setting as well, although there are few data comparing different chemotherapy regimens.

In the phase II NOAH trial, the addition of trastuzumab to a neoadjuvant anthracycline- and taxane-containing regimen resulted in a pCR rate of 38% compared to 19% with chemotherapy alone. More women in the trastuzumab arm were able to undergo BCS (23% vs. 13%), and EFS was also improved (58% vs. 43%).[42] In a meta-analysis, the addition of trastuzumab to neoadjuvant chemotherapy resulted in an improvement in pCR rate from 23% to 40% in women with HER2+ breast cancer. pCR was also found to be a predictor of EFS (HR 0.39; 95% CI, 0.31 to 0.50) and OS (HR 0.34; 95% CI, 0.24 to 0.47).[24]

More recently, the development of pertuzumab, a monoclonal antibody that binds to the HER2 protein at the site of HER2/HER3 dimerization, has led to even further improvements in pCR rates when added to trastuzumab and chemotherapy. NeoSphere was a phase 2 study of 417 patients with HER2+ breast cancer who were randomized to receive neoadjuvant therapy with 4 cycles of docetaxel/trastuzumab versus docetaxel/trastuzumab/pertuzumab versus trastuzumab/pertuzumab versus docetaxel/pertuzumab. Following surgery, all patients received an anthracycline in the adjuvant setting. pCR rates were 29%, 46%, 17%, and 24%, respectively.[43]

The benefit of adding pertuzumab to chemotherapy and trastuzumab was corroborated by results from the phase II TRYPHAENA trial, which yielded a pCR rate of 56% in patients receiving neoadjuvant FEC (fluorouracil, epirubicin, cyclophosphamide)-THP (docetaxel, trastuzumab, pertuzumab) and 64% for TCHP (docetaxel, carboplatin, trastuzumab, pertuzumab).[44] Based on the results of these two studies and the improvement in DFS that was subsequently demonstrated when pertuzumab was added to trastuzumab and chemotherapy in the adjuvant setting,[45] the FDA granted approval for the use of pertuzumab in

the neoadjuvant treatment of patients with HER2-positive, locally advanced, inflammatory, or early stage breast cancer (either greater than 2 cm in diameter or node positive).

Table 60.2 lists recommended regimens for treatment of HER2-positive breast cancer.

TABLE 60.2 RECOMMENDED NEOADJUVANT/ADJUVANT REGIMENS FOR HER2-POSITIVE BREAST CANCER (PER NCCN GUIDELINES VERSION 1.2018)

Preferred Regimens[a]
AC × 4 followed by paclitaxel + trastuzumab ± pertuzumab (various schedules)
TCH ± pertuzumab
Paclitaxel + trastuzumab (for low-risk stage I disease)
Other Regimens[a]
AC × 4 followed by docetaxel + trastuzumab ± pertuzumab various schedules
TC × 4 + trastuzumab

[a]Following completion of chemotherapy, trastuzumab should be continued in the adjuvant setting to complete 1-y total of anti-HER2 therapy.
AC, doxorubicin/cyclophosphamide; FEC, fluorouracil/epirubicin/cyclophosphamide; TC, docetaxel/cyclophosphamide; TCH, docetaxel/carboplatin/trastuzumab.

Selection of Patients for Breast-Conserving Surgery

The decision to offer BCS is dependent on the extent of tumor present after completion of neoadjuvant therapy and the breast size relative to residual tumor size. Clinical and radiographic assessments are used to determine eligibility for BCS. In those patients who undergo BCS after neoadjuvant chemotherapy, advanced nodal involvement at diagnosis, residual tumor larger than 2 cm, multifocal residual disease, and lymphovascular space invasion predict higher rates of LRR and IBTR.[21] Although the presence of these features should not preclude BCS, they are relevant prognostic factors, and mastectomy may be considered in patients who possess multiple risk factors after neoadjuvant chemotherapy. It is important to note that a complete clinical or radiographic response may still be associated with residual disease on pathologic examination of the final surgical specimen. The discrepancy may be due to persistence of scattered areas of invasive cancer in a background of tumor that has been partially eradicated in a fragmented fashion, or of intraductal cancer, which is not affected by chemotherapy.

All areas containing cancer must be resected to provide optimal breast cancer

outcomes. In a meta-analysis of 9 randomized trials, a higher rate of BCS was seen in patients who had received neoadjuvant chemotherapy compared to those who had received adjuvant therapy. Although there was no difference in OS and distant disease recurrence between the two groups, there was an increased risk of locoregional recurrence in the group that received neoadjuvant chemotherapy. However, these results were confounded by the inclusion of three trials in which patients who achieved a clinical complete response (CR) received radiation but were not required to undergo surgery.[16] After excluding these trials, locoregional recurrence rates were similar between neoadjuvant and adjuvant groups.[17] These results underscore the importance of performing definitive surgery in all patients undergoing neoadjuvant therapy even if a clinical CR is achieved.

Systemic Therapy After Surgery

A full discussion of adjuvant systemic therapies is beyond the scope of this chapter. However, the following section will highlight the salient points of adjuvant therapy as they pertain to patients with locally advanced breast cancer who have completed neoadjuvant chemotherapy.

Chemotherapy

Until recently, there were no data to support the use of additional chemotherapy in the postoperative setting if the full intended course of neoadjuvant chemotherapy was administered. The CREATE-X trial, however, was the first to demonstrate a potential benefit of adding capecitabine in patients with residual disease found at the time of surgery. In this study conducted in Japan, 910 women with HER2-negative breast cancer who had residual disease after neoadjuvant therapy with an anthracycline and/or taxane were randomized after surgery to either standard therapy (endocrine therapy for patients with hormone receptor–positive disease or no systemic therapy for hormone receptor–negative disease) or to standard therapy plus capecitabine for 8 cycles. At 5 years, DFS was 74% for the capecitabine arm compared to 68% for the control arm (HR 0.70, $P = .01$). OS was also improved (89% vs. 84%, HR = 0.59, $P = .01$). In the triple-negative subgroup, DFS was 70% vs 56% (HR 0.58) and OS was 79% vs 70% for the capecitabine and controls groups, respectively. These results have been practice changing and offer the opportunity to improve long-term outcomes in a population with high-risk disease.[45] Other ongoing clinical trials are evaluating the role of platinum chemotherapy versus capecitabine, as well as the role of the immune checkpoint inhibitor pembrolizumab, in the postoperative

setting in patients with residual triple-negative breast cancer following neoadjuvant chemotherapy.

Adjuvant Endocrine Therapy

Patients with HR+ breast cancer should receive adjuvant endocrine therapy to reduce the risk of recurrence and breast cancer–specific mortality. The choice of therapy is influenced by menopausal status. Although tamoxifen remains a standard for both pre- and postmenopausal women, the use of aromatase inhibitors is limited to women who are postmenopausal, though there are now data supporting the use of aromatase inhibitors when given concurrently with ovarian function suppression in the premenopausal setting.

The EBCTCG meta-analysis demonstrated that 5 years of adjuvant tamoxifen was associated with a one-third proportional reduction in breast cancer mortality at 15 years in patients with estrogen receptor–positive disease, irrespective of age, nodal status, or receipt of chemotherapy. Subsequent data from the ATLAS trial demonstrated a further reduction in recurrence risk and breast cancer mortality with 10 years of tamoxifen compared to 5 years, suggesting that compared to no endocrine therapy, 10 years of tamoxifen was associated with an almost 50% reduction in disease-specific mortality.[46]

For postmenopausal women with HR+ breast cancer, use of an aromatase inhibitor is recommended in the adjuvant setting, either as upfront therapy or following tamoxifen. Support for this recommendation comes from multiple studies demonstrating improvement in recurrence rates and breast cancer mortality with the use of an aromatase inhibitor compared to tamoxifen. In a recent meta-analysis conducted by the EBCTCG, 5 years of aromatase inhibitor therapy was associated with a 15% reduction in 10-year breast cancer mortality compared with 5 years of tamoxifen.[47]

Recent data from the SOFT and TEXT trials have demonstrated a role for ovarian function suppression plus either tamoxifen or aromatase inhibition in select premenopausal women with HR+ breast cancer. Although the addition of ovarian suppression did not confer benefit over tamoxifen alone for the overall population of premenopausal women with HR+ disease, there was an improvement in DFS when ovarian suppression was administered with tamoxifen or an aromatase inhibitor in the subset of women who were younger than 35 years or whose disease was considered to be of sufficiently high risk to warrant the administration of chemotherapy. Given that women with locally advanced breast cancer comprise a high-risk group, those who are

premenopausal should be offered this strategy in the adjuvant setting.[48,49]

Adjuvant HER2-Directed Therapy

For patients with HER2-positive breast cancer, trastuzumab should be continued in the adjuvant setting to complete 1-year total of HER2-directed therapy. This recommendation is based on studies demonstrating improved DFS and OS with the addition of 1 year of trastuzumab.[40,41] More recently, results from the APHINITY trial demonstrated that the addition of 1 year of pertuzumab to trastuzumab in the adjuvant setting led to a small but statistically significant improvement in DFS (94% in the pertuzumab group vs. 93% in the placebo group, HR 0.81, $P = .045$).[45] The KATHERINE trial is comparing trastuzumab emtansine (TDM-1), a novel antibody–drug conjugate approved in the metastatic setting, versus trastuzumab as adjuvant therapy in patients with HER2-positive breast cancer with residual disease after neoadjuvant therapy.

Treatment Results for Locally Advanced Breast Cancer

As noted earlier in this chapter, stage III breast cancer historically has been associated with a very poor prognosis, with high rates of locoregional recurrence, distant metastases, and death. However, advances in all of the disciplines involved in breast cancer treatment have improved the outcome of such patients. With modern treatment strategies that include systemic therapy with taxanes and anthracyclines, appropriate surgical intervention, and locoregional irradiation, outcomes have significantly improved. A reasonable estimate of 10-year survival rates for patients given modern treatments for stage III breast cancer is approximately 50%.[7]

Patients with supraclavicular lymph node (SCV) disease at diagnosis have a poorer outcome than do other patients with stage III disease. However, because some studies of patients treated with chemotherapy have reported 10-year survival rates of 25%, the AJCC recategorized this stage of disease from stage IV to stage IIIC.[50] One study investigating the outcome of 71 patients with supraclavicular disease who were treated with neoadjuvant chemotherapy, surgery, and radiation reported a 5-year locoregional control rate of 77% and a 5-year OS rate of 47%.[51] Patients in whom the supraclavicular disease showed a clinical CR to neoadjuvant chemotherapy had better outcomes than did those with persistent disease after chemotherapy.

IM nodal involvement at presentation also confers a poor prognosis, although the incidence of IM involvement is difficult to assess in modern series as

extended radical mastectomies are not typically performed. Older series, prior to the use of routine screening mammography, have shown that IM involvement is a risk factor for poor OS independent of axillary nodal status.[52] A more modern series from the European Institute of Oncology included 107 patients with either IM or SCV involvement between 1997 and 2009.[53] Nodal involvement was determined by a combination of clinical examination, surgical biopsy, FDG-PET, and ultrasound. Five-year outcomes were better in those with IM compared to SCV disease (DFS 84% vs. 39%, respectively). Patients with both IM and SCV involvement have a particularly high risk of distant disease. A study from Korea found a 33% 5-year DFS among 18 patients with disease involving both nodal sites.[54]

Patients presenting with SCV or IM disease should receive treatment similar to other patients with stage III disease. Typically, this includes preoperative systemic therapy and breast and axillary surgery, followed by comprehensive adjuvant radiation therapy. As neither SCV nor IM sites are typically operated on, these areas should be included in the radiation fields. There are insufficient data to guide radiation dose selection in this setting, but consideration should be given to a cone down to the area of clinical involvement. Dose is typically limited in this site because of the adjacent brachial plexus (SCV) and heart and/or lung (IM).

INFLAMMATORY BREAST CANCER

Epidemiology of Inflammatory Breast Cancer

IBC is an important subcategory of locally advanced breast cancer that is notable for both its similarities to and differences from noninflammatory locally advanced breast cancer. IBC is not common and accounts for 0.5% to 2% of all invasive breast cancers diagnosed in the United States but is disproportionately lethal, accounting for about 10% of breast cancer deaths.[55] In a study of 9 SEER registries (Surveillance, Epidemiology, and End Results), the incidence of IBC was found to have increased slightly during the 1990s, even while the incidence of locally advanced breast cancer (LABC) and non-T4 breast cancer decreased.[56] The rates of IBC, and mortality from IBC, were higher in black women than in white women. IBC tends to occur in younger patients than non-IBC. Women with IBC are more likely to have positive axillary lymph nodes, higher tumor grade, and negative hormone receptors.[55–57] Distant metastases at diagnosis are also more common with IBC. Risk factors for IBC, including

menstrual/reproductive factors, obesity, smoking, alcohol, and exposure to the mouse mammary tumor virus (MMTV), have been evaluated, but results are not consistent.[57] The strongest epidemiologic associations of IBC are with black race, young age, and high body mass index (BMI).[58]

Natural History of Inflammatory Breast Cancer

Inflammatory breast cancer, as defined by the AJCC, is a composite clinical–pathologic entity characterized by diffuse edema and erythema of the breast with acute/subacute onset and pathologic demonstration of invasive breast cancer. The erythema and skin changes must involve at least one-third of the breast, and duration of symptoms must be <6 months. A critical and determinative feature of IBC is the rapid onset of clinical findings including skin erythema, peau d'orange, brawny breast induration, warmth, and asymmetric enlargement (Fig. 60.4).

One hallmark of IBC is extensive lymphovascular invasion of the superficial plexus of vessels in the papillary and high reticular dermis by tumor emboli. These emboli can be demonstrated with skin punch biopsies directed to areas of erythema in up to 75% of cases.[58] However, the presence of invasive cells in the dermal lymphatics alone is neither sufficient nor necessary for the diagnosis.

It is important to distinguish IBCs from locally advanced breast cancer with secondary lymphatic congestion. Neglected primary tumors can also lead to breast erythema, edema, warmth, and asymmetric enlargement, particularly when bulky axillary adenopathy impedes the normal lymphatic flow from the breast. However, the former has a history of rapid onset, whereas the latter tends to have a long interval between the first symptom and the presentation for medical treatment.

Despite the natural history of IBC being one of rapid disease progression and early distant dissemination, in the United States, approximately 70% of patients with IBC have only evidence of locoregional disease at the time of diagnosis.[55] Patients with IBC typically have a worse clinical outcome than do other patients with T4 disease, suggesting that IBC is a distinct biologic entity.[59] However, the prognosis for patients with IBC has improved with combined (or tri-) modality therapy including neoadjuvant chemotherapy, mastectomy, and postmastectomy radiation therapy (PMRT). Before the availability of combination chemotherapy, IBC was almost uniformly fatal. Fewer than 5% of patients treated with surgery, radiation therapy, or both survived past 5 years, and the expected median survival time for such patients was <15 months.[60] Local recurrence rates after

surgery or radiation therapy were also high at approximately 50%.[61,62] The introduction of doxorubicin-based chemotherapy was the first step toward improved outcomes.[63,64] An evaluation of the outcome of patients with IBC registered in the SEER Program found that breast cancer–specific survival rates for patients with IBC improved continuously throughout the 1990s.[55] Currently, local control rates for patients treated with chemotherapy, mastectomy, and postmastectomy radiation approach 80% to 95%, and 5-year survival rates are approximately 40% to 60%.[65–69]

FIGURE 60.4. Photograph of a patient with erythema and peau d'orange consistent with IBC.

Diagnostic Workup

Although mammograms are considered a routine part of imaging workup for unspecified breast cancer, they are often of limited value for IBC. Over 90% of women with IBC have dense breasts[70] (a finding that has contributed to the "soil hypothesis" of IBC pathogenesis,[71] which may also obscure skin changes, masses, and nodules. The diagnosis of IBC is often made without a clinically detectable mass. There are no specific IBC findings on mammography, but skin and trabecular thickening are the most frequent findings. MRI, with dynamic contrast enhancement studies, is the most accurate test for identifying primary breast lesions in IBC. MRI abnormalities on MRI can include asymmetric non–mass-like enhancement, multifocality/centricity, and postcontrast peak signal intensity higher than that for other presentations of LABC. As discussed earlier in the chapter, there is increasing interest in the use of [^{18}F]fluorodeoxyglucose PET-CT for disease staging of patients with locally advanced breast cancer, particularly those with IBC.

Pathology and Biology of Inflammatory Cancer

IBC cells appear similar to high-grade ductal breast cancer cells from noninflammatory breast carcinoma. Molecular subtypes of non-IBC, including the basal subtypes, all exist in IBC. However, inflammatory cancer is more commonly high histologic grade and shows high percentages of cells in S phase and aneuploidy. IBC is also more likely to lack expression of ER/PR and more likely to express high levels of p53 and epidermal growth factor.[72] Most strikingly, HER2/neu amplification/overexpression is more frequent in IBC (36% to 60%) than in non-IBC. Other more recently discovered markers include the propensity of inflammatory tumors to overexpress RhoC GTPase and to not express the tumor suppressor gene WIPS3.[73,74] Finally, others have described that IBCs with loss of MUC-1 may be associated with poorer survival than tumors that express MUC-1. More recently, investigators have noted that overexpression of E-cadherin may play an important role in the tumor emboli formation that is typically noted in the dermal lymphatics, and preclinical work suggests that targeting E-cadherin may decrease invasiveness.[75,76] As such, there are several important areas of research that may further characterize IBC and lead to the development of novel therapeutics.

General Management and Treatment Results for Inflammatory Breast Cancer

Because IBC is relatively uncommon, no data from randomized studies are available regarding the optimal therapeutic approach for this disease. From the aggregate of data reporting on IBC, it is quite clear that the best reported outcomes are with trimodality therapy, with a general sequence of neoadjuvant chemotherapy, mastectomy, and PMRT. Clearly, management of IBC requires integrated care by a multidisciplinary team. Ideally, such patients should be evaluated in a multidisciplinary center by all specialists at the time of presentation to confirm the diagnosis of inflammatory disease, document the extent of disease (including photographs of areas of the involved skin), and agree on a treatment plan.

Chemotherapy for Inflammatory Breast Cancer

IBC is considered inoperable at presentation and should be treated initially with neoadjuvant chemotherapy (with consideration of trastuzumab if the tumor is HER2/neu-positive). Patients should be carefully monitored for response, and after achievement of the maximal clinical response, patients should be reevaluated for mastectomy. About 80% of patients with IBC will achieve a clinical response, and their disease will become operable.[77]

The optimal chemotherapy regimen for patients with IBC includes both anthracyclines and taxanes. The introduction of anthracycline chemotherapy, when combined with locoregional treatments, provided the first evidence of treatment efficacy in this disease. Investigators at MD Anderson conducted a series of single-group prospective trials for patients with IBC and found that neoadjuvant chemotherapy with FAC followed by locoregional therapy led to a 5-year survival rate of 25%. Subsequently, these investigators introduced sequential FAC or FEC followed by weekly paclitaxel and reported that the addition of taxanes improved the progression-free and OS of patients with inflammatory disease.[77]

IBC outcome is also affected by biologic subtype, as determined by ER, PR, and HER2/neu status. An update of the MD Anderson IBC experience analyzed 316 patients with nonmetastatic IBC treated with curative intent between 1974 and 2008 who had known ER, PR, and HER2/neu status.[78] The 5-year rate of locoregional recurrence in patients with triple-negative disease was much higher than that for other subtypes—39% despite aggressive locoregional treatments—and the 5-year rate of distant metastasis was 57%. New therapeutic targets are needed in such patients, and recent research has identified potential biologic roles of NF-κB, RhoC GTPase, WISP3, and E-cadherin.[58]

Surgery for Inflammatory Breast Cancer

Locoregional treatment is an essential component of therapy for inflammatory disease. Before the routine use of chemotherapy, mastectomy, with or without postmastectomy radiation, was associated with a dismal prognosis, and so many physicians abandoned mastectomy in favor of radiation-only treatments. Outcomes after radiation therapy as the sole treatment modality were equally poor. After neoadjuvant chemotherapy became routine, combinations of surgery and radiation have been reevaluated.

De Boer et al.[79] reported on 54 patients with IBC treated after neoadjuvant chemotherapy with either radiation only (n = 35) or mastectomy plus radiation (n = 19). For the patients treated with radiation only, the median progression-free survival time was only 16 months, and the local recurrence rate was 34%. These results were not statistically different from the patients treated with mastectomy, and the authors concluded that surgery provided no clinical advantage over chemotherapy and radiation alone. In contrast, Perez et al.[80] found that the addition of mastectomy to local treatment significantly improved the outcome of IBC treatment. Patients given neoadjuvant chemotherapy, mastectomy, and postmastectomy radiation had a local control rate of 79% and a 5-year DFS of 40%. This was among the earliest demonstration of the efficacy of trimodality therapy. These data were supported by the report from Panades et al.,[81] who evaluated 308 patients given chemotherapy as a component of their treatment and found that the 10-year local recurrence–free survival rates were significantly better for patients who underwent mastectomy than for those who did not (about 60% vs. 34%, respectively; P = .0001), as were the 10-year breast cancer–specific survival rates (about 34% with mastectomy vs. 23% without, P = .005). A multivariate analysis that considered other potential prognostic factors found that the use of mastectomy remained a significant factor for improved local recurrence–free survival (P = .04). Results from an MD Anderson study also confirmed these results, with multivariate analysis revealing that a complete or partial response to neoadjuvant chemotherapy, the use of radiotherapy, and the addition of mastectomy to the therapeutic regimen all significantly improved disease-specific survival.[82]

A related question is whether breast conservation is appropriate and safe for patients who achieve a CR to neoadjuvant chemotherapy.[83–85] The enthusiasm for breast conservation has been limited due to the diffuse nature of IBC coupled with its predilection for skin involvement. One report from Arthur et al. challenges this conventional wisdom.[83] In that study, 52 patients treated for IBC

at Virginia Commonwealth University hospitals and Tufts-New England Medical Center were treated on a prospective study of breast conservation, accelerated "suprafractionated" radiotherapy (1.5 bid to the entire breast and nodes and boost of 18 to 21 Gy for total of dose of 63 to 66 Gy to all initially involved areas). Mastectomy was reserved for nonresponders. With a median follow-up of 24 months, the breast preservation rate was 74%. In contrast, Swain reported a local recurrence rate of 30% despite their patients having achieved a clinical CR to neoadjuvant chemotherapy and multiple negative biopsies before irradiation.[86] Low and colleagues also reported a 40% local recurrence rate in 15 patients with IBC treated with radiation therapy alone after a biopsy-proven CR.[84] Finally, Brun et al.[85] reported a 54% local failure rate with attempts at breast conservation, and Chevallier et al.[87] reported a 61% local failure rate in patients treated with breast conservation after they had achieved a CR to neoadjuvant chemotherapy. In summary, mastectomy appears to be the prudent surgical choice based on current data.

Radiation therapy for IBC: Radiation therapy also has an important role in the management of IBC. The randomized data supporting PMRT for LABC have been discussed elsewhere and will not be reviewed. Although IBC was not represented in those trials, the lessons are still germane to a discussion on IBC. Furthermore, the best reported outcomes in IBC have all employed trimodality therapy and had aggressively designed and dosed radiation therapy. Because IBC has a rapid doubling time, investigators from MD Anderson investigated an accelerated hyperfractionated radiation delivery schedule in which 51 Gy is delivered to the chest wall and draining lymphatic fields by giving 1.5 Gy twice a day.[88] Subsequently, the chest wall was boosted to an additional 15 Gy, given in ten 1.5-Gy fractions twice daily. This approach was found to significantly improve locoregional disease control compared with a group treated with only 60 Gy, but also with a twice daily schedule. Respective 10-year locoregional control rates were 77% versus 58% (P = .04). Statistically significant improvements were also seen in 5- and 10-year OS rates between these two groups (P = .03), and a trend toward improvement in 5- and 10-year DFS rates was noted as well (P = .06). In a more recent update from these investigators in which the outcome of 192 patients treated with neoadjuvant chemotherapy, mastectomy, and postmastectomy radiation was evaluated, the authors reported a 5-year locoregional control rate of 84%.[69] Factors associated with higher rates of locoregional control included partial response to chemotherapy, negative margins, three or fewer positive lymph nodes, and the use of taxane

chemotherapy. Similarly good outcomes have also been reported from centers that used once-daily RT with high doses or daily use of bolus. Nonetheless, a recent report from Loveland-Jones et al.[89] demonstrated distressing underutilization of any PMRT in the National Cancer Database and identified several parameters associated with underutilization.

In summary, all patients with IBC require management by a multidisciplinary team. After initial staging and careful documentation of the extent of disease, patients should receive initial chemotherapy. The chemotherapy course should include both an anthracycline and a taxane, which can be given either concurrently or sequentially. Anti-HER2 therapy (trastuzumab) should be given with chemotherapy for patients with HER2/neu–positive disease. The majority of patients who exhibit a disease response and become operable should then undergo a modified radical mastectomy. Comprehensive and aggressive postmastectomy radiation treatments to the chest wall and draining lymphatics should be given as adjuvant therapy. This approach was recently endorsed by a consensus panel of IBC experts.[69] The dose of radiation to the initial fields should be 50 Gy in 25 fractions given once a day or 51 Gy in 1.5-Gy fractions given twice a day. Subsequently, the chest wall and any areas of gross disease that has not been resected should be boosted to 60 to 66 Gy. Attention should be paid to skin dose, and many institutions use tissue equivalent bolus material to ensure full dose to the skin of the chest wall. Patients with ER-positive disease should also receive hormonal therapy.

Some patients will continue to have inoperable disease after neoadjuvant chemotherapy. In a retrospective review of 38 patients with IBC who were inoperable after neoadjuvant chemotherapy, 32 (84%) of the 38 patients were able to undergo mastectomy after radiotherapy.[90] Preoperative radiation doses of 54 Gy or higher were significantly associated with the development of complications that required surgical treatment. Therefore, these patients should receive either preoperative radiation to the breast and draining lymphatics to a dose of 50 to 51 Gy, or, if the disease is unlikely to become resectable, high dose (72 Gy) definitive radiation is indicated using a reduced-field technique.

Clearly, great strides have been made over the last two decades in the management of IBC, and patients whose disease is managed with trimodality therapy can have locoregional control rates >80% and 5-year survival rates of ≥40% to 60% or more. Improvements in systemic therapy will, it is hoped, further augment these results.

GENERAL MANAGEMENT AND TREATMENT RESULTS FOR LOCALLY OR REGIONALLY RECURRENT BREAST CANCER

Women who receive initial potentially curative therapy for invasive cancer with either breast conservation therapy or mastectomy are at risk of developing locoregional recurrence. Locoregional recurrences are relatively uncommon with recurrence rates at approximately 5% to 10% and 10% to 15% after mastectomy and breast conservation therapy, respectively.[91] Most patients present clinically with a palpable mass or with findings on post–conserving therapy surveillance imaging.[92] Although still potentially curable, the development of a locoregional recurrence after primary treatment of an invasive breast cancer portends a high risk for distant metastases and death because of breast cancer. Accordingly, patients should undergo disease restaging at the time of recurrence to rule out metastatic disease and should have a biopsy for histopathologic confirmation and reevaluation of hormone receptor and HER2 status. Given that locoregional recurrences are relatively uncommon and are heterogeneous in presentation and prior treatment, treatment strategies must be tailored to individual cases.

Recurrence in the Breast After Breast Conservation Therapy

Local recurrences after breast conservation therapy are classified and can sometimes be distinguished from second primary cancers based on location, appearance on imaging, histologic subtype, and HER2 status. It is important to try to identify true relapses, as there are data showing that compared with patients with new primaries, patients with true relapses have poorer 10-year OS (55% vs. 75%; $P < .0001$) and distant DFS (41% vs. 85%; $P < .0001$).[93] Risk factors for developing local recurrence after an initial breast-conserving approach are dictated mostly by margin status and receipt of radiotherapy; other known poor prognostic factors include greater T-stage, younger age, higher-grade histology, receptor-negative disease, and LVI.[94,95]

Appropriate management for locoregional recurrence after breast-conserving therapy depends on initial disease presentation and management. However, mastectomy remains the standard salvage treatment and is associated with a 50% to 95% local control rate depending on other prognostic factors of the disease.[96–98] There is no high-level evidence to support the use of postmastectomy radiotherapy after mastectomy for locoregional recurrence after initial breast-conserving therapy; however, this may be considered in patients with positive nodes (who did not receive initial regional nodal irradiation as a

part of initial therapy), tumors larger than 5 cm, or multiple adverse risk factors, particularly in patients in whom their initial radiation was many years prior to the recurrence.

Given most patients treated with initial lumpectomy are also treated with breast irradiation, mastectomy remains the standard of care at the time of recurrence. However, some single-institutional studies investigated additional BCS with or without radiation. Salvadori et al.[99] compared the outcome of 134 patients treated with mastectomy for a localized breast recurrence to 54 highly selected patients treated with a second BCS alone. They found that a second breast recurrence was more common at 5 years in the reexcision group (19% vs. 4%); however, there was no difference in disease-specific survival between the two groups at 5 years. Komoike et al.[100] also reported a relatively high rate (30%) of a second breast relapse after local surgery only for recurrent disease. Gentilini et al.[101] examined outcomes for BCS alone after recurrence by predictive factors and found that repeating conserving therapy alone was associated with a 15.2% 5-year risk of local recurrence in patients with a tumor 2 cm or smaller and time to recurrence >2 years, whereas small tumors with early recurrence had a 31.2% 5-year local recurrence risk, and tumors >2 cm were associated with a 71.2% risk of 5-year local recurrence. This suggests that the best candidates for second BCS may be those with small tumors and late recurrence.

Experience with giving a second course of radiation therapy following local resection of a breast recurrence has also been limited, with most approaches being limited to a partial breast reirradiation strategy because of concerns for the morbidity of reirradiation to the whole breast. Deutsch et al.[102] treated 39 women with 50 Gy to the operative area using electrons after a repeat lumpectomy for an intact breast recurrence but reported a rate of second recurrence of 23%, whereas Wahl et al.[103] found a 53% recurrence rate at 1 year after repeat external beam radiotherapy. Resch et al.[104] treated 17 ipsilateral breast tumor recurrence patients with pulsed–dose rate brachytherapy following repeat lumpectomy and noted a second breast recurrence in 5, whereas Guix et al.[105] treated 36 patients with small low-risk local recurrences with excision and high dose rate brachytherapy and noted a local control rate of 89.4% at 10 years. Furthermore, Hannoun-Levi et al.[106] treated 69 highly selected patients with interstitial brachytherapy after a second lumpectomy for an intact breast recurrence and after a median follow-up of 50 months reported that 11 (16%) developed a second recurrence. Grade 2 to 3 late complications developed in 0%

to 32% of the patients, depending on the radiation dose. In RTOG 1014, a phase II trial of 55 patients who received accelerated partial breast irradiation following repeat lumpectomy for in-breast recurrence, there was only one grade 3 or higher toxicity (grade 3 fibrosis of deep connective tissue) at 1 year; however, long-term toxicity data are not yet available.[107]

There are limited data on reirradiation of the whole breast. In a small retrospective study of 47 women who received reirradiation for locally recurrent refractory breast cancer, investigators from the University of Toronto reported that the mean 2-Gy equivalent dose (EQD2) to the whole breast and tumor cavity was 99.8 Gy and 109.2 Gy, respectively. Two-year local control and OS were 50% and 67%, respectively, with acceptable short- and long-term toxicity (five cases of grade 3 to 4 acute radiation dermatitis and four cases of grade 3 fibrosis).[108]

Patients with recurrence in the breast are also at risk of axillary metastases. No high-level evidence or consensus exists for the management of the axilla in this setting. Rates of positive nodes in the recurrent setting in older series where axillary dissection was standardly employed at initial diagnosis report rates of lymph node involvement at the time of recurrence at approximately 25% but are as high as 50%.[109] In patients who have already had an axillary dissection at initial presentation, radiographic staging followed by surgical resection of gross axillary disease should be attempted if technically feasible. For patients who initially underwent sentinel lymph node surgery, restaging with repeat sentinel node evaluation may be feasible, but its diagnostic accuracy and prognostic significance are unknown.[110]

Although there are no high-level data regarding radiation of the regional nodes in the setting of nodal relapse, radiation of the axillary and supraclavicular nodes may provide durable local control. In this setting, maximal debulking with either surgical resection of disease or systemic chemotherapy is recommended to maximize local control.

The use of chemotherapy in the recurrent setting was studied in the phase III Chemotherapy for Isolated Locoregional Recurrence of Breast Cancer (CALOR) trial where 162 patients with locoregional recurrence after mastectomy or breast-conserving therapy were randomized to chemotherapy versus no chemotherapy.[111] Compared to the control group, chemotherapy was associated with significant improvements in OS (HR 0.41, 88% vs. 76%) and DFS (HR 0.59, 69% vs. 57%), with a larger benefit ($P_{\text{interaction}}$ = .046) noted among women with ER-negative disease (67% vs. 35%) compared to ER-positive

disease (70% vs. 69%). Although these data support the use of chemotherapy in the locoregionally recurrent setting especially for ER-negative disease, this trial was limited by small size and poor accrual and thus poor generalizability. The use of systemic therapy after breast recurrence should be decided on an individual basis according to the risk of metastatic disease, the previous systemic treatments used, and the hormone receptor status.

Several investigators have examined prognostic factors associated with outcome for patients with breast recurrence after treatment for an invasive breast cancer. A consistent finding in these studies is the finding that patients with an interval to development of recurrence of ≤2 years have a worse outcome than those who develop recurrent disease many years after treatment. In part, this may be explained by the hypothesis that early breast recurrences develop from repopulation of persistent microscopic disease, whereas some late breast recurrences represent a new primary tumor. Investigators from Yale University were among the first to provide insights into the prognostic importance of this distinction. These authors evaluated a series of 136 such patients and used clinical criteria to classify recurrences as either true recurrences or new primary tumors.[93] New primary tumors were defined by one of the following: location in the breast remote from the original tumor bed site, a change in histology, or a change from aneuploid to diploid status. Subsequently, a retrospective series from MDACC of 126 patients suggested that patients with a new primary tumor had significantly better 10-year survival (77% vs. 46%, $P = .0002$), cancer-specific survival (83% vs. 49%, $P = .0001$), and distant DFS (77% vs. 26%, $P < .0001$).[112] Both studies found that patients considered to have new primary tumors had significantly longer intervals between their initial primary tumor and the recurrence and had significantly lower rates of distant metastasis and death after the recurrence. These data were later validated in a study of 447 patients.[113] Furthermore, a retrospective study from Harvard suggests that estrogen receptor–negative status is associated with poorer DFS compared to patients with estrogen receptor–positive disease.[114] These findings may be valuable in decisions regarding management of recurrent disease.

Reconstructive surgery should be considered for patients treated with mastectomy, although previous history of breast radiation may limit the success of implant-based procedures. Forman et al.[115] reported significant complications in 6 of the 10 patients in whom a tissue expander and implant were attempted after mastectomy in the setting of an ipsilateral breast recurrent treatment. Autologous tissue reconstruction may provide better outcomes. Moran et al.[116]

reported on 14 patients who underwent free TRAM flaps with anastomosis to the thoracodorsal vessels in patients being treated for a breast recurrence. The complication rate was only 14%, and the aesthetic result was rated as excellent. Determination of reconstructive approach should be made based on institutional experience for the best chances at successful outcome.

Locoregional Recurrence After Mastectomy

Recurrences after mastectomy tend to occur earlier and are more likely to be diagnosed on exam when compared to recurrence after breast-conserving therapy. The major risk factors for recurrence after mastectomy as initial therapy are the number of axillary lymph nodes positive at surgery in addition to other poor prognostic factors including younger age, higher-grade histology, receptor-negative disease, and LVI.[30,117]

Patients with recurrent disease after initial mastectomy may have a worse prognosis than those with recurrent disease after initial breast conservation therapy. In the Canadian and the Danish postmastectomy radiation randomized control trials, patients who developed locoregional recurrence had very high rates of subsequently developing metastatic disease.[118,119] In the Vancouver trial, of the 39 patients who developed a locoregional recurrence, 37 eventually developed metastatic disease.[118] In the Danish trial, the 5-year rate of distant metastatic disease development after an isolated locoregional recurrence was 73%. This rate was no different for those in whom disease recurred after mastectomy only versus those with recurrent disease after mastectomy and radiation,[119] though the ability to use radiation for salvage therapy, especially in isolated chest wall recurrences, may influence outcome, as discussed below.[120]

The general management strategy for an isolated locoregional recurrence after mastectomy requires input from a multidisciplinary team, but whenever possible should be wide local excision. The initial evaluation should define the sites of disease involvement and determine whether the patient is able to undergo resection of all gross disease with negative surgical margins. Surgical therapy is recommended for patients with resectable disease, provided surgery can be done with acceptable morbidity. If the patient had not previously been given radiation therapy, a standard approach would be comprehensive locoregional radiation with similar techniques used for newly diagnosed disease. A study from Washington University found that patients who had radiation therapy to the chest wall and regional lymphatics had better outcomes than those in whom radiation fields were limited to the site of the recurrent disease.[121] Finally, because

patients with recurrent disease after mastectomy are at high risk of developing distant metastatic disease, those who have not been previously treated with chemotherapy (or trastuzumab if the tumor is HER2/neu-positive) should strongly consider treatment with these agents.[111,122] Patients with ER-positive disease should receive appropriate second-line endocrine therapy. A retrospective series of 115 patients with recurrence after mastectomy suggest that patients who receive combined modality therapy with wide local excision and radiotherapy in addition to systemic therapy have better DFS (52% vs. 39%) and OS (63% vs. 50%) compared to patients who get more limited treatment.[123] Patients presenting with bulky unresectable disease or who are poor surgical candidates should be considered for neoadjuvant chemotherapy if active systemic agents are available. If the disease responds favorably, some of these patients may become candidates for surgical resection, which then can be consolidated with comprehensive radiation. The prognosis for those with persistent gross disease is very poor, and radiation treatments alone are unlikely to render such patients free of disease. Nevertheless, aggressive locoregional radiation is often used to help stabilize the disease and to avoid the significant adverse consequences of uncontrolled growth of locoregional disease. The dose of radiation depends on the presence or absence of gross disease and whether patients have previously undergone radiation therapy. For patients who have not had prior radiation therapy and do not have residual gross disease, we recommend comprehensive treatment to the chest wall and draining lymphatics to a dose of 50 Gy followed by a boost to the sites of prior disease to 60 to 66 Gy. Hyperfractionated chest wall irradiation does not seem to provide any benefit over that of conventional therapy given once daily.[124] Investigators from Duke University have had modest success with combining a second course of radiation with chemotherapy and hyperthermia.[125]

Few data are available to quantify the benefits of systemic therapy for patients with locoregional recurrence. As discussed under management for recurrent disease of conservation therapy, the use of chemotherapy was studied in the CALOR trial where, compared to the control group, chemotherapy was associated with significant improvements in OS. A randomized trial that investigated tamoxifen use versus no systemic therapy after salvage local therapy for patients with recurrent disease after mastectomy found improvement in 5-year DFS from 36% to 59% (P = .007),[126] supporting the use of endocrine treatments in the management of patients with recurrent disease. Finally, investigators from MD Anderson conducted a series of four prospective single-

group protocols evaluating systemic therapies for patients with either locoregional recurrence or metastatic disease that was converted to “no evidence of disease” after surgery, radiation, or both.[127] The findings suggest that for patients with anthracycline-naïve disease, the introduction of doxorubicin at the time of recurrence may be associated with improved survival. More recently, the use of docetaxel also seemed to lead to favorable outcome for patients who had previously had anthracycline treatment. The 3-year DFS rate for such patients was 58%.[127] The use of systemic therapy after breast recurrence should be decided on an individual basis according to the risk of metastatic disease, the previous systemic treatments used, and the hormone receptor status.

Several publications have provided insight into the factors of prognostic significance for patients with locoregional recurrence after mastectomy. One of the largest series was an analysis of the 535 patients who developed a postmastectomy recurrence after treatment in the Danish 82b and 82c randomized trials.[119] In multivariable analyses, the investigators found the following factors to be associated with a poorer outcome at recurrence: large initial primary tumor and high number of positive lymph nodes, extracapsular extension, recurrence in the infraclavicular or supraclavicular regions, and a disease-free interval of <2 years. Other series have reported similar findings. In general, patients who present with an isolated chest wall recurrence, particularly those who have resectable disease and have not undergone radiation, may have a greater probability of disease control and improved outcome compared to patients with other locoregional recurrences. Investigators from MD Anderson found that initial nodal status, time to recurrence, and ability to use radiation to treat the recurrence were all independent predictors of outcome for patients with a chest wall recurrence.[120] The 19 patients in whom these three factors were favorable had a 5-year OS of 86% (median survival time, 141 months). The 5-year survival rate for the 89 patients who had one or two unfavorable features was 48% (median survival time, 54 months), and all 22 of the patients who had all three unfavorable factors died within 5 years of the recurrence (median survival, 16 months). Outcome for patients with T1/T2 disease with one to three positive lymph nodes was as poor after a locoregional recurrence as was the outcome for patients with four or more positive lymph nodes.[128] In contrast, patients with initial lymph node–negative disease had a significantly better outcome.

Axillary Metastases with Unknown Primary

The presentation of metastatic disease within axillary lymph nodes without an identifiable primary source is unusual, accounting for <1% of newly diagnosed breast cancer cases.[129–131] The initial workup for patients who present with axillary disease and an occult primary is typically directed toward establishing the source, that is, a regional metastasis from breast cancer or a distant metastasis from a different site. As such, the initial evaluation should include a history and physical examination, routine serum studies, bilateral mammography, chest radiography, liver imaging, and bone scan. If no primary disease is detected with mammography, ultrasound and MRI scan of the breast are indicated. Although literature in this area is quite scant to begin with, most of it predates the widespread availability of MRI. Contrast-enhanced MRIs can detect occult lesions in about 80% of patients with "occult" primary and a negative mammogram. As such, true "occult" presentations will likely become even more uncommon in the current era. Cytologic confirmation of disease within axillary lymph nodes can be obtained with ultrasound-guided fine needle aspiration. Tumor markers, including ER, PR, and HER2/neu, can and should be performed on the cytologic specimens. In the absence of evidence for a remote, nonbreast primary, and a negative mammogram/ultrasound, a patient can be assumed to have an occult or unknown breast primary, and treated as such, particularly if the nodal biopsy results support a breast primary (i.e., based on markers). Most individuals present with advanced nodal disease at presentation and are clinically staged as having T0 N2 to 3 disease.

Modified radical mastectomy and postmastectomy radiation have been the historical locoregional treatments for patients with occult breast primary and axillary metastases. Studies vary significantly with respect to the frequency with which a primary is found within the breast during pathologic examination. Again, most of these studies predate the use of MRI screening or other improvements in diagnostic imaging. In general, however, approximately two-thirds of the patients are found to have an invasive breast cancer on pathologic examination of a mastectomy specimen.[129] Many patients with inoperable nodal disease (LABC) at presentation may receive neoadjuvant chemotherapy, and the probability of finding pathologic evidence of disease within the breast is likely lower in the current era.

A few investigators have investigated and reported on the safety of breast conservation therapy for patients with occult primary disease. One reported strategy for such patients includes neoadjuvant chemotherapy, reimaging of the breast to evaluate for calcifications resulting from tumor cell death, axillary

dissection, and irradiation of the breast and draining lymphatics. Early attempts at breast conservation without breast irradiation resulted in high subsequent breast recurrence rates.[132,133] More recent studies that incorporate breast irradiation have yielded better results. In one of the largest series, investigators from MD Anderson evaluated 45 patients treated over a 47-year period and compared the outcome of those treated with mastectomy (n = 13) to those treated with breast conservation (n = 32).[131] These authors found equivalent rates of locoregional control, DFS, and OS between the mastectomy and breast conservation cohorts. With a median follow-up of 7 years, only 2 of the 25 breast conservation patients who received breast irradiation developed a local recurrence. Similar results have been reported from The Royal Marsden Hospital. In a series of 48 patients, they found a 14% locoregional recurrence rate after breast radiation and an unacceptable rate of 80% if breast radiation was omitted.[134] These data suggest that microscopic/undetectable primary lesions can successfully be sterilized with the combination of systemic therapy and radiation therapy. One can feel particularly reassured with this strategy for lesions treated in the MRI age (i.e., for lesions below the threshold for MRI detectability). Patients presenting with an occult breast primary and axillary disease should receive regional nodal RT, whether as a part of PMRT or breast conservation therapy.[135,136]

Male Breast Cancer

Breast cancer developing in males is uncommon and accounts for <1% of total new breast cancer cases in the United States.[4] The American Cancer Society estimated that in 2017, there would be approximately 2,470 new cases of male breast cancer and 460 deaths because of male breast cancer in the United States. The incidence of male breast cancer is positively correlated with age, and the highest rates occur in black males (2.7 per 100,000) and white males (1.9 per 100,000).[4]

The presenting symptom for male breast cancer patients is typically a breast mass or axillary adenopathy, and most male breast cancer patients present with locally advanced disease. The ratio of the number of deaths to new cases is 19% for males, compared to a ratio of 16% for females, with a 5-year OS of 84% in men compared to 90% in women.[4] Retrospective national database evidence suggests differences in cancer-specific mortality may be attributable to stage migration, as there are no gender-specific differences when comparing outcome within stage II or stage III.[137]

The known risk factors for male breast cancer, similar to those in postmenopausal female breast cancer, include family history, age, conditions that affect testosterone and estrogen levels, BRCA2 mutations, and prior history of radiotherapy.[138] Germ-line mutations in the BRCA2 gene have been reported in 4% to 16% of men with breast cancer and, unlike female breast cancer, are more common than germ-line mutations in BRCA1.[139,140] Nevertheless, most male breast cancers present without an identifiable risk factor.

Males have a similar histopathologic spectrum of breast cancers to females with the exception of lower rates of invasive lobular carcinoma given the lack of acini and lobules in normal breast tissue. Specifically, <2% of invasive male breast carcinomas are lobular, as compared to approximately 15% in female cancers.[141] In addition, male breast cancers more frequently are ER-positive (estimated rate of 90%) and HER2/neu-negative compared to female breast cancer.[137] Diagnostic workup and staging are similar to that for female breast cancer and should include bilateral mammography, biopsy, and staging workup. Treatment decisions are also similar to those used in women.

Mastectomy with or without postmastectomy radiation is the most common locoregional treatment approach, with increasing attention being placed on postmastectomy reconstruction and potential psychological distress related to cosmetic outcomes. Investigators at MD Anderson reviewed 142 patients treated with mastectomy without radiation therapy and found that, similar to female patients, margin status, number of positive nodes, and tumor size predicted locoregional failure.[142] Accordingly, decisions concerning postmastectomy radiation should be based on the same criteria used in the treatment of female breast cancer.

Similarly, systemic treatments are indicated for male breast cancer patients who have a clinically relevant risk of distant metastases, and treatment decisions should follow those for female breast cancers. Level 1 data supporting the use of particular chemotherapy regimens specifically in men are lacking, given the rarity of the disease. In addition to chemotherapy, because most male breast cancers are receptor positive, tamoxifen is indicated for the majority of cases. Retrospective series have suggested that tamoxifen can reduce the risk of recurrence and death.[143] The role of aromatase inhibitors in males is unclear, but retrospective data support the adjuvant use of tamoxifen rather than aromatase inhibitors.[144]

CHAPTER 61

Breast Cancer: Locally Advanced, Part 2

Meena S. Moran and Pauline Truong

INTRODUCTION

Locally advanced breast cancer (LABC) is a heterogeneous entity in the spectrum of malignant breast diseases. Definitions of LABC vary but generally encompass stage III A, B, and C (TNM stage T3 to T4 or N2 to N3) and may include stage IIB (T3N0 or T2N1) disease, as defined by the *AJCC Cancer Staging Manual*, 6th edition.[1] It is well established that women with stage III breast cancer have high risks of locoregional and distant recurrence compromising survival. Corresponding recurrence risks in women with stage IIB cancer are lower but may still be substantial. Breast cancer management is evolving toward an era of personalized medicine with advances in pathologic processing, molecular profiling, sentinel nodal staging, chemotherapy and targeted drug therapies, and conformal radiation treatment techniques. Although these advances are shifting paradigms and increasing complexities in prognostication and therapeutic decisions, the shared goals among multidisciplinary cancer care professionals treating patients with LABC remain focused on improving survival and disease control, minimizing treatment-related toxicity, and providing optimal function and cosmesis. In this context, communication between radiation oncologists with allied radiation medicine professionals, surgical and medical oncologists, plastic surgeons, radiologists, and pathologists is essential to achieve coordinated, individualized care plans for each patient with LABC.

An overview of the general management strategies for LABC has been provided in the previous chapter. The current chapter will focus on the role of radiation therapy, including regional nodal irradiation (RNI), as an adjunct to mastectomy or breast-conserving surgery in the setting of stage IIB and III disease. Data from meta-analyses and prospective randomized trials conducted in the past three decades providing valuable data to define the role of locoregional radiation therapy in contemporary practice will be reviewed. Locoregional recurrence (LRR) risks after mastectomy and systemic therapy will be examined. With the expanded use of neoadjuvant chemotherapy (NCT) not

only in the setting of inoperable LABC but also in less advanced cases, radiation therapy decisions taking into consideration pretreatment disease extent, and response after NCT will be discussed.

In contemporary practice, the goal of safe and effective implementation of locoregional radiation therapy for women with LABC has been advanced by technological innovations in treatment planning and delivery. We will review and provide illustrative examples of locoregional radiation therapy techniques, with an emphasis on standardized contouring methods and rigorous adherence to dose–volume constraints. Dosimetric considerations to achieve conformal targeting and dose homogeneity to the breast/chest wall and regional nodes will be discussed. We will examine the effects of radiation therapy on critical organs at risk (OAR), particularly the cardiovascular structures, along with modern techniques including three-dimensional conformal planning and gating or active breath hold techniques to minimize cardiac exposure. Finally, issues regarding the complex interdisciplinary integration of radiation therapy with mastectomy and breast reconstruction will be discussed.

LOCOREGIONAL RADIATION THERAPY AFTER MASTECTOMY OR BREAST-CONSERVING SURGERY

Meta-Analyses of Prospective Trials

The foundation of radiation therapy as an integral component of locoregional treatment for patients with stage IIB and stage III breast cancer was built upon decades of clinical trials dating back to the 1960s, when mastectomy was considered standard of care. Accordingly, the available data from meta-analyses of adjuvant locoregional radiation therapy were predominantly derived from postmastectomy radiation therapy (PMRT) trials, which enrolled patients with operable breast and nodal disease, a proportion of whom had stage IIB or III breast cancer. In comparison, prospective trials and meta-analyses of patients with inoperable LABC and of patients with LABC managed with breast-conserving therapy are much fewer.

In an early meta-analysis published in 1987 of 7,941 patients enrolled in eight PMRT trials initiated before 1975, Cuzick et al.[2] reported no difference in survival in the first 10 years of follow-up; but beyond 10 years, an excess of deaths among radiated patients was observed. Radiation therapy was associated with reduced breast cancer–specific mortality, but this was counterbalanced by an increased risk of cardiovascular death, a risk related to radiation treatment

techniques that would be considered substandard today, such as large photon fields that exposed substantial volumes of the cardiovascular and pulmonary structures to high radiation doses.[3] Although these trials were conducted in an era that predated effective systemic therapies and many of the surgical and radiation practices used are no longer applied in modern practice, the work by Cuzick et al. provided relevant early lessons in the association between locoregional control and improved breast cancer–specific survival and the importance of using heart-sparing radiation techniques to mitigate the risks of cardiac injury and cardiac death.

In 1985, the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) formed an international collaborative organization with the mandate of generating and regularly updating meta-analyses using individual patient data from randomized trials of breast cancer treatment. The group defined early breast cancer as disease "in which all clinically apparent disease can be removed surgically."[4] As such, the trials analyzed in the EBCTCG overview may include LABC cases with stage IIB and III disease. As large systematic overviews using individual patient data provide the highest level evidence to address issues that may not be readily addressed by smaller trials,[5,6] the EBCTCG has, over time, contributed important data which provide the basis for current treatment guidelines and which continue to inform contemporary practice.

The first cycle of the EBCTCG meta-analysis, published in 1995, included 36 randomized trials comparing surgery alone versus surgery plus radiation therapy. Among 17,273 women enrolled in these trials, the use of radiation therapy after surgery was associated with a threefold reduced rate of local recurrence compared with surgery alone.[4]

In 2000, the group reported the 10- and 20-year results from 40 randomized trials of radiation therapy enrolling 20,000 women, half of whom had node-positive disease.[7] In these trials, adjuvant radiation therapy generally included not only the breast or chest wall, but also the axillary, supraclavicular, and internal mammary nodes (IMN). Across the trials, radiation therapy was associated with a decrease in LRR by approximately two-thirds (8.8% vs. 27.2% at 10 years), a decrease in breast cancer mortality ($2P = .0001$) but an increase in cardiovascular mortality ($2P = .0003$), and no significant difference in overall survival at 20 years ($2P = .06$).[7]

In 2005, the EBCTCG published an influential analysis reporting that, among 8,340 subjects with node-positive breast cancer treated with mastectomy and axillary dissection, PMRT to the chest wall and regional lymphatics reduced 5-

year LRR by 17% from 22.8% to 5.8%.[8] By 15 years, breast cancer mortality was reduced by 5.4% (54.7% vs. 60.1%, 2*P* = .0002) and overall mortality was reduced by 4.4% (64.2% vs. 59.8%, 2*P* = .0009), suggesting the concept that for every four local recurrences prevented at 5 years by radiation therapy, one breast cancer death may be spared at 15 years. Importantly, radiation therapy produced similar reductions in the relative risk of LRR across trials and across subjects, irrespective of age, stage, and tumor characteristics. Although the relative risk in LRR was consistently decreased by two-thirds, the absolute risk reduction in individual subjects varied, depending on the baseline (or control) risk without therapy. As such, women with baseline LRR risks >10% would have larger absolute reductions in LRR with radiation therapy, compared to women with low risks <10%.

In the breast-conservation therapy setting, the EBCTCG investigators have contributed data in women with node-negative and node-positive breast cancer treated with breast-conserving surgery with versus without adjuvant radiation therapy.[9] Among 1,050 women with node-positive disease, radiation therapy conferred an absolute 10-year recurrence reduction of 21.2% (42.5% vs. 63.7%; 95% confidence interval [CI], 14.5 to 27.9; 2*P* < .00001) and a 15-year absolute reduction in breast cancer death of 8.5% (42.8% vs. 51.3%; 95% CI, 1.8 to 15.2; 2*P* = .01).

Although the EBCTCG meta-analyses provided valuable insight into the long-term effects of radiation therapy on recurrence and survival, there were limitations. Many trials included in these analyses were conducted in the 1960s and 1970s, time periods in which systemic therapy was not used and the available radiation techniques were suboptimal. Generalizability of results from such trials to the modern setting is hence limited. To address these concerns, several investigators have performed meta-analyses of trials selected based on study time period and treatment quality.

In a reanalysis of trials included in the EBCTCG meta-analysis, but with exclusion of trials initiated prior to 1970, trials with small samples, and trials that employed suboptimal radiation techniques and dose prescriptions, Van de Steene et al.[10] found significant survival benefits with radiation therapy, highlighting the need for techniques that limit radiation exposure to the cardiopulmonary structures and other normal tissues. Similarly, Gebski et al.[11] reanalyzed data from the EBCTCG 2000 meta-analysis using predefined categories of radiation therapy, classified as “optimal: doses ranging between 40 and 60 Gray (Gy) in 2 Gy fractions or a biologically equivalent dose to the chest

wall, axilla, and supraclavicular fossa with or without the IMN," "inadequate or excessive: doses <40 Gy or >60 Gy in 2-Gy fractions," and "incomplete tissue coverage: target volume covered less than the chest wall and regional nodes." Local control, breast cancer–specific survival, and overall survival were all significantly improved in the "optimal" radiation group, whereas there were no survival benefits with radiation in the other groups.

To address the effect of radiation therapy in the context of systemic therapy reducing risks of distant dissemination, Whelan et al. conducted a meta-analysis of 6,367 subjects, the majority of whom had node-positive disease, enrolled in 18 trials of PMRT between 1967 and 1999. Systemic therapy was used in all subjects. Postmastectomy radiation was associated with significant reductions in local recurrence (odds ratio [OR] 0.25; 95% CI, 0.19 to 0.34) and overall mortality (OR 0.83; 95% CI, 0.74 to 0.94).[12]

In the most recent fifth update of the EBCTCG meta-analysis, published in 2014, 8,135 patients in 22 PMRT trials from 1964 to 1986 were analyzed. In this version of the overview, disease recurrence and survival outcomes were examined with stratification by pathologic nodal status. The 20-year breast cancer mortality reduction associated with PMRT was statistically significant for all patients with node-positive disease, including those with 1 to 3 and 4 or more positive nodes.[13] Among 3,786 women who underwent axillary dissection, 700 had node-negative disease, 1,214 had 1 to 3 positive nodes, and 1,772 had 4 or more positive nodes. Distinct from women with node-negative disease in whom radiation therapy had no significant effect on LRR or breast cancer mortality, women with 1 to 3 positive nodes treated with radiation experienced significantly reduced rates of LRR ($2P < .00001$), overall recurrence (relative risk [RR] 0.68; 95% CI, 0.57 to 0.82; $2P = .00006$), and breast cancer mortality (RR 0.80; 95% CI, 0.67 to 0.95; $2P = .01$). These improved outcomes were also observed among 1,133 women with 1 to 3 positive nodes who received systemic therapy with cyclophosphamide, methotrexate, and fluorouracil (CMF) or tamoxifen. In these women, PMRT was associated with significantly lower rates of 10-year isolated LRR (4.3% vs. 21.0%, $P < .00001$), overall recurrence (33.8% vs. 45.5%, $P < .00001$), and 20-year breast cancer mortality (41.5% vs. 49.4%, $P = .01$). Among 1,677 women with 4 or more positive nodes treated with systemic therapy, PMRT similarly reduced LRR (13.6% vs. 31.5%, $P < .00001$), overall recurrence (RR 0.79; 95% CI, 0.69 to 0.90; $2P = .0003$), and 20-year breast cancer mortality (70.0% vs. 78.0%, $P = .08$).

Compared to the previous 2005 EBCTCG report, which suggested a 4 to 1

relationship between recurrences and breast cancer death avoided, the 2014 EBCTCG postmastectomy analysis included women with more advanced cancer treated with more extensive radiation therapy. For these women, the 2014 meta-analysis suggested that for every 1.5 recurrences of any type avoided during the first 10 years after radiation therapy, 1 breast cancer death would be avoided at 20 years.[13]

Phase III Randomized Trials—Postmastectomy Radiation Therapy

In 1982, the Eastern Cooperative Oncology Group (ECOG) initiated a trial of PMRT, which enrolled 426 patients with operable LABC, including pathologic T3 disease with positive nodes, T4a to T4c disease (excluding T4d), N2 disease, or primary tumors fixed to underlying muscle.[14] Subjects underwent mastectomy and axillary dissection, followed by chemotherapy and hormone therapy, then restaging. The 332 patients without disease progression were randomized to PMRT versus observation with radiation reserved at time of progression. Of these, 312 patients were eligible for analysis for both time to relapse and death. After a median follow-up of 9 years, there were no significant differences in these endpoints between the two treatment arms. Patients who received radiotherapy had significantly lower LRRs (15% vs. 24%, *P* value not reported), but higher rates of distant progression (50% vs. 35%, $P = .003$). The trial, while well designed to address a relevant clinical issue, was ultimately limited by high proportions of noncompliance with study treatment allocation, and the numbers of patients analyzed were likely insufficient to detect a small but clinically meaningful survival difference.

In 1995, Arriagada et al.[15] reported results of a randomized trial with 960 patients treated with mastectomy without adjuvant systemic therapy randomized to receive preoperative radiotherapy, postoperative radiotherapy, or no adjuvant therapy. In this trial, PMRT use in patients with node-positive disease was associated with significantly reduced distant metastasis and overall mortality compared to unirradiated patients. These results were among the earliest data illustrating the concept that effective locoregional disease control can reduce distant dissemination and improve survival.

Danish Breast Cancer Cooperative Group and British Columbia Trials

The Danish Breast Cancer Cooperative Group (DBCG) 82b and 82c trials and the British Columbia, Canada, trials, published in 1997 and 1999, demonstrated

that PMRT was associated with not only improved locoregional control but also improved overall survival.[16–18] These landmark trials, which employed protocol-defined radiation techniques treating the chest wall, IMN, supraclavicular, and axillary nodes in women treated with adjuvant systemic therapy, contributed important prospective data that defined the role of PMRT in contemporary practice.

The DBCG 82b trial enrolled 1,708 premenopausal subjects with high-risk pathologic stage II or III breast cancer, accrued between 1982 and 1989.[16] In this trial, high-risk status was defined as one or more of the following features: involvement of axillary nodes, primary tumors more than 5 cm, or invasion of the skin or pectoral fascia. After mastectomy and level I to II axillary surgery removing a median of 7 nodes, women were randomized to systemic therapy with 9 cycles of CMF chemotherapy without radiation therapy versus 8 cycles of CMF plus radiation therapy, 50 Gy in 25 fractions or 48 Gy in 22 fractions using megavoltage equipment. At a median follow-up time of 9.5 years, compared to the control group, women who received PMRT had significantly lower LRR (9% vs. 32%, $P < .001$), improved disease-free survival (48% vs. 34%, $P < .001$), and improved overall survival (54% vs. 45%, $P < .001$).

The DBCG 82c trial evaluated 1,375 postmenopausal women, accrued between 1982 and 1990, randomized to mastectomy plus 1 year of tamoxifen versus mastectomy, tamoxifen, and radiation therapy.[17] Similar to the DBCG 82b results, PMRT was associated with reduced 10-year LRR (8% vs. 35%, $P < .001$), improved disease-free survival (36% vs. 24%, $P < .001$), and improved overall survival (45% vs. 36%, $P = .03$).

In the updated analysis of both DBCG 82b and 82c trials with 15-year follow-up, which also analyzed outcomes stratified by nodal subgroups (1 to 3 vs. ≥4 positive nodes), PMRT significantly reduced LRR from 51% to 10% in patients with ≥4 positive nodes and from 27% to 4% in patients with 1 to 3 positive nodes.[19] Overall survival improvement with PMRT use was demonstrated in both subgroups with 1 to 3 positive nodes (57% vs. 48%, $P = .03$) and with ≥4 positive nodes (21% vs. 12%, $P = .03$). Chest wall failures were the most common type of LRR, representing 55% of all LRR events in the no-PMRT group and 70% of all LRR events in the PMRT group. Axillary failures were more common in the no-PMRT group, representing 43% of all LRR events in the no-PMRT group and 24% of all LRR events in the PMRT group.[20]

In an important analysis examining relationships between locoregional control and survival in three subgroups classified as good, intermediate, or poor

based on tumor size, nodal status, grade, and biomarkers, Kyndi et al. reported that the magnitude of overall survival improvement with PMRT use was highest in patients with favorable-risk disease (tumors <2 cm, fewer than 3 positive nodes, grade 1, hormone receptors positive, Her2-negative disease).[21] In contrast, the high-risk subgroup (>3 positive nodes, tumors >5 cm, grade 3) had larger improvements in locoregional control, but no overall survival advantage. These findings suggest that improved locoregional control may exert a greater impact on survival in patients with favorable-risk disease with low competing risks of distant metastasis. Accordingly, these patients may gain larger survival improvements with radiation therapy optimizing locoregional control, compared to counterparts with high LRR risk and concomitant high distant progression risk.

The DBCG trials also contributed useful subset analyses documenting the risks of radiation-related late toxicities.[22–24] As older trials and meta-analyses have raised concerns regarding cardiovascular morbidity and mortality in radiated subjects, Højris et al. retrospectively analyzed data from both DBCG trials, which employed PMRT techniques that avoided cardiac exposure. At 10-year median follow-up, the rates of ischemic heart disease, acute myocardial infarction (MI), and cardiac death were similar between women treated with or without PMRT.[22] In a subset of 84 patients without evidence of disease, women who received PMRT had higher rates of lymphedema (14% vs. 3%, P = ns) and impaired shoulder function (17% vs. 2%, P = .001).[23] Disabling brachial plexopathy was present in 5% of radiated patients.[24]

The British Columbia trial was a smaller study that randomly assigned 318 premenopausal women with node-positive disease after mastectomy and CMF chemotherapy to PMRT or no additional treatment.[18] In this trial, PMRT employed hypofractionated prescriptions of 37.5 Gy in 16 fractions to the chest wall and IMN and 35 Gy in 16 fractions to the midaxilla. In the 20-year update, women treated with PMRT were confirmed to have significantly reduced rates of LRR (10% vs. 26%, P = .002) and improved distant relapse-free survival (31% vs. 48%, P = .004) and overall survival (47% vs. 37%, P = .03).[25] The rates of cardiac death were 1.8% in the PMRT group and 0.6% in the control group (P = .62). Women treated with PMRT had higher rates of lymphedema (9% vs. 3%, P = .035).

In summary, the Danish and British Columbia PMRT trials reported consistent outcomes. Women with high-risk breast cancer treated with PMRT and systemic therapy had significantly reduced risks of LRR. These

improvements led to improved disease-free survival and overall survival at 15- and 20-year follow-up.[19,25] These trials, taken together with the EBCTCG meta-analyses, supported the principle that by reducing LRR in the setting of effective systemic therapies, radiation therapy contributed to improved overall survival. As systemic treatment lowered the competing risk of distant metastasis, the effect of optimal locoregional control on improved survival became evident.

Phase III Randomized Trials—Regional Nodal Irradiation after Breast-Conserving Surgery or Mastectomy

In the setting of LABC, particularly in patients presenting with large T3 tumors or T4 disease, including inflammatory breast cancer, standard surgical treatment remains modified radical mastectomy. The use of breast-conserving surgery for patients with LABC, while more controversial, is being increasingly considered. Breast-conservation therapy may be applied to patients with T2 tumors with positive nodes, selected patients with operable T3 tumors with clinically node-negative disease or limited N1 involvement, and may be considered on an individualized basis with multidisciplinary review for patients with LABC with excellent response to neoadjuvant systemic therapy.

In patients with operable stage II to III breast cancer who are candidates for breast-conservation therapy, prospective trial results have emerged evaluating the role of RNI as a component of adjuvant management. The characteristics and results of these trials are summarized in Table 61.1.

TABLE 61.1 SUMMARY OF RESULTS OF THE MA20, EORTC, AND FRENCH IMN TRIALS EVALUATING REGIONAL NODAL IRRADIATION

	MA20[26]	EORTC 22922[27]	French IMN[28]
Number of subjects	1,832 N+ or high-risk N0	4,004 N+ or medial/central tumor	1,334 N+ or medial/central tumor
Accrual period	2000–2007	1996–2004	1991–1997
Breast surgery	All BCS	75% BCS	All mastectomy
Randomization	Breast alone vs. breast + IMN/SCN/level III ± level I–II	Breast/chest wall alone vs. breast/chest wall + IMN/SCN	IMN vs. no IMN
Node positive	90% (85% 1–3N+)	56%	75%
Chemotherapy	91%	55%	61%
Outcomes	LRRFS 95.2% vs.	LRRFS not reported	LRRFS not

(RNI vs. control)	92.2%, *P* = .009 DMFS 86.3% vs. 82.4%, *P* = .03 DFS 82% vs. 77%, *P* = .01 OS 82.8% vs. 81.8%, *P* = .38	DMFS 78.0% vs. 75.0%, *P* = .02 DFS 72.1% vs. 69.1%, *P* = .04 OS 82.3% vs. 80.7%, *p* = .06	reported DMFS not reported DFS 53.2% vs. 49.9%, *P* = .35 OS 62.6% vs. 59.3%, *P* = .8

BCS, breast-conserving surgery; DFS, disease-free survival; DMFS, distant metastasis-free survival; IMN, internal mammary nodes; LRRFS, locoregional recurrence-free survival; N+, node positive; OS, overall survival; RNI, regional nodal irradiation; SC, supraclavicular nodes.

National Cancer Institute of Canada Clinical Trial Group MA20 Trial

In 2015, the National Cancer Institute of Canada Clinical Trial Group (NCIC-CTG) MA20 trial was published after a median follow-up time of 9.5 years.[26] In this multicenter trial, 1,832 patients who underwent breast-conserving surgery and systemic therapy were randomized to receive radiation therapy to the whole breast alone (50 Gy in 25 fractions) versus radiation therapy to the whole breast (50 Gy in 25 fractions) plus regional nodes (45 Gy in 25 fractions). Axillary dissection was performed in 96% of subjects. Overall, 85% had 1 to 3 positive nodes, 5% had 4 or more positive nodes, and 10% had high-risk node-negative disease, defined as tumors >2 cm with ≤10 nodes removed, plus one or more of the following features: grade 3 histology, lymphovascular invasion, or estrogen receptor (ER)-negative disease. LABC, defined as stage IIB to III disease, was represented by 45% of subjects. RNI included the ipsilateral IMN in the first 3 intercostal spaces and the supraclavicular and level III axillary nodes. For patients with fewer than 10 nodes removed or 4 or more positive nodes, the target volume also included level I and II axillary nodes.

At 10 years, RNI was associated with improved locoregional disease-free survival (95.2% vs. 92.2%, *P* = .009) and distant disease-free survival (86.3% vs. 82.4%, *P* = .03), but no difference in overall survival (82.8% and 81.8%, *P* = .38). In a planned subset analysis, women with ER-negative disease randomized to RNI had improved disease-free survival and overall survival compared to no RNI. The majority of regional recurrences occurred in the axilla (63% of patients) or the supraclavicular nodes (27%). The rate of lymphedema was higher in the RNI group (8.4% vs. 4.5%, *P* = .001). The rates of grade 2 or higher cardiac and pulmonary toxicities were low (<1%) and were similar in the two study groups.

European Organisation for Research and Treatment of Cancer

22922 Trial

The European Organisation for Research and Treatment of Cancer (EORTC) 22922 trial evaluated elective radiation to the IMN and medial supraclavicular fossa in conjunction with whole-breast radiation after breast-conserving surgery or chest wall radiation after mastectomy.[27] Between 1996 and 2004, 4,004 patients with stage I to III breast cancer with a central or inner quadrant tumor with node-negative or node-positive disease or an outer quadrant tumor with node-positive disease were enrolled after breast-conserving surgery (76%) or mastectomy (24%). In this trial, the majority of patients had early-stage breast cancer (34% stage I and 32% stage IIA disease). 33% of subjects had LABC, including 19% stage IIB and 14% stage III disease. Systemic therapy was used in 99% of node-positive and 66% of node-negative subjects. Subjects were randomized to radiation to the IMN and supraclavicular nodes: 50 Gy in 25 fractions, 26 Gy with photons (ranging from Co60 to 10 MV photons), and 24 Gy with electrons or no IMN–supraclavicular radiation. Radiation was delivered to the IMN in the first three intercostal spaces, up to and including the first five intercostal spaces in patients with lower inner quadrant tumors. Among subjects who underwent mastectomy, 76% had chest wall radiation in conjunction with RNI. The axillary nodes were included in the target volume in 8.3% of the IMN–supraclavicular radiation group and 7.4% in the control (no IMN–supraclavicular radiation) group. At 10 years, the RNI group had lower rate of any first recurrence (19.4% vs. 22.9%, $P = .02$) and higher rates of distant disease-free survival (78% vs. 72%, $P = .02$). Overall survival was 82.3% in the RNI group and 80.7% in the control groups ($P = .06$). As in the MA20 trial, the EORTC trial demonstrated that RNI was beneficial for women with node-positive disease with respect to breast cancer–specific outcomes, but the difference in overall survival at 10 years was small and did not reach statistical significance. The rate of lung fibrosis was higher in the RNI group (4.4% vs. 1.7%, $P < .001$), whereas the rate of cardiac disease was comparable in the two groups (6.5% vs. 5.6%, $P = .25$).

French Trial of Internal Mammary Nodal Irradiation

The MA20 and EORTC trials both reported improved recurrence and disease-free survival with RNI including the IMN and supraclavicular nodes, but their studies were not designed to address the question of which specific nodal basin coverage contributed to the observed improvements in outcomes. A French multicenter prospective trial attempted to evaluate the impact of specific IMN

targeting in patients undergoing total mastectomy and axillary dissection.[28] From 1991 to 1997, 1,334 patients with stage I to III disease were enrolled, approximately 35% of whom had LABC. All subjects received radiation with two-dimensional planning to the chest wall, supraclavicular, and apical axillary nodes, with randomization to radiation to the IMN in the first five intercostal spaces versus no IMN inclusion. Ten-year overall survival rates were 62.6% in the IMN-treated group and 59.3% in the control group, but this difference was not statistically significant (P = .8).

Although the trial attempted to address an important question, its design was unfortunately limited. The sample size was calculated to detect a 10% difference in 10-year overall survival, an expectation inconsistent with the finding from the EBCTCG meta-analysis that the survival benefit with PMRT was approximately 4% to 5%.[8] The trial was hence underpowered to detect a small survival difference. Other limitations include the use of two-dimensional planning and a lack of rigorous methods to capture cardiac toxicity events, further limiting the trial's applicability to modern practice.

Budach et al. Meta-Analysis

After publication of the MA20, EORTC, and French IMN trials, Budach et al.[29] performed a meta-analysis of these three trials. RNI of the IMN and supraclavicular nodes as delivered in the MA20 and EORTC trials was associated with significant improvement in disease-free survival (HR 0.86; 95% CI, 0.78 to 0.95), distant disease-free survival (HR 0.84; 95 % CI, 0.75 to 0.94), and overall survival (HR 0.88; 95% CI, 0.78 to 0.99). Adding results of the French trial using a random effects model to take into account the different design of the French trial, the effect of RNI on overall survival remained significant (HR 0.90; 95% CI, 0.82 to 0.99).

In summary, the meta-analyses and randomized PMRT trials with 15- to 20-year follow-up and the more recent trials of RNI after breast-conserving surgery or mastectomy with 10-year follow-up have advanced our insight into the role of radiation therapy in the management of patients with operable LABC. Although LABC is a heterogeneous entity, consistent improvements in the recurrence and survival outcomes reported across these trials support the use of locoregional RT as an essential component of management for women with LABC, a population with high to extreme risks of locoregional and distant recurrence. When used in conjunction with systemic therapy, radiation therapy can optimize locoregional and distant disease control, reduce the morbidity of uncontrolled cancer

progression, and provide incremental improvements in survival.

ADJUVANT REGIONAL NODAL IRRADIATION CONSIDERATIONS

Indications in Stage IIB and IIIC Disease

The EBCTCG meta-analyses and randomized trials of locoregional radiation therapy after mastectomy or breast-conserving surgery have provided valuable data for the development of clinical practice guidelines and consensus statements from national and international expert panels.[30–39] Across the available guidelines, there is clear consensus that locoregional radiation therapy encompassing the breast/chest wall plus regional nodes is indicated for patients with advanced primary T3 and T4 tumors, N2 to N3 disease, and inflammatory breast cancer because of their high risk of LRR in excess of 30% to 40%.[40–46] The role of locoregional radiation therapy for patients with stage IIB disease with 1 to 3 positive nodes or T3N0 disease requires multidisciplinary, individualized consideration.

Target Volume Considerations

As the randomized trials of locoregional radiation therapy employed comprehensive targeting of the IMN and supraclavicular/apical level III axillary nodes and, in some cases, level I and II axilla, data regarding the individual effects of targeting specific nodal basins are lacking. Recognizing this caveat, decision-making regarding when to treat the regional nodes and which nodal basins to target may still be informed by available prospective trials and studies of patterns of relapse.

After mastectomy without radiation therapy, the most common site of locoregional relapse is the chest wall, occurring in more than 50% of patients who experienced LRR.[20,43–46] Another common site of LRR is the supraclavicular nodes and axillary apex, representing 20% to 40% of all LRR events.[43–46] Based on these relapse patterns, for women with stage IIB to III disease who are candidates for locoregional radiation therapy, the target volume should encompass at a minimum the entire chest wall, supraclavicular nodes, and axillary apex.

As LABC represents a wide spectrum of nodal recurrence risk, the use of full axillary nodal irradiation should be individualized. In an analysis of regional nodal failure patterns in 1,031 patients treated with mastectomy including level I

to II axillary dissection and enrolled in five trials doxorubicin-based chemotherapy with no PMRT at the MD Anderson Cancer Center (MDACC), Strom et al.[45] reported that the 10-year rates of recurrence were 3% within the low-mid axilla. The risk of failure in the low-mid axilla was not significantly higher for patients with increasing numbers of involved nodes, percentage of involved nodes, nodal size, or gross extranodal extension. These findings suggest that radiation targeting the dissected axilla may not be warranted for most patients, when balanced against increased risks of lymphedema and arm morbidity. This benefit versus risk balance, however, is changing as nodal staging standards have shifted from routine axillary dissection to sentinel node biopsy.[47–51] As in all therapeutic decision-making for locoregional RT, the estimated risks of regional nodal recurrence and estimated benefits that axillary RT may provide should be carefully balanced against risks of adverse effects including lymphedema, chronic arm morbidity, and brachial plexopathy.

IMN Irradiation

Indications for the specific targeting of the IMN remain controversial.[52–54] Historically, studies of extended radical mastectomy have identified IMN metastases in large proportions of patients with LABC, particularly in association with extensive nodal disease and central or medial tumor location.[55] Patients with clinically or pathologically detected IMN disease clearly warrant radiation therapy targeting the disease. In patients without IMN involvement, the relative benefits of treating the IMN are unclear and hence difficult to balance against potential risks of increasing heart and lung exposure with IMN inclusion. It is noted that in all of the randomized trials that demonstrated benefits with RNI, the IMNs were routinely included in the target volume. Although the benefits observed with RNI in these trials may be attributed to the principle of radiation eradicating subclinical disease that may be a source for distant metastasis, it is not possible to assess how much of the benefits observed may be specifically attributed to IMN treatment.

In this context, additional insight into the effect of IMN radiation may be gained from the DBCG IMN study, a prospective population-based cohort study with 3,089 patients with node-positive breast cancer.[56] In this study, patients with right-sided disease were treated with IMN irradiation and patients with left-sided disease were followed without IMN treatment. At a median follow-up of 8.9 years, statistically significant improvements in breast cancer–specific survival and overall survival were observed with IMN irradiation. In an

exploratory subset analysis, the benefit of IMN irradiation was more pronounced in patients at high risk of IMN involvement, specifically those with node-positive medial/central tumors and those with 4 or more positive nodes irrespective of tumor location. The rate of death from ischemic heart disease was not elevated in the IMN-treated group. These data, while interesting, should be interpreted with caution. The study was nonrandomized, and the use of systemic therapy was lower than today's standards. It is also noteworthy that in this analysis, IMN irradiation was not observed to be associated with improved survival in women with lateral tumors and 1 to 3 positive nodes, a group of women likely with lower risk compared to central/medial tumors or more advanced nodal disease.

Based on the available data discussed, decisions regarding IMN inclusion in the target volume require caution and careful consideration of the uncertainty regarding its relative benefit and the potential for increased cardiopulmonary exposure. IMN treatment is justified for women with clinical or pathologically IMN involvement. As a component of adjuvant locoregional treatment, in light of randomized controlled data demonstrating benefits with comprehensive nodal treatment, IMN inclusion may be considered, particularly for women with advanced primary (T3/T4) or nodal disease (N2/N3), and women with node-positive medial/central tumors. When the decision is made to include the IMN as a component of PMRT or RNI, careful treatment planning using conformal techniques is essential to ensure that dose constraints to the heart and lungs are safely met.

RISKS OF LOCOREGIONAL RECURRENCE AFTER MASTECTOMY AND SYSTEMIC TREATMENT

Stage III

Estimates of the risks of LRR after mastectomy and systemic treatment may be derived from meta-analyses of prospective trials comparing cohorts treated with versus without radiation therapy. The 2014 EBCTCG meta-analysis suggested that for every 1.5 recurrences of any type avoided during the first 10 years after radiation, 1 breast cancer death would be avoided at 20 years.[13] It is thus important to note that, with the exception of patients with node-negative cancer treated with axillary dissection who have low LRR risk <10%, all other subgroups, the majority of whom had node-positive disease treated with mastectomy and axillary dissection without RT, had LRR risks in the 20% to

30% range. At this risk magnitude, adjuvant locoregional radiation may reasonably be considered for the potential benefits in reductions of recurrence and breast mortality risk previously discussed.

Corroborating data from randomized trials and meta-analyses, multiple institutional studies have reported that patients with advanced primary T3 or T4 tumors or ≥4 positive lymph nodes have high LRR risks >30% following mastectomy and chemotherapy.[57–62] As modern randomized trials have demonstrated that PMRT improved the 15- and 20-year overall survival outcomes of breast cancer patients with LRR risks of this magnitude, international consensus statements and guidelines have clearly endorsed recommendations for PMRT in these high-risk subgroups.[31–40]

Stage IIB T2N1

Distinct from patients with advanced primary tumors or extensive nodal burden, LRR risk estimates and locoregional management in patients with T1 to T2 breast cancer with 1 to 3 positive axillary nodes have long been more controversial. A paradigm shift, however, may be occurring as we now have data from the 2014 EBCTCG meta-analysis providing evidence that PMRT significantly improves overall survival in all patient subsets with node-positive breast cancer, including women with 1 to 3 positive nodes, irrespective of axillary surgery extent or systemic therapy use.[13] We also now have consistent data from the MA20 trial (which included predominantly women with 1 to 3 positive nodes) and the EORTC trial that RNI significantly reduced not only LRR but also distant relapse and breast cancer mortality.[27,28] The DBCG PMRT subset analysis showed that the magnitude of overall survival improvement was greatest not in women with the highest LRR risk but in women with more favorable risk in whom the competing risk of distant metastasis was lower.[23] These data, interpreted in light of the concept from the EBCTCG 2014 meta-analysis that for every 1.5 recurrences avoided, 1 breast cancer death could be spared,[13] support considerations for using RNI for women with 1 to 3 positive nodes after mastectomy and breast-conserving surgery.

The long-standing controversy in the setting of 1 to 3 positive nodes centered on observed discrepancies between the magnitudes of LRR risks reported in the PMRT trials compared to large institutional series of patients treated with mastectomy and systemic therapy. In the Danish trials, the 10-year LRR rate without PMRT was approximately 30%[16,17] and the 18-year rate was 37%,[20] substantially higher than the LRR rates observed in the British Columbia trial

(16% at 10 years and 21% at 20 years)[18,21] and in numerous institutional studies of patients treated with mastectomy and adjuvant systemic therapy without radiation (LRR ~10% to 15% at 10 years).[58–80] Variations in surgical staging and axillary clearance have been implicated as the source of discrepancy in these observed risks. The disproportionately greater rates of LRR in the DBCG trials have been attributed to limited axillary surgery potentially compromising staging accuracy and locoregional disease control. The DBCG investigators have addressed this by reanalyzing their data evaluating specifically subjects with eight or more nodes resected.[19] Among patients with 1 to 3 positive nodes, PMRT was still associated with significant reduced LRR (4% vs. 27%) and improved overall survival (57% vs. 48%).

In the EBCTCG 2014 meta-analysis, 10-year LRR rates among patients with 1 to 3 positive nodes treated with mastectomy and systemic therapy were 21% without PMRT and 4.3% with PMRT ($P < .0001$).[13] The 10-year LRR rates reported in institutional studies in women with 1 to 3 positive nodes treated with mastectomy and systemic therapy without PMRT were lower by comparison, approximating 10% to 15%.[58–80] Notably, the more recent series reported rates even lower LRR rates of <10%.[74–76] These trends in declining LRR rates over time may be attributable to earlier diagnosis, less advanced stage at presentation, improved surgical techniques, and availability of more effective systemic therapies.

Numerous groups have examined prognostic factors for high LRR risk among patients with 1 to 3 positive nodes treated with mastectomy and systemic therapy without radiation therapy. Factors that have been identified to be associated with LRR risk include age, tumor size, tumor location, grade, lymphovascular invasion, surgical margins, number of positive nodes, nodal ratio, extranodal extension, biomarker status, and systemic therapy use. Prognostic models have been proposed[62–66] using combinations of such factors to estimate LRR risk, but these models require validation before they can be applied to routine practice. Molecular subtyping[81–83] has also emerged as a promising tool to improve prognostication and treatment selection, but further studies are still needed.

A joint ASCO/ASTRO/SSO expert panel recently convened to formulate a focused PMRT guideline update in response to the publication of the 2014 EBCTCG meta-analysis.[37] Although the panel unanimously accepted that the available evidence supported the findings that PMRT reduced the risks of recurrence and mortality in patients with T1 to T2 breast cancer with 1 to 3 positive nodes, concerns remained that the results of EBCTCG meta-analysis

based on older trials may not be generalizable to the advances available in modern practice. Concerns also remained that there may still be some patient subsets with such low LRR risks that the absolute benefit of radiation therapy may be offset by potential toxicities. The panel hence agreed that clinicians should consider factors that may be associated with decreased risks of LRR when balancing benefits versus risks of PMRT. Although there are no current validated methods to identify node-positive, low-risk subsets, the panel suggested that these factors may include patient characteristics such as age, life expectancy, and comorbid conditions; pathologic findings such as T1 tumors, no lymphovascular invasion, single positive node, and/or small size of nodal metastasis; substantial response to neoadjuvant systemic therapy; and favorable intrinsic characteristics such as low-grade disease and strongly positive hormone receptors.

Until such low-risk subsets can be clearly identified, decision-making in patients with 1 to 3 positive nodes should continue to be multidisciplinary, taking into consideration the results of the randomized trials and meta-analyses demonstrating that radiation therapy reduces LRR, distant recurrence, and breast cancer mortality not only in patients with high LRR risks but also in those with more favorable-risk disease. The benefits in reducing recurrence and improving survival should be balanced against potential risks and should be carefully communicated, taking into consideration the individual patient's therapeutic goals and personal preferences.

Prospective randomized trials are needed to provide evidence-based data for prognostication and locoregional treatment decisions in women with 1 to 3 positive nodes. The United Kingdom *S*elective *U*se of *P*ostoperative Radiotherapy Aft*E*r Mastect*O*my (SUPREMO) randomized trial is designed to evaluate the role of postmastectomy radiation to the chest wall in women with intermediate-risk stage II disease.[84] The trial has enrolled 1,688 patients between 2006 and 2013. Although the trial is not generalizable to the vast majority of patients with LABC and does not address ongoing questions regarding nodal irradiation, it will provide valuable data regarding the role of chest wall irradiation, patterns of relapse, and survival outcomes for patients with intermediate-risk breast cancer.

Another highly pertinent trial is the Canadian Cancer Trials Group MA39 Tailor RT trial, currently in planning stages. In this multi-institutional phase III trial, molecular analysis will be performed to identify women with favorable-risk subtype with 1 to 2 positive nodes after sentinel node staging or 1 to 3 positive

nodes after axillary dissection. Eligible subjects treated with breast-conserving surgery will be randomized to radiation therapy to the breast alone versus breast and regional nodes, whereas subjects treated with mastectomy will be randomized to PMRT versus observation. The trial, which will be conducted internationally during the modern era of sentinel node staging, 3D conformal RT planning, and effective targeted systemic therapy, will provide essential data to advance our efforts to optimize therapy for women with 1 to 3 positive nodes.

Stage IIB T3N0

Women with pT3N0 breast cancer, as defined by the AJCC Cancer Staging Manual, 6th edition, as stage IIB breast cancer with primary tumor >5 cm without direct extension to the chest wall or skin, and no nodal metastasis,[1] comprise another group of patients in whom LRR risk estimate is controversial. Prospective randomized trials included very few pT3N0 cases.[16–18,26–28] The relative rarity of pT3N0 breast cancer is likely related to the fact that the majority of patients with large tumors >5 cm will be found to have nodal involvement at surgery, including those deemed clinically node-negative. As with other uncommon clinical scenarios, risk estimates in pT3N0 disease are challenging because of limited data available.

The DBCG 82b and 82c trials performed subgroup analysis on high-risk node-negative disease, comprising 8% to 10% of subjects enrolled. This subgroup included pT3 and pT4 disease with involvement of chest wall and skin.[16,17] In the DBCG82b trial of premenopausal women treated with CMF, PMRT in this subgroup was associated with reduced 10-year LRR from 17% to 3% and improved overall survival from 70% to 82%.[16] However, in the DBCG82c trial of postmenopausal women treated with tamoxifen, PMRT reduced 10-year LRR from 23% to 6%, but there was no difference in overall survival (56% with PMRT vs. 55% without PMRT).[17]

In the absence of consistent prospective data on LRR risk and the effect of PMRT in pT3N0 breast cancer, investigators have used other data sources to address the controversy. Floyd and Taghian[85] highlighted a wide range in reported LRR from 7.1% to 60% among patients with T3N0 disease. In a multi-institutional analysis that combined pT2 = 5 cm N0 and pT3 > 5 cm N0 cases treated without PMRT yielding 70 cases, the 5-year cumulative LRR rate was 7.6%.[86] Similarly, in a pooled analysis of five National Surgical Adjuvant Breast Project (NSABP) randomized trials of systemic therapy with 313 cases, Taghian et al.[87] reported a 10-year isolated LRR of 7%. Although neither study included

a comparison cohort treated with PMRT, the low LRR rates observed raised questions regarding whether PMRT should be routinely used in these subjects.

Several retrospective studies have reported LRR rates in women with T3N0 breast cancer treated with and without PMRT. Mignano et al.[88] reported on 101 cases with T3N0 breast cancer treated with mastectomy without radiation. At a median follow-up of 93 months, the rate of LRR was 11%. Helinto et al.[89] compared 33 patients with pT3N0 breast cancer treated with PMRT with 5 patients treated without PMRT. LRR was significantly lower in the PMRT compared to the no-PMRT group, 9% versus 40%. In analysis from the British Columbia Cancer Agency with 100 node-negative cases with tumors ≥5 cm, 44 of whom received PMRT, Goulart et al.[90] reported that the 10-year LRR rates in women treated with PMRT was 2.3%, compared to 8.9% without PMRT. These series, however, were limited by very small samples and selection biases inherent in their retrospective design.

The effect of PMRT on disease-specific survival and overall survival has also been examined in retrospective, registry-based analyses with variable results. Using the Surveillance Epidemiology and End Results (SEER) database, McCammon et al.[91] analyzed a cohort of 1865 women with T3N0 tumors treated with mastectomy from 1988 to 2002, in which one-third of patients received PMRT. No significant difference in 10-year breast cancer–specific survival was found between the subgroups treated with or without PMRT. In contrast, in a more contemporary SEER analysis, Johnson et al.[92] examined 2,525 women with T3N0 disease treated with mastectomy from 2000 to 2010, 1,063 of whom received PMRT. At a median follow-up of 56 months, PMRT was found to be associated with significant improvements in both breasts cancer–specific survival and overall survival. Similarly, Cassidy et al.[93] analyzed 3,437 patients with T3N0 breast cancer treated with mastectomy between 2003 and 2011 identified in the National Cancer Database (NCDB). PMRT was found to be associated with improved overall survival, regardless of surgical margin status, tumor size, and systemic therapy use. Francis et al. reported comparable results in another NCDB analysis of 4291 T3N0 patients treated between 2004 and 2012, 47% of whom underwent PMRT.[94] After propensity score matching analysis to address potential confounders, PMRT use was found to be associated with improved overall survival at 5 years and 10 years.

Acknowledging the limitations of available data, in the 2001 ASCO guidelines, PMRT was “suggested” for patients with pT3, node-positive and operable stage III breast cancer.[36] Similarly, the 2017 NCCN Guidelines advised

clinicians to “consider” radiation therapy after mastectomy for patients with pT3N0 disease.[34]

LOCOREGIONAL RADIATION THERAPY AFTER NEOADJUVANT CHEMOTHERAPY

In the multimodality management of patients with LABC, NCT is now standard of care. As an initial treatment, NCT has the potential to simultaneously reduce tumor bulk in the breast and regional nodes and reduce the risk of distant dissemination. In recent years, NCT use has expanded beyond the setting of inoperable disease to also include patients with operable tumors who may experience disease downstaging and gain opportunities to be considered for breast-conserving therapy or less extensive and morbid axillary surgery. As NCT use increases, knowledge on its impact on subsequent locoregional treatment decisions continues to evolve. Data to guide radiation therapy decision-making after NCT are limited. A systematic review by Fowble et al. included 24 studies, 23 of which were single institution retrospective analyses plus one combined analysis of the NSAPBP B18 and B27 trials of NCT providing the sole source of prospective, multi-institutional data.[95]

Retrospective Data of LRR Risk after NAC and Mastectomy with Versus without PMRT

The MDACC has contributed several retrospective analyses documenting recurrence risks in patients with predominantly stage II to III disease treated with NCT followed by mastectomy with or without PMRT. In these series, when used, locoregional radiation therapy encompassed the chest wall, IMN, and undissected lymphatics in the supraclavicular and axillary regions. Among 150 patients with LABC treated with NAC followed by mastectomy without radiation therapy, Buchholz et al.[96] documented that the 10-year rate of LRR was 27%. On multivariable analysis, clinical IIIB or more advanced disease, pathologic involvement of 4 or more axillary nodes, and lack of tamoxifen use were significantly associated with higher LRR.

In another series also from MDACC, Huang et al. compared 542 patients treated with NAC and mastectomy with PMRT to 134 patients treated with NAC and mastectomy without PMRT.[97,98] At 10 years, PMRT was associated with reduced LRR (11% vs. 22%, $P = .0001$). Patients with clinical stage III to IV disease and pathologic complete response (pCR) who received PMRT had lower

rates of LRR at 10 years compared to counterparts who did not receive PMRT (3% vs. 33%, *P* = .006).

McGuire et al. reported a series of 226 patients treated at MDACC who achieved pCR after NAC and mastectomy. Patients with stage I to II disease with pCR who were treated with PMRT did not experience LRR. The 10-year LRR rates among patients with stage III disease who had pCR treated with PMRT was 7.3%, compared to 33% without PMRT (*P* = .04).[99] Finally, Garg et al.[100] reported on 132 patients with clinical stage I to II disease treated with NAC and mastectomy without PMRT. Factors associated with increased LRR were young age, stage T3N0 disease, 4 or more positive nodes, and lack of tamoxifen use.

Despite selection biases inherent in retrospective studies, these contributions from the MDACC were instructive in highlighting the finding that patients with locally advanced or T3N0 disease, despite having pCR to NAC, still have high LRR risk when PMRT was not used and that patients with early-stage (I to II) disease with pCR had low rates of LRR, irrespective of PMRT use.

NSAPBP B18 and B27 Combined Analysis of Recurrence Patterns after NCT and Mastectomy

The NSABP B18 and B27 randomized trials were trials of NAC with doxorubicin and cyclophosphamide alone or followed by neoadjuvant/adjuvant docetaxel.[101] These trials did not permit the use of chest wall/RNI after mastectomy or RNI after breast-conserving surgery as during that study era (accrual between 1988 and 1993 for B18 and between 1995 and 2000 for B27), it was not yet known that radiation can improve survival. Trial participants had operable cT1-3N0-1 breast cancer, diagnosed by fine needle aspiration or core biopsy. Patients with LABC with T4 or N2/3 disease were not included. In the combined analysis with 3,088 patients (1,947 mastectomy and 1,100 breast-conserving surgery), the 10-year cumulative incidence of LRR after mastectomy was 12.3% (8.9% local and 3.4% regional) and 10.3% after breast-conserving therapy (8.1% local and 2.2% regional). The 10-year LRR risks after NAC and mastectomy according to pre-NAC clinical stage and post-NAC pathologic response are summarized in Table 61.2. Among patients treated with mastectomy with pathologic node-positive disease after NAC, LRR risks ranged between 11.2% and 22.5%, a risk magnitude at which locoregional RT should be considered. Patients who presented with either clinical node-negative or node-positive disease who were found to have no pathologic nodal disease after NAC had LRR risks ranging from 6% to 12%. Finally, in patients with clinically node-

positive disease before NAC but who achieved pCR at mastectomy, the LRR rate was 0% at 10 years, suggesting that this may be a favorable-risk subset in whom PMRT avoidance may be studied in a clinical trial setting. In patients treated with breast-conserving therapy, the risk of regional nodal recurrence was approximately 7% to 9% in patients with clinical or pathologic node-positive disease, supporting consideration for RNI.

TABLE 61.2 SUMMARY OF RESULTS OF THE NSABP B18 AND B27 COMBINED ANALYSIS OF 10-YEAR LRR RISK AFTER NCT IN PATIENTS TREATED WITH MASTECTOMY

	ypN0; Breast pCR		ypN0; No Breast pCR		ypN+; Any Breast Response	
	N	10-year LRR	*N*	10-year LRR	*N*	10-year LRR
≤5 cm; cN0	46	6.5%	178	6.3%	184	11.2%
>5 cm; cN0	16	6.2%	95	11.8%	179	14.6%
≤5 cm; cN+	21	0%	37	10.8%	143	17.0%
>5 cm; cN+	11	0%	33	9.2%	128	22.5%

cN0 or cN+, clinical node-negative or node-positive before NAC; NAC, neoadjuvant chemotherapy; pCR, pathologic complete response; ypN0 or ypN+, pathologic node-negative or node-positive after NAC.

On multivariable analysis, clinical node-positive disease before NAC and no breast or nodal pCR after NAC were predictors of increased LRR after mastectomy or breast-conserving therapy. Additional risk factors for LRR were clinical tumor size >5 cm in patients treated with mastectomy and age <50 in patients treated with breast-conserving therapy. Although the NASBP combined analysis provided useful data from a large patient cohort documenting the 10-year LRR risks without adjuvant PMRT or post–breast-conserving surgery (BCS) RNI after NAC, interpretation of these results in the modern context is limited as the study lacked information on hormone receptors and Her2 status at presentation and was conducted before the era of more effective chemotherapy and targeted anti-Her2 therapy.

Until additional data from more modern prospective trials become available, the outcomes derived from available institutional series and the NSABP B18 and B27 combined analysis support the position that PMRT should be recommended after NAC and mastectomy for patients presenting with stage III disease as these patients, including those with pCR, have high LRR risks. Patients with pathologically positive nodes after NAC constitute another group with high LRR risk warranting PMRT consideration. These recommendations are consistent

with a National Cancer Institute statement that supports the use of PMRT to the chest wall and regional nodes for patients with clinical stage III disease or patients with residual histologically positive nodes after NAC.[102]

In contrast, the role of PMRT in patients with stage I to II disease is less clear as these patients have intermediate LRR risks. The ASCO/ASTRO/SSO panel stated that, on the basis of available data, stage I to II patients with persistently involved nodes on axillary dissection after NAC have sufficiently high risks of LRR to warrant PMRT recommendations.[37] Rates of LRR in patients with residual invasive cancer in the breast but pathologically negative nodes after NAC were inconsistent across different reports. Although stage I to II patients with pCR may have low rates of LRR, there remain insufficient data to exclude the possibility that some subgroups may still benefit from PMRT. Hence, the panel was not able to provide recommendations for or against PMRT use in these patients at this time.

Since the publication of the combined analysis of the NSABP B18 and B27 trials, other investigators have examined the impact of PMRT or post-BCS RNI in patients with clinically node-positive disease treated with NAC. In an analysis of 15,315 patients identified in the National Cancer Database (NCDB) with cT1-3cN1 disease, stratified into four subgroups by type of surgery and pathologic nodal status after NAC (ypN0 vs. ypN+), the use of PMRT was associated with improved overall survival for all pathologic nodal subgroups, whereas the addition of post-BCS RNI to breast RT was not associated with overall survival differences.[103] Interesting reports have also emerged suggesting that molecular subtype[104,105] and novel strategies to combine clinical and pathologic staging variables[106] may be used to improve prognostication of LRR risk after NAC.

Finally, in a study of practice patterns, Haffty et al.[107] evaluated participants of the American College of Surgeons Oncology Group Z1071 trial, a prospective study designed to evaluate the false-negative rate of sentinel node surgery after NAC. In this trial, RT decisions were at the discretion of the treating radiation oncologists. Although the majority of patients with clinically node-positive cancer treated with NAC received PMRT, the use of PMRT was less common in patients undergoing reconstruction and that there were wide variations in PMRT field design. These practices were not consistent with expert recommendations, highlighting the need for improved uniformity in RT following NAC.

Ultimately, prospective trial data are needed to address the role of locoregional RT after NAC and surgery. Two North American multicenter trials are underway for patients with biopsy-proven node-positive disease before NAC.

The NRG Oncology Group 9353 trial, initiated in 2013, randomizes patients with clinical T1 to T3, N1 breast cancer (after fine needle aspiration cytology or core biopsy confirmation of positive nodes) who undergo NAC followed by mastectomy or BCS and have pathologically negative nodes, to either no radiation or PMRT to the chest wall or reconstructed breast and regional nodes or radiation to the breast or breast plus RNI (ClinicalTrials.gov identifier NCT01872975). The Alliance for Clinical Trials in Oncology A011202 trial will randomize patients with a positive sentinel node biopsy after NAC to axillary dissection versus axillary radiation therapy without axillary surgery (ClinicalTrials.gov identifier NCT01901094). These trials will provide valuable data to improve our understanding of the role of locoregional radiation after NCT for patients with LABC.

TREATMENT TECHNIQUES AFTER MASTECTOMY OR BCT WITH REGIONAL NODAL IRRADIATION

Though external beam radiation can be delivered using cobalt machines or linear accelerators (LINACs), the techniques for radiation treatment to the breast and chest wall have evolved significantly since their initial use in the 1940s. Compared with cobalt machines, which deliver photon energies of 1.2 and 1.3 MV and only have the ability to adequately penetrate superficial depths, modern radiation delivery techniques utilize LINACs with multiple beam energies up to 20 MV, and three-dimensional treatment planning and delivery are facilitated by tools such as multislice computed tomography (CT) simulators, computerized treatment planning software, and on-board imaging systems. It is now widely recognized that the techniques utilized in the early breast-conservation therapy and PMRT trials using cobalt machines and older radiation delivery techniques subjected patients unintentionally to excessive doses to normal tissues such as the heart, lung, and contralateral breast. Over time and with longer follow-up, we have learned that this exposure to normal tissue increases risks of cardiovascular, pulmonary, and soft tissue complications including cardiac-related deaths (in left-sided treatment) and secondary malignancies (contralateral breast, lung cancer).[2–4,7,8]

With improvements in treatment planning and delivery, the benefits of radiation for locoregional and disease-free outcomes for breast cancer after breast-conserving surgery and after mastectomy have resulted in a small but significant survival benefit.[7–13] Though it is unlikely that these modern radiation

advances have improved the *absolute* magnitude of the benefits in locoregional control, these technologic improvements have resulted in more precise and conformal treatment delivery that spares normal tissue. In this context, improved techniques have the potential to significantly affect survival outcomes, by shifting the proportions in the risks to benefits to ultimately achieve an improvement in the therapeutic ratio. This section will examine the traditional tangential and more conformal radiation techniques for breast, chest wall, and regional nodal radiation. We will discuss considerations in target volume delineation, dose prescriptions, optimal dosimetry to optimize homogeneity to target tissues and meet normal tissue constraints, and methods of delivery to maximize locoregional control and minimize toxicity.

Simulation

At the time of simulation, a virtual simulation with CT simulator is preferable for treatment planning purposes, though a fluoroscopic simulator may be used for two-dimensional treatment planning when CT technology or modern treatment planning software and linear accelerators are not available. Patients are initially immobilized in the treatment position, with immobilization devices ranging from commonly utilized commercial supine breast boards or prone boards to customized VacLok, Alpha Cradle, and lateral decubitus positioning devices.[108] Typically, one or both arms may be positioned above the head when in the supine or prone position but may be adjusted as needed for patient comfort but ensuring that the arm(s) do not intercept with treatment beams. The supine position is most common, with the ipsilateral arm abducted to 90 to 120 degrees and externally rotated. In assessing arm position, it is important to have the soft tissues of the arm cranial to the junction of the tangent and supraclavicular fossa field. In addition, skin folds within the supraclavicular fossa should be avoided if possible. Patients are placed on a 10- to 15-degree angle board to flatten the slope of the chest wall in the region of the sternum. The face should be turned to the contralateral side to displace the mandible from the supraclavicular field.

At simulation, patients should be clinically assessed with palpation of the areas at risk and delineation of the clinical borders of the breast/chest wall and surgical scars with radio-opaque wire markers. Thus, the clinical target volume (CTV) may be visualized on the planning CT together with the anatomic landmarks, allowing for conformal treatment beam design. The volumes to be wired should include all breast tissue, and in the case of mastectomy, the entire chest wall and mastectomy scar. The traditional clinical borders were typically

defined at the inferior portion of the clavicular head superiorly; the midaxillary line laterally; the midsternum medially; 2 cm below the inframammary fold (using the contralateral inframammary fold as a reference, in patients treated with mastectomy), clearing air by 2 to 3 cm over the chest wall/breast tissue anteriorly; and 1 to 3 cm of the lung posteriorly to the edge of the tangential field edge.[109] For PMRT, the entire chest wall and mastectomy scar should be encompassed. Although these clinical borders solely define the treatment borders with fluoroscopic simulation, they also provide a general guide in the case of three-dimensional CT planning and therefore should be considered at the time of CT simulation.

Typically, CT slice thicknesses of 2 to 3 mm should be used. Because the anatomic structures are reconstructed from these slices with a certain thickness from the planning CT, a maximum slice thickness exceeding 3 mm is generally not recommended, in order to minimize enlargement of the field borders, as during the planning process, the clinical treatment volume (CTV) is typically enlarged by 1 slice thickness in the craniocaudal direction to compensate for partial volume effect.[110]

Target Delineation

In the era of 3D treatment planning, consistent delineation of the breast, chest wall, regional lymph nodes, and OAR is critical for accurate assessment of the dose distributions prior to approving a treatment plan. Inadequate delineation of target tissues and OARs can result in the misinterpretation of dose–volume histograms (DVHs) and ultimately influence treatment plan evaluation. The OARs include the heart, ipsilateral/contralateral lung, contralateral breast, brachial plexus, esophagus, thyroid, and spinal cord.

Significant variations have been reported in contoured volumes among radiation oncologists.[111,112] To reduce these inconsistencies, several contouring proposals and guidelines have been published, with the goal of reducing multi-institutional and interobserver variability in target delineation.[110,113–115] These include institution-based studies with proposals for anatomic delineation and professional organizations, which have developed definitions from data systematically quantified and collected from experts in breast radiation oncology. For example, the Radiation Therapy Oncology Group (RTOG) has established a breast cancer atlas based on target delineation of 3 illustrative patient cases performed by 9 breast radiation oncologists and describes the general principles of contouring for CTVs of the breast, chest wall, and nodal

regions, which include the axilla, supraclavicular fossa, and IMN (Table 61.3).[113,116] Similarly, the European Society Therapeutic Radiation Oncology (ESTRO) has developed a breast-contouring consensus for delineation of the CTV for the breast, chest wall, and regional lymph node basins, which additionally includes the interpectoral (Rotter) nodes, and describes planning target volumes (PTV).[110] Finally, the Danish Breast Cancer Cooperative Group has published a national guideline and contouring atlas, which additionally provides recommended dose–volume constraints (Table 61.4).[114]

TABLE 61.3 RTOG CONSENSUS DEFINITIONS FOR BREAST CANCER TREATMENT PLANNING

		Axilla			
	Breast/Chest Wall	I	II	III	Supraclavicular Fossa
Cranial	Clinical reference + second rib insertion	Axillary vessels cross lateral edge of pectoralis minor muscle	Axillary vessels cross medial edge of pectoralis minor muscle	Pectoralis minor muscle insert on cricoid	Caudal to the crico cartilage
Caudal	Clinical reference + loss of CT apparent breast	Pectoralis major muscle insert into ribs	Axillary vessels cross lateral edge of pectoralis minor muscle	Axillary vessels cross medial edge of pectoralis minor muscle	Junction of brachioceph.– axillary veins/cau edge clavicle hea
Lateral	Clinical reference/mid Axillary line, excludes latissimus dorsi muscle	Medial border of latissimus dorsi muscle	Lateral border of pectoralis minor muscle	Medial border of pectoralis minor muscle	Caudal: junction firs rib, clavicle Cranial: lateral edg SCM muscle
Medial	Sternal–rib junction	Lateral border of pectoralis minor muscle	Medial border of pectoralis minor muscle	Thoracic inlet	Excludes thyroid ar trachea
Posterior	Br: Excludes pectoralis muscles, chest wall	Anterior surface of subscapularis muscle	Ribs and intercostal muscles	Ribs and intercostal muscles	Anterior aspect of t scalene muscle

	muscles, ribs CW: Includes ribs, pectoralis muscles, pleural interface. ribs, chest muscles				
Anterior	Skin	Plane defined by anterior surface of pectoralis major muscle and lateral dorsi muscle	Anterior surface pectoralis minor muscle	Posterior surface of the pectoralis major muscle	Sternocleidomasto muscle

Typically, in early-stage patients, the pectoralis muscle, chest wall muscles, and ribs may be excluded when contouring the breast; but for locally advanced cases, the chest wall and ribs should be included irrespective of the breast conservation or mastectomy setting.[113] In the case of advanced breast cancer, it is important to note that the abovementioned guidelines can be used as a starting

point for contouring but require individual adaptation based on the extent of the primary tumor and the lymph node involvement, with the obvious need for coverage of any gross disease with an added margin to the CTV to obtain a PTV for planning purposes.

Ultimately, there remain significant variations in philosophies regarding the target volumes requiring irradiation and the contouring of these volumes for LABC. Often, they are based on specific clinical/pathologic details of an individual case but can be influenced also by the treating physician's opinions regarding these issues and policies of the treating institution.[6] These variations in RNI patterns of practice have been highlighted in an international survey of radiation oncologists.[117,118]

Treatment Techniques

Various methods to incorporate the regional nodes in the locoregional treatment volume have been described. Two-dimensional tangential techniques in the breast-conserving therapy and PMRT settings have used bony and soft tissue landmarks to treat the entire breast or chest wall (with mastectomy scar) and typically only assess the dose at the level of the isocenter. In contrast, three-dimensional treatment planning uses CT imaging to delineate the volume to be radiated and can use "wedges" to attenuate the beam depending on the slope and thickness of the breast or chest wall to achieve a more uniform distribution and match anatomic contour using wedge-shaped pieces of metal in the head of the machine. When electron beams are used, such as for IMN treatment or delivery of a "boost" to the tumor bed after breast-conserving surgery or, in selected cases, the mastectomy scar, physical blocks are placed in the path of beam in the machine head to deliver a more conformal electron beam dose.

In contrast, 3D/IMRT techniques are based on the volumes delineated on planning CT and permits dosimetric and volumetric assessment at all levels above and below the central axis. As described earlier in this chapter, there are variations in the definitions for anatomic volumes and in physician judgment regarding which nodal basins require treatment (i.e., supraclavicular, internal mammary [IM], axilla).[15] Nevertheless, the vast majority of patients with locally advanced disease treated with either breast-conservation therapy or mastectomy have node-positive disease with high LRR risk, and therefore, the ipsilateral supraclavicular (SC) fossa and axillary apex (level III axilla) are generally included in the treatment volume. The intentional inclusion of the dissected axilla and IM nodes is significantly more variable and decisions regarding their

inclusion require individualized consideration.[117,118] Typically, the volume for the IM vessels is within the first three intercostal interspaces, though the depth of the supraclavicular fossa and level III axilla varies greatly depending on individual anatomy and patient habitus. Inclusion of the intended nodal volumes in the CTV will ensure that these targets are adequately covered within the desired isodose volumes.

Various forward and inverse planning solutions have been described to generate 3D/IMRT plans that have been shown to significantly improve dose distribution over the standard wedge pair.[119,120] Additionally, methods using a combination of both forward and inverse planning have been described and are termed hybrid plans.[121,122] Unlike other disease sites such as head and neck and prostate cancer where intensity-modulated radiation therapy (IMRT), by definition, is inverse planned, for breast treatment planning, the modulation of the tangential beams can be achieved with forward planning, inverse planning, or a combination of both. For this reason, the exact definitions of breast IMRT versus three-dimensional treatment in breast cancer radiation treatment remain broad.[109] In this chapter, these modulated treatment plans will be termed 3D/IMRT.

Several forward-planned, “field-within-field” techniques have been described to deliver a more conformal dose by shaping the radiation beam and modulating high-dose regions.[123] Initially, the diverging posterior edges of the medial and lateral borders of the tangential beams are adjusted to be nondivergent and the fields are weighted and optimized with adjustments to the beam depth, gantry angles, and collimator angles to minimize irradiation to OAR and ensure full coverage of the treatment volume. Unlike a standard 3D treatment plan with wedges, forward-planned 3D/IMRT has additional sub-fields with manually created apertures that are used to block specific hot spots in the original tangential fields. The dose distribution for these tangential fields is typically equally weighted, with open medial and lateral fields, and the normalization point defined at approximately middepth and 1 to 1.5 cm superficial to the deep edge of the chest wall in the plane of the central axis of the beams. Next, the highest dose cloud of the >115% isodose curve volume is projected in the beam’s eye view of the treatment fields. A new segment is created using MLCs onto the medial/lateral tangent fields to account for 15% of the dose. This process can then be repeated for the 110% dose cloud, the 107% dose cloud, and so on, typically requiring 2 to 6 additional subfields to optimize dose homogeneity, as shown in Figure 61.1.[109,122] When using forward planning

techniques, modifications to the weighting of the subfields and mixing of 4 to 6 MV with higher-energy photons should be manually adjusted to enhance dose homogeneity, particularly when the patient separation is large.[124] The criteria used for choosing the numbers of additional subfields is generally based on reducing maximum isodose volumes by approximately 3% per subfield down to a goal of 107% of the prescription dose or until PTV starts to break up.

With inverse treatment planning, multisegment fields are created using inverse planning software that makes use of computer-generated intensity-modulated fields by adding dose to particular areas of the breast or chest wall using supplementary individually shaped beam portals (segments) that are coplanar to the tangential fields. The inverse-planned IMRT technique uses optimization algorithms to create fluence maps to shape dose distributions with the number of segments varying based on the different types of planning and optimization tools used to plan each case[125] and can be performed using a linear accelerator with either dynamic or static MLCs, arc therapy, or tomotherapy.[126,127] Typically, the same beam orientations and angles used for forward planning are used with inverse planning when the intent is to deliver a more homogeneous plan, although non-coplanar beams are often necessary to generate a more conformal treatment plan. The PTV is the same used for the 3D plans plus an extension into the air anteriorly of the chest of 1.5 cm to ensure appropriate opening of the multileaf collimator. The dose is prescribed to the PTV, and initial dose–volume constraints are provided. These automated priority-based computer algorithms deliver the prescribed dose to the predefined PTV volume while taking into consideration the relative prioritized dose constraints for normal tissues. Although the use of automated inverse software provides excellent homogeneity and normal tissue sparing, particularly for anatomically challenging cases, a more conformal plan typically requires rotational IMRT techniques or fixed-gantry IMRT techniques using multiple angles and non-coplanar beams, which result in larger volumes of normal tissue structures being exposed to low-dose radiation.[128]

Overall, no one breast modulation method (forward or inverse) has been shown to have a clear dosimetric or clinical advantage over another[120,129] and the method for developing the modulated plan is often based on institutional preferences and practices or determined based on anatomic specifics of an individual patient. Nevertheless, inverse planning typically results in a reduced treatment planning time with the trade-off of increasing monitor units to the patient compared to forward planning.[121] Unless necessary for particularly

anatomically challenging cases, the routine use of multiple-angle rotational IMRT techniques and non-coplanar beams is discouraged, because of the potential for long-term sequelae from the exposure of low-dose radiation to a significantly higher volume of normal tissue (Fig. 61.2).[128,129]

Coverage of SC/Axilla/IMN

Whether using 2-D treatment planning using bony landmarks or 3-D treatment planning with regional nodal basins contoured to guide field design, the

inclusion of SC/axilla may require the addition of a third anterior–posterior field to deliver a dose to a depth that will adequately cover the SC and axillary regions. This anterior field is typically angled 10 to 20 degrees to avoid the spinal cord and esophagus.

In all cases, it is important that the inferior border of the supraclavicular (with or without axilla) field be nondivergent to avoid overlap with the tangents. This can be accomplished using either independent collimator jaws or a half-beam block. A commonly used method is the single isocenter technique, in which the isocenter is identified on the axis conjoining the tangential fields and AP supraclavicular field with a gantry angle of zero, and shielding and wedges are typically used because table and collimator angles would result in asymmetric exit dose. When the depth of the axillary nodes exceeds approximately 5 cm and may not be adequately covered with the AP field using 4- to 6-MV photons, the use of higher photon energy or anterior–medial/posterior–lateral beam arrangement may be considered. The additional posterior–anterior (PA) supplemental field, traditionally referred to as the posterior axillary boost (PAB), allows delivery of additional dose to the midaxillary depth.

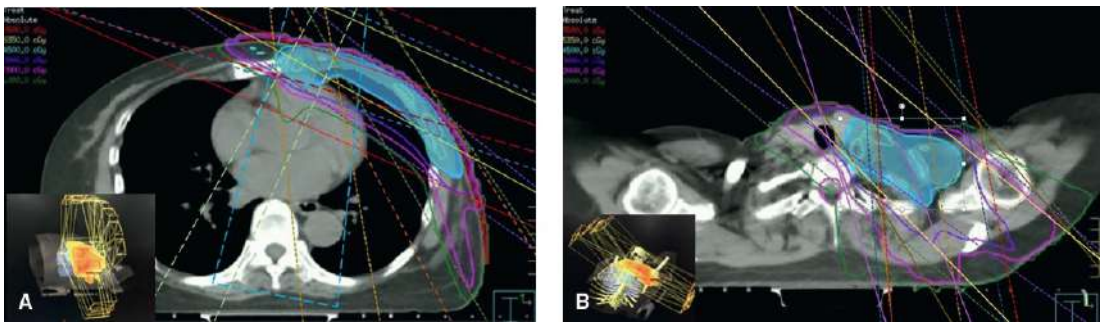

FIGURE 61.2. Inverse-planned IMRT plan of postmastectomy and comprehensive regional nodal radiation. As depicted in *blue*, the prescribed dose is very conformal to the PTV, but multiple beams and beam angles are required, resulting in a greater volume of low-dose radiation to normal tissue structures. *Inset* depicts the multiple coplanar beams, resulting in exposure to contralateral and posterior normal tissue. **A:** Chest wall and IM chain inverse IMRT plan. **B:** Supraclavicular, high axilla inverse IMRT plan.

More challenging is the coverage of the IMN, particularly in patients with left-sided disease, because the heart is located directly below the IMN and inevitably will receive more radiation than when the IMN are not covered. Several commonly described methods for IMN inclusion are described below.

Wide Tangents/Partially Wide Tangents

This is particularly useful when deep inspiration breath hold (DIBH) techniques are available (see below). Three photon beams are used including the supraclavicular, wide medial and wide lateral tangential fields, with the isocenter at the inferior border of the supraclavicular photon beam. Overlapping the inferior supraclavicular field with the tangents is assured without divergence using half-beam blocking and prohibiting collimator rotation. The medial border is extended onto the opposite breast/chest wall, to ensure that the ipsilateral IMNs are covered. When the wide tangents are to be split inferiorly with a heart block and computer-optimized wedge angles to minimize dose to heart and lung, this technique is termed partially wide tangents. This technique avoids the issue of matching fields and, depending on the patient's anatomy, offers an attractive alternative to a separate IMN field in selected patients. Care must be taken to ensure complete coverage of all target tissue and the entire chest wall and mastectomy scar in the inferior portion of the field, in the region of the block, if a partially wide tangent is used, and should be adjusted to follow the chest wall at the rib cage so that the IMN, breast, and chest wall receive adequate dose while sparing normal lungs.

Photon/Electron Matching Techniques

These techniques may be considered when attempts to encompass the IMN in the wide tangential fields result in excessive heart and lung exposure and when DIBH techniques are not available or successful. The supraclavicular and tangential photon fields are created using the standard single isocenter, 3-field technique described above. An IMN field using electron beams is matched on the skin to the medial tangential field, with the medial tangential border moved laterally so that it does not include the IMC. Traditionally, IMN portals have been 5 to 6 cm in width, extending from midline medially, just below the clavicular head superiorly to include the first 3 intercostal spaces, with the inferior border at the fourth interspace, but should be tailored three-dimensionally based on the CT contour.[109] The electrons may be a combination of two electron beam energies, a higher energy superiorly to provide full coverage to the IM regions at risk, whereas lower-energy electron beams are used at the inferior portion to encompass the breast/chest wall. The electron IM field can be treated with electrons alone or a combination of low-energy photons and electrons, with a maximum of 50% of the dose being delivered by photons to minimize the dose to underlying heart and lung tissue. A popular technique is to tilt the gantry angle of the electron field 5 degrees to 15 degrees less than the

medial tangent, minimizing the cold triangle just below the skin match of the 2 fields, and to feather this junction 1 to 3 times during the treatment course.

IMRT Inverse-Planned IMN Treatment

Using the contoured volumes to define the PTV, the inverse planning software uses a set of procedural guidelines to include specifications of the clinical planning goals to fulfill. Dose constraints for the OARs are prioritized and the software program automatically generates an optimized treatment plan, using optimization algorithms to create fluence maps to shape dose distributions. Intended dose distributions for targets are achieved while reducing OAR doses with the use of MLCs (dynamic or static), arc therapy,[127] tomotherapy, or topotherapy.[126] Although the development of a plan that will meet heart and lung dose constraints is achievable with inverse-planned IMRT, this typically comes at the cost of spreading low dose radiation to larger volumes of normal healthy tissue (Fig. 61.2).[128]

Dosimetry and Dose

For treatment planning purposes, the breast/CTV volume is defined as clinically demarcated tissue at CT simulation, and the volume may be adjusted to include all glandular breast tissue visualized by CT. In patients with early-stage disease, the breast CTV is typically limited anteriorly to within 5 mm from the skin and excludes the chest wall. In patient with LABC, it is particularly important to contour volumes that correlate with the clinical presentation, pathology, and residual disease, if present when planning treatment. As mentioned above, for advanced breast cancer and recurrent disease, it is important to remember that the target delineation guidelines can only be used as a starting point for contouring, but individual adaptation is essential to ensure coverage of all gross disease and tissues at risk.

The recommended dose prescriptions for whole-breast irradiation are 46 to 50 Gy in 23 to 25 fractions or 40 to 42.5 Gy in 15 to 16 fractions (in appropriately selected patients),[130] delivered 5 days per week, with a boost to the tumor bed with 10 to 16 Gy in 4 to 8 fractions for higher-risk patients.[131] In the postmastectomy setting, the target includes the ipsilateral chest wall, mastectomy scar, and drain sites when indicated. The typical prescribed dose to the PTV (chest wall with or without reconstruction and regional nodes) is 46 to 50 Gy in 23 to 25 or 40 Gy in 16 fractions. The use of a boost to the mastectomy scar is controversial. When the decision is made to boost, a typical prescription of 2 Gy

per fraction to a total dose of approximately 60 Gy is reasonable.

The use of tissue-equivalent bolus in the PMRT setting to increase the dose to skin[131,132] is also controversial.[133] Although bolus use is known to increase acute skin toxicity,[134] its specific contribution to improve local control is unknown. Reports have emerged suggesting that postmastectomy local recurrence rates are low in the absence of bolus.[135,136] For patients with inflammatory breast cancer or advanced primary tumors with high risks of skin recurrence, the use of bolus is justified. For other situations such as patients with low-risk disease and patients undergoing reconstruction, the bolus may be reasonably omitted. When the decision is made to use bolus, tissue-equivalent material of 0.5 to 1.0 cm is typically incorporated into the treatment plan and may be applied every day to every other day on the entire chest wall skin surface or, alternatively, may be applied during the initial portion of the radiation and removed for the second half, depending on the clinical scenario and physician and institutional preference.[132]

Although routine use of inverse planning and noncoplanar beam techniques may be appealing to generate homogenous plans requiring less treatment planning time compared with manual planning, many centers continue to routinely use forward planning techniques because of the disadvantages of inverse planning, which, as described previously, result in higher radiation monitor units, longer daily treatment time, increased low-dose exposure to larger volumes of normal tissue (which is associated with concerns for potential long-term toxicity such as secondary malignancies), and the inevitable association with higher health care costs. For this reason, 3D/IMRT with inverse-planned, non-coplanar techniques should be reserved for select cases where acceptable dose constraints cannot be met using 3D conformal RT (3D-CRT) methods.

Although standards for dose homogeneity have yet to be consistently adopted, most 3D/IMRT planning techniques typically achieve no more than 110% of the prescribed dose to the intact breast. In the case of PMRT, achieving this inhomogeneity can sometimes be more challenging depending on patient anatomy. DVHs of the PTV and OAR of the 3D/IMRT plans should be generated and compared. All attempts should be made to observe dose constraints for OAR, though these parameters vary depending on the volumes targeted and varying protocols. For example, the Danish Breast Cancer Guideline/Atlas suggests that the heart $V_{20\ Gy}$ should be <10%, heart $V_{40\ Gy}$ should be <5%, and the ipsilateral lung $V_{20\ Gy}$ should be <25% using tangents only and <35% when a third supraclavicular/axillary field is included.[114] These dose constraints

typically pertain to early-stage disease, and occasionally, despite the use of contemporary techniques in the PMRT setting, left-sided PMRT heart dose constraints may be difficult to meet. One study evaluated 3 different modern PMRT planning techniques, which included (a) forward-planned FIF 3D/IMRT, (b) inverse-planned 3D/IMRT (using 5 beams consisting of 2 opposed tangential beams with the same gantry angles as the forward planning technique, 2 anterior beams with a 10-degree angle from the tangential ones, and a supraclavicular beam, and segments with 166 control points), and (c) a VMAT 3D/IMRT plan consisting of two optimized coplanar partial arcs. This study demonstrated that the heart $V_{20\ Gy}$ was 12.48% ± 6.36, 10.54% ± 5.17, and 19.48% ± 8.84, respectively, for each of the techniques.[137] Another dosimetric evaluation of forward versus inverse-planned 3D/IMRT in the PMRT setting described mean heart doses of 877 and 704 cGy, respectively.[138]

Comparison of homogeneity and conformality across treatment plans can be quantitatively assessed using parameters such as the homogeneity index (HI), calculated as the fraction of the PTV with a dose between 95% and 105% of the prescribed dose ($V_{95\%}$ to $V_{105\%}$) and the conformity index (CI), defined as the fraction of the PTV surrounded by the reference dose ($V_{95\%}$) multiplied by the fraction of the total body volume covered by the reference PTV dose ($[PTV_{95\%}/PTV] \times [PTV_{95\%}/V_{95\%}]$).[138]

When using inverse planning to generate a 3D/IMRT plan, various optimization algorithms and techniques have been described and are often institution based. For example, one described optimization process starts with dose–volume constraints of as follows: 90% of PTV to receive 50 Gy/25 fractions; ipsilateral mean lung dose ≤20 Gy and ≤30% of the ipsilateral lung to receive ≤20 Gy; ≤5% of the heart to receive ≤30 Gy, mean heart dose ≤8 Gy for left-sided lesions, and ≤10 Gy if IMN is included; spinal cord maximum dose ≤45 Gy; and contralateral breast mean dose ≤1.5 Gy. Priority is high for the PTV, heart and lung constraints relative to other structures, and optimization proceeds with these settings until no further improvement are seen. Priority is then increased for other structures until a balance is reached between PTV coverage and normal tissues sparing. Once PTV and normal tissue dose constraints are met, the dosimetrist expands the anterior border of chest wall field 1.5 to 2 cm beyond the skin surface to ensure coverage of the chest wall (and bolus, if used).[139,140]

BREAST RADIOTHERAPY AND THE HEART

Cardiac Toxicity with Breast XRT

It has been well documented that standard tangential radiotherapy fields used for breast cancer consequentially result in irradiation of cardiac tissues, particularly in women receiving left-sided radiotherapy, who have been demonstrated to have more cardiac exposure when comparing right- versus left-sided breast cancer patients receive radiotherapy.[141] As a direct result of older techniques, this increase in cardiac exposure historically mitigated some of the benefits of adjuvant radiation, though more recently, with improvements in technology and treatment planning to sparing normal tissue, more recent meta-analyses in both the breast conservation and mastectomy setting demonstrate the ultimate benefits of radiation in reducing breast cancer–specific mortality.[8,9]

It is now established that incidental dose to the heart results in coronary events such as pericarditis, pericardial fibrosis, diffuse myocardial fibrosis, coronary artery disease (CAD), and, in more rare cases, valvular disease.[142] Although breast cancer–related cardiac toxicity typically takes a decade or more years to manifest, there is a dose gradient such that high-dose exposure above 30 Gy results in cardiac complications that become apparent within a year or two of exposure, with the risk of cardiac complications increasing with younger age of exposure and the presence of conventional risk factors.[142]

Cardiac Injury Pathogenesis

Radiation exposure to the heart results in an increase in micro- and macrovascular injury. The cardiac damage that results from radiation typically can be characterized into four major categories: pericardial fibrosis, myocardial fibrosis, pericarditis, and CAD.[142] The development of fibrosis consists of the deposition of collagen in either the parietal pericardium or the myocardial, which over time replaces normal tissue, and inhibits normal function. With pericardial fibrosis, the normal peripheral adipose layer (typically measuring <0.5 mm) is replaced with a thick fibrous layer, increasing the thickness of pericardium to as much as 8 mm and resulting in a rigid, constricted pericardial sac that is often accompanied by effusion. When collagen is deposited in the myocardium, which classically occurs in patches on the anterior wall of the left ventricle, this results in damage to the endothelium of the myocardial blood capillaries and can lead to transient ischemia and myocardial fibrosis, which, if extensive, can result in congestive heart failure.[143]

Alternatively, when a variable amount of protein-rich exudate accumulates

within the pericardial sac resulting in a pericardial effusion, this accumulation of fluid result in pericarditis or cause potentially fatal cardiac tamponade.[143] Atherosclerosis and the resultant CAD resulting from radiation exposure occurs with the same pathogenesis as normal physiologic atherosclerosis from other causes. The reduction in the arterial lumen is a result of intimal proliferation of myofibroblasts, with lipid-containing macrophages forming plaques that can fracture and cause thrombosis and can clinically manifest in symptoms of ischemic heart disease such as stable and unstable angina pectoris, MI, and chronic ischemic heart disease.[144]

Cardiac Toxicity Dose–Volume Data

Though QUANTEC recommends restricting the volume of the heart receiving at least 25 Gy (V_{25}) to <10% to keep the risk of cardiac mortality under 1%, much of the data supporting this recommendation come from a combination of both lymphoma and breast cancer patients.[145,146] Unlike studies that have evaluated radiation-related cardiac toxicity from diseases like Hodgkin disease where the degree of the cardiac exposure has been significantly larger, RT in breast cancer patients has resulted in cardiac complications of smaller magnitude, which have been much more difficult to elucidate. Much of data were derived from women enrolled in prospective, phase III trials in which half of the women were randomized to receive adjuvant radiotherapy. Earlier analysis of these randomized trials demonstrated that long-term survival beyond 10 years was significantly worse in women receiving radiation[2,3] and, ultimately, that mortality from heart disease was significantly increased by 27% in patients receiving RT.[8] Most of the increase was due to CAD. It has been elucidated that delivery techniques utilized in the earlier trials, including tangential field placement in close proximity to the heart, large daily fraction size and high total doses, use of anterior–posterior (AP) fields, inclusion of IMN, and use of orthovoltage and cobalt radiation, all may have contributed to these earlier results.[147] Updated analyses of these trials provide clear evidence demonstrating the larger mean cardiac RT doses with the risk of death from heart disease. The EBCTCG assessed the risk of death from RT-related heart disease, though notably not estimated from individual patient treatment plans, to be approximately increased by 3% per Gy mean cardiac heart dose,[148] whereas Darby et al.[149] estimated major coronary events in population-based case–control study of patients treated in Sweden and Denmark between 1958 and 2001 to be estimated at 7.4% per Gy. Although they attempted to estimate this

risk correcting for differences in doses and fractionation schedules using the linear-quadratic model to convert all treatments to an equivalent dose in 2-Gy fractions, and estimated cardiac volumes and doses of these pre-CT era patients with reconstruction using one standard representative CT scan, the validity of individual variability and correcting for these dosing differences brings to question the applicability of their findings to current clinical practice.[149] Nevertheless, since the time of this publication, cardiac dose constraints for the whole heart in breast cancer of a mean heart dose <4 Gy have generally been considered an achievable standard.

Outside the context of a randomized trial, comparisons of mortality after various different treatment regimens are often misleading because the prognosis of patients given different treatments will vary.[141] Radiation-induced heart disease is generally regarded a classical “deterministic” radiation effect, which is only expected to occur if the radiation dose exceeds a well-defined threshold. Cardiac dose–volume data from studies among atomic bomb survivors in the Hiroshima-Nagasaki Life Span Study, with mortality from heart disease after radiation exposure, suggest that although it remains unclear if there is any increased cardiac mortality risk when mean heart dose is below 0.5 Gy, at some undefined point in this range, there begins to be a clear association with level of exposure and the increased cardiac death risk is estimated at 14% per Gy.[150] Specifically, there is a significant quadratic dose–response relationships for MI among survivors exposed at <40 years of age (P = .049).[151]

This difference in the estimates of cardiac mortality risk of 14% in atomic bomb survivors versus 7.4% to 3% per Gy mean heart dose from women treated for breast cancer has been suggested to be unlikely because of confounding factors such as predisposing cardiac risk factors, because of the minimal presence of confounders such as obesity, diabetes, alcohol use, and smoking in the atomic bomb cohort. More likely, this difference in risk-per-Gy has been postulated to be secondary to the fractionated exposure and substantially less homogeneous cardiac radiation exposure in breast cancer patients or differences in age at exposure.[152]

The first study to assess cardiac toxicity outcomes in a population treated uniformly with RT using three-dimensional, CT-based simulation and assess this risk with consideration for the individual’s cardiac risk factors (including hypertension, smoking history, and body mass index [BMI], diabetes, etc.) reported a risk of acute coronary events to be 16.5% (95% CI, 0.6 to 35.0) per Gy of radiation to the whole heart in the first 9 years after treatment, similar to

that reported by Darby et al. at 15.5% between 5 and 9 years after RT. Additionally, the authors describe that the normal tissue complication probability (NTCP) model could be improved by using left ventricular V_5 instead of mean heart dose.[153]

Cardiac Avoidance Techniques

In the contemporary era where the vast majority of breast cancer patients receive some form of systemic treatment, efforts to spare the heart are even more crucial, because of increased cardiovascular risks associated with modern systemic agents, such as trastuzumab and anthracyclines and long-term use of aromatase inhibitors. More contemporary data support the decrease in incidental cardiac exposure to radiation for left-sided breast cancers with the use of modern techniques. Nevertheless, there will be significant variability in cardiac exposure based on individual patient factors, which include anatomy, history of smoking, and preexisting comorbidities. Several techniques for reducing the radiation exposure to the heart and lung have demonstrated significant impact in decreasing incidental dose to these OAR.

This section reviews some of the common techniques utilized to effectively decrease heart (and lung) exposure.[154,155]

Heart Blocks

A heart block is one of the oldest and possibly the simplest methods for minimizing heart dose, though it is only technically possible in certain patients in whom the lumpectomy cavity is readily identifiable to be remote from the heart block. The relationship between the tumor(s) to the chest wall is particularly important in the setting of oncoplastic reduction or any situation in which the lumpectomy cavity is ambiguous, to avoid placing the heart block in a location even remotely close to the original tumor(s). With selective and appropriate use of the heart block, the dose to the PTV has been shown to be reduced by only 2.8% and has been demonstrated to have no effect on compromising local control in appropriately selected patients (Fig. 61.3).[156]

Patient Positioning Using Prone Breast Board

In certain patients requiring left-sided breast cancer treatment, and occasionally for right-sided patients with large, pendulous breasts, those in whom the lung dose needs to be further minimized, or those with challenging anatomy such as pectus excavatum, positioning using a prone breast board at the time of

simulation for treatment planning can significantly reduce heart and lung doses. The traditional immobilization is the supine breast board, which allows for variable incline but nevertheless results in flattening of the breast across the chest wall so that larger volumes of chest wall receive incidental radiation when covering the PTV. With the prone board, gravity facilitates the anterior displacement of the breast tissue, allowing for significantly less inclusion of tissues deep to the chest wall (and hence underlying normal tissue).[157,158] In a dosimetric analysis comparing women simulated with both prone and supine positioning, prone positioning decreases lung exposure in 100% of patients and heart exposure in 85% of patients with left breast cancer, irrespective of breast size (Fig. 61.4).[159] Furthermore, cosmetic assessment using photographs of patients treated in the prone versus supine position suggests more favorable cosmesis with lower rates of hyperpigmentation and cosmetic deterioration among patients treated in the prone position.[160] No difference in 5-year local recurrence was observed in patients treated in the prone position.[158] There are a variety of commercially available prone breast boards, each with advantages and disadvantages, with the limitations of each prone board including the learning curve for daily positioning and reproducibility. Furthermore, prone boards can only be utilized for patients who are able to lie relatively comfortably on their abdomen with the head turned away at a >45 degree angle. Lastly, most current commercially available boards are intended to treat tangential breast plans and therefore are not used to treat 3-field breast plans to include a matched supraclavicular/axillary field. However, data are emerging reporting feasibility of locoregional treatment in the prone position, creating a potential for expansion of prone applications for patients with more advanced-stage disease.[161]

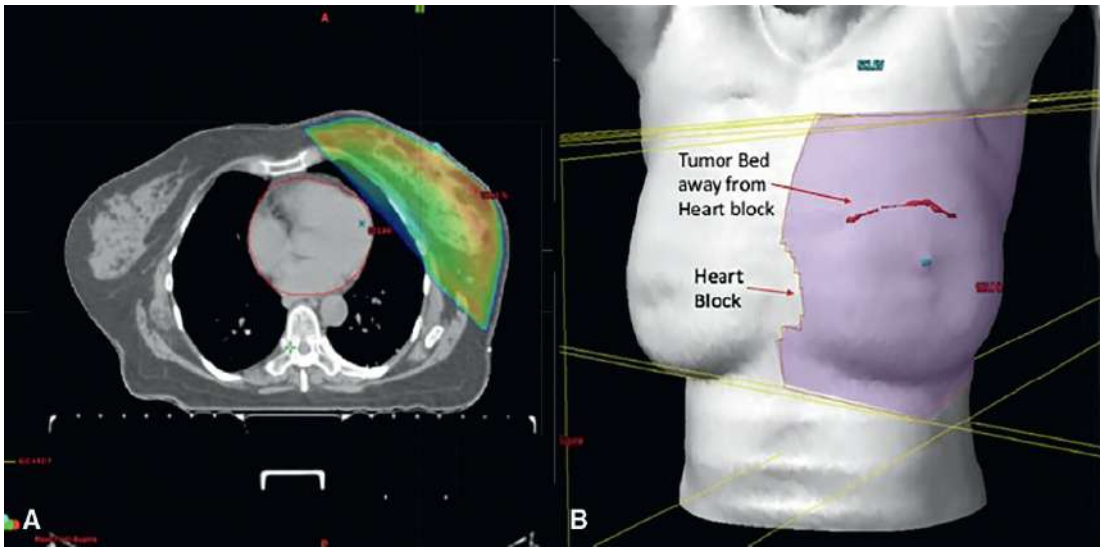

FIGURE 61.3. Heart block placement allows for $Mean_{heart\ dose}$ = 193 cGy. Multileaf collimators are added to the cardiac silhouette on the digital reconstruction and should be confirmed clinically on the patient and on the skin rendition to verify its placement away from the tumor bed. **A:** Axial dose distribution at the level of the heart. **B:** Skin rendition showing that the heart block placement not compromise coverage when limited to the cardiac silhouette and tumor bed is remote from the heart block.

Deep Inspiration Breath Hold/Respiratory Gating Methods

There are several commercially available devices for delivering radiation in breast cancer patients, which synchronize the delivery of radiation with the respiratory cycle. This concept makes use of the normal physiologic inferior and posterior–medial movement of the heart when a patient takes (and holds) a deep breath and only delivers radiation when the patient is in specified portions of the breath (or breath hold) cycle. This, in turn, reduces the irradiated volume and dose to the heart.

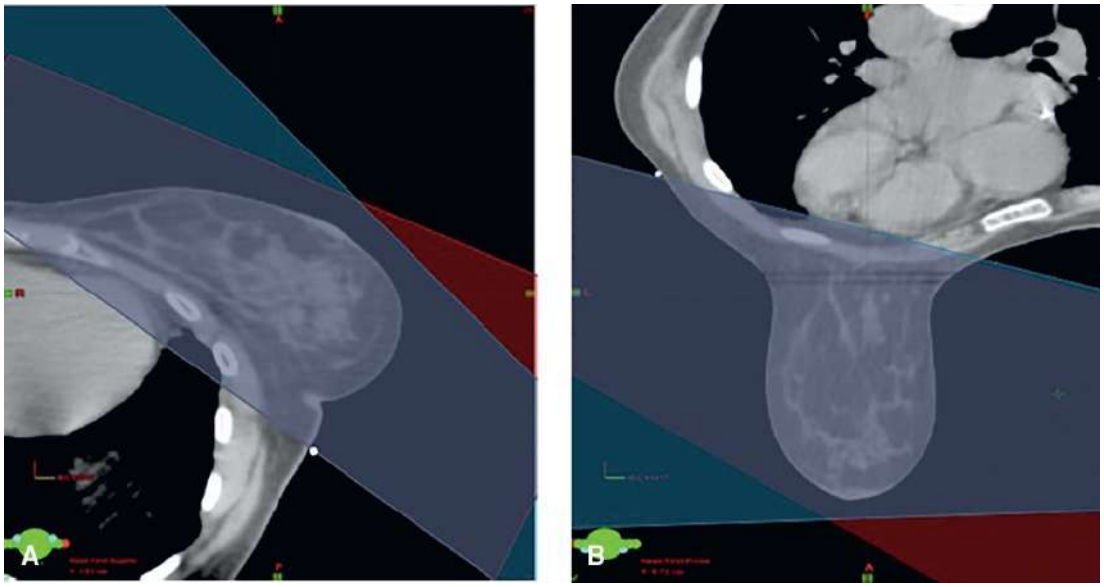

FIGURE 61.4. Supine versus prone positioning. **A:** Axial image depicting the tangential beams in the supine position at the level of the heart; $Mean_{heart\ dose}$ = 450 cGy. **B:** Axial image depicting the tangential beams in the prone position at the level of the heart; $Mean_{heart\ dose}$ = 173 cGy.

There are two major methods that make use of the respiratory cycle. The first is an active-breathing control (ABC) device used for regulation of respiratory inspiratory volume; the second relies on patient coaching for voluntary DIBH that is verified with either surface anatomy verification or direct volume measurement. For this, the patient is trained to hold a deep breath, typically for 20 to 30 seconds. At the time of simulation, each patient undergoes two CT simulation scans, one with free breathing, which is obtained as a reference for treatment setups, and the second in the deep breath hold position, which is used for the actual treatment plan. Use of this method has resulted in significant lowering of cardiac dose and volumes in both the breast conservation and postmastectomy settings (Fig. 61.5).

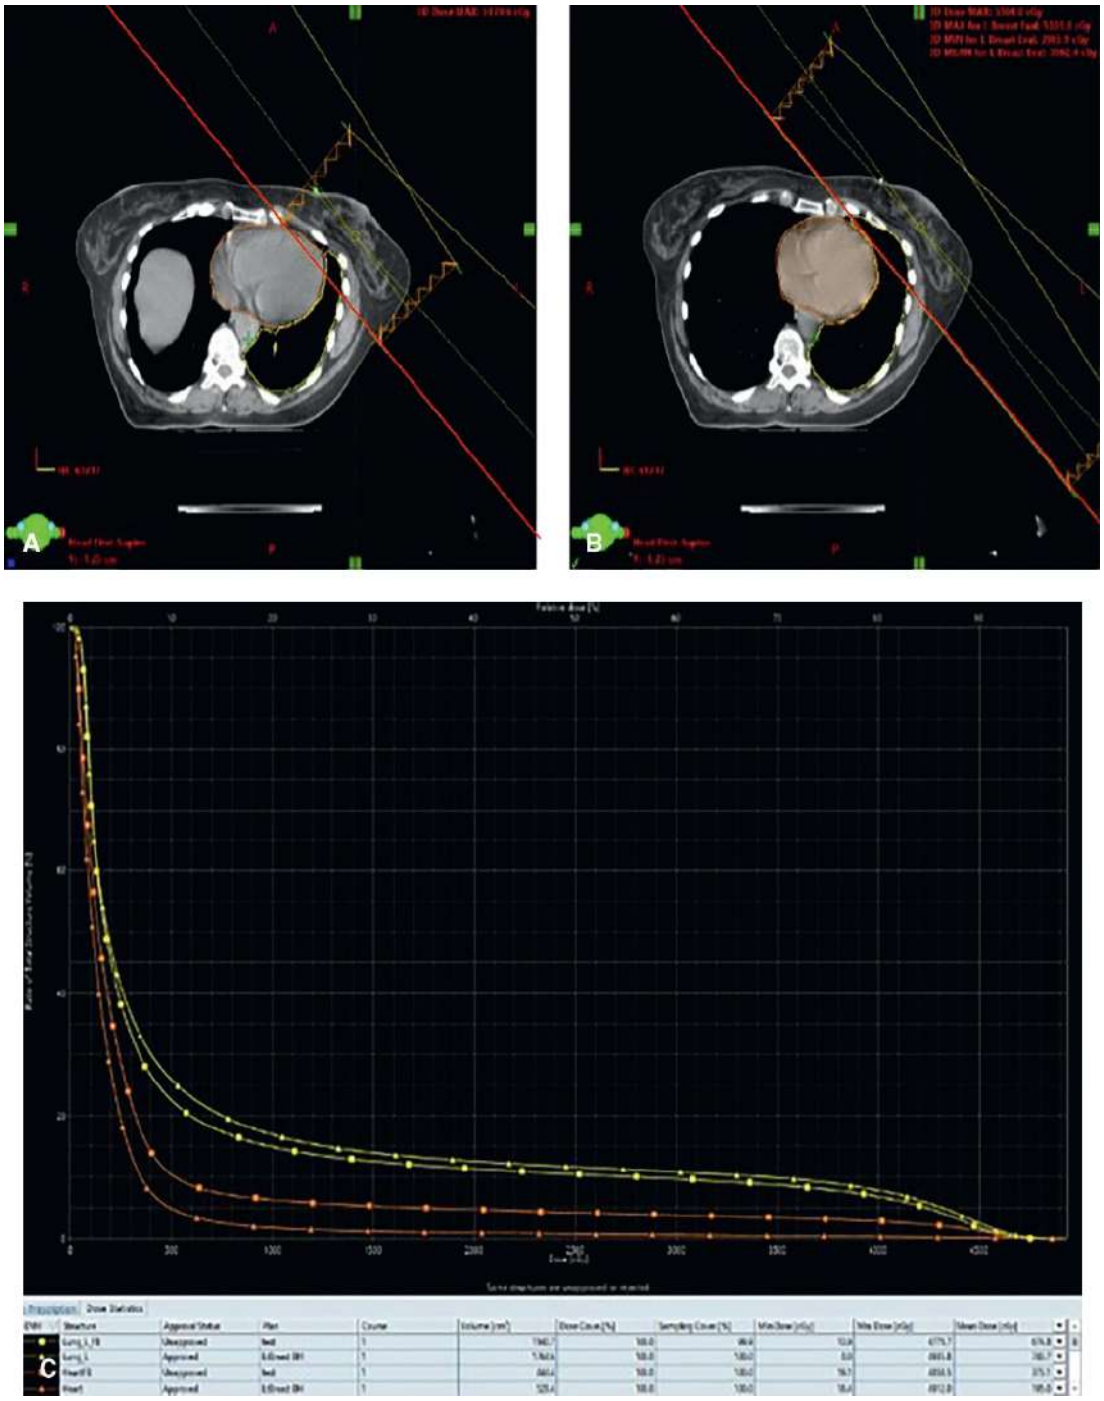

FIGURE 61.5. The use of DIBH significantly reduces cardiac volume irradiated. **A:** Free breathing scan showing tangential beams with a substantial portion of the left ventricle in the radiated field. **B:** DIBH scan—heart moves away from the chest wall with expansion of the diaphragm. **C:** Using the same clinical borders, the dose–volume histogram (DVH) showing $Mean_{heart\ dose}$ = 377 cGy with free breathing and $Mean_{heart\ dose}$ = 195 cGy with DIBH.

CT-based studies have demonstrated the magnitude in the benefit of DIBH to

approximate *complete* removal of the heart from the radiated field in nearly half of the patients and an approximately 80% reduction in cardiac volumes overall.[162]

In one study, moderate DIBH with ABC resulted in a significant decrease in mean heart dose in 88% of the patients studied (mean heart dose $_{\text{ABC}}$ = 254 cGy vs. mean heart dose $_{\text{free breathing}}$ = 423 cGy, $P < .001$).[163] Although the reductions in cardiac exposure are considerable in most patients with left-sided breast cancers, it is particularly notable that the benefits in decreasing cardiac dose with DIBH appear to be of greater magnitude in patients receiving PMRT, for which treatment planning to minimize cardiac dose can be more challenging because of the need to treat the much larger surgical bed including scars, compared to whole-breast irradiation following BCS.[164]

BREAST RECONSTRUCTION

The benefits of reconstruction after mastectomy are well described in the literature and include improvements in cosmetic outcomes, psychological health, self-esteem, body image, postdiagnosis sexuality, and overall satisfaction scores.[165,166] Although the benefits of PMRT have been described in detail elsewhere, in brief, for patients undergoing mastectomy with high-risk features such as node-positive disease, positive margins, large tumors, or recurrent disease, the adjuvant use of PMRT results in a decrease in LRRs and, in selected patients, has long-term survival benefits.

Although an increasing proportion of patients are opting to undergo reconstruction after mastectomy, the timing of when to incorporate reconstruction with adjuvant radiation remains challenging. It is well documented that the use of radiation and reconstruction results in increased complications, such as a higher risk of fibrosis and soft tissue shrinkage, capsular contractions around prosthesis, increased need for revision surgeries, and increased autologous reconstruction failures.[167–169] Ultimately, the complications associated with PMRT and reconstruction have the potential to significantly affect the quality of life and cosmetic outcomes of these women. Unfortunately, the data regarding patient-centered outcomes with regard to types of reconstruction and timing of reconstruction relative to PMRT are largely retrospective series or population-based analysis, and published prospective data are limited.

Types of Breast Reconstruction

There are two major categories of postmastectomy breast reconstruction. The most common has traditionally been an implant-based reconstruction, which can be performed as a one- or two-step procedure. With the one-step procedure, the implant of choice (saline or silicone) is placed immediately after the mastectomy and PMRT is delivered thereafter. With the two-step procedure, an expander is placed at the time of mastectomy and optimally expanded prior to the delivery of PMRT. The benefits of a two-step procedure include the ability to revise any radiation effects and allow for correction of PMRT-related asymmetry. Furthermore, with a two-step procedure, it is not mandated that the patient decide on implant-based or autologous reconstruction prior to the mastectomy, as this can be determined at the time of tissue expander removal and, if needed, allows for patient flexibility in changing their decision from one reconstruction approach to another. Options for autologous reconstruction include immediate reconstruction versus a delayed one-step or possibly a delayed two-step operative approach. The method of delayed autologous or two-step delayed-immediate autologous reconstruction has been reported to be utilized to decrease the soft tissue effects of PMRT.[170] With delayed-immediate reconstruction, patients who do not require radiation therapy can achieve aesthetic outcomes similar to those undergoing immediate reconstruction, and patients whose need for postoperative PMRT becomes apparent after review of the permanent pathologic sections after mastectomy, as it can avoid delivery of radiation to the permanent reconstruction.

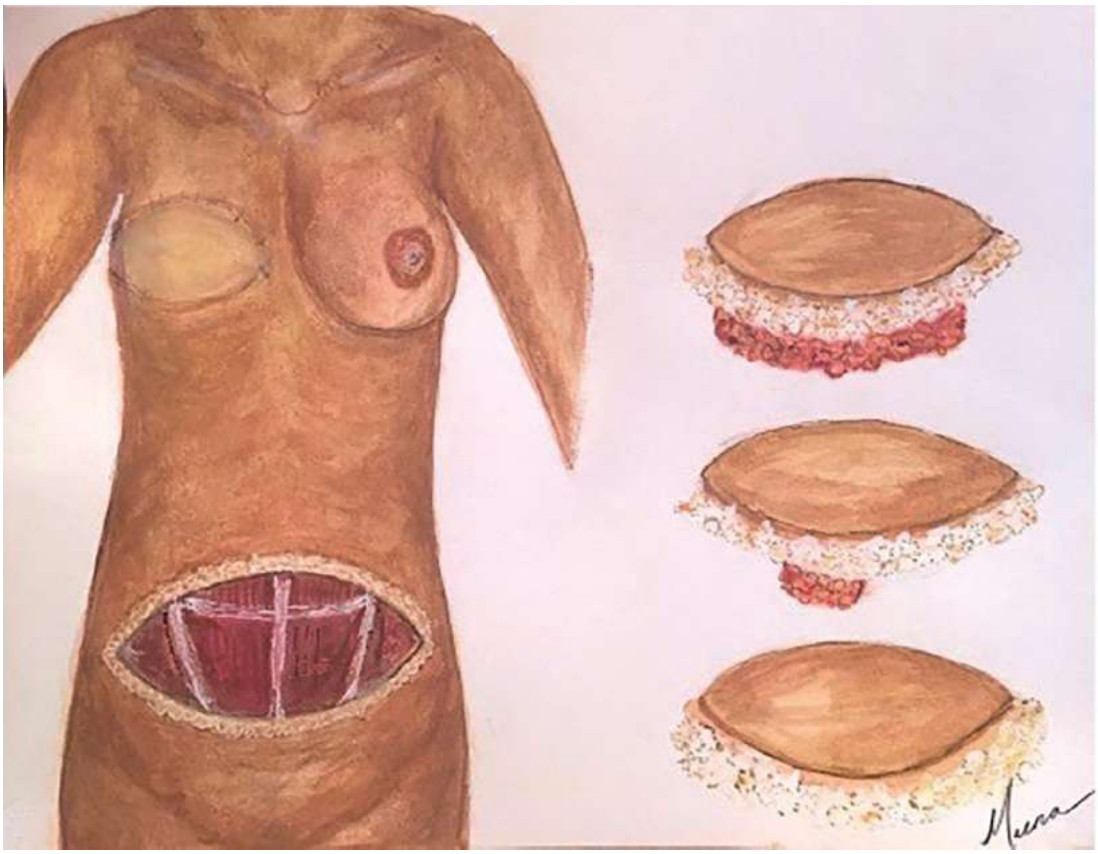

FIGURE 61.6. Illustration of TRAM and DIEP autologous reconstructions by Meena S. Moran. *Right top*: The traditional TRAM flap-A pedicled, full-thickness flap of the lower abdominal tissue (skin, fat and ipsilateral, full rectus abdominal muscle). Disadvantages include loss of abdominal muscle strength, and risks of "tunneling" of the flap under the skin around the rib cage area and abdominal hernia. *Right middle*: A "muscle-sparing free TRAM" uses only a small portion of the rectus muscle dissected from the anterior rectus sheath, which is completely detached from the abdominal wall and microsurgically reanastomosed to the blood supply on the chest wall. Advantages of this technique include a better blood supply than the pedicled flap, no "tunneling," less risk of healing and fat necrosis complications, and increased preservation of lower abdominal motor–sensory function. *Right bottom*: The DIEP (deep inferior epigastric perforator) flap uses the patient's abdominal skin and fat to reconstruct a natural, soft breast after mastectomy, but without removal of any rectus muscle, which is associated with faster recovery, less associated postsurgical pain, long-term maintenance of abdominal strength, and minimal risk of complications such as abdominal bulging and hernia.

Although patients with locally advanced disease historically have not been eligible for implant-based reconstruction because of the absence of a breast skin envelope following mastectomy and PMRT, which resulted in a fibrotic chest wall that was difficult to expand and made delayed breast reconstruction extremely challenging, the use of delayed-immediate reconstruction has resulted in a paradigm shift in allowing patients with locally advanced disease to have

reconstruction options by allowing immediate expander placement so that the breast skin envelope can be preserved for subsequent delayed reconstruction after PMRT.[171]

The 2 most common form of autologous reconstruction methods currently used are the TRAM and DIEP flaps (Fig. 61.6). The traditional autologous implant for many years was the TRAM flap, which was classically performed in one of three ways. The initial TRAM approach was the pedicled TRAM, which requires an incision from hip to hip after which the lower abdominal tissue (including skin, fat and ipsilateral, full-thickness rectus abdominal muscle) below the navel is tunneled under the upper abdominal skin to the ipsilateral chest wall to reconstruct the new breast (Fig. 61.6, right top). With this procedure, the surgery is generally difficult and long, and the patient experiences clinically significant loss of abdominal muscle strength, and there is also some degree of "tunneling" under the skin with an upper abdominal bulge around the rib cage area.

The free-TRAM flap uses the same tissue as the pedicled TRAM but in this case is completely detached from the abdominal wall, transplanted to the chest, with the blood supply reestablished with microsurgery. The main advantage of the free TRAM over the pedicled TRAM is a better blood supply and therefore less risk of healing problems and fat necrosis, and no "tunneling." Most recently, the technique for muscle-sparing free TRAM was developed, which requires dissection of the anterior rectus sheath with procurement of only a small portion of the rectus muscle as part of the flap (Fig. 61.6, right middle). This approach has the benefit of preservation of an increased amount of rectus abdominis muscle to improve the integrity of the abdominal wall and preserve lateral intercostal nerve innervations, which are reported to be important to the strength of the abdominal wall than the muscles themselves.[172,173]

The most advanced autologous reconstruction to date is the DIEP (deep inferior epigastric perforator), which is increasingly replacing the TRAM techniques. Similar to the muscle-sparing free TRAM, the DIEP uses the patient's abdominal skin and fat to reconstruct a natural, soft breast after mastectomy, but without removal of any rectus muscle (Fig. 61.6, right bottom). Sometimes described as the "tummy tuck" reconstruction, it is associated with a faster recovery, with less associated pain after surgery, long-term maintenance of abdominal strength, and minimal risk of complications such as abdominal bulging and hernia.

Sequencing of PMRT and Reconstruction

The timing of breast reconstruction is of critical importance in the decision-making process and needs to be discussed early with any patient considering mastectomy. The expanding indications for PMRT have added to the complexity of the reconstruction decision-making process, and therefore, a multidisciplinary approach is required to discern the likelihood of requiring PMRT based on the preoperative risk assessment. Whether or not a patient has a likelihood to require PMRT is a critical factor in the decision-making process when discussing reconstruction options and timing of (possible) radiation. Currently, the typical approach is to do immediate (permanent) reconstruction if the patient is considered low risk for requiring PMRT RT, as this generally results in better cosmesis.[171] Alternatively, if the patient is considered intermediate to high risk for requiring PMRT, delaying the definitive (flap or implant placement) with initial placement of a tissue expander to preserve and expand the breast skin envelope for a skin preservation and then delayed placement of the permanent reconstruction after PMRT is typically the preferred course.[174] Currently, the vast majority of reconstructions currently performed in the United States in the setting of PMRT consist of delayed reconstruction,[175] which is not necessarily supported by the published literature but may be related to risk aversion and medical–legal implications for radiating a permanent implant.

Timing for Implant-Based Reconstruction

There are numerous publications describing and attempting to discern the best algorithm for reconstruction to minimize the effects of PMRT. The vast majority of the existing literature assesses absolute risk of complications such as contractures, revision surgeries, and reconstruction failures (and not patient-centered outcomes). Although there is significant controversy about the optimal approach regarding strategies for timing of reconstruction with PMRT to the tissue expander versus the permanent implant, the published data to date are difficult to interpret because of differences in outcomes measured.

Although delivering radiation therapy to a temporary tissue expander is feasible, there are challenges. Large expanders can make radiation treatment planning more challenging, creating steep sloping contours particularly at the medial chest wall that can increase normal tissue exposure and compromise dose distribution. In a survey study, 66% of radiation oncologists agreed that tissue expander volume affects radiation dose distribution and render planning more difficult[176] and 47% will ask plastic surgeons to adjust expander volume to 150

to 250 cc, with the most common reason for this request being to minimize dose to the heart and lungs. With few data to guide radiation oncologists regarding whether an expander should be deflated or inflated during PMRT, decision-making must be individualized taking into consideration the patient's anatomy and may require an initial planning CT for assessment prior to deciding whether adjustments in the volume of fluid in the implant is needed.

For example, the data are consistent in demonstrating higher rates of reconstructive failures in patients receiving PMRT to the tissue expander compared with permanent implants.[177–179] Yet conflicting these results, the risk of GIII/IV capsular contractures is reported to be worse when irradiating the permanent implant.[180,181] Confounding these findings further, very few patient-centered studies assessing irradiation to permanent implant versus tissue expander have been published. An institutional experience of nearly 300 patients with either expanders or permanent implants from Memorial Sloan Kettering reported that although tissue expanders had a higher risk of reconstructive failure, permanent implants were associated with worse aesthetic results and capsular contracture. Though the patient-reported outcomes did not differ across the 2 cohorts, these authors concluded that any sequence of radiotherapy in two-stage prosthetic reconstruction negatively impacts the final aesthetic outcome and survival of the implant.[180] From the same institution, these group of authors reported on outcomes of a cohort of 151 stage II or III patients that underwent a 2-step immediate expander placement, followed by initiation of systemic chemotherapy and expansion of expander and exchange of expander for permanent implant at the completion of chemotherapy prior PMRT. They reported the 7-year permanent implant failure to be 29%, with the most common causes for failure reported as severe capsular contractures and infection.[182] More recently, these data were updated to report an overall success rate of 94% when the permanent implant was in place prior to PMRT versus 60% when the exchange occurred after radiation.[183]

Nevertheless, the traditional and most common preferred method for implant-based reconstruction has been to wait until after the completion of radiation therapy to perform the exchange procedure to the permanent implant. This practice pattern has likely been more popular because of concerns regarding potential delays in initiating PMRT, the opportunity to release capsular contractures around the expander after PMRT, and capacity to revise any radiation effects and allow for correction of PMRT-related asymmetry. However, there are increasing body of data, including meta-analysis, to suggest that

exchanging the expander for the permanent implant prior to starting PMRT is associated with decreased complications and improved cosmetic outcomes.[180,181,183–190]

For example, one meta-analysis of studies of reconstruction published reported on results from 37 combined studies and found that for the cohort undergoing implant-based reconstruction, there were more complications and a higher revision rate if the permanent implant reconstruction was performed after radiotherapy.[185] Ultimately, the use of variable endpoints across studies makes it difficult to draw definitive conclusions from these data, and patients undergoing mastectomy should have risks and benefits presented to them prior to their definitive surgery, with the integration of reconstruction and PMRT addressed in a multidisciplinary setting.

Timing for Autologous Reconstructions

The literature regarding the timing of autologous reconstruction, similar to implant-based reconstruction, continues to be conflicting and remains a topic of debate. Options when discussing PMRT with patients intending on mastectomy and autologous reconstruction include immediate autologous reconstruction prior to PMRT, a delayed autologous procedure performed 6 or more months after PMRT, or the delayed-immediate (2-step) approach discussed above. To date, the studies evaluating these approaches and the best cosmetic outcomes and satisfaction scores have reported conflicting results. There are several studies that have suggested that the outcomes of aesthetics and satisfaction are better with immediate reconstruction,[186–189] though these studies are limited in their small cohort size and use of non-validated outcomes measures.

A meta-analysis of studies of reconstruction published in 2014 reported on results from 37 combined studies. They found that, for the cohort undergoing autologous reconstruction, though the incidence of fibrosis was higher if autologous reconstruction was done prior to PMRT, they were not able to demonstrate any significant differences in total complication rate before or after PMRT, ultimately concluding that in the setting of autologous implants, the data do not support sequencing of PMRT and autologous reconstruction has any impact on severe complication rates.[181] Currently, most plastic surgeons opt for immediate versus delayed versus two-step based on their own clinical experience and institutional preferences rather than data- or patient-driven timing decisions. Other factors that may play a role when considering sequencing of PMRT and autologous reconstruction include the technical and economic benefits of

immediate reconstruction, which include performing a technically less challenging procedure when performed prior to PMRT, the decrease in cost associated with one versus two separate surgeries and hospitalizations for the patient, and data suggesting an association with patient-reported improvements in measures of quality of life when autologous implants are performed immediately compared with delayed.[190–193]

Comparison of Implant Versus Autologous Reconstruction in the Setting of PMRT

Generally, much of the existing literature suggests that autologous reconstruction has a better complication and PMRT-related toxicity profile compared with implant-based reconstruction. Furthermore, autologous reconstruction has been demonstrated to result in superior patient-centered cosmetic outcomes in settings where PMRT is delivered.[192,194]

The effects of PMRT and systemic chemotherapy with either autologous or implant-based reconstructions were comprehensively assessed in a meta-analysis that analyzed 62 published manuscripts and over 6,000 reconstructed patients. Pooled analysis of the PMRT cohort revealed significantly higher-weighted incidences of reoperation ($P < .0001$), total complications ($P < .0001$), and reconstructive failure ($P < .0001$) in prosthetic compared to autologous reconstructions. The use of postoperative chemotherapy did not appear to affect the overall outcomes of the reconstruction.[175] Though together, the body of data to date suggest that autologous reconstruction results in a better complication profile and success rate than implant-based reconstruction when PMRT is needed,[175,192–194] there are many significant factors to consider when counseling a patient regarding reconstruction and PMRT, which include but are not limited to patient preferences, comorbidities, technical feasibility, clinical–pathologic features and ultimate breast cancer-related prognosis (i.e., reconstruction in an inflammatory breast cancer patient with 14/14+ axillary lymph nodes in comparison to a patient undergoing mastectomy for a T1, N1 breast cancer).

CONCLUSIONS

Indications for radiation therapy have expanded with contemporary prospective trials and meta-analyses providing evidence-based data that radiation therapy reduces not only LRR but also distant recurrence and improves survival for women with breast cancer. In the setting of women with node-positive breast

cancer, including LABC, locoregional treatment decision-making is complex and requires multidisciplinary assessment to generate individualized recommendations. A meticulous approach should include interdisciplinary input to coordinate systemic therapy, radiation therapy, surgery, and potentially reconstruction. Modern technologic advances in radiation planning and delivery, using CT-based three-dimensional treatment planning to minimize radiation to OAR and deliver a homogenous treatment plan using techniques described in this chapter, will increase the potential for radiation oncologists to improve the therapeutic ratio for patients with breast cancer.

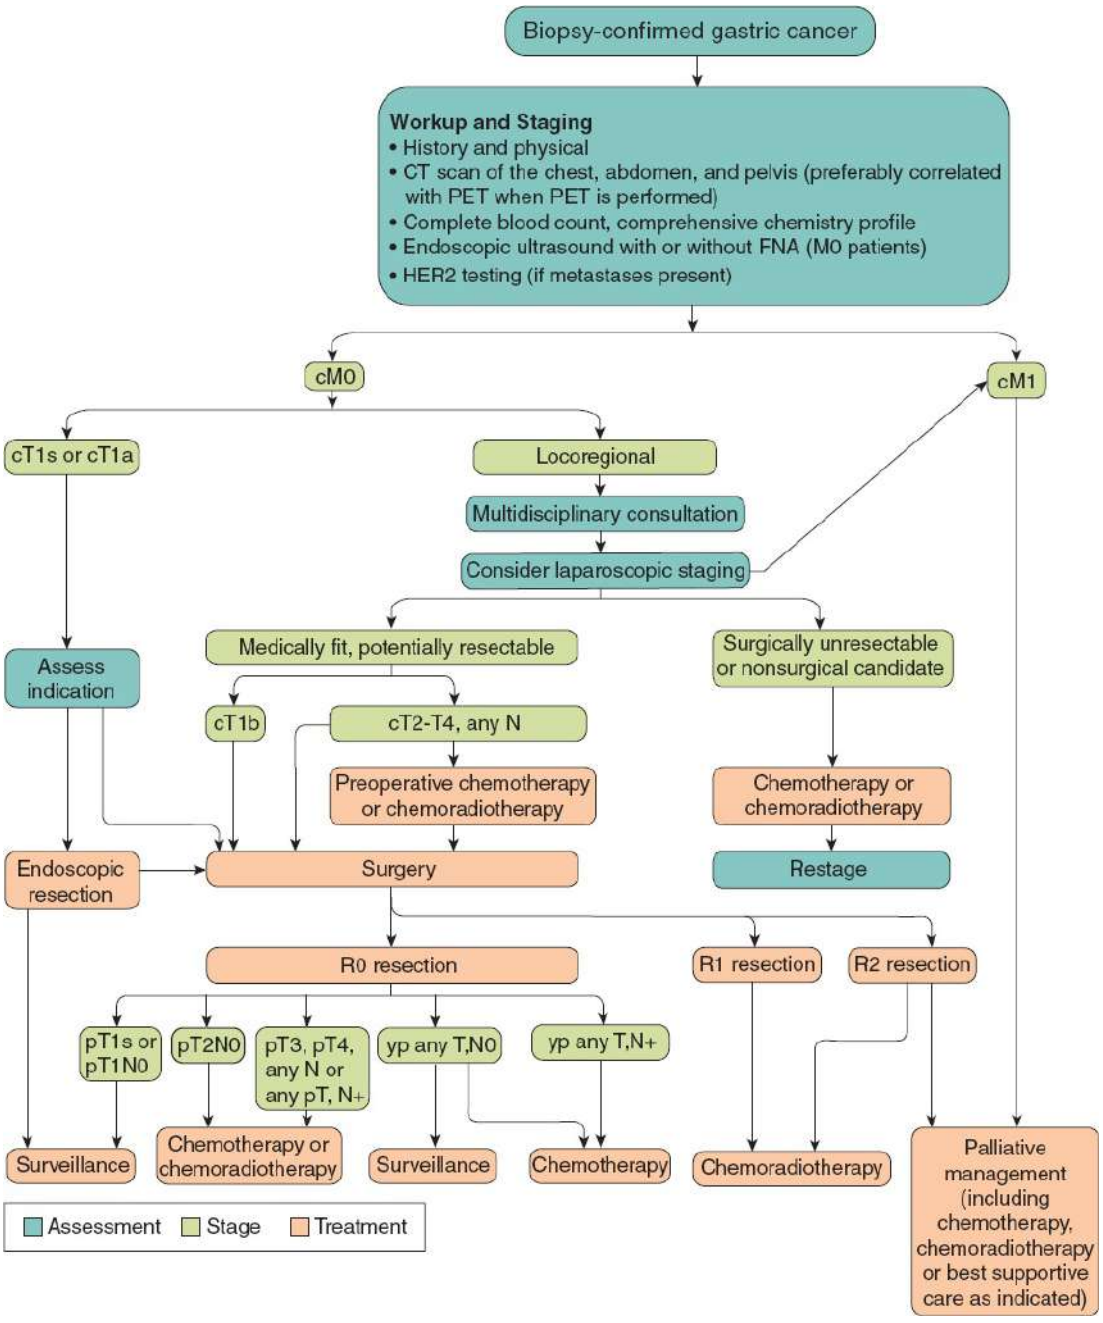
CHAPTER 62

Stomach Cancer

Brian G. Czito, Manisha Palta, and Christopher G. Willett



Treatment algorithm for newly diagnosed gastric cancer. Treatment approaches are based in location and stage of the tumor, as well as surgical resectability and medical comorbidities of the patient. CT, computed tomography; EUS, endoscopic ultrasound; FNA, fine-needle aspiration; PET, positron emission tomography. Reprinted by permission from Nature: Ajani JA, Lee J, Sano T, et al. Gastric adenocarcinoma. Nat Rev Dis Primers 2017;3:17036. Copyright © 2017 Springer Nature.

ANATOMY

The stomach begins at the gastroesophageal (GE) junction and ends at the pylorus. The stomach is generally divided into anatomic regions, including the gastric cardia (the region surrounding the superior opening of the stomach where it connects with the GE junction/level of the lower esophageal sphincter), the fundus (situated superiorly, a rounded portion superior to the body and to the left of the cardia), the body (a large, central portion of the stomach), and the pyloric canal (distally, connecting to the duodenum). The pylorus is composed of two parts: the pyloric antrum, which connects to the body of the stomach, and the pyloric canal, which empties into the duodenum (Fig. 62.1). The pylorus communicates with the duodenum of the small intestine via the pyloric sphincter (valve). This valve regulates the passage of chyme from the stomach to the duodenum and prevents backflow from the duodenum to the stomach. A plane passing through the incisura angularis on the lesser curvature divides the stomach into the body and the pyloric portion (antrum). The anterior surface of the stomach is covered with the peritoneum of the greater sac. At the left and cranially, it abuts the diaphragm. In view of the increasing incidence of gastric cancer at the GE junction, it is important to note that there is either no or variable visceral peritoneal covering at the most proximal portion of the GE junction.[1] Positive radial margins at this site are often “true” positive margins, whereas many other positive margins in the stomach are free serosal margins unless the tumor is adherent to an adjacent organ or structure. The right portion of the anterior gastric surface is adjacent to the left lobe of the liver and the anterior abdominal wall. Posteriorly, the stomach is covered with peritoneum of the lesser sac or omental bursa. The stomach contacts many visceral structures; from superior to inferior, it is adjacent to the spleen, left adrenal gland, superior portion of the left kidney, ventral portion of the pancreas, and transverse colon. The hepatogastric ligament or lesser omentum is attached to the lesser curvature and contains the left gastric artery and the right gastric branch of the hepatic artery. Histologically, the wall of the stomach has five layers: the mucosa, submucosa, muscular layer, subserosa, and serosa. The muscularis layer is

composed of an outer longitudinal layer, a middle circular layer, and inner oblique layer.

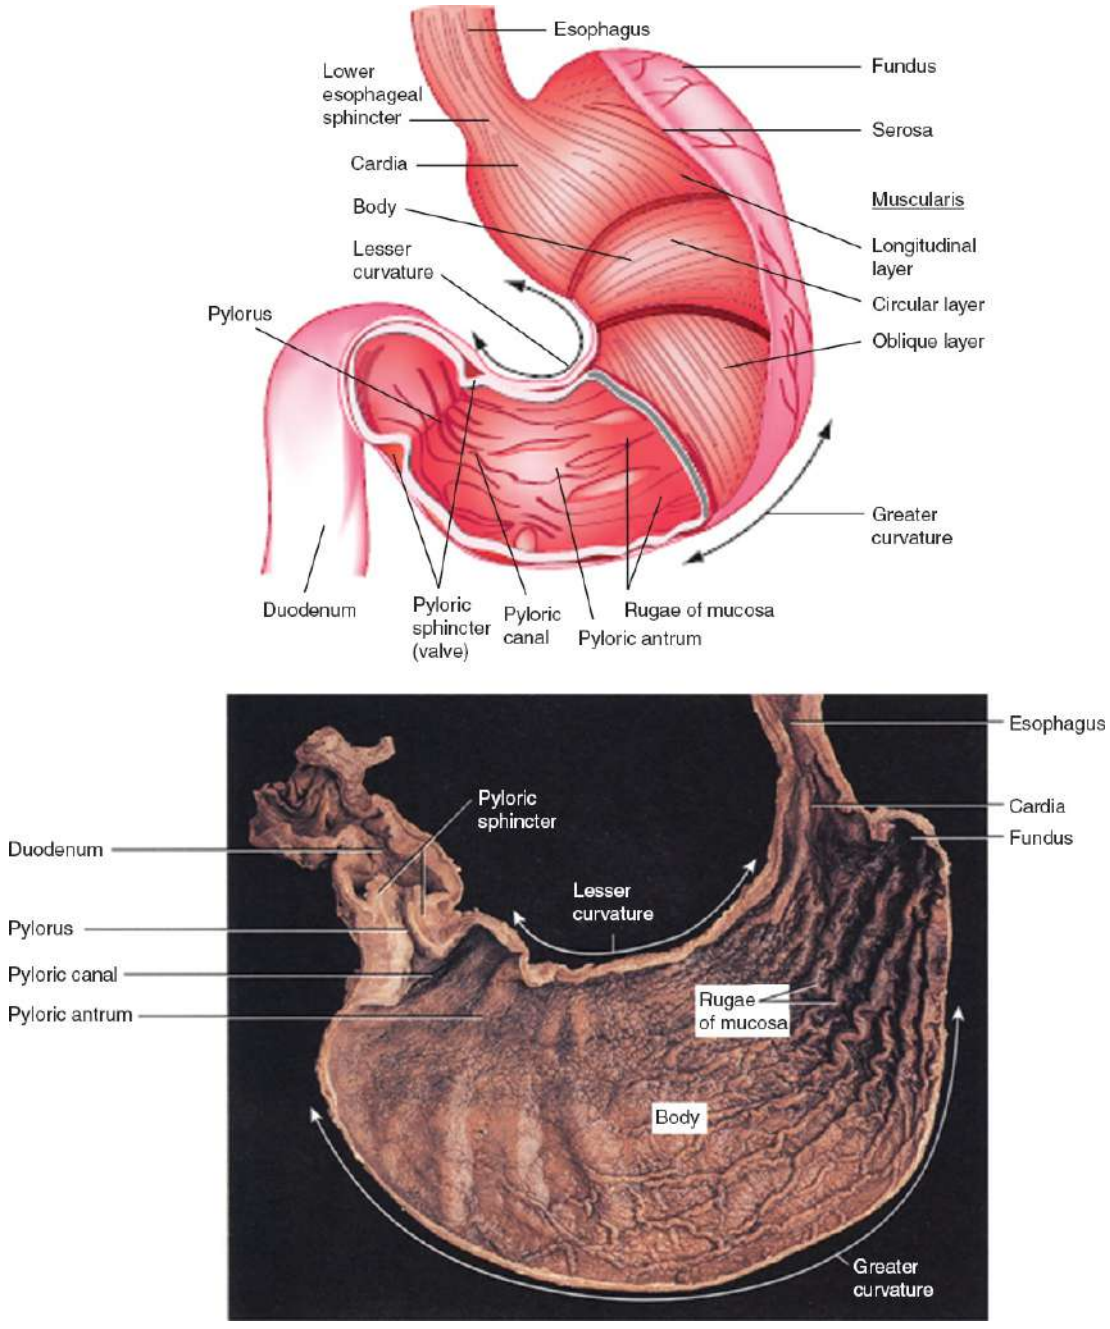


FIGURE 62.1. Gastric anatomy. (Republished with permission of John Wiley & Sons, Inc. from Tortora GJ, Grabowski SR. *Principles of anatomy and physiology*. 9th ed. New York: John Wiley & Sons, Inc. The stomach's vascular supply is derived from the celiac axis. The celiac

artery usually has three branches: the left gastric artery, which supplies the upper right portion of the stomach; the common hepatic artery, which gives rise to the right gastric artery supplying the lower right portion of the stomach and the right gastroepiploic branch supplying the lower portion of the greater curvature; and the splenic artery, which gives rise to the left gastroepiploic supplying the upper portion of the greater curvature and the short gastric arteries supplying the fundus. Variations in this normal vascular supply are common. The celiac axis originates at or below the pedicle of T12 in approximately 75% of patients and at or above the pedicle of L1 in 25% of patients.[2] The lymphatic drainage of the stomach follows the arterial supply. Although most lymphatics ultimately drain to the celiac nodal basin, lymph drainage sites can include the splenic hilum, suprapancreatic nodal groups, porta hepatis, and gastroduodenal areas.

EPIDEMIOLOGY

Gastric cancer is estimated to afflict 26,240 people in the United States in 2018 and result in 10,800 deaths.[3] Worldwide, gastric cancer remains a significant cause of cancer-related mortality, with approximately 1,313,000 new cases annually and an estimated 819,000 deaths, making it the third-leading cause of cancer-related deaths.[4] During the past 70 years, there has been a significant decline in the incidence of gastric cancer in both sexes in Western countries. The causes of this decline are unknown.[4–6] Although the overall decrease in gastric cancer incidence is encouraging, there has been a steady and dramatic increase in the incidence of proximal lesser curvature, cardia, and GE junction tumors over the past 20 years, especially in white males.[7] In contrast to the increasing incidence of more proximal gastric cancers seen in the Western Hemisphere and parts of Europe, distal tumors continue to constitute most gastric cancers in the Far East and other parts of the world.

Risk factors for gastric cancer can be classified as modifiable or nonmodifiable (Table 62.1). Race or ethnicity, specifically being of East Asian or Pacific Islanders descent, portends increased risk. Although potentially related to environment, this incidence persists following immigration and into offspring when migrating to the West. Age is also an important risk factor, with 90% of cases occurring in patients older than 45 years. Family history similarly contributes to risk, with studies from the East and West demonstrating a first-degree relative likely increases an individual’s risk from two- to fourfold. Similarly, male sex portends a two- to fivefold increased risk, possibly accounted

for by protective effects of estrogen in females. Approximately 10% of gastric cancers are linked to genetic syndromes, with the most common being hereditary diffuse gastric cancer (HDGC), which is characterized by an autosomal dominant inheritance, portending a 60% to 80% increase risk of gastric cancer and 40% to 50% increase in breast cancer. Some of these cases are believed to be due to mutations in E-cadherin (CDH1). The presence of CDH1 mutations portends a lifetime risk of gastric cancer development of 70% to 80%.[8] Prophylactic gastrectomy is often recommended once patients are >20 years of age in these patients. Other syndromes associated with increased risk include Lynch syndrome (a DNA mismatch repair gene mutation), familial adenomatous polyposis (an APC gene mutation), Peutz-Jeghers syndrome, juvenile polyposis syndrome, hereditary breast and ovarian cancer syndrome, and Li-Fraumeni syndrome.[9]

TABLE 62.1 RISK FACTORS FOR GASTRIC CANCER DEVELOPMENT

Modifiable	Intrinsic
H. pylori infection	Ethnicity (East Asian or Pacific Islander)
Tobacco smoking	Male gender
Obesity	Age
High-salt diet; low-fruit or -vegetable diet	Family history

In terms of modifiable risk factors, the most common is *Helicobacter pylori* (*H. pylori*) infection. Although the risk of developing gastric cancer is approximately 1% once present, more than 90% of patients with gastric cancer diagnosis have been previously infected. *H. pylori* appears to contribute to gastric cancer development through development of gastritis with subsequent histopathologic changes. The increased association of *H. pylori* appears to be confined to patients with distal gastric cancer and intestinal-type histology. The Epstein-Barr virus (EBV) has been found in 5% to 16% of gastric cancers, supporting its possible role in the genesis of such.[8] Additionally, cigarette use appears to increase the risk of both cardia and noncardia cancers, whereas obesity (BMI > 30) appears to increase the risk of noncardia cancers. A high-salt diet seems to increase risk, whereas diets high in fruit and vegetables seem to be protective.[5,9–11]

Historically, gastric adenocarcinomas have been labeled as intestinal or diffuse types per the Lauren classification system. Intestinal types are more

prevalent in high-incidence areas and responsible for much of the observed global ethnic variation of disease, although the incidence is believed to be decreasing.[12] Intestinal-type carcinomas are primarily well to moderately differentiated. Histologically, these tumors generally show malignant epithelial cells in hyperchromatic, irregular, angulated glands with cohesiveness and glandular differentiation infiltrating the stroma. These tumors can be polypoid with a wide base, ulcerated with sharp/heaped-up margins, and ulcerated disease without obvious limits. These are generally seen more in males than females in a 2:1 ratio. In contrast, the incidence of the less common diffuse gastric cancer appears to be increasing and is fairly uniform among geographic regions or race. More recently, there has been an emergence of another distinct subtype—proximal gastric (cardia) cancers. These are often grouped with GE junction and distal esophageal adenocarcinomas, with a rapidly rising incidence in industrialized nations. Gastric cardia cancers are associated with reflux and obesity, resembling esophageal adenocarcinomas. These malignancies are generally more aggressive and carry a worse prognosis than do noncardia tumors. These tumors are associated with white populations with a strong male predominance.

The risks factors for these individual types appear to vary significantly. Risk factors for intestinal, noncardia gastric cancers appear to center around inflammatory causes and environmental factors, primarily *H. pylori*, as well as chronic gastritis, tobacco, high salt intake, and alcohol consumption. The less common diffuse gastric cancer subtype appears to be distinct, with E-cadherin mutations/silencing thought to be a common precursor event with this histology. HDGC is a genetic syndrome in which there is loss of function/mutation in the E-cadherin gene. In proximal gastric cancer (and in contrast to intestinal types), *H. pylori* infection has been found to be potentially protective in several randomized trials, possibly through associated atrophic gastritis and reduced acid production with subsequent reduction in gastroesophageal reflux disease (GERD), although this remains controversial.[13] As opposed to intestinal types, there is often no precancerous lesion seen, and histologically, cells generally lack cohesion and invade independently or in smaller clusters. Diffuse carcinomas are poorly differentiated. These are often more diffusely infiltrating and nonulcerated and can present as a “signet-ring” carcinoma, which is a variant with cytoplasmic mucin that displaces the cell nucleus peripherally. The presence of signet-ring (or poorly differentiated) phenotype has been associated with therapy resistance and poor prognosis[13] (Fig. 62.2). However, a large

database analysis indicated patients with signet-ring gastric cancer, when compared to adenocarcinoma patients, tended to present at a younger age and less often in men. Additionally, despite more advanced stage, median survival was not different relative to “traditional” adenocarcinoma patients.[12,14,15]

An alternative gastric cancer classification from the World Health Organization is based predominantly on histologic cancer patterns (tubular, papillary, mucinous, poorly cohesive, and rare variants). The tubular and papillary subtypes roughly correspond to the Lauren intestinal type and poorly cohesive to the diffuse type. More recently, the Cancer Genome Atlas Research Network published the results of genomic profiling of 295 primary gastric adenocarcinomas. Four tumor subtypes were identified: (a) Epstein-Barr virus (9%), (b) microsatellite-unstable tumors (22%), (c) genomically stable tumors (20%), and (d) chromosomally unstable tumors (50%). This classification has the potential to determine prognosis and help individualize treatment in the future.[14]

PATTERNS OF SPREAD

Cancer of the stomach may extend directly into the omentum, pancreas, diaphragm, transverse colon or mesocolon, and duodenum. Peritoneal contamination with carcinomatosis is possible after a lesion extends beyond the gastric wall to a free peritoneal (serosal) surface.[16]

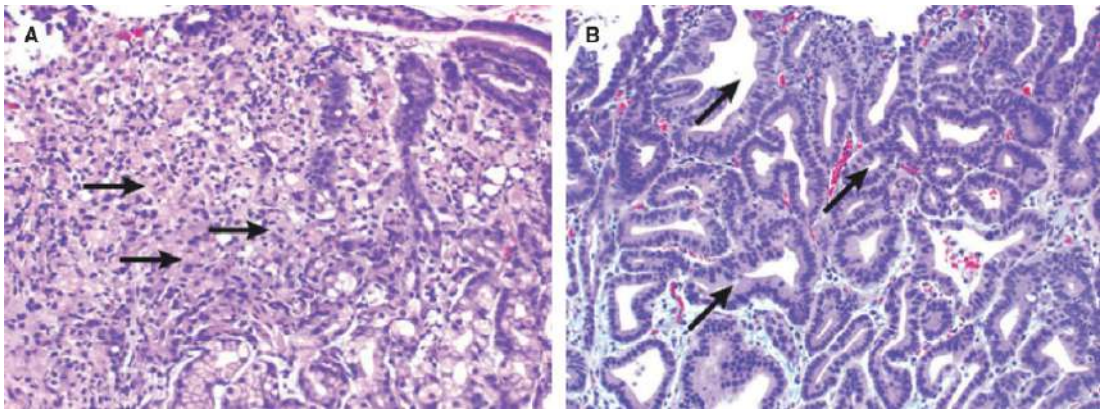

FIGURE 62.2. **A:** Hematoxylin and eosin–stained slide of Lauren classification diffuse-type gastric adenocarcinoma (GAC) with many cancer cells isolated from other cells. *Arrows* point to signet-ring cells, in which the nucleus is pushed out to the periphery of the cytoplasm. **B:** Hematoxylin and eosin–stained slide of Lauren classification intestinal-type GAC. *Arrows* are pointing to gland formation by tumor cells. Microscopic or subclinical spread beyond the visible gross lesion occurs frequently because of the abundant lymphatic channels within the submucosal and subserosal layers of the gastric wall. The submucosal plexus in the esophagus and subserosal plexus in the duodenum allow proximal and distal spread.

It is difficult to perform a complete node dissection because of the numerous pathways of lymphatic drainage from the stomach (Fig. 62.3). Initial drainage is to lymph nodes along the lesser and greater curvatures (i.e., gastric and gastroepiploic nodes) but also includes the celiac axis, porta hepatis, splenic, suprapancreatic, pancreaticoduodenal, adjacent para-aortics, and distal paraesophageal system. The relative risks for nodal involvement in gastric cancer depend on the location of the primary tumor as well as extent of gastric wall involvement.

Gastric venous drainage is primarily to the liver by the portal system. Liver involvement is found in as many as 30% of patients at initial exploration, and it can occur as a result of venous metastasis, peritoneal-based spread, and direct extension (Fig. 62.4).

CLINICAL PRESENTATION

The most common presenting symptoms of stomach cancer are anorexia, early satiety, abdominal discomfort, unintentional weight loss, dysphagia (notably if GE junction or proximal stomach involvement), anemia-related weakness, nausea and vomiting, and tarry stools. Duration of symptoms is <3 months in almost 40% of patients and >1 year in 20%. Physical examination can reveal advanced disease, for which the presentation may include an abdominal mass (epigastric or liver mass as well as a periumbilical node [i.e., Sister Mary Joseph node]), palpable left supraclavicular nodes (i.e., Virchow node), an enlarged left axillary lymph node (Irish node), or a rectal shelf (representing peritoneal seeding [i.e., Blumer shelf]).

DIAGNOSTIC WORKUP

Many patients with early-stage gastric cancer are asymptomatic, and therefore patients are often diagnosed with a more advanced stage. Diagnosis is usually confirmed by upper gastrointestinal endoscopy as well as imaging studies in some instances. Double-contrast x-ray studies may reveal small lesions limited

to the inner layers of the gastric wall. Endoscopy with direct visualization, cytology, and biopsy yields the diagnosis in ≥90% of exophytic lesions; however, infiltrative (linitis plastica), small (<3 cm), or cardia lesions may be more difficult to diagnose endoscopically. Endoscopic ultrasonography is the most accurate method of determining depth of tumor invasion (intramural vs. extramural extension) prior to resection but is less accurate in detecting regional nodal metastases.[17,18] In some institutions, needle biopsies of suspicious nodes are performed at the time of endoscopic ultrasound.

One principle goal of staging computed tomography (CT) is the identification of distant metastases, although it can also provide T- and N-stage data. Abdominal CT is useful in determining the abdominal extent of disease and may help to determine which lesions extend to surgically unresectable structures but are of lesser value in detecting small lymph node metastases or peritoneal spread. Distant metastases should be ruled out with contrast-enhanced CT of the chest, abdomen, and pelvis. CT may provide valuable tumor localization information if radiation is indicated. If a proximal gastric cancer extends to involve the esophagus, CT of the chest will help to rule out involvement of mediastinal nodes or the lung parenchyma. A meta-analysis suggested that CT accuracy in terms of T stage was 72% although there was an indication that multidetector (4 or more) scanners demonstrated an overall accuracy of 80%.[19] However, multidetector status did not seem to influence nodal or distant metastatic assessment. In the same study, CT accuracy, compared to histologic findings, was 66% in terms of N stage.

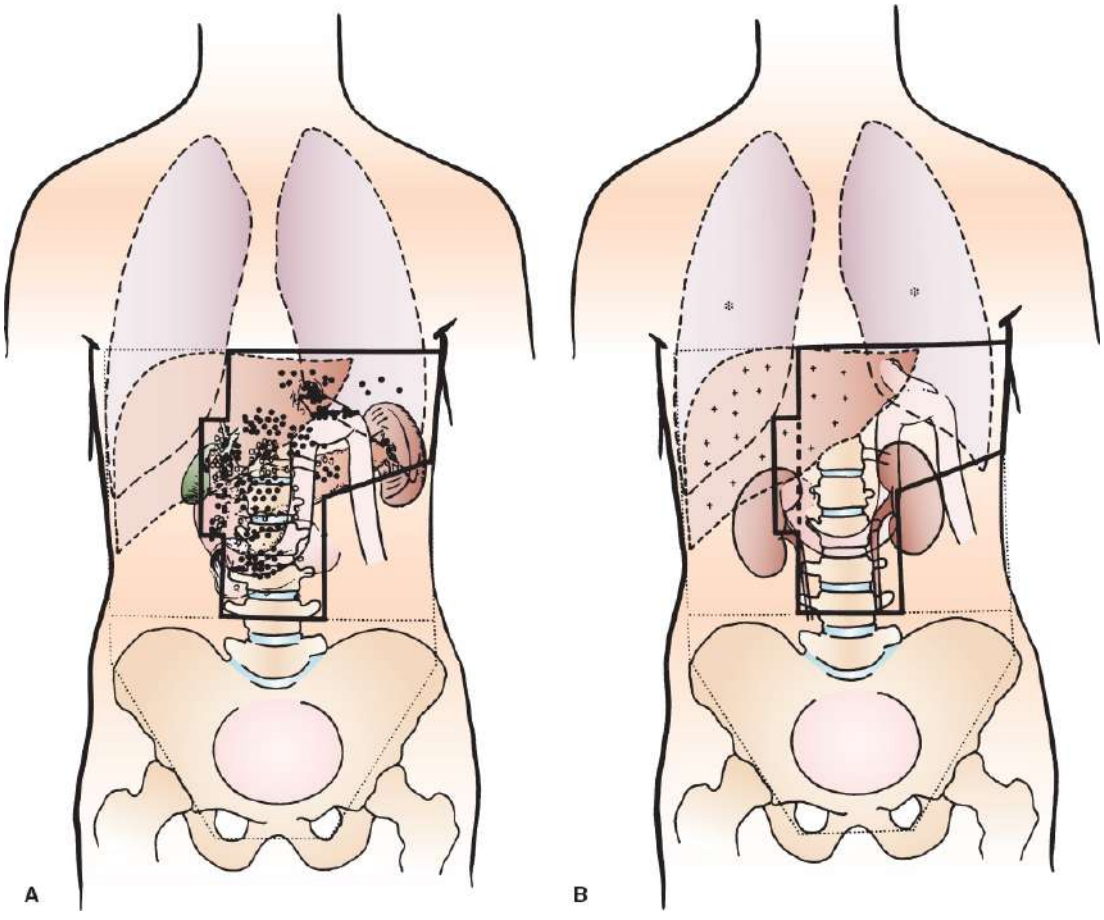

FIGURE 62.4. Patterns of failure in 82 evaluable patients in the University of Minnesota Reoperation series. **A:** *Large bold circles* indicate local failures in surrounding organs or tissues; *large open circles* indicate lymph node failures. **B:** *Asterisk* (*) indicates lung metastasis; *plus* (+) indicates liver metastasis. Clinicopathologic correlation and implications for adjuvant therapy. *Int J Radiat Oncol Biol Phys* 1982;8[1]:1–11. Copyright © 1982 Elsevier. With permission.)

The value of laparoscopy in the staging of gastric cancer remains a subject of study. The primary value of laparoscopy lies in the detection of occult metastatic deposits. A large series from Memorial Sloan Kettering Cancer Center of >600 patients with potentially resectable gastric adenocarcinoma by conventional imaging underwent laparoscopic staging, resulting in distant metastases being detected in 31% of patients.[20] A systematic review on the role of diagnostic laparoscopy showed that change in patient management occurred in 9% to 60% of patients initially deemed resectable by preoperative imaging, with 9% to 44% avoiding laparotomy, predominantly through the identification of patients with metastatic disease who would not benefit from either laparotomy or neoadjuvant therapy, thereby avoiding unnecessary interventions. This is primarily related to patients with advanced (T3, T4) gastric cancer, with relatively minimal benefit in early-stage patients, prompting the authors to recommend diagnostic laparoscopy for patients with locally advanced-stage disease.[21,22] In addition, peritoneal fluid can be sampled for cytology at laparoscopy by direct aspiration of ascitic fluid or peritoneal lavage. If positive, this is a poor prognostic indicator, and although the bearing on treatment approach remains somewhat controversial, the patient should be considered as having M1 disease.

Overall treatment planning in gastric cancer may be improved by accurate preoperative classification of key prognostic factors, namely, depth of invasion (T category) and lymph node involvement (N category). A prospective study in 108 patients evaluated endogastric ultrasonography (EUS), CT, and intraoperative surgical assessment for T and N classification.[23] T staging was accurately characterized by CT in 43% of the cases, EUS in 86% of cases, and intraoperative assessment in 56% of cases. Staging of N1 and N2 lymph nodes was correct with CT in 51% of the cases, 74% with EUS, and 54% with intraoperative assessment. Advanced gastric tumors tended to be more accurately staged with CT, although CT, in general, overstages the T category

and understages the N category. EUS showed a high accuracy for all the T categories, although it also tends to understage N categories. Finally, intraoperative assessment was equally accurate for all N categories but tended to overstage early T stages and to understage N categories. A meta-analysis and systematic review of the role of EUS in T and N staging in nearly 2,000 patients with gastric cancers suggested that the sensitivity for detecting T1, T2, T3, and T4 disease was 88%, 82%, 90%, and 99%, respectively. Nodal staging sensitivity for N1 and N2 disease was 58% and 65%, respectively, also suggesting that accuracy was higher with more advanced disease.[24] Another meta-analysis demonstrated the ability of endoscopic ultrasound to discriminate between T1-T2 versus T3-T4 gastric cancers, with a sensitivity of 0.86 (CI 0.81 to 0.90); additionally, the sensitivity for diagnosis of superficial (T1a vs. T1b) and lymph node involvement was 0.87 (0.81 to 0.92) and 0.83 (0.79 to 0.87), respectively.[25] Another meta-analysis showed a pooled accuracy for T-stage diagnosis of 75%, with individual studies reporting rates from 57% to 88%. However, the diagnostic accuracy for N staging was less, with a wide range from 30% to 90%, with a pooled accuracy of 64%, sensitivity of 74%, and specificity of 80%.[26] EUS accuracy depends highly on the experience and expertise of the operating physician.

The role of MRI in gastric cancer remains the subject of investigation. Early reports suggest that there is good agreement with histologic T staging, with an accuracy of 83% (range 77% to 87%), although experience with this technique is more limited and the subject of ongoing investigation.[22] Another systematic review concluded that EUS, multidetector CT, and MRI achieve similar results in terms of diagnostic accuracy of T staging and assessing serosal involvement.[27] Presently, MRI is primarily used in further characterization of indeterminate liver lesions seen on other staging investigations in gastric cancer patients.

Positron emission tomography (PET) scan has a lower detection rate in some cases of gastric cancers owing to the low fluorine-18 fluorodeoxyglucose (FDG) accumulation in patients with diffuse or mucinous/signet-ring tumors.[28] Approximately 40% of gastric carcinomas, notably the above histologies, may not be detected with PET scan.[29] PET alone has been described as displaying a lower sensitivity when compared to CT in detecting nodal involvement, although specificity is improved.[30] Because of its low-resolution images, the value of PET-CT primarily lies in its ability to detect metastatic disease, with a relatively low T-stage sensitivity for T1-T2 tumors, with improvement for more advanced disease. Estimated sensitivity for N stage is 40%, although specificity has been

reported as high as 98%. As above, the accuracy in identifying distant metastases was 88% and higher than CT alone, and PET has been reported to detect occult metastases in operable patients in 10% and changing patient management in 15%. Additionally, PET response to neoadjuvant therapy, including treatment modification in poor responders as well as a potential indicator of prognosis in these patients, remains an active area of investigation.[22] The ongoing Alliance A021302 study is comparing overall survival of patients with locally advanced gastric cancer classified as PET nonresponders following one cycle of preoperative chemotherapy, with nonresponding patients receiving either salvage chemotherapy before and after surgery or immediate surgery followed by fluorouracil-sensitized radiotherapy. Given the above, PET alone is likely not an adequate diagnostic procedure for evaluation of gastric cancer and generally should be used in conjunction with CT scan for correlation, allowing more accurate preoperative staging than either modality alone. A suggested diagnostic evaluation for gastric cancer is shown in Table 62.2.

TABLE 62.2 DIAGNOSTIC WORKUP FOR GASTRIC CANCER

History and physical
Upper gastrointestinal endoscopy and biopsy
Chest, abdomen, pelvic CT with oral and intravenous contrast (preferably correlated with PET when PET is performed)
Complete blood count (CBC) and comprehensive metabolic panel
Endoscopic ultrasound if no evidence of metastases with fine-needle aspiration (FNA) as indicated
Biopsy confirmation of suspected metastatic gastric cancer
HER2 testing if metastatic
H. pylori testing performed and treatment delivered where clinically indicated

STAGING

The current tumor–node–metastasis (TNM) system is depicted in Table 62.3.[31] In the most recent American Joint Committee on Cancer (AJCC) staging of gastric cancers, cancers whose midpoint is in the lower thoracic esophagus, GE junction, or within the proximal 2 cm of the stomach (cardia) *and* extending to the GE junction or esophagus are staged as esophageal neoplasms. All other cancers with a midpoint in the stomach lying more than 2 cm distal to and involving the GE junction or those within 2 cm of the GE junction (but not involving the GE junction or esophagus) are staged using the gastric cancer

staging system.

PATHOLOGY

Adenocarcinomas account for 90% to 95% of all gastric malignancies. Lymphomas are the second most common malignancies. Rarely, gastrointestinal stromal tumors (GISTs), carcinoid (neuroendocrine) tumors, adenoacanthomas (1%), and squamous cell carcinomas (1%) occur.

The site of origin of gastric cancers within the stomach has changed in the United States over recent decades, and proximal lesions are being diagnosed and treated more frequently. Although the highest frequency is still in the antrum/distal stomach (~40%), the lowest frequency is now in the body (~25%) rather than the proximal portion of the stomach, with intermediate frequency in the proximal stomach and GE junction (~35%). Several investigators have reported an increased frequency of cardia lesions. As described previously, cardia lesions appear to have different epidemiologic factors, exhibit different tumor biology, and have an inferior prognosis relative to lesions in the other sites.[32–36] Gastric cancers have historically been categorized according to Borrmann's five types. Type I tumors are polypoid or fungating; type II are ulcerating lesions surrounded by elevated borders; type III have ulceration with invasion of the gastric wall; type IV are diffusely infiltrating (linitis plastica); and type V are unclassifiable.[37]

PROGNOSTIC FACTORS

The most important prognostic indicators reflect tumor extent. If hematogenous or transperitoneal spread is present, the outcome is, essentially, uniformly fatal. Survival rates decrease with progressive tumor extension within or beyond the gastric wall.[32,38–40] The number of involved lymph nodes also has a significant impact on survival. Lymph node involvement is important, as are the number and locations of nodes affected.[32,40–42] Minimal nodal involvement adjacent to the primary lesion only moderately affects prognosis.[38,42,43] The finding of either involved lymph nodes or complete wall penetration is usually not as ominous as the presence of both[38,40,42,44] Additional prognostic indicators include a poor performance status, elevated alkaline phosphatase levels, and ethnicity.[45] In one study, Asian Pacific Islanders born in the United States were compared to those born abroad, finding that only foreign-born Asian Pacific

Islanders had a more favorable survival compared to indigenous Caucasians.[46] Proposed hypothesis to explain disparities in survival outcomes between Western and Asian populations include early detection in the latter, leading to stage migration, differences in treatment policy, as well as potential differences in tumor biology.

TABLE 62.3 AMERICAN JOINT COMMITTEE ON CANCER 8TH EDITION GASTRIC CANCER STAGING

T Category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*: intraepithelial tumor without invasice of the lamina propria, high grade dysplasia
T1	Tumor invades the lamina propria, muscularis mucosae or submocosa
T1a	Tumor invades the lamina propria or muscularis mucosae
T1b	Tumor invades the submocosa
T2	Tumor invades the muscularis propria[a]
T3	Tumor penetrates the subserosal connective tissue without invasion of the visceral peritoneum or adjacent structures[b,c]
T4	Tumor invades the serosa (visceral peritoneum) or adjacent structures[b,c]
T4a	Tumor invades the serosa (visceral peritoneum)
T4b	Tumor invades the adjacent structures/organs

Definition of Distant Lymph Node (M)

N Category	N Criteria
NX	Regional lymph node(s) cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1 or 2 regional lymph nodes
N2	Metastasis in 3 to 6 regional lymph nodes
N3	Metastasis in 7 or more regional lymph nodes
N3a	Metastasis in 7 to 15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes

Definition of Distant Metastasis (M)

The specific regional nodal areas are as follows.

- Perigastric along the greater curvature (including greater curvature, greater omental)
- Perigastric along the lesser curvature (including lesser curvature, lesser omental)
- Right and left paracardial (cardioesophageal)
- Suprapyloric (including gastroduodenal)
- Infrapyloric (including gastroepiploic)
- Left gastric artery
- Celiac artery
- Common hepatic artery
- Hepatoduodenal (along the proper hepatic artery, including portal)
- Splenic artery
- Splenic hilum

[a]A tumor may penetrate the muscularis propria with extension into the gastrocolic or gastrohepatic

ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified as T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified as T4.
[b]The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.
[c]Intramural extension to the duodenum or esophagus is not considered invasion of an adjacent structure, but is classified using the depth of the greatest invasion in any of these sites.

Flow cytometry may also be prognostically valuable; aneuploidy is associated with unfavorable tumor location, lymph node metastasis, and primary tumor invasion.[47–49] Unfavorable DNA flow cytometry correlates with a poor prognosis.[47] The prognosis is worse for cardia lesions, and flow cytometry reveals a greater incidence of aneuploidy.[49] The gross pathologic appearance of the primary lesion also reveals prognostic information, although it is not known whether this factor is independent of tumor stage. Patients with Borrmann type I and II tumors have relatively favorable 5-year survival rates, although patients with type IV (linitis plastica) fare poorly.[43,50–52]

The molecular biology of gastric cancer reflects the heterogeneity of its causes and its histologic subtypes. A detailed discussion of the molecular biology of gastric cancer is beyond the scope of this chapter and is well detailed elsewhere.[13] However, identification of the genetic and phenotypic variables existing among gastric cancers may lead to more directed therapeutic approaches and a more accurate prediction of clinical outcome. Changes that may affect the behavior of gastric tumor cells involve four major types of alterations. Loss of tumor suppressor gene function, especially inactivation of the p53 gene, appears to play a critical role. The p53 gene is located on the short arm of chromosome 17 and plays a key role in tumor suppression and cell cycle regulation.[53] The p53 gene halts DNA replication and triggers programmed cell death in response to DNA damage.[54] Loss of p53 function allows malignancy to develop, affects the effectiveness of chemotherapy and irradiation, and predisposes cells to genetic instability.[55,56] The latter is particularly important because p53 mutations occur early in tumorogenesis.[57]

A second major aberration affecting gastric epithelial cells is the impact of alterations in mismatch repair genes. Two such genes, hMSH3 and hMLH1, on chromosomes 2 and 3, respectively, account for replication errors throughout the genome. Mutations in these genes are implicated in cancer family syndromes and hereditary nonpolyposis colorectal cancer, which is a disease associated with

an increased tendency for the development of gastric tumors.[58] Mutations in these genes generate genetic instability and have the potential to lead to further alterations in oncogenes.

Two proto-oncogenes, c-met and k-sam, are associated with scirrhous carcinoma of the stomach. The former encodes hepatocyte growth factor, which is a potent endogenous promoter of gastric epithelial cell growth.[59] Its overexpression correlates with tumor progression and metastasis.[60] The latter encodes a tyrosine kinase receptor family.[60] In scirrhous carcinoma, c-met and k-sam amplification may occur independently. There is a tendency for k-sam to be activated in women <40 years of age and c-met to be amplified in men >50 years of age.[57,61]

Peptide receptors, including estrogen receptors and epidermal growth factor receptors, are associated with adverse prognoses.[62,63] Epidermal growth factor receptors and levels correlate with higher rates of primary tumor infiltration, poorer histologic differentiation, and linitis plastica.[64] The pathophysiologic relation between these peptide receptors and their association with poor prognoses is not well understood.

Modern molecular biology observations confirm the heterogeneity of human gastric cancer. Genetic alterations detected and potentially associated with a worse prognosis include CD44 expression; telomerase reactivation; p53 gene inactivation; dysfunction of repair genes such as hMSH3 and hMLH1; overexpression of proto-oncogenes such as erb-B2, bcl-2, c-met, and k-sam; estrogenic receptor expression; and presence of viral genomes.[65] Gastric cancers with class II major histocompatibility complex antigen expression have a better prognosis; however, the loss of expression is not an independent prognostic factor.[64] Illustrating the importance of understanding and potential exploitation of these genetic alterations, a randomized study was conducted in patients with HER2 overexpression. Patients with locally advanced or metastatic gastric or GE cancer (the ToGA trial) were randomized to determine whether trastuzumab (an antibody against the HER2 gene product/receptor) enhanced treatment efficacy when added to cisplatin and 5-fluorouracil (5-FU)/capecitabine therapy. This study demonstrated that the addition of trastuzumab achieved a significant improvement in overall and progression-free survival.[66] These and other data have led to the ongoing Radiation Therapy Oncology Group (RTOG) 1010 trial, which is randomizing patients with esophageal/GE junction tumors to receive preoperative radiation therapy concurrent with paclitaxel/carboplatin, with or without trastuzumab, followed by resection.

GENERAL MANAGEMENT

Surgical Management

Complete tumor and regional lymph node resection remains the primary curative modality for gastric adenocarcinoma and may require total or distal gastrectomy. Operative attempts are highly successful if disease is limited to the mucosa; however, the incidence of such early lesions at diagnosis is <5% in most US series. In Japan, the incidence of lesions initially confined to the mucosa or submucosa was only 3.8% in 1955 and 1956, although by 1966, as a result of screening procedures, this figure had increased to 34.5%, with corresponding survival rates of 90.9%.[67] For very early gastric cancer (Tis and T1a), endoscopic mucosal dissection and endoscopic submucosal dissection have been successfully used as less radical alternatives to standard surgery. Appropriateness of endoscopic resection is based on the tumor depth, tumor diameter, histologic grade, and ulcerative component. As in other endoscopic procedures, outcomes are operator dependent. Endoscopic laser surgery has been applied successfully to patients with very early gastric cancer whose tumors are inoperable because of complicating medical illness. Small lesions that are pedunculated, noninvasive, and well differentiated have lymph node metastasis in <5% of cases and can be completely removed endoscopically in 75% of cases.[67] Radiation therapy with chemotherapy may be considered as adjuvant therapy in selected situations. These approaches in early gastric cancer (uncommonly seen in Western society) require meticulous patient selection and remain a topic of investigation.

Curative or palliative surgical resection is possible for 50% to 60% of patients at the time of initial disease presentation. However, only approximately 25% to 40% are eligible for potentially curative resection. Generally, patients with evidence of peritoneal involvement, distant metastases, or locally advanced disease (including encasement of unresectable/major blood vessels) are generally considered to have unresectable disease. Palliative resection is usually reserved for rare cases, including symptomatic palliation of bleeding uncontrolled by other methods, and is generally considered a last resort in patients with locally unresectable or metastatic disease. A recent randomized trial from Asia (the REGATTA trial) enrolled 175 gastric cancer patients. Patients were randomized to receive either chemotherapy (oral S1 + cisplatin) or palliative D1 gastrectomy followed by the same regimen. At interim analysis, no significant difference was seen in 2-year survival between the arms. The authors concluded that palliative

gastrectomy could not be justified even in the setting of a solitary metastasis.[68] In some instances, unresectable tumors may be debulked successfully, with sites of minimal residual disease marked judiciously with clips. This may palliate and permit accurate delivery of postoperative radiation therapy. In patients with gastric outlet obstruction, gastrojejunostomy may be performed as an alternative to endoscopic placement of a stent in patients with expected longer survival.

No prospective randomized trials have definitively established optimal surgical therapy.[69,70] Generally, it is recommended that gastric cancer surgery be performed by experienced surgeons in high-volume centers, entailing removal of the perigastric lymph nodes (D1) as well as those along the main vessels of the celiac trunk (D2), with the goal of examining ≥16 lymph nodes (discussed later).[7] Total gastrectomy is generally necessary in most cases of proximal and midgastric carcinomas, although proximal gastrectomy may be appropriate depending on extent of disease. However, for more distal lesions, distal gastrectomy is preferred if adequate margins can be obtained. Generally, the distal margin in subtotal gastrectomy needs to be approximately 2 cm. This operation removes approximately 80% of the stomach along with the node-bearing tissue, the gastrohepatic and gastrocolic omenta, and the first portion of the duodenum. Larger lesions may require total gastrectomy. Total gastrectomy is not recommended where 4- to 6-cm margins can be achieved with partial gastrectomy given improved safety and long-term functional outcome improvements in the latter.[71] Patients treated with total gastrectomy characteristically have 5-year survival rates of 10% to 15%, and those undergoing radical subtotal gastrectomy have 5-year survival rates of 25% to 45%.[41,70,72] The inferior survivorship of patients undergoing total gastrectomy reflects larger tumors and unfavorable proximal lesions that prompt such a procedure. The value of splenectomy has not been addressed in prospective randomized trials; however, retrospective Japanese data do not support a survival benefit.[73] Because routine splenectomy has not shown significant improved outcomes and potentially increases complication rates, complete removal of splenic nodes is not commonly performed by Western surgeons. Roux-en-Y reconstruction may be used to avoid bile reflux gastritis/esophagitis. Vitamin B supplementation is generally required following total gastrectomy because of lack of intrinsic factor production from the stomach.

Minimally invasive gastrectomy (including laparoscopic or robot-assisted resection) is being increasingly utilized, although these approaches remain a subject of investigation. These approaches carry potential advantages, including

less intraoperative blood loss, faster recovery times, reduced pain, and decreased hospital length of stay. Multiple trials have indicated that minimally invasive techniques provide equivalent surgical and oncologic outcomes to open approaches.[74] However, patient selection is important. In patients who undergo adjuvant chemoradiotherapy, it may be prudent to place feeding jejunostomy at the time of resection.

The propensity for gastric carcinoma to spread via the submucosal lymphatics suggests that a 5-cm margin of normal tissue proximally and distally may be optimal. It may be necessary to include a portion of the esophagus or duodenum to achieve adequate margins. Frozen section pathologic evaluation of surgical margins has been advocated to confirm their adequacy.[41] The importance of careful evaluation of longitudinal margins is emphasized in multiple series with documented positive pathologic margins in approximately one-quarter of "curatively" resected specimens.[75–82] The approximate 25% positive longitudinal margin correlates almost precisely with the incidence of locoregional recurrence in the anastomosis or stump, as discussed later.

Although R0 resection with adequate lymph node sampling is a primary goal for gastric cancer surgery, many patients end up with involved margins. Even though the longitudinal margin is routinely evaluated, equally important but frequently not assessed are the radial or circumferential margins. The incidence of radial margin positivity is not well reported in the literature. The rising incidence of T3 and T4 GE tumors will likely result in an increasing rate of microscopically positive radial margins. Because the perigastric tissue surrounding the GE junction and distal esophagus has no serosa, lesions that extend to the pathologic radial margin likely represent a true positive margin in a large percentage of cases.

The extent of lymph node dissection remains an ongoing area of controversy. The Japanese Research Society for gastric cancer categorizes draining stomach lymph nodes into 16 stations, 6 perigastric and 10 regional along major vessels and adjacent to the pancreas (Fig. 62.3). A D1 dissection only includes perigastric nodes (stations 1 to 6); a D2 dissection includes those along the common hepatic, left gastric, celiac, and splenic arteries (stations 7 to 11); a D3 dissection includes additional nodes with any of the porta hepatis and adjacent to the aorta (stations 12 to 16).[71] According to the most recent AJCC Cancer staging manual, accurate nodal staging demands evaluation of at least 16 lymph nodes. This may reduce stage migration. In a D0 dissection, there is generally incomplete removal of the lymph nodes along the greater and lesser curvature. In

series with rigorous pathologic evaluation of these nodes,[83] the likelihood of discovering lymph node metastasis increases markedly in both D1 and D2 procedures. There appears to be a small subset of patients who have limited metastasis in the celiac axis, superior pancreatic, or retroduodenal chains and may be cured by a D2 lymph node resection.[84,85] Data from the Surveillance Epidemiology and End Results (SEER) database show that the number of nodes examined correlated with overall survival, potentially reflecting improved staging in these patients.[86] Japanese researchers advocate complete lymph node removal to improve the rates of local control and survival. Several nonrandomized clinical trials suggested that extended lymphadenectomy may improve survival.[87–90] Others[91] reported that increasingly radical lymphadenectomies failed to improve survival or reduce the risk of locoregional failure. Multiple prospective randomized trials of lymphadenectomies have been reported[84,92–96] and show no survival advantage with more extensive lymph node dissection. A more recent update of a Dutch randomized trial showed D2 dissections to be associated with improved disease-specific survival versus D1 at a median follow-up of 15 years.[97] However, morbidity and mortality rates have been significantly higher for patients undergoing more extensive nodal dissection. Despite the mixed evidence of randomized trials, it is generally recommend that spleen-sparing D2 lymphadenectomy be performed by experienced surgeons in high-volume centers. An even more extensive lymph node dissection may entail para-aortic nodal dissection. However, a Japanese trial comparing D2 lymphadenectomy versus the same with para-aortic (D3) nodal dissection did not show any differences in overall or relapse-free survival between the groups, indicating the latter approach should not be used in patients with curable gastric cancer.[98] However, other important principles of lymph node dissection have been elucidated through these trials. The first is that as more lymph node areas are dissected and as pathologic lymph node evaluation is more rigorous, considerable stage migration occurs. This stage migration produces an apparent improvement in stage-specific survival without improvement in survival in the group overall.

TABLE 62.4 PATTERNS OF FAILURE AFTER "CURATIVE" RESECTION OF GASTRIC CANCER

	Incidence in Total Patient Group (%)
Pattern of	University of Minnesota

Failure	Clinical[103]	Reoperation[a39]	Autopsy[1,100,101,104]
Locoregional[b]	38	67	80–93
Peritoneal seeding	28	41	30–43
Localized	—	19	—
Diffuse	—	22	—
Distant metastases	52	22	49

[a]107 patients at risk.
[b]Local or regional failure based on direct extension of tumor, lymphatic spread, or operative wound implant; one or more distant metastases on hematologic basis; abdominal involvement on the basis of peritoneal seeding or peritoneal lymphatics.

Failure Patterns after Surgical Resection

Local failures in the tumor bed and/or regional lymph nodes and distant failures by hematogenous or peritoneal routes are common mechanisms of failure after "curative" resection in clinical, reoperative, and autopsy series[44,99–102] (Tables 62.4 and 62.5). For GE junction lesions, the liver and lungs are common sites of distant metastases. With gastric lesions that do not extend to the esophagus, the initial site of distant metastasis is usually the liver, and many failures could be prevented if an effective abdominal treatment could be combined with treatment to the primary site. In the series of Landry et al.,[103] 50 of 88 (57%) failing patients had disease progression within the abdomen only. Abdominal treatment also could address peritoneal seeding, which occurs in 23% to 43% of postgastrectomy patients.[99–107]

Locoregional failures occur commonly in organs and structures of the gastric bed and in lymph nodes and an established mode of failure (Table 62.5). Clinically detectable locoregional recurrence following surgical resection alone generally exceeds 25%. As an example, in long-term follow-up of the previously described Dutch Gastric Cancer Trial, even with D2 dissection, locoregional recurrence rates were 25%, and 41% following D1 surgery.[97] However, reoperation and autopsy series have suggested that these rates are much higher.[44,99–102,105] Failures in the anastomoses, gastric remnant, or duodenal stump also are frequent, as suggested by the incidence of positive longitudinal resection margins (Table 62.5). As is true for most sites, clinical series underestimate the true incidence of locoregional failure when compared with reoperative or autopsy series (Table 62.4). Progressive extension of the operative procedure to include routine splenectomy, omentectomy, and radical lymph node dissection neither improved survival nor decreased the incidence of locoregional

failures in the University of Minnesota series.[44] Subsequent failure in areas of initial node dissection occurred frequently, even with radical lymph node dissections[44] (Fig. 62.4). The high rate of regional node relapse (including para-aortic basins) provides a partial explanation for the lack of survival benefit with a D2 (extended lymphadenectomy) versus D1 (limited lymphadenectomy) node dissection in the phase III surgical trials discussed previously. A more contemporary analysis of 382 patients with stage III (N3) disease undergoing D2 resection receiving adjuvant chemotherapy alone demonstrated that first site of recurrence (some patients had multiple) was local in 7% (most at anastomosis and few in gastric bed), regional failure as any component of first recurrence occurred in 24% of patients (isolated in 12.8% of patients), and peritoneal based in 33%. Most commonly involved lymph node groups were 16, 12, 14, 13, and 9 (primarily outside of the D2 nodal basin).[108] A further analysis of this trial of nodal CT recurrences suggested that vessel-based delineations of these volumes on CT may assist in target design.[109] (Fig. 62.5A). A pattern of failure analysis of the ARTIST trial (discussed below) evaluating patterns of recurrence suggested a significant decrease in regional recurrence with the addition of radiation therapy in node-positive patients. Specifically, patients in the nonradiation arm had significantly higher likelihood of failure in the retroperitoneal lymph node basins, emphasizing the importance of covering this area in gastric cancer patients, whereas as true local recurrence rates did not differ significantly between the two arms (Fig. 62.5B).[110]

TABLE 62.5 PATTERNS OF LOCOREGIONAL FAILURE AFTER RESECTION OF GASTRIC CANCER

	Incidence (%)		
Failure Area	**Clinical[a]105**	**Reoperation[b]39**	**Autopsy[c]106**

[c]92 patients at risk and 28 patients at risk.

Indications for Radiation Therapy

The results of the U.S. Gastrointestinal Intergroup Gastric Adjuvant Trial

changed the standard of care in the United States to the use of both chemotherapy and radiation therapy in the postoperative setting for patients with disease extension through the gastric wall and/or with lymph nodes positive for tumor (discussed later).[111] Postoperative irradiation plus concurrent and maintenance fluoropyrimidine-based chemotherapy is recommended for patients with stage IB-IV and M0 gastric cancer.[111] Quality control of irradiation field design was conducted during the cycle of chemotherapy given before the start of concurrent chemoradiation. The up-front quality control provided the mechanism to correct most of the major or minor deviations (35% incidence) in irradiation field design before the start of treatment and resulted in only a 6.5% final major deviation rate.

Radiation therapy, usually administered with concomitant fluoropyrimidine-based chemotherapy, is also indicated for locally confined gastric cancer that either is not technically resectable or occurs in medically inoperable patients. In this setting, therapy can be administered with curative or palliative intent, depending on the clinical situation. Those who undergo gastric resection with incomplete tumor resection or have truly positive margins of resection are also managed appropriately by combined modality postoperative therapy.

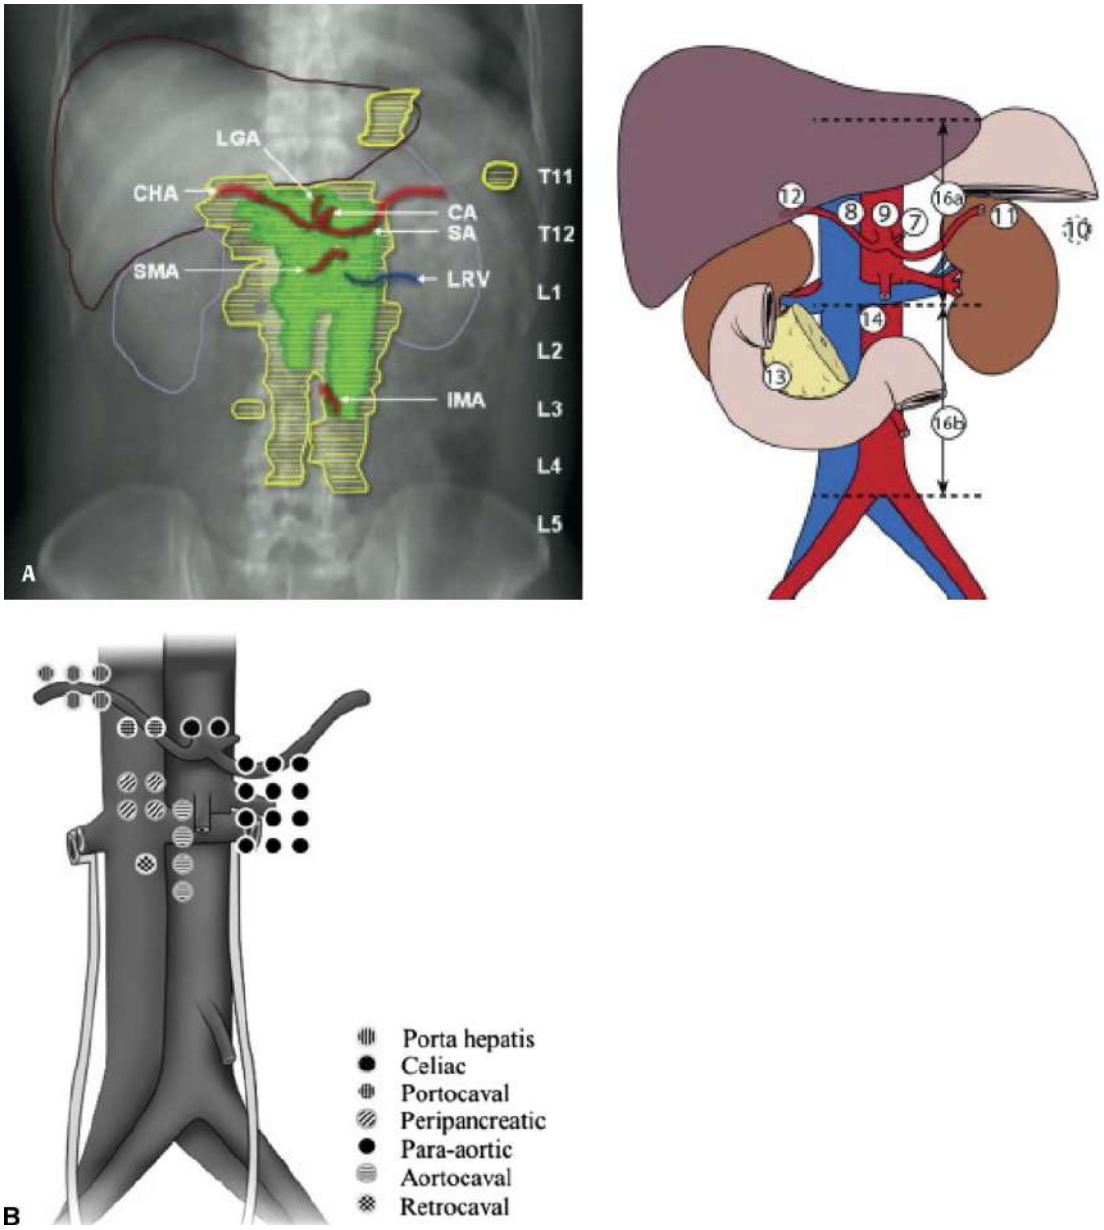

FIGURE 62.5. A: Common nodal recurrent regions (*green*) overlapped by more than five recurrent nodal gross tumor volumes depicted on a digitally reconstructed radiograph image. The volume of total GTVs (*yellow*), liver (*cobalt purple*), and both kidneys (*violet*) are also seen. Common hepatic artery (CHA), splenic artery (SA), left gastric artery (LGA), celiac artery (CA), superior mesenteric artery (SMA), inferior mesenteric artery (IMA), and left renal vein (LRV) are shown in *solid lines*. **B:** Retroperitoneal patterns of failure in the nonradiation arm of the ARTIST trial.

RADIATION THERAPY TECHNIQUES

Simulation

When gastric cancer patients are simulated, the radiation oncologist should know the extent of disease based on imaging (barium swallow, CT, PET) as well as

endoscopic procedures. CT simulation is appropriate for treatment planning. Some authors have recommended fasting for >2 hours before simulation as well as at treatment.[112] During simulation, the patient is positioned, straightened, and immobilized on the simulation table. An immobilization device is used to minimize variation in daily setup. Arms are generally placed. The administration of oral contrast to delineate the stomach is generally used and may help define the extent of mucosal irregularity (if the patient is surgically naïve). The patient is placed on the CT simulator in the treatment position, and a scan of the entire area of interest with margin is obtained. At minimum, 3- to 5-mm slices should be used, allowing accurate tumor characterization as well as improved quality of digitally reconstructed radiographs. If patients lose >10% of their body weight during therapy, consideration should be given to repeat CT planning. IV contrast is generally used to delineate mediastinal and abdominal vascular nodal basins, including the celiac axis, and to allow the radiation oncologist to discern normal vasculature from other adjacent normal structures and potential adenopathy. The tumor (if the patient is surgically naïve) and vital structures are then outlined on each slice on the treatment planning system, enabling a three-dimensional (3-D) treatment plan to be generated. The use of respiratory gating or breath hold techniques may help to reduce target motion with respiration and, therefore, avoidance of normal tissue irradiation associated with larger margins used in free-breathing approaches. Four-dimensional (4-D) CT scan may be appropriate to assess respiratory/tumoral motion, facilitating appropriate margin placement on the target volumes.

Treatment Planning

Target Design

For a detailed description of target and field design in proximal gastric cancer involving the GE junction, the reader is referred to Chapter 56. In the design of radiation fields for neoadjuvantly treated or locally unresectable gastric cancer (as well as in the re-creation of tumoral volumes in adjuvantly treated patients), it is important to define varying target volumes, including gross disease as well as potential areas of subclinical involvement (i.e., the gross tumor volume [GTV] and clinical target volume [CTV], respectively). Defining GTV (including re-creation of volumes in the adjuvant setting) is based on multiple studies, including endoscopic descriptions (from both esophagogastroduodenoscopy and endoscopic ultrasound) as well as cross-sectional imaging. Gastric wall thickening correlating to the GTV can frequently

be visualized on diagnostic and radiation planning CT. Similarly, EUS appears to be the most reliable test in detecting lymphadenopathy related to nodal spread. The endoscopist should be encouraged to accurately define not only the primary disease extent on EGD but also depth of penetration and potential involvement of adjacent structures on EUS, which can also be used to help guide GTV delineation. Similarly, EUS may allow detection of lymph nodes that may not be appreciated on CT or PET imaging, and the endoscopist should be encouraged to describe the size as well as location (e.g., relationship to tumor or adjacent structures). Additionally, radiographic areas of lymphadenopathy should similarly be included in the GTV. In GTV design, basing potential nodal involvement (and therefore target volumes) on nodal size is problematic given that metastatic nodes may frequently be below the resolution of conventional imaging. Therefore, it is not appropriate to rely exclusively on imaging modalities to define areas of subclinical spread for gastric cancer, realizing established pathologic patterns of spread data are important in determining radiation field design.

The identification of potential direct and nodal pathways for spread of subclinical disease (i.e., CTV definition) in gastric cancer is of paramount importance. These areas vary significantly depending on site of origin of disease, making gastric cancer planning somewhat complex. As described previously, the stomach is characterized by a rich network of lymphatics that facilitates early lymph node spread of disease. Some authors have recommended dividing the stomach into three equal lengths (upper/proximal, middle, and distal), with tumors classified by location of the bulk of their masses in these respective sites. Therefore, practically speaking, the stomach can be divided into proximal (remembering that in the AJCC eighth edition staging system, involvement of the GE junction by very proximal third tumors would be classified as an esophageal tumor), middle, or distal segments (Fig. 62.6).

Primarily based on extensive analysis of patterns of nodal spread from surgical series, Japanese investigators have developed lymph node station classifications (the Japanese classification of gastric carcinoma of the Japanese Gastric Cancer Association) that have been validated in other series (Fig. 62.3). Based on this system, general recommendations for CTV definition for tumors in varying parts of the stomach are as follows. Proximal third stomach tumors should include the contour of the stomach with exclusion of the pylorus and antrum (keeping a minimal margin of 5 cm from the GTV). Middle third tumors should include the contour of the stomach from the cardia to the pylorus. Distal

third tumor CTVs should include the stomach except for the cardia/fundus, again keeping a minimal margin of 5 cm from the GTV. However, some authors have noted that surgical series have demonstrated that <5% of patients have microscopic mucosal extension >3 cm beyond gross disease, suggesting smaller margins may be feasible.[112] If pyloric/duodenal invasion is present, the CTV would be expanded along the duodenum with a margin of 3 cm from the tumor. Nodal volumes to be included are further described later, and it has been recommended that the CTV consist of a 5-mm margin around corresponding vessels. An internal target volume (ITV) may be created based on 4-D imaging, with PTV expansion variable, although this typically ranges from 5 to 15 mm depending on immobilization technique and use of image guidance. If target motion is not accounted for, the minimal recommended 3-D margins to the CTV to obtain the ITV are 1.5 cm in all directions, taking into account physiologic organ motion, particularly respiratory motion. The PTV can then be defined as the ITV volume plus a 3-D margin of 5 mm.[113]

radiation of adenocarcinomas of the gastroesophageal junction and the stomach. *Radiother Oncol* 2009;92[2]:164–175. Copyright © 2009 Elsevier Ireland Ltd. With permission.)

Field Design

Field design is based on established patterns of nodal involvement following gastrectomy and lymph node dissection as well as patterns of disease recurrence (Table 62.5). This is also dependent on tumor location within the stomach, stage of disease, as well as extent of lymph node dissection. In resected patients, the gastric/tumor bed, anastomosis and gastric remnant, and pertinent regional lymphatics should be included in most patients.[44,102,106,107,111,113] Major nodal chains at risk include the lesser and greater curvature, celiac axis, pancreaticoduodenal, splenic, suprapancreatic, porta hepatis, and, in many, para-aortics to the level of mid-L3. However, included basins are frequently modified based on margin status, type of surgery (i.e., D0, D1, D2), location within the stomach, as well as stage.

The relative risk of nodal metastases at a specific nodal location depends on both the site of origin of the primary tumor[113–115] and other factors including width and depth of invasion of the gastric wall. On the basis of previously described patterns of failure data, general guidelines in terms of field design can be made as illustrated in Figures 62.7 through 62.9 and are discussed below. These are general guidelines, and all plans should be individualized according to available imaging and endoscopic data, and generalized portals based on patterns of failure data frequently need to be modified on the basis of the individual patient's initial extent of disease.[113–115] As seen in Figures 62.7 to 62.9, gastric tumors (i.e., without GE junction involvement) that originate in the proximal portion of the stomach have a higher propensity of spread to nodes in the paracardial region but a lower likelihood of involvement of nodes in the region of the gastric antrum, periduodenal area, and porta hepatis. In patients with proximal gastric cancers (gastric cardia and GE junction) undergoing esophagogastrectomy with intrathoracic anastomosis, the CTV typically includes 3 to 4 cm of the mucosa of the esophagus and distal stomach, tumor bed (typically determined by preoperative imaging and including the medial two-thirds of the left hemidiaphragm), as well as lymph node stations 1 to 4, 7, and 9 to 11 with some authors recommending inclusion of stations 12 to 13.[112]; if the GE junction is involved, stations 20 and 110 to 111 are also included, and if the tumor extended to the middle stomach, stations 5, 6, and 8 frequently are included.[112] Tumors that originate in the body of the stomach can spread to all

nodal sites but have the highest likelihood of spreading to nodes along the greater and lesser curvature near the location of the primary tumor mass. Nodal basins are similar to upper third tumors with the exception of inclusion of nodal basins along the pyloric region, common hepatic artery, and additional coverage along the greater curvature. For middle third patients undergoing total gastrectomy with Roux-en-Y esophagojejunal anastomosis, the CTV typically includes 3 to 4 cm of mucosa of the esophagus and jejunum, tumor bed delineated as above, as well as lymph node stations 3 to 11, with some authors advocating inclusions of stations 12 to 13,[112] as well as considerations of 1 to 2 if there is proximal third stomach involvement. Tumors that originate in the distal stomach, in the region of the gastric antrum, have a high likelihood of spread to the periduodenal, peripancreatic, and porta hepatis nodes, whereas they have a lower likelihood of spread to the nodes near the cardia of the stomach, the periesophageal and mediastinal nodes, or to the splenic hilar nodes—that is, there is less emphasis placed on more proximal nodes (including coverage of the splenic artery course, including splenic hilum) and more comprehensive coverage of pancreaticoduodenal nodal basins. For distal third tumors undergoing distal gastrectomy with gastrojejunal anastomosis, the CTV typically includes 3 to 4 cm of the mucosa of the proximal stomach and jejunum as well as 3 to 4 cm of the duodenal stump, tumor bed as delineated using preoperative imaging as above, and lymph node stations 3 to 9 and 11 to 13.[112] Figure 62.10 shows an example of 3-D fields for a T3N1 antral tumor involving the gastric body. Figure 62.11 shows examples of varying nodal locations on axial CT images. Any tumor originating in the stomach has a high propensity of spread to nodes along the greater and lesser curvature, although they are most likely to spread to those sites in close anatomic proximity to the primary tumor mass.

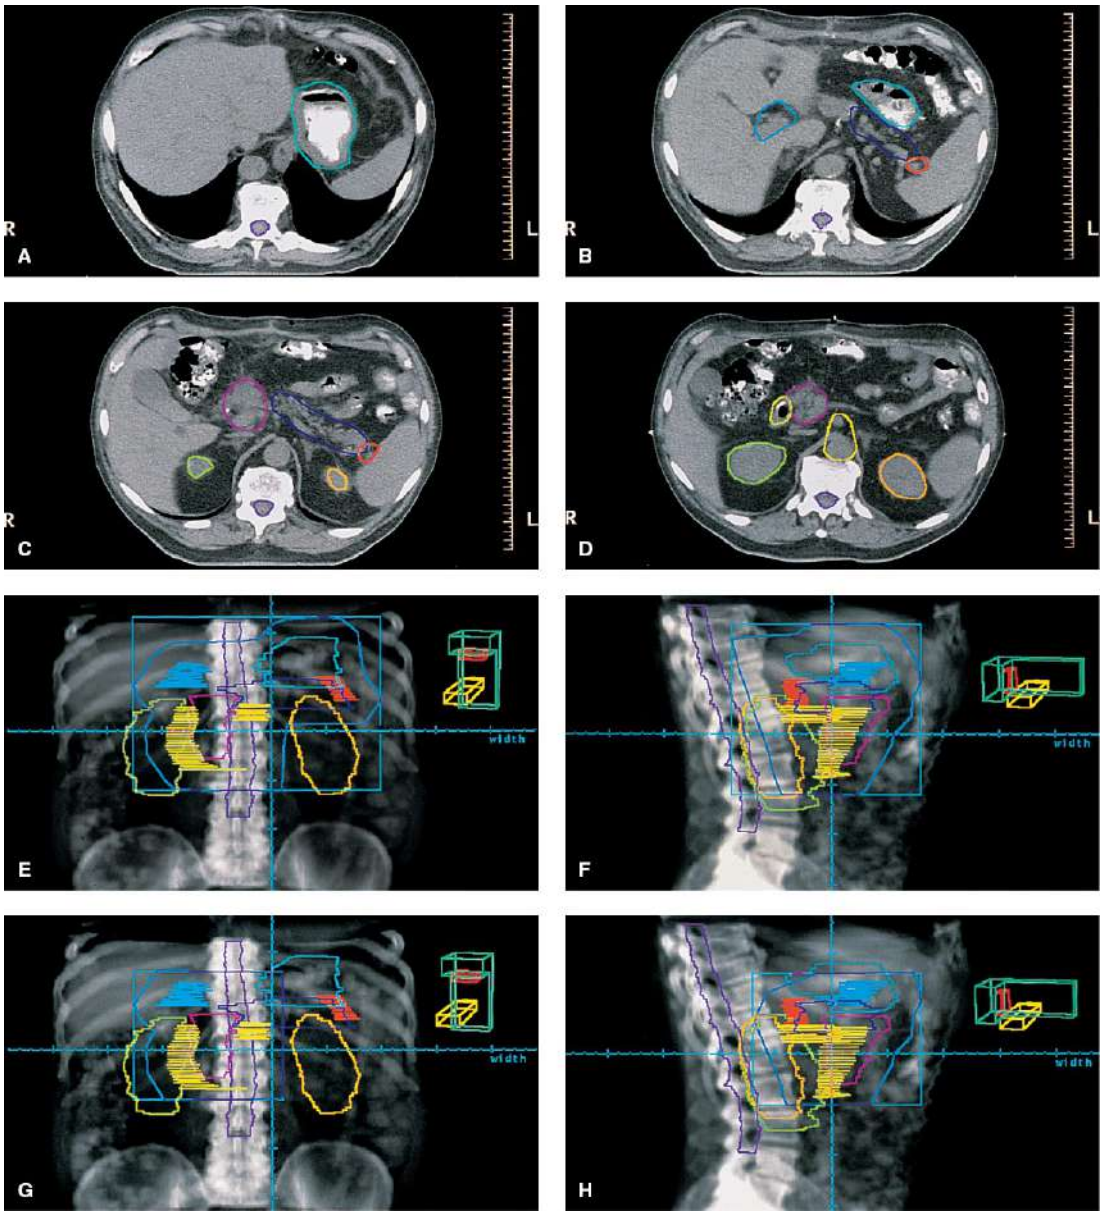

FIGURE 62.10. Optimized postoperative irradiation fields for patient with T3N1 antral primary. Structures of interest were delineated at the time of computed tomography simulation **(A–D)**, and irradiation fields were designed with the aid of digitally reconstructed radiographs **(E–H)**. **A:** Gastric remnant (*teal*). **B:** Gastric remnant plus body/tail of the pancreas (*dark blue*), splenic hilum (*salmon*), and porta hepatis (*medium blue*). **C:** Head of the pancreas (*magenta*) and kidneys (*left*, *orange*; *right*, *light green*) are delineated in addition to body/tail of the pancreas and splenic hilum. **D:** Celiac artery (*yellow*) and duodenum (*yellow–green*) are shown together with head of pancreas and kidneys. A four-field technique of AP (anteroposterior), PA (posteroanterior), and paired laterals was designed to include the gastric remnant (*teal*), tumor bed (head of the pancreas [*magenta*], first and second part of the duodenum [*yellow–green cross hatched*]), pertinent nodal volumes (perigastric, pancreaticoduodenal, porta hepatic [*medium blue cross hatched*], celiac [*yellow cross hatched*], and suprapancreatic), and the optional nodal volume of splenic hilum (*salmon cross hatched*). **E:** Initial AP field (field margins as shown in medium blue

exclude approximately two-thirds of the left kidney while including about 50% of the right kidney). Exclusion of the optional splenic hilar nodes would have allowed additional but minimal sparing of the left kidney in view of the adjacency of gastric antrum and splenic hilum. **F:** Initial right lateral field demonstrated exclusion of the spinal cord. **G:** Reduced AP field with exclusion of splenic hilar nodes and most of the gastric remnant. **H:** Reduced right lateral field.

TABLE 62.6 GENERAL GUIDELINES OF IMPACT OF T AND N STAGE ON INCLUSION OF REMAINING STOMACH, TUMOR BED, AND NODAL SITES WITHIN IRRADIATION FIELDS

TN Stage	Remaining Stomach[a]	Tumor Bed	Nodes
T1-T2 (not into subserosa) N0	N	N	N
T2N0 (into subserosa)[b]	Variable	Y	N
T3N0	Variable	Y	N
T4N0	Variable	Y	Variable
T1-2N+	Y	N	Y
T3-4N+	Y	Y	Y

[a]Inclusion of the remaining stomach is preferable in most patients if two-thirds of one kidney can be excluded. This depends on the extent of surgical resection and uninvolved margins (in centimeters).
[b]Posterior wall T2N0 lesions, or those that extend beyond the muscularis propria, especially tumors located in the proximal or distal stomach, are at risk for local relapse. In addition, patients with low-stage disease with close or positive surgical margins should be considered for treatment to the tumor bed.
N, no; Y, yes.

Additional guidelines for defining the CTV for postoperative irradiation fields have been developed based on location and extent of the primary tumor (T stage) and location and extent of known nodal involvement (N stage).[114] Table 62.6 presents general guidelines on the impact of T and N stages on inclusion of the remaining stomach (gastric remnant), tumor bed, and nodal sites, whereas Tables 62.7 to 62.9 present treatment guidelines based on TN stage within each of three primary sites (proximal, mid, and distal stomach). With proximal gastric lesions or lesions at the GE junction, a 3- to 5-cm margin of distal esophagus should be included; if the lesion extends through the entire gastric wall, a major portion of the left hemidiaphragm should be included. In these circumstances, blocking can decrease the volume of irradiated heart. For unresectable lesions with moderate periesophageal extension, it may not be possible to exclude an adequate amount of the heart with anteroposterior/posteroanterior (AP/PA) fields, and the use of lateral or oblique fields for a portion of treatment, as well as adopting intensity-modulated radiation therapy (IMRT) techniques, is likely indicated (Fig. 62.12;

discussed below). In general, for patients with node-positive disease, there should be wide coverage of tumor bed, remaining stomach, resection margins, and nodal drainage regions. For node-negative disease, if there is a good surgical resection with pathologic evaluation of at least 16 nodes, and there are wide surgical margins on the primary tumor (at least 5 cm), treatment for the nodal beds may be optional. However, it is the authors' opinion that in most cases (particularly node positive) that the celiac basins/associated branches as well as periaortic nodes should be similarly covered (see above patterns of failure discussion). Treatment for the remaining stomach should depend on a balance of the likely normal tissue morbidity and the perceived risk of local relapse in the residual stomach.

TABLE 62.7 IMPACT OF SITE OF PRIMARY GASTRIC LESION AND TN STAGE ON IRRADIATION VOLUMES: CARDIA/PROXIMAL ONE-THIRD OF THE STOMACH (GENERAL GUIDELINES)

Site of Primary and TN Stage	Remaining Stomach	Tumor Bed Volumes[a]	Nodal Volumes	Tolerance Organ Structures
Cardia/proximal one-third of the stomach	Preferred, but spare two-thirds of one kidney (usually right)	T-stage dependent	N-stage dependent	Kidneys, spinal cord, liver, heart, lung
T2N0 with invasion of subserosa	Variable dependent on surg–path findings[b]	Medial left hemidiaphragm, adjacent body of the pancreas (± tail)	None or perigastric[c]	
T3N0	Variable dependent on surg–path findings[b]	Medial left hemidiaphragm, adjacent body of the pancreas (± tail)	None or perigastric; optional: periesophageal, mediastinal, celiac[c]	
T4N0	Variable dependent on surg–path findings[b]	As for T3N0 plus site(s) of adherence with 3–5-cm margin	Nodes related to site of adherence, ± perigastric, periesophageal, mediastinal, celiac	
T1-2N+	Preferable	Not indicated for T1, as above for T2 into	Perigastric, celiac, splenic, suprapancreatic ±	

		subserosa	periesophageal, mediastinal, pancreaticoduodenal, porta hepatis[d]
T3-4N+	Preferable	As for T3, T4N0	As for T1-2N+ and T4N0

[a]Use preoperative imaging (computed tomography [CT], barium swallow), surgical clips, and postoperative imaging (CT, barium swallow).
[b]For tumors with wide (>5 cm) surgical margins confirmed pathologically, treatment of residual stomach may not be necessary, especially if this would result in substantial increased normal tissue morbidity.
[c]Optional node inclusion for T2-3N0 lesions if adequate surgical node dissection (D2 dissection) and at least 10 to 15 nodes are examined pathologically.
[d]Pancreaticoduodenal and porta hepatis nodes are at low risk if nodal positivity is minimal (i.e., 1 to 2 positive nodes with 10 to 15 nodes examined), and this region may not need to be irradiated. Periesophageal and mediastinal nodes are at risk if there is esophageal extension.
Surg–path, surgical–pathologic.

Although parallel-opposed AP/PA fields are a practical arrangement for tumor bed and nodal irradiation, multifield techniques should be used if they can improve long-term tolerance of normal tissues. Tightly contoured AP/PA fields should be designed to spare as much normal tissue as possible (Figs. 62.13 and 62.14). In institutional series, the average irradiation field measured 15 cm × 15 cm.[39,115,116] More routine use of multifield techniques should be implemented when preoperative imaging exists to allow accurate reconstruction of target volumes. Single-institution data suggest that multifield arrangements may produce less toxicity. Although AP/PA fields can be weighted anteriorly to keep the spinal cord dose at acceptable levels, a four-field technique, if feasible, can spare spinal cord with improved dose homogeneity. Depending on the posterior extent of the gastric fundus, either obliqued or more routine lateral portals can be used to deliver a 10- to 20-Gy component of irradiation to spare spinal cord or kidney. When lateral fields are used, liver and kidney tolerance limits the use of lateral fields to ≤20 Gy. Patients should be treated with high-energy photons when possible. With the wide availability of 3D treatment planning systems, it may be possible to more accurately target the high-risk volume and to use unconventional field arrangements to produce superior dose distributions. To accomplish this without marginal misses, it will be necessary to both carefully define and encompass the various target volumes because the use of oblique or noncoplanar beams could exclude target volumes that would be included in AP/PA fields or nonoblique four-field techniques (AP/PA and laterals). Although, historically, two-dimensional (2D)-based radiation planning has been carried out primarily using anatomic landmarks as well as fluoroscopic barium swallow to determine field borders (Figs. 62.13 and 62.14), contemporary treatment planning using CT-based planning allows improved visualization of

both target and nontarget structures, along with 3D reconstruction and creation of a "beam's eye" view of varying fields, allowing improved conformality around target structures and improvements in normal tissue sparing. Because volumetric data can be obtained by CT scans, dose–volume histogram data can also be generated. A variety of 3D techniques are presently used and described later. Similarly, with the implementation of IMRT, utilization of this approach should be considered where meeting dose constraints with 3D techniques proves challenging.

Because it is important to account for daily setup uncertainty as well as physiologic internal organ motion (secondary to respiration, peristalsis, cardiac motion, etc.), an additional margin must be added to a CTV. Interfraction variability in stomach location occurs, often owing to variations in gastric filling. Intrafraction changes in target shape and location may be attributable to respiratory motion, which, particularly in the superior to inferior direction, may exceed 1 to 1.5 cm. In effort to reduce this, kilovoltage radiographic matching can be used with particular emphasis on matching of surgical clips. An additional technique that may improve treatment accuracy is cone-beam CT, which allows direct target matching within a given fraction. Movement related to respiratory motion can be assessed using 4D CT, which images the patient in all phases of respiration (similar to what is performed fluoroscopically but using CT). Similarly, respiratory gating techniques may allow reduction in the target volume/smaller margins, allowing for treatment during a more stationary phase of the respiratory cycle (either in expiration or breath hold).

TABLE 62.9 IMPACT OF SITE OF PRIMARY GASTRIC LESION AND TN STAGE ON IRRADIATION VOLUMES: ANTRUM/PYLORUS/DISTAL ONE-THIRD OF THE STOMACH (GENERAL GUIDELINES)

Site of Primary and TN Stage	Remaining Stomach	Tumor Bed Volumes[a]	Nodal Volumes	Tolerance Organ Structures
Antrum/pylorus/distal one-third of the stomach	Yes—but spare two-thirds of one kidney, usually left	T-stage dependent	N-stage dependent	Kidneys, liver, spinal cord
T2N0 with invasion of subserosa	Variable dependent	Head of the pancreas	None or perigastric; optional:	

	on surg–path findings[b]	(± body), first and second part of the duodenum	pancreaticoduodenal, porta hepatis, celiac, suprapancreatic[c]
T3N0	Variable dependent on surg–path findings[b]	Head of the pancreas (± body), first and second part of the duodenum	None or perigastric; optional: pancreaticoduodenal, porta hepatis, celiac, suprapancreatic[c]
T4N0	Preferable but dependent on surg–path findings[b]	As for T3N0 plus site(s) of adherence with 3–5-cm margin	Nodes related to site(s) of adherence ± perigastric, pancreaticoduodenal, porta hepatis, celiac, suprapancreatic
T1-2N+	Preferable	Not indicated for T1; as for T2N0 with invasion of subserosa	Perigastric, pancreaticoduodenal, porta hepatis, celiac, suprapancreatic, optional—splenic hilum
T3-4N+	Preferable	As for T3, T4N0	As for T1-2N+ and T4N0

[a]Use preoperative imaging (computed tomography [CT], barium swallow), surgical clips, and postoperative imaging (CT, barium swallow).
[b]For tumors with wide (>5 cm) surgical margins confirmed pathologically, treatment of residual stomach is optional if this would result in substantial increased normal tissue morbidity.
[c]Optional node inclusion for T2-3N0 lesions if adequate surgical node dissection (D2 dissection) and at least 10 to 15 nodes examined pathologically.
Surg–path, surgical–pathologic.

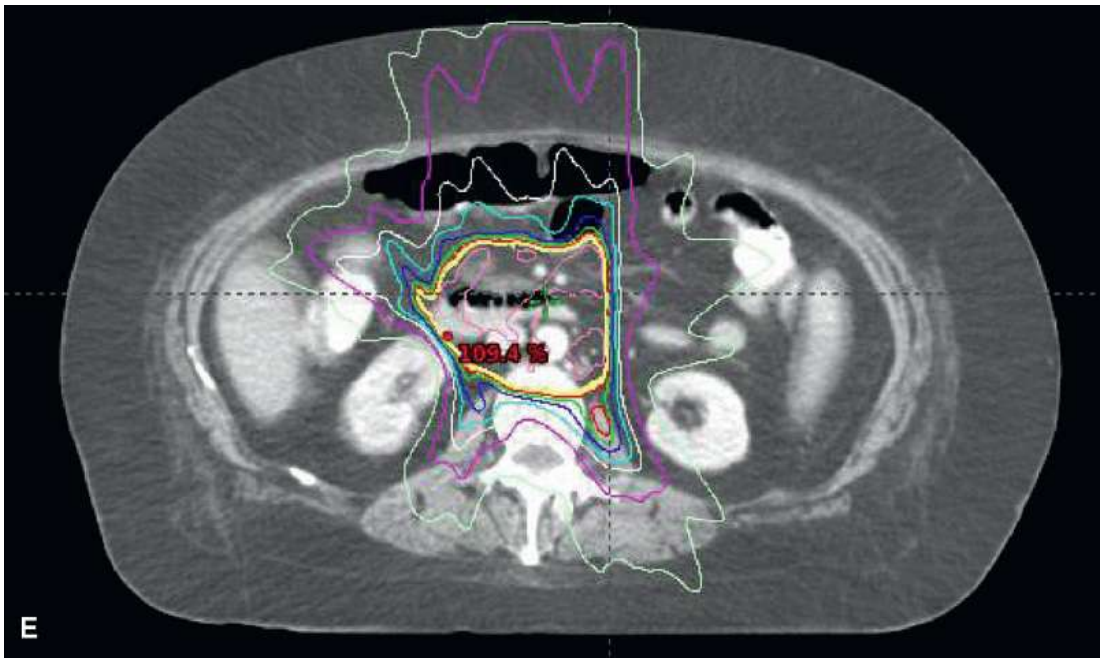

FIGURE 62.12. A 50-year-old female with a gastric body adenocarcinoma with multiple suspicious nodes noted on CT scan (delineated in *red*), including lower paraesophageal, perigastric, gastrohepatic, porta, and splenic hilum. IMRT was utilized to minimize adjacent normal tissue including the heart, liver, kidneys, and spinal cord.

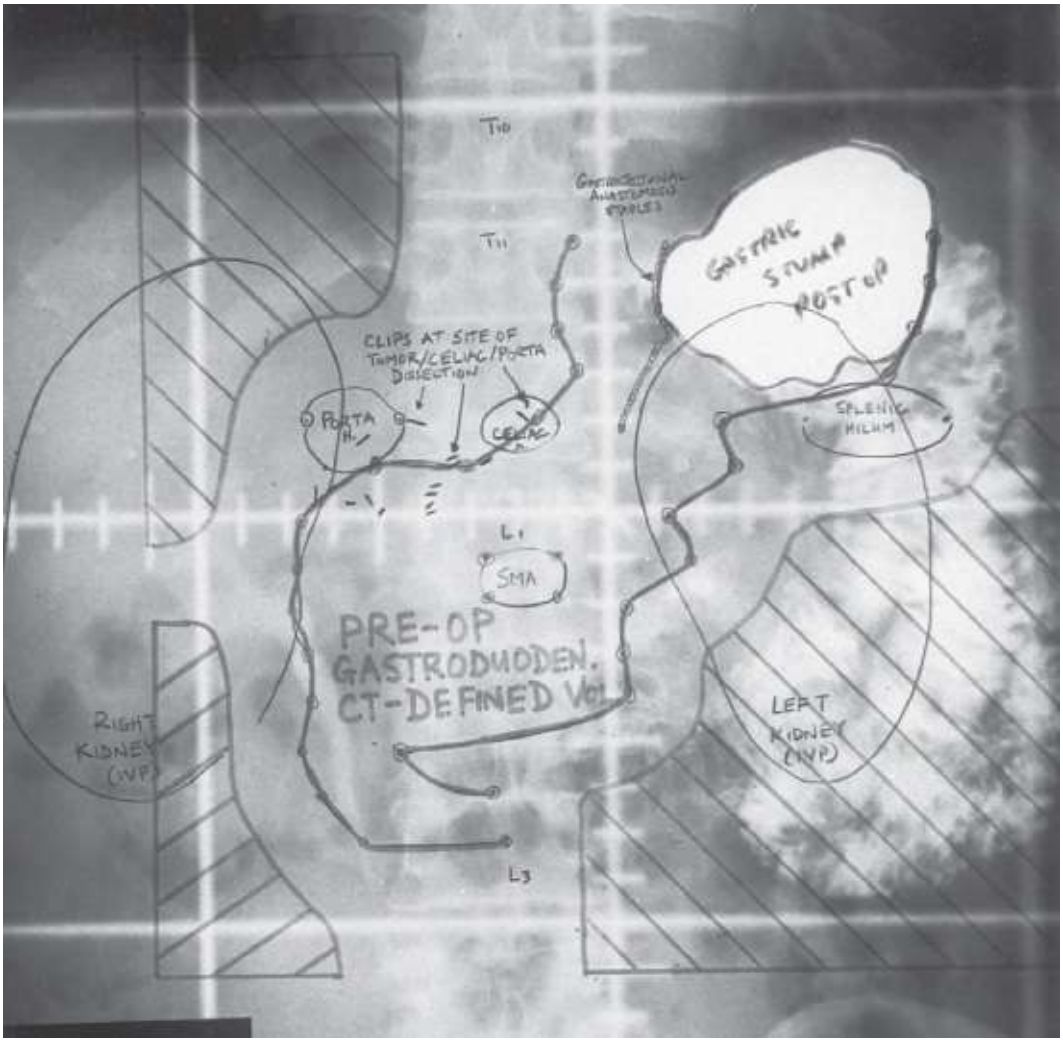

FIGURE 62.13. Simulation film for T3 antral tumor with two of five peritumoral lymph nodes metastatically involved (radical subtotal gastrectomy with D1 node dissection). Simulation film identifies areas at risk for recurrence, including preoperative gastric/tumor bed (defined by preoperative computed tomography [CT] scan), anastomotic sites and gastric stump (staple line seen on precontrast simulation films and marked on postintravenous pyelogram/postcontrast film), and regional lymphatics (celiac, porta hepatis, superior mesenteric artery, and splenic nodes identified on CT and pancreaticoduodenal nodes lie in C-loop of the duodenum identified by preoperative CT). The right kidney is spared for approximately three-fourths of its volume, whereas the left kidney has about one-third of its volume blocked. (Reprinted from Smalley SS, Gunderson L, Tepper J, et al. Gastric surgical adjuvant radiotherapy consensus report: rationale and treatment implementation. *Int J Radiat Oncol Biol Phys* 2002;52[2]:283–293. Copyright © 2002 Elsevier. With permission)

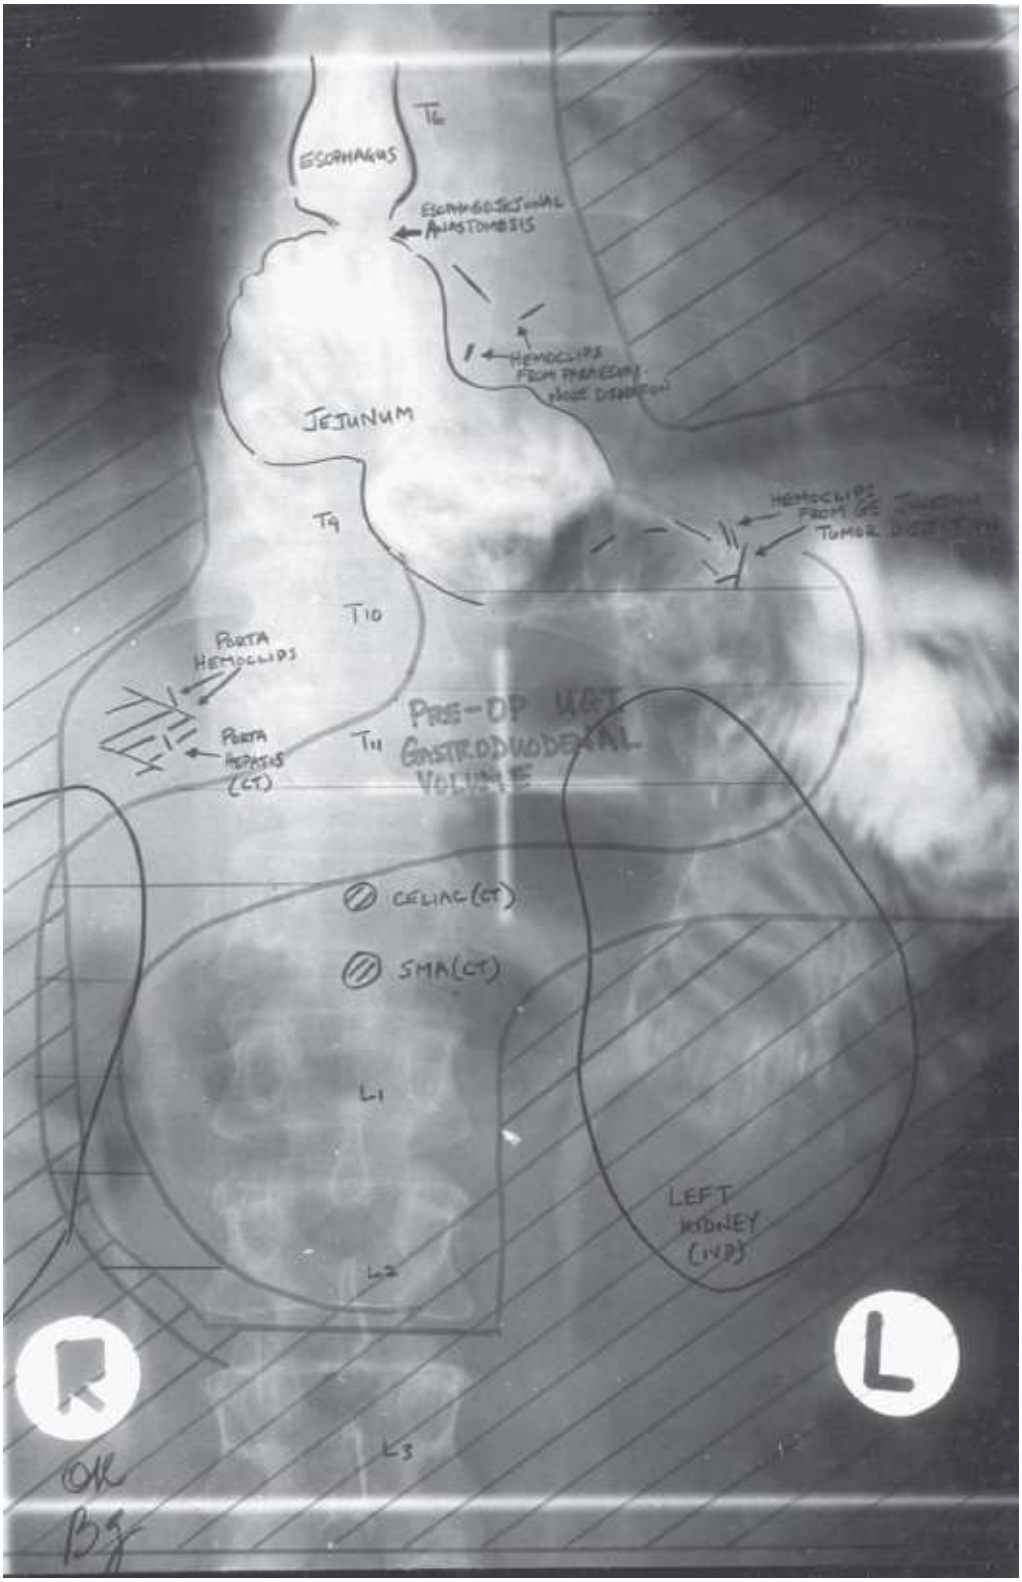

FIGURE 62.14. Simulation film for a T4 (diaphragm invasion) gastroesophageal junction tumor with 4 of 15 involved lymph nodes (total gastrectomy with modified R3 node dissection). Areas at risk for recurrence include preoperative gastric/tumor bed (defined by preoperative upper gastrointestinal radiographs and hemoclips placed at

the time of resection to mark tumor bed and diaphragm invasion), anastomotic sites and stump (anastomosis visualized at the juncture of residual distal esophagus and jejunum), and regional lymphatics (including the celiac, porta hepatis, and pancreaticoduodenal areas as well as the distal paraesophageal nodes). (Reprinted from Smalley SS, Gunderson L, Tepper J, et al. Gastric surgical adjuvant radiotherapy consensus report: rationale and treatment implementation. *Int J Radiat Oncol Biol Phys* 2002;52[2]:283–293. Copyright © 2002 Elsevier. With permission.)

Another potential approach in the treatment for gastric cancer is the use of IMRT. IMRT also uses CT-based planning, again allowing 3D reconstruction of varying structures. However, IMRT differs from 3D planning through the delivery of radiation dose by partitioning a radiation field into multiple smaller fields of various shapes and sizes, varying the dose intensity between each area. This is carried out with either dynamic IMRT (where collimating leaves move in and out of the radiation beam path during treatment) or “step-and-shoot” IMRT (where the leaves change the radiation field shape while the beam is turned off). Either method is particularly effective at conforming radiation dose to the target structures while avoiding dose to normal tissue. Radiation oncologists must determine which structures are most critical and weight their importance during the treatment planning process. Importantly, the greater the number of “avoidance” normal structures, the more difficult it is to meet all dose constraints. IMRT utilizes “inverse planning,” where an intended prescription dose is placed on target volumes and dose constraints are placed on normal tissue structures. Thereafter, computer software algorithms allow design of unconventional treatment fields that would not otherwise be possible with standard planning methods. Radiation oncologists and medical physicists critically evaluate numerous plans until dose constraints are satisfactorily met. The result should be a series of radiation doses that closely conform to the target volumes while minimizing dose to normal tissues. IMRT may be appropriate in selected cases to reduce doses to normal structures, including the heart, liver, and kidneys. A potential disadvantage of IMRT is the possibility of delivering low doses of radiation therapy to normal tissue areas that might not normally be irradiated using 2D or 3D techniques. Another potential disadvantage to IMRT is possible dose inhomogeneity, leading to potential “hot spots” in normal organs. Because IMRT requires precise target definition, the potential for “marginal miss” increases and careful, accurate target delineation is of paramount importance.

With setup uncertainty and physiologic organ motion, care must be taken to ensure accurate and reproducible setup, including with the use of immobilization

devices as well as possible respiratory gating/breath-hold techniques. Block margins may be minimized with efforts to reduce intrafractional position variability, including breath-hold techniques. Generally, high-energy photons (10 to 18 MV) are recommended when using 3D conformal or IMRT therapy, potentially facilitating a reduction in the integral dose. When using more advanced radiation planning techniques, daily image guidance is generally recommended, with consideration of frequent cone-beam CT imaging and adaptive planning pending anatomic changes.[112]

Multiple dosimetric studies comparing IMRT to two-field and 3D conformal radiation therapy plans have shown significant reductions in kidney, liver, heart, lung, and spinal cord dose with the former. Although IMRT may result in improved normal tissue sparing, many of the acute toxicities encountered during radiation may persist given that many symptoms arise from radiation of the target, including gastric mucosa. The value of IMRT may lie primarily in normal organ sparing with potential reductions in long-term toxicity in surviving patients. There is ongoing investigation into further enhancements of this technique using volumetric modulated arc therapy, helical TomoTherapy, as well as proton therapy. This may also become important with the integration of newer/novel systemic agents, in conjunction with radiation therapy, of which many act as potent tumoral (as well as normal organ) radiation sensitizers and may reduce treatment-related toxicities as well as avoidance of treatment interruptions.

Dose Constraints

In radiation therapy planning of gastric cancer, normal tissue tolerance should always be considered. The spinal cord dose is generally limited to 45 Gy using 1.8-Gy fractions (and potentially less when delivered with novel systemic agents). Accurate delineation of adjacent organs including lungs, liver, kidneys, heart, and spinal cord is important. Varying dose–volume normal organ constraints have been suggested. Historically, heart dose constraints have included maintaining one-third, two-thirds, and total heart volumes <45, 40, and 30 Gy, respectively. Recommended heart constraints include keeping <30% of the cardiac volume to a total dose of 40 Gy and <50% receiving 25 Gy, minimizing dose to the left ventricle. In a recent secondary analysis of the NRG Oncology RTOG 0617 Randomized Clinical Trial in which lung cancer patients received concurrent chemotherapy of carboplatin and paclitaxel with or without cetuximab, and 60- versus 74-Gy radiation doses, IMRT produced lower heart

doses ($P < .05$), and the volume of heart receiving 40 Gy (V40) was significantly associated with OS on adjusted analysis ($P < .05$).[117] In the setting of potentially significant volumes of the heart in the radiation field, consideration of 4D CT and/or respiratory motion management can be made. It is recommended that at least 70% of one physiologically functioning kidney receive a total dose <20 Gy and that collectively ≤50% of the combined functional renal volume should receive >20 Gy.[113] In some patients, a portion of both kidneys will fall within the treatment field; however, at least two-thirds to three-fourths of one kidney should be excluded beyond a dose of 20 Gy. For proximal gastric lesions, ≥50% of the left kidney is commonly within the irradiation portal, and the right kidney must be appropriately spared. For distal lesions with narrow or positive duodenal margins, a similar amount of right kidney often is included, and every effort must be taken to spare enough left kidney to maintain function. Late renal sequelae have not generally been encountered with these techniques.[39,79,118] One should also consider the possibility of impaired kidney function in the context of varying comorbidities, using nuclear medicine renal studies to assess individual renal function in such situations or where significant volumes of kidneys are anticipated to be within the radiation field. Generally, 70% of the liver parenchyma should be kept to a dose <30 Gy. Many of these constraints can be achieved through the use of 3D planning with appropriate and careful design of shielding blocks/multileaf collimation and dose–volume histogram analysis, with the use of IMRT in appropriate cases. Table 62.10 shows examples of recommended normal tissue constraints.

Doses of Radiation

Generally, doses in the range of 45 to 50.4 Gy should be delivered at 1.8 Gy per fraction. Although primarily limited by normal tissue constraints in the upper abdomen, several series have reported improved locoregional control with radiation dose escalation in the adjuvant setting. A report from Mayo Clinic investigators reported high locoregional control rates with radiation doses >54 Gy.[118] Similarly, a report from Italian investigators treating patients adjuvantly with hyperfractionated radiation therapy to a dose of 55 Gy, with concurrent 5-FU, showed an in-field recurrence rate of only 7.5% and survival rate of 52% with a median follow-up >5 years.[119] With regimens using single daily fractions, the usual dose is 45 delivered in 1.8- to 2-Gy fractions over 5 weeks, with a field reduction after 45 Gy in patients receiving boost-field treatments. Reduced boost fields to small areas of residual disease and a small volume of stomach or small

intestine sometimes can be cautiously carried to doses of 55 to 60 Gy with multifield techniques. In such instances, informed consent should include a discussion of an increased risk of grade 3 to 4 gastrointestinal toxicity.

TABLE 62.10 EXAMPLE NORMAL TISSUE CONSTRAINTS

	EORTC[113]	National Comprehensive Cancer Network[a]
Spinal Cord	<45 Gy	≤45 Gy
Lungs	V20 < 20%	V20 ≤ 30%; mean ≤20 Gy
Heart	V40 < 30%, V25 < 50%	V30 ≤ 30% (closer to 20% preferred); mean 30 Gy
Kidneys	Total V20 < 50%; at least one with V20 < 30%	(evaluate each separately): V20 ≤ 33%; mean <18 Gy
Liver	V30 < 30%	V30 ≤ 33%; mean < 25 Gy

RESULTS OF THERAPY

Locally Advanced Unresectable or Subtotally Resected Gastric Cancer

For patients with locally advanced unresectable or subtotally resected gastric carcinoma, radiotherapeutic approaches both with and without chemotherapy have been used because these tumors appear localized without clinically detectable metastases. Combined treatment with radiation therapy and chemotherapy appears to prolong survival but rarely results in long-term cure.[120] Although only a modest effect on survival is seen, these studies have established, importantly, the foundation of contemporary combined modality therapy and have served as a stimulus to further clinical investigation in gastric cancer as well as other gastrointestinal disease sites. The results of these phase III studies have had a significant impact on clinical trial development in gastrointestinal malignancies (Table 62.11).

In a historical trial from 1969, Moertel et al.[120] reported the results of a prospective, controlled double-blind study of patients with locally advanced unresectable gastric cancer. In this study, 48 patients were randomized to 35 to 40 Gy of radiation therapy over 4 weeks with and without 5-FU. Mean survival

was 13 months in patients receiving radiation therapy and 5-FU versus 5.9 months for the radiation therapy patients ($P < .01$). These results demonstrated for the first time the clinical benefit of combining concurrent 5-FU with radiation therapy and encouraged further investigation of combination therapy in gastric cancer and other gastrointestinal disease sites (esophageal, pancreatic, rectal, and anal carcinomas).

As a follow-up to this study, the Gastrointestinal Tumor Study Group (GITSG) examined the combination of 5-FU/MeCCNU, or 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1 nitrosourea, and radiotherapy (RT; 50 Gy/split course/8 weeks) versus the same chemotherapy alone in locally advanced gastric cancer.[121] Patients were eligible if the tumor involved regional lymph nodes or adjacent structures that could be completely resected en bloc. Of the 90 patients entered, 66 patients had a resection of the primary tumor. Of these, 23 patients had gross residual disease, 36 patients had microscopic residual, and 7 patients had no documented residual disease. The study was closed prematurely because of an excess of early deaths in the combined chemotherapy–RT arm. The excessive early mortality of the combined-modality arm was attributed to early tumor progression and poor tolerance of the combined-modality regimen. However, further follow-up beyond 3 years indicated continuing mortality among the chemotherapy-alone arm, whereas the combined chemoradiotherapy arm exhibited a plateau with 18% of patients surviving 5 years. Thus, despite an excess of early mortality, the combined-modality arm exhibited an overall superiority in 5-year survival. It is important to note that patients who had had their primary tumor resected experienced superior survival to those without resection. All of the survival benefit in patients receiving combined modality was in patients whose primary tumor had been resected. This trial showed that combined chemoradiation therapy is capable of rendering a substantial percentage of patients with microscopic residual gastric cancer free from disease. It furthermore supported the rationale of exploring chemoradiation adjuvant trials in completely resected patients at high risk for locoregional relapse, and that chemoradiation was able to control microscopic disease and lead to long-term survival in a significant number of these patients.

A more recent multicenter phase II trial from China treated patients with medically inoperable or unresectable gastric cancer with pre- and postradiation docetaxel, cisplatin, and 5-fluorouracil (DCF), in combination with chemoradiation with concurrent cisplatin in between. Clinical complete response rate was 36%, overall response rate 83%, median survival 26 months, and 2-year

survival 52%. Medically inoperable patients had a better prognosis than patients with frankly unresectable disease.[122]

Resectable Gastric Cancer

The recognition of the high rates of local and regional failure following surgery in patterns of failure analyses has served as the basis for clinical trials assessing the value of radiation therapy both with and without chemotherapy as an adjuvant treatment (Table 62.4). Although these studies have all addressed the important question of whether clinical outcome is enhanced by adjuvant radiation therapy, there has been marked variability in radiation dose and schedule, sequence with surgery (preoperatively, intraoperatively, or postoperatively), and the use of concurrent and maintenance chemotherapy (Table 62.12). These differences in study design and included patients may explain in part the conflicting results observed in phase III studies.

Adjuvant Radiation Therapy

Two randomized phase III studies have studied the use of external beam radiation therapy (EBRT) alone with surgery.[76,123] Although both studies used similar radiation dose and schedule, sequence with surgery differed. In the British Stomach Cancer Group study, 436 patients were randomized to surgery alone, postoperative radiation therapy (45 to 50 Gy in 25 to 28 fractions), or cytotoxic chemotherapy with mitomycin, doxorubicin, and fluorouracil (FAM).[76,123] The 5-year survival for surgery alone was 20%, for surgery plus radiation therapy 12%, and for surgery plus chemotherapy 19%. In this study, no survival advantage was observed for patients who received postoperative EBRT, although there was an apparent improvement in local control, demonstrating that local disease could be affected by adjuvant radiation therapy. Locoregional failure was documented in only 15 of 153 patients (10%) in the irradiation arm versus 39 of 145 patients (27%) in the surgery-alone arm and 26 of 138 patients (19%) in the FAM group. Interpretation of the results is complicated by the inclusion of 171 patients undergoing resection with gross or microscopic residual carcinoma. These patients would not be candidates for contemporary gastric surgical adjuvant trials in the United States. In addition, approximately one-third of patients randomized to receive adjuvant treatment did not receive the assigned therapy. Of 153 patients randomized to the irradiation arm, only 104 (68%) received a dose ≥40.5 Gy, and 36 (24%) received none.

TABLE 62.11 UNRESECTABLE OR RESIDUAL GASTRIC CANCER: TREATMENT RESULTS OF RANDOMIZED TRIALS

Group or Institution	Treatment Arms	Number of Patients	EBRT Dose	Chemotherapy	Survival Results
Mayo Clinic[120]	EBRT + ChT vs. EBRT	48	35–40 Gy	5-FU	Increased survival for EBRT + 5-FU with mean survival 13 vs. 5.9 mo and 3/25 (12%) vs. 0/23 5-y survival
GITSG[121]	EBRT + ChT vs. ChT	90	50-Gy split course	5-FU + MeCCNU	Advantage in long-term survival with EBRT + ChT at 18% vs. 7% ($P < .05$)

ChT, chemotherapy; EBRT, external beam radiation therapy; 5-FU, 5-fluorouracil; GITSG, Gastrointestinal Tumor Study Group; MeCCNU, 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1 nitrosourea.

TABLE 62.12 ADJUVANT/NEOADJUVANT IRRADIATION FOR RESECTED GASTRIC CANCER: TREATMENT RESULTS OF RANDOMIZED TRIALS

Series/Treatment Method	Patients	Median Survival (Months)	Survival		Locoregional Relapse

[a]Long-term survival is 5-year data for Mayo Clinic, ARTIST, CRITICS, and Beijing series, and 3-year data are for British and Intergroup 0116.
[b]In node-positive patients, 3-year disease-free survival 72% vs. 76%, *P* = .04; 83% vs. 94% in intestinal-type tumors.
ChT, chemotherapy; EBRT, external beam radiation therapy; N, patient number; preop, preoperative; postop, postoperative; 5-FU, 5-fluorouracil.

Neoadjuvant Radiation Therapy

In contrast, the results of a phase III study from Beijing demonstrated a survival benefit for patients with gastric cardia carcinoma receiving preoperative irradiation and surgery versus surgery only.[124] In this study, 370 patients with gastric cardia carcinoma were randomized to 40 Gy in 20 fractions over 4 weeks of preoperative irradiation and surgery or surgery only. The 5-year survival rates of preoperative irradiation and surgery and the surgery-alone group were 30% and 20%, respectively (10-year, 20% and 13%, respectively). These differences were statistically significant (*P* = .009). Further, local and regional nodal control was improved in patients undergoing preoperative irradiation and surgery (61% and 61%) versus surgery (48% and 45%) only. Morbidity and mortality rates were not increased in patients receiving preoperative irradiation and surgery.

Intraoperative Radiation Therapy

An alternative approach to postoperative or preoperative irradiation is intraoperative radiation therapy (IORT).[127,128] The advantage of this technique is the ability to deliver a single large fraction (10 to 35 Gy) of radiation to the tumor or tumor bed while excluding or protecting surrounding normal tissue from the high-dose field. This approach permits high-dose irradiation with minimal normal tissue treatment. Two randomized trials have examined the

efficacy of IORT in combination with surgery for patients with gastric carcinoma. Abe et al.[127] from Kyoto University performed a randomized trial of 211 patients with gastric cancer comparing surgery alone with surgery and intraoperative radiation (28 to 35 Gy). Patients were randomized based on hospital day of admission for surgery. For patients with tumor confined to the gastric wall, 5-year survival rates were similar for IORT and for resection alone. However, patients with Japanese stages II to IV disease who received IORT in conjunction with resection showed improved survival over patients who underwent resection without irradiation. Among patients with stage IV disease (who usually had local residual disease after maximal resection), there were no 5-year survivors in patients who received surgery alone; however, 15% of the patients who received IORT were alive at 5 years. The experience with IORT in gastric cancer at Kyoto University suggested that IORT may be beneficial in the treatment for locally advanced malignancies of the stomach.

To further evaluate this approach, Sindelar et al.[128] at the National Cancer Institute conducted a prospectively randomized controlled trial comparing surgical resection and IORT with conventional therapy in gastric carcinoma. Patients in the experimental group underwent gastrectomy, and IORT was administered to the gastric bed (20 Gy). Patients in the control group underwent resection and postoperative EBRT to the upper abdomen (50 Gy in 25 fractions) in advanced-stage lesions extending beyond the gastric wall. Of the 100 patients screened for the study, 60 patients were randomized and underwent exploratory surgery. Nineteen patients were excluded intraoperatively because of unresectability or metastases, leaving 41 patients in the study. The median survival for patients with tumors of all stages was 25 months for the IORT group and 21 months for the control group (P = not significant [NS]). Locoregional disease relapse occurred in 7 of 16 IORT patients (44%) and in 23 of 25 control patients (92%) ($P < .001$). Complication rates were similar between IORT and control patients. Although IORT failed to afford a significant advantage over conventional therapy in overall survival, it significantly improved control of locoregional disease. The use of IORT in gastric cancer remains a topic of investigation.

Adjuvant Chemoradiation Therapy

Because of the promising results in the early studies of combined-modality therapy for locally advanced unresectable or subtotally resected gastric cancer, investigators also have studied this combination in resectable gastric carcinoma.

A small study from South Africa randomized 66 patients with resected gastric cancer (T1 to T3, N1 or N2, M0) to low-dose postoperative irradiation (20 Gy in eight fractions over 10 days) and 5-FU or no further therapy.[96] No difference in survival was observed between the patients undergoing surgery and adjuvant therapy and those undergoing surgery alone. Given the subtherapeutic doses of radiation used in this study, it is difficult to draw any conclusions as to the efficacy of adjuvant radiation therapy and 5-FU.

In 1984, Moertel et al.[107] reported the results of a prospective randomized trial conducted at the Mayo Clinic of 62 patients with poor prognosis but completely resected gastric cancers who were randomized to either surgery alone or surgery followed by irradiation (37.5 Gy in 24 fractions over 4 to 5 weeks) with concurrent 5-FU. A nonstratified, prerandomization scheme was used with a 2:3 ratio favoring treatment. Informed consent was requested of only the 39 patients randomized to treatment. Ten of the 39 patients refused further therapy and were observed. When analyzed by intent to treat, the adjuvant arm had statistically significant improvement in both relapse-free and overall survival (overall 5-year survival 23% vs. 4%, $P < .05$). When patient outcome was compared with actual treatment received (29 adjuvant treatment, 33 surgery alone), 5-year survival still favored the adjuvant group (20% vs. 12%), although the differences were not statistically significant in view of the small patient numbers. The 10 patients who refused assignment to adjuvant treatment had more favorable prognostic findings than the other two groups of patients. When the two groups with equally poor prognostic factors were compared, the 5-year overall survival was 20% versus 4%, with an advantage to those receiving adjuvant treatment. When analyzed by treatment delivered, locoregional relapse was decreased with adjuvant treatments (54% incidence with surgery alone vs. 39% with irradiation and 5-FU).

Because of these conflicting results and the fact locoregional failure remained an established source of recurrence, an Intergroup trial (INT 0116) was initiated to evaluate postoperative combined 5-FU–based chemotherapy and irradiation to the gastric bed and regional nodes versus surgery only following resection of gastric cancer.[111] Eligibility included patients with pathologic stage group IB through IV nonmetastatic adenocarcinoma of the stomach or GE junction. After an en bloc resection (patients underwent D0-D1 dissection), 556 patients were randomized to either observation alone or postoperative 5-FU/leucovorin for one cycle followed by combined-modality therapy consisting of 45 Gy in 25 fractions plus concurrent 5-FU and leucovorin (4 days in week 1, 3 days in week

5) followed by two monthly 5-day cycles of 5-FU and leucovorin. Minor or major errors in field design were seen in 35% during preirradiation quality assurance review, allowing most deviations to be corrected prior to radiation therapy initiation, resulting in a 6.5% final major deviation rate. Nodal metastases were present in 85% of the cases. With 5 years of median follow-up, 3-year relapse-free survival was 48% for adjuvant treatment and 31% for observation (P = .001); 3-year overall survival was 50% for treatment and 41% for observation (P = .005). The median overall survival in the surgery-only group was 27 months, compared with 36 months in the chemoradiotherapy group; the HR for death was 1.35 (95% CI 1.09 to 1.66, P = .005). The HR for relapse in the surgery-only group as compared with the chemoradiotherapy group was 1.52 (95% CI 1.23 to 1.86, P < .001). The median duration of relapse-free survival was 30 months in the chemoradiotherapy group and 19 months in the surgery-only group. Patterns of failure were based on the site of first relapse only and were categorized as local, regional, or distant. Local recurrence occurred in 29% of patients who relapsed in the surgery-only group and 19% of those who relapsed in the chemoradiotherapy group. Regional relapse—typically abdominal carcinomatosis—was reported in 72% of those who relapsed in the surgery-only group and 65% of those who relapsed in the chemoradiotherapy group. Extra-abdominal distant metastases were diagnosed in 18% of those who relapsed in the surgery-only group and 33% of those who relapsed in the chemoradiotherapy group. Treatment was tolerable, with three (1%) toxic deaths. Grades 3 and 4 toxicity occurred in 41% and 32% of cases, respectively, and 17% of patients assigned to the chemoradiotherapy group stopped treatment owing to toxicity from therapy. Long-term results at >10-year median follow-up continued to show significant improvement in overall and disease-free survival in the chemoradiation group, benefiting all T- and N-stage patients included in the trial.[129] The results of this large study demonstrate a clear survival advantage for the use of postoperative chemoradiation and strongly support its integration into the routine care of patients with curatively resected high-risk carcinoma of the stomach and GE junction.[129]

The follow-up Intergroup trial CALGB 80101 randomized 546 patients with resected gastric or GE junction adenocarcinoma to receive either (a) one cycle of 5-FU/leucovorin, followed by 45 Gy with concurrent continuous infusion 5-FU, followed by two additional cycles of 5-FU/leucovorin, or (b) one cycle of ECF (epirubicin, cisplatin, 5-FU), followed by 45 Gy with concurrent, continuous infusional 5-FU, followed by two additional cycles of reduced dose ECF. With a

median follow-up duration of 6.5 years, 5-year overall survival rates were 44% in the FU plus LV arm and 44% in the ECF arm (P = .69; hazard ratio, 0.98; 95% CI, 0.78 to 1.24 comparing ECF with FU plus LV). Five-year disease-free survival rates were 39% in the FU plus LV arm and 37% in the ECF arm (P = .94; hazard ratio, 0.96; 95% CI, 0.77 to 1.20). The authors concluded that following curative resection of gastric or GE junction adenocarcinoma, postoperative chemoradiotherapy using ECF before and after 5-FU–based radiation does not improve survival compared to bolus 5-FU/leucovorin given in the same manner.[130]

A large retrospective study from Korea evaluated the role of adjuvant chemoradiation in patients undergoing D2 gastric cancer resection, a group that was not adequately represented in the aforementioned Intergroup trial. In the Korean study, 544 patients treated with D2 dissection and postoperative chemoradiation therapy were compared to 446 patients with similar characteristics treated with D2 dissection alone. Overall survival was significantly higher in patients treated with adjuvant chemoradiation (median survival 95 vs. 63 months, P = .02) as well as significant improvement in relapse-free survival.[91] Additionally, a collective review of nine randomized trials incorporating radiation therapy approaches with surgery alone also demonstrated a significant 5-year survival benefit with the addition of radiation therapy in resectable gastric cancer patients.[131]

A Korean phase III trial (the Adjuvant Chemoradiation Therapy in Stomach Cancer [ARTIST] study) compared the effects of adjuvant chemoradiation (capecitabine/cisplatin [XP] + RT) to adjuvant chemotherapy alone (capecitabine/cisplatin) following D2 resection of gastric cancer in 458 patients.[125] Treatment was completed as planned by 75.4% of patients (172 of 228) in the XP arm and 81.7% (188 of 230) in the XP/RT/XP arm. The addition of radiation to XP chemotherapy did not significantly prolong disease-free survival (P = .086). However, in the subgroup of patients with pathologic lymph node metastasis at the time of surgery (n = 396), patients randomly assigned to the XP/RT/XP arm experienced superior disease-free survival when compared with those who received XP alone (P = .0365), and the statistical significance was retained at multivariate analysis (estimated HR 0.69, P = .047). The authors concluded that the addition of RT to XP chemotherapy did not significantly reduce recurrence after curative resection and D2 lymph node dissection in gastric cancer. Of note is there was a relatively high proportion of early-stage disease in both trial arms, with approximately 60% of patients exhibiting stage

Ib-II gastric cancer, as well as >60% demonstrating diffuse-type histology (vs. 39% in the Intergroup 0116 trial). A report of long-term outcomes of the ARTIST trial with 7-year follow-up showed disease-free survival remains similar between the treatment arms (hazard ratio 0.74, CI 0.52 to 1.05, *P* = .09), with similar overall survival rates. In this analysis, the effect of the addition of radiation therapy in disease-free and overall survival differed by Lauren classification and lymph node ratio. Subgroup analysis showed that chemoradiotherapy significantly improved disease-free survival in node-positive disease and intestinal-type gastric cancers with a similar trend for disease-free and overall survival by stage of disease[126]; a subsequent trial by this group (ARTIST-II) in patients with lymph node–positive/stage II-III gastric cancer undergoing D2 resection stage II-III gastric cancer is randomizing patients to receive (a) adjuvant S1 for 1 year versus (b) adjuvant S1/oxaliplatin for 6 months versus (c) two cycles of S1/oxaliplatin, followed by concurrent S1/radiotherapy, followed by four additional cycles of S1/oxaliplatin with stage IB- IVA resectable gastric or gastro-oesophageal adenocarcinoma. Interpretation of these trial results are challenging given the high noncompliance rates, given that only 62%o f patients assigned to the radiation arm initiated radiation, with only 50% received the intended 5 weeks of therapy.

Chinese investigators randomized 380 patients undergoing D2 lymph node dissection to either radiation therapy using IMRT (45 Gy) with concurrent 5-FU and leucovorin or 5-FU and leucovorin alone. Five-year local recurrence rate in the radiation arm was 15.6% versus 24.2% without radiation (*P* = .042), although 5-year overall survival was not significantly different (48.4% vs. 41.8%, *P* = .122). However, median relapse-free survival (50 vs. 32 months, *P* = .029) was higher in the radiation group, and rates of all grade adverse events were similar between the two groups.[132]

Finally, a study by the Dutch Colorectal Cancer Group (the Chemoradiotherapy after Induction Chemotherapy in Cancer of the Stomach [CRITICS] trial) randomized 788 patients to receive preoperative chemotherapy (epirubicin, cisplatin, capecitabine or, alternatively, epirubicin, oxaliplatin, and capecitabine) for three cycles followed by D1+ resection, followed by a similar postoperative chemotherapy regimen, with or without radiotherapy concurrent with cisplatin/capecitabine. After preoperative chemotherapy, 372 (95%) of 393 patients in the chemotherapy group and 369 (93%) of 395 patients in the chemoradiotherapy group proceeded to surgery, with a potentially curative resection acheived in 310 (79%) of 393 patients in the chemotherapy group and

326 (83%) of 395 in the chemoradiotherapy group. Postoperatively, 233 (59%) of 393 patients started chemotherapy and 245 (62%) of 395 started chemoradiotherapy. At a median follow-up of 61·4 months, median overall survival was 43 months in the chemotherapy group and 37 months in the chemoradiotherapy group (p=0·90). After preoperative chemotherapy, in the total safety population of 781 patients (assessed together), there were 368 (47%) grade 3 adverse events; 130 (17%) grade 4 adverse events, and 13 (2%) deaths. During postoperative treatment, grade 3 and 4 adverse events occurred in 113 (48%) and 22 (9%) of 233 patients in the chemotherapy group, respectively, and in 101 (41%) and ten (4%) of 245 patients in the chemoradiotherapy group, respectively. The authors concluded postoperative chemoradiotherapy did not improve overall survival compared with postoperative chemotherapy in patients with resectable gastric cancer treated with adequate preoperative chemotherapy and surgery, although given the poor postoperative patient compliance in both treatment groups, future studies should focus on optimizing preoperative treatment strategies.[133]

Preoperative Chemoradiation Therapy

Because preoperative radiation therapy and chemotherapy have improved the surgical and disease-related outcomes in patients with rectal and esophageal cancer, this treatment is a logical approach to explore in gastric cancer as well. In the context of established limitations of perioperative and adjuvant strategies, potential advantages of preoperative therapy include improved tolerance relative to adjuvant treatments, potential downstaging with associated improvement in R0 resection rates, better target definition, better vascularization for optimal chemotherapy and radiosensitizing oxygen delivery, and allowing biologic stratification of patients for surgery, notably given that the presence of micrometastases is at initial diagnosis. Although no completed phase III trials have tested the value of preoperative radiation plus chemotherapy for patients with gastric cancer to date, two phase III trials for patients with esophagus cancer have included either lesions of the gastric cardia[134] or the esophagogastric junction.[135] In both trials, the trimodality arm demonstrated an improvement in survival when compared with the control arm of surgery alone. The series by Walsh et al.[134] (adenocarcinoma of the esophagus or gastric cardia) demonstrated a median survival of 16 versus 11 months and 3-year survival of 32% versus 6% (P = .01), with the advantage to trimodality treatment. The U.S. Gastrointestinal Intergroup phase III trial (adenocarcinoma or squamous cell of

the esophagus or GE junction), which closed prematurely owing to low accrual, resulted in a median survival of 54 versus 21.6 months and 5-year survival of 39% versus 16% (P = .008), with an advantage to the trimodality arm.[135]

Preoperative chemoradiation data for patients with gastric cancer are primarily limited to phase II studies from single institutions and cooperative groups. MD Anderson Cancer Center investigators reported a study in which 33 patients completed a preoperative protocol that started with induction chemotherapy of 5-FU, leucovorin, and cisplatin, followed by 45 Gy of radiation therapy in 25 fractions over 5 weeks. Infusional 5-FU was administered concurrently with radiation therapy. In 28 patients (85%), a gastrectomy was performed and D2 lymph node dissection was attempted. Pathologic complete and partial response was found in 64% of all operated patients. These patients showed a significantly longer median survival of 64 months in comparison with 13 months in patients with tumors not pathologically responding.[136] In a study from the same institution, 41 patients with operable gastric cancer received two cycles of continuous 5-FU, paclitaxel, and cisplatin followed by 45 Gy of radiation therapy with concurrent 5-FU and paclitaxel. An R0 resection was achieved in 78% of patients, pathologic complete response in 25%, and pathologic partial response in 15%. Pathologic response, R0 resection, and postoperative T and N stage were correlated with overall and disease-free survival.[137] The RTOG reported the results of a phase II study of 49 patients undergoing induction 5-FU, leucovorin, and cisplatin followed by concurrent radiation therapy and infusional 5-FU and paclitaxel.[138] Resection was attempted 5 to 6 weeks after radiation therapy and chemotherapy. The pathologic complete response and R0 resection rates were 26% and 77%, respectively. At 1 year, more patients with tumors exhibiting a pathologic complete response (89%) were living than patients with tumors exhibiting a less favorable response (66%). Grade 4 toxicity occurred in 21% of patients. These data appear to support a randomized phase III study evaluating preoperative versus postoperative radiation therapy and chemotherapy.[138] Although some concerns exist regarding potential for neoadjuvant radiation to increase perioperative morbidity, a national database analysis showed no differences in overall complications or 30-day mortality relative to up-front surgery alone with this approach.[139]

Preoperative Chemoradiation Versus Preoperative Chemotherapy

A randomized trial comparing neoadjuvant chemotherapy alone versus neoadjuvant combined modality therapy was conducted by German investigators

(the Preoperative Chemotherapy or Radiochemotherapy in Esophago-gastric Adenocarcinoma Trial [POET]).[140] Patients with advanced esophagogastric adenocarcinoma were randomized to receive (a) cisplatin/5-FU–based chemotherapy alone versus (b) a similar induction chemotherapy followed by concurrent cisplatin/etoposide with 30 Gy of radiation therapy. Both groups went on to receive surgery. Although this study closed early owing to poor accrual, patients receiving preoperative chemoradiotherapy had significantly higher N0 rates (37% vs. 64%, *P* = .04) and pathologic complete response rates (2% vs. 16%, *P* = .03), as well as statistical trends toward improved local control (59% vs. 76%, *P* = .06) and overall survival (3-year survival 28% vs. 47%, *P* = .07, HR 0.67). The authors concluded that preoperative combined modality improves overall survival as compared to chemotherapy alone in patients with locally advanced esophagogastric adenocarcinoma.[140] Long-term follow up of this study showed local progression-free survival after tumour resection was significantly improved by CRT (hazard ratio 0.37; 0.16-0.85, p = value 0.01) and 20 versus 12 patients were free of local tumour progression at 5 years (p = 0.03). Although the rate of postoperative in-hospital mortality was somewhat higher with CRT (10.2% versus 3.8%, p = 0.26), more patients were alive at 3 and 5 years after CRT (46.7% and 39.5%) compared with chemotherapy (26.1% and 24.4%). Thus, overall survival showed a trend in favour of preoperative CRT (HR 0.65, 95% confidence interval [CI] 0.42-1.01, p = 0.055).[140a] Along these lines, an Australian randomized phase II/III trial (the TOPGEAR study) was initiated, randomizing resectable gastric and GE junction cancer patients to (a) preoperative chemotherapy alone (ECF) versus (b) the same regimen followed by concurrent 5-FU–based chemoradiotherapy, with both arms followed by adjuvant ECF. Interim analysis of the first 120 patients from this study demonstrated that preoperative chemoradiation could be safely delivered to the vast majority of patients without a significant increase in treatment toxicity or surgical morbidity. Specifically, 92% of patients allocated to preoperative chemoradiation received the specified treatment, which is much higher than the 50% compliance rate seen in the previously described CRITICS trial; greater than or equal to grade III gastrointestinal toxicity occurred in 30% of combined modality patients versus 32% in the chemotherapy-alone arm.[141] Similarly, a follow-up Dutch phase II trial (the CRITICS-II trial) is planning on examining the role of preoperative chemoradiotherapy using three preoperative strategies: chemotherapy (docetaxel, oxaliplatin, capecitabine), chemoradiotherapy (45 Gy, carboplatin, paclitaxel), and a combination of both in these patients.

Adjuvant Chemotherapy

The use of adjuvant chemotherapy has been explored in >30 randomized trials, most of which showed no benefit in survival compared to surgery alone. A randomized trial from Japan evaluated 579 patients undergoing resection to receive adjuvant chemotherapy alone versus observation alone. Primarily early T-stage patients in the treatment group received a combination of mitomycin and fluorouracil twice weekly for 3 weeks following surgery, followed by delivery of UFT (uracil + tegafur [an oral 5-FU prodrug]). No survival benefit was seen with adjuvant chemotherapy.[142] However, a more recent study from Japan (the ACTS-GC trial) evaluated the efficacy of adjuvant chemotherapy in patients with stage II/III gastric cancer undergoing R0, D2 dissection (excluding T1 patients). This study randomized 1,059 patients to surgery alone versus treatment with S1, an oral fluoropyrimidine combining tegafur and oxonic acid. Three- and five-year survival was significantly improved in patients receiving adjuvant chemotherapy (80% vs. 70%; 72% vs. 61%, respectively) in favor of the chemotherapy arm (hazard ratio of 0.669).[143,144] Whether the impact of S1 in the Asian population can be extrapolated to Western patients remains less clear and the subject of investigation, including potential biologic differences among populations regarding how this drug is metabolized.

A follow-up Japanese trial (the SAMIT trial) randomized patients with T4a/b gastric cancer following D2 dissection to (a) adjuvant UFT alone, (b) S1 alone, or (c) intermittent weekly paclitaxel, followed by either (a) UFT or (b) S1. The authors concluded that sequential treatment did not improve disease-free survival and UFT was not noninferior to S1 (and S1 was superior to UFT). The authors recommended S1 monotherapy should remain the standard adjuvant treatment for locally advanced gastric cancer in Japan.[145]

Another Asian study, the CLASSIC (capecitabine and oxaliplatin adjuvant study in stomach cancer) was conducted in South Korea, China, and Taiwan. A total of 1,035 patients with pathologic stage II-IIIB gastric cancer were randomized to a surgery-alone arm versus surgery plus adjuvant capecitabine/oxaliplatin for 6 months. Again, all patients underwent D2 gastrectomy. At a median follow-up of 62 months, the adjuvant chemotherapy group had a significant improvement in disease-free survival compared to the surgery-alone group (68% vs. 53%, $P < .0001$).[146]

A meta-analysis of 17 randomized controlled trials using individual patient data comparing surgery alone to surgery with adjuvant chemotherapy in patients with resectable gastric cancer was performed. In this study, adjuvant

chemotherapy was associated with a significant survival benefit in terms of overall survival (hazard ratio [HR] 0.82, confidence interval [CI] 0.76 to 0.90, $P < .001$) and disease-free survival. Estimated 5-year overall survival was increased from approximately 50% to 55% with the use of chemotherapy. The authors[147] concluded that adjuvant chemotherapy with fluorouracil-containing regimens reduce the risk of death in gastric cancer compared to surgery alone. As discussed previously, how these varying studies apply to Western patients remains unclear.

Perioperative Chemotherapy

Various combinations of active drugs have been reported to improve the response rate among patients with metastatic or locally unresectable gastric carcinoma.[11] A combination of FAM (fluorouracil, doxorubicin, and methotrexate) has been associated with a 30% to 40% response rate and was the most widely prescribed regimen for patients with advanced disease in the 1980s.[11] Despite an initial response rate of 64% when a combination of etoposide, doxorubicin, and cisplatin (EAP) was used by German investigators, in subsequent trials, this regimen was considerably less effective and deemed extremely toxic.[148–150] A combination of fluorouracil, doxorubicin, and high-dose methotrexate (FAMTX) was associated with a significant improvement in response rate compared with either EAP or FAM. As a result of these studies, FAMTX became standard therapy for metastatic disease.

In a British study of patients with unresectable or metastatic gastric and esophageal adenocarcinoma, 274 patients were randomized to either 5-FU, doxorubicin, and methotrexate (FAMTX) or epirubicin, cisplatin, and continuous infusion 5-FU (ECF).[151,152] ECF was associated with a superior response rate (45% vs. 21%, $P = .0002$), median survival (8.7 vs. 5.7 months, $P = .0006$ vs. .006), and 1-year survival (36% vs. 21%). Moreover, ECF was associated with a superior quality of life and less toxicity.

The Medical Research Council (MRC) subsequently initiated a trial (the Medical Research Council Adjuvant Gastric Infusional Chemotherapy [MAGIC] trial) to address the question of perioperative chemotherapy (pre- and post-) in operable gastric cancer patients. Patients with resectable adenocarcinoma of the stomach, GE junction, or lower esophagus were randomized to preoperative and postoperative chemotherapy with epirubicin, cisplatin, and 5-FU (ECF) versus surgery alone. Although originally designed to include patients with only tumors of the stomach, eligibility was later expanded to include tumors of the lower

third of the esophagus, with approximately one-fourth of patients having adenocarcinoma involving the lower esophagus or GE junction. Of note is that there were more patients with T1/T2 disease (52% vs. 37%, *P* = .002) as well as more N0/N1 patients (84% vs. 71%, *P* = .01) in the chemotherapy group. Additionally, a significantly higher percentage of gastric cancer patients receiving perioperative chemotherapy underwent surgery (79% vs. 70%, *P* = .03). Nonetheless, the resected tumors were significantly smaller and less advanced in the perioperative chemotherapy group. With a median follow-up of 4 years, 149 patients in the perioperative chemotherapy group and 170 patients in the surgery group had died. As compared with the surgery group, the perioperative chemotherapy group had statistically improved progression-free and overall survival rates. No patient achieved pathologic complete response. However, patients receiving perioperative chemotherapy had a HR for death of 0.75, which was highly significant, with 5-year survival in patients receiving chemotherapy 36% versus 23% in patients undergoing surgery alone (*P* = .009).[153] A follow-up MRC study (the ST03 trial) randomized 1,063 patients with perioperative resectable esophagogastric adenocarcinoma (36% gastric cancer, an additional 20% Siewert type III esophagogastric cancers) to epirubicin, cisplatin, and capecitabine (ECX) versus the same regimen plus bevacizumab. Three-year survival was 50.3% versus 48.1% (NS), with a higher rate of wound healing complications and anastomotic leaks in the bevacizumab group. The authors concluded their results did not provide evidence for the use of bevacizumab in combination with ECX in resectable esophagogastric patients.[154]

French investigators reported the results of a similar randomized trial of 224 patients assigned to perioperative chemotherapy (cisplatin and 5-FU only) versus surgery alone. Although originally designed to include only patients with tumors of the lower third of the esophagus or GE junction, eligibility was later expanded to include gastric cancers, although most (75%) of patients had disease of the lower esophagus or GE junction. Chemotherapy consisted of a planned two to three preoperative and three to four postoperative cycles. This study was prematurely terminated because of low accrual. Nonetheless, patients receiving chemotherapy had improved overall survival (5-year 38% vs. 24%, *P* = .02), disease-free survival (5-year 34% vs. 19%, *P* = .003), and R0 resection rates (84% vs. 73%, *P* = .04). Only 50% of patients received postoperative chemotherapy. T0 disease (complete pathologic response at the primary site) was seen in 3% of neoadjuvantly treated patients. Total locoregional recurrence rates

were 24% and 26%, respectively, in the chemotherapy versus surgery group, with distant recurrence rates of 42% versus 56%, respectively.[155]

An EORTC study enrolling patients with locally advanced adenocarcinoma of the stomach or GE junction randomized patients to receive either cisplatin, leucovorin, and infusional 5-FU followed by surgery or surgery alone. Although only accruing 144 of 360 planned patients, neoadjuvantly treated patients had higher R0 resection rates (82% vs. 67%, $P = .036$); however, at a median follow-up of 4.4 years, no significant difference in overall survival was seen ($P = .466$).[156]

A meta-analysis of these along with other small trials was performed, revealing that neoadjuvant chemotherapy was associated with a significant improvement in overall survival and progression-free survival and improved R0 resection rates.[157] Given the above, some authors have suggested that in terms of patient selection, a perioperative chemotherapy strategy may be most appropriate for patients with bulky primary tumors or bulky adenopathy in which there is a significant risk of micrometastatic disease as well as incomplete resection.[158]

A preliminary report from Dutch investigators described a study randomizing patients with resectable gastric or GE junction patients to 5-FU, leucovorin, oxaliplatin, and docetaxel (FLOT) versus epirubicin, cisplatin, and 5-FU or capecitabine (ECF or ECX) given in a perioperative fashion. At a median of 43 months, median overall survival was 35 months in the ECF/ECX arm and 50 months with FLOT (hazard ratio 0.77, $P = .012$). Corresponding 3-year survivals were 48 and 57%, respectively.[159] Additionally, an ongoing French study (FFCD1103) is randomizing resectable signet-ring gastric cancer patients to receive neoadjuvant chemotherapy using perioperative ECF versus initial surgery followed by adjuvant ECF.

Palliative Radiation Therapy

Radiation therapy is capable of providing substantial palliation of local gastric cancer symptoms.[160–165] It appears that 50% to 75% of patients can expect improvement of symptoms such as gastric outlet obstruction, pain from local tumor extension, bleeding, or biliary obstruction.[163] The likelihood of benefit may increase with concomitant 5-FU administration, with less tumor bulk, and if the patient's performance score is better before therapy.[118,161,166,167] The median duration of palliation varies from 4 to 18 months in reports addressing this issue.[161,166,167] A systematic review of the use of palliative radiotherapy in gastric cancer showed large variations in radiation dose and fractionation. The

pooled overall response rates for bleeding, pain, and obstruction were 74%, 67%, and 68%, respectively. No difference in bleeding response rates was seen with a BED of ≥39 versus lower doses. Grade III/IV toxicities occurred in up to 15% of patients treated with radiation alone versus up to 25% with combined modality therapy. The authors concluded that more than two-thirds of patients receiving radiation therapy would derive clinical benefit.[168]

SEQUELAE OF THERAPY

Anorexia, nausea, and fatigue are very common complaints during gastric radiation therapy; these symptoms can lead to potentially detrimental treatment breaks, with a National Cancer Data Base analysis evaluating overall adjuvant radiation therapy treatment time suggesting prolonged breaks were associated with inferior survival and that efforts to minimize cumulative interruptions to <7 days should be considered.[169] However, the understanding of these side effects is somewhat limited.[170–173] Although visceral afferents may play some role in the acute emetogenic effects of radiation, other unknown factors, possibly chemical in nature and mediated by the chemoreceptor trigger zone, appear to be more important. Although selective serotonin (5-HT_3) antagonists effectively treat radiation-induced emesis, it is not clear whether the mechanism of action is directed at the 5-HT_3 receptor alone or has an effect on inhibition of serotonin release.[174] Additionally, the use of low-dose corticosteroids may be beneficial in patients with refractory nausea. Other compounding factors may include the altered gastric motility and prolonged gastric emptying time observed in animal experiments as a response to irradiation.[104,170,171,175] Chemotherapy-related leukopenia and thrombocytopenia may occur. If chemotherapy is used with irradiation, blood counts are generally obtained once to twice weekly. Additional acute toxicities of radiation therapy include esophagitis, epidermitis, fatigue, and weight loss in most patients. Nausea, vomiting, dehydration, and anorexia are relatively common, particularly in patients with lower esophageal and GE junction tumors. During therapy, patient tolerance, weight, and blood counts are checked at least weekly. Many symptoms resolve within 1 to 2 weeks of treatment completion. Because of potential toxicities in the treatment for gastric cancer patients (dehydration, weight loss, anorexia, etc.), aggressive supportive measurements and symptom management are indicated in efforts to avoid treatment-related interruptions, hospitalizations, or failure to complete the intended treatment course. Varying antiemetics should be used liberally,

including on a prophylactic basis. Antacids including proton pump inhibitors are frequently implemented, and antidiarrheal medications may be appropriate. Additionally, nutritional supportive measurements are paramount and, when appropriate, the use of enteral methods is implemented. In selected cases, the use of feeding jejunostomy may be appropriate. Patients may require intermittent hydration both during and shortly following the treatment course. Postoperatively, B_{12}, iron, and calcium levels should be monitored and supplemented as appropriate.

Nutritional complications of treatment and myelosuppression, if concurrent chemotherapy is used during irradiation, can carry substantial morbidity and even occasional mortality from therapy. The historical GITSG reported a minimum 13% treatment-related mortality from nutritional problems or septic events on their concurrent chemoradiation arm,[120] and almost 20% of the patients of Caudry et al.[176] were unable to complete therapy because of nutritional problems. However, others reported no severe or life-threatening nutritional compromise with aggressive chemoradiation.[116,118,177] Toxic gastrointestinal effects usually are managed with careful nutritional support and antiemetic therapy. It may be prudent to proactively prescribe antiemetics at the initiation of therapy in patients undergoing aggressive upper abdominal irradiation.

Myelosuppression causing serious or, rarely, lethal toxicity is also reported in many of the combined-modality trials.[116,118,177,178] If blood counts are monitored weekly during combined-modality therapy, serious problems with sepsis or bleeding should be uncommon.[177,178]

Moderate doses of 16 to 36 Gy reduce secretion of pepsin and hydrochloric acid.[1,104,179] For this reason, radiation therapy was once a common and successful therapy for peptic ulcer disease. Most of the gastric ulcers healed, although they recurred in approximately 40% of patients.[1,104,179] Gastric acid secretion decreased in almost all cases, with achlorhydria in 25% to 40%. The gastric acid decrease usually persisted from 1 to 6 months; however, 25% showed persistent decrease in acid production for 1 to 5 years or more.

Gastric late effects were categorized by the Walter Reed Group as dyspepsia, radiation gastritis, uncomplicated gastric ulcer, or gastric ulcer with perforation or obstruction.[180–182] The associations between dose and these late effects are described in Table 62.13. These data suggest a 20% to 30% incidence of ulceration with doses of 45 to 59 Gy, with complications of these ulcers in 30% to 50% of the treated patients. Some caution is necessary in interpreting this

experience because the Walter Reed cohort was treated with 200-keV photons or 1-MV photons using a 70-cm target-skin distance, usually using only one field each day with daily fraction sizes of 3 Gy to midline, which sometimes produced daily given doses of 4 to 6 Gy.[181,182]

Most data suggest that gastric late effects are rare with doses of 40 to 52 Gy using conventional fractionation of 1.8 to 2 Gy. The relatively low risk of gastric late effects with doses <50 Gy is corroborated by many series using radiation therapy with or without chemotherapy for locally advanced gastric cancer.[42,48,62,73,81,134] However, doses in the range of 50 to 55 Gy may produce variable gastric late effects, which have been reported to reach 9% in some series. Doses of 60 Gy carried a 5% to 15% risk of gastric late effects.[1–3,52,62,69,90,118,134,152,161,167,172,174–177,179–184] The ability of histamine (H_2) blockers, proton pump inhibitors, and sucralfate to prevent the later development of radiation-induced gastric ulcerations is unproven. It may be reasonable to administer H_2 blockers or proton pump inhibitors prophylactically to patients receiving >45 Gy to any significant volume of the stomach or proximal duodenum.

Several series have described a gradual decline in renal function occurring ≥18 to 24 months following postoperative radiation therapy for gastric cancer. However, it is unclear that this is of clinical significance, and long-term renal function among gastric cancer survivors has not been reliably reported. One recent report described a dose-dependent nephrotoxicity as manifested by hypertension in gastric cancer patients, which may take years to manifest.[185] Similarly, another study indicated that mean creatinine clearance as well as changes in renal parenchymal volume occurred primarily within the first 4 years following radiation therapy with a clear relationship between these changes and DVH parameters.[186] Nonetheless, advanced techniques may enhance renal sparing and also allow potential dose escalation as well as integration of novel (and potentially nephrotoxic) systemic agents.[187]

TABLE 62.13 RADIATION DOSE COMPARED WITH LATE EFFECTS IN THE WALTER REED EXPERIENCE

		Radiation Late Effects (%)[a]			
Dose (Gy)	Number of Patients[b]	Dyspepsia	Gastritis	Ulcer	Complicated Ulcer[c]
<40	111	5	2	3	0
40–44.99	23	0	22	0	0

45–49.99	27	4	19	11	11
50–54.99	34	0	24	18	12
55–59.99	14	0	50	14	7
>60	8	0	0	13	38

[a]Results reported as number of patients with injury/total number of patients treated with this dose.
[b]Total number of patients treated at this dose.
[c]Ulcers complicated by obstruction or perforation.

Radiation-induced cardiac toxicity is a broad term describing potential radiation injury to a number of cardiac structures, including the pericardium (as manifested by effusion, pericarditis), coronary arteries, the heart muscle itself, and cardiac valves as well as nerve/conduction injury. Radiation injury primarily consists of fibrosis and/or small-vessel injury. The mechanism of radiation-induced cardiac injury is relatively poorly defined, particularly in the context of gastric cancer. Historical data from the treatment for Hodgkin disease patients have suggested that dose >40 Gy may increase the risk of cardiac death as well as pericarditis.[188,189] Several studies of cardiac toxicity and esophageal cancer patients have demonstrated that an increasing V_{30} predicted for a significant increase in pericardial effusion and increasing fraction size (particularly ≥3.5 Gy) also predicted for the same. Additionally, some authors have shown a possible trend for decrease in ejection fraction in patients with increasing V_{20} of the left ventricle.[190] A more detailed discussion on potential long-term cardiac sequelae of radiation therapy can be found in Chapter 56.

CONCLUSIONS AND RECOMMENDATIONS

Radiation therapy, usually administered with concomitant fluoropyrimidine-based chemotherapy, is indicated for locally confined gastric cancer that either is not technically resectable or occurs in medically inoperable patients. In this setting, therapy can be administered with curative or palliative intent, depending on the clinical situation. Those who undergo gastric resection with incomplete tumor resection or have truly positive margins of resection are also appropriately managed by combined-modality therapy. Preferably, patients with locally advanced disease that is unresectable with negative margins would be identified preoperatively with endoscopic ultrasonography and CT staging. Preoperative chemoradiation then could precede an attempt at gross total resection, alone or in combination with IORT, and maintenance chemotherapy.

The results of the U.S. Gastrointestinal Intergroup Gastric Adjuvant Trial

established a standard of care in the United States to the use of both chemotherapy and radiation therapy in the postoperative setting for patients with disease extension through the gastric wall and/or with nodes positive for tumor. Postoperative irradiation and concurrent and maintenance fluoropyrimidine-based chemotherapy are generally recommended for patients with stage IB, II, IIIA, IIIB, or IV and M0 gastric cancer. The role of postoperative chemoradiation in patients with T2N0 tumors remains more controversial. In patients with high-risk features (i.e., poorly differentiated or higher-grade cancers, lymph vascular invasion, perineural invasion, age <50 years, or suboptimal resection including lymph node resection), postoperative chemoradiotherapy may also be indicated.

Because extended node dissections were not commonly performed as a component of surgery in the Intergroup trial, some have questioned whether postoperative chemoradiation would give added benefit following a D2 nodal resection. Similarly, given the survival benefit from the use of perioperative chemotherapy alone in European esophagogastric patients, ongoing trials are examining the role of adjuvant chemoradiation in both the settings of perioperative chemotherapy and D2 lymph node dissection, including attempts to better stratify which patients might be most appropriate for adjuvant combined modality therapy. Additionally, further trials are investigating new systemic agents with radiation therapy to establish efficacy compared with 5-FU and leucovorin. Given the poor prognosis with patients receiving either perioperative chemotherapy or adjuvant chemoradiotherapy, integration of the approaches has the potential to improve disease-related outcomes compared to either alone. Similarly, on the basis of encouraging outcomes with phase II preoperative chemoradiation trials in patients with gastric cancer and phase III esophagus (and other gastrointestinal) cancer trials, ongoing evaluation of this approach in patients with potentially resectable lesions is occurring in phase III trials and will likely help guide future treatment approaches.

The irradiation field design from the phase III U.S. Gastrointestinal Intergroup trial was based on optimized field design related to both site of the primary lesion and T and N stage of disease.[114] With the wide availability of 3-D conformal treatment planning systems, it may be possible to more accurately target the high-risk volume and to use unconventional field arrangements and/or IMRT to produce superior dose distributions. To accomplish this without marginal misses, however, it will be necessary to both carefully define and encompass the various target volumes (tumor bed, nodal sites at risk) given

target volumes that would be included using older approaches may be missed with more contemporary planning approaches.

CHAPTER 63

Pancreatic Cancer

Manisha Palta, Christopher G. Willett, and Brian G. Czito

ANATOMY AND PATHWAYS OF SPREAD

The pancreas lies in the retroperitoneal space of the upper abdomen at about the level of the first two lumbar vertebrae. It is divided into head (including the uncinate process), neck, body, and tail (Fig. 63.1). It has intimate contact with surrounding organs, including stomach, duodenum, jejunum, kidneys, spleen, and major vessels, which can be involved by direct tumor extension. Tumors in the pancreatic head often invade or compress the common bile duct, causing jaundice and dilatation of the bile and pancreatic ducts and gallbladder.

The rich lymphatic drainage of the pancreas is interconnected with duodenal lymphatics. Regional drainage of the pancreatic head is to the peripancreatic, pancreaticoduodenal, porta hepatis, celiac, and superior mesenteric lymph nodes. The pancreatic body and tail drains to splenic artery, peripancreatic, celiac, superior mesenteric, and paraaortic nodal basins.[1] With posterior, retroperitoneal tumor extension, paraaortic nodes are at risk. The main venous channels drain via the portal system to the liver. The lungs and pleura may be involved with posterior tumor extension into tissues with venous drainage by the vena cava or its tributaries. Generalized peritoneal involvement is more common with carcinoma of the body and tail than with carcinoma of the head of the pancreas.

EPIDEMIOLOGY AND RISK FACTORS

In 2017, an estimated 53,670 new cases of pancreatic cancer will be diagnosed in the United States, with 43,090 estimated deaths from the disease, making pancreatic cancer the fourth leading cause of cancer-related death in the United States.[2] At present, surgery offers the only means of cure. Unfortunately, only 10% to 20% of patients present with tumors amenable to resection. Even among patients who present with localized disease, the 5-year overall survival (OS) is

approximately 20%.[3] Contemporary survival rates have reported improved results, particularly in patients with complete surgical resection (R0) and node-negative (N0) disease.[4–6] Patients who present with locally advanced, unresectable pancreatic cancer have a median survival of approximately 8 to 14 months, with rare long-term survival. Up to 60% of patients present with metastatic disease, which carries a shorter median survival of 4 to 12 months.[7]

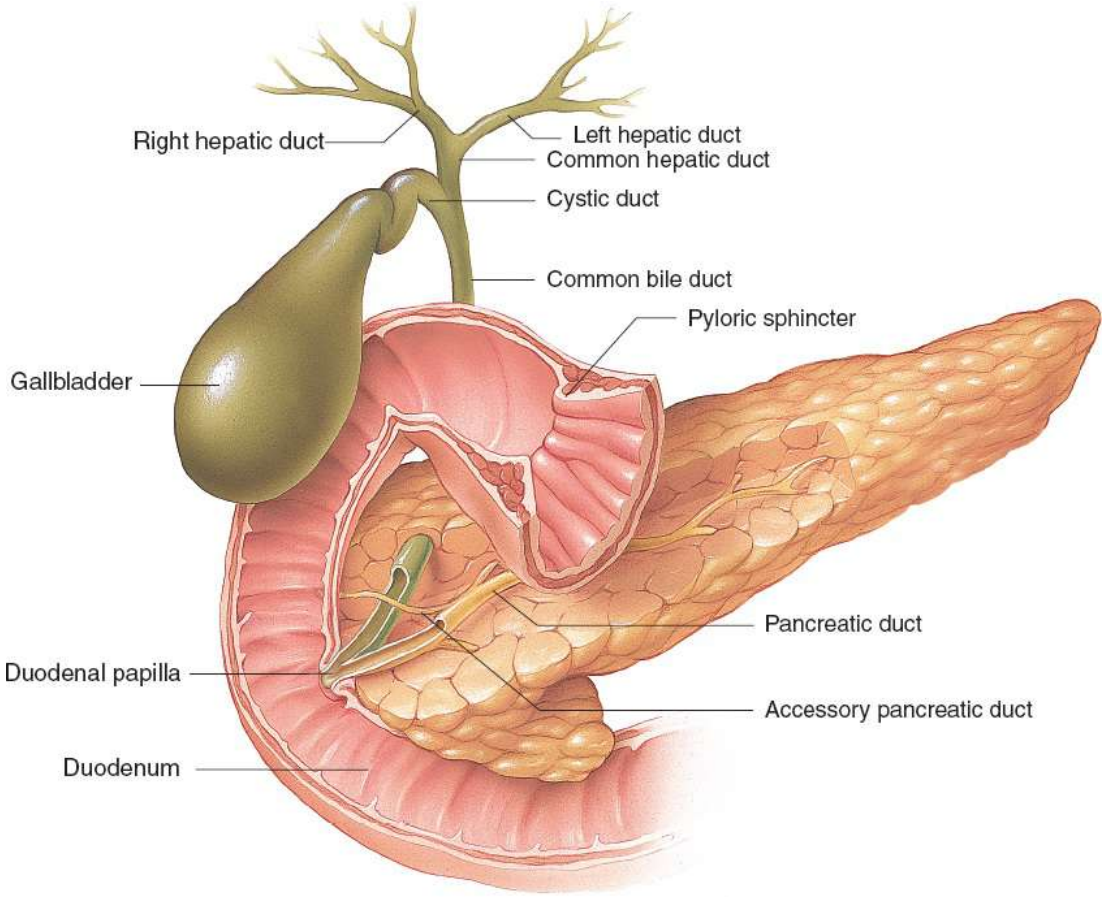

FIGURE 63.1. Pancreas and gallbladder duct anatomy. (Provided by the Anatomical Chart Company.)

The incidence of pancreatic cancer rises sharply after age 45, with higher rates in males than in females (1.3:1) and in black males compared with the general population (14.8/100,000:8.8/100,000).[8] Familial aggregation of pancreatic cancer is estimated in 5% to 10% of newly diagnosed cases. It is associated with *BRCA1/2* and PALB2 mutations, familial atypical multiple mole melanoma syndrome, Peutz-Jeghers syndrome, familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, hereditary pancreatitis, ataxia telangiectasia, and Li-Fraumeni syndrome, with lifetime risk ranging from 5% to

40%.[9,10] Described risk factors for pancreatic cancer include chronic pancreatitis, smoking, alcohol consumption, *Helicobacter pylori* infection, and factors associated with metabolic syndrome such as obesity and glucose intolerance.[11,12]

CLINICAL PRESENTATION

Most patients with pancreatic cancer experience pain, weight loss, or jaundice. Classically, pain from pancreatic cancer is characterized by radiation to the back, given the retroperitoneal location of the pancreas. Jaundice, due to biliary obstruction, is often accompanied by pruritus, acholic stools, and dark urine color. The initial presentation varies according to tumor location. Patients with tumors in the pancreatic body or tail usually present with pain and weight loss, whereas those in the head of the gland typically present with jaundice, steatorrhea, weight loss, and pain. Recent onset of atypical or exacerbation of preexisting diabetes mellitus, unexplained thrombophlebitis, or history of pancreatitis is often noted. Patients with pancreatic cancer frequently present with unresectable or metastatic disease, in part due to these nonspecific presenting symptoms and the tendency for local and distant spread. No effective screening method to detect disease at the localized stage has been identified. Positive physical findings, if any, generally reflect incurable disease. These may include a palpable abdominal mass (i.e., pancreas, liver, or gallbladder due to biliary obstruction), ascites, supraclavicular nodes, or palpable rectal shelf (i.e., peritoneal seeding).

EVALUATION

Significant advances have been achieved in the imaging and staging of pancreatic cancer.[13] Currently, the principal diagnostic tools are multiphasic, helical computed tomography (CT) scan; endoscopic ultrasound (EUS); and laparoscopy. Magnetic resonance imaging (MRI) and positron emission tomography (PET) imaging techniques may be used in initial evaluation of pancreatic malignancies. These tools have facilitated the characterization of the primary tumor (resectable or borderline resectable vs. unresectable) as well as the identification of metastatic disease so patients can be appropriately and reliably triaged to operative and nonoperative therapies.

CT scan is the most commonly used staging modality. Newer generation,

multidetector, high-speed helical CT coupled with and thin section imaging allows high-resolution images of the pancreas and its surrounding structures to be obtained at varying phases of enhancement. This allows for adequate imaging of the pancreas and assessment of metastatic deposits in other intra-abdominal organs such as the liver.[14] Over 90% of patients deemed unresectable because of vascular involvement by CT are truly inoperable at time of surgery.[15] Although CT staging is limited in detection of nodal involvement and peritoneal disease, it is useful in evaluating for metastatic disease.

Another tool for local tumor staging and diagnosis is EUS. In this procedure, an endoscope with an ultrasound transducer at its tip is passed into the stomach and duodenum, where it provides high-resolution images of the pancreas and surrounding vessels. EUS facilitates FNA without exposing the peritoneum to potential tumor seeding, as may occur with CT-guided biopsy. Sensitivity for EUS is at least comparable to CT, with tumor detection reported as high as 97%.[16] An advantage of EUS over CT is the ability to detect small or isoattenuating lesions, which might not be well visualized on cross-sectional imaging.[17] Interpretation of EUS is highly operator dependent. Frequently, EUS is performed in conjunction with endoscopic retrograde cholangiopancreatography.[18] This combined diagnostic approach allows for staging, therapeutic stenting of the common bile duct when indicated, and diagnostic FNA simultaneously.

A limitation of current imaging techniques is the inability to visualize small (1 to 2 mm) liver and peritoneal implants. Staging laparoscopy has been used preoperatively to assess for intraperitoneal metastases. One meta-analysis demonstrated that the adoption of staging laparoscopy and laparoscopic ultrasound will prevent up to 50% of patients from undergoing unnecessary laparotomy.[19] Patients with locally advanced disease and involved peritoneal washings or positive peritoneal biopsies have the same prognosis as do those with metastatic disease.[20]

Advances in MRI, including high-resolution imaging, faster acquisition time, three-dimensional (3D) reconstruction, functional imaging, and MR cholangiopancreatography, have led to an improved ability of MRI to diagnose and stage pancreatic cancer.[14] This modality can be used in patients with poor renal function to assess the primary tumor and determine resectability; however, studies suggest that MRI is not as sensitive as EUS or CT in tumor detection.[21] A potential advantage of MRI is identification of small foci of hepatic metastatic disease difficult to appreciate by CT or to further characterize ill-defined lesions

seen on CT.[22]

Initial studies showed that PET has a higher sensitivity, specificity, and accuracy than does CT in diagnosing pancreatic carcinomas.[23–25] Integrated PET-CT had a higher sensitivity for malignancy detection than did either PET or CT alone (96% vs. 84% vs. 77%) but did not improve specificity (64%). PET may also be a useful adjunct in the identification of benign versus malignant lesions and presence of metastatic disease. Although PET-CT may be useful in initial diagnosis, its role in determining resectability has been questioned as coregistration is often performed with lesser resolution CT images and high metabolism can obscure peripancreatic planes.[26]

High-resolution pancreatic CT and EUS remain the current standard for diagnosis and staging of pancreatic malignancies. Staging laparoscopy is useful in assessing for intraperitoneal and liver disease. MRI and PET-CT are technologies that may also be useful. All imaging modalities are inadequate to stage lymph node involvement, and further advances may improve the ability to diagnose, stage, and appropriately select further therapies.

TUMOR STAGING

Staging is rarely used in published series, and tumors are instead characterized as resectable, borderline resectable, unresectable, or metastatic.

The current American Joint Committee on Cancer 2010 tumor, node, and metastasis staging system is described in Table 63.1. Common criteria of resectability are outlined in Table 63.2.

PATHOLOGIC CLASSIFICATION

Approximately 85% to 90% of pancreatic cancers are adenocarcinomas. Other neoplasm histologic cell types include intraductal papillary mucinous neoplasm, mucinous cystic, solid pseudopapillary, acinar cell, pancreaticoblastoma, neuroendocrine, squamous cell, serous cystadenocarcinoma, and lymphoma. Management and treatment sections will focus on pancreatic adenocarcinomas, given this is the predominate histologic subtype. The histopathology of lesions in the periampullary region of the head of the pancreas is of particular importance as different types of adenocarcinomas, originating from the pancreas, bile duct, ampullary region, or duodenum, respectively, portend different prognoses.[27]

Pancreatic adenocarcinomas evolve from noninvasive pancreatic

intraepithelial neoplasias, acquiring various genetic and epigenetic mutations. Several molecular abnormalities have been implicated in contributing to the development of pancreatic cancer. The most frequent genetic alterations are activation of the oncogene *KRAS* and inactivation of tumor suppressor genes including *TP53*, p16 (*CDKN2*), *DPC4 (SMAD4*), and *BRCA2*, with reported incidences ranging from 50% to 95% in pancreatic tumors.[28] These molecular changes have the potential to identify precursor lesions with a high likelihood of progressing into carcinomas, characterizing pathologically ambiguous lesions, and useful in development of screening regimens.

TABLE 63.1 AMERICAN JOINT COMMITTEE ON CANCER STAGING 2010 CLASSIFICATION FOR PANCREATIC CANCER

American Joint Committee on Cancer (AJCC)
TNM Staging of Pancreatic Cancer (2010)

Because only a few patients with pancreatic cancer undergo surgical resection of the pancreas (and adjacent lymph nodes), a single TNM classification must apply to both clinical and pathologic staging.

Primary Tumor (T)

TX Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma *in situ**
T1 Tumor limited to the pancreas, 2 cm or less in greatest dimension
T2 Tumor limited to the pancreas, more than 2 cm in greatest
T3 Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
T4 Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)

* This also includes the “PanIn III” classification

Regional Lymph Nodes (N)

NX Regional lymph nodes cannot be assessed
N0 No regional lymph node metastasis
N1 Regional lymph node metastasis

Distant Metastasis (M)

M0 No distant metastasis
M1 Distant metastasis

Stage Grouping

Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage III	T4	Any N	M0

	Stage IV	Any T	Any N	M1

GENERAL MANAGEMENT

Operative Considerations

Surgery, as part of a multimodality treatment approach for patients with resectable pancreatic cancer, represents the only potentially curative treatment strategy.[29] More than 80% of patients present with advanced disease that is not amenable to curative resection, with roughly two-thirds presenting in the pancreatic head. The standard surgical treatment for pancreatic cancer of the head or uncinate is pancreaticoduodenectomy, first described by Whipple et al.[30] in 1935. For pancreatic tail lesions, distal pancreatectomy is employed, frequently with splenectomy. Initially, high operative morbidity and mortality rates led to technical modifications of the operation that, combined with improvements in anesthesia and critical care, have resulted in current perioperative mortality rates of ≤2% at high-volume centers.[31–33] With reduced morbidity from the Whipple procedure, there is no age limitation, and selected patients, even at ages >80 years, may undergo pancreaticoduodenectomy.[34–36]

Several studies report low postoperative mortality rates and appropriate patient selection at high-volume institutions, highlighting the importance of performing such procedures at institutions with extensive experience.[37–40] In addition, the definition of resectable lesions has broadened with the ability to perform venous reconstructions with minimal increase in morbidity or mortality.[41,42]

The prognosis, even among resectable patients, remains poor, with 5-year survival rates of 10% to 25%. The number of nodes harvested appears to impact outcomes; data suggest that 12 to 15 lymph nodes constitute an adequate assessment, although impact on outcomes may simply reflect accurate staging.[43,44] Although appropriate lymph node dissection is desirable, trials of extended lymphadenectomy conveyed no survival benefit and compromised quality of life.[45,46] Pathologic assessment provides important prognostic information, including margin status, tumor grade, tumor size, lymphovascular invasion, and lymph node involvement. The presence of positive operative margins, poor histologic grade, larger tumor size, lymphovascular invasion, and

lymph node involvement portends a poorer prognosis.[47–51] Similarly, patients with elevated pre- and postoperative carbohydrate antigen 19–9 (CA19-9) have inferior disease-free survival (DFS) and OS rates.[51–54]

TABLE 63.2 CRITERIA DEFINING RESECTABILITY STATUS

Resectable (head, body, and tail)
No distant metastases
No arterial tumor contact (celiac axis [CA], superior mesenteric artery [SMA], or common hepatic artery [CHA])
No tumor contact with the superior mesenteric vein (SMV) or portal vein (PV) or ≤180-degree contact without vein contour irregularity
Borderline resectable (head/uncinate)
Solid tumor contact with CHA without extension to celiac axis or hepatic artery bifurcation allowing for safe and complete resection and reconstruction
Solid tumor contact with the SMA of ≤180 degrees
Solid tumor contact with variant arterial anatomy (ex: accessory right hepatic, replaced right hepatic artery, replaced CHA, and the origin of replaced or accessory artery and the presence and degree of tumor contact should be noted if present as it may affect surgical planning
Solid tumor contact with the SMV or PV >180 degrees, contact of ≤180 degrees with contour irregularity of the vein or thrombosis of the vein but with suitable vessel proximal and distal to the site of involvement allowing for safe and complete resection and vein reconstruction
Solid tumor contact with the inferior vena cava (IVC)
Borderline resectable (body/tail)
Solid tumor contact with the CA of ≤180 degrees
Solid tumor contact with the CA of >180 degrees without involvement of the aorta and with intact and uninvolved gastroduodenal artery thereby permitting a modified Appleby procedure
Unresectable
Distant metastases
Unresectable (head/uncinate)
Solid tumor contact with SMA >180 degrees
Solid tumor contact with the CA >180 degrees
Solid tumor contact with the first jejunal SMA branch
Unreconstructible SMV/PV due to tumor involvement or occlusion (can be due to tumor or bland thrombus)
Contact with most proximal draining jejunal branch into SMV
Unresectable (body/tail)
Solid tumor contact of >180 degrees with SMA or CA
Solid tumor contact with the CA and aortic involvement
Unreconstructible SMV/PV due to tumor involvement or occlusion (can be due to tumor or bland thrombus)

Modified from the NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines®) for Pancreatic Adenocarcinoma (V.2.2017).

In an effort to minimize surgical morbidity, pylorus-preserving pancreaticoduodenectomy and laparoscopic resection techniques have developed. Pylorus-sparing pancreaticoduodenectomy potentially improves gastrointestinal function without compromising oncologic management.[55,56]

Laparoscopic pancreatic resection was first explored in the late 1990s, and its use has increased dramatically.[57,58] Although most experiences are small, retrospective, single-institution series, laparoscopic resection, in experienced hands, appears a reasonable option for distal pancreatic resections.[59–62] The data on laparoscopic pancreaticoduodenectomy are more limited; the difficulty with this procedure arises from more complex dissection and the need for reconstruction.[42,58] Data suggest, however, that despite prolonged operative times and potential increase in postoperative fistula formation, laparoscopic resection offers shortened hospitalization and equivalent oncologic results.[58,63–65]

Cause of Death and Patterns of Failure

For patients with locally unresectable tumors or metastatic disease, death usually results from hepatic failure secondary to biliary obstruction by local tumor extension or hepatic replacement by metastases. For the 10% to 20% of patients undergoing a potentially curative pancreaticoduodenectomy, three major sites of disease relapse dominate: locoregional, peritoneal cavity, and liver (Table 63.3). High local recurrence rates of 50% to 86% occur despite resection because of frequent lymphatic and perineural involvement and cancer invasion into the retroperitoneal soft tissues, with an inability to achieve wide retroperitoneal soft tissue margins due to anatomic constraints (SMA and SMV, portal vein, and inferior vena cava).[50,76,77] The incidence of microscopic residual disease after careful evaluation of the posterior peripancreatic soft tissue margin is as high as 40%.[77] Therefore, tumor stage, grade, and resection margin status are the best predictors of survival after surgery.[76,77] The use of adjuvant therapy after surgery can reduce the incidence of local failure, but distant disease recurrence rates remain high.

RADIATION THERAPY TECHNIQUES

Dose-Limiting Tissues

The dose-limiting organs for irradiation of upper abdominal malignancies include the small bowel, stomach, liver, kidneys, and spinal cord. Various techniques, such as 3D conformal radiotherapy (3DCRT) and intensity-modulated radiotherapy (IMRT), can spare these organs. Given long-term survival is low, the actual number of patients at risk for late complications is small. Late small bowel and gastric effects may also be decreased through reduction of the volume of these organs within the high-dose field.

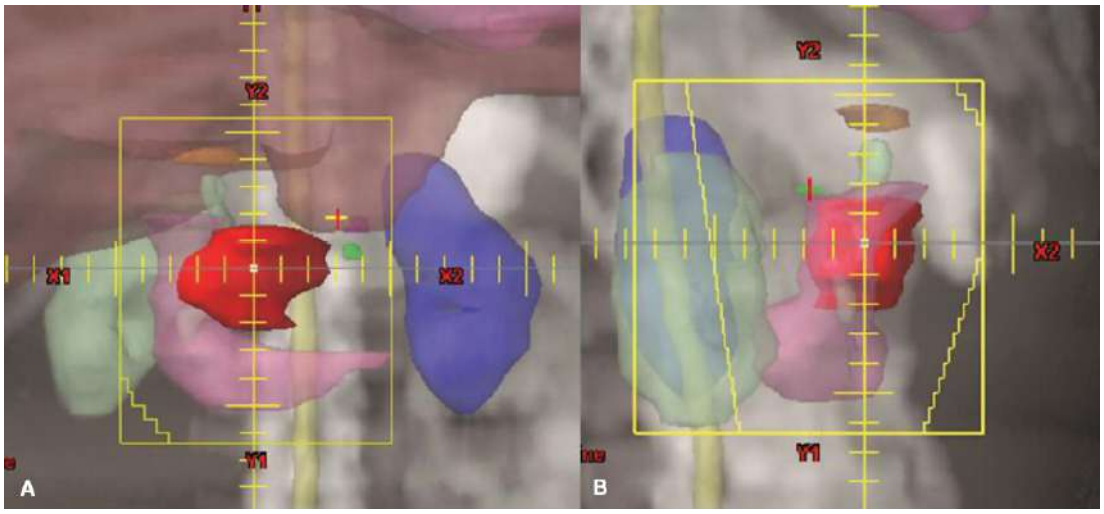

FIGURE 63.2. External beam four-field technique for pancreatic head lesion. **A:** The anteroposterior/posteroanterior (AP/PA) field, which includes gross tumor (*red*), duodenal loop (*pink*) (plus approximately 50% of the right kidney [*light green*]), liver (*brown*), and nodal areas at risk (porta hepatis: *orange,* superior mesenteric arteries: *green,* celiac: *magenta*). Most of the left kidney (*blue*) is excluded from the AP/PA field. **B:** The right lateral field with an anterior margin beyond gross disease and a posterior margin behind front edge of vertebral body. The liver contour (*brown*) has been removed from lateral field for visualization of other structures.

Treatment Volumes, Fields, and Doses

In patients undergoing surgery, clips should be placed to mark the extent of the lesion for postoperative irradiation. The patient should be positioned supine during simulation and treatment. 3DCRT radiotherapy allows visualization of internal organs and target delineation. CT-based treatment planning allows the construction of normal tissue dose–volume histograms and the generation of treatment plans that optimize radiation dose delivery to tumor while sparing critical normal tissues. Multiple field, fractionated, external beam techniques utilizing high-energy photons to deliver 45 to 50 Gy in 1.8 Gy fractions to tumor bed, unresected or residual tumor, and lymph node–bearing areas at risk. After the primary fields, a boost field can be designed to include unresected or gross residual disease, as defined by CT scans and clips, while excluding most of the stomach and small bowel.

With lesions in the head of the pancreas, major node groups include the pancreaticoduodenal and peripancreatic (resected at the time of Whipple) and porta hepatis and paraaortic regions. Approximately two-thirds of the left kidney must be excluded from the AP/PA field because the right kidney is often in the field because of duodenal (bed) inclusion. The superior field extent is often at the middle or upper portion of the T11 vertebral body for adequate margins on the celiac vessels (T12, L1) and the inferior limit at the level L2–L3 to include the superior mesenteric lymph nodes and third portion of the duodenum. The upper field extent is sometimes more superior with body lesions to obtain adequate margin on the primary lesion. With lateral fields, the anterior field margin is 1.5 to 2.0 cm beyond initial gross disease. The posterior margin is often 1.5 cm behind the anterior portion of the vertebral body to allow adequate margins on paraaortic nodes, which are at risk with posterior tumor extension in head or body lesions. The lateral contribution usually is limited to 15 to 18 Gy because a moderate volume of kidney or liver may be in the irradiated volume (Fig. 63.2).

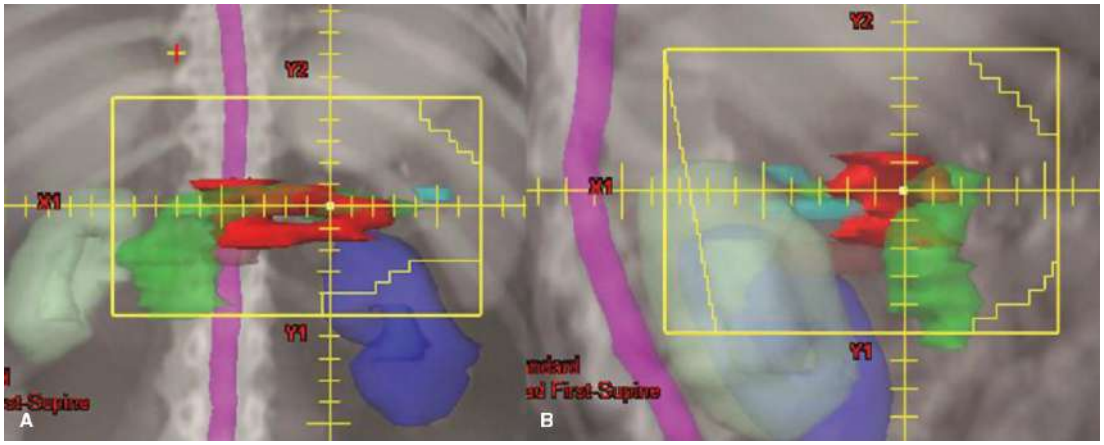

FIGURE 63.3. External beam four-field technique for unresectable tail of pancreas lesion. **A:** The anteroposterior/posteroanterior (AP/PA) field showing lesion (*red*) and head of pancreas (*green*). The field is extended to the patient's left to include coverage of the splenic hilum (*cyan*). Much of the right kidney (*light green*) is excluded from the field and multileaf collimators block most of the left kidney (*blue*). **B:** The right lateral field with an anterior margin beyond gross disease and a posterior margin at least 1.5 cm behind front edge of vertebral body.

With pancreatic body or tail lesions, at least 50% of the left kidney may be included to achieve adequate margins on node groups at risk (i.e., lateral suprapancreatic, splenic artery, and splenic hilum nodes). Inclusion of the pancreaticoduodenal nodes is often not indicated with body or tail lesions, and at least two-thirds of the right kidney can be preserved (Fig. 63.3).

After resection, AP/PA and lateral fields are often designed on the basis of preoperative CT primary tumor volumes, preoperative duodenal loop location, operative clip placement, and postoperative CT nodal volumes (Radiation Therapy Oncology Group [RTOG] contouring atlas accessible on their website). The anterior border is determined by vascular or nodal boundaries (porta hepatis, superior mesenteric, and celiac), as demonstrated on CT, as well as preoperative tumor location.[78]

RADIATION THERAPY RESULTS

Resectable Tumors: Adjuvant Therapy

After surgical resection of pancreatic cancer, local recurrence rates range from 50% to 86% and distant recurrence rates from 40% to 90%, most commonly to the liver or peritoneum.[50,66,67,69,70,77,79] This provides the rationale for adjuvant therapy, which have been employed in an effort to improve patient outcomes (Table 63.4). Despite multiple randomized trials, a definitive role for adjuvant radiotherapy for resected pancreatic cancer has not been established.

PROSPECTIVE TRIALS

Historical Prospective Studies

The Gastrointestinal Tumor Study Group (GITSG) conducted the first multicenter prospective trial of adjuvant CRT for patients with resected pancreatic cancer and negative surgical margins, laying the foundation for the adoption of CRT in the United States. Forty-three patients were randomized to observation or CRT to 40 Gy delivered in split-course fashion with concurrent 5-fluorouracil (5-FU) (500 mg/m^2) as an intravenous bolus on the first 3 and last 3 days of radiation, followed by maintenance weekly 5-FU for 2 years or until disease progression. At interim analysis, improvements in median DFS and OS with CRT were observed: 11 versus 9 months and 20 versus 11 months, respectively. Two-year OS was 42% in the CRT group versus 15% in the surgery-alone arm.[80] An additional 30 patients were later enrolled to receive adjuvant CRT. These additional patients confirmed the survival outcomes seen in the original trial, with median survival of 18 months and a 2-year survival of 46%.[81]

CONKO, Charite Onkologie; EORTC, European Organisation for Research and Treatment of Cancer; ESPAC, European Study Group for Pancreatic Cancer; GITSG, Gastrointestinal Tumor Study Group; NA, not available; RTOG, Radiation Therapy Oncology Group; 5-FU, 5-fluorouracil.

The GITSG trial has been criticized for a number of reasons. The trial closed prematurely following enrollment of 43 of an intended 100 patients because of slow accrual over the 8-year enrollment period. The EBRT approach in this trial was considered low dose and antiquated by contemporary standards because of a split-course technique and use of large treatment fields, which encompassed the entire pancreas or pancreatic bed and the celiac, pancreaticosplenic, peripancreatic, and retroperitoneal regional lymph nodes. Additionally, the inclusion of both CRT and adjuvant chemotherapy after surgery evaluated two treatment variables, making it difficult to discern the true effect of either treatment alone. In the CRT arm, there were issues of compliance, with 32% of patients assigned to CRT receiving inappropriate radiation and 25% of patients failing to initiate treatment within 10 weeks postsurgery, the protocol-specified time limit. Only 9% of patients completed the planned 2-year maintenance chemotherapy course. In addition, survival in the control arm was low compared to historical studies. Despite these limitations and the failure to reach the desired patient accrual, the GITSG trial demonstrated a benefit for CRT, which became standard adjuvant therapy, particularly in the United States.

A second study sponsored by the European Organisation for Research and Treatment of Cancer (EORTC) sought to confirm the findings of the original

GITSG study. Two hundred eighteen patients with resected pancreas (*n* = 114) or periampullary cancers (*n* = 104) were randomly assigned to observation or CRT to 40 Gy in a split-dose fashion with concurrent continuous infusional 5-FU (25 mg/kg) without further adjuvant chemotherapy. This study showed no significant improvement (*P* = .208) in median survival (19 months [observation] vs. 24.5 months [CRT]) or 2-year survival (41% [observation] vs. 51% [CRT]).[82] Long-term follow-up of the EORTC trial demonstrated no difference in 5-year OS with CRT use: 22% (surgery alone) versus 25% (CRT). *Post hoc* analysis of pancreatic head lesions failed to demonstrate a benefit with CRT, with a median OS of 1.3 years for CRT versus 1 year for surgery alone.[83]

This trial has been criticized for its heterogeneous patient population, which included patients with both pancreatic and periampullary primary tumors. Periampullary carcinomas have a significantly better prognosis compared with pancreatic cancer; the two entities thus represent truly different diseases and potentially dilute any evidence of benefit for adjuvant CRT.[91] Similar to the GITSG trial, older EBRT techniques—split course and low total dose—were used. Also, >20% of patients in the CRT arm did not receive the intended treatment because of postoperative complications or patient refusal. The trial did not include maintenance chemotherapy in the treatment arm. Finally, although a small subset, patients undergoing noncurative resection and patients with positive surgical margins were still eligible for enrollment. The discordant results of the EORTC and GITSG trials have led some investigators to attribute the OS benefit seen in the GITSG trial to maintenance chemotherapy administration rather than to EBRT.

An additional European trial conducted by the European Study Group for Pancreatic Cancer (ESPAC) aimed to further explore the question of appropriate adjuvant therapy for “macroscopically” resected pancreatic cancers. Treating physicians were allowed to enroll patients into one of three parallel randomized studies:

- Chemoradiation versus no chemoradiation (*n* = 68), consisting of 20 Gy over 2 weeks with 5-FU (500 mg/m^2) on days 1 through 3, then repeated after a 2-week break;
- Chemotherapy versus no chemotherapy (*n* = 188), consisting of bolus 5-FU (425 mg/m^2) and leucovorin (20 mg/m^2) given for 5 days every 28 days for 6 cycles; or
- A 2-by-2 factorial design of 285 patients enrolled on chemoradiotherapy (*n* = 70), chemotherapy (*n* = 74), chemoradiotherapy with maintenance

chemotherapy (n = 72), or observation (n = 69).

The data from the treatment groups from all three parallel trials were then pooled for analysis. There was no survival difference between the 175 patients who received adjuvant chemoradiation and the 178 patients who did not receive therapy (median survival, 15.5 vs. 16.1 months; P = .24). In the chemotherapy arm, however, a 35% reduction in death was seen in the group who received adjuvant chemotherapy (n = 238) compared with those who received no chemotherapy (n = 235), with a difference in median survival of 19.7 versus 14 months (P = .0005).[84] On further follow-up of patients randomized using the 2-by-2 factorial design, the 5-year survival rate for the patients who received chemotherapy was 21% versus 8% for those who did not. Additionally, adjuvant CRT was associated with a deleterious effect on survival.[85]

A number of problems are associated with the interpretation of these data. First, the complex trial design has the potential for bias, because patients or physicians could select randomization for one treatment variable. Also, as in the aforementioned trials, the EBRT technique used was, by contemporary standards, considered outdated, using split course and low total dose. No details of EBRT delivery or central quality assurance for EBRT, surgery, or pathology are available. In addition, many treatment violations occurred, as only 62% of patients received full CRT treatment and only 42% of patients in the chemotherapy arms completed the predefined regimen. Although many have attempted to draw conclusions from the updated publication, the 2-by-2 factorial cohort of the study was not powered to detect OS differences. Additionally, patients receiving CRT in the ESPAC trial experienced poorer survival outcomes compared with those in other reported CRT series. Also, patients who had received prior “background” chemotherapy or radiation therapy were still eligible for enrollment. As in the EORTC trial, no maintenance chemotherapy was administered. Despite these critiques, some have speculated that the detriment seen in the CRT group may have resulted from delayed administration of systemic therapy shown to improve survival in the ESPAC trial.

A common critique of the aforementioned trials of adjuvant therapy is the lack of restaging to evaluate for the presence of persistent or metastatic disease after surgical resection and prior to the initiation of adjuvant therapy. The time between initial staging and the commencement of adjuvant treatment can be as long as 3 to 4 months, during which a significant number of patients would be expected to develop radiographically apparent metastases. Without interval restaging, these patients may inappropriately receive CRT. Although these three

trials formed the foundation for adjuvant treatment approaches to resectable pancreatic cancer, perhaps because each trial was fraught with flaws, there continues to be little consensus regarding the “most appropriate” treatment. A relative dichotomy in adjuvant treatment approaches for resectable pancreatic cancer has emerged between the United States and parts of Europe, with adjuvant CRT frequently implemented in the United States and adjuvant chemotherapy alone administered in parts of Europe.

Modern Studies: Adjuvant Systemic Therapy

Building from the data showing potential benefit to adjuvant chemotherapy, investigators in Europe conducted a randomized phase III trial of observation versus adjuvant gemcitabine in patients with resected pancreatic cancer. Three hundred sixty-eight patients were enrolled on the Charite Onkologie (CONKO) trial and randomized to observation or adjuvant gemcitabine (1,000 mg/m^2 intravenous days 1, 8, and 15 every 4 weeks for 6 months).[86] The primary end point was DFS, and patients treated with gemcitabine achieved a statistically significantly longer DFS (14.2 vs. 7.5 months) than those observed after surgery. This improvement was seen in both the R0 and R1 subgroups. At initial publication, there was no difference in OS. With longer follow-up, median and 5-year OS were both improved in patients receiving gemcitabine (23 vs. 20 months, and 21% vs. 9%, respectively).[87] These findings were supported by a smaller randomized study from Japan, which again demonstrated a DFS benefit for gemcitabine compared to surgery alone.[92]

At the same time the CONKO trial was enrolling patients, ESPAC-3, the largest randomized controlled trial in pancreatic cancer to date, enrolled 1,088 patients with pancreatic adenocarcinoma who underwent R0 or R1 resection. Patients were randomly assigned to 6 cycles of adjuvant gemcitabine (3 weekly infusions of 1,000 mg/m^2) or 6 cycles of bolus 5-FU (425 mg/m^2)/leucovorin (LV) (20 mg/m^2). Patients receiving 5-FU/LV experienced significantly higher rates of grade 3 or 4 gastrointestinal toxicity (stomatitis and diarrhea), whereas patients receiving gemcitabine experienced significantly higher rates of grade 3 or 4 hematologic toxicity. At a median follow-up of 34.2 months, there was no difference between the two groups in the primary end point of OS.[88]

The recently completed ESPAC-4 trial randomized patients with resected pancreatic cancer to gemcitabine alone versus gemcitabine/capecitabine. Seven hundred and thirty patients with R0/R1 resection were evaluable for the primary end point of overall survival. The median survival for patients receiving adjuvant

gemcitabine and capecitabine was 28 months compared to 25.5 months in the gemcitabine-alone arm. Estimated overall survival was 80.5% (95% CI 76.0 to 84.3) at 12 months and 52.1% (46.7 to 57.2) at 24 months in the gemcitabine group and 84.1% (79.9 to 87.5) at 12 months and 53.8% (48.4 to 58.8) at 24 months in the gemcitabine plus capecitabine group. Although clinically significant toxicities were low in both arms, the rates of grade 3 to 4 diarrhea, infection, neutropenia, and hand–foot syndrome were statistically higher in the combined chemotherapy arm. These data suggest that adjuvant gemcitabine and capecitabine may be a reasonable alternative to single-agent gemcitabine. The focus of future European adjuvant therapies for resectable pancreatic cancer has centered on finding the ideal combination of systemic agents.[93]

Modern Studies: Adjuvant Chemoradiation

In the United States, the GITSG trial laid the foundation for CRT as the predominant adjuvant treatment modality. The RTOG/Gastrointestinal Intergroup trial 9704 was a phase III randomized study comparing adjuvant 5-FU–based chemotherapy to gemcitabine-based chemotherapy, with both regimens followed by CRT. Four hundred fifty-one patients with resected pancreatic cancer were randomized to continuous infusion 5-FU (250 mg/m^2/d) or gemcitabine (1,000 mg/m^2 weekly) for 3 weeks prior to CRT and 12 weeks after CRT. CRT in both groups consisted of 50.4 Gy delivered with continuous infusion 5-FU (250 mg/m^2/d).[75] Prospective quality assurance of all radiation therapy plans was required. This trial was powered to demonstrate a survival benefit for the entire cohort and for the subgroup of patients with pancreatic head lesions. On initial analysis of the pancreatic head subgroup (n = 388), a nonsignificant trend toward improved median and 3-year OS was seen in the gemcitabine arm: 20.5 versus 16.9 months and 31% versus 22%, respectively. However, a higher incidence of grade 3 or higher hematologic toxicity was also seen in the gemcitabine group, with no significant differences seen in severe nonhematologic toxicities.

An update of this trial reported median and 5-year OS rates in patients with pancreatic head tumors of 20.5 months and 22% in those who received gemcitabine, compared with 17.2 months and 18% in those who received 5-FU. On multivariate analysis, in the subgroup of patients with pancreatic head lesions who received gemcitabine, there was a nonsignificant trend toward improved OS (P = .08).[89,90]

A secondary aim of RTOG-9704 was to assess the ability of postresection

CA19-9 levels to predict survival. When CA19-9 levels were analyzed in a cohort of 385 patients as a dichotomized variable (<180 IU/mL vs. ≥180 IU/mL, ≤90 IU/mL vs. >90 IU/mL), there was a significant survival difference favoring patients with CA19-9 levels of <180 IU/mL. This corresponded to a 72% reduction in the risk of death.[52] Unlike preceding randomized CRT studies, a major strength of the RTOG study was the rigorous, centralized quality control of radiation therapy techniques and delivery. A recent analysis demonstrated that patients treated per study guidelines had a significant survival advantage, indicating the importance of centralized review and treatment technique in this disease.[72]

The high rates of local failure and need for more efficacious systemic therapy, as well as controversy surrounding the role of CRT is resected patients, led to the design of the current RTOG-0848/EORTC trial. This trial randomly assigns patients with resected pancreatic head adenocarcinoma (stratified based on CA19-9 level, nodal involvement, and margin status) to receive treatment with gemcitabine alone for 5 cycles. If no progression is seen on restaging following the completion of systemic therapy, patients are further randomized either to receive an additional cycle of chemotherapy (for a total of 6 cycles) or to receive CRT (50.4 Gy with concurrent capecitabine or 5-FU) using modern techniques and central radiation therapy quality assurance. This trial seeks to evaluate the role of CRT in the era of modern chemotherapy, particularly in patients who do not experience early disease progression. (https://clinicaltrials.gov/ct2/show/NCT01013649)

Neoadjuvant Therapy

Even after undergoing curative resection for pancreatic cancer, 80% to 85% of patients will recur. In addition, positive margins or nodal disease increases this rate of recurrence to approximately 90%.[77,94] The use of neoadjuvant therapy offers an alternative approach to improve on these figures for several reasons:

- Approximately one-third of patients experience a significant delay or do not receive adjuvant therapy following resection.[49,95,96]
- Twenty percent to 40% of patients will be spared the morbidity of resection as their metastatic disease becomes clinically apparent during course of neoadjuvant therapy.[97–99]
- Preoperative therapy could theoretically be less toxic and more effective as the chemotherapy and radiation would be given without the postsurgical issues of small bowel in the radiation field, decreased oxygenation and decreased drug

delivery to the remaining tumor bed.[100,101]

- Patients with local, borderline, and unresectable lesions may be able to be downstaged to allow for surgical resection and sterilization of the operative region, which potentially facilitates R0 resection and reduces the risk of spread during surgical manipulation.

Neoadjuvant Chemoradiation

Unlike with adjuvant therapy, no phase III randomized trials of neoadjuvant CRT in resectable pancreatic lesions have been conducted, and the vast majority of data come from phase II and retrospective studies.[102] At the MD Anderson Cancer Center, multiple trials of neoadjuvant CRT with a variety of radiosensitizers have been performed.[103–107]

A review of the Surveillance, Epidemiology, and End Results (SEER) database supports the use of neoadjuvant treatment. This analysis included 3,885 patients treated for resectable pancreatic cancer: 70 patients (2%) received neoadjuvant EBRT, 1,478 (38%) received adjuvant EBRT, and 2,337 (60%) were treated with surgery alone. Given that the SEER database does not provide information on administration of chemotherapy, this variable could not be assessed. Median OS was 23 months in patients receiving neoadjuvant EBRT, 17 months with adjuvant EBRT, and 12 months in the surgery-alone cohort.[108]

Despite the potential advantages and encouraging results using a neoadjuvant CRT approach, no randomized trial results exist comparing neoadjuvant to adjuvant therapy, and its role continues to be investigational. Therefore, in the future, the design of a trial with neoadjuvant radiotherapy might include induction chemotherapy in analogy to the current treatment strategies for LAPC as distant progression during neoadjuvant therapy is a more substantial problem.[109] With respect to chemoradiation, the first RCT phase II study comparing immediate surgery (arm A) with surgery after neoadjuvant chemoradiotherapy (arm B) for (potentially) resectable tumors was reported. Of note, the experimental arm started with chemoradiotherapy without induction chemotherapy. Simultaneous chemotherapy was gemcitabine 300 mg/m^2 and cisplatin 30 mg/m^2 weekly in weeks 1, 2, 4, and 5 of radiotherapy. Conventionally fractionated, 3DCRT included a tightly restricted elective nodal volume to a dose of 50.4 Gy and 55.8 Gy to the tumor. The trial under-recruited (73/254 planned patients) with considerable impact on statistical power. However, an important finding is that neoadjuvant therapy was well tolerated with only 7% grade 4 leukopenia and 3% grade 4 thrombocytopenia. No grade 4

gastrointestinal toxicity was observed but grade 3 nausea and vomiting was seen in 35% which was attributed to cisplatin. Resections were R0 in 67% versus 90% in arm A versus arm B. Postoperative complications were not more frequent after chemoradiotherapy compared to immediate surgery. At intention-to-treat analysis, OS was not different; at per-protocol analysis, mOS was 18 versus 25 months in arm A versus arm B (P >.05). After chemoradiotherapy, a trend for fewer local recurrences as the first site of progression was observed. Four versus eight patients (Arm A vs. B) had distant metastasis between randomization and laparotomy.[109]

Neoadjuvant Chemotherapy

With recent data demonstrating efficacy of combination chemotherapy in the metastatic setting, there has been growing interest to assess these agents in less advanced disease. The ongoing Southwest Oncology Group (SWOG) phase II study is comparing neoadjuvant gemcitabine and nab-paclitaxel to modified 5-FU, leucovorin, and irinotecan (m-FOLFIRNOX) for resectable pancreatic adenocarcinoma. The goal of this study is to identify the superior arm to test in a larger randomized trial. (https://clinicaltrials.gov/show/NCT02562716)

Therapy for Locally Advanced Carcinoma

Approximately 30% of patients present with locally advanced carcinoma of the pancreas, comprising a group of patients with an intermediate prognosis between resectable and metastatic disease. These patients have pancreatic tumors that are defined as surgically unresectable but have no evidence of distant metastases. A tumor is usually considered to be unresectable if it has one of the following features:

- Distant metastases
- Encasement or occlusion of the SMV or SMV/portal or vein confluence that is not amenable to reconstruction, contact with the most proximal draining jejunal branch into the SMV
- ≥180 degree involvement of the SMA, celiac axis, first jejunal SMA branch, or aorta or celiac axis involvement with a body or tail lesion

Recent advances in surgical technique allow for resection of selected patients with tumors involving the SMV.[41,110] Treatment with radiation and chemotherapy increases median survival for patients with locally advanced cancers to approximately 8 to 14 months but rarely results in long-term survival. The therapeutic options of patients with locally advanced pancreatic cancer

include chemotherapy alone, CRT, intraoperative radiotherapy (IORT), and stereotactic body radiation therapy (SBRT). In evaluating the results of these various therapies, it is useful to remember that a median survival of 3 to 6 months has been reported for this subset of patients undergoing palliative gastric or biliary bypass only.[111]

PROSPECTIVE TRIALS

Prospective trials have evaluated the role of EBRT versus CRT, variations in CRT regimens, and CRT versus chemotherapy alone (Table 63.5). The Mayo Clinic undertook an early randomized trial in the 1960s in which 64 patients with locally unresectable, nonmetastatic stomach, large bowel, and pancreas adenocarcinoma received 35 to 40 Gy of EBRT alone or with concurrent bolus 5-FU (45 mg/kg). A significant survival advantage was seen for patients receiving EBRT with 5-FU versus EBRT only (10.4 vs. 6.3 months).[112]

The GITSG followed with a similar study comparing EBRT alone to EBRT with concurrent and maintenance 5-FU. One hundred and ninety-four eligible patients with surgically confirmed unresectable and nonmetastatic pancreatic adenocarcinoma were randomized to receive 60-Gy split-course EBRT alone, 40-Gy split-course EBRT with 2 to 3 cycles of concurrent bolus 5-FU chemotherapy (500 mg/m^2), or 60-Gy split-course EBRT using a similar chemotherapy regimen. Patients in the latter groups received 2 years' maintenance 5-FU (500 mg/m^2) after EBRT completion. The EBRT-alone arm was closed early as a result of an inferior survival rate. The 1-year survival rate in the two combined modality therapy arms was roughly 40% (with no statistical difference between CRT arms) versus 11% in the EBRT-alone arm.[113]

The Eastern Oncology Group's trial ECOG-8282 randomized 114 patients to EBRT alone (59.4 Gy) with or without continuous infusion 5-FU (1,000 mg/m^2/d) on days 2 to 5 and 28 to 31 and mitomycin-C (10 mg/m^2) on day 2. There was no difference in response rates, DFS, or OS with the addition of concurrent chemotherapy. Higher rates of toxicity, primarily hematologic, were noted in the CRT group.[114]

Further studies sought to determine a more efficacious CRT regimen. A second GITSG trial randomized 157 and analyzed results for 143 eligible patients with unresectable disease to 60-Gy split-course EBRT with concurrent and maintenance 5-FU (500 mg/m^2) (as in the prior GITSG trial) or 40-Gy continuous course radiation with weekly, concurrent doxorubicin chemotherapy

(10 mg/m^2), followed by maintenance doxorubicin and 5-FU. A significant increase in treatment-related toxicity was seen in the doxorubicin arm, with no survival difference observed between the two groups (median survival 8.5 vs. 7.6 months). No clinical benefit was seen in substituting doxorubicin for 5-FU.[115]

As studies emerged demonstrating significant survival advantages with gemcitabine-based chemotherapy in the metastatic setting, it was incorporated into the locally advanced setting. A trial from Taipei randomized 34 patients to EBRT with concurrent 5-FU (500 mg/m^2) or gemcitabine (600 mg/m^2). Patients received 50.4- to 61.2-Gy EBRT and maintenance gemcitabine (1,000 mg/m^2) at the completion of CRT. Median OS and time to progression were prolonged in the gemcitabine arm: 14.5 months and 7.1 months (gemcitabine) versus 6.7 months and 2.7 months (5-FU). There were no observed differences in grade 3 or 4 toxicity or hospitalization days between the two arms. Study criticisms include the small number of patients and relatively poor outcomes in the 5-FU arm compared with historical controls.[116]

A number of trials have compared CRT with chemotherapy alone. A subsequent GITSG trial compared combination streptozocin, mitomycin-C, and 5-FU (SMF) chemotherapy to chemoradiation with 5-FU. Forty-three patients were randomized to receive SMF chemotherapy or 54 Gy of EBRT with 2 cycles of concurrent bolus 5-FU chemotherapy followed by adjuvant SMF chemotherapy. The chemoradiation arm demonstrated a significant survival advantage over the chemotherapy-alone arm (1-year survival 41% vs. 19%, respectively).[117]

TABLE 63.5 PROSPECTIVE RANDOMIZED TRIALS FOR LOCALLY ADVANCED, UNRESECTABLE PANCREATIC CANCER

Series (Reference)	Number of Patients	Median Survival (Month)	Local Progression (%)	1-Year (%)	18-Month (est %)

CCDP, neoadjuvant cisplatin; CRT, chemoradiation; EBRT, external beam radiation therapy; ECOG, Eastern Cooperative Oncology Group; FFCD/SFRO, Fédération Francophone de Cancérologie Digestive/Société Francophone de Radiothérapie Oncologique; GITSG,

Gastrointestinal Tumor Study Group; LAP, Locally advanced pancreas; MMC, mitomycin-C; NA, not available; SMF, streptozocin, mitomycin-C, and 5-flurouracil; 5-FU, 5-flurouracil.

In contrast, the ECOG reported no benefit to chemoradiation versus chemotherapy only. In this study, 191 patients with unresectable, nonmetastatic pancreatic or gastric adenocarcinoma were randomized to receive either 5-FU chemotherapy (600 mg/m^2) alone or 40-Gy EBRT with concurrent bolus 5-FU during week 1 (600 mg/m^2) followed by maintenance chemotherapy. Patients with locally recurrent disease as well as patients undergoing surgery with residual disease were eligible for this trial. In the 91 analyzable pancreatic patients, no survival difference was observed between the two groups (median survival 8.2 vs. 8.3 months).[119]

The FFCD/SFRO trial randomized 119 patients to CRT consisting of 60-Gy EBRT with continuous infusion 5-FU (300 mg/m^2/d) on days 1 to 5 for 6 weeks and intermittent CDDP (20 mg/m^2/d) on days 1 to 5 in weeks 1 and 5 with maintenance gemcitabine (1,000 mg/m^2) versus gemcitabine alone (1,000 mg/m^2). Survival was inferior in the CRT arm at 8.6 months compared with 13 months with gemcitabine alone. Higher grade 3 or 4 toxicity rates were observed in the CRT arm during CRT (36% vs. 22%) and maintenance chemotherapy phases (32% vs. 18%). This trial closed early because of poor accrual. Many criticize the inferior survival in the CRT arm, which is similar to early GITSG trials, despite use of continuous infusion chemotherapy and modern EBRT techniques.[120]

The ECOG published results from a randomized trial of CRT (50.4 Gy with concurrent gemcitabine: 600 mg/m^2/wk, weeks 1 to 5) versus gemcitabine alone (1,000 mg/m^2/wk). The trial closed early because of poor accrual. Analysis of the eligible, randomized 71 patients demonstrated no difference in progression-free survival; however, a survival benefit was seen in the CRT arm: 11.1 versus 9.2 months. This benefit came at the expense of higher grade 4 or 5 toxicity rates in the CRT arm (mainly hematologic) but with no difference in quality of life.[121]

A multicenter phase II study, the SCALOP trial, evaluated the role of gemcitabine-based or capecitabine-based CRT. All patients received 12 weeks of induction gemcitabine and capecitabine chemotherapy. Seventy-four patients were randomized and median OS in the capecitabine group was 15.2 months compared with 13.4 months in the gemcitabine arm (P = .012). More patients in the gemcitabine group than in the capecitabine group had grade 3 to 4 hematologic toxicity and grade 3 to 4 nonhematologic toxicity during CRT. These data suggest that concurrent capecitabine-based CRT may be preferable to

gemcitabine-based CRT.[123]

More recently, the Locally Advanced Pancreas Cancer 07 (LAP07) trial was published. In this 2 × 2 randomization, all patients were initially randomized to gemcitabine or gemcitabine and erlotinib for 4 months. A second randomization was performed in patients with no evidence of progression to continuation of chemotherapy for an additional 2 months or chemoradiation. The primary study end point was overall survival. A total of 442 patients underwent the first randomization and 269 patients underwent the second randomization. Interim analysis was performed after 221 patients died and early stopping rule for futility were reached. The median overall survival was 16.5 months for patient receiving systemic therapy and 15.2 months in the cohort receiving chemoradiation. Chemoradiation was associated with decreased local progression from 46% to 32% (P = .03)[122] and median delay to treatment reintroduction was 6.1 months (95% CI, 4.8 to 7.0 months) for the chemoradiotherapy group, significantly longer than the 3.7 months (95% CI, 3.0 to 4.6) for the chemotherapy group (P = .02). Some authors have critiqued the older chemotherapy regimen of gemcitabine alone, which has now largely been replaced with combination systemic therapies such as gemcitabine/nab-paclitaxel and m-FOLFIRINOX. In addition, quality of life analyses were not performed, which could have demonstrated a clinically meaningful difference between the arms.

With the recent publication of LAP07, many consider upfront chemotherapy with subsequent response assessment and directed CRT to facilitate selection of patients most likely to benefit from locoregional therapy as the current standard of care.

Borderline Resectable Disease

As surgery of the primary tumor remains the only potentially curative treatment for pancreatic cancer, neoadjuvant therapy has been evaluated to assess its ability to convert locally unresectable pancreatic cancer to resectable disease. Although the definition of borderline resectable disease is contentious, the National Comprehensive Cancer Network definition is accepted by many institutions (Table 63.2). Approximately 30% of patients with borderline resectable disease become resectable after neoadjuvant therapy.[124,125] Similarly, there appears to be higher rates of local control, R0 resection, and N0 disease in this patient subset after neoadjuvant therapy.[126–129]

A number of single-institution retrospective studies have evaluated this patient subset. An early study from the MD Anderson Cancer Center assessed

160 patients with borderline resectable disease. Patients received 50.4 Gy in 28 fractions or 30 Gy in 10 fractions with concurrent 5-FU, paclitaxel, gemcitabine, or capecitabine at radiosensitizing doses. Forty-one percent underwent pancreatectomy with margin-negative resection in 94%. Median survival in the 66 patients who completed preoperative therapy and surgery was 44 months, comparable to patients with initially resectable disease.[127]

A review from Fox Chase Cancer Center evaluated 109 patients who underwent resection of pancreatic adenocarcinoma with varying involvement of the portal vein or superior mesenteric vein as determined by CT. Patients received 5-FU or gemcitabine-based CRT. Median survival in the 74 patients who received preoperative therapy was 23 months compared with 15 months in the cohort undergoing upfront surgery. Preoperative CRT was associated with a higher rate of R0 resection and N0 disease.[128]

A smaller series from the University of Virginia reviewed the outcomes of 40 patients with borderline resectable disease. Patients received 50.4 Gy in 28 fractions or 50 Gy in 20 fractions with concurrent capecitabine. Forty-six percent of patients underwent surgery, with 75% undergoing an R0 resection. Patients undergoing surgery after neoadjuvant treatment had similar median survival rates as patients undergoing upfront surgery.[129]

The ECOG initiated a randomized phase II study of two neoadjuvant gemcitabine-containing regimens in patients with potentially resectable cancer. Patients received 50.4-Gy EBRT with weekly gemcitabine (500 mg/m^2) or induction chemotherapy with gemcitabine (175 mg/m^2), CDDP (20 mg/m^2), and 5-FU (600 mg/m^2) prior to CRT with 5-FU (225 mg/m^2). All patients received adjuvant gemcitabine (1,000 mg/m^2). This trial, the only randomized trial of borderline resectable pancreatic cancer, closed early because of poor accrual with 21 patients.[130] Although the subject of ongoing study, an approach utilizing neoadjuvant chemoradiotherapy in patients with borderline resectable disease, in efforts to facilitate R0 resection, seems appropriate.

A systematic review and meta-analysis was performed of 18 studies with neoadjuvant chemotherapy or CRT with a total of 959 patients evaluating posttreatment response rates. The following response rates were achieved: CR, PR, SD, and PD were observed in 2.8%, 28.7%, 45.9%, and 16.9%, respectively. The weighted frequency of resected patients was 65.3% who achieved a median OS of 25.9 months. In contrast, patients without resection had a median OS of 11.9 months and the total group of 17.9 months.[131]

Dose Escalation

Given the limited tolerance of normal tissue in the upper abdomen (liver, kidney, spinal cord, and bowel) to EBRT, total doses of only 45 to 54 Gy in 25 to 30 Gy fractions have traditionally been administered. For an unresectable tumor, this dose of radiation is inadequate, as demonstrated by the high rates of local tumor progression and poor survival seen in both prospective and retrospective studies. Local progression as first site of failure occurred in 58% of patients treated to 60 Gy with concurrent 5-FU in the second GITSG trial.[115] Similarly, the Mayo Clinic reported a local recurrence rate of 72% for 122 patients with unresectable pancreatic cancer treated with an EBRT dose of 40 to 60 Gy.[132] Attempts have been made to evaluate whether increasing dose of radiation may improve outcomes through 3DCRT, IORT, IMRT, and stereotactic body radiotherapy (SBRT).

In a report from Thomas Jefferson University Hospital, 46 evaluable patients with unresectable disease by laparotomy were treated with 63- to 70-Gy EBRT with or without chemotherapy. Despite high-dose EBRT, the local recurrence rate was 78%.[133]

IORT is an alternative method to deliver higher radiation doses. This technique allows for administration of a single high dose of radiotherapy with the advantage of enabling healthy tissues to be displaced and shielded from radiation. IORT has been utilized postoperatively and in treatment of locally advanced disease. Institutional reports and a randomized trial have shown that surgery followed by IORT yields lower rates of locoregional recurrence; however, no significant difference in survival has been seen.[134–137] IORT has also been evaluated in patients with unresectable disease.[138,139] A study from investigators at Massachusetts General Hospital reported the results of 150 patients with unresectable pancreatic cancer treated with IORT, EBRT, and chemotherapy. Although the study spanned nearly 25 years, it demonstrated that long-term survival is possible for patients with unresectable pancreatic cancer. Furthermore, this study shows that postoperative and late treatment-related toxicity rates were acceptable.[139,140] A lower incidence of local recurrence in most series and improved median survival in some have been reported with these techniques when compared with conventional external beam irradiation, but it is uncertain whether this is due to treatment superiority or case selection.[132]

Advances in radiation technique and delivery, such as IMRT and SBRT, also enable dose escalation and potential sparing of normal tissues. IMRT is a technique that breaks up a typical radiation treatment field into smaller beamlets.

It is implemented either as dynamic IMRT (collimating leaves move in and out of the radiation beam path during treatment) or as “step-and-shoot” IMRT (leaves change field shape while the machine is off). The cumulative effect is that the prescription dose conforms around delineated target volumes, significantly reducing doses to adjacent normal tissues. This technology has increasingly been used in a number of gastrointestinal malignancies, including pancreatic cancer. Early clinical data support both the feasibility of this technique and its potential for reducing acute gastrointestinal toxicity.[141–143]

An analysis from the University of Maryland evaluated 46 patients treated with IMRT and concurrent 5-FU–based chemotherapy. Acute toxicities in these patients were compared with those in a control group enrolled in RTOG-9704 who received conventional 3D treatment. There was a statistically significant reduction in acute grade 3 or 4 gastrointestinal toxicity in the patients who received radiotherapy via IMRT compared with those who received 3DCRT.[143] IMRT can also result in a significant reduction of dose to normal structures, including the liver, kidneys, stomach, and small bowel.[142] This may allow alternate novel systemic agents to be administered with radiotherapy.[141]

Although IMRT can reduce the dose to surrounding normal tissues, it also allows the opportunity for dose escalation. A phase I/II study by Ben Josef et al attempted to define the maximum tolerated radiation dose via IMRT in combination with gemcitabine for unresectable pancreas cancer. Fifty patients were accrued and dose-limiting toxicity was seen at 55Gy. Median survival was 14.8 months and 12 patients subsequently underwent resection.[144]

Another technique for dose escalation in the treatment of pancreatic cancers is SBRT, which involves the delivery of high dose per fraction radiation treatments over a small number of fractions (generally 1 to 5 treatments), utilizing techniques that allow very highly conformal dose delivery of external beam radiotherapy. The postulated advantage of SBRT is potentially improving local control through the delivery of ablative doses of radiation, while minimizing associated side effects. Early experience and data using this technique are in the setting of locally advanced disease.[145,146] Stanford University has implemented an institutional protocol for the treatment of locally advanced pancreatic cancer using a 25-Gy single fraction with systemic therapy. This single, high dose of radiation has been estimated to result in delivery of a higher biologically equivalent dose compared with a more standard, protracted course of radiation therapy, albeit at the potential for increased risk of normal tissue injury. A report from these investigators described 77 patients who were treated with SBRT and

found that freedom from local progression was 91% at 6 months and 84% at 12 months. No patients experienced grade 3 acute toxicity, and 9% had grade 3 or higher late toxicity.[146]

Based on these data, a prospective, multi-institutional phase II study was conducted utilizing 5 fraction SBRT with primary end point to achieve a lower rate of late grade 2+ toxicity than with single-fraction SBRT. Forty-nine patient received up to 3 doses of gemcitabine followed by 33 Gy in 5 fractions. The rate of grade 2+ late toxicity was 11% and 1-year freedom from local progression was 78%. Four patients (8%) subsequently underwent a margin-negative resection.[147]

A meta-analysis of 19 studies encompassing over 1,000 patients treated with SBRT demonstrated a 1-year local control rate of 72%. The rate of acute grade 3+ toxicity ranged from 0% to 36% and the rate of late grade 3+ toxicity did not exceed 11%.[148] Select series have demonstrated high rates of margin-negative resection in patients with borderline and unresectable pancreas cancer who ultimately underwent surgical resection.[149,150]

Ultimately, the role of IMRT and SBRT as well as integration with systemic therapy are ongoing areas of active investigation.

Chemoradiation Effects on Quality of Life

Pain, anorexia, fatigue, and cachexia are relatively common symptoms, which significantly impact a patient's quality of life. When using EBRT with or without chemotherapy, approximately 35% to 65% of patients will experience pain resolution as well as some improvement in cachexia and obstructive symptoms.[115,151,152] Definite but less dramatic improvements in performance status and anorexia may be observed as well.[151,152] Patient-reported quality of life (QOL) with SBRT in unresectable pancreas cancer demonstrates no change in QOL at pretreatment compared to 1-month follow-up but statistical and clinical improvements in pancreatic pain and body image at 1 month.[153] Palliation from therapy can take many weeks for maximal effect, and alternative treatments, such as biliary and duodenal stents, may provide more rapid relief of obstructive symptoms. Given the high mortality rate associated with pancreatic cancer, QOL should be a study end point in trials for these patients.

TARGETED THERAPIES AND FUTURE DIRECTIONS

There is much room for improvement in the diagnosis and treatment of

pancreatic cancer. Screening of high-risk individuals may allow for detection of disease in earlier disease stages by means of novel imaging methods or assessment of serum biomarkers.[154,155] As the biologic basis of cancer is better understood, the successful use of cancer-specific targeted therapies in other cancers supports the need to identify new targets and better predictors of response to therapy in pancreatic cancer.

There is evidence of additive or synergistic effects for several targeted agents (such as antibodies against EGFR and vascular endothelial growth factor [VEGF] receptor) with both chemotherapy and radiation therapy, making these topics of investigation. These targeted agents have been studied most extensively in the metastatic setting prior to evaluation in locally advanced and resectable disease. Currently, the only targeted agent that has shown a modest statistically significant survival benefit in the metastatic setting compared to chemotherapy alone is erlotinib, an anti-EGFR tyrosine kinase inhibitor. However, the survival benefit with addition of erlotinib is small, with median survival increased from 5.9 to 6.2 months and 1-year survival improvement from 17% to 24%.[156] The clinical significance of this difference has been questioned by investigators and treating physicians.

Another EGFR/*HER-1* inhibitor, cetuximab, initially showed promising phase II results in the metastatic setting. Efficacy was initially seen with the combination of cetuximab and EBRT in the treatment of locally advanced squamous cell carcinoma of the head and neck and subsequently tested in a phase III trial.[157] However, in pancreatic cancer, a phase III randomized study of gemcitabine plus cetuximab versus gemcitabine plus placebo (Southwest Oncology Group S0205) as first-line therapy in locally advanced, unresectable, or metastatic disease enrolled over 700 patients from the United States and Canada. No survival improvement was seen with the addition of cetuximab to gemcitabine (6.3 months gemcitabine plus cetuximab vs. 5.9 months gemcitabine alone). Even among patients tested for EGFR expression (90% specimens positive for expression), no benefit to cetuximab was seen in this patient subgroup.[158] An additional phase II study evaluated the efficacy and safety of multiagent chemotherapy in combination with cetuximab. Sixty-nine patients with locally advanced pancreatic cancer received cetuximab, gemcitabine, and oxaliplatin followed by cetuximab, capecitabine, and radiotherapy. Diagnostic cytology specimens were stained for Smad4 (Dpc4) expression. Median overall survival was 19.2 months, and the pattern of failure for patients with Smad4 (Dpc4) expression was primarily local, rather than

distant, disease failure.[159] The addition of EGFR inhibitors in localized disease is currently being evaluated in phase I and phase II trials.

VEGF inhibitors bind to receptors involved in tumor growth via vasculogenesis and angiogenesis pathways. Preclinical data have shown that inhibition of VEGF has radiosensitizing effects. Initially, promising results in the metastatic setting, however, have ultimately not shown a benefit from the addition of an anti-VEGF antibody to chemotherapy. A phase II trial of the combination of gemcitabine and bevacizumab in 52 treated patients with advanced pancreatic cancer showed a response rate of 21%, a median progression-free survival of 5.4 months, and median overall survival of 8.8 months.[160] In response to these positive results, a phase III randomized study of gemcitabine plus bevacizumab versus placebo (Cancer and Leukemia Group B CALGB-80303) was initiated. No significant difference was observed in OS or PFS.[161] Bevacizumab has also been evaluated in combination with radiotherapy. An initial phase I study of radiotherapy, capecitabine, and bevacizumab led to incorporation in the phase II setting in patients with locally advanced pancreatic cancer (RTOG-0411).[162] Eighty-two patients were treated with radiotherapy to the gross tumor, capecitabine (825 mg/m^2), and bevacizumab (5 mg/kg on days 1, 15, 29) followed by adjuvant gemcitabine (1,000 mg/m^2). The median and 1-year survival rates were 11.9 months and 47%, respectively. These results were similar to prior RTOG trials of locally advanced pancreatic cancer.[163] An additional phase II trial assessed the efficacy of full-dose gemcitabine (1000 mg/m^2), bevacizumab (10 mg/kg), and radiotherapy to 36 Gy (in 2.4 Gy fractions) with maintenance gemcitabine and bevacizumab in patients with unresected tumors with no evidence of disease progression. Median progression-free and overall survival were 9.9 and 11.8 months, respectively.[164] The incorporation of bevacizumab with radiotherapy has not led to profound improvements in treatment outcomes compared to 5-FU–based CRT.

Although improvements with targeted agents have been modest, other pathways are being evaluated. Pancreatic cells deficient in *BRCA* repair pathways are sensitive to poly-adenosine diphosphate-ribose polymerase (PARP) inhibitors. PARP inhibitors have been evaluated in ovarian and breast cancer, with response rates of 40%; clinical trials of PARP inhibitors in treatment of pancreatic cancer are under way.[7] Other therapeutic agents under evaluation include hedgehog pathway inhibitors, multikinase inhibitors (sorafenib), and agents targeting v-src sarcoma, γ-secretase, stem cell factor receptor (c-kit), secreted protein acidic and rich in cysteine, mitogen-activated protein kinase,

mesothelin, *RAS*, prostate stem cell antigen, tumor necrosis factor-α, mucin-1, mammalian target of rapamycin, tumor necrosis factor superfamily member 10, and type 1 insulin-like growth factor receptor.[7,165]

There is growing interest in immunotherapies to target the heterogeneous pancreas tumor and immunosuppressive microenvironment. A number of clinical trials in pancreas cancer alone or advanced solid tumors have been completed or ongoing evaluating the role of immune checkpoint monotherapy, dual checkpoint blockade, immune checkpoint in combination with vaccine therapy, and in combination with cytotoxic and other systemic therapies.[166,167]

Summary

Treatment of pancreatic cancer remains a challenge in oncology. Despite advances in many aspects of oncologic evaluation and management, including preoperative evaluation, surgical techniques, perioperative care, systemic therapy, and radiotherapy, the 5-year OS rate for patients with resectable pancreatic cancer remains around 20%. Local tumor control has been improved by the use of specialized radiation techniques, allowing safe dose escalation. Even with these techniques, it is not clear that a survival benefit is achieved given the proclivity of metastases in this malignancy. Similarly, even in patients with metastatic disease, morbidity and mortality associated with locoregional progression remains a major cause of morbidity and mortality. Further advances in systemic therapies, study of the optimal sequencing of therapies, earlier detection of disease, and development of new and novel therapeutic options are urgently needed in the treatment of this formidable disease. Quality of life should be considered a paramount end point in the care and protocol design of clinical trials for these patients. Significant improvements in long-term survival will likely be achieved through ongoing attempts at exploitation of the malignancy's basic biologic anomalies.

CHAPTER 64

Cancer of the Liver and Hepatobiliary Tract

Mirrorer Ming-Jiung Liu, Tsun-I Cheng, Skye Hung-Chun Cheng, and Andrew T. Huang

LIVER CANCER

Hepatobiliary malignancies include hepatocellular carcinoma (HCC), gallbladder cancer, intrahepatic cholangiocarcinoma (ICC), extrahepatic cholangiocarcinoma, and rare neoplasms such as sarcoma and hepatoblastoma.[1] Worldwide, there were estimated 792,000 patients with liver cancer in 2013. The male-to-female incidence ratio was about 2.5.[2] People living in developing countries, such as eastern Asia and middle and western Africa, have higher incidence of liver cancer than those live in the developed countries.[3] Age-standardized incidence rates per 100,000 population for liver cancer were higher in developing versus developed countries (16:7) for both genders in 2013.[2]

Patients with liver cancer usually are asymptomatic except for symptoms related to chronic liver disease. Disease-related symptoms, however, are associated with advanced disease. The overall prognosis is dismal, with a 5-year survival rates ranging from 0% to 10%. Only about one of five affected patients was amenable to curative resection[4,5] before the implementation of screening programs using α-fetoprotein (AFP) and ultrasonography. In recent years, improvements in surgical techniques have brought resection rates up to 30% to 50%.[6,7] The advent of liver transplantation in the recent decades contributes to the curability of the disease. Surgical resection remains to be the primary curative treatment for hepatobiliary malignancies, as the majority of patients have inoperable or unresectable disease at diagnosis. For patients with unresectable intrahepatic disease, treatment modalities such as transplantation, transcatheter arterial chemoembolization (TACE), local radiofrequency ablation (RFA), systemic chemotherapy, radiotherapy, molecular target therapy, and the

use of current form of immunotherapy are treatment options.

HEPATOCELLULAR CARCINOMA

Topographic Anatomy

The liver is the largest solid organ of humans. Traditionally, it is divided into left and right lobes separated by the falciform ligament. Surgeons interested in hepatic resection need to understand the spatial relationship of a tumor to the hepatic vascular system preoperatively to determine resectability. Fortunately, progress in imaging modalities has made segmental division of the liver based on the anatomy of portal and hepatic veins feasible. The most common segmentation scheme proposed by Couinaud divides the liver parenchyma into right and left lobe with four segments each (Fig. 64.1). The left lobe of the liver consists of caudate lobe (segment I), lateral segment (segments II and III), and medial segment (segment IV). The anatomic landmark between the medial segment and lateral segment is drawn between the gallbladder and inferior vena cava (the falciform ligament). The right lobe of the liver consists of anterior segments (segments V and VIII) and posterior segments (segments VI and VII). The anatomic landmark that separates the anterior from posterior segment is the right hepatic vein; the anatomic landmark that divides the anterior segment from the left medial segment is the middle hepatic vein. No good anatomic landmarks exist that further divide the anterior and posterior segments into superior and inferior subsegments.[8] Dynamic computerized tomography is useful in distinctly defining segmental anatomy because the portal vein, hepatic vein, and inferior vena cava can be opacified at the same time.[9,10] Details of the anatomic information is available in the Web site: http://www.radiologyassistant.nl/en/p4375bb8dc241d.

Epidemiology

HCC is the most frequent primary cancer of the liver and ranks as the fifth most common cancer in the world and the third most common cause of cancer mortality.[11] The age-standardized incidence rate of liver cancer in 1990 worldwide was 14.7 per 100,000 men and 4.9 per 100,000 women.[12] The male-to-female ratio was 3:1. High-risk regions are eastern and southeast Asia and middle Africa.[11] The highest incidence rate is seen in the male population of South Korea, North Korea, Thailand, China, Gambia, and Senegal (28.5 to 48.8 per 100,000 populations).[11] In low-risk areas, such as Canada, Columbia, and

United Kingdom, HCC occurs in only 1 to 3 per 100,000 population.[11] But the incidence rates of primary liver cancer have recently declined in Chinese population in Hong Kong, Shanghai, Taiwan, and Singapore.[11] On the contrary, the incidence rates in some low-rate areas such as United States, United Kingdom, and Australia have increased. The incidence of HCC tripled between 1975–1976 (1.4 per 100,000) and 2005–2007 (4.8 per 100,000) in the United States.[13,14] The most likely reason for this rise is related to higher prevalence of hepatitis C infection.[14]

Risk Factors

HCC is clearly associated with hepatitis B (HBV) and hepatitis C (HCV) viral infections and chronic liver disease. With persistent HBV infection, the relative risk of incidence of HCC is 223-fold higher than the uninfected population.[15] The risk of HCC is even higher in patients who are HBeAg positive compared with those who are HBeAg negative.[16] Similar to HBV, the relative risk of HCC among individuals with chronic HCV infection and cirrhosis is also approximately 100 times the risk of uninfected persons.[17] There also exists a synergistic interaction in patients having HBV and HCV combined infection toward the development of HCC.[18]

Other chronic liver cell injury is also associated with the development of HCC. Chemical injury induced by ethanol, nitrites, hydrocarbons, solvents, organochlorine pesticides, primary metals, and polychlorinated biphenyls has been implicated.[19,20] Ethanol is the most common culpable chemical agent and is thought to produce HCC through the development of liver cirrhosis or to play the role of a cocarcinogen. Chronic alcohol use of >80 g/day for more than 10 years increases the risk for HCC by approximately fivefold. In patients with HCV, alcohol use doubles the risk of HCC.[21] Environmental toxins including aflatoxin, contaminated drinking water, and betel nut chewing may also be associated with the pathogenesis of HCC. Aflatoxins, a well-known group of hepatotoxic agent, produced by the fungi, *Aspergillus flavus* and *Aspergillus parasiticus*, are associated with HCC. Aflatoxins could contaminate corn, soybeans, and peanuts. High dietary aflatoxin intake is known to be related to the development of HCC.[22,23] There is a synergistic interaction between chronic HBV infection and aflatoxin exposure on the risk of developing HCC.[18] Patients with hereditary liver disease, such as hemochromatosis, Wilson disease, hereditary tyrosinemia, and type I glycogen storage disease, are also at higher risk of developing HCC.[18,24] The common mechanism in these incidences of

HCC may be related to chronic injury and inflammation of the liver.

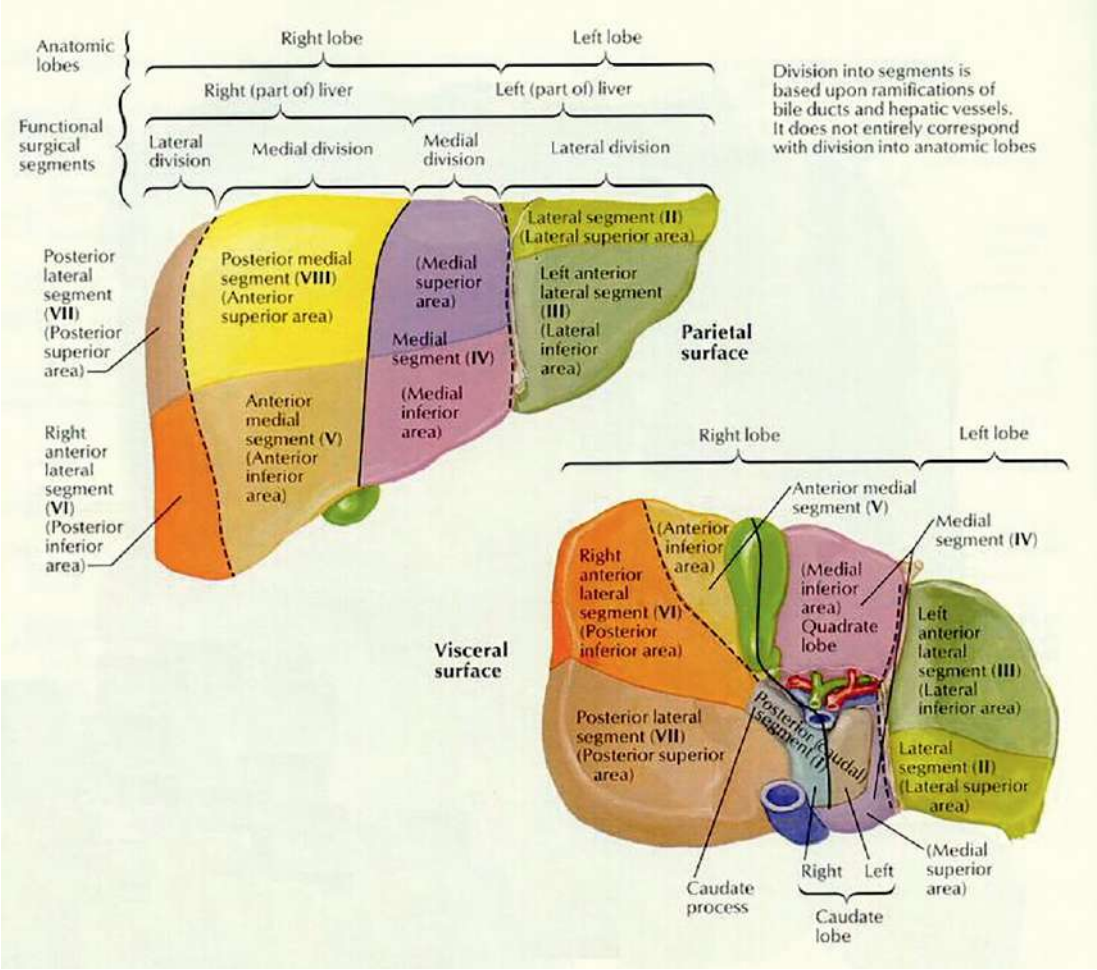

FIGURE 64.1. Segmentation schemes of the liver based on Couinaud proposal.

Prevention

Because HCC is causally related to viral hepatitis and chemical injuries, public health measures against viral infection and avoidance of chemical exposure are essential for the prevention of HCC. The HBV vaccine has been available for decades. Universal HBV vaccination in many countries such as Taiwan has shown significant decrease in the incidence of HCC, from 0.70 to 0.36 per 100,000 children at the age of 6 to 14.[25] In patients with evidence of HBV or HCV infection, oral antiviral agents should be chosen to effectively control the progression of infection. Antiviral therapy has also been shown to reduce recurrence and improve survival for HBV-related HCC.[26] When patients with HCC are treated with radiotherapy, HBV carriers or individuals with Child-Pugh B cirrhosis exhibit significantly greater susceptibility to radiation-induced liver

disease.[27] Caution should be taken to survey and follow patients with HCC from hepatitis B endemic areas and patients with compromised liver reserve when radiotherapy is being considered. Prophylactic use of antiviral agents is recommended in this instance.

Vaccination against HCV is currently unavailable. Strategies of prevention of HCV infection include blood screening, the use of disposable needles and syringes, adoption of universal precaution for health care workers, and timely treatment of chronic HCV infection with currently available anti-HCV agents.[28] Recent advances in interferon-free anti-HCV treatment have achieved highly effective control of HCV in infected individuals. Readers are referred to the recent reports by van der Meer et al. and Morgan et al.[29,30]

Surveillance

The goal of surveillance is to detect HCC at its early stage by serial screening tests when curative treatment can be applied. Patients with cirrhosis developed HCC with an approximate rate of 2% to 4% per year.[31] A randomized study demonstrated a 37% reduction in mortality for hepatitis B patients who had undergone surveillance.[32] A systematic review on surveillance also showed a relationship of improved survival to increased detection of early-stage HCC.[33]

Patients infected with hepatitis B and C virus, and autoimmune hepatitis are candidates for surveillance. However, several professional organizations have proposed different surveillance guidelines. National Comprehensive Cancer Network (NCCN) includes patients with cirrhosis from all causes and hepatitis B surface antigen carriers without cirrhosis and proposes to use ultrasound and optional AFP as screening tools. For patients with elevated AFP > 100 ng/mL or a nodule >10 mm, further tests are warranted. If nodules are <20 mm, then ultrasonography and AFP are repeated in every 3 to 6 months. If ultrasonography alone turns out negative, then combined ultrasonography and AFP are repeated every 6 months (NCCN guideline version 2, 2017). Readers may follow the updated guidelines for HCC management based on their geographic area of clinical practice. The four available guidelines are listed as follows: the Asian Pacific Association for the Study of the Liver (APASL) in 2010, the European Association for the Study of the Liver (EASL) in 2012, the American Association for the Study of Liver Disease (AASLD) in 2017, and specific country: Japanese Society of Hepatology (JSH) in 2014, etc.

Clinical Presentation

HCC in the early stage is asymptomatic; it is generally detected by elevation of AFP and/or ultrasonography screening or as an incidental finding in the evaluation of other conditions such as chronic liver disease.[34] Even in the advanced stages, some patients are still asymptomatic. Symptoms in HCC patients are usually related to their chronic hepatitis and liver cirrhosis. Clinical symptoms include general fatigue, poor appetite, ascites, jaundice, upper gastrointestinal bleeding, splenomegaly, dilated abdominal veins, palmar erythema, gynecomastia, testicular atrophy, leg edema, and weight loss. Tumor-related symptoms include palpable masses in the upper abdomen (hepatomegaly), acute onset of pain (because of hemorrhage from ruptured tumor) and dull pain in the right upper quadrant of the abdomen, abdominal fullness, low-grade fever, obstructive jaundice, and splenomegaly.[35] Very few individuals with HCC present initially with metastatic disease that affects extrahepatic organs such as lungs, bones, adrenal glands, pancreas, and neck lymph nodes.[31,36]

Diagnostic Workup

In a patient in whom HCC is suspected, the clinical history frequently includes a history of hepatitis, jaundice, blood transfusion, use of intravenous drugs, or exposure to aflatoxins. A family history of hepatitis or hemochromatosis is also an important risk factor.[31] Details concerning alcohol abuse and industrial exposure to potential carcinogens are also helpful. The physical examination should include a search for signs of underlying liver disease such as jaundice, ascites, ankle edema, spider angiomata on the anterior chest wall, palmar erythema, splenomegaly, increasing abdominal girth, and weight loss. Evaluation of the abdomen for liver size, existence of tumor masses, tenderness, and abdominal bruits should also be included.

Blood tests should include serology for HBV and HCV and AFP. If HBV or HCV serology is positive, quantitative HBV DNA or HCV RNA should be obtained.[37] Evaluation of hepatic functional reserve includes prothrombin time, activated partial thromboplastin time, and serum albumin. Platelet, red cell, and white blood cell counts should also be obtained to look for simultaneous existence of portal hypertension and hypersplenism from liver cirrhosis. Fifteen-minute retention rate of indocyanine green (ICG) before treatment is very useful for determining resectability and/or the feasibility of radiation.[38] The diagnosis of HCC should be considered in the differential diagnosis for any patient with underlying liver disease such as cirrhosis or chronic viral hepatitis. In patients

having hepatitis or cirrhosis, any dominant solid nodule that is not clearly a hemangioma should be considered as HCC unless proven otherwise.[39] Noninvasive criteria for diagnosing HCC suggested by the AASLD in 2005 consist of serum AFP level > 200 ng/mL or a typical enhancement pattern (arterial enhancement and delayed portal vein washout) on dynamic imaging of hepatic mass >2 cm in a cirrhotic liver.[40] The AASLD further validated the diagnostic accuracy of a single dynamic technique if intense arterial uptake followed by "washout" of contrast in the delayed venous phases can be demonstrated as evidence of suspicion for HCC in patients with chronic hepatitis B or cirrhosis of any etiology.[41] A prospective validation study in 206 consecutive patients from Korea showed that the positive predictive value (PPV) of typical CT findings or serum AFP > 200 ng/mL were 97.8% in patients with cirrhosis, 89.6% in high-risk patients without cirrhosis, and 82.4% in low-risk patients.[42] In the absence of cirrhosis, histologic diagnosis is recommended.

Histologic diagnosis of HCC is also recommended for patients whose treatment plan is nonsurgical.[43] For patients in whom surgery is considered, a concern over the possibility of tumor seeding from biopsy or fine needle aspiration exists.[43] The reported risk ranges from 1.6% to 5%.[44–46] In patients who demonstrate coagulopathy or significant ascites, biopsy or fine needle aspiration may be contraindicated. At authors' institution, fine needle aspiration cytology and cell block performed under ultrasound guidance are frequently performed for tissue confirmation.[45] Core biopsy of the mass is generally reserved for patients in whom a definitive diagnosis by fine needle aspiration and cell block cannot be made. Coaxial cannula is then used to reduce the chance of needle track seeding.[47] In patients who demonstrate small hepatic nodules with diagnostic possibilities ranging from well-differentiated malignancy to benign disease such as nodular hyperplasia, ultrasound-guided needle or core biopsy should be considered.[48] Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are the most common diagnostic imaging modalities used to evaluate tumors in the liver.

Ultrasound examination of the liver is commonly used as a screening tool. Small tumors are often hypoechoic. As the tumor grows, the echo pattern tends to become isoechoic or hyperechoic, and HCC can be difficult to distinguish from the surrounding liver.[49] Nodules <1 cm should be followed with ultrasonography again at intervals of 3 months. Nodules over 1 cm in a cirrhotic liver should be investigated further with four-phase dynamic CT scan. If the four-phase dynamic CT scan cannot confirm the diagnosis of HCC, contrast-

enhanced MRI or biopsy is the next step. Another option is to use ultrasonography with carbon dioxide (CO_2) microbubbles or the like as ultrasound contrast agent given intra-arterially, which can overcome limitations of conventional B-mode and Doppler ultrasound techniques for studies of the focal lesion in the cirrhotic liver.[41] Extrahepatic metastases are not common at presentation; however, they occur mainly in patients with T4, multicentric disease, or in earlier stage disease following treatment. The most common sites of metastasis are lung, abdominal lymph nodes, and bone.[50] Routine metastatic survey in patients with early-stage HCC is not recommended unless transplantation is being considered.

Staging

HCC carries a generally poorer prognosis compared to other cancers because the underlying liver disease can negatively affect prognosis. Several factors have been identified as being important determinants of survival: the severity of underlying liver disease, the size and number of the tumor, vascular invasion, regional lymph node metastasis, and the presence of distant disease. There is no worldwide consensus on the use of any given HCC staging system. However, most major trials of HCC therapy have chosen the Barcelona clinic liver cancer (BCLC) staging system (Table 64.1), making it the *de facto* reference staging system.[41] Other systems such as the American Joint Committee on Cancer TNM staging system,[51] Okuda staging systems,[52] and the Cancer of the Liver Italian Program (CLIP) scoring system[48] are also in common use.

TABLE 64.1 BCLC STAGING SYSTEM FOR HEPATOCELLULAR CARCINOMA

BCLC Stage	ECOG Performance Status	Tumor Features	Liver Function
0	0	Single nodule < 2 cm	Child-Pugh A
A	0	Single or 3 nodules < 3 cm	Child-Pugh A–B
B	0	Multinodular	Child-Pugh A–B
C	1–2	Portal invasion, N1, M1	Child-Pugh A–B
D	3–4		Child-Pugh C

N, node classification; M, metastasis classification.

Pathologic Classification

Histologic classification of malignant tumors of the liver includes HCC (conventional type), HCC (fibrolamellar variant), cholangiocarcinoma

(intrahepatic bile duct carcinoma), mixed hepatocellular cholangiocarcinoma, undifferentiated carcinoma, and hepatoblastoma. The fibrolamellar variant of HCC has a relatively better prognosis. It occurs more frequently in adolescents or young adults and has a more indolent clinical course than conventional HCC.[53] Hepatoblastoma occurs most commonly in young children (median age, 13 to 16 months) and usually presents in an advanced stage.[54,55]

General Management

HCC is often multicentric when it is associated with HCV infection. The incidence of multicentric disease in HCV-associated HCC (53.3%) is significantly higher ($P < .05$) than in the non–HCV-related HCC (7.7%).[56] The risk of multicentric occurrence increases with the progression of chronic liver disease and cirrhosis.[57,58] Although multiple tumors occur less often in HBV-associated HCC, the incidence of intrahepatic recurrence of HCC is significantly higher in patients with a sustained HBeAg positivity and high serum concentration of HBV DNA.[59] Despite these observations, the mainstay of therapy is surgical resection. The majority of patients, however, are not eligible for surgery because of the extent of tumor involvement or underlying liver dysfunction. Several other treatment modalities can be considered, including liver transplantation, RFA, percutaneous ethanol or acetic acid injection, TACE, cryoablation, radiation therapy, systemic chemotherapy, and immunotherapy, which is being tested for its efficacy currently.

Surgical Resection

Surgical resection is a reliable method to obtain long-term disease control. The main limiting factors for resection are poor liver function above all and size, location, and number of tumor. In virus-related HCC, the extent of surgical resection of hepatic tumor depends on the functional reserve of the residual liver after surgery. Previously, the selection of patients for resection has been based on the Child-Pugh functional classification (Table 64.2), but this method is known to be inconsistent with the outcome. Many Japanese and other Asian investigators rely on the ICG retention test.[59] In Europe and the United States, selection of optimal candidates for resection is usually based on the assessment of the presence of portal hypertension, which is assessed clinically or by hepatic vein catheterization.[60] Clinically significant portal hypertension is suspected when the platelet count is below 100,000/μL associated with significant splenomegaly. The goal of surgery is to remove gross tumor with a margin of 1

to 2 cm of normal liver. Today, however, the 5-year survival after resection has improved by careful preoperative assessments as stated above and can exceed 50%.

TABLE 64.2 GRADING SYSTEM FOR CIRRHOSIS: THE CHILD-PUGH SCORE

Score	Bilirubin (mg/dL)	Albumin (g/dL)	Prothrombin Time (s)	Hepatic Encephalopathy (Grade)	Ascites
1	<2	>3.5	<4	None	None
2	2–3	2.8–3.5	4–6	1–2	Mild (detectable)
3	>3	<2.8	>6	3–4	Severe (tense)

Child class: A, 5 to 6; B, 7 to 9; C, >9.

Liver Transplantation

Many patients are not candidates for definitive surgery because of underlying liver dysfunction. The increasing availability of liver transplantation has made this procedure a viable alternative to tumor resection for selected patients. Based on the Milan study and others, liver transplantation is an effective option for HCC patients.[61] Milan criteria are still today's benchmark for patient selection. The major selection criteria are solitary tumor 5 cm or up to three tumors of smaller than 3 cm. Elevated AFP concentration adds prognostic information and may be used for decision-making in combination with imaging criteria.[62] When these selection criteria are strictly applied, excellent overall 3- to 4-year actuarial (75% to 85%) and recurrence-free survival rates (83% to 92%) can be achieved.[61,63,64] Risk factors of recurrence after transplantation include tumor size, number of tumors, vascular invasion, and persistence of HBV infection.[64–66] A major disadvantage with orthotopic liver transplantation is the unpredictable, potentially long waiting time for donor organs.[66] Living donor transplantation can be offered for HCC if the waiting time would likely be long.[62] Local treatment such as TACE or RFA could downstage HCC for transplantation purposes. Downstaging could increase the opportunity for transplantation and improve survival. Besides, local treatment could also be a

bridging therapy for patients on the waiting list to keep them away from progression of disease diminishing the chance of transplantation.

Percutaneous Ablation

For patients with early-stage HCC who are not suitable for resection or transplantation, percutaneous ablation could be a treatment option.[67,68] Other methods by destroying tumor cells can also be achieved by the injection of chemical substances (using ethanol or acetic acid) or by modifying the temperature (with radiofrequency, microwave, laser, or cryotherapy). Percutaneous ethanol injection is highly effective for small HCC. It achieves necrosis rate of 90% to 100% of the HCC <2 cm in size, but the necrosis rate is reduced to 50% if HCC is >3 cm.[69–71]

RFA involves the local application of radiofrequency thermal energy to the lesion. RFA is a reasonable option for patients who do not meet resectability criteria for HCC and yet are candidates for a liver-directed procedure based on the presence of liver-only disease. The best outcomes are in patients with a single tumor >2 and <4 cm in diameter. Randomized control trials comparing RFA and ethanol injection have shown that RFA provides superior local disease control that could result in an improved survival.[72–75]

Transcatheter Arterial Chemoembolization

HCC is a highly vascular tumor supplied mostly by the hepatic or adjoining arteries and has strong neoangiogenic activity during its progression. This character provides the theoretical basis for the radiological diagnosis of the disease. It is also the rationale in support of arterial embolization as a treatment option. TACE combines selective injection of chemotherapeutic agents through arteries feeding the tumor followed by intra-arterial embolization of tumor-feeding arteries with lipiodol, an iodized oily contrast agent, Gelfoam, or plastic particles such as Ivalon. Despite two prospective randomized studies failed to show significant survival benefit over conservative management in patients with unresectable HCC,[76,77] more recent systematic review of randomized prospective studies has shown TACE to have a positive impact on survival.[78] TACE has currently been accepted as the standard treatment for unresectable disease or inoperable patients such as with multicentric disease or repeated relapses, and it can be used selectively for tumors of different organ location and can be repeated if necessary.[1,79]

Conventional Radiotherapy

HCC is a radiosensitive tumor.[38] The major drawback is the poor radiation tolerance of adjacent normal liver and the difficulty of tumor localization.[80,81] Recent technological and conceptual developments in the field of radiation therapy, such as intensity-modulated radiation therapy, image-guided radiation therapy, respiratory gating, and stereotactic body radiation therapy (SBRT), raised the potential and feasibility of radiation treatment. By conforming the delivery of radiation dose distribution closer to the tumor or target volume outlined more accurately, radiotherapy can result in sparing more normal liver tissue from high-dose radiation.[82,83] For patients with liver-confined disease treated with conformal radiotherapy with or without TACE, local control response rates ranged from 40% to 90%, and the median survival ranged from 10 to 25 months.[84] Indications for conformal radiotherapy include larger unresectable HCC, relieving portal vein tumor–induced thrombosis, obstructive jaundice, failure of prior TACE to control disease progression and as component of a combined modality treatment with TACE, or percutaneous ablation therapy.[38,85,86] However, the combination of TACE and conformal radiotherapy in large unresectable HCC has not been shown to have added efficacy in randomized trial.

Radiation Doses

The tumor response to radiotherapy and survival of patients with HCC are related to the dose delivered.[85,87] Before the era of conformal radiotherapy, the dose of radiation treatment was limited to <30 to 40 Gy for the hepatic toxicity, as a result, partial response usually was <30%.[88,89] Seong et al.[90] reported an objective tumor-specific response rate of 67% after a mean dose of 51.8 ± 7.9 Gy for patients who failed TACE and were treated with conformal radiotherapy. Dawson et al.[87] escalated radiation doses for unresectable hepatobiliary cancer and observed that patients who received radiation doses >70 Gy had better median survival (>16.4 months). It appears that the higher the radiation doses given, the better the tumor response seen (Table 64.3). However, caution should be given in HBV-related HCC, and local radiotherapy may cause deterioration of liver function by radiation-induced liver disease (RILD), portal hypertension, and HBV reactivation. To fend off HBV reactivation, prophylactic anti-HBV treatment should be considered.

TABLE 64.3 RADIOTHERAPY WITH AND WITHOUT CHEMOTHERAPY FOR UNRESECTABLE HEPATOCELLULAR

CARCINOMA

Treatment Volumes

Although higher radiation doses have been shown to produce higher treatment response, unfortunately, patients with HCC are often accompanied by liver cirrhosis and dysfunction, which forbids higher doses of radiation. Published reports on three-dimensional conformal radiotherapy (3DCRT) with photon beam suggest that tumor-affected portions of the liver can be treated with higher doses with acceptable side effects. Lawrence et al. developed a normal tissue complication probability (NTCP) model of radiotherapy for intrahepatic malignancy. Based on this model, authors have designed a protocol in which each patient receive maximum tolerated doses of radiation with no more than 10% risk of radiation-induced liver disease.[94] Thus, the mean doses that can be delivered according to this protocol are 56.6 ± 2.31 Gy (range, 40.5 to 81 Gy). Using this dosing range, they observed a reduction of radiation injury to 4.8% (95% confidence interval, 0% to 23.8%). This model, however, was derived using patients with relatively normal liver function, and only 4 of 21 of their study population had HCC.[94] The NTCP model for patients with impaired liver function still requires further evaluation.[95] For patients with cirrhosis but within Child-Pugh grade A functional classification, the mean dose of hepatic radiation tolerated for normal liver is 23 Gy.[96] The authors suggested a dose–volume histogram for irradiation to normal liver that the irradiated hepatic volume over 10, 20, 30, and 40 Gy should be <68%, 49%, 28%, and 20%, respectively. Multivariate analyses demonstrated that the severity of hepatic cirrhosis was the only independent predictor for radiation-induced liver disease.

ICG retention test can guide the treatment volume of HCC.[97] We propose a treatment guideline using ICG test for conformal radiotherapy for patients with

impaired liver function (Table 64.4). We advise no radiation treatment for patients with Child-Pugh class C liver cirrhosis or prolonged ICG retention unless only a very small portion of the liver is included in the radiation treatment fields.[38]

TABLE 64.4 RADIATION TREATMENT GUIDELINES FOR HEPATOCELLULAR CARCINOMA

	ICG (Gy)

Stereotactic Body Radiotherapy

Stereotactic body radiotherapy (SBRT) to the intrahepatic lesion has emerged recently as a novel option of treatment following the advent of improved planning system using more current models of linear accelerators. For patients with unresectable tumors or medical conditions denying surgery, SBRT could be an alternative treatment. Stereotactic technique could deliver higher biologic equivalent doses (BED) to local tumor with similar or reduced normal tissue damages. There is a wider variety of dosing and fractionation schedules of SBRT for HCC, ranging from 24 to 60 Gy in 3 to 10 fractions. The local tumor control rate in the past 2 to 3 years ranged from 70% to 90%,[98–101] but the complete response rate measured with CT images is generally <20% by current size-based criteria, this discrepancy with local tumor control requires functional imaging assessment.[102] The progression-free survival and overall survival rates are still disappointing because of out-of-field progression after SBRT.

Simulation

Simulation for SBRT is best done with the four-dimensional (4D) CT to minimize the treatment volume to decrease normal tissue damage. The 4D CT with gating can generate 10-phase images to detect the tumor motion during

respiratory cycle.[103] In addition, small bowel contrast and intravenous contrast should be done to allow tumor, stomach and intestine being clearly demarcated. Abdominal compression belt and breath-holding technique can minimize inter- and intrafraction motion during radiation treatment.[104]

Tumor Contouring

The tumor target is often difficult to delineate with images of 4D. We prefer patients to have TACE using Lipiodol as landmarks before SBRT. If possible, contrast MRI can be obtained to provide complimentary information to aid the target delineating process as MRI often offer high soft tissue contrast resolution. Deformable registration of image technique can be used to fuse the diagnostic CT scan and MRI.[105]

Planning and Prescription

The goal of conformal radiotherapy is to precisely target the tumor(s) and to reduce injury to the surrounding normal tissue. Respiratory organ motion induces the largest "intrafraction" organ motion during treatment. Aruga et al.[106] studied organ motions involving the use of CT images obtained during both the static exhalation phase and the static inhalation phase for upper abdomen irradiation. They found that the tumor shifted between the two respiratory phases. The variation ranged from 0.4 to 5.9 mm in the lateral direction, 2.2 to 24.5 mm in the longitudinal direction, and 0.2 to 11.7 mm in the vertical direction with the patient in supine position. As mentioned in previous section, breath-gating or breath-holding techniques may help overcome the problem of respiratory movement during radiotherapy to a certain degree.[107] In general, the radiation field margin to the target in the lateral direction could be within 6 to 9 mm, vertical direction 9 to 12 mm, superior (subphrenic) direction 10 mm, and inferior direction 19 to 21 mm.[108,109] To preserve more liver function, the radiation field margins can be set only 5 mm and patient receives radiation treatment in the expiratory or inspiratory phase, the beam-on time will occupy about 30% to 40% of the whole respiratory cycle. The exact radiation delivery interval is generally set based on the observation of tumor motion on 4D CT images.

TABLE 64.5 COMBINATION TACE AND LOCAL RADIOTHERAPY IN UNRESECTABLE HEPATOCELLULAR CARCINOMA

Patient	Mean Tumor	Overall Survival	Median

Series	Number	Size (cm)	Treatment	(3 y) (%)	Survival (mo)

TACE, transcatheter arterial chemoembolization; RT, radiation therapy.

Dose and Organs at Risk

The SBRT dose is dependent on the tolerance of surrounding organs (liver, stomach, duodenum, kidney, and spinal cord). The large fraction size with SBRT still makes tolerance of surrounding tissues difficult. Son et al.[110] reported that at least 800 mL of normal liver should receive no more than 18 Gy to reduce the risk of deterioration of hepatic function. For patients with Child-Pugh score B, a 5-fraction regimen is recommended.[111] The dose to one-third of the uninvolved liver should be restricted to ≤18 Gy (3.6 Gy per fraction), and ≥500 cc of uninvolved liver should receive <12 Gy (2.4 Gy per fraction). For patients with a Child-Pugh score of ≥B and score ≥ 8, the risk of radiation-induced liver disease will be much higher and SBRT may not be safe unless the patients are already on the list for liver transplantation soon enough. For lesions adjacent to the duodenum or stomach, Mahadevan et al.[112] reported that 24 to 36 Gy in 3 fractions was associated with acceptable side effects. Bujold et al.[113] suggested the maximal dose of 32 to 34 Gy in 6 fractions to the stomach, duodenum, and small bowel and 12 Gy to the kidney in SBRT to HCC were acceptable.

Acute and Late Complications

The dose-limiting tissue injuries in radiation treatment for HCC include the liver, stomach, duodenum, bowels, and kidneys. Acute complications include general fatigue, transient elevation of liver function test, and nausea and vomiting (mainly for tumors in the left lobe of the liver), fever, and pancytopenia.[38,90] Subacute and late complications include hepatic failure, radiation pneumonitis, and gastrointestinal bleeding (caution should especially be given in tumor located in the inferior portion of the right lobe of the liver where the duodenum and jejunum are nearby and radiation doses plan to give more than 50 Gy).[38,114]

Hepatic failure can be avoided by limiting the radiation dose to the organs at risk as mentioned above.

Combined TACE and Local Radiation Therapy

TACE alone rarely produces complete pathologic remission for HCC > 5 cm, especially in the peripheral zone of the tumor.[115,116] Additional therapy is required to eradicate the residual disease or produce longer-term control of HCC. The combination of TACE and conformal radiotherapy shows promising results in large HCC (Table 64.5). Guo and Yu[120] reported 107 patients with large unresectable HCC treated with TACE followed by external beam irradiation. The largest dimension of the tumors ranged from 5 to 18 cm. After a median follow-up interval of 24 months, the cumulative survival rates at 3 and 5 years were 28.4% and 15.8%, respectively, with a median survival of 18 months. Cheng et al.[38] reported 17 patients with unresectable HCC treated with TACE and conformal radiotherapy. The mean tumor size was 8.6 cm (range, 3.7 to 18 cm). The overall survival rate at 2 years was 58%, and local progression-free tumor control was 83%. After 24 months of median follow-up, the median survival had not been reached, and 4 of 17 patients remained progression free (Fig. 64.2). Another study that combined TACE and local radiotherapy in 50 unresectable HCC patients reported a partial response rate of 66% and survival rates at 3 years of 43%.[114] Wu et al.[121] reported 94 patients with HCC who received 3DCRT combined with TACE. The response rate was 90.5%. The overall survival rates at 1, 2, and 3 years were 93.6%, 53.8%, and 26.0%, respectively, with the median survival of 25 months. Patients with branch portal vein thrombosis may benefit from combined treatments. Tazawa et al.[122] reported 19 patients with thrombus, presumably caused by the tumor, in the first branch of portal vein received 3DCRT with TACE. Eleven patients (58%) had an objective response, and 1-year survival rate was 41% (8 patients). Although we do not know yet whether combined TACE and conformal radiotherapy is a superior to TACE alone, the result of these studies suggests that in patients with large unresectable HCC, combined treatment can be a promising alternative treatment modality and is worthy of further investigation.

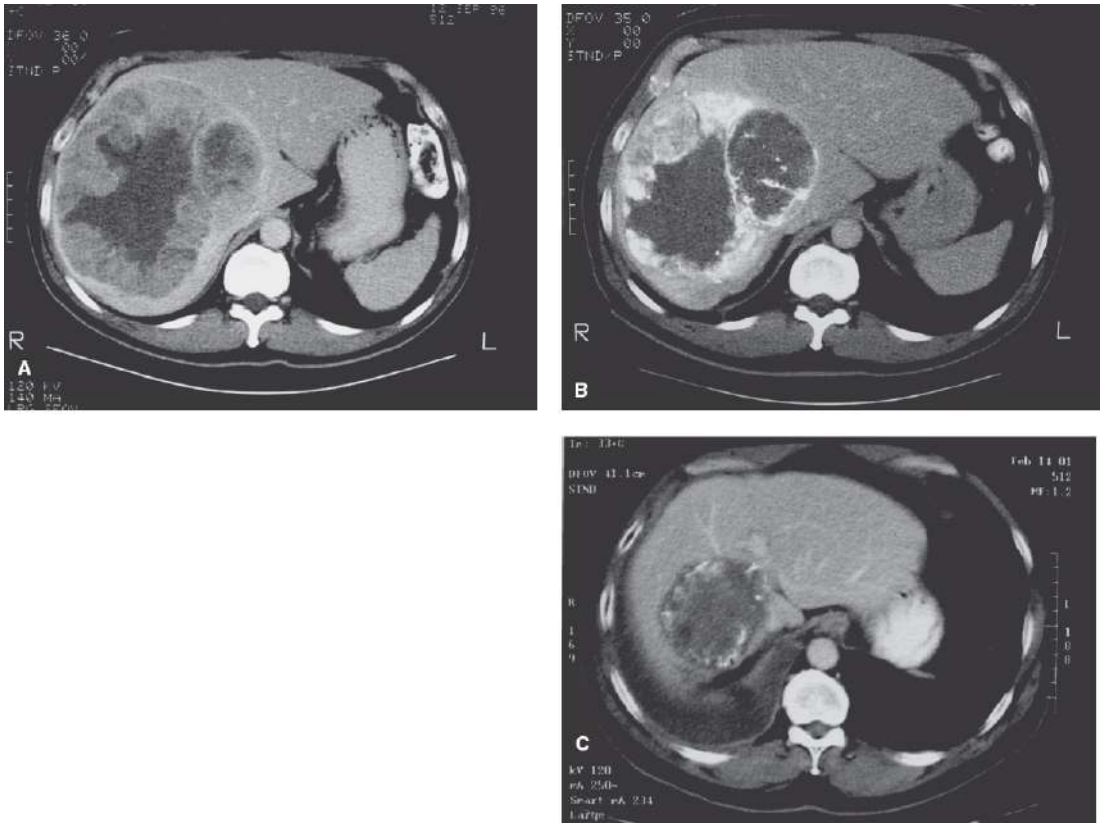

FIGURE 64.2. A: A 55-year-old man with hepatitis B virus infection developed a large hepatocellular carcinoma in the right lobe of the liver. The tumor measured 12 × 15 × 15 cm. Alpha-fetoprotein (AFP) was 901 ng/mL. **B:** After a first course of transcatheter arterial chemoembolization (TACE), his AFP dropped to 150 ng/mL. It rose again to 440 ng/mL 3 months later. Immediately thereafter, he had a second TACE followed by three-dimensional conformal radiotherapy. This image was taken after the second TACE but before conformal radiotherapy, revealing viable tumors in the peripheral zone of the main mass. **C:** Four years and 4 months after the first treatment, computed tomography revealed a nonenhancing tumor in the right lobe of the liver suggesting an effective control of the disease. His AFP remained <10 ng/mL after completion of radiotherapy.

Chemotherapy

Systemic chemotherapy for HCC has limited value in clinical practice because only a small portion of patients obtain significant benefit at the price of remarkable toxicity.[123] In general, cytotoxic therapy should be reserved for medically appropriate patients with adequate hepatic functional reserve, preferably administered within the context of a clinical trial. The side effect profile of any chemotherapy regimen is substantial, and its use should be carefully assessed in patients having advanced liver disease and a short life expectancy.

Several new drugs have been tested recently. One of the more promising of

these drugs is gemcitabine. It has a lower toxicity profile, but its antitumor activity in patients with advanced HCC is marginal: the response rate is no more than 18%, and the response duration is about 35 weeks.[124] Combination chemotherapy regimens have shown better responses. Leung et al.[125] reported 50 patients treated with intravenous chemotherapy PIAF (cisplatin, doxorubicin, 5-fluorouracil, and interferon-α). The partial response was 26% (13/50), and 4 patients achieved pathologic complete remission.[125] Louafi et al.[126] reported 34 patients of advanced HCC treated with gemcitabine and oxaliplatin. The disease control rate was 76%. Median progression-free and overall survival times were 6.3 months and 11.5 months, respectively.

Molecular Targeted Therapy

Recent advances in molecular biology have uncovered the structures and/or functions of many cytokines thought to have a strong relationship with the mechanisms of the antitumor effect of biologic therapies. Thalidomide, a sedative with antiangiogenesis potential previously associated with severe fetal malformations but highly effective for myeloma, has limited value in the treatment of HCC.[127,128] Molecular targeted therapy to the epidermal growth factor receptor and vascular endothelial growth factor has exhibited potential of inhibiting tumor growth of HCC.[129] The randomized trial of sorafenib, a tyrosine protein kinase inhibitor, has shown statistically significant tumor suppression with a median overall survival of 10.7 versus 7.9 months without sorafenib and longer median time to radiological progression (5.5 vs. 2.8 months).[130] Some clinical studies showed benefit in local control by combining sorafenib with conventional irradiation.[131] But hepatic toxicity and out-of-field progression remains the key factor affecting survival. Concurrent treatment of sorafenib with SBRT awaits further investigation.[132] However, the combination of sorafenib with radiation should be given cautiously; a single 8 Gy irradiation to lumbar spine has been reported associated with a complication of bowel perforation.[133] We recommend stopping antiangiogenic agent during radiotherapy. Combination of sorafenib or regorafenib with immunotherapy is also under active investigation.

Immunotherapy

HCC is most frequently a virally associated disease. Immune tolerance and imbalance are thought to be one of the mechanisms leading to the development of cancer.[134] There is evidence that immunotherapy may play a role in treating

HCC. A phase I/II study including 48 patients demonstrated that the PD-1 inhibitor, nivolumab, is safe and effective in advanced HCC, and the overall response rate was 15%. The preliminary overall 1-year survival was 62%. Dose-limiting toxicity was hepatic decompensation. The most common adverse effects are skin rash, pruritus, and elevation of AST, ALT, lipase, and amylase.[135] Combination of immunotherapy and radiotherapy is in active clinical trial.

Areas of Failure and Cause of Death

Survival of HCC with various treatments depends largely on the clinical stage and liver function. Five-year survival in resectable HCC after partial hepatectomy is 50% to 73% in stage I patients, 30% to 56% in stage II patients, 10% to 29% in stage III patients, and approximately 10% in stage IV patients.[136,137] The 5-year survival for patients with unresectable HCC is usually <10%.[138] The major cause of failure after resection is tumor recurrence within the liver. Extrahepatic metastasis in advanced HCC has become more frequently encountered in recent years, probably related to improvements in the survival from intrahepatic disease.[139,140]

Future Study

The outcome in HCC from various treatments is generally unsatisfactory. The main cause of failure is intrahepatic recurrence. Future efforts should be directed more toward prevention of HBV via vaccination and HCV infection through screening of blood products and universal needle precaution in endemic regions. Antivirals including the recent advent of anti-HCV agents have been effective in the control of infected individuals. Treatment of HCC unfortunately relies mainly on surgical resection for limited stage disease at this moment in time. Investigation for newer target agents or novel immunotherapy is only in the early stage of development.

BILIARY TRACT CANCER

Biliary tract cancers consist of cancer of the gallbladder, the bile ducts, and the ampulla of Vater. They are clinically highly aggressive tumors and are usually discovered in locally advanced stage of disease at diagnosis. Gallbladder cancer is the most common cancer of the biliary tract and accounts for two-thirds of these cancers, whereas bile duct cancer accounts for the remaining one-third.[141] Biliary tract cancer can appear in small intrahepatic bile ducts, as well as large intrahepatic and extrahepatic bile ducts. The term cholangiocarcinoma is used to

describe cancers arising from the epithelial cells of the bile ducts. At present, surgical excision of all resectable biliary tract cancers is associated with a good long-term survival, whereas for unresectable tumors, the treatment is usually palliative aiming to relieve obstructive jaundice with drainage of bile and management of biliary tract infection, pain, and ascites.

CHOLANGIOCARCINOMA

Topographic Anatomy

The bile ducts originate within the liver, with the left and right hepatic ducts joining to form the common hepatic duct. At the origin of the cystic duct, it becomes the common bile duct. The cystic duct drains bile from the gallbladder into the common bile duct. The gallbladder is adjacent to the undersurface of the liver.

There is a rich lymphatic network along the submucosa of bile ducts. The primary lymphatic drainage of the biliary tract is to the lymph nodes in the pericholedochal area, periportal region, hepatoduodenal ligament, common hepatic artery, and pancreaticoduodenal groups.[83,142,143]

Epidemiology and Risk Factors
