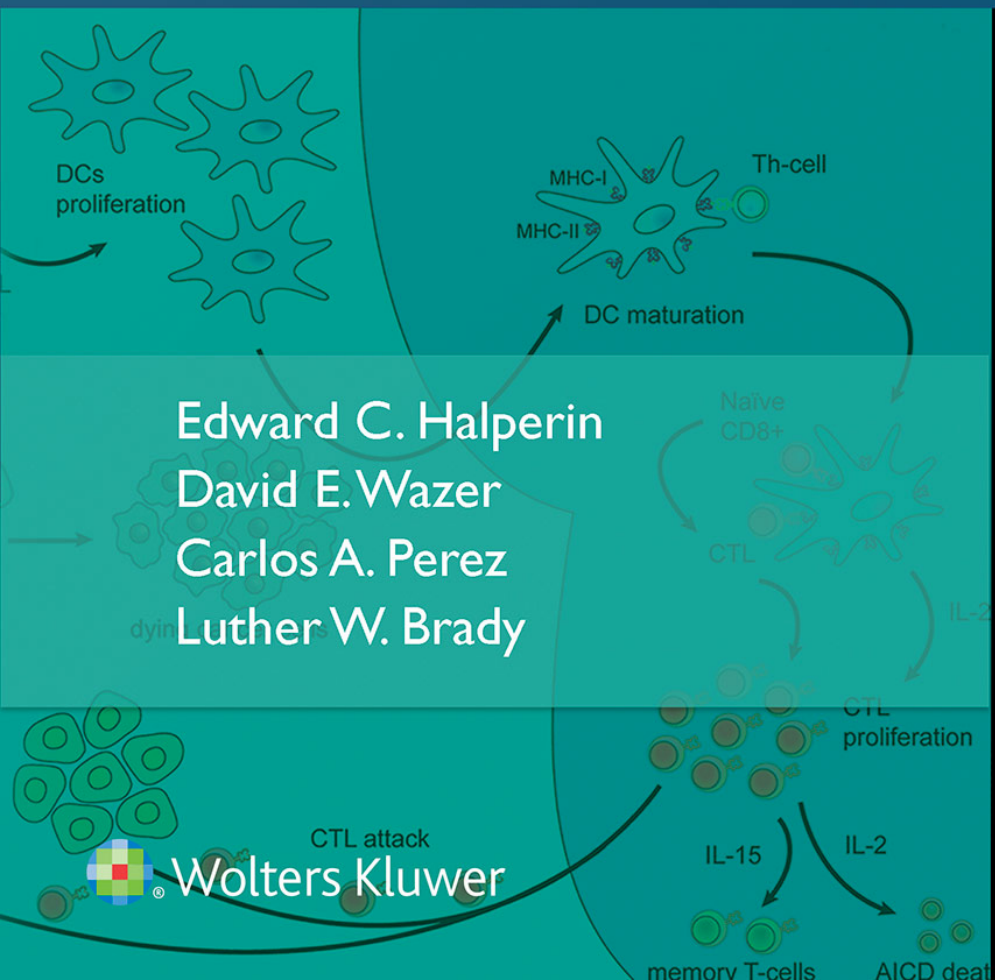
Principles and Practice of

Radiation Oncology

SEVENTH EDITION



Edward C. Halperin
David E. Wazer
Carlos A. Perez
Luther W. Brady

Wolters Kluwer

Perez & Brady's

Principles and Practice of Radiation Oncology

Seventh Edition

Wolters Kluwer

Philadelphia • Baltimore • New York • London
Buenos Aires • Hong Kong • Sydney • Tokyo

EDITORS

Edward C. Halperin, MD, MA

Chancellor for Health
Affairs and Chief
Executive Officer
New York Medical College
Professor of Radiation Oncology, Pediatrics, and History
Provost for Biomedical Affairs
Touro College and University
Valhalla, New York

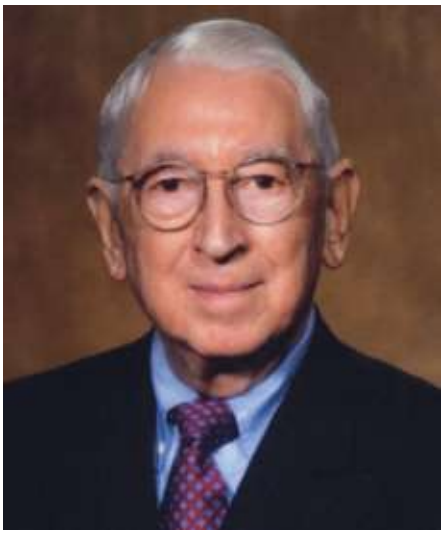
David E. Wazer, MD, FASTRO

Professor and Chairman
Radiation Oncologist-in-Chief
Department of Radiation Oncology
Tufts Medical Center
Tufts University School of Medicine
Boston, Massachusetts
Rhode Island Hospital
Alpert Medical School of Brown University
Providence, Rhode Island

Carlos A. Perez, MD

Professor Emeritus
Department of Radiation Oncology

Mallinckrodt Institute of Radiology
Siteman Cancer Center
Washington University
St. Louis, Missouri



Luther W. Brady, MD

Distinguished University Professor
Hylda Cohn/American Cancer Society
Professor of Clinical Oncology
Professor, Department of Radiation Oncology
Drexel University College of Medicine
Philadelphia, Pennsylvania

Acquisitions Editor: Ryan Shaw
Editorial Coordinator: Lindsay Ries

Names: Halperin, Edward C., editor. | Wazer, David E., editor. | Perez, Carlos A., 1934- editor. | Brady, Luther W., 1925- editor.
Title: Perez and Brady's principles and practice of radiation oncology / [edited by] Edward C. Halperin, David E. Wazer, Carlos A. Perez, Luther W. Brady.
Other titles: Principles and practice of radiation oncology
Description: Seventh edition. | Philadelphia : Wolters Kluwer, 2018. | Preceded by Perez and Brady's principles and practice of radiation oncology / editors, Edward C. Halperin … [et al.]. 6th ed. c2013. | Includes bibliographical references and index.
Identifiers: LCCN 2018023918 | eISBN 9781496386823
Subjects: | MESH: Neoplasms—radiotherapy | Radiotherapy—methods | Radiometry
Classification: LCC RC271.R3 | NLM QZ 269 | DDC 616.99/40642—dc23 LC record available at https://lccn.loc.gov/2018023918

This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare

professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

LWW.com

To our patients, who have taught us through both their courage and their suffering,

To our teachers, who inspired and mentored us with knowledge and wisdom,

To our trainees, who will make the cancer care of tomorrow better than today's,

To the universities where we work—institutions that are committed to generation, conservation, and dissemination of knowledge about the causes, prevention, and treatment of human disease and disability:

To our families, who unselfishly endorsed our work on this book.

Contributors

Todd Adams, MD

Iowa City, Iowa

Roger M. Macklis, MD

Staff Physician
Department of Radiation Oncology
Taussig Cancer Institute
Cleveland Clinic
Professor of Medicine
Cleveland Clinic Lerner College of Medicine
Cleveland, Ohio

Anita Mahajan, MD

Professor
Department of Radiation Oncology
Mayo Clinic
Rochester, Minnesota

Brandon A. Mahal, MD

Physician

Department of Radiation Oncology
Brigham and Women’s Hospital/Dana-Farber Cancer Institute

Physician
Department of Radiation Oncology
Harvard Medical School
Boston, Massachussets

Anthony A. Mancuso, MD

Professor and Chair
Department of Radiology
University of Florida Health Shands Hospital
Professor and Chair
Department of Radiology
University of Florida
Gainesville, Florida

Rafael R. Mañon, MD

Vice Chairman
Department of Radiation Oncology
Orlando Health
Orlando
Adjunct Faculty
Department of Radiation Oncology
University of Florida
Gainesville, Florida

David B. Mansur, MD

Associate Professor and Vice Chair for Education
Department of Radiation Oncology
Case Western Reserve University School of Medicine
Director of Pediatric and Hematologic Radiation Oncology
University Hospitals Seidman Cancer Center
Rainbow Babies and Children's Hospital
Cleveland, Ohio

Lawrence B. Marks, MD, FASTRO

Professor and Chair
Department of Radiation Oncology
University of North Carolina School of Medicine
North Carolina Cancer Hospital
Chapel Hill, North Carolina

John D. Martin, PhD

JSPS Postdoctoral Fellow
Department of Bioengineering
The University of Tokyo
Tokyo, Japan

Ursula A. Matulonis, MD

Chief, Division of Gynecologic Oncology

Department of Medical Oncology
Dana-Farber Cancer Institute
Professor of Medicine
Department of Medical Oncology
Harvard Medical School
Boston, Massachusetts

Joel L. Mayerson, MD

Professor
Orthopaedic Surgery
The Ohio State University School of Medicine
Director, Sarcoma Service
Orthopaedic Surgery
The Arthur G James Cancer Hospital at The Ohio State University Wexner Medical Center
Columbus, Ohio

Lukasz Mazur, PhD

Director of Healthcare Engineering
Department of Radiation Oncology
Assistant Professor
Department of Radiation Oncology, School of Medicine
School of Library and Information Science
University of North Carolina
Chapel Hill, North Carolina

William H. McBride, PhD, DSc

Distinguished Professor Emeritus
Department of Radiation Oncology
University of California at Los Angeles
Los Angeles, California

Minesh P. Mehta, MD, FASTRO

Deputy Director
Miami Cancer Institute
Chief of Radiation Oncology, and Professor
Florida International University
Miami, Florida

Loren K. Mell, MD

Professor and Vice Chair, Clinical & Translational Research
Department of Radiation Medicine and Applied Sciences
University of California San Diego
La Jolla, California

Nancy P. Mendenhall, MD, FASTRO

Professor and Associate Chair
Department of Radiation Oncology
University of Florida

Gainesville, Florida
Medical Director
University of Florida Health Proton Therapy Institute
Jacksonville, Florida

William M. Mendenhall, MD
Department of Radiation Oncology
University of Florida College of Medicine
Gainesville, Florida

Lucas C. Mendez, MD
Clinical Fellow
Department of Radiation Oncology
University of Toronto
Sunnybrook Odette Cancer Centre
Toronto, Ontario, Canada

Jeff M. Michalski, MD, MBA
Vice Chair and Director of Clinical Programs
Department of Radiation Oncology
Barnes-Jewish Hospital
Carlos A. Perez Distinguished Professor
Department of Radiation Oncology
Washington University School of Medicine
St. Louis, Missouri

Joseph Mikhael, MD, Med
Chief Medical Officer
Department of Hematology
International Myeloma Foundation
North Hollywood
Professor
Department of Hematology
City of Hope National Medical Centre
Duarte, California

Michael T. Milano, MD, PhD
Associate Professor
Department of Radiation Oncology
Strong Memorial Hospital
Associate Professor
Department of Radiation Oncology
University of Rochester
Rochester, New York

Eric D. Miller, PhD
Assistant Professor
Department of Radiation Oncology

Ohio State University Wexner Medical Center
Columbus, Ohio

Mark Mishra, MD

Assistant Professor and Director of Clinical Research
Department of Radiation Oncology
University of Maryland Medical Center
Baltimore, Maryland

Gustavo S. Montana, MD, FACR, FASTRO

Emeritus Professor
Department of Radiation Oncology
Duke University Medical Center
Durham, North Carolina

Meena S. Moran, MD

Director, Yale Radiation Breast Program
Department of Therapeutic Radiology
Smilow Cancer Center
Professor
Department of Therapeutic Radiology
Yale University School of Medicine

Preface

The first edition of *Principles and Practice of Radiation Oncology* was published in 1987. This seventh edition is being published in 2018. After 31 years, approximately 11,000 pages of printed text, many tens of thousands of pages of typed and computer printed text, and an immeasurable number of meetings, phone calls, letters, e-mails, faxes, and text messages utilized to produce these seven volumes, many things have changed and others have stayed the same.

What has stayed the same? For 31 years, radiation therapy has remained a major component of the curative and palliative therapy of cancer and plays a major role in the management of many benign diseases. Patients with cancer are generally best managed by a combined modality approach that requires the participation of a well-informed, well-trained, and well-equipped radiation oncologist collaborating with a radiation oncology team. The radiation oncologist must be capable of taking a detailed medical history; performing a thorough and accurate physical examination of the patient; assessing and integrating the information from diagnostic imaging, from gross and microscopic pathology—incorporating a growing list of chemical and molecular markers that guide therapy and predict outcome—and from clinical chemistry; and formulating and implementing a treatment plan that is cognizant of the wishes of the patient and realistic in its goals. For this book, in particular, what has also stayed the same since 1987 is the vision and participation of Carlos A. Perez and Luther W. Brady, of Edward C. Halperin since 2004, and of David Wazer since 2008. We recognize that having such stability in the editorial team is exceptional in the history of textbook publishing and a blessing for the four of us. As we note below and in our acknowledgments, we remember and mourn those who contributed to previous editions of this book but are no longer with us: Ruth Aultman, Jonathan Pine, and Rupert Schmidt-Ullrich.

What has changed? There has been an explosion of knowledge concerning the molecular biology of cancer and tumor physiology. Concepts that were unknown in the 1980s are now considered fundamental building blocks of knowledge

concerning cancer. As it concerns the technology of this specialty, when the first edition of this book was published, some radiation oncology residents were training, in part, on orthovoltage units; cobalt-60 machines remained in widespread use; simulation using diagnostic radiographs still vied with clinical setups of treatment fields using surface anatomy; and many radiation oncologists carried slide rules, protractors, right angle drafting triangles, and rulers to calculate and map radiation dose distributions. Now, elaborate linear accelerators with multileaf collimators, particle machines, intensity-modulated and/or image-guided radiation therapy, complex brachytherapy devices, dose painting, image fusion, metabolic imaging, and increasingly powerful computers that support the preceding list of technologies have become the norm in the developed world. (And, unfortunately, the paucity of even the most minimal radiation therapy services remains the norm in many parts of the economically less-developed world, and economic and racial disparities persist in cancer care and outcomes in the economically developed world….) In some diseases, the diagnostic and staging workup has changed profoundly in the past quarter of a century—for example, the role of staging laparotomy in Hodgkin disease. In other diseases, the role of radiotherapy in treatment has shifted dramatically, as demonstrated by the decline in the role or frequency of use of radiation therapy in the management of retinoblastoma and Wilms tumor, following balloon angioplasty and stenting for coronary artery disease, or for AIDS-associated malignancies, and the change in the use of radiation therapy for breast and prostate cancer.

The editors have striven to be cognizant of change by constantly adding and pruning chapters to document the current state of knowledge of cancer biology, medical radiation physics, dosimetry, cancer epidemiology, clinical radiation oncology, and radiation oncology economics, education, ethics, and policy. Particular attention in the fifth through seventh editions has been devoted to an attractive and useable design of the printed version of this book and the new electronic versions. We have taken care to have this book evolve with the times, and we have simultaneously striven to be true to the core mission of being “the book of record” for clinical care, providing the data that justify treatment recommendations as well as comprehensive illustrations and references in radiation oncology. We take this responsibility very seriously.

We have been gratified by the public reception of this book. Sales of the fifth edition rose dramatically compared to the fourth edition—an atypical pattern in the medical book business. It is, we like to believe, evidence that the pact wordlessly exchanged between the editors, the chapter authors, and our readers

is being honored by all parties.

The editors sincerely hope that this seventh edition of *Principles and Practice of Radiation Oncology* will continue to advance understanding of the causes, prevention, and treatment of human cancer. We pray that this new edition will contribute to the cure of some malignancies, the amelioration of suffering for many patients and their families, the relief of pain, and the ultimate triumph of human knowledge over cancer.

Edward C. Halperin, MD, MA

Carlos A. Perez, MD
Luther W. Brady, MD

In Memoriam

Luther W. Brady, MD (1925–2018)

The founding co-editor of this book, Luther W. Brady, died as the seventh edition of *Principles and Practice of Radiation Oncology* was being printed. As we note in the Acknowledgments section, this book has been through so many editions that we, as co-editors, have now sadly experienced the deaths of four of our collaborators: Ruth Aultman, Jonathan W. Pine, Jr., Rupert Schmidt-Ullrich, and now Luther W. Brady.

Raised in North Carolina, Luther Brady arrived at George Washington University (GWU) as, in his own words, a “wet-behind-the-ears 16-year-old” to encounter the professors, the packed lecture halls, and “the salacious lectures.” He would go on to earn three degrees from GWU (AA in 1944, BA in 1946, MD in 1948) and serve on its board of trustees.

Writing 72 hours after his death, it is impossible for us to do justice to his life and career and meet the demands of publishing this book on time. This will be rectified in the lengthy tributes that will follow in the next few months.

Dr. Brady received post-graduate training in radiology and radiation oncology at the U.S. Naval Hospital in Bethesda, Jefferson Medical College, and the Hospital of the University of Pennsylvania. Except for a year at Harvard and a brief time at Columbia University, his entire academic career was in Philadelphia, first at the University of Pennsylvania and then at Hahnemann University Hospital and Drexel University School of Medicine. He was named professor in 1963; in 1970, he was appointed chair of the Department of Radiation Oncology and Nuclear Medicine. In 1975, he was named the Hylda Cohn/American Cancer Society Professor of Clinical Oncology. Hahnemann established the Luther W. Brady Pavilion in 1980.

He was president of the American College of Radiation Oncology, American Radium Society, American Society for Therapeutic Radiology and Oncology, American Board of Radiology, Intersociety Council for Radiation Oncology, Radiological Society of North America, Society of Chairmen of Academic Radiology Departments, and Society of Chairmen of Academic Radiation

Oncology Departments. He was chair of the Radiation Therapy Oncology Group and of the radiation oncology committee for Accreditation Council for Graduate Medical Education.

Dr. Brady worked on behalf of the Philadelphia Museum of Art, chaired its executive committee, and was a member of the board of trustees. The museum established the Luther W. Brady Curatorship of Japanese Art. The Luther W. Brady Art Gallery at GWU was also created in his honor. He served on the board of directors of the Opera Company of Philadelphia, the Opera Company of New Mexico, the Santa Fe Opera Company, the Settlement Music School, and the Curtis Institute of Music.

In addition, Dr. Brady received multiple medals from universities and scholarly societies and honorary degrees, delivered many named lectures around the world, and was elected to honorary fellowships of many European scholarly societies.

His scholarly interests ranged from tumors of the eye and orbit to cancers of the breast, lung, and cervix to lymphoma. He had more than 600 publications to his name, was editor-in-chief of the *American Journal of Clinical Oncology*, and was a member of the editorial advisory boards of many other professional journals.

Dr. Brady was passionate about this book. He loved telling and retelling his "founding story" wherein, he claimed, he flipped a coin with Philip Rubin and thus decided who would become the founding editor of the *International Journal of Radiation • Oncology • Biology • Physics* and who would become the founding editor of this book. In the preparation of the fourth edition of this book, the representative of Lippincott Williams & Wilkins, J. Stuart Freeman, Jr., proposed the use of a specific thickness and type of paper for the pages. Dr. Brady strongly disagreed. One of us (ECH) gently suggested that after all, Mr. Freeman was in the publishing business and he probably knew what he was talking about when it came to paper. Mr. Freeman pressed his point. Dr. Brady responded in arched tones. "Don't tell me about paper, Stuart. I know paper. I am on the board of trustees of the Philadelphia Museum of Art and I know quality paper. I'll tell you the type of paper appropriate for our text and our illustrations."

Needless to say, when the dust settled, Dr. Brady got the kind of paper he wanted.

He was a gracious host and a cultured gentleman. We shall not see his like again.

May his memory be for a blessing.

Edward C. Halperin, MD, MA
David E. Wazer, MD, FASTRO
Carlos A. Perez, MD

July 16, 2018

Acknowledgments

We are grateful for the scholarly, meticulous, and thorough work of the contributors to this volume. Through seven editions, this book has become the “book of record” for the specialty of radiation oncology. It has achieved that distinction through the hard work of the individual chapter authors.

The staff of Wolters Kluwer have professionally seen this work through from planning to distribution. We are in their debt.

Our fellow faculty members, residents, and medical students have supported our work, providing consistent intellectual stimulation, valuable suggestions, and materials that have contributed to this book. We are grateful to the many librarians of our respective institutions who have come to our aid in finding the necessary books and articles to support the preparation of this book. Rupert K. Schmidt-Ullrich, MD, of the Medical College of Virginia/Virginia Commonwealth University, served as co-editor of the fourth edition. A consummate physician–scientist, a man who held himself and others to very high standards, and a valued colleague, his positive contributions live on. Ruth Aultman faithfully served as secretary to Dr. Halperin for 21 years and diligently worked on the fourth through sixth editions. She died in 2012 and was working on the manuscript for Chapter 1 until shortly before her death. Jonathan Pine served as our publisher’s supervising editor for the fifth and sixth editions of this book. Jonathan was an endearing gentleman, kind, and possessed of gentle sense-of-humor. The four of us did not know of his long-standing diagnosis of lymphoma until what was perceived by us as his unexpected death in 2013. An obituary in *The Baltimore Sun* quoted one of Mr. Pine’s friends, who calls him the “perfect gentleman. He had manners you don’t see anymore, and he also had his first job. He was a rarity for this generation.” Special recognition is due to Vilma Bordonaro, Mary Lou Chin, and Chris Trimble, who diligently worked on the preparation of materials for this volume. Our families have patiently endured the loss of time and attention to other matters that occurs as a result of the demands of a project of this magnitude. To them, especially, we express our

gratitude and love.

Luther W. Brady, MD

Contents

SECTION I Overview and Basic Science of Radiation Oncology

1. The Discipline of Radiation Oncology

Edward C. Halperin

PART A: Cancer Biology

2. Molecular Cancer and Radiation Biology

Michael Baumann, Ina Kurth, Nils Cordes, Mechthild Krause, and Annett Linge

3. Biologic Basis of Radiation Therapy

William H. McBride, H. Rodney Withers, and Dörthe Schaue

4. Molecular Pathophysiology of Tumors

Rakesh K. Jain, John D. Martin, and Dan G. Duda

5. SMART Radiotherapy

C. Norman Coleman, Pataje G. Prasanna, Jacek Capala, Mansoor M. Ahmed, Jeffrey C. Buchsbaum, Bhadrasain Vikram, and Eric J. Bernhard

PART B: Medical Radiation Physics

6. Principles of Radiation Physics and Dosimetry

James A. Purdy and Sasa Mutic

7. Photon External-Beam Dosimetry and Treatment Planning

James A. Purdy and Sasa Mutic

8. Electron Beam Therapy Dosimetry, Treatment Planning, and Techniques

Angelica Perez-Andujar and Eric E. Klein

9. Conformal Radiation Therapy Physics, Treatment Planning, and Clinical Aspects

James A. Purdy and Sasa Mutic

10. Physics and Dosimetry of Proton Therapy

Brian Winey

11. Intensity-Modulated Radiation Treatment Techniques and Clinical Applications

Tony J. C. Wang, Cheng-Shie Wuu, and K. S. Clifford Chao

12. Image-Guided Radiation Therapy

Daniel Robert Simpson, Loren K. Mell, Arno J. Mundt, and Todd F. Atwood

SECTION II Techniques, Modalities, and Modifiers in Radiation Oncology

13. Altered Fractionation Schedules

Anthony E. Dragun

14. Late Effects and QUANTEC

John P. Kirkpatrick, Michael T. Milano, Jimm Grimm, Louis S. Constine, Zeljko Vujaskovic, and Lawrence B. Marks

15. Methodology of Clinical Trials

Abigail T. Berman, Erin F. Gillespie, Clifton David Fuller, Yiyi Chen, and Charles R. Thomas Jr.

16. Stem Cell Transplantation and Total-Body Irradiation

Sarah Jo Stephens, Kenneth B. Roberts, Zhe (Jay) Chen, Stuart Evan Seropian, and Chris R. Kelsey

17. Stereotactic Radiosurgery

John C. Flickinger

18. Stereotactic Irradiation of Tumors Outside the Central Nervous System

Brian D. Kavanagh, Jeffrey D. Bradley, and Robert D. Timmerman

19. Stereotactic Radiation Therapy Techniques

Mark J. Amsbaugh and Shiao Y. Woo

20. Intraoperative Radiotherapy

Timothy J. Kinsella

21. Proton Therapy

Nancy P. Mendenhall and Zuofeng Li

22. Neutron Therapy and Boron Neutron Capture Therapy

George E. Laramore

23. Carbon Ions

Pascal Pommier, Stephanie E. Combs, and Tadashi Kamada

24. Patient Positioning Methods: Immobilization, Stabilization, and Monitoring

Josh Evans, Bruce Libby, Laura Padilla, and Stanley H. Benedict

25. Physics and Biology of Brachytherapy

Jeffrey F. Williamson and David J. Brenner

26. Clinical Applications of Brachytherapy: Low Dose Rate and Pulsed Dose Rate

Sophie J. Otter, Caroline Holloway, Phillip M. Devlin, and Alexandra J. Stewart

27. The Physics and Dosimetry of High Dose Rate Brachytherapy

Bruce Thomadsen and Rupak K. Das

28. Clinical Aspects and Applications of High Dose Rate Brachytherapy

Subir Nag, Granger R. Scruggs, and John A. Kalapurakal

29. Radioimmunotherapy and Unsealed Radionuclide Therapy

Tod W. Speer

30. Radiation Therapy and the Immune System

Chandan Guha, James W. Hodge, and Adam P. Dicker

31. Photodynamic Therapy

Theodore E. Yaeger

32. Reirradiation

Carsten Nieder and Anthony E. Dragun

33. Global Radiation Oncology

Timothy P. Hanna and C. Norman Coleman

34. Chemical Modifiers of Radiation Response

Yvonne Marie Mowery, David S. Yoo, and David M. Brizel

35. Oncologic Imaging and Oncologic Anatomy

Junzo P. Chino, Chris R. Kelsey, Jared D. Christensen, and Lawrence B. Marks

36. Basic Concepts of Chemotherapy and Irradiation Interaction

D. Nathan Kim, Michael Story, and Hak Choy

SECTION III Clinical Radiation Oncology

PART A: Skin

37. Skin

William M. Mendenhall, Anthony A. Mancuso, Jessica M. Kirwan, Peter T. Dziegielewski, and Christiana M. Shaw

PART B: Central Nervous System

38. Primary Intracranial Neoplasms

Vinai Gondi, Michael A. Vogelbaum, Sean Grimm, and Minesh P. Mehta

39. Pituitary Gland Cancer

Theodore E. Yaeger

40. Spinal Canal

Jiayi Huang, Clifford G. Robinson, and Jeff M. Michalski

PART C: Head and Neck

41. Tumors of the Eye and Orbit

Nicholas J. Sanfilippo and Silvia C. Formenti

42. Ear

Tony J. C. Wang and K. S. Clifford Chao

43. Locally Advanced Squamous Carcinoma of the Head and Neck

David M. Brizel and Jessica L. Geiger

44. Nasopharynx

Benjamin H. Lok, Jonathan E. Leeman, and Nancy Y. Lee

45. Cancer of the Nasal Cavity and Paranasal Sinuses

Steven J. Frank, Anesa Ahamad, and Carlos A. Perez

46. Salivary Glands

Chris H. J. Terhaard

47. Oral Cavity

Rafael R. Mañon, Jeffrey N. Myers, and Paul M. Harari

48. Oropharynx

Joseph K. Salama and David M. Brizel

49. Hypopharynx

Matthew E. Witek, Timothy J. Kruser, Henry T. Hoffman, Christopher J. Kandl, and Paul M. Harari

50. Laryngeal Cancer

William M. Mendenhall, Anthony A. Mancuso, Robert J. Amdur, Brian J. Boyce, and Peter T.

Dziegielewski

51. Unusual Nonepithelial Tumors of the Head and Neck

Carlos A. Perez and Wade L. Thorstad

52. Neck Cancer Including Carcinoma of Unknown Primary

William M. Mendenhall, Anthony A. Mancuso, Robert J. Amdur, Brian J. Boyce, and Peter T. Dziegielewski

53. Thyroid Cancer

Robert J. Amdur and Roi Dagan

PART D: Thorax

54. Lung Cancer

Jing Zeng, Ramesh Rengan, Indrin J. Chetty, Roy H. Decker, Rafael Santana-Davila, Corey J. Langer, William P. O'Meara, and Benjamin Movsas

55. Mediastinum and Trachea

Shervin M. Shirvani, Daniel R. Gomez, Clifton David Fuller, and Charles R. Thomas Jr.

56. Esophageal Cancer

Brian G. Czito, Manisha Palta, and Christopher G. Willett

57. Tumors of the Heart, Pericardium, and Great Vessels

Gregory M.M. Videtic and Roger M. Macklis

PART E: Breast

58. Breast Cancer: Stage TIS

Alfredo I. Urdaneta, Todd Adams, David E. Wazer, and Douglas W. Arthur

59. Breast Cancer: Early Stage

Sharad Goyal, Thomas Buchholz, and Bruce G. Haffty

Overview and Basic Science of Radiation Oncology

CHAPTER 1

The Discipline of Radiation Oncology

Edward C. Halperin

SKETCHES OF SOME IMPORTANT HISTORICAL FIGURES IN THE DEVELOPMENT OF RADIATION ONCOLOGY

Wilhelm Conrad Röntgen (1845–1923)

On March 27, 1845, in Lennep, Germany, a son, Wilhelm Conrad, was born to Friedrich Conrad Röntgen and his wife, Charlotte Constanze (Fig. 1.1). Röntgen's father was a textile merchant. When Wilhelm was 3, the family moved from Prussia to Apeldoorn in the Netherlands, about 100 miles to the northwest, where Wilhelm's maternal grandparents lived. Wilhelm enrolled in the Utrecht Technical School in 1862. A fellow student caricatured a teacher on the fire screen of the schoolroom. The schoolmaster demanded the name of the unflattering artist, but Wilhelm refused to betray his classmate and was expelled. There was a risk that his education would come to an end after this episode. Fortunately, the Polytechnical School in Zurich, Switzerland, accepted students based on stiff entrance examinations. The black mark of expulsion was no impediment. Röntgen began classes in 1865 and received his diploma in mechanical engineering in 1868.[1–3]

Röntgen's considerable skill in designing and constructing precision instruments for measuring physical phenomena attracted the attention of Dr. August Kundt, a theoretical physicist. Röntgen became Kundt's assistant at the University of Zurich. When Kundt moved, in turn, to the University of Würzburg and then to the University of Strasbourg, Röntgen followed. In 1879, Röntgen struck out on his own as a professor at the University of Giessen.

In 1888, Röntgen accepted a professorship of theoretical physics at the University of Würzburg (Fig. 1.2). On November 8, 1895, Röntgen saw the effects of an unusual phenomenon while doing laboratory experiments. He presented his results to the president of the Physical Society at Würzberg on December 28, 1895[2–5] (Fig. 1.3).

There are many accounts of Röntgen's discovery. Among the multitude of reporters who rushed to interview Röntgen was H. J. W. Dam, an Englishman who was a correspondent for the Canadian *McClure's Magazine*. Dam had a letter of introduction but, like all other reporters, when he arrived in Würzberg, he was turned away. Dam, however, was persistent and wrote a letter in French to Röntgen insisting upon an interview. "You are very difficult, much more difficult than Berthelot, Pasteur, Dewar, and other men of science about whose discoveries I have written." Apparently taken by Dam's audacity and, perhaps, willing to have a sensible article written by a knowledgeable reporter, Röntgen granted Dam an exclusive interview.

Dam's lead story in the April 1896 *McClure's* is generally regarded as an accurate depiction.[6] Dam told his readers that "in all the history of scientific discovery there has never been, perhaps, so general, rapid, and dramatic an effect wrought on the scientific centers of Europe as has followed, in the past four weeks, upon an announcement made to the Wurzburg Physio-Medical Society, at their December meeting, by Professor William Konrad Röntgen, professor of physics at the Royal University of Wurzberg…. Röntgen's own report arrived, so cool, so business-like, and so truly scientific in character, that it left no doubt either of the truth or of the great importance of the preceding [newspaper] reports."[6]

> Dam, who was able to converse with Röntgen in English, French, and German, conducted an on-site interview in Röntgen's laboratories and had him describe the circumstances related to the discovery. Dam's charming description, excerpted here, gives an excellent insight into Röntgen the man and the nature of his scientific inquiry.
>
> "Now, Professor," said I, "will you tell me the history of the discovery?"
>
> "There is no history," he said. "I have been for a long time interested in the problems of the cathode rays from a vacuum tube as studied by Hertz and Lenard. I had followed theirs and other researches with great interest, and determined as soon as I had time to make some researches of my own. This time I found at the close of last October. I had been at work for some days when I discovered something new."
>
> "What was the date?"

“The eighth of November.”

“And what was the discovery?”

“I was working with a Crookes’ tube covered with a shield of black cardboard. A piece of barium platinocyanoide paper lay on the bench there. I had been passing a current through the tube and I noticed a peculiar black line across the paper.”

“What of that?”

“The effect was one which could only be produced, in ordinary parlance, by the passage of light. No light could come from the tube, because the shield which covered it was impervious to any light known, even that of the electric arc.”

“And what did you think?”

“I did not think; I investigated. I assumed that the effect must have come from the tube, since its character indicated that it could come from nowhere else. I tested it. In a few minutes there was no doubt about it. Rays were coming from the tube which had a luminescent effect on the paper. I tried it successfully at greater and greater distances, even at two metres. It seemed at first a new kind of invisible light. It was clearly something new, something unrecorded.”

“Is it light?”

“No.”

“Is it electricity?”

“Not in any known form.”

“What is it?”

“I don’t know. Having discovered the existence of a new kind of rays, I of course began to investigate what they would do. It soon appeared from the tests that the rays had penetrative power to a degree hitherto unknown.

They penetrated paper, wood and cloth with ease, and the thickness of the substance made no perceptible difference within reasonable limits. The rays passed through all the metals tested with the facility varying, roughly speaking, with the density of the metal. These phenomena I have discussed carefully in my report to the Würzburg Society and you will find all the technical results therein stated. Since the rays had this great penetrative power, it seemed natural that they should penetrate flesh, and so it proved in photographing the hand I showed you."

A detailed discussion of the characteristics of his rays the professor considered unprofitable and unnecessary. He believes, though, that these mysterious radiations are not light, because their behavior is essentially different from that of light ways, even those light rays that are themselves invisible. The Röntgen rays cannot be reflected by reflecting surfaces, concentrated by lenses, or refracted or diffracted. They produce photographic action on a sensitive film, but their action is weak as yet, and herein lies the first important field of their development. The professor's exposures were comparatively long—an average of 15 minutes in easily penetrable media, and half an hour or more in photographing the bones of the hand. Concerning vacuum tubes, he said that he preferred the Hittorf, because it had the most perfect vacuum, the highest degree of air exhaustion being the consummation most desirable. In answer to the question, "What of the future?" he said:

"I am not a prophet, and I am opposed to prophesying. I am pursuing my investigations, and as fast as my results are verified I shall make them public."

"Do you think the rays can be so modified as to photograph the organs of the human body?"

In answer he took up the photograph of the box of weights. "Here are already modifications," he said, indicating the various degrees of shadow produced by the aluminum, platinum, and brass weights, the brass hinges, and even the metallic stamped lettering on the cover of the box, which was faintly perceptible.

"But, Professor Neusser has already announced that the photographing of the various organs is possible."

“We shall see what we shall see,” he said; “we have the start now; the developments will follow in time.”

“You know the apparatus for introducing the electric light into the stomach?

“Yes.”

“Do you think that this electric light will become a vacuum tube for photographing, from the stomach, any part of the abdomen or thorax?”

The idea of swallowing a Crookes tube, and sending a high frequency current down into one’s stomach, seemed to him exceedingly funny. “When I have done it, I will tell you,” he said, smiling, resolute in abiding by results.

“There is much to do, and I am busy, very busy,” he said in conclusion. He extended his hand in farewell, his eye already wandering toward his work in the inside room. And his visitor promptly left him; the words, “I am busy,” said in all sincerity, seeming to describe in a single phrase the essence of his character and the watchword of a very unusual man.[6]

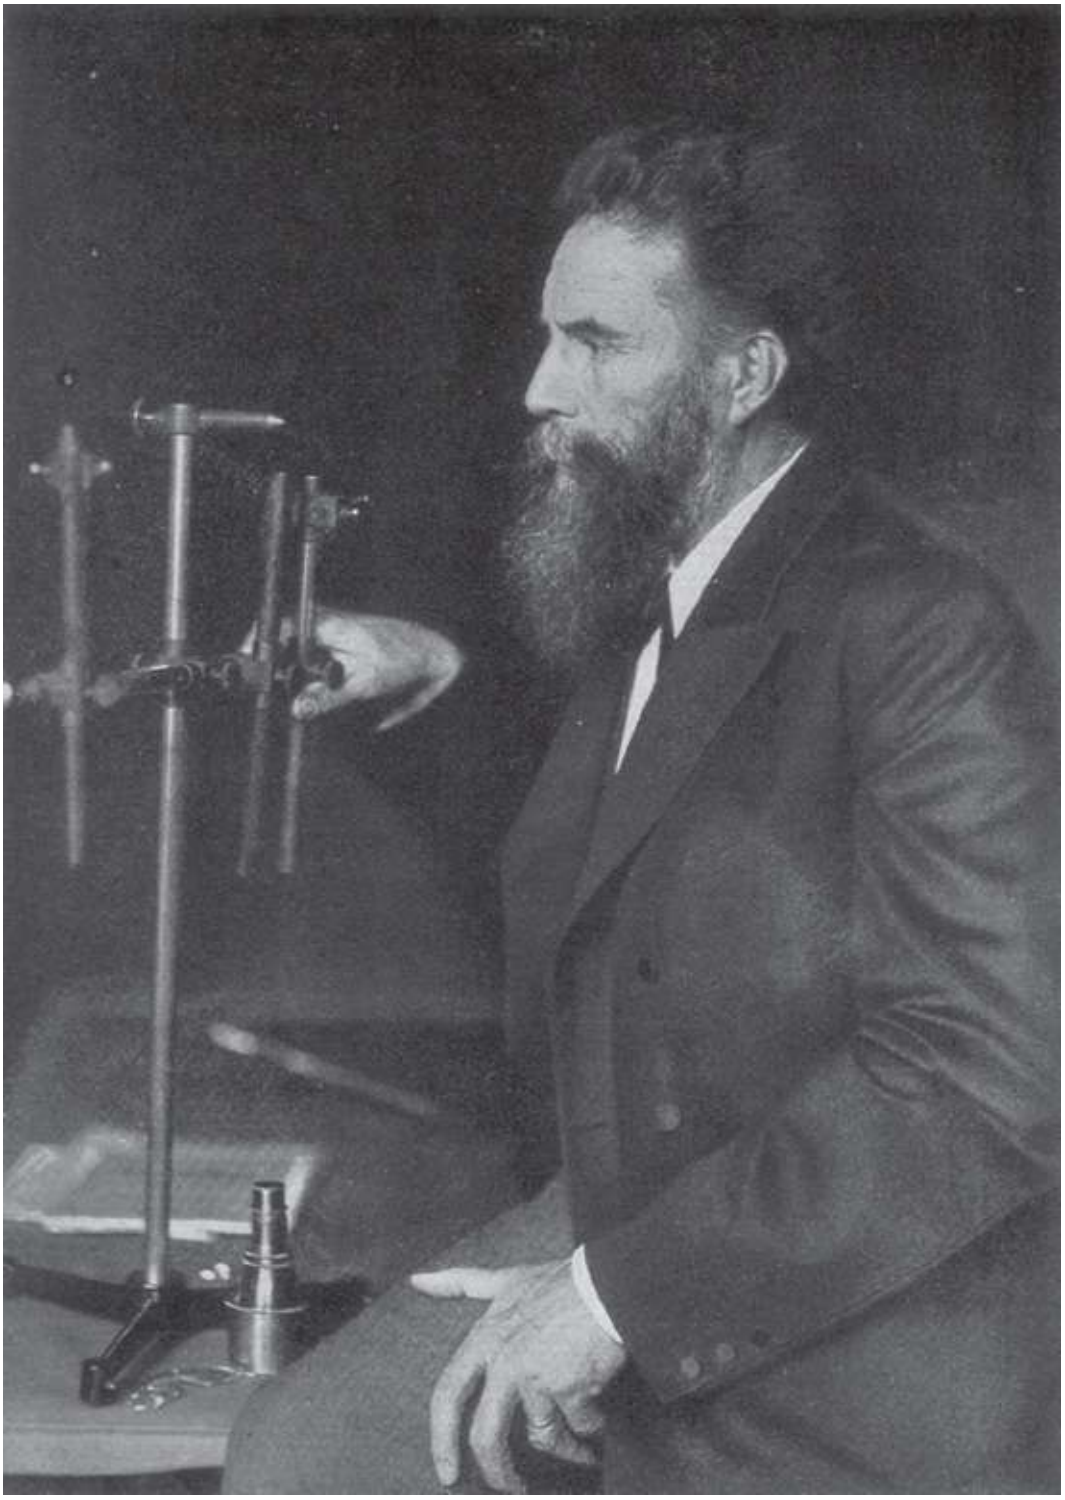

FIGURE 1.1. Wilhelm Conrad von Röntgen. He is shown in this photograph with physics instruments. (From Glasser O. *Wilhelm Conrad Röntgen and the early history of the Roentgen rays*. Springfield, IL: Charles C. Thomas, Publisher, Ltd., 1934, with permission.)

FIGURE 1.2. Photograph of the Physical Institute of the University of Würzburg from 1896. Professor Röntgen and his wife lived on the top floor. On the left side of the upper story can be seen the conservatory, of which Röntgen and his wife were particularly fond. (From Glasser O. *Dr. W.C. Röntgen*. Springfield: Charles C. Thomas, 1945, with permission.)

FIGURE 1.3. Röntgen made this image on December 22, 1895, and sent it to Vienna physicist F. Exner. (From Glasser O. *Dr. W.C. Röntgen*. Springfield: Charles C. Thomas, 1945, with permission.)

Kaiser Wilhelm II invited Röntgen to the imperial court at Potsdam in January 1896, shortly after the scientist had mailed out reprints to prominent physicists. Röntgen demonstrated his findings and was decorated with the Prussian Order of the Crown, Second Class. On January 23, he gave a lecture to the Würzburg Physical-Medical Society and was startled and overwhelmed by the cheers of the audience. At the end of the talk, Röntgen invited Albert von Kölliker, one of Germany's most distinguished anatomists, to come to the podium and have his hand x-rayed. When the audience saw the bones of his

hand, it erupted in thunderous applause. This was one of Röntgen's last formal lectures on x-rays. He became flustered before large groups and, when lecturing to small groups of students, was generally regarded as lusterless and dull.

Röntgen received the Nobel Prize in Physics in 1901 from the Swedish king. He thanked him but gave no speech. He willed the prize money to the University of Würzburg.[1] In the presentation speech, the president of the Royal Swedish Academy of Sciences, C. T. Odhner, commented on the enormous potential of Röntgen's discovery for diagnosis and therapy:

> The Academy awarded the Nobel Prize in Physics to Wilhelm Conrad Röntgen, Professor in the University of Wurzburg, for the discovery with which his name is linked for all time: the discovery of the so-called Röntgen rays, or, as he himself called them, x-rays. These are, as we know, a new form of energy and have received the name "rays" on account of their property of propagating themselves in straight lines as light does. The actual constitution of this radiation of energy is still unknown. Several of its characteristic properties, however, have been discovered first by Röntgen himself and then by other physicists who have directed their research into this field. And there is no doubt that much success will be gained in physical science when this strange energy form is sufficiently investigated and its wide field has been thoroughly explored. Let us remind ourselves of one of the properties that has been found in Röntgen rays—the basis of the extensive use of x-rays in medical practice. Many bodies, just as they allow light to pass through them in varying degrees, behave likewise with x-rays but with the difference that some that are totally impenetrable to light can be penetrated easily by x-rays, whereas other bodies stop them. Thus, for example, metals are impenetrable to them; wood, leather, cardboard, and other materials are penetrable as are the muscular tissues of animal organisms. Now, when a foreign body impenetrable to x-rays (e.g., a bullet or a needle) has entered these tissues, its location can be determined by illuminating the appropriate part of the body with x-rays and taking a shadowgraph of it on a photographic plate, whereupon the impenetrable body is detected immediately. The importance of this for practical surgery and how many operations have been made possible and facilitated by it is well known to all. If we add that in many cases severe skin diseases (e.g., lupus) have been treated successfully with Röntgen rays, we can say at once that Röntgen's discovery already has brought so much benefit to mankind that to reward it with the Nobel Prize fulfills the intention of the testator to

a very high degree.[7] (Figs. 1.4 and 1.5).

Antoine Henri Becquerel (1852–1908)

Antoine Henri Becquerel was born in Paris in 1852 into a family of scientists. His father was a professor of applied physics who had conducted research on solar radiation and phosphorescence. His grandfather was the inventor of an electrolytic method of extracting metals from ores.

Becquerel's early scientific work concerned the plane polarization of light, phosphorescence, terrestrial magnetism, and the absorption of light by crystals. Becquerel first heard of Röntgen's discovery in January 1896 at a meeting of the French Academy of Science. He wondered if there was a connection between phosphorescence and x-rays. He had inherited, from his father, a supply of uranium salts, which phosphoresced upon exposure to light.

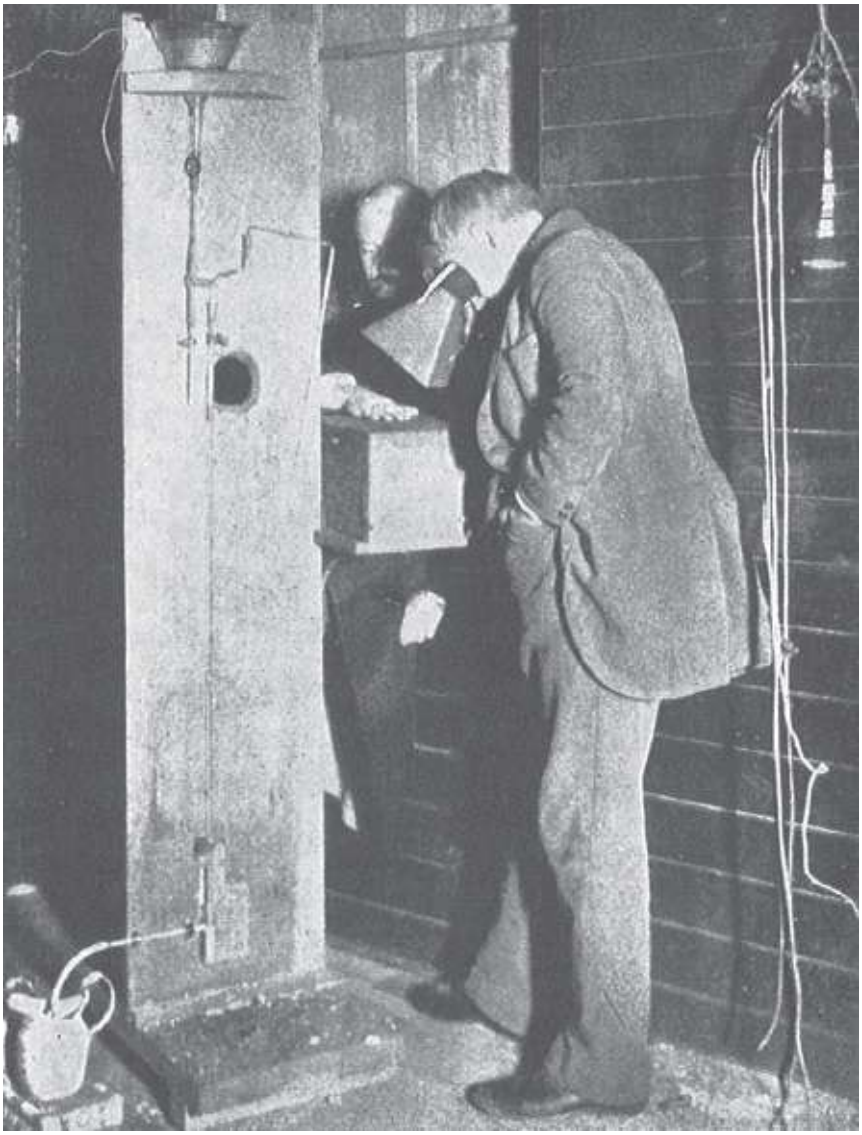

FIGURE 1.4. Thomas A. Edison experimenting with x-rays with, obviously, no radiation protection. (From Glasser O. *Dr. W.C. Röntgen*. Springfield: Charles C. Thomas, 1945, with permission.)

Becquerel thought that the phosphorescent uranium salts might absorb sunlight and, in turn, re-emit the energy as x-rays. He placed crystals of the uranium salts on top of photographic plates wrapped in opaque black paper. After placing the experimental setup in the sun, he developed the plates and saw an outline of the crystals. When he placed coins and other metal objects between the crystals and the plates, he could produce outlines of the shapes of the metal objects. These initial experiments seemed to confirm his suspicions.

When he encountered several overcast days in February 1896, Becquerel put his uranium crystals and photographic plates in a drawer. On March 1, he opened

the drawer and developed the plates. It is not clear why he did this. Nonetheless, he saw a clear image of the crystals on the plates. He had demonstrated that the uranium crystals were emitting x-rays on their own and had discovered spontaneous radioactivity.

Becquerel subsequently showed that the radioactive emissions from uranium could ionize gases and be deflected by electric or magnetic fields.[8–10]

Half of the 1903 Nobel Prize in Physics was awarded to Becquerel. The other half was given to Pierre and Marie Curie.[11]

Marie Sklodowska Curie (1867–1934) and Pierre Curie (1859–1906)

Marya Sklodowska was born in Warsaw on November 7, 1867. The youngest of four sisters and a brother, she lived under Russian rule in partitioned Poland. At 17, she left home to work as a governess to the daughters of the supervisor of a large sugar beet factory northeast of Warsaw in order to save enough money to attend university. In 1891, Sklodowska enrolled at the Faculte des Sciences at the Sorbonne in Paris—one of just 23 women in a student body of about 1800. She completed degrees in mathematics and physics and in 1893 was hired by the Society for the Encouragement of National Industry to study the magnetic properties of steel. While in the process of securing additional laboratory space, she was introduced to Pierre Curie.

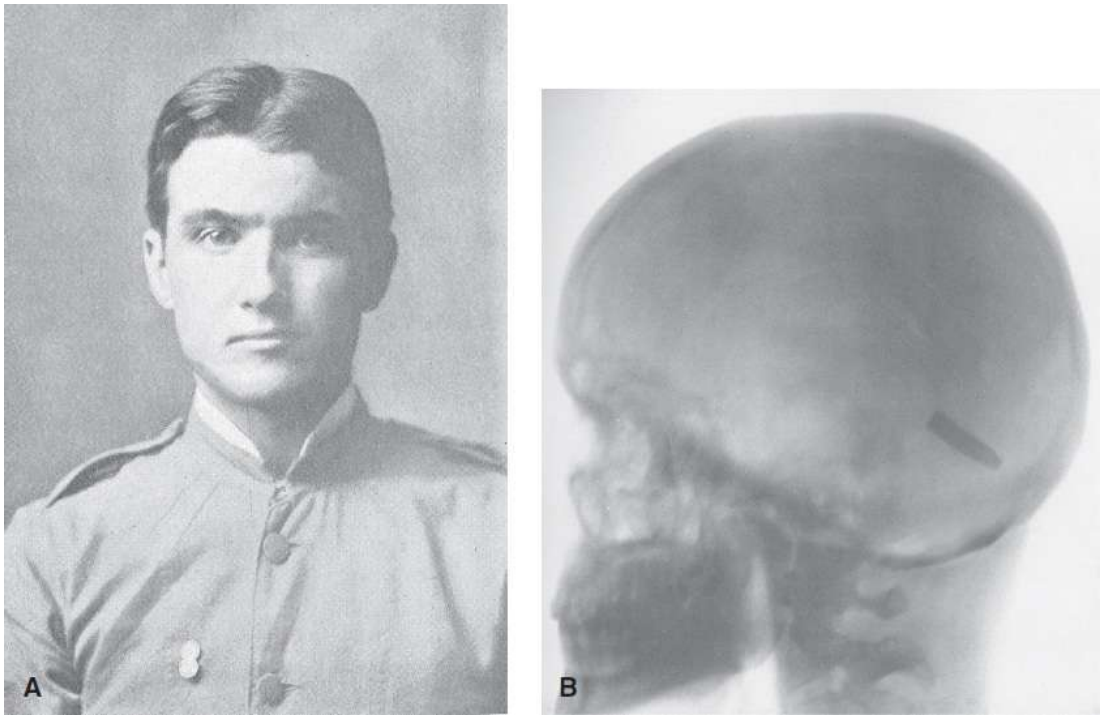

FIGURE 1.5. **A** and **B:** Private John Gretzer, Jr., Company D, First Nebraska

Volunteers, U.S. Army injury, wounded above his left eye at long range in combat at Mariboa, Philippines. Five months after the injury, he returned to duty in the military mail service. Diagnostic x-ray units were utilized by the U.S. Army Medical Department in the 1898 war with Spain and the Philippine insurrection—within 4 years of the discovery of the x-ray. (From *The use of the Roentgen ray by the Medical Department of the United States Army in the war with Spain (1898)*. Washington, DC: Government Printing Office, 1900.)

Curie was the son of a physician who had worked in the laboratory of Louis Pierre Gratiolet (1815–1865), who described the occipital visual pathways. Pierre Curie's doctoral thesis, "Magnetic Properties of Bodies at Diverse Temperatures," evaluated changes in magnetic properties of materials heated to high temperatures. He found that the magnetic properties of a substance change at a very specific temperature. This temperature is called the "Curie point" and is of great importance in studying plate tectonics, understanding extraterrestrial magnetic fields, and measuring the chemical contents of liquids. Curie also found that when crystals were pressed along their axis of symmetry, they produced an electric charge. This phenomenon is called "piezoelectricity," from the Greek word *piezin*, meaning "to squeeze," and is of importance in the operation of quartz watches, ink-jet printers, autofocus cameras, and medical ultrasound.

Marya Sklodowska (now using the French form of her first name, "Marie") and Pierre Curie wed on July 26, 1895.

For her doctoral thesis, Marie chose to investigate Becquerel's rays. She found that the intensity of the rays was affected neither by external conditions nor by any chemical process—they were an atomic property of the element. Marie observed that "it was obvious that a new science was in the course of development…. I coined the word *radioactivity.*"[12]

After confirming Becquerel's observations, Marie and Pierre Curie in 1898 published a paper entitled "Sur une substance fortement nouvelle radio-active, continue dans la pechblende on a new, strongly radio-active substance contained in pitchblende." The new radioactive substance was called polonium (named in honor of Poland). In late 1898, while working on polonium, they noticed another substance, chemically akin to barium and more radioactive than polonium. Demarçay found specific spectral characteristics of this new element, which was called radium (from the Latin word for "ray"). The Curies declined to patent their findings because, in Pierre's words, "it would be contrary to the scientific spirit." In 1903–1904, radium-226 began to be used in the treatment of patients with skin cancer and uterine cancer.[12] On June 25, 1903, Marie defended her

thesis “Researches on Radioactive Substances” and became the first woman in France to receive a doctorate. Later that year, the Curies and Becquerel shared the Nobel Prize in Physics.

On April 19, 1905, Pierre Curie was killed while crossing the Rue Dauphine near the Seine—run down by a horse-drawn carriage carrying 13,000 pounds of military equipment. Marie returned to work and described the radioactive decay series of polonium. In 1911, she became the first person to win the Nobel Prize twice, this time in chemistry.

When France entered World War I, Marie Curie assembled hospital and mobile x-ray units for the care of the wounded. The mobile units were dubbed “petites Curies.”[12] In March 1912, a glass tube containing 20 mg of radium was declared the international radium standard after comparison with a similar standard prepared in Vienna. The radioactivity unit was called Curie and defined as the emanation in equilibrium with 1 g of radium. In 1975, the International Commission on Radiation Units and Measurements replaced the Curie with the Becquerel (1 Curie = 3.7×10^{10} Bq). Marie Curie died on July 4, 1934, from the consequences of radiation exposure.

Irene (1897–1956) and Frederic Joliot-Curie (1900–1958)

In 1924, Marie Curie interviewed Frederic Joliot for a position in her laboratory. Joliot had a recommendation from the famed physicist Paul Langevin (1872–1946). Marie Curie’s daughter Irene also worked in the laboratory. Romance blossomed and Frederic and Irene were married in 1926. The two worked together in the laboratory.[13] A reporter for *Time* magazine wrote:

> Husband and wife work like one person with two heads, four hands, 20 fingers. “We compare notes,” says M. Joliot, “and exchange our thoughts so constantly that we honestly don’t know which of us is the first to have an original idea. Don’t you agree, ma chere?”[13]

Toward the end of 1931, the Joliot-Curies were studying the effects of alpha-particle irradiation of elements such as boron and beryllium. These metals gave off secondary radiations more penetrating than the gamma rays of radium. Interposing substances containing hydrogen in the beam, such as paraffin or cellophane, increased the intensity of secondary radiation. The couple considered these secondary radiations to be high-energy x-rays that knocked out protons from the atomic nucleus of hydrogenated substances. In England, James Chadwick conducted similar experiments with superior equipment.

Remembering that Ernest Rutherford had predicted the probable existence of a nuclear chargeless particle, Chadwick correctly deduced that the secondary radiations were this chargeless particle, the neutron. Frederic Joliot-Curie admitted that he had not read Rutherford's Bakerian Lecture where he had predicted the existence of this particle and said the credit for the discovery ought go to Chadwick.

In 1934, Irene and Frederic Joliot-Curie, by bombarding aluminum targets with alpha particles, transformed a naturally stable element into radioactive phosphorus. Additional radioactive isotopes were produced by the irradiation of fluorine, sodium, and other metals. The induction of "artificial radioactivity" created the field of nuclear medicine—but Frederic always insisted that so-called artificial radioactivity was identical with natural radioactivity. In 1935, they learned that they had been awarded the Nobel Prize in Physics for their work. Husband and wife divided the Nobel Lecture between them Frederic predicted that researchers would find ways of exploiting progressive transmutations of elements by irradiation such that "veritable chemical chain reactions" would be produced—intimating the creation of self-sustaining nuclear fission chain reactions. In 1936, Irene Joliot-Curie was appointed by the Socialist President of France Léon Blum as undersecretary of state for scientific research.[12–14]

Frederic Joliot realized the possibility of atomic release of large amounts of energy and the potential of this for warfare. He pursued experiments designed to establish that a sustained chain reaction could be produced through nuclear fission leading to the production of vast amounts of energy.

Joliot may well have been the first to achieve a sustained nuclear chain reaction had not the German invasion of France and the capture of Paris intervened. Frederic Joliot-Curie and his scientific collaborators spirited their stock of heavy water and uranium out of France just ahead of the Germans. The Joliot-Curies hid their scientific papers on nuclear fission in a vault. Frederic joined the French Resistance, whereas Irene, her health in decline, moved to the French Alps with the couple's daughter. Eventually, mother and daughter crossed over to Switzerland in 1944. One wonders what would have been different in the history of science if the couple had taken the opportunity to escape to England in 1940 and continue their work. They would, perhaps, have played an even greater role in the development of atomic energy.[13]

The work of Joliot-Curie was invoked in the famous letter Albert Einstein signed sent to President Franklin D. Roosevelt on August 2, 1939. The letter, written by the Hungarian American physicist Leo Szilard, was designed to spur

American action to assure that the United States would acquire nuclear weapons before Nazi Germany.

Einstein wrote:

> Some recent work by E. Fermi and L. Szilard, which has been communicated to me in manuscript, leads me to expect that the element uranium may be turned into a new and important source of energy in the immediate future. Certain aspects of the situation which has arisen seem to call for watchfulness and if necessary, quick action on the part of the Administration. I believe therefore that it is my duty to bring to your attention the following facts and recommendations.
>
> In the course of the last four months it has been made probable through the work of Joliot in France as well as Fermi and Szilard in America—that it may be possible to set up a nuclear chain reaction in a large mass of uranium, by which vast amounts of power and large quantities of new radium-like elements would be generated. Now it appears almost certain that this could be achieved in the immediate future.
>
> This new phenomenon would also lead to the construction of bombs, and it is conceivable—though much less certain—that extremely powerful bombs of this type may thus be constructed. A single bomb of this type, carried by boat and exploded in a port, might very well destroy the whole port together with some of the surrounding territory.
>
> In view of this situation you may think it desirable to have some permanent contact maintained between the Administration and the group of physicists working on chain reactions in America.
>
> I understand that Germany has actually stopped the sale of uranium from the Czechoslovakian mines which she has taken over. That she should have taken such early action might perhaps be understood on the ground that the son of the German Under-Secretary of State, von Weizsacker, is attached to the Kaiser-Wilhelm Institute in Berlin, where some of the American work on uranium is now being repeated.[13]

After the war, France created a civilian atomic energy authority. Frederic was appointed head of the Commisariate de l”Energie Atomique (CEA), the French

Atomic Energy Commission. In 1946, he was promoted to Commandeur de la Legion d'Honneur and was awarded the Croix de Guerre for heroism during the Nazi occupation of France. A member of the French Communist Party, Joliot was dismissed as high commissioner for atomic energy in 1950 because of his political views.

Irene Joliot-Curie died of acute leukemia in 1956. Frederic Joliot-Curie died in 1958.[13,14]

James Ewing (1866–1943)

For much of the 20th century, if a person was selected by the editors of *Time* magazine to appear on the weekly newsmagazine's cover, it was a mark of distinction. Individuals on the cover of the magazine were "newsmakers": important, notable, and worthy of your attention. The January 12, 1931, issue of *Time* portrayed a dignified pathologist in a drawing. "Cancer Man Ewing": The "weapon" referred to dedicated cancer institutions. "He wants six $10,000,000 weapons" (Fig. 1.6).

James Ewing, born in Pittsburgh in 1866, was the son of Thomas Ewing who began his career as a teacher and undertook the study of law at age 36. He became a judge in the Court of Common Pleas in Pittsburgh, became an elder of the Presbyterian Church, and was viewed as a leading local citizen. Ewing's mother, Julia, graduated in the first class of Mt. Holyoke College and became a teacher.[15,16]

Ewing's personal life was marked by a series of illnesses and tragedies. He developed osteomyelitis of the femur when he was 14 and was bedridden for two years, his wife died after <3 years of marriage from toxemia of pregnancy, he suffered from tic douloureux and was operated on by Harvey Cushing, a urinary calculus developed later in life, and he ultimately died of bladder cancer. It was said of him that adversity, suffering, disappointment, and sorrow left their mark on him not in the form of bitterness or disillusionment but in increasing sensibleness for the misfortune of others. "His sympathy and kindliness became almost legendary during his lifetime and the very legend of his benignity impressed itself on his character…That this benignity was not of the mere sentimental variety was shown by his intolerance of sham, hypocrisy, and mental laziness, which led him to be an unsparing critic."

FIGURE 1.6. James Ewing was on the cover of *Time* on January 12, 1951.

Ewing received his undergraduate education at Amherst College and was in the first class of the College of Physicians and Surgeons of New York that graduated after the institution had become affiliated with Columbia University.[15,16]

In 1899, Ewing was appointed the first professor of pathology at Cornell Medical College and held that position for 33 years. Ewing began to focus his interest on cancer when Mrs. Collis P. Huntington (c1851–1924) established the C.P. Huntington Fund for Cancer Research in 1902. The thrice-married Mrs.

Huntington was the heiress to a railway and industrial fortune and was said, by some, to be "the richest woman in America." Income from the fund was expended for cancer research at Cornell Medical College under Ewing's direction. Ewing's early studies focused on lymphosarcoma of dogs. (Many other US institutions benefited from the philanthropic support of C.P. Huntington and his wife including the Collis P. Huntington Memorial Hospital in Boston, the site of important early work in radiation therapy. After the closure of this hospital, some of its equipment was moved to the Massachusetts General Hospital.)

In 1919, after a decade of work, Ewing published the first of four editions of *Neoplastic Diseases*, the definitive reference of its time on tumor pathology. Unlike the multiauthored oncology books of today, including the one you are holding in your hands, *Neoplastic Diseases* was solely Ewing's work with >450 illustrations and 49 chapters (Box 1.1). He wrote in the preface to the first edition:

Box 1.1

A Definition of Cancer

For many years, it has been the habit of the author to ask medical students beginning a clinical elective on the radiation oncology service or new radiation oncology residents beginning their training, "How do you define the word cancer?" For someone beginning the study of cancer, this would seem to be the most fundamental question to answer at the outset. The question is most often met by a blank stare. Faced with the likelihood that, like these trainees, many of my readers have not grappled with this question, it seems worthy of some consideration in these pages.

James Ewing, who is profiled elsewhere in this chapter, spends many pages in the four editions of his definitive textbook, *Neoplastic Diseases*, trying to present a succinct definition. He settles on "a tumor is an autonomous new growth of tissue" while citing the attempts of others. He writes "Ziegler defined a tumor as a new growth of tissue which apparently originates and grows spontaneously, possesses an atypical structure, does not subserve the uses of the organism, and reaches no definite termination of its growth…. Adami accepts White's descriptive definition: 'A tumor proper is a mass of cells, tissues or organs resembling those normally present, but arranged atypically. It grows at the expense of the organism without at the same time subservient any useful function.'"[17]

The National Cancer Institute (NCI) Dictionary of Cancer Terms offers the following definition: Cancer is "a term for diseases in which abnormal cells divide without control and can invade nearby tissues. Cancer cells can also spread to other parts of the body through the blood and lymph systems."

If you were to line up a series of dictionaries and pathology textbooks on your desk, a turn each to the proffered definition of cancer, you will find phrases such as "an uncontrolled division of abnormal cells…," "a malignant tumor of potentially unlimited growth that expands locally by invasion and systemically by metastasis…," and "an abnormal growth of cells which tend to

proliferate in an uncontrolled way and, in some cases, to metastasize (spread)."

No matter what definition what chooses, there will always be exceptions. The best is the enemy of good, as Voltaire reminded us, and the lack of a perfect definition should not dissuade us from finding a good, working, reasonable definition. Here is the one the author recommends:

Cancer is a heritable disease of abnormal cell proliferation. In their abnormal cell proliferation the cells do not respect the usual constraints of space and time. Cancer is characterized by invasion and metastases.

Let's unpack the definition and look at its components.

Heritable: cancerous behavior is passed from mother to daughter cells;

Abnormal cell proliferation: the fundamental disease-causing aspect of cancer is abnormal cell proliferation.

Cells do not respect the usual constraints of space and time: Normal cell growth is constrained. If you cut yourself then fibroblasts being to proliferation to heal the wound. They grow and grow and then a cellular switch turns the grown off (except in keloid formation). Similarly, in embryonic development our cells proliferate to grow organs, at some point, however, the growth stops. Cancer cells don't stop growing when they bump up against adjacent cells (contact inhibition) or according to some internal time clock. Their growth is not constrained.

Invasive: As Ewing wrote "growth is infiltrative, single cells or cell groups pushing their way through and destroying adjacent tissues";

Metastases: Cancers can send forth colonizing cells via the blood, lymph, cerebrospinal fluid, or in the pleural or peritoneal spaces which can establish themselves and grow.

> Up to a very recent time it has been the prevailing impression that tumors fall into a limited number of grand classes in which the forms occurring in the several organs are so nearly related as to be virtually identical. Hence the practical physician or surgeon has been content without regard to the organ involved, and on this theory to treat the members of each class alike…I believe that this point of view has greatly retarded the progress of the knowledge of tumors, and it has been the writer's effort to combat such a conception, so far as present knowledge permits.[17]

In 1920, Ewing reported to the New York Pathological Society that he had observed a malignant tumor of the bone most frequently arising in teenagers and "composed of broad sheets of small polyhedral cells with pale cytoplasm, small hyperchromatic nuclei, well-defined cell borders, and complete absence of inter-

cellular material." He considered the tumor to be an "endothelioma of bone" arising from blood vessels. In a second report, he called the tumor an "endothelial myeloma." Ewing commented on the tumor's marked radiosensitivity, its tendency to invade soft tissues, and its ability to metastasize to lymph nodes.[18,19]

Ewing was quick to recognize the potential of radiation therapy for cancer treatment. He called it "the first rational treatment of cancer ever devised."[20] Ewing revisited radiation therapy many times in his publications:

> "From the most unexpected source, experimental physics, a new and powerful weapon has been brought into play."[21,22]

> "Radiation therapy, by demanding a detailed knowledge of the symptoms, clinical course and pathology of tumors, has introduced a new era in the study of cancer."[21]

> "Cancer research has entered a…fruitful era of therapeutics and more intelligent descriptive study…The developments of radiotherapy have opened a new biology of tumors, have stimulated new lines of research and suggested new concepts…many new facts and principles of tumor growth have been brought to light."[22,23]

Ewing conducted experimental work on cancer, vigorously worked to secure the funding for the establishment of New York's Memorial Hospital for Cancer and Allied Diseases (now called Memorial Sloan Kettering Cancer Center), investigated the role of radium in the treatment of cancer and worked to establish the production of radium in the United States, wrote four editions of the *Neoplastic Diseases*, and helped found the American Society for the Control of Cancer (now called the American Cancer Society) in 1913 and served on the organization's governing board for more than 30 years.[24]

Ewing viewed an organized war on cancer was a societal imperative and that success would be slow and incremental (Fig. 1.6):

> It is a growing conviction that to know cancer in man, one must study the disease most carefully in the human subject. Personally, I do not look for any startling advances or sensational discoveries, since it is much more likely that a steady reduction in the mortality from cancer will come chiefly from a large number of separate factors, of which the most significant appear to be increased control of the conditions leading to cancer, more

> general recognition of the preliminary stages of the disease, early diagnosis, and treatment of the established disease. From the consideration of these various functions of the modern cancer research hospital, I think that it must be evident that such an institution not only can justify its existence, but fill a very urgent need without which progress of cancer research would be handicapped and much relief that might early be extended to cancer victims would be unavailable. Nor is there any doubt that the function of supporting such an institution is properly exercised by the State, which support should be continuous and liberal.[25]

At the age of 76, Ewing fractured his right femur. The fracture site showed metastatic bladder carcinoma. He died of bladder cancer in 1943.

M. Vera Peters (1911–1993)

Mildred Vera Peters (known throughout her career as Vera) was born and raised on a farm in Ontario, Canada, and received her elementary education in a one-room schoolhouse. After high school, she enrolled in the Faculty of Medicine of the University of Toronto and graduated in the class of 1934. During medical school, she met her future husband. Peters' mother had been treated at the Radiotherapy Institute of the Toronto General Hospital by Dr. Gordon Richards but died while her daughter was still in medical school.

Dr. Peters, after a one-year internship at St. John's Hospital, a women's surgical hospital in Toronto, joined Richards as a trainee—although there was no formal residency program in radiotherapy. A 400-kV treatment unit was installed at Toronto General Hospital in 1937, the same year Dr. Peters was appointed to the hospital's full-time staff as junior assistant radiotherapist. She became one of the first female physicians to have a clinical appointment at a Toronto teaching hospital.

Peters can be justly credited for two major contributions to modern radiotherapy. We will consider, first, her role in the development of curative treatment for Hodgkin disease. In 1947, Richards stopped Peters in the hallway at the Toronto Radiotherapy Institute and in his characteristically formal way said, "Dr. Peters, how would you like to review out experience with Hodgkin's disease? All the textbooks say it is a fatal disease, but we seem to be seeing patients who are cured." In response, Peters carefully reviewed the Toronto clinical experience, working at night at home on records and files at her kitchen table while balancing her career, her marriage, and the care of her children[26].

Richards died in 1949 before Peters completed her study. By 1950, Peters published the first of a series of landmark papers in which she described a three-level staging system for Hodgkin disease and observed the prognostic importance of constitutional symptoms[26]. The current staging system of Hodgkin disease is based on the foundation laid by Peters. She also reported superior survival rates to those previously described and observed that irradiation of involved lymph nodes along with inclusion of adjacent nodal groups in the radiotherapy fields improved survival in early-stage disease. Peters also identified factors, which predicted findings in staging laparotomy and the value of lymphangiography. She persisted in reporting her findings and advocating for the curability of Hodgkin disease in spite of denigrating treatment by prominent male radiation oncologists.

Peters was also one of the pioneers in the development of techniques for the conservative management of early-stage breast cancer. She began to study a cohort of women who were treated with lumpectomy and radiation therapy in contrast to the prevailing wisdom favoring modified radical mastectomy. The patients Peters studied had received limited surgery and radiation either because of advanced age, poor general medical condition, the patients' refusal to accept their surgeon's advice to have radical surgery and, instead, insisting upon breast conservation, or the views of a limited number of surgeons favoring more conservative treatment. Peters observed that cancer-specific survival rates in these women seemed no different than those treated with radical surgery. In 1967, Peters published a paper in JAMA (*Journal of the American Medical Association*) titled "Wedge resection and irradiation: an effective treatment in early breast cancer."[27]. She also began giving lectures arguing that for stage I and early-stage II breast cancer patients, lumpectomy and radiotherapy were as effective as radical surgery. She continued to publish and lecture on the topic until her retirement in the mid-1970s. The rise of the women's movement and its associated contribution to the insistence of women to have a say in their treatment, and not be subservient to the dictates of a largely male-dominated medical profession, helped promote Peters' views. Large-scale randomized prospective clinical trials ultimately validated her initial observations.

Ernest Rutherford (1871–1937)

Many essential aspects of our understanding of atomic structure can be directly or indirectly attributed to the work of Ernest Rutherford. Rutherford's supervisor discovered the electron, Rutherford discovered the proton, and Rutherford

predicted the existence of the neutron and his student discovered it. In the words of one of his biographers, the radiation oncologist Juan A. del Regato, “He became the outstanding atomic physicist of his time: amid a constellation of brilliant protagonists, he was second to none; in an era of rapidly developing, new revolutionary concepts, his own prevailed.”[28]

Born in New Zealand, Ernest Rutherford received his BA and MS degrees at Canterbury College, Christchurch, New Zealand, received a scholarship to continue his studies at Cambridge University in England, and began work in the Cavendish Laboratories under the supervision of Professor Sir J. J. Thomson (1856–1940), discoverer of the electron and recipient of the 1906 Nobel Prize in Physics for his work on the conduction of electricity in gases. Within a few weeks of Rutherford’s arrival in England, Röntgen’s discovery of the x-ray became known. Thomson and Rutherford soon demonstrated the ability of x-rays to produce ionization in gases.

In 1898, Rutherford accepted the professorship of physics at Montreal’s McGill University. It was at McGill that he identified and named alpha- and beta-radiation and also described the concept of radioactive half-life. In collaboration with the chemist Frederick Soddy (1877–1956), he developed a disintegration theory of radioactivity in which chemically different elements undergo a series of changes with decreasing radioactivity at each step. Most radioactive elements, they concluded, are the product of this successive decay[28].

In his 1904 Bakerian Lecture, he laid out a broad and prescient view of radioactivity. In 1907, Rutherford became professor of physics at Victorian University of Manchester, England. He demonstrated that alpha particles were helium atoms. The next year, he was awarded the Nobel Prize in Chemistry for “investigations into the disintegration of elements and the chemistry of radioactive substances.”

Rutherford collaborated with Hans Wilhelm Geiger (1882–1945) and invented what is generally called the Geiger counter or scintillation counter to identify radioactivity. Working in Rutherford’s laboratory, Geiger and Sir Ernest Marsden (1889–1970) observed that alpha particles that were streamed into a thin metal foil were sometimes scattered at very wide angles. Rutherford reasoned that this was the result of the alpha particles encountering an atomic particle of large size. The atom, he concluded, had a central, large, positively charged portion surrounded by negatively charged electrons.

After World War I ended, Rutherford returned to Cambridge University to succeed Thomson as professor and director of the Cavendish Laboratory.

Rutherford proved that the hydrogen nucleus is present in other nuclei. He could show that hydrogen nuclei were produced as a product of the impact of alpha particles on nitrogen gas. The majority of air consists of nitrogen. When alpha particles passed through air scintillation, detectors showed the signatures of typical hydrogen nuclei as a product. When alphas were fired into pure nitrogen gas, the effect was larger. Rutherford determined that hydrogen could have come only from the nitrogen, and therefore nitrogen must contain hydrogen nuclei. One hydrogen nucleus was being knocked off by the impact of the alpha particle, producing oxygen-17. $^{14}N + \alpha \rightarrow {}^{17}O + p$.[86,88]

Insofar as the hydrogen nucleus is present in all other nuclei as an elementary particle, Rutherford decided to give the hydrogen nucleus a special name as a particle, since he suspected that hydrogen, the lightest element, contained only one of these particles. He named this new fundamental building block of the nucleus the *proton*, after the neuter singular of the Greek word for "first."

After the experiments of Walther Wilhelm Georg Franz Bothe (1891–1957) and Herbert Becker who, when they bombarded boron and beryllium with alpha particles, found that they produced a beam more penetrating than gamma rays, and the work of the Joliot-Curies (described in the section devoted to them), and Sir James Chadwick (1891–1974), the neutron was identified. Rutherford had predicted its existence in 1923. Chadwick was the 1935 Nobel Laureate in Physics. Bothe shared the 1954 Nobel Prize in Physics for his role in the description of wave–particle duality.[28]

THE ORIGINS OF CLINICAL RADIATION THERAPY

External beam radiation therapy (EBRT) quickly showed itself to be a useful form of cancer treatment. Only 8 years after Röntgen's discovery, Dr. Charles L. Leonard, in 1903, observed that:

> in spite of the most diligent study, there is nothing known of the etiology and histology of malignant disease that aids its treatment. Its development and fatal termination cannot be retarded, if the diseased tissue be permitted to remain in the body. Total extirpation by surgical intervention has been the only chance of cure.[29]

Leonard, however, discerned some promise in a new form of treatment"

> The results obtained by the use of the Röntgen rays seems to… have demonstrated their power to alter the character of malignant cells, to

> prevent their spread and development, and to produce retrograde changes that result in fatty and cystic degeneration or absorption, and often terminate in a restoration of the affected part to a nearly normal state…. The Röntgen treatment applied as a palliative in many hopeless, operatively impossible cases, has resulted frequently in cures that, if not permanent, have at least restored the patient to health and given months and even years of usefulness…. The results so far obtained are, therefore, very encouraging. An agent has been found which has a greater influence in retarding the growth of malignant tumors than any heretofore known. Many remarkable and apparently permanent cures have been obtained.[29]

Although it is controversial, most likely Leopold Freund was the first to report, in 1897, the use of ionizing radiation to "cure" a large nevus pigmentosus on the back of a young girl. Unfortunately, she later developed skin ulceration and scars.[30] Another pioneer in the therapeutic use of x-rays was Victor Despeignes who, in 1896, published on the treatment of a 52-year-old man who had an advanced stomach tumor (likely a lymphoma), with "considerable improvement in the condition of the patient."[31]

At the International Congress of Oncology in Paris in 1922, Coutard[32] and Hautant presented evidence that advanced laryngeal cancer could be cured without disastrous, treatment-induced sequelae. By 1934, Coutard[33] had developed a protracted, fractionated scheme that remains the basis for current radiation therapy, and, in 1933, Paterson[34] published results on the classification of tumors in relation to radiosensitivity.

The use of brachytherapy, starting with radium 226 (^{226}Ra) needles and tubes, is useful in the treatment of malignant tumors in many anatomic locations. Isotopes such as cesium, iridium 192 (^{192}Ir), iodine 125 (^{125}I), and palladium 103 (^{103}Pd) were generated from nuclear reactors, and the use of afterloading techniques, including remote afterloading devices and high–dose rate (HDR) brachytherapy, has contributed to this important treatment modality. With time, ionizing radiation became more precise; high-energy photons, electrons, protons, neutrons, and carbon ions became available for treatment; and treatment planning and delivery became more accurate and reproducible. Advances in computer and electronic technology fostered the development of more sophisticated treatment planning and delivery techniques, leading to the development and eventually broad implementation of three-dimensional conformal radiation therapy (3DCRT) and intensity-modulated radiation therapy

(IMRT) (Box 1.2).

Box 1.2

A Call to Arms

An Institute on Cancer meeting was conducted at the University of Wisconsin in Madison in 1936. Among the prominent scientists in attendance were James Ewing, professor of oncology at Cornell University Medical College, after whom Ewing sarcoma is named; Gioacchino Failla, the famous radiation physicist of the Memorial Hospital for Cancer and Allied Diseases of New York; and Henri Coutard, pioneer radiation therapist of the Curie Institute of Paris. Glenn Frank, president of the University of Wisconsin, addressed the scientists on the first day of the meeting. Seventy-five years later, Frank's opening address remains a moving call to arms for basic science, translational, and clinical researchers, physicists, and clinicians.[35]

"Down the ages, cancer has been the most hideously persistent and the most persistently hideous enemy of mankind, the suffering it lays upon men intolerably horrible, its toll of life progressively devastating, its blows falling so often just when men have reached the years of ripest usefulness to family and state. But not all these tragic consequences together are the worse evil wrought by cancer. For every *body* that is *killed* by the *fact* of cancer, multiplied thousands of *minds* are *unnerved* by the *fear* of cancer. What cancer, as an unsolved mystery, does to the morale of millions who may never know its ravages is incalculable. This is an incidence of cancer that cannot be reached by the physician's medicaments, the surgeon's knife, or any organized advice against panic. Nothing but the actual conquest of cancer itself will remove this sword that today hangs over every head. I can remember, as a boy in rural Missouri, that death from cancer was rarely mentioned and then only with bated breath. I realize now that this reaction was born of a feeling of utter helplessness and awe in the presence of a mysterious enemy. That almost primitive reaction to cancer has happily vanished. We have not penetrated the mystery, but, thanks to you and your colleagues the world over, we have made notable rents in the veil surrounding the mystery. The world is determined to conquer this thing that steals upon men like a thief in the night and without warning strikes down the strong and weak alike. By one thing alone can this conquest come, and that is by the tireless, painstaking, and self-sacrificing genius of scientists who, like yourselves, go to their laboratory tables as to an altar and sink their lives in the great adventure of emancipating mankind from the fact and fear of this plague. Surely, if anywhere in the secular activities of men, there is a spark of divinity in lives so dedicated!"[35]

A DEFINITION OF RADIATION ONCOLOGY

Radiation oncology is that discipline of human medicine concerned with the generation, conservation, and dissemination of knowledge concerning the causes, prevention, and treatment of cancer and other diseases involving special expertise in the therapeutic applications of ionizing radiation (Box 1.3). As a discipline that exists at the juncture of physics and biology, radiation oncology addresses the therapeutic uses of ionizing radiation alone or in combination with other treatment modalities such as biologic and immunologic and cellular

therapies, surgery, drugs, oxygen, and heat. Furthermore, radiation oncology is concerned with the investigation of the fundamental principles of cancer biology, the biologic interaction of radiation with normal and malignant tissue, and the physical basis of therapeutic radiation. As a learned profession, radiation oncology is concerned with clinical care, scientific research, and the education of professionals within the discipline.

Radiation therapy is a clinical modality dealing with the use of ionizing radiations in the treatment of patients with malignant neoplasias (and occasionally benign diseases). The aim of radiation therapy is to deliver a precisely measured dose of irradiation to a defined tumor volume with as minimal damage as possible to surrounding healthy tissue, resulting in eradication of the tumor, a high quality of life, and prolongation of survival or palliation of symptoms at a reasonable cost. In addition to curative efforts, radiation therapy plays a major role in cancer management in the effective palliation or prevention of symptoms of the disease: Pain can be alleviated, luminal patency can be restored, skeletal integrity can be preserved, and organ function can be re-established with minimal morbidity[36] (Box 1.2).

Box 1.3

The Etymology of *Radiate*

The defining verb of the discipline of radiation oncology, *radiate*, is derived from the Latin verb *radiatus. Radiatus* is the participial stem. Some dictionaries cite the origin of the word *radiate* as being from other tenses of the verb such as the present infinitive *radiarae* or the first-person singular present indicative *radio.* Radiate is defined as “to spread from the common center” or “to diverge or spread from the common point” or “to issue and raise.” Radiate shares a common root and related meanings with other English words such as *ray*, *radius*, and *radial.* The verb *radiate* is more distantly related to other words. For example, if one proceeds along the ray from the political center to the extreme, then one is called *radical.*

The verb *irradiate* means “to direct rays upon” or “to cause rays to fall upon something.” In Latin, the prefix *in* conveys the meaning of in, within, on, upon, or against. When the prefix *in* is used with the word that begins with the letter *r*, the letter *r* is substituted for the letter *n* in the prefix to assimilate the initial sound of the verb. Thus, the verb that indicates the placement of water within or on the ground changed from *inrigate* to *irrigate.* Similarly, *inradiate* was changed to *irradiate.*

An object may be said to radiate something or to emit a ray. For example, “The block of cobalt 60 radiates gamma rays.” The verb that indicates directing rays on or into an object is *irradiate.* An example of proper usage would be “I recommend that we irradiate the tumor to a total dose of 45 Gy.” Incorrect usage would be “I think the primary tumor should be radiated to a dose of 45 Gy.”[37]

In 1962, Buschke defined a radiotherapist as a physician whose practice is

limited to radiation therapy. He emphasized the active role of the radiation oncologist:

> While the patient is under our care we take full and exclusive responsibility, exactly as does the surgeon who takes care of a patient with cancer. This means that we examine the patient personally, review the microscopic material, perform examinations and take a biopsy if necessary. On the basis of this thorough clinical investigation we consider the plan of treatment and suggest it to the referring physician and to the patient. We reserve for ourselves the right to an independent opinion regarding diagnosis and advisable therapy and if necessary, the right of disagreement with the referring physician…. During the course of treatment, we ourselves direct any additional medication that may be necessary… and are ready to be called in an emergency at any time.[38]

To integrate the various disciplines and provide better care to patients, the radiation oncologist must cooperate closely with other specialists.[38,39]

THE PLANNING AND CONDUCT OF A COURSE OF RADIATION THERAPY

When a physician proposes administering radiation therapy to a patient, six fundamental questions must be answered. Once these questions have been answered, an appropriate first step has been taken toward the development of a comprehensive justification and plan for the conduct of a course of radiation therapy. The six questions are:

- What is the *indication* for radiation therapy?
- What is the *goal* of radiation therapy?
- What is the treatment *volume*?
- What is the treatment *technique*?
- What is the treatment *dose* and *fractionation*?
- What is the radiation *tolerance* of surrounding normal tissues?

The *indication* for radiation therapy is that body of data that can be brought to bear showing that radiation therapy would be efficacious for the patient's condition. Such data might exist in the form of retrospective single-institution reviews of the specific malignancy, which provide evidence favoring the role of radiotherapy. Phase I and II studies demonstrating safety and possible efficacy

could be invoked to justify a course of radiation therapy. For many physicians, the gold standard, however, is a prospective, randomized, phase III trial that demonstrates the value of radiation therapy. There remains a role for sound personal clinical experience. Although there is increasing reliance on published trials, and special deference is given to double-blind, prospective, randomized phase III trials, it is still appropriate for a physician to rely firmly on his or her clinical experience in the context of an intimate knowledge of the patient's problems. A sound scientific basis and an extensive knowledge of clinical research augment the essential nature of the physician–patient relationship, but they do not substitute for it.

Radiation therapy can be justified either because it improves local tumor control, ameliorates a specific symptom, improves the quality of life, or increases the probability of cure. Any data used to justify a course of radiation therapy must have a clearly defined endpoint, appropriate data analysis, and accepted statistical methodology. It is incumbent on the radiation oncologist to know how to critically evaluate the scientific literature and synthesize it in the best interest of the patient.

There are two possible *goals* of radiation therapy. *Curative* radiation therapy is used for the purpose of curing the patient where one is willing to engender a small risk of significant side effects in return for the possibility of cure. An example is the use of radiation therapy for the treatment of early-stage breast cancer. In return for a high probability of cure, one is willing to engender a very small risk of pneumonitis. *Palliative* radiation therapy is designed to ameliorate a specific symptom such as pain, obstruction, or bleeding. When palliative radiation therapy is used in the context of an incurable malignancy, one is not willing to engender a significant risk of side effects to achieve a palliative goal. Thus, if one wishes to relieve pain from lung cancer metastatic to a bone, one would pick a dose and technique of radiation therapy sufficient to relieve pain but not enough to run a risk of radiation osteonecrosis.

The questions of *indication* and *goal* are generic. They should be answered irrespective of the modality of therapy being used for the treatment of malignancy. It is reasonable to ask for indications and goal if one is planning on using chemotherapy, surgery, cellular therapy, immunotherapy, hyperthermia, biologic therapy, or radiation therapy.

Oncologists are often better at formulating indications for curative than for palliative therapy. It is not good palliative medicine to make the patient ill from therapy in order to make asymptomatic metastatic masses smaller. In palliative

cancer treatment, one must treat the patient and his or her symptoms and not treat the mass devoid of its context.

The next three of the six major questions, *volume*, *dose*, and *technique*, are not generic—they are specific to the discipline of radiation oncology. First, the radiation oncologist must consider *volume* (Fig. 1.7). What is the appropriate volume of tissue that needs to be irradiated for the purpose of achieving the desired curative or palliative goal in the context of the justification? Does one need to treat strictly the visualized or palpable tumor mass? Is it also appropriate to treat the mass and surrounding lymphatic drainage? Does one have to worry about the routes of spread of microscopic disease? All of these are crucial questions in formulating a plan for a course of radiation therapy. If radiation oncologists only needed to treat visible or palpable masses, then radiation oncology would be more of a physics exercise than the practice of human medicine. Understanding a cancer's routes of spread and the tolerance of organs surrounding the cancer requires honed clinical judgment.

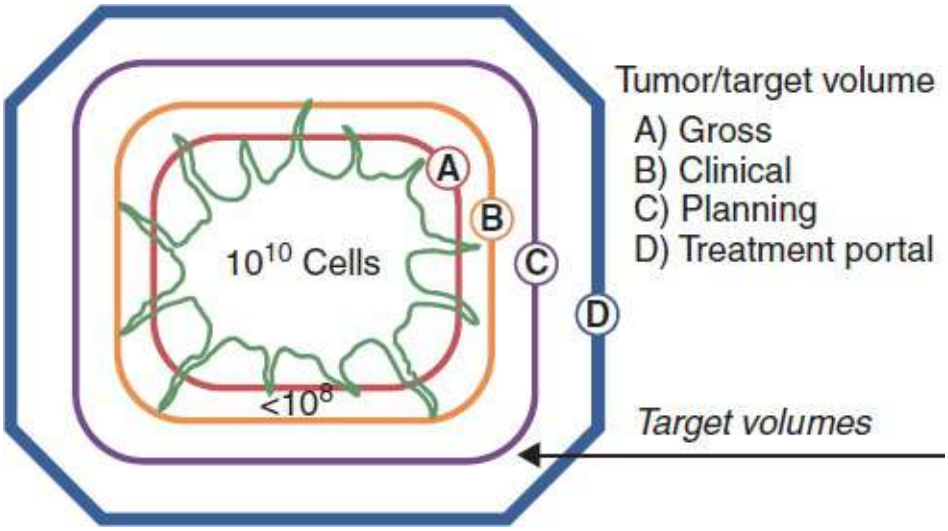

FIGURE 1.7. Schematic representation of "volumes" in radiation therapy. The treatment portal volume includes the tumor volume, potential areas of local and regional microscopic disease around the tumor, and a margin of surrounding normal tissue. (Modified from Perez CA, Purdy JA. Rationale for treatment planning in radiation therapy. In: Levitt SH, Khan FM, Potish RA, eds. *Levitt and Tapley's technological basis of radiation therapy: practical clinical applications*. 2nd ed. Philadelphia: Lea & Febiger, 1992. With permission.)

An example of the problem of volume in the radiation therapy of cancer is medulloblastoma, a tumor that arises in the posterior fossa of the human brain. If, however, one treats with resection alone, patients almost uniformly relapse both locally and by leptomeningeal dissemination via the cerebrospinal fluid.

Thus, the treatment volume for radiation therapy of medulloblastoma, in children >3 years old, is the area within the posterior fossa wherein the tumor arises and the entire craniospinal axis. Another example of the problem of treatment volume would be in head and neck cancer. Many of these tumors, by physical examination and by diagnostic imaging, appear to be localized at their site of origin. For many of these squamous cell cancers, there is, however, a high incidence of dissemination to the lymph nodes of the neck. Thus, the appropriate radiation therapy treatment volume would include both the primary tumor site and the neck.

The next question that the radiation oncologist must face is what is the appropriate *technique*.

Radiation oncologists, in general, have two techniques at their disposal. The first, *teletherapy*, has a similar etymology to telephone, telegraph, and telepathy. It refers to the projection of radiation through space. Teletherapy is administered with external beam sources such as a cobalt 60 (^{60}Co) machine or a linear accelerator. If one elects to treat a patient with teletherapy, one must derive appropriate external beam treatment plans. These plans include considerations such as whether the patient should be treated with photons, electrons, neutrons, carbon ions, or protons; with parallel-opposed fields, four fields, or multiple oblique fields; with IMRT; with or without respiratory gating; with or without compensators; and the like. There has been an explosion of interest in techniques of EBRT related to improvements in sophisticated diagnostic imaging and the rapidly increasing power of computers to allow manipulation of vast amounts of data.

Brachytherapy is the other important technique of radiation therapy. The word brachytherapy shares an etymology with words such as brachycephaly and brachydactyly. It refers to short or slow therapy (i.e., a radioactive implant). There are several broad categories of brachytherapy. These include *interstitial* brachytherapy, *intracavitary* brachytherapy, and *mold* therapy. Interstitial brachytherapy refers to the placement of radioactive sources directly into tissue. An example might be the implantation of the tumor bed for breast cancer or soft tissue sarcoma. Intracavitary radiotherapy refers to the placement of a radioactive source in a body cavity such as sources placed within the nasopharynx or against and through the cervical os. Mold brachytherapy refers to the placement of radioactive sources on the skin surface, such as treatment utilized for a superficial malignancy on the back of the hand. If brachytherapy is used, the radiation oncologist must determine the appropriate isotope and

whether that isotope is to be delivered by an afterloading technique or by a direct radioactive application (a hot implant).

Once the radiation oncologist has determined the appropriate treatment volume and the treatment technique(s), he or she must determine the appropriate radiation *dose.* Radiation dose selection is a complex issue. One must determine the correct number of *fractions* of radiation per day, the correct dose per fraction, and the proposed total dose of irradiation. Furthermore, in certain situations, the dose rate (i.e., the number of cGy per minute) matters, such as in total-body irradiation (TBI) for bone marrow transplantation and in brachytherapy. Decisions concerning dose will, in part, be driven by decisions concerning treatment volume and technique. Paramount in the physician's mind will be the goal of treatment. The physician must determine what the correct dose is to achieve the proposed curative or palliative goal. In broad terms, the radiation oncologist must consider what is known about the dose–response relationship for tumor control in a particular clinical situation. This subject, addressed in detail elsewhere in this chapter, concerns the probability of tumor control within a radiation therapy field as a function of the dose administered.

Finally, the radiation oncologist must consider normal tissue *tolerance.* In general terms, the probability of acute and late ill effects of radiation is a function of dose. Ultimately, the prescription of a dose requires the radiation oncologist to engage in a balancing act between a sufficient dose of radiation to achieve the desired treatment goal and not giving so much dose as to engender an unacceptable risk of side effects.

The fundamental questions of radiation therapy are not for the physician alone. A patient has the right to be apprised of the physician's views on these questions, probability of tumor control (and cure, if possible), and sequelae. This information should be presented to the patient in an appropriate intellectual, social, and cultural context (i.e., in a manner in which the patient can understand), translated skillfully into the patient's preferred language if necessary, so that the patient becomes a full partner in his or her care. The signing of an informed consent document by the patient is the norm, but a signed document does not substitute for a proper doctor–patient conversation.

EXTERNAL BEAM RADIATION TREATMENT PLANNING

Treatment Volume

Tumor cell killing by ionizing radiation is an exponential function of dose (Box

1.4). The dose required for a certain level of tumor control probability (TCP, or local control) is proportional to the logarithm of the number of clonogenic cells in the tumor. Subclinical extensions of tumor (also called microscopic disease or disease below the level of ready clinical detection) should be controlled, in general, by a lower dose of radiation than is required for a palpable tumor mass. Microscopic tumor extensions may be less likely than bulky tumors to contain hypoxic cells. This also means that they may be more readily controlled by radiation.

Insofar as the dose tolerated by normal tissue is inversely related to the volume of normal tissue irradiated, delivering a uniform physical dose of radiation requires that one choose between the risks of marginal recurrence around small volumes of high dose, central recurrences in large volumes of low dose, or excessive normal tissue damage and large volumes of high dose. We may conclude that different doses of radiation are required for a given probability of tumor control, depending on the type and initial number of clonogenic cells present.

Box 1.4

Logarithmic Cell Kill

Among the simplest exercises a radiation oncologist–in-training can undertake is the creation of a table of logarithmic cell kill. At first, such an exercise seems trivial. The effort expended on this somewhat tedious exercise will, however, be repaid many times over.

Let us assume that we have a tumor that follows a typical cell survival curve. These tumor cells have a 50% probability of cell survival after a radiation dose of 2 Gy. If we assume, for the purpose of this exercise, that there are no changes in the probability of cell kill wrought by changes in tumor oxygenation, pH, or other factors during the course of treatment; that there is no accelerated repopulation; and that only the simplest conditions apply (i.e., that there is 50% kill for each dose), then we can create a table showing the number of cells killed and the number of cells remaining after each dose (Table 1.7).

Let us assume that we begin with a relatively small tumor (i.e., a spherical tumor a bit more than 1 cm in diameter containing, say, 10^9 cells). At each dose of 2 Gy, 50% of the cells are killed. Thus, after the first dose, 500 million cells are killed and 500 million cells remain. At each successive dose, 50% of the cells are killed. Therefore, by the end of the course of radiation, very few cells are killed with each individual dose.

One can see, from going through the exercise, that even for a very small tumor, the number of initial cells is very large and the marginal killing of the absolute number of cells, with the last few doses, is small. It is not surprising, therefore, that for a tumor of average radiation sensitivity, quite a high dose of radiation is required.

Obviously, the exercise would change if we were to use a different radiation dose per fraction, producing a different probability of survival, or if the intrinsic radiosensitivity of the tumor cell line were different and the probability of survival were different.

Based on Suit HD. Radiation biology: a basis for radiotherapy. In Fletcher GH, ed. *Textbook of radiotherapy*. Philadelphia: Lea & Febiger, 1966.

A shrinking field technique is a rational approach to the problem of heterogeneous tumor distribution (Fig. 1.8). Withers and Taylor[40] have argued that "in the ideal case, the doses would be graded to provide a homogeneous TCP throughout the treatment volume rather than a homogeneous physical dose distribution." We are entering an era of "dose painting" where a heterogenous dose will be layered on a tumor as determined by sophisticated imaging tools.[41] The radiation oncologist delivers varying radiation doses to certain portions of the tumor (periphery vs. central portion or metabolically active vs. inactive on computed tomography [CT]/positron emission tomography [PET]) or may vary the dose in cases in which gross tumor has been surgically removed.

The International Commission on Radiation Units and Measurements (ICRU) Report 50 has recommended definitions of terms and concepts for radiation therapy treatment volumes and margins[42]:

- The gross tumor volume (GTV) denotes demonstrable tumor. It includes all known gross disease including abnormally enlarged regional lymph nodes. In the determination of GTV, it is important to use the appropriate imaging modality and physical examination to give the maximum dimension of what is considered potential gross disease.
- The clinical target volume (CTV) denotes the GTV and subclinical disease (i.e., volumes of tissue with suspected tumor).
- The planning target volume (PTV) denotes the CTV and includes margins for geometric uncertainties. One also should account for variation in treatment setup and other anatomic motion during treatment such as respiration.

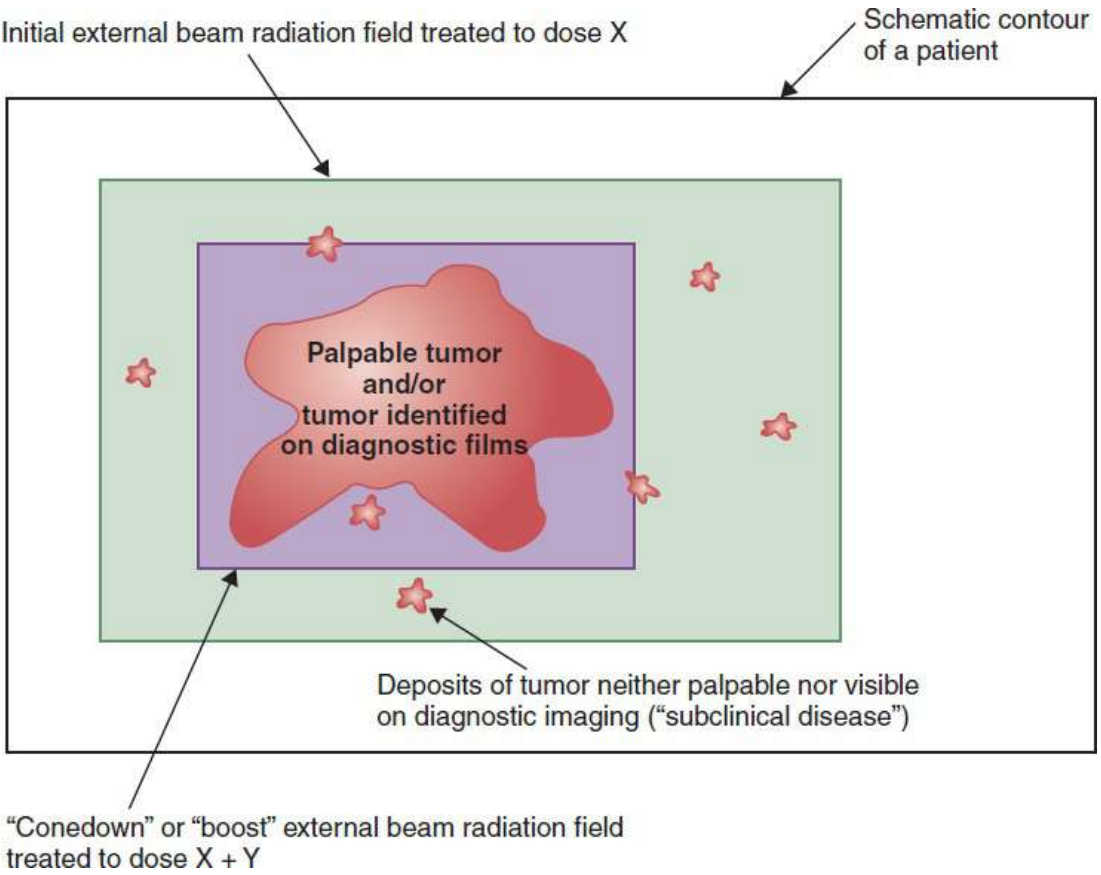

FIGURE 1.8. Cell killing by ionizing radiation is an exponential function of dose. It follows that the dose required for a certain level of tumor control probability (TCP) is directly proportional to the logarithm of the number of clonogenic cells in the tumor deposit. It would be reasonable to expect that subclinical extensions of disease could be controlled by a lower dose of irradiation than what is required for a bulky palpable tumor mass. It has been argued by some researchers that microscopic tumor extensions are less likely to contain hypoxic foci that will minimize the requirement for reoxygenation for their control—but this is controversial. Insofar as the dose tolerated by a tissue is inversely related to the volume of tissue irradiated, delivering a uniform physical dose requires that one choose between the risk of marginal recurrences around small volumes of high dose, central occurrences in large volumes of low dose, or excessive normal tissue damage in large volumes of high dose. A reasonable approach is to use a shrinking-field technique in which one delivers an initial external beam field that is treated to dose X and then "cones down" to a smaller field to treat to dose X + Y. In the ideal case, doses are graded to provide a homogeneous TCP throughout the treatment volume rather than a homogeneous physical dose distribution. (Based on a concept articulated by Withers HR, Peters LJ. Biologic aspects of radiotherapy. In: Fletcher GH, ed. *Textbook of radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger, 1980:142.)

Because the PTV does not account for treatment machine characteristics, the actual treated volume is that volume enclosed by an isodose surface that is selected and specified by the radiation oncologist as being appropriate to achieve the goal of treatment. It is impossible to design a radiation therapy treatment

plan that limits the prescribed dose to the PTV only. Some tissues en route to the target or near the target also will be irradiated to the same dose as the target. The treated volume is, therefore, almost always larger than the PTV and usually has a somewhat simpler shape.

- The irradiated volume is that volume of tissue that receives a dose considered significant in relationship to tissue tolerance. This would include tissues in the exit region of unopposed photon, electron, or neutron beams or in the penumbra region of a beam.
- The planning organ at risk volume refers to the definition of margins around organs at risk (OARs) for injury by radiation. For example, one might define a 0.5-cm margin around the optic chiasm to avoid the risk of blindness.

Uncertainties

There are, inevitably, uncertainties in the planning and delivery of a course of radiation therapy. These were well characterized by the esteemed dosimetrist Gunilla Bentel[43,44] (1936–2000), to whom I am grateful for the following discussion (Box 1.5).

Uncertainties are divided into two general categories. First, there are uncertainties related to the delivery of dose. These include inhomogeneities in the beam, problems related to dose calculations, variables in the output of treatment machines, instability of the beam monitoring technique, and problems related to beam flatness. Spatial uncertainties in the delivery of radiation therapy may be divided into those related to mechanical inaccuracies in the equipment and those related to the patient.

Mechanical Uncertainties

- *Field-size settings.* There can be errors related either to mechanical dials or digital settings in which the field-size set on the machine is not precisely the same as that delivered.[290]
- *Rotational settings.* Mechanical or digital settings that display the degree of angulation of the gantry or the collimator may be in error.
- *Cross hairs.* Wires in the linear accelerator designed to show the central axis or the field edges may become displaced.
- *Isocenter.* Deviations in the position of the isocenter may occur as a result of sagging of the gantry head.
- *Light-beam congruence.* The light beam within the treatment machine may be in error. These misalignments may be caused by small shifts in the mirror or the light bulb.

- *Alignment systems.* The laser beam systems used for alignment may be in error.[386] They may not intersect exactly at the isocenter, they may not be perpendicular, and some systems may display relatively thick lines allowing for errors in judgment.
- *Couch top.* There can be differences in sag between radiation treatment couches. In addition, there may be differences in sag between the simulator couch, the CT couch used for 3D or IMRT planning, and the accelerator couch. Sometimes, in the treatment room, a tennis racket–type insert is used. Over time, couch tops can become tilted from side to side or from end to end.
- *Beam-shaping blocks or collimators.* At institutions that are still using blocks rather than a multileaf collimator, there may be errors in constructing the blocks related to user error or because the cutting wire becomes too hot or is moved too fast around a corner when the Styrofoam mold is cut. If multileaf collimators are used, there may be errors in alignment.

Box 1.5

Gunilla Bentel (1936–2000)

Gunilla Bentel was an international leader in the application of practical innovations to improve the accuracy of the planning and delivery of radiation therapy. Born in Sweden, Gunilla was formally trained as a nurse/radiation therapist, but spent most of her career functioning as a dosimetrist and physicist at Duke University in Durham North Carolina. She was a superb clinician who had a knack to develop practical solutions to real clinical problems. Her major contributions were in the areas of treatment planning, dose calculation, patient setup and immobilization, and she authored three textbooks on these topics (packed with helpful illustrations),which were the mainstay for students in our field for decades. She was active in the clinic, often working closely with her physician colleagues, assessing patients, and their technical challenges, together. She was a founding member of the American Association of Medical Dosimetrists (in 1975) and served as editor of the Medical Dosimetry journal. Through her books, her leadership, and other activities, Gunilla helped to improve the quality of care for patients around the world. Lawrence B. Marks MD, University of North Carolina—Chapel Hill.

Patient-Related Uncertainties

- *Target delineation.* No matter how sophisticated the computerized treatment planning system, it will be to no avail if the physician is uncertain about where the tumor is located. The inherent problems related to PET, MRI, CT, and our ability to make correlations between anatomic and functional imaging and the location of tumor may result in difficulty determining the extent of tumor as well as in transferring anatomic information from imaging studies to the 3D or IMRT treatment planning system.
- *Organ motion.* Organ motion can occur from respiration, heartbeat, or changes in the size or shape of an organ as a function of digestive or excretory function (i.e., changes in the size and position of the stomach, intestines, bladder, and rectum and, in the last case, its influence on prostate position)
- *Skin marks.* Skin marks can shift relative to deeper tissues. This can change as a result of alterations in patient weight, patient positioning, or the use of steroids during a course of radiation therapy. A particular problem is related to the width of set-up lines drawn by therapists on the patient's skin. The thickness of the point of the marking pen used can produce variation in the width of the lines drawn. When this is accompanied by variation in the position of the light fields in relationship to the lines, it can cause uncertainty in treatment delivery.
- *Repositioning.* Day-to-day problems in reproducing the position may occur.
- *Patient motion.* Some patients simply will not hold still during radiation therapy. Whether this is related to the patient being anxious, in pain, demented, or subject to a neurologic disorder, it can lead to uncertainties in radiation therapy treatment delivery.

Immobilization

The magnitude of uncertainties in radiation therapy treatment delivery varies. Furthermore, some uncertainties may be additive and some may cancel each other out. The net effect, on any given day, can be quite variable.

To irradiate a tumor while minimizing the radiation dose to uninvolved normal tissue, control of patient movement must be precise and absolute. Sophisticated tumor localization, 3D treatment planning, radiosurgery, and/or IMRT will be of no use if the patient is not holding still. Often, positioning and mobilization can be the weakest link in the chain of treatment planning.[45] Quality radiotherapy demands that a daily set-up accuracy of a few millimeters be ensured.

Mechanical immobilization of the awake radiotherapy patient is an adjunct to patient education and psychological preparation of the patient. Although not a substitute for education and psychological preparation, mechanical aids can greatly facilitate accurate treatment. The ideal mechanical aid for patient positioning will achieve the following goals[45]:

- The patient must be comfortable and secure. There must be no danger of falling. The patient should not become claustrophobic.
- The device must satisfy the radiotherapy treatment plan regarding patient position for correct geographic irradiation.
- The setup should be quick and easy for the radiation therapist.
- The body part treated should be rendered immobile.
- Position of the body part should be reproducible for daily treatment.
- Construction of the device should be reasonably quick. It should not be difficult to train therapists, dosimetrists, and physicians in the construction procedure.
- The stabilization device should not adversely affect beam buildup and backscatter characteristics.
- This system should be economical.
- If anesthesia is being used, the device must not interfere with the establishment of a secure airway, intravenous access, or the use of monitoring equipment.

A variety of immobilization devices meet these stated criteria to varying degrees. There is no perfect system. Techniques will vary among institutions. It is reasonable to expect, however, that the radiation oncologist should be knowledgeable in several techniques that can be brought to bear as the situation demands.

There are a variety of stabilization devices. These include commercially available accessories such as plastic headholders and sponges; bite blocks; thermoplastics; plaster of Paris; vacuum-molded thermoplastics; polyurethane foams; vacuum bags; intrarectal balloons to stabilize the prostate and rectal wall during prostate radiotherapy, respiratory-gated radiotherapy, and therapy while breath holding to minimize respiratory excursion; and mechanical devices to compensate for patient movement by compensatory couch movement, collimator leaf movement, or robotic arms to move the linear accelerator.

Accuracy of external beam placement was typically assessed periodically with portal (localization) films. It is now more common to use online imaging verification (electronic portal imaging) devices or online CT, fluoroscopy, or ultrasound.[46,47] Portal localization errors may be systematic or occur at random.

Online electronic portal imaging has been used to document inter- or intratreatment portal displacement.

Clinical evidence supports the benefit of stabilization devices in reducing patient motion. Marks et al.[48,49] demonstrated, by systematic use of verification films, a high frequency of localization errors in patients irradiated for head and neck cancer or malignant lymphomas. These errors were corrected with improved patient immobilization; with the use of a bite block in patients with head and neck tumors, localization errors were reduced from 16% to 1%[49] (Table 1.1). The use of 3DCRT and IMRT, as well as the emphasis on stereotactic body radiosurgery, has led to several excellent contributions to the literature assessing the value of stabilization devices. Such devices are particularly important in the treatment of lung, liver, and paraspinal tumors. Often, these devices include a combination of a thermoplastic body cast, vacuum pillow, arm and leg support, wooden backing and/or sides, or a carbon plate. It has been demonstrated that such devices can achieve set-up errors and deviations in the 1- to 3-mm range.[50,51] Some institutions rely on vacuum-molded plastic shells. These devices, similarly, will achieve displacements on the order of 1 to 3 mm.[52]

TABLE 1.1 THE IMPACT OF STABILIZATION DEVICES ON EXTERNAL BEAM SET-UP REPRODUCIBILITY

	Number of Position Adjustments per Number of Times Tested (%)	*P*
Hodgkin disease (*n* = 56)[a]		
Short cradle stabilization device	48/237 (20)	.009
Whole-torso cradle stabilization device	21/213 (10)	—
Head and neck cancer (*n* = 71)[b]		
Three casting strip stabilization device	55/307 (18)	.23
Customized mask device	40/291 (14)	—
Lung cancer (*n* = 60)[c]		
No stabilization device	17/119 (14)	.139
Cradle	14/171 (8)	—

[a]Bentel GC, Marks LB, Krishnamurthy R, et al. Comparison of two repositioning devices used during radiation therapy for Hodgkin's disease. *Int J Radiat Oncol Biol Phys* 1997;38(4):791–795.

[b]Bentel GC, Marks LB, Hendren K, et al. Comparison of two head and neck immobilization systems. *Int J Radiat Oncol Biol Phys* 1997;38(4):867–873.
[c]Bentel GC, Marks LB, Krishnamurthy R. Impact of cradle immobilization on setup reproducibility during external beam radiation therapy for lung cancer. *Int J Radiat Oncol Biol Phys* 1997;38(4):527–531.

In a randomized trial from the Karolinska University Hospital in Stockholm, Sweden, patients with head and neck cancer were randomly assigned to be stabilized with a thermoplastic head mask or a thermoplastic head and shoulder mask. Reproducibility was assessed by comparing port films in these three-dimensionally planned patients with simulator films. This was done twice during treatment and by comparing the actual treatment table positions weekly. Patient tolerance and skin reactions were also assessed. A total of 241 patients were evaluated. There were no statistically significant differences between the head mask stabilization device or the head and shoulder mask stabilization device in terms of reproducibility. It was of note, however, that patients with the thermoplastic mask extending over the head and shoulders experienced significantly more claustrophobic reactions and greater skin reactions. This study has been criticized for its reliance on thermoplastic devices rather than the vacuum-formed clear polyethylene masks.[53]

Because different stabilization devices are utilized in different clinical situations, there is no simple way to know which is the best stabilization device. An excellent comparative study done at the Northeast Proton Therapy Center analyzed the length for which there is a 95% probability that the total displacement will be smaller as a result of intrafractional patient motion. It is reasonable to expect that customized closely fitting molds should achieve intrafractional stabilization of 2 to 7 mm, with the best stabilization being obtained in precision treatment of the brain utilizing a rigid halo and bite block (Table 1.2).[54]

We may expect further benefits from research on stabilization. For example, air-filled rectal balloons have been shown to decrease prostate motion during prostate radiotherapy. The perturbation of the radiation dose near the air–tissue interface appears to produce some sparing of the rectal mucosa without incremental detriment to the dose to the prostate.[55] Active breathing control, gated radiotherapy, and compensatory motion of the treatment couch to account for patient motion are also all under active investigation.[56]

Respiratory-Dampened, Respiratory-Gated, and Respiration-Synchronized Radiotherapy

The movement associated with respiration affects the position of multiple organs. If the radiation oncologist wishes to administer highly conformal fractionated or single-fraction treatment(s) to tumors of the liver, lung, pancreas, kidney, retroperitoneum, thoracic wall, mediastinal region, and adjacent structures, it will be necessary to either account for respiration-induced movement by putting a larger margin around the tumor or use an intervention to reduce this movement (Table 1.3).

TABLE 1.2 INTRAFRACTIONAL PATIENT MOTION AS A FUNCTION OF THE IMMOBILIZATION DEVICE[a]

Immobilization Device	Patient Motion
Alpha cradle	5.0 mm
Beanbag	6.8 mm
Head Aquaplast	3.6 mm
Duncan headrest	7.0 mm
Modified Gill-Thomas-Cosman frame	1.8 mm
Prone craniospinal head support	3.0 mm
Head Aquaplast with bite block	2.9 mm
Wing board	5.9 mm

[a]Based on an analysis of >10,000 fields, there is a 95% chance that the change in patient position between the initial patient setup and the position before the next treatment field setup will be less than the measurement shown.

Modified from Engelsman M, Rosenthal SJ, Michaud SL, et al. Intra and interfractional patient motion for a variety of immobilization devices. *Med Phys* 2005;32(11):3468–3474. Copyright © 2005 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.

TABLE 1.3 AVERAGE DIAPHRAGM MOTION DURING ACTIVE BREATHING CONTROL (ABC) (MEAN, RANGE)[80,98,381]

By Fluoroscopy at Simulation	By Fluoroscopy During Treatment	Beam's Eye View During Treatment
1.4 mm (0–3.4 mm)	1.2 mm (0.4–2.5 mm)	0.5 mm (0–4.2 mm)

One method for limiting respiratory motion during radiotherapy is the *abdominal compression method.* This involves placing a plate or some other restrictive device above or around the abdomen and chest, sometimes in association with supplemental oxygen, in an effort to minimize the amount of diaphragmatic motion during radiotherapy.[57] This is also referred to as *respiratory-dampened radiotherapy.*[58] Many patients can be trained to modify

their respiratory excursion by use of feedback by showing their respiration graphed on a video screen. Another technique involves general anesthesia and high-frequency jet ventilation to minimize diaphragm motion during liver radiosurgery.[59]

Respiratory-gated radiotherapy involves turning the beam on only during portions of the respiratory cycle. Some techniques call for the patient to hold his or her breath during the irradiation.[382]

DNA DAMAGE BY IONIZING RADIATION

The biologic effects of ionizing radiation are largely the result of DNA damage, which is caused directly by ionization within the DNA molecule or indirectly from the action of chemical radicals formed as a result of local ionizations in water. The general forms of DNA damage are base damage, DNA–protein cross-links, single-strand breaks, double-strand breaks, and complex combinations of all of these.[60]

Normal mammalian cells repair a significant proportion of radiation-induced DNA damage. Long-term biologic consequences are the result of those injuries, which are irreparable or misrepaired. The cell will attempt to repair DNA injury induced by radiation via several pathways. Key genes are involved in repair of double-strand DNA breaks.

There is some evidence that clustered local damage to DNA, such as a double-strand break accompanied by additional breaks, base damage, or DNA–protein cross-links, is especially difficult for cells to repair. Even lesions that are potentially repairable may be repaired incorrectly (misrepaired) if lesions are accumulating very rapidly because of HDR or dose rate radiation or if the cell enters M phase and attempts DNA synthesis while repair is in progress. Conversely, radiation, which is given at a low dose rate or is highly fractionated, provides an opportunity for repair of radiation-induced lesions and recovery from injury. DNA damage that is not repaired may cause cell death, prevent cell division, or permanently give rise to heritable lesions such as point mutations, small and large deletions and translocations of DNA sequences, and a wide variety of DNA aberrations[61–63].

RELEVANCE OF RADIOBIOLOGIC CONCEPTS IN CLINICAL RADIATION THERAPY

Radiation and Cancer Biology's Contributions to the Clinical Practice of Radiation Oncology

Generations of radiation oncologists have grappled with the question of radiation and cancer biology's contribution to the clinical practice of radiation oncology. The question was posed and addressed in two classic lectures: first by Stanford's Henry S. Kaplan[64] in his 1970 Failla Lecture to the Radiation Research Society and then by Harvard's Herman D. Suit[65,66] in his 1983 Failla Lecture. Treading on the ground prepared for us by Kaplan and Suit, we will reconsider the question in the context of the explosion of knowledge concerning the molecular and cellular basis of cancer.

One can look at the history of cancer biology's contribution to the clinical practice of radiation oncology in terms of two debates: *empiricism versus research-based radiation oncology* and *biology versus physics.*

Empiricism Versus Research-Based Radiation Oncology

Empiricism harkens to the views of David Hume (1711–1776) and other British philosophers of the 17th and 18th centuries and their distrust of the power of unaided reason. In the philosopher's view of empiricism, the best contact between one's understanding of knowledge and the world is not the point at which a mathematical proof crystallizes, but the point at which you see and touch a familiar object. Their paradigm was knowledge by sensory experience rather than by reason alone.[67–69]

Empirical radiation oncologists rely on accumulated clinical experience, also known as "what has worked in the past." They are suspicious of therapies based on theories and laboratory research and feel safest when treading the pathway of tested experience. One can find very strong signs of empiricism in the radiation oncology literature: case reports, single-institution retrospective clinical series, and a marked concern with retrospective clinical analyses of radiation therapy that mine clinical experience to aid the selection of radiation treatment volume, dose, and treatment techniques.

There can be no doubt that the development of radiation oncology has been extensively based on empiricism. We must note, however, that radiation biologists worked closely with the early radiation oncologists. It would be erroneous to suggest that the early history of radiation oncology was completely devoid of reliance on radiation biology.

The theme of hostility to empiricism and support for finding a firm basis for clinical radiation oncology in radiation and cancer biology research is easily

identified in the development of the specialty. “Some people do the same thing wrong for 30 years and then call it accumulated clinical experience,” said one critic; or it has been said, “If radiation oncologists were put in charge of the war against polio in 1945, they certainly would have perfected the iron lung by now.”[70,71] Our growing knowledge of the genome, proteomics, secondary messengers, and solid tumor biology and the identification of new molecular targets for drugs, immunotherapies, cellular therapies, angiogenesis, oxygenation, and cell cycle control are changing the present and future of medicine. If clinical radiation oncologists have a future, these individuals say, then they must actively participate in the investigation of the molecular and cellular basis of cancer and in translational research.

Physics Versus Biology

One also may formulate the debate over the role of basic biology in clinical radiation oncology as a pull and tug between physics and biology. Medical radiation physics has dominated the thinking of clinical radiation oncologists. Among the major achievements of this discipline are the following:

- The identification and characterization of physical units of radiation dose
- Significant changes in photon and electron radiation therapy apparatus (initially, kilovoltage and later ^{60}Co, high-energy linear accelerators, the Gamma Knife [Elekta Corp., Stockholm, Sweden], and the CyberKnife [Accuray, Sunnyvale, CA])
- The development of 3D treatment planning for identification of tumor volume and characterization of irradiated normal tissue
- IMRT for improved conformality of treatment beams
- Particle therapy including neutrons, protons, pions, and stripped nuclei
- Improved stabilization devices to aid the reproducibility of treatment
- Advances in brachytherapy technology including new isotopes, the afterloading technique, and remote HDR machines
- The apparatus for intraoperative radiation therapy (IORT)
- Equipment for heat deposition in tumors leading to the clinical applications of hyperthermia

At present, a considerable effort in clinical radiation oncology is focused on the tools and techniques provided to the physician by the physicist. Radiation oncology meetings are dominated by discussions of proton therapy, IMRT, radiosurgery/conformal radiation, and innovations in equipment. Simply put, these techniques all offer better radiation dose distributions, which, one hopes,

will lead to an increase in local control of tumors and a decrease in normal tissue toxicity. At present, a better dose distribution is the solution physics offers to the problems of oxygenation, monitoring of tumor blood flow, tumor pH, secondary messengers, tumor suppressor genes, oncogenes, the biology of metastasis, normal tissue radioprotectors, and tumor radiosensitizers. Could it be that “if all you have is a hammer, then everything looks like a nail”?

What has cancer biology ever done for the clinical radiation oncologist? It is, we think, a generally fair question, although it might be characterized as somewhat narcissistic, along the lines of “What have you done for me lately?”[65,70,72–74] Among the areas one should consider on the list of laboratory contributions to the clinic are the following:

- As early as 1906, Bergonie and Tribondeau[75] enunciated a series of famous laws of radiosensitivity. This was followed by the work of the French investigators Regaud and Ferroux,[76] who demonstrated that whereas a single dose of radiation to the testes always produced maximal damage to the scrotal skin, fractionated exposure spared the skin but destroyed spermatogenesis. They speculated that this same technique of fractionation might be differentially advantageous in the treatment of tumors. This led to Coutard’s[32,33,77] studies that culminated in the fractionated EBRT techniques of today.
- The identification of the relationship between radiation dose and cell kill led to the characterization of the radiation cell survival curve. This contributed to our understanding of radiation therapy dose and fractionation and, consequently, contributed to our knowledge of radiation repair. This development placed our grasp of radiation fractionation on sound footing and led to investigations of alternative fractionation schemes. This has contributed to improved tumor control as well as limitation of normal tissue toxicity. Ultimately, the radiation cell survival curve also provided the underpinnings for our views of elements of the dose–response relationship for tumor control and normal tissue toxicity.
- In 1909, Schwarz[78,79] demonstrated that compression of the skin to diminish capillary blood flow reduces severity of cutaneous radiation reactions. This may have been the first demonstration of the “oxygen effect.”[80] L. H. Gray[81] pointed out the relevance of the “oxygen effect” to radiation oncology by identifying the fact that human neoplasms contain a significant subpopulation of hypoxic cells.[82] A series of important developments has driven home the centrality of hypoxia to our understanding of radiation’s effects on tumors. Clearly, histopathologic studies and invasive measurements of intratumoral partial oxygen pressure have shown that many human tumors contain regions

with low oxygen tension.[83] We now believe that there are at least two different mechanisms, called *diffusion-limited* and *perfusion-limited* hypoxia, behind this observation. Some have called these *permanent* and *transient* hypoxia.[84] Diffusion-limited hypoxia results from inadequate angiogenesis, whereas perfusion-limited hypoxia is associated with intermittent closure of tumor vessels, leading to acute hypoxic conditions for tumor cells downstream from the obstruction. In addition, we now understand how hypoxia activates genes and may produce tumor differentiation and increase a tumor's metastatic potential. Clinical studies have associated the prognostic value of hemoglobin level with tumor local control.[80,85] The characterization of the hypoxia problem has led to a variety of strategies to overcome it. One has been to have the patient breathe high–oxygen content gas mixtures or to irradiate patients in hyperbaric oxygen chambers. Another option involves the use of oxygen-mimetic chemicals. Other treatment strategies include blood transfusions or the specific use of hypoxic-specific cytotoxins such as mitomycin C.

- There has been considerable growth in our understanding of cell proliferation, the cell cycle, and cell repair mechanisms. We now understand that cells are more sensitive to radiation in M phase and more sensitive to hyperthermia in S-phase. Our understanding of the differential sensitivity of cells to radiation during the cell cycle helps provide a rational basis for the use of radiation and chemotherapy.
- As an extension of the knowledge associated with the radiation cell survival curve, clinicians obviously need to have a good understanding of the radiation dose and response for both normal and malignant tissues. The development of research involving the lethal dose 50% (LD50), local control rates, and normal tissue toxicity in animal models has led to an improved understanding of the radiation dose–response relationship. Correlates of this understanding have included the use of the progressive shrinking-field technique, IORT, and brachytherapy as a "boost" and the use of increasingly conformal beams associated with our improved understanding of how radiation dose should be associated with tumor volume and dose painting. One expects, in the future, to see increasing work in intentional dose heterogeneity as a technique for improving local control.

In his 1983 Failla Lecture, Herman Suit[65] considered the evolution of the principles of clinical radiation therapy. He prepared a table in which he attempted to articulate the principles of radiation therapy invoked in the United States in 1956 and 1982. This is reproduced in the first two columns of Table 1.4. The author of this chapter has added a third column identifying the

appropriate principles for 2018. One can see, by scanning across the table, the significant changes that have taken place in our discipline. It is clear that the future holds a role both for empiricism and for research-based radiation oncology as well as a role for improvements in physics and biology. Through cooperation and constructive dialogue, all may contribute to the future of cancer care.

TABLE 1.4 PRINCIPLES OF RADIATION ONCOLOGY DERIVED FROM THE INITIAL WORK OF SUIT

1956	1982	2013
1. Aim for uniform dose throughout the treatment volume. Treatment volume is constant for entire treatment (i.e., no shrinking field). 2. Initial large treatment volume is carried to tolerance. 3. No special emphasis to push dose to higher levels for larger tumors. 4. Little priority given to planned combinations of radiation and surgery. 5. Treatment fields are square or rectangular. 6. Radiation alone is the general rule.	1. Use shrinking-field technique (i.e., a nonuniform dose distribution related to number of tumor cells). 2. Dose to the initial volume is usually less than tolerance. Only the final treatment volume is carried to tolerance dose level. 3. Dose aim is planned on the basis of tumor size or estimated tumor cell number. a. Maximum doses (with higher risk of morbidity) for large tumors. b. Modest well-tolerated dose levels for subclinical disease.	1. Moderate, conform, and “paint” the external beam or brachytherapy dose distribution in accordance with the viable tumor cell distribution. 2. Dose to the initial volume is less than tolerance and may be moderated because of the specific host and treatment factors affecting tolerance. 3. Dose aim is planned on the basis of tumor size, estimated tumor cell number, extent and completeness of surgical resection, biologic and genetic predictors of tumor aggressiveness, and response to induction chemotherapy. a. Maximum doses (with higher risk of morbidity) for large and more aggressive tumors. b. Modest well-tolerated dose levels for subclinical disease. c. For combinations of radiation and surgery, chemotherapy, and/or biologic therapy, one might use less than radical dose level in certain situations. d. For combinations of external beam radiation therapy and brachytherapy or radiation therapy and hyperthermia, the dose of each modality is modified as a function of the other modalities used. 4. Major emphasis on planned combinations of radiation, surgery, chemotherapy, hormonal therapy, and biologic therapy. 5. Multileaf collimators and intensity modulation are used on virtually all fields in an attempt to improve conformality of the radiation and reduce irradiation of tissue not suspected of being involved with tumor. Radiation dose distribution is based on sophisticated imaging technologies. 6. The radiation oncologist is expected to be trained in and make use of pathology for tumor subtyping and grading; anatomic and molecular staging; diagnostic imaging; and the therapeutic role of chemotherapy, hormonal therapy, biologic therapy, and surgical

7. Results of treatment described almost exclusively in terms of absolute survival at a fixed period (e.g., 5 years).	c. For combination of radiation and surgery use less than radical dose level. 4. Major emphasis on planned combinations of radiation and surgery. 5. Secondary collimation is utilized on virtually all fields to reduce irradiation of tissues not suspected of involvement by tumor. 6. Multidisciplinary approach accepted as most effective for most tumor problems. 7. Results analyzed on the basis of detailed assessment of causes of failure (e.g., local persistence or regrowth, local complication, marginal miss, regional spread, distant metastases, intercurrent disease).	therapy. 7. The phase III randomized prospective trial is the gold standard for clinical decision-making. Decisions based on properly planned and conducted cancer trials concerning radiation therapy dose, volume, and technique are most appropriate. It is expected that evidence-based medicine will guide clinical decision-making. If such trials are not available or are inadequate, then phase II trials or retrospective reviews involving survival, local control, patterns of failure, and multivariate analysis of outcome are often useful. The future will depend on basic and translational research in cancer biology and medical physics being brought to the clinic.

It is essential that radiation oncologists remaining current with scientific findings that will be critical in the development of improved therapeutic strategies. Approaches that alter the cell's surface membrane, receptors,

secondary messengers, or nuclear contents may overcome cellular radiation resistance. By exploitation of cellular mechanisms related to apoptosis, it may be possible to kill cells with irradiation by inducing changes other than unrepaired DNA damage. With understanding of the tumor microenvironment and techniques such as complementary DNA (cDNA) microarrays, as well as an understanding of how growth factors may alter cellular processes, innovative bioinformatics and improved combined modality strategies may emerge. The ability to genetically sequence tumors will provide information beyond the era when biologic effects were attributed to a single gene. Better understanding of hypoxia may improve clinical outcome with antihypoxia strategies, including hypoxic cell radiosensitizers and hypoxic cytotoxic agents. Cyclins and growth factors may be useful as clinical radiation modifiers. Pharmacogenomics may inform how we prescribe drugs.

There is a critical need to balance the investment in technical aspects of radiation therapy with concepts and innovative approaches derived from better understanding of cancer biology. These scientific developments will greatly alter the way in which we practice our discipline.

EFFECTS OF IRRADIATION ON CELLS

The radiation-induced lesion most detrimental to cell survival involves damage to the DNA. This may result in either mitotic cell death or apoptosis. If the cell survives and repairs the damage, it may achieve a normal status. If there is misrepair, it may be associated with permanent mutations and induction of carcinogenesis. The physical interaction of ionizing radiation with the molecular infrastructure of the cell results in chemical reactions that occur within 10^{-18} to 10^{-3} seconds.[58] Absorption of the photon energy destabilizes the target molecule, resulting in molecular breaks or release of energetic electrons and secondary energy-attenuated photons, which may interact with other cellular molecules, leading to a chain reaction that produces a variety of short-lived ions and chemically unstable free radicals. The most common radicals are produced from the radiolysis of cellular water and include hydroxyl radicals ($^{\bullet}OH$), hydrated electrons (e_{aq}), hydrogen atoms ($H^{\bullet}$), and hydrogen peroxide (H_2O_2). Free radicals are extremely unstable and interact nearly instantaneously with neighboring molecules to produce chemically stable lesions. This process can be modified by free radical scavengers or by oxygen, which have opposing effects on the number of stable lesions and on the level of cellular radiosensitivity.

However, if all factors remain constant, the permanent damage is linear with dose. Experiments in which the cell nucleus and the cytoplasm were selectively irradiated show that the dose required in the cytoplasm to kill a cell is larger than doses required in the nucleus.[231,232] It is generally accepted that most target molecules for radiation-induced cell killing are located in the nucleus and involve damage to the DNA.[233] However, other targets such as the cell membrane and the membrane of mitochondria have been proposed as the origin of apoptotic cascades that follow irradiation also contributing to cell death.

In many cells, radiation-induced lethality is not instantaneous because cells continue to function and even undergo several divisions before final mitotic death occurs. Noncycling lymphocytes, thymocytes, and hematopoietic cells were shown to undergo an interphase cell death without progressing through the mitotic phase of the cell cycle.[234,235] Two patterns of morphologic changes are associated with cell death in mammalian cells. Cell necrosis, which is degenerative, is the most usual type of cell damage. Necrotic cell death results from collapse of cellular metabolism and depletion of its adenosine triphosphate storage. The final events of necrosis involve membrane rupture, loss of lysosomal enzymes, degradation of nuclear chromatin, and karyolysis. The other process of radiation-induced cell death is apoptosis. Programmed cell death, or apoptosis, is a physiologic process that involves a series of characteristic, genetically controlled steps. These include chromatin condensation and segmentation, fragmentation of the nucleus into apoptotic bodies, cell shrinkage, and loss of cellular contact with neighboring cells.[64,236–238] Apoptosis culminates in the engulfment of the cell by neighboring cells, such as macrophages, without a concomitant inflammatory response.[239] Apoptosis occurs spontaneously in various solid tumors and contributes to the balance between tumor cell gain and cell loss.[240]

Within minutes after irradiation, signal transduction pathways mediated by protein kinase C and tyrosine kinase are stimulated.[86] Genes and enzymes involved in genetic control of radiation damage repair are activated, stress genes are induced, and growth factors and cytokines that modulate response of mammalian cells to ionizing radiation are activated.[116] Radiation-induced stimulation is probably critical to induction of many genes and proteins, including early response genes, which, in turn, activate other genes, including those for tumor necrosis factor, fibroblast growth factor, and transforming growth factor.[231] In addition, new proteins, such as tissue plasminogen activator, are synthesized.[241] This cascade of gene activation and transcription and protein

synthesis is related to key cellular functions that the cell invokes in an attempt to survive a dose of radiation.[241]

Modifiers of Radiation Response

Several approaches have been used to enhance the therapeutic ratio in radiation therapy:

- *Physical modifiers of low-LET radiations.* IMRT, three-dimensional treatment planning, improvements in anatomic and functional imaging, the increasing power of computer hardware and software, and treatment machine improvements have led to better photon, electron, and proton dose distributions; less side scatter; less differential absorption in the bone and normal tissues; and, with charged heavy particles, selective energy deposition at specific depths.[283]
- *High-LET radiations.* The importance of tumor hypoxia and cells residing in relatively resistant phases of the mitotic cycle are factors that are less likely to cause unsatisfactory results with neutrons, pi mesons, and heavy ions than with standard radiation doses delivered with low-LET beams.[242]
- *Hyperbaric oxygen or tourniquet techniques.* These techniques involve the use of increased oxygen tension to improve the effects of irradiation on the tumor or use of a tourniquet to produce severe hypoxia in the surrounding normal tissues so that higher irradiation doses can be delivered.[243] Theoretically, these approaches yield better tumor control without damaging normal tissues. Interest in the tourniquet technique waned years ago. Some investigators continue to evaluate hyperbaric oxygen. The logistics are formidable, and clinical trials have been inconclusive.[181,244–246]
- *Hypoxic sensitizers.* Compounds with electron affinity, from the nitroimidazole group, theoretically produce free radicals in a manner similar to that of oxygen, selectively sensitizing hypoxic cells to radiation. Misonidazole (RO-07–0582) was evaluated in numerous clinical trials by the RTOG, with no evidence of clinical efficacy; however, in the Danish Head and Neck Cancer trial, there was a highly significant survival benefit in the subgroup of patients with pharynx tumors.[247,248]
- *Perfluorocarbons.* These agents are administered in emulsion (they are insoluble in water) in sufficient concentrations coupled with inhalation of 95% to 100% oxygen to enhance oxygen transport and release in the presence of low oxygen tension. Their potential application in the treatment of patients with cancer was evaluated.[249,250] Interest in the technique waned.
- *Cytotoxic agents.* Actinomycin D, doxorubicin, 5-fluorouracil,

cyclophosphamide, cisplatin, methotrexate, bleomycin, and others have been shown to interact with radiation in several forms to maximize tumor cell killing. In some instances, increased normal tissue reactions have been observed.[277]

- *Epidermal growth factor receptor (EGFR).* EGFR, a member of the ErbB family of receptor tyrosine kinases, is activated in several epithelial cancers. Radiotherapy increases the expression of EGRF in cancer cells and blockade of EGFR signaling can sensitize cells to radiation. Cetuximab is a chimeric monoclonal antibody that targets EGFR. The drug appears to improve locoregional tumor control and survival in locally advanced squamous cell carcinoma of the head and neck.[234]
- *Radioprotectors.* Sulfhydryl-containing compounds, such as cystine and cysteamine, have been used in animals to protect normal tissues against irradiation. Amifostine (WR-2721), a thiophosphate derivative of cysteamine, has been shown to selectively protect normal tissues, including the bone marrow, salivary glands, and intestinal mucosa, in animals, with little effect on tumor response to irradiation.[251] Amifostine undergoes dephosphorylation by cellular-bound alkaline phosphatase to an active metabolite, WR-1065. This alkaline phosphatase–dependent activation is thought to contribute to selective normal tissue protection because of a higher concentration of alkaline phosphatase in normal tissue. Cytoprotection is believed to be the result of the elimination of free radicals.[252] The compound was widely investigated in phase II and III clinical trials.[253] It is now approved by the U.S. Food and Drug Administration (FDA) and the European Medicines Agency for the reduction of xerostomia in patients with head and neck cancer undergoing radiotherapy.[212] A meta-analysis has shown that amifostine does not reduce overall or progression-free survival in patients treated with radiotherapy or chemoradiotherapy—arguing against amifostine protecting tumor tissue.[254]
- *Hyperthermia.* Heat at temperatures of more than 42.5°C kills cells by itself or enhances the effects of irradiation and numerous cytotoxic agents. Heat selectively kills cells that are chronically hypoxic, acidotic, and nutritionally deficient—characteristics shared by tumor cells in comparison with the better-oxygenated and better-nourished normal cells. Furthermore, heat preferentially kills cells in the S-phase of the proliferative cycle, which are known to be relatively resistant to irradiation.[91,270,351]

RADIOSENSITIVITY AND RADIOCURABILITY

In 1906, Bergonie and Tribondeau[86] formulated a law relating radiosensitivity to

reproductive capacity of cells, based on their experiments on rat testis in which they were able to destroy the germinal cells while the interstitial tissue and Sertoli syncytium remained unimpaired. They wrote that “X-rays are more effective on cells which have a greater reproductive activity; the effectiveness is greater on those cells which have a longer dividing future ahead…. From this law, it is easy to understand that roentgen radiation destroys tumors without destroying healthy tissues.” Fletcher[87] felt that this observation, which was interpreted to indicate that radiosensitivity of tumors was linked to that of the mother organ, did much harm to clinical radiation therapy, leading to the erroneous concept that undifferentiated tumors with mitotic activity were radiosensitive and that more differentiated tumors were radioresistant.

In 1914, Schwarz[78] introduced the concept of fractionation by postulating that it was inefficient to deliver the total radiation dose in one treatment because cells were in different states of radiosensitivity and because there was a better chance that multiple exposures could hit the cells in a radiosensitive phase (e.g., mitosis). Fractionation was assumed to create a favorable therapeutic ratio because the tolerance of normal tissues increased relative to that of tumors and because malignant cells had a greater reproductive capacity and were, therefore, more likely to be in a radiosensitive phase.

Based on these and other observations, the term *radiocurability* was coined. It refers to the eradication of tumor at the primary or regional site and reflects a direct effect of the irradiation producing logarithmic cell killing; this does not necessarily equate with the patient’s cure from cancer (Table 1.5 and Box 1.5). In contrast, *radiosensitivity* is a measure of tumor–radiation response, thus describing the degree and speed of regression during and immediately after radiotherapy. However, for some malignant tumors, no significant correlation exists between the responsiveness of a tumor to irradiation and its radiocurability.

The response of human tumors to irradiation is a key issue for radiation oncologists and has been addressed by many leading radiobiologists.[88] At least four explanations have been considered that could alone or in combination account for the different radiosensitivities of tumors[89–91]:

- *Hypoxia.* To explain the spectrum of clinical radioresponsiveness on this basis, it is likely that the less responsive tumors either have a high hypoxic fraction, have failed to reoxygenate during fractionated treatment, or both.[92] Direct oxygen electrode measurements have shown that cervical cancer, breast cancer, and squamous cell cancers are human tumors reported to have mean

oxygen pressures below those of the surrounding tissue.[93–96] Despite a wide range of values, the oxygen pressure in tumors tends to decrease with increasing tumor size.[97] Although it is not possible to prove that hypoxia is unimportant in conventional radiation therapy, some doubts about its importance have been expressed based on the limited success of neutron therapy or hypoxic cell radiosensitizers.[98,99] Hypoxia can act as an important determinant of selecting for tumor cells of a more malignant phenotype that is likely to adversely affect treatment outcome.[94,98,100]

- *Proportion of clonogenic cells.* Proliferating cells are more radiosensitive and have a greater turnover (cell loss) rate. Tumor regression during irradiation may be proportional to the total number of proliferating cells (growth fraction) or the proliferative rate, which may accelerate for certain tumor cells as a result of adaptive processes (accelerated repopulation) during fractionated irradiation.
- *Inherent radiosensitivity of tumor cells.* Fertil and Malaise[101] and Deacon et al.[102] established a positive correlation between the steepness of the initial slope of the oxic cell survival curve for human tumor cells and their response to radiation. The magnitude of differences between cell lines at low doses is sufficient to explain the range of curability observed clinically. Steel and Peacock[103] analyzed human tumor radiosensitivity in light of existing concepts of cell killing based on the linear-quadratic (LQ) equation. However, despite encouraging correlations in some studies, these radiobiologic parameters have not been accepted for routine clinical use.
- *Repair of radiation damage.* Repair of sublethal damage (SLD; split-dose effect) is observed in almost all tumor cell lines.[104–106,384] Potentially lethal damage (PLD) repair after a single dose varies considerably from one cell line to another and has been reported by Weichselbaum and Little[107] to correlate with clinical radiocurability, with less curable tumors showing the greatest degree of PLD recovery. These repair parameters have not been confirmed in larger clinical experiences to justify their use as predictors of radiotherapy outcomes (see later in this chapter).

TABLE 1.5 VARIOUS LEVELS OF IRRADIATION WILL YIELD DIFFERENT PROBABILITIES OF TUMOR CONTROL, DEPENDING ON THE SIZE OF THE LESION

Cumulative Dose (Gy)	Initial Cell Number	Probability of Survival	Remaining Cell Number
2	1,000,000,000	×0.5 =	500,000,000

4	500,000,000	×0.5 =	250,000,000
6	250,000,000	×0.5 =	125,000,000
8	125,000,000	×0.5 =	62,500,000
10	67,500,000	×0.5 =	31,250,000
12	33,750,000	×0.5 =	15,625,000
14	15,625,000	×0.5 =	7,812,500
16	7,823,500	×0.5 =	3,906,250
18	3,906,250	×0.5 =	1,953,125
20	1,953,125	×0.5 =	976,562
22	976,562	×0.5 =	488,281
24	488,281	×0.5 =	244,140
26	244,140	×0.5 =	122,070
28	122,070	×0.5 =	61,035
30	61,035	×0.5 =	30,517
32	30,517	×0.5 =	15,258
34	15,258	×0.5 =	7,629
36	7,629	×0.5 =	3,814
38	3,814	×0.5 =	1,907
40	1,907	×0.5 =	953
42	953	×0.5 =	476
44	476	×0.5 =	238
46	238	×0.5 =	119
48	119	×0.5 =	59
50	59	×0.5 =	29
52	29	×0.5 =	15
54	15	×0.5 =	7
56	7	×0.5 =	4
58	4	×0.5 =	2
60	2	×0.5 =	1
62	1	×0.5 =	<1

Some investigators have reported a correlation between the clinical or pathologic response of a tumor after the completion of irradiation with ultimate probability of local tumor control.[108] For this analysis to be valid, it is necessary to compare patients with the same initial stage because, in general, more advanced lesions have a greater probability of tumor persistence at the completion of radiation therapy and local recurrence may be more frequent. Barkley and Fletcher[109] reported 82% tumor control in 88 patients with tumors of the oropharynx that had regressed completely at the end of therapy, in contrast to 41% in 237 patients with persistent tumor at completion of therapy. Sobel et al.[110] concluded that local tumor control in head and neck carcinomas could be

predicted with the greatest accuracy and consistency 1 to 3 months after completion of radiotherapy. They noted that the prediction was 80% accurate in favorable tumors (T1 and T2) but decreased to 50% to 60% in more advanced primary lesions; complete tumor clearance was a more accurate predictor of tumor control. This was confirmed for the radiotherapeutic management of N2 (>3 cm) neck disease, where complete clinical resolution of tumor within 8 weeks of completion of irradiation correlated with a >90% freedom from neck failures.[111,112] Contemporary studies based on pathologic confirmation of complete tumor response or PET scan response show similar results.

Tumor Radiosensitivity and Predictive Assays

Since the inception of the use of ionizing radiation, many investigators have categorized the response of tumors according to their sensitivity to irradiation. Wetterer[113] in 1913 characterized tumor radiosensitivity based on histologic types, and Paterson[114] divided tumors into three groups: radiosensitive, intermediate, and radioresistant. The first category included germ cell tumors and reticuloses; the second included squamous cell and adenocarcinomas; and the third group included soft tissue and bone sarcomas and melanomas. However, depending on variation in proliferative rates and cell loss, endpoints for response assessment may vary substantially, as has been pointed out for malignant melanoma.[115] Attempts have been made to predict the response of tumors to radiation depending on several parameters, such as the assay proposed by Glucksmann[116] consisting of differential cell counts of mitotic, resting, and degenerating cells in biopsy samples from the growing edge of the tumor before and after initiation of radiotherapy. It is generally accepted that tumors contain mixed cell populations of stem cells with differing sensitivity to antineoplastic agents and that therapy can be selected for resistant cell populations or, in the case of certain cytotoxic agents, to induce cellular resistance.[117] Peters et al.[118,119] described a predictive assay to assess tumor response *in vitro* and the difficulties in predicting the probability of tumor control by irradiation in a given patient. Unfortunately, despite promising correlations between radiosensitivity *in vitro* and radioresponsiveness of normal tissues and tumors,[120,121] sufficiently powered predictive assays have not been identified. Given the inherent intertumor variability of predictive parameters, such as SF_2[122,123] or T_{POT},[124,125] and the genetic profile of tumor cells, a single predictive assay is unlikely to carry sufficient predictive power. The incorporation of multiple radiobiologic tumor cell parameters (e.g., markers for radiosensitivity and proliferation

potential) into TCP (see later in this chapter) models appears more promising but awaits broader validation in clinical trials.[126]

Probability of Tumor Control

For many histologic types of cancer, higher radiation doses produce better tumor control. Numerous dose–response curves for a variety of tumors have been published. The first dose–response data were reported for skin cancer by Miescher[127] in 1934; 10 years later, Strandqvist[128] published a dose–response curve for skin cancer. The Strandqvist plots were refined by von Essen,[129] who demonstrated from a large skin carcinoma experience that the slopes for 97% tumor control and 3% skin necrosis differed and permitted, through appropriate fractionation schedules also considering the volume of disease, a dissociation of the two endpoints. As Fletcher[130] pointed out, meaningful dose–response curves can be generated only when a group of homogeneous tumors is given a range of radiation doses, indicating that tumor control is a probabilistic event. For every increment of radiation dose, a certain fraction of cells will be killed; therefore, the total number of surviving clonogenic cells will be proportional to the initial number present and the fraction killed with each dose.[104,105] Thus, various levels of irradiation will yield different probabilities of tumor control, depending on the extent of the lesion (number of clonogenic cells present). For subclinical disease in squamous cell carcinoma of the upper respiratory tract or for adenocarcinoma of the breast, doses of 45 to 50 Gy will result in disease control in more than 90% of patients.[130,131] Subclinical disease has been referred to as deposits of tumor cells that are too small to be detected clinically and even microscopically but, if left untreated, subsequently may evolve to clinically apparent tumor.[132,133] It must be emphasized that microscopic evidence of tumor, such as at the surgical margin, should not be regarded as subclinical disease; cell aggregates $\geq 10^5/cm^3$ are required for the pathologist to detect them. Therefore, these volumes must receive higher doses of irradiation, in the range of 60 to 65 Gy, in 6 to 7 weeks for epithelial tumors. This distinction of disease extent is re-emphasized by clinical results, demonstrating the need for irradiating patients with likely subclinical carcinoma to postoperative doses near 60 Gy.[134]

For clinically palpable head and neck tumors, doses of 65 (for T1) to 75 to 80 Gy or higher (for T4 tumors) are required at 2 Gy/day using five fractions weekly. This dose range and probability of tumor control have been documented for squamous cell carcinoma and adenocarcinoma.[87,130,131,135–138] Even with preoperative irradiation, the dose effect on probability of tumor control can be

documented.

Baclesse[139] introduced the concept of different doses of irradiation for various portions of the tumor. The higher dose administered through small portals to residual disease is called a *boost*, which is delivered in an effort to achieve the same probability of tumor control as for subclinical aggregates.[130] One consequence of the concepts discussed earlier is use of portals that are progressively reduced in size. This *shrinking-field* technique administers higher radiation doses to the entire gross tumor where more clonogenic cells (including hypoxic cells) reside, relative to lower doses to tissues in the immediate proximity of the clinically apparent (gross) tumor. The tissues making up the "tumor margin" contain a lower number of tumor clonogens that are better oxygenated (see Fig. 1.8).

Normal Tissue Effects

A variety of normal tissue changes are induced by ionizing radiation, depending on the total dose, fractionation schedule (daily dose and overall treatment time), and volume treated.[307] These factors are closely interrelated (Fig. 1.9). Hermann Holthusen (1886–1971) created a diagram, which represented the hoped-for relationship between radiation dose and tumor control and radiation dose and normal tissue injury. First published by Holthusen in the 1930s, it has been reproduced innumerable times (Fig. 1.10). Holthusen "maintained that the margin of safety between effective tumor dose and safe tissue tolerance was dependant on volume of tissue irradiated and fractionation of the total dose… tolerance could be increased by fractionation."[140,141]

It has been postulated that for many normal tissues, the radiation dose necessary to produce a particular sequela increases as the irradiated fraction of volume of the organ decreases. This concept was demonstrated for skin by Paterson,[114] who plotted doses delivered with orthovoltage x-rays that would produce moist desquamation (Fig. 1.11). The same phenomenon later was reported for supervoltage irradiation of other organs[142] and for brachytherapy.

Higher tolerance doses (TDs) than initially reported have been observed for a variety of organs,[137,138,143–145] as a result of conform a-1 irradiation. This stresses the importance of updating tolerance information in light of more precise treatment planning and delivery of irradiation and more accurate evaluation and recording of sequelae. Examples are radiation dose escalation studies using conformal radiotherapy delivery techniques. A compilation from the literature of data on TDs for whole- or partial-organ irradiation was

published by Emami et al.[146] The comprehensive update of this compilation, QUANTEC, is described in Chapter 14.

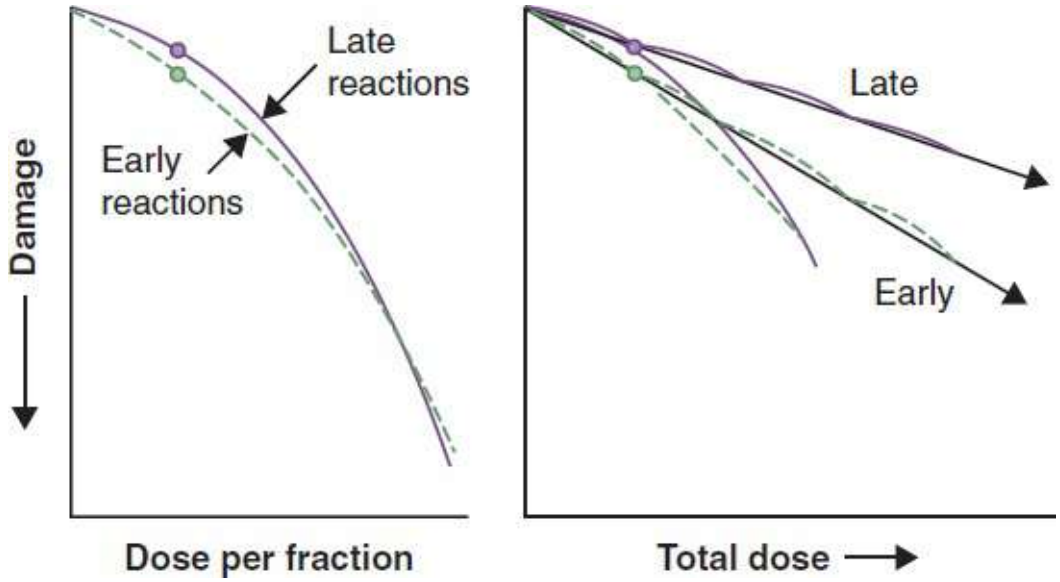

FIGURE 1.9. Difference in cell survival curves for acute and late radiation effects with single or multifractionated doses of irradiation. (Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. *Biological basis of radiotherapy*. 2nd ed. Amsterdam: Elsevier Science, 1983:181–194. Copyright © 1983 Elsevier. With permission.)

FIGURE 1.10. Hermann Holthusen (1886–1971) created these hypothetical curves for tumor control and normal tissue injury to demonstrate the dose–response of radiotherapy. One tries to shift the curves as far apart as possible.

In studying late radiation effects, an organ can be considered to be made up of multiple functional subunits (FSUs) that are arranged serially or in parallel.[40,147] For serially structured organs, such as gastrointestinal tract or nervous tissue, damage to one portion of the organ may render the entire organ dysfunctional. In contrast, in organs with parallel structure, FSU damage may not impair the entire organ function because the remaining FSUs operate independently from the

damaged group, and clinical injury occurs only when a critical volume of the organ (or proportion of FSUs) is damaged and the surviving FSUs are unable to maintain organ function. Therefore, the sensitivity of an organ depends on the number of FSUs. Marks and others[148,149] have discussed the importance of organ structure in determining late radiation effects and pointed out that conventional dose–volume histograms (DVHs) and normal tissue complication probability (NTCP) models are frequently inadequate because they ignore functional and structural heterogeneities. Such considerations will be particularly important for partial irradiation of the lung, liver, and kidney to doses that approach the tolerance of the organs' functional units. Jackson et al.[150] presented a thorough discussion of the subject, including its mathematical basis, and addressed the problem of calculating NTCP for inhomogeneously irradiated organs with parallel architecture. They showed that variations in FSUs and functional reserve in a patient population may produce NTCP dose–response curves, the widths of which are comparable with those observed clinically.

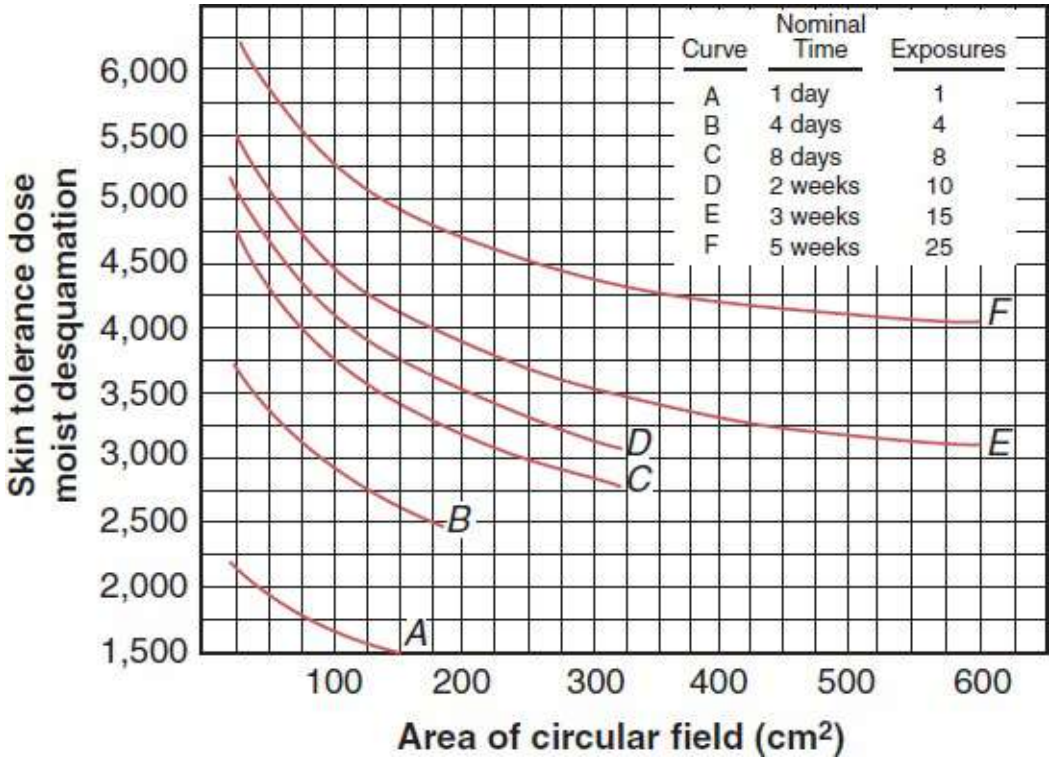

FIGURE 1.11. Graph showing the relationship between dose and size of area irradiated (healthy skin in an "average" site) to produce moist desquamation for various overall treatment times (daily irradiation at about 50 R/minute for each exposure with radiation of half-value layer 1.5 mm Cu). (From Paterson R. *The treatment of malignant disease by radium and x-rays*. Baltimore: Williams & Wilkins, 1949:39. With permission.)

Structural alterations without anatomic or functional impairment may be noted, whereas in other instances, substantial injuries with tissue destruction, severe dysfunction, or even death may occur. Normal tissues have a substantial capacity to recover from sublethal or PLD induced by radiation (at tolerable dose levels). Injury to normal tissues may be caused by the radiation effect on the microvasculature or the support tissues (stromal or parenchymal cells).[90]

Rubin et al.[151–153] indicated the usefulness of assigning a certain percentage of risk of complication, depending on the dose of the radiation. The minimal TD is defined as $TD_{5/5}$, which represents the dose of radiation that could cause no more than a 5% severe complication rate within 5 years after treatment. (Some authors use the equivalent terms "tissue tolerance dose," or $TTD_{5/5}$. Both the $TD_{5/5}$ and the $TTD_{5/5}$ are based on treatment at 2 Gy per fraction, five fractions per week.) Acceptable complication risk rate for severe injury of 5% in most curative clinical situations is generally viewed as acceptable. Moderate sequelae are noted in varying proportions (10% to 25% of patients), depending on the dose of irradiation given and the OARs.

Chronologically, the effects of irradiation are subdivided into acute (first 3 months) and late effects (more than 3 months after irradiation), according to the National Cancer Institute Common Toxicity Criteria. The gross manifestations depend on the kinetic properties of the cells (slow or rapid renewal) and the total radiation dose given.[310]

Early applications of time–dose considerations were applied by Baclesse[154,155] based on observations by Coutard[32,33,77] that various degrees of mucositis and moist desquamation were repaired by re-epithelialization of the mucosa and skin from the periphery of the irradiated field and from cells surviving in the center of the field. Protracted fractionation schedules for carcinoma of the breast with lower daily doses over 10 to 12 weeks were successful in avoiding acute moist desquamation,[155] but the higher radiation doses caused severe tissue damage in a large number of patients.[156]

No correlation has been established between the incidence and severity of acute reactions and the occurrence of late effects. Withers et al.[157] compiled data depicting isoeffect lines for acute or late effects in several organs. The slopes for late reactions were steeper than for acute effects, and there was a lack of correlation between the doses producing similar severities of acute or late effects.[158,159] This may result from the difference in the slopes of cell survival curves for acute or late-reacting tissues[70] (Figs. 1.12 and 1.13).

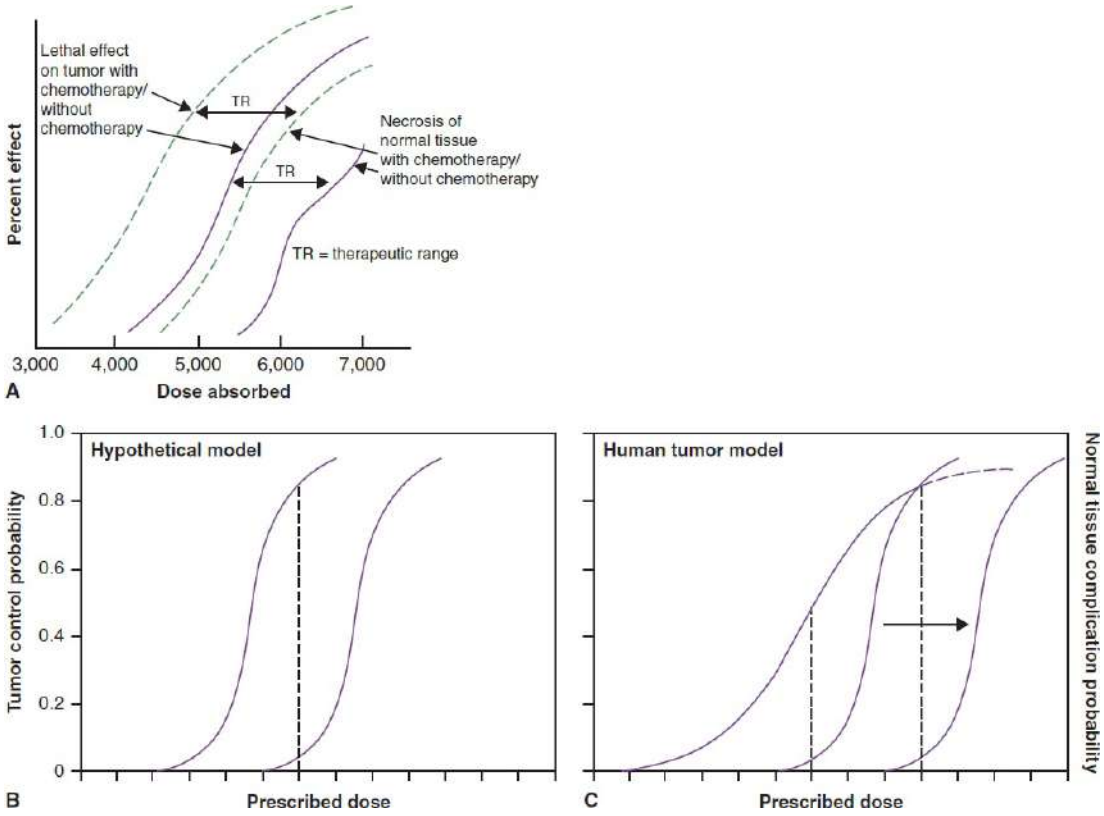

FIGURE 1.12. A: Building the work of Holthusen (Fig. 1.10) theoretical curves for tumor control and complications as a function of radiation dose with and without chemotherapy. *TR* is the therapeutic ratio, or the difference between tumor control and complication frequency. (Reprinted from Perez CA, Thomas PRM. Radiation therapy: basic concepts and clinical implications. In: Sutow WW, Fernbach DJ, Vietti TJ, eds. *Clinical pediatric oncology.* 3rd ed. St. Louis, MO: CV Mosby, 1984:167–209. Copyright © 1984 Elsevier. With permission.) **B:** Hypothetical dose–response curves for tumor control and for normal tissue injury. Because the tumor control and the normal tissue complication curves are approximately parallel in shape and are sufficiently separated, the dose levels necessary to cure a high percentage of patients can be administered without producing excessive normal tissue damage (indicated by the *vertical dotted line*). **C:** Human tumor model. The slope of the tumor control curve is less steep than the normal tissue–complication curve; thus, for an acceptable level of normal tissue injury, the probability of tumor control is decreased compared to the hypothetical model. Because of the volume effect, reducing the volume of normal tissues shifts the curve to the higher-dose region, thereby effectively increasing the separation of the dose–response curves. Consequently, a higher dose can be given to the tumor, improving the probability of tumor control without increasing the probability of normal tissue injury. Combining irradiation with surgery or cytotoxic agents frequently modifies the tolerance of normal tissues to a given dose of irradiation, which may necessitate adjustments in treatment planning and dose prescription. The lack of correlation between acute and late-reacting tissues represents one rationale for combining radiotherapy with chemotherapy. As long as the enhanced acute toxicities of combined treatment can be managed, no significant increased damage in late-reacting tissues is expected.[159]

QUANTITATION OF TREATMENT TOXICITY

There is a critical need to accurately assess and record morbidity of treatment because this, in addition to therapeutic efficacy, is a crucial parameter in the evaluation of new regimens and in the selection of therapy for an individual patient. Multiple schemata have been developed, although a complete consensus has not been reached as to ideal grading scores. Toxicity grading systems for various organs were developed by RTOG and the European Organisation for Research and Treatment of Cancer (EORTC). Overgaard and Bartelink[34] stressed the importance of proper recording of morbidity in clinical radiation oncology, with quantification of the normal tissue effects and description of the treatment-related factors correlating with morbidity.

The evolution of radiation treatment planning and delivery, with innovative techniques (3DCRT, IMRT, image-guided radiation therapy, image-guided brachytherapy), particle therapy allowing for better definition of target and sensitive structure volumes and more precise quantitation of dose, has

introduced more complexity into the evaluation of radiation effects on OARs. Journal articles and a book have been devoted to the "Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC)," which provided an updated review of knowledge in this area and practical guidance on toxicity risks and attempted to identify future research to elucidate radiation effects in normal tissues and organs. The QUANTEC program has continued its efforts and produced other publications. (See Chapter 14.)

Therapeutic Ratio (Gain)

The improved definitions of TCP and NTCP[160] imply that there is an optimal radiation dose that produces a maximum tumor control with a minimum (reasonably acceptable) frequency of complications, also called treatment sequelae. The farther the TCP and NTCP curves diverge, the more favorable is the therapeutic ratio (Fig. 1.14). The therapeutic ratio or therapeutic gain factor (TGF) of a given regimen could be expressed as a ratio:

$$\text{TGF} = \frac{\%\ \text{tumor control with therapy A versus therapy B}}{\%\ \text{complications with therapy A versus therapy B}}$$

FIGURE 1.14. Treatment outcomes. Uncomplicated curves (*dashed line*) are the desired results of treatment. This is illustrated as a function of the therapeutic ratio; that is, the greater the separation of the tumor control curve and the normal tissue–complication curve, the greater the number of uncomplicated cures that will result. The letters *A*, *B*, and *C* represent three different dose levels, which, if chosen, would lead to three different outcomes: *A* would result in few tumor cures but no complications; *C* would lead to complete cure in many cases, but virtually all patients would suffer complications. The optimal choice in this group of dose levels is *B*, which would result in the greatest number of cured patients without complications. (From Mendelsohn ML. The biology of dose-limiting tissues. In: *Time and dose relationships in radiation biology as applied to radiotherapy*. Brookhaven National Laboratory [BNL] Report 5023 [C-57]. Upton, NY: Brookhaven National Laboratory, 1969:154–173. Courtesy Brookhaven National Laboratory.)

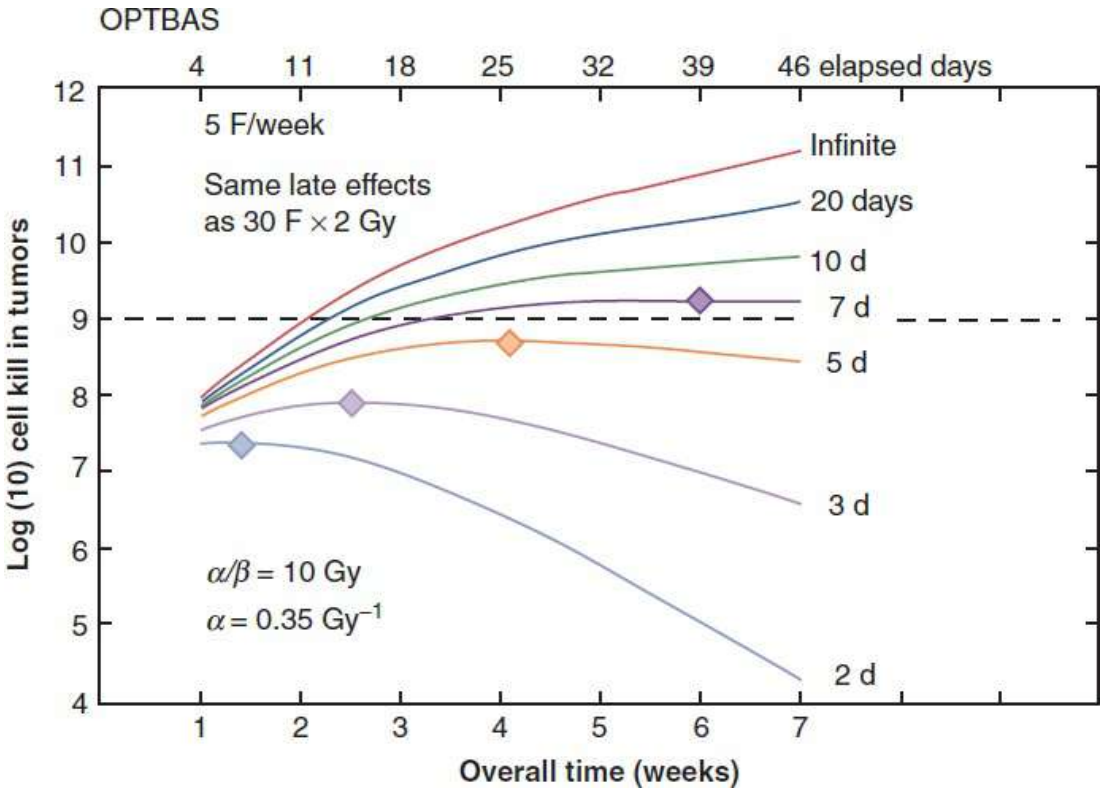

FIGURE 1.15. Log cell kill in tumors as a function of overall time, for schedules using five fractions per week to a total dose that gives the same late effects as 30 fractions of 2 Gy (assuming α/β = 3 Gy for late effects). Each curve is for the stated proliferation doubling time (average over the overall time). The diamond-shaped symbols show the maximum cell kill for that doubling time, at the optimum overall time for that number of fractions per week. If there is no diamond, the optimum overall time is longer than 7 weeks. The dotted line is drawn arbitrarily at 9 logs of cell kill. (Reprinted from Fowler JF. How worthwhile are short schedules in radiotherapy? A series of exploratory calculations. *Radiother Oncol* 1990;18[2]:165–181. Copyright © 1990 Elsevier Ireland Ltd. With permission.)

The higher the TGF, the more efficient a particular therapy. Such a quantitative expression could be used to compare different therapeutic strategies.

Mendelsohn[161] expressed this concept in terms of "uncomplicated tumor ablation."

The selection of a dose must weigh the probability of major complications for any potential enhancement of tumor control. Models for decision-making, using Bayesian theory, incorporate values assigned to positive or negative outcomes.[161] Positive outcome is considered tumor cure without complication, whereas negative outcomes include tumor cure with significant complications or tumor recurrence with or without complications (Fig. 1.15).

Impact of Local Tumor Control on Survival

Systemic chemotherapy, immunotherapy, and molecularly targeted therapy have been emphasized as therapies that could improve survival of cancer through control of systemic metastatic disease. The effect of locoregional tumor control on patient survival has been emphasized repeatedly.[162] Clinical experiences and randomized trials demonstrate for cancers with high metastatic potential, such as breast, prostate, and lung, that improved locoregional control by radiotherapy with or without chemotherapy enhances overall survival. This has revived the interest in locoregional radiotherapy as a survival-prolonging treatment modality, also confirming earlier clinical experiences in patients with carcinoma of the lung, prostate, and uterine cervix.

Because of the emphasis on control of systemic disease, assessment of the importance of locoregional tumor control in patients with malignant tumors has been relatively underemphasized. In a large proportion of patients with cancer seen in the United States, locoregional recurrence is just as prevalent (69% of patients dying with locoregional disease) as distant metastases. A large proportion of patients (50%) have both locoregional recurrence and distant metastases.

Clinical data demonstrate that tumor persistence after initial therapy does, because of tumor progression, carry as poor a prognosis as treatment of a more advanced cancer. In addition, radiotherapy has been shown for tumor with high metastatic potential, such as breast, prostate, and lung, to prolong overall survival if higher radiation doses are delivered and achieve improved local control rates.[115,163,164]

DOSE–TIME FACTORS

Dose–time considerations constitute complex relationships that express the

interdependence of total dose, time, and number of fractions in the production of a biologic effect within a given tissue volume. This phenomenon, from a radiobiologic viewpoint, is closely related to the four Rs of ionizing radiation:

- *Repair* of sublethal and PLD
- *Repopulation* of cells between fractions
- *Redistribution* of cells throughout the cell cycle (partially, the result of radiation-induced synchrony secondary to transient arrest at cell cycle checkpoints and cell cycle–dependent cell killing)
- *Reoxygenation* occurring during repeated radiation exposures

The advantages of dose fractionation include:

- Reduction in the number of hypoxic cells occurs through cell killing and reoxygenation. There is increased oxygenation in the tumor after irradiation, whereas changes in normal tissue oxygen are slight or nonexistent.[165]
- Reduction in the absolute number of clonogenic tumor cells by the preceding fractions with the killing of the better-oxygenated cells. Assuming a constant supply of oxygen, fewer cancer cells will have access to an increased amount of oxygen.
- Blood vessels compressed by a growing cancer are decompressed secondary to tumor regression, thus permitting better oxygenation despite the constant diffusion distance of oxygen in tissue near 200 μm.
- Fractionation exploits the difference in recovery rate between normal, acute, and late-reacting tissues and tumors. Radiation-induced redistribution of cells within the cell cycle tends to sensitize rapidly proliferating cells as they move into the more sensitive phases of the cell cycle.
- The acute normal tissue toxicity of single radiation doses can be decreased with fractionation. Thus, patients' tolerance of radiotherapy will improve with fractionated irradiation.

In general, fractionated irradiation will spare acute reactions because of compensatory proliferation in the epithelium of the skin or the mucosa, acceleration of which can be measured experimentally 2 or 3 weeks after initiation of therapy, but most likely starts with initiation of irradiation.[166–169] However, a prolonged course of therapy with small daily fractions will decrease early acute reactions but not necessarily prevent serious late damage to normal tissues. This approach also promotes accelerated repopulation and permits the growth of rapidly proliferating tumors. A major research effort in clinical radiobiology is and will be devoted to the optimization of dose–time

fractionation schedules for various tumors that are individualized depending on cell kinetic characteristics, molecular biology, and clinical observations.[126,170,171] Fowler[71] published theoretic considerations based on a series of assumptions of the values used in the LQ equation with a time factor in which he attempted to predict the optimal dose fractionation schedules for tumors with various cell doubling times. He concluded that optimal overall times depend primarily on the doubling time of the tumor cells and intrinsic radiosensitivity, alpha (assumed to be proportional to α/β). Short overall treatment times are required for tumors with a low α/β ratio or fast proliferation. For median potential doubling times of 5 days and intermediate radiosensitivity, overall times of 2.5 to 4 weeks would be optimal. More slowly proliferating tumors, he argued, should be treated with longer overall times (Fig. 1.15). Clinical studies, however, support relatively short overall treatment times in several common solid malignancies, in contrast to Fawler's conclusions. *In vitro* techniques to assess tumor radiosensitivity in biopsy specimens ultimately may be helpful as predictive assays.

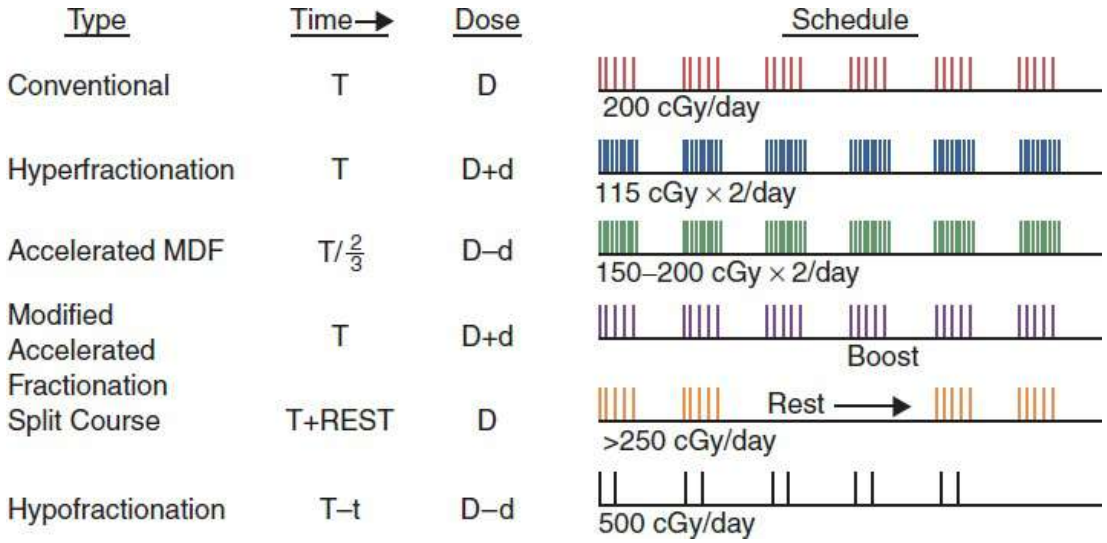

FIGURE 1.16. Various types of fractionation used in radiation therapy.

Altered Fractionation

Without a solid biologic basis and out of empiricism and convenience, the "standard fractionation" for radiation therapy has evolved into five fractions weekly. Other fractionation schedules have been proposed that deliver multiple fractions daily or six fractions weekly or use a hyperfractionation split-course regimen (Fig. 1.16). Based on the narrow window between improvements in tumor control and enhanced normal tissue toxicities,[55] any altered fractionation

schedule is potentially harmful and must be approached with caution. However, the improved quality of clinical trials by national study groups and by individual institutions has generated a growing body of clinical outcome data that, together with improved biologic modeling, allows relatively accurate predictions of clinical outcomes based on relative biologic effectiveness (RBE) calculations[172] (Table 1.6).

Multiple daily fractions are likely to be more effective in rapidly growing tumors with a high growth fraction. Normal tissues behave as actively proliferating cells for expression of acute reactions but as slowly proliferating cells in the manifestation of late injury.[173,174] As suggested by several biologic studies,[175] clinical trial results conducted by EORTC and RTOG demonstrated that a minimum of 6 hours of interfraction interval should be allowed when multiple daily fractions are used to allow maximum repair of normal tissues. This is supported by reduced complication rates in patients irradiated for carcinoma of the lung and a highly uniform cohort of patients with tonsillar squamous cell carcinomas.[72,134]

Accelerated fractionation aims at shortening the overall treatment time. Schedules may use larger than standard size fractions five times weekly or more than five fractions per week of 2 Gy. In addition, multiple fractions of radiation may be given daily exclusively or in combination with standard fractions of 2 Gy. Some reduction in the total dose delivered may have to be used for fractions >2 Gy for normal tissue sparing. These schedules may be preferable with hypoxic cell sensitizers or other chemical modifiers of radiation response that require the presence of a high concentration of the compound in the tumor at the time of the radiation exposure.

With hyperfractionation, a larger number of smaller-than-conventional dose fractions are given daily; the total daily dose is usually 10% to 20% greater than with standard fractionation; the total period of time is minimally changed; and the total dose needs to be escalated to achieve tumor toxicity similar to that of standard fractionation. The aim of hyperfractionation is to achieve the same incidence of late effects on normal tissue as observed with a comparable conventional regimen while increasing the probability of tumor control through dose escalation.[176]

TABLE 1.6 COMPARISON OF VARIOUS FRACTIONATION SCHEDULES

	Conventional	Split-Course	Accelerated Fractionation	Hyperfractionation
Indication, in tumors, of growth rate	Average	Average or slow	Rapid	Slow (with large cell loss factors)
Normal tissue effects, acute	Standard	Standard or greater	Greater	Standard or greater
Normal tissue effects, late	Standard	Greater	Standard (if complete repair of sublethal damage occurs) or greater	Lower
Advantages	—	Shorter actual treatment time (fewer fractions)	Destroys more tumor cells; prevents tumor cell repopulation; less overall treatment time	Lower OER with small doses; spares late damage; allows reoxygenation; allows stem cell repopulation
Disadvantages	—	May permit tumor repopulation	—	More fractions

OER, oxygen enhancement ratio.

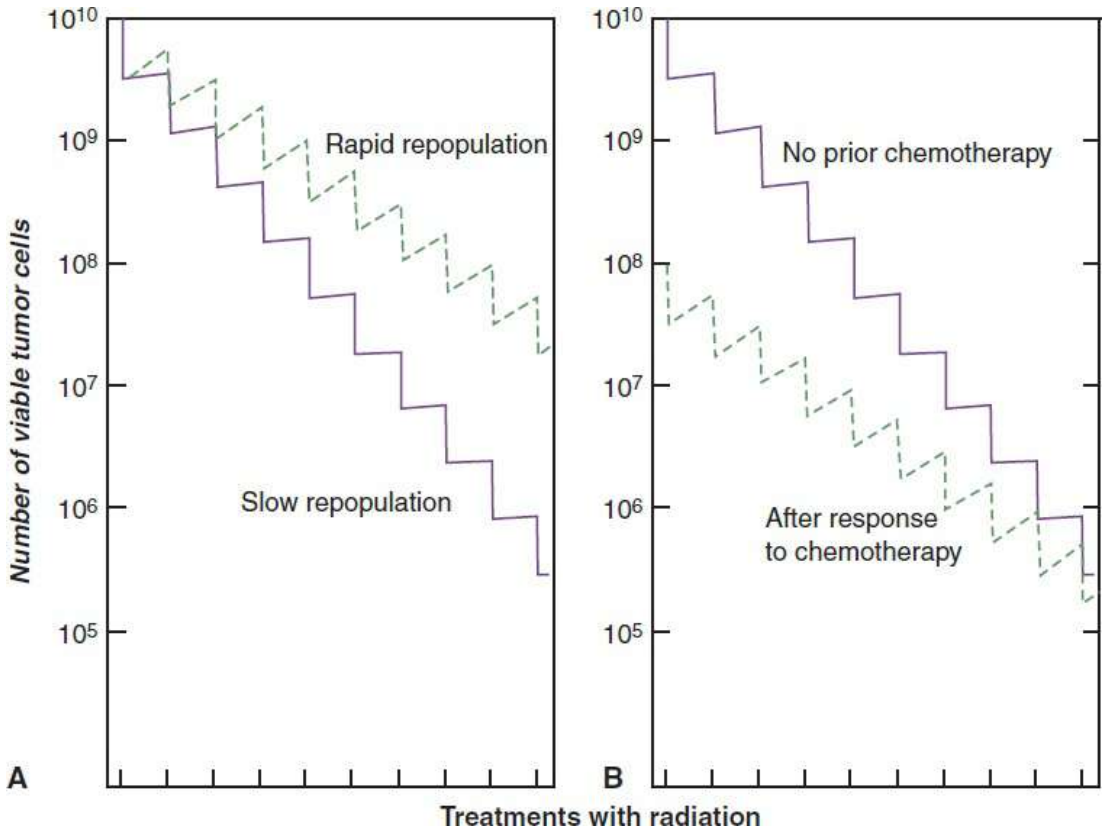

FIGURE 1.17. A: Schematic diagram indicating that cell survival during a course of fractionated irradiation depends not only on the proportion of cells killed with each dose (equal for the two curves shown) but also on the rate of proliferation of surviving cells between dose fractions, which differs for the two curves. **B:** Hypothetical diagram to illustrate the number of surviving cells in a tumor during treatment with irradiation alone (*solid line*) or during radiation therapy delivered to a tumor that has responded to chemotherapy (i.e., cell number reduced to 1% at start of irradiation) but where proliferation has been stimulated (*dashed line*). Note that cell survival is similar after fractionated irradiation, despite the initial response to drugs. (Reprinted from Tannock IF. Combined modality treatment with radiotherapy and chemotherapy. *Radiother Oncol* 1989;16[2]:83–101. Copyright © 1989 Elsevier Ireland Ltd. With permission.)

Accelerated Repopulation

Withers and Taylor[40] described experimental observations documenting accelerated repopulation of tumor cells during fractionated radiotherapy and provided convincing evidence that this phenomenon occurs in clinical situations (Figs. 1.17 and 1.18). Although Withers and Taylor's analyses suggested that accelerated repopulation occurs preferentially after the 4th week of radiotherapy, reanalysis of the same data by Bentzen[41] and Thames et al.[177] and independent derivations by Fowler[168] suggested that repopulation starts early during fractionated irradiation. The latter is supported by experimental data of Schmidt-Ullrich et al.,[169] showing that molecular processes of accelerated repopulation, mediated through radiation-induced receptor activation and cellular growth stimulation, occur after a single radiation exposure of 2 Gy. The effectiveness of a course of fractionated irradiation depends in part on the killing by individual fractions as well as on the rate of proliferation of surviving cells between irradiation fractions. Neoadjuvant chemotherapy also may lead to increased proliferation of surviving tumor cells after partial regression of the lesion, which could result in decreased cell killing by subsequent fractionated irradiation.

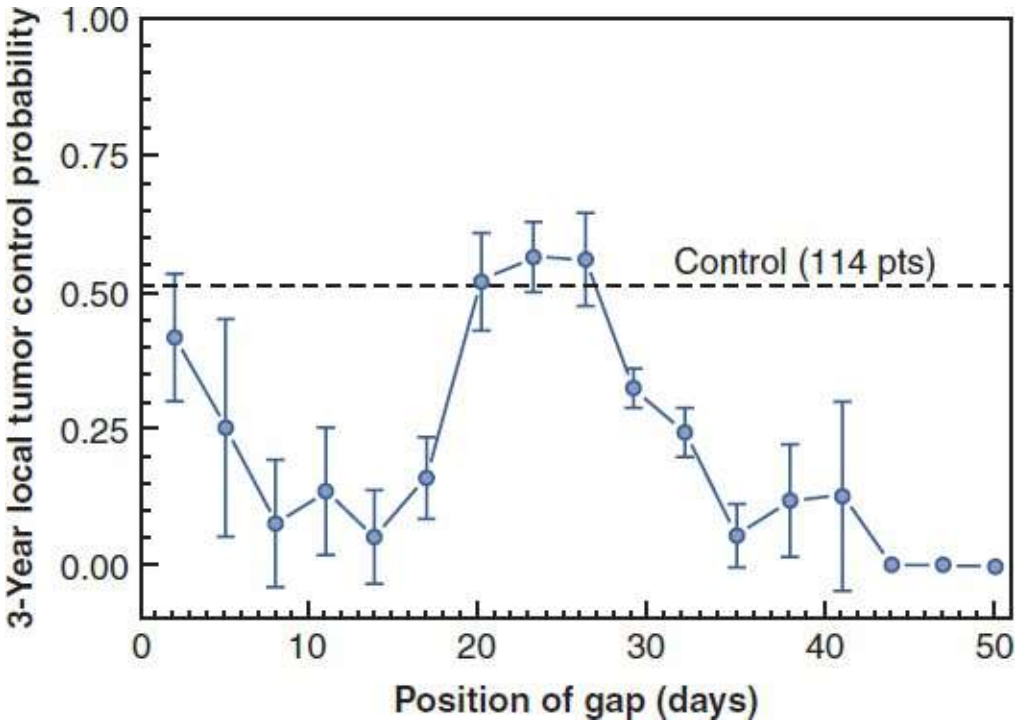

FIGURE 1.18. Dependence of tumor control probability (TCP) on the position of a single-treatment gap in 533 patients. Gap duration ranged from 3 to 20 days. Position of a gap is defined by its starting point. Each point shows the TCP averaged over 3 consecutive days (±SD). (Reprinted from Skladowski K, Law MG, Maciejewski B, et al. Planned and unplanned gaps in radiotherapy: the importance of gap position and gap duration. *Radiother Oncol* 1994;30[2]:109–120. Copyright © 1994 Elsevier Ireland Ltd. With permission.)

Isoeffect Graphs

To express an equal biologic effect produced by various fractionation schedules, isoeffect lines have been generated. Kronig and Friedrich[178] first published the observation that a specific physical dose of irradiation is less biologically effective if given in multiple fractions, which embodies the original concept of recovery between fractions. Later, MacComb and Quimby[179] and Reisner[180] established the rate of recovery in experimentally produced skin reactions in patients.

In 1944, Strandqvist[128] published a monograph describing the results of treatment of 280 patients with skin cancer (squamous cell and basal cell carcinoma); most tumors were treated within 14 and 29 days, and only one was treated within 45 days. An isoeffect line was drawn, with a slope of 0.22. He fitted the recovery factors of MacComb and Quimby and Reisner using an extrapolated value of 0.35 per day as the time for a single dose. He also produced a graph for various degrees of radiation reaction on the skin, ranging

from erythema to necrosis (Fig. 1.19). It should be emphasized that in these curves, the vertical coordinate represents the total dose given, and the abscissa represents the total duration in days after the first irradiation. However, some authors have plotted similar graphs representing the number of fractions in the horizontal coordinate. It is critical to identify these two parameters because one could deliver 60 Gy in 6 weeks in 30 fractions given five times weekly or the same dose delivered in 18 fractions given three times weekly. The effects on normal tissues certainly would be different. von Essen,[181] using the Strandqvist data as well as his own, pointed out the importance of the volume irradiated when isoeffect parameters are studied and generated a 3D display of these data.

Dutreix et al.[182] published observations on the influence of fraction size in patients with cancer of the lung, on whom one of the supraclavicular areas received a single exposure and the other area received two exposures separated by 6 hours. They noticed that two fractions of 1 Gy produced the same skin reaction as one fraction of 2 Gy. As the fraction size increased, however, it took a higher dose in the two-fraction schedule to produce the same reaction as with the single-fraction schedule. With mucositis of the faucial arch used as an endpoint, researchers at MD Anderson Cancer Center observed that 10 Gy per week given in five fractions of 2 Gy is equivalent to 11 Gy given in 10 fractions, twice a day, separated by 3 hours.[87]

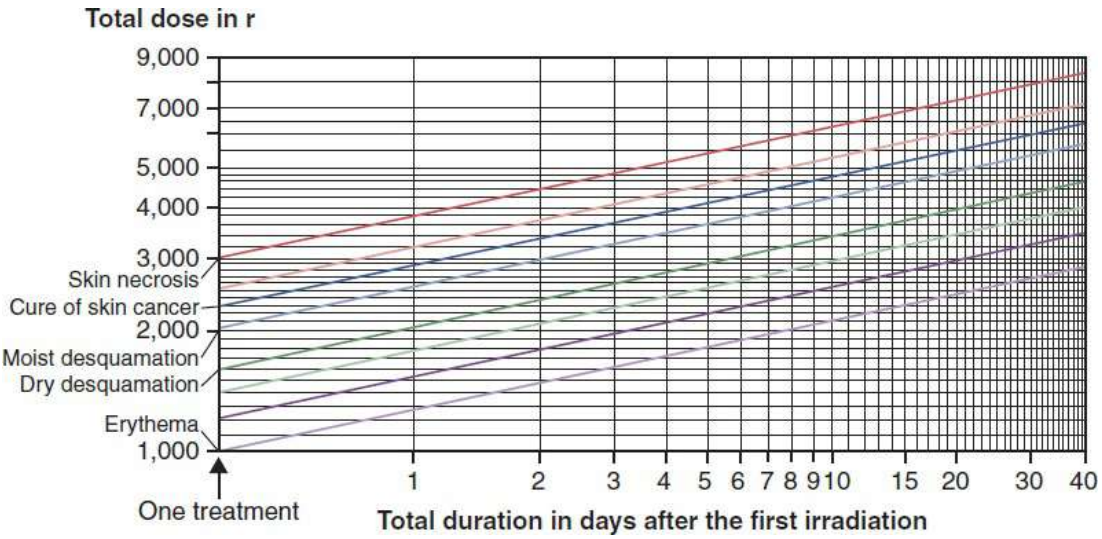

FIGURE 1.19. Strandqvist's curves on log paper. The slope of the curves (0.22) is the same for the tumoricidal dose for squamous cell carcinoma for various degrees of skin reactions. (From Strandqvist M. Sutdien uber die kumulative wirkung der rontgenstrahlen bie frakionierung. *Acta Radiol* [*Stockh*] 1944;55[Suppl]:1–300.)

The slopes for reactions for various normal tissues differ, as do slopes of

tumor curability and normal tissue late effects. In general, the slope for tumor curability is less steep than that for normal tissue reactions. Isoeffect lines for various squamous cell carcinomas of the head and neck, different stages, have slopes varying from 0.33 to 0.38.[135,183] Furthermore, as stated earlier, tolerance of normal tissues is strongly related to the volume irradiated. Whereas 60 Gy could be given safely in 5 weeks for a small glottic tumor with a 5-cm by 4-cm portal, the same dose delivered in the same period for a supraglottic carcinoma, with a larger portal covering the entire larynx, would result in more severe acute and late sequelae[135] (Box 1.6).

Linear-Quadratic Equation (α/β Ratio)

Formulations based on dose survival models have been proposed to evaluate the biologic equivalence of various doses and fractionation schedules. These assumptions are based on an LQ survival curve represented by the equation:

$$\log_e S = \alpha D + \beta D^2,$$

in which α represents the *linear* (i.e., first-order dose-dependent) component of cell killing and β represents the *quadratic* (i.e., second-order dose-dependent) component of cell killing. Thus, β represents the more reparable (over a few hours) component of cell damage (Figs. 1.20–1.22). The dose at which the two components of cell killing are equal constitutes the α/β ratio.

In a study of 17 human tumor cell lines, Steel and Peacock[92] observed that the average surviving fraction at 2 Gy is 0.44 from the α component and 0.88 from the β component. The β effect at that dose level appears to be similar in radiosensitive and radioresistant tumors; thus, among radiosensitive tumors in which the survival from the α component is below 0.3, the β effect makes a very small contribution to overall radiosensitivity in the lower dose region. The overall effect of many small fractions is to amplify the dominance of the α component. The β effect is unimportant because repair will be almost complete. In the more radiocurable tumors, cell killing by the α component represents the predominant fraction of tumor cell killing.

The shape of the dose survival curve with photons differs for acutely and slowly responding normal tissues. This difference in shape is not observed with neutrons. The severity of late effects changes more rapidly with a variation in the size of dose per fraction when a total dose is selected to yield equivalent acute effects. With a decreasing size of dose per fraction, the total dose required to achieve a certain isoeffect increases more for late-responding tissues than for

acutely responding tissues. Thus, in hyperfractionated regimens, the tolerable dose would be increased more for late effects than for acute effects. Conversely, if large doses per fraction are used, the total dose required to achieve isoeffects in late-responding tissues would be reduced more for late effects than for acute effects. In general, tumors and acutely reacting tissues have a high α/β ratio (8 to 15 Gy), whereas tissues involved in late effects have a low α/β ratio (1 to 5 Gy).

Box 1.6

Nominal Standard Dose and Time–Dose Factor

The nominal standard dose (NSD) concept is of historic interest. For 20 years, NSD was used frequently to express equivalency of clinical doses of irradiation based on human skin tolerance and curability of squamous cell carcinoma. Cohen[378] pointed out that the regression coefficient for squamous cell carcinoma was different from that of normal skin (0.24). In 1969, Ellis[379] suggested that if one number could be used to represent the dose of irradiation that reached normal tissue tolerance, this would be advantageous in comparing different techniques. This figure should represent the normal connective tissue tolerance because this was, in his thinking, the limiting factor in most tumor therapies.

The unit for NSD expression was the *ret.* It could never be assumed that the NSD value represented a “single equivalent dose” because the isoeffect time calculated by Ellis used data from four to 30 fractions. Another flaw of the NSD calculation was that it did not allow for the effect of variations in volume treated or for interruptions of therapy (split-course therapy). Orton[380] estimated that NSD calculations were misused about 50% of the time by unaware clinicians comparing different radiation therapy regimens. The NSD formula did not predict isoeffect in pig skin irradiation with ^{184}Co using two to five fractions per week. Moreover, early reactions did not predict the magnitude of late damage when dose fractionation was altered from conventional daily schedules.

In 1973, Orton and Ellis[185] published a simplification of the NSD concept more applicable to clinical radiation therapy, stating that when a treatment did not result in normal connective tissue tolerance, treatment effectiveness should be described in terms of partial tolerance. Although there was no definite basis for the application of the time–dose factor (TDF) concept to clinical radiation therapy, equivalency of various dose schedules is sought constantly. For split-course regimens, the TDF values (in units of ret) were used by adding the TDF value for each of the partial tolerance factors corresponding to each component of the treatment and correcting for the decay of the first part of the treatment TDF.

In 1974, Orton[186] defined TDF values for continuous irradiation that could be used with temporary or permanent brachytherapy implants, using various isotopes. A standard radium therapy regimen of 60 Gy in 168 hours was used for comparison with other equivalent techniques. According to Ellis,[187] this was equivalent to 1,800 ret of fractionated external irradiation.

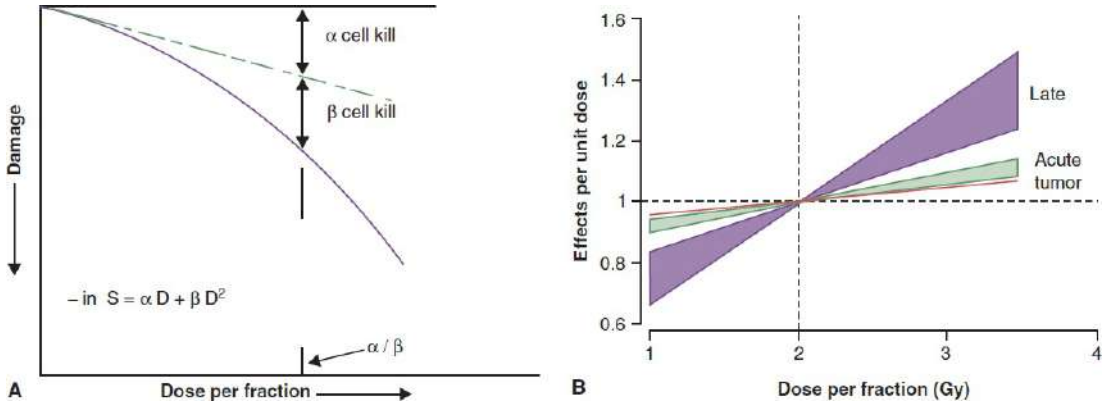

FIGURE 1.20. A: At a dose equal to the *α*/*β* ratio, the log cell kill because of the *α*-process (nonreparable) is equal to that because of the *β*-process (reparable injury); *α*/*β* is thus a measure of how soon the survival curve begins to bend over significantly. The *α*/*β* ratio for late effects on normal tissue generates a "curvier curve" than the *α*/*β* ratio for radiation's effects on acutely reacting normal tissue and tumor cells. Thus, the relative effect of dose per fraction is higher for late-responding tissue than for acutely responding tissues. In particular, for the central nervous system, high–dose-per-fraction radiation therapy is associated with an increased risk of late effects. An *α*/*β* ratio of 2 to 3 commonly is used in calculations of radiation effects on late-reacting tissue, whereas the ratio of 10 is used more commonly for acute-responding tissues or tumor. (Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. *Biological basis of radiotherapy*. 2nd ed. Amsterdam: Elsevier Science, 1983:181–194. Copyright © 1983 Elsevier. With permission.) **B:** A schematic representation of biologic data relating dose per fraction to effect on tumors, early-reacting, and late-reacting normal tissues. (Reprinted from Saunders MI. Programming of radiotherapy in the treatment of non-small-cell lung cancer—a way to advance cure. *Lancet Oncol* 2001;2[7]:401–408. Copyright © 2001 Elsevier. With permission.)

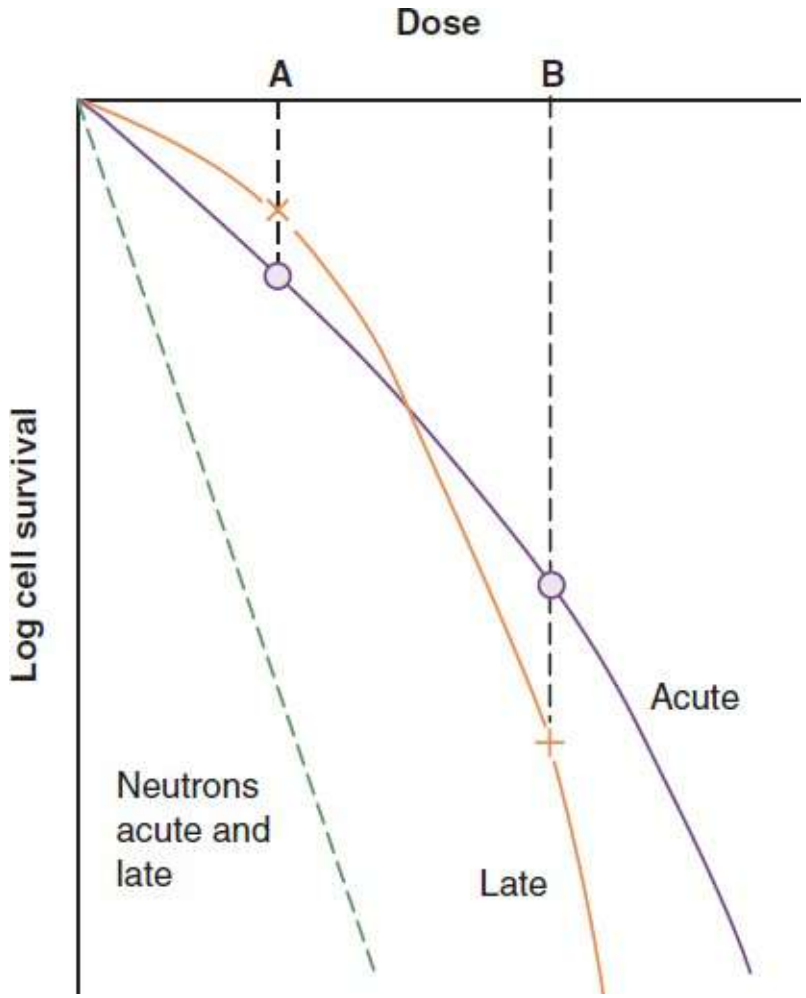

FIGURE 1.21. Hypothetical survival curves for the target cells for acute and late effects in normal tissues exposed to x-rays or neutrons. The α/β ratio in the equation for surviving fractions ($SF = e^{-\alpha D+\beta D_2}$) is higher for late effects than for acute effects in x-irradiated tissues, resulting in a greater rate of change in effect in late-responding tissues with change in dose. At dose A, survival of target cells is higher in late effects than in acute effect tissues, whereas at dose B, the reverse is true. Therefore, increasing the dose per fraction from A to B results in a relatively greater increase in late rather than acute injury. In the case of neutrons, the α/β ratio is low, with no detectable influence on the quadratic function ($e\beta D \pm D_2$) over the first two decades of reduction in cell survival, implying that accumulation of sublethal injury plays a negligible role in cell killing by doses of neutrons of clinical interest. At these doses, the relative biologic effectiveness is higher for late effects than it is for acute effects. (Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. *Biological basis of radiotherapy*. 2nd ed. Amsterdam: Elsevier Science, 1983:181–194. Copyright © 1983 Elsevier. With permission.)

The values for α and β can be obtained from graphs in which the reciprocal of the total dose (Gy^{-1}) and the dose per fraction (Gy) are plotted (Table 1.7). A straight line is obtained. The intercept of this line with the zero dose-per-fraction

axis is proportional to α and equal to α/ln S, wherein S is the natural logarithm of survival. The slope is proportional to β and equal to β/ln S.

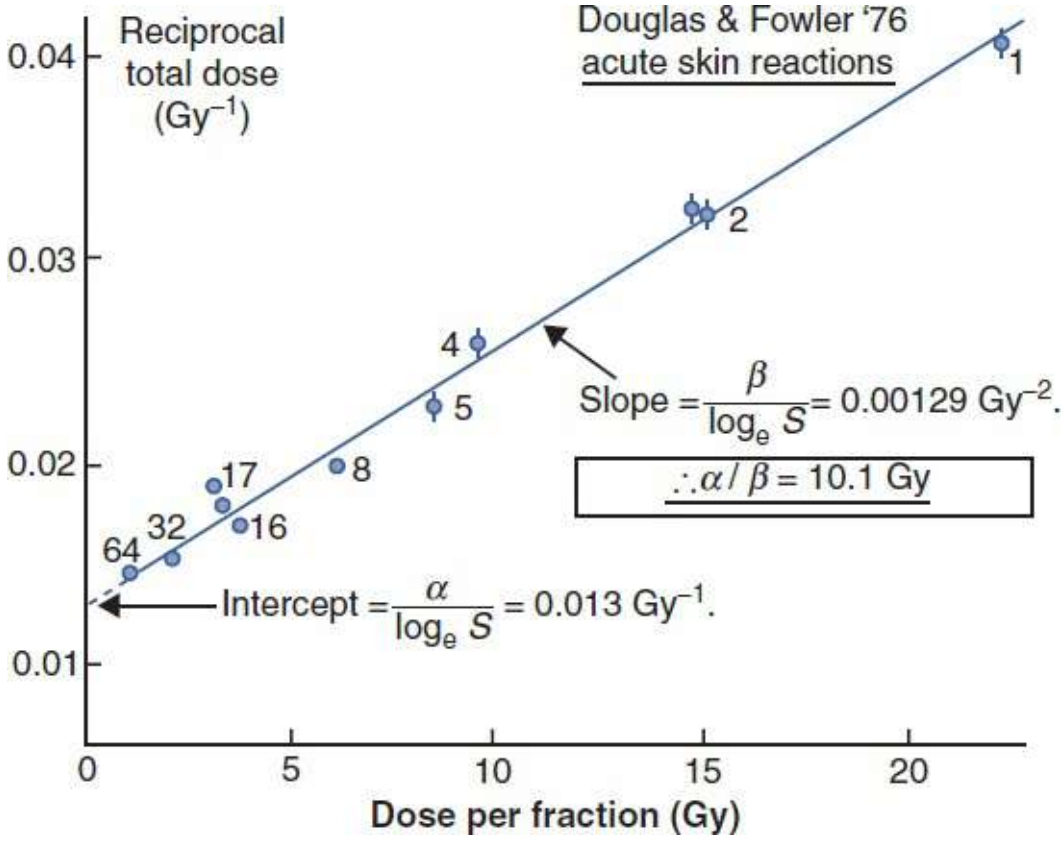

FIGURE 1.22. Values of α and β. If the reciprocal of total dose (for several multifraction schedules) is plotted against dose per fraction, a straight line will be obtained. The intercept of this line with the zero dose-per-fraction axis is proportional to α (α/ln S). The slope is proportional to β (β/ln S). The α/β ratio is readily determined. For absolute values of α and β, clonogenic assay is necessary for the endpoint. (Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. *Biological basis of radiotherapy*. 2nd ed. Amsterdam: Elsevier Science, 1983:181–194. Copyright © 1983 Elsevier. With permission.)

The algebraic functions to derive the straight line from the reciprocal total dose per fraction plot are as follows: Tumor cell survival following n fractions, each of dose d:

$$\begin{aligned} -\ln S &= n(\alpha d + \beta d)^2 \\ &= \alpha nd + \beta nd^2 \\ &= nd(\alpha + \beta d) \end{aligned}$$

Dividing both sides by total dose nd:

$$\frac{-\ln S}{nd} = \alpha + \beta d$$

$$\uparrow \qquad \uparrow$$

Intercept Slope

Withers et al.[188] proposed a method for using these survival curve parameters for calculating the change in total dose necessary to achieve an equal response in tissue when the dose per fraction is varied, using the α/β ratios. This calculation accounts only for the effect of repair of cellular injury. The isoeffect curves vary for different tissues. A biologically equivalent dose (BED) can be obtained using this formula:

$$BED = \frac{\ln S}{\alpha}$$

$$BED = nd\left[1 + d/(\alpha/\beta)\right]$$

If one wishes to compare two treatment regimens, the following formula can be used:

$$\frac{Dr}{Dx} = \frac{\alpha/\beta + dx}{\alpha/\beta + dr}$$

in which Dr is the known total dose (reference dose), Dx is the new total dose (with different fractionation schedule), dr is the known fractionation (reference), and dx is the new fractionation schedule.

Let's consider an example of the use of this formula (with some reservations). Suppose 50 Gy in 25 fractions is delivered to yield a given biologic effect. If one assumes that the subcutaneous tissue is the limiting parameter (late reaction), it is desirable to know what the total dose to be administered will be using 4-Gy fractions. Assume α/β for late fibrosis equals 2 Gy.

Using the above formula:

$$Dx = \frac{Dr(\alpha/\beta + dr)}{\alpha/\beta + dx}$$

Thus,

$$Dx = 50\ Gy\left(\frac{5+2}{5+4}\right) = 39\ Gy$$

The basic LQ equation addresses the inactivation of a homogeneous population of cells. One should be wary, however, of accepting the basic equation as being complete. Because it is likely that accelerated repopulation of tumor clonogens occurs during the course of radiotherapy, and that cell cycle redistribution and reoxygenation also occur, we should consider how these factors can be accounted for in the formula.[89,189,190]

Repopulation may be accounted for, in broad approximation, by describing the number of clonogens (N) at time *t* as being related to the initial number of clonogens (No).

Then,

$$N = No^{e\lambda t}$$

The parameter λ determines the speed of cell repopulation and is given by

$$\lambda = \frac{\log e^2}{T\ pot} = \frac{0.693}{T\ pot}$$

where Tpot is the effective doubling time of cells in the tumor. If we ignore

spontaneous cell loss, then Tpot is approximately the same as the measurable *in vitro* doubling time of tumor cells. Reported values of Tpot are 2 to 25 days with a median value of approximately 5 days. For late-responding tissues, Tpot is so large that λ is effectively zero.

Incorporating the allowance for tumor proliferation, with t representing time, the LQ equation becomes

$$\mathrm{BED} = \mathrm{nd}\left(1 + \frac{\mathrm{d}}{\alpha/\beta}\right) - \frac{0.693\mathrm{t}}{\alpha \mathrm{Tpot}}$$

Let's assume an α/β for an acutely reacting tissue, such as a tumor, of 10, and an α of 0.3 with a Tpot of 5. The BED of 70 Gy of 2 Gy/fraction, five fractions per week, in 46 days, is

$$\mathrm{BED} = 70(1 + 0.2) = 84\ \mathrm{Gy}_{10}.$$

Now let's add the correction for tumor repopulation during the course of treatment:

$$\mathrm{BED} = 70\left(1 + \frac{2}{10}\right) - \frac{0.693}{0.3} \times \frac{46}{5}$$

$$\mathrm{BED} = 84 - 21 = 63\ \mathrm{Gy}_{10}$$

The decrease in clonogens by radiotherapy is attenuated, in part, by the repopulation of the surviving clonogens.

In the LQ equation, redistribution in the cell cycle and reoxygenation may be modeled by a single term called *resensitization.* Immediately after a dose of radiation, the average radiosensitivity of the cell population falls and then gradually returns to greater sensitivity. In contrast to tumor proliferation, resensitization probably increases as overall treatment time increases. Not enough is known about resensitization's clinical importance to make it useful to incorporate a numeric value for it in the LQ formula.

The LQ model can be used to construct a biologically oriented dose distribution algorithm for clinical radiation therapy.[94,191,192] A physical dose distribution can be translated to a BED using published biologic parameters. We are certainly not in a position to begin the routine use of this approach in clinical radiation therapy, although it may help clinicians to optimize treatment plans, and the technique may be used for outcome analysis in clinical research when

the biologic parameters and the assumptions can be validated.

Brachytherapy and the Radiobiologic Dose Rate Effect

In 1901, Alexander Graham Bell suggested that cancer might be treated by directly implanting radioactive sources into a tumor. This form of radiotherapy is referred to as brachytherapy or endocurietherapy. The prefix brachy, from the Greek, means short, slow, or short range. The suffix therapy is derived from *therapeaia,* also Greek, meaning care or service to the sick. Some physicians use the alternative term endocurietherapy. The prefix endo, also from the Greek, means "within."

There are several ways we can describe the forms of brachytherapy. First, we can subdivide brachytherapy into a classification system based upon the physical placement of the radioactive sources. Thus, (1) interstitial brachytherapy is the placement of the radioactive sources directly into the tumor of tumor bed. Implanting radioactive seeds into the prostate would be an example of this form of treatment. (2) Intracavitary brachytherapy is the placement of the radioactive sources inside a body cavity and up against a tumor-bearing structure. The placement of tandem and ovoids for the treatment of carcinoma of the cervix or of a radioactive source-bearing catheter inside the nasopharynx are examples of this form of brachytherapy. Finally, (3) mold brachytherapy is the placement of radioactive sources upon the skin surface bearing a tumor. The use, for example, of radioactive sources embedded in a glove worn upon the hand for a period of time to treat a tumor of the dorsum of the hand, while preserving the function of the ligaments controlling the fingers, is an example of this form of treatment.

Another way we can subdivide the forms of brachytherapy is by duration of the treatment. A (1) temporary brachytherapy application resides in the tumor, body cavity, or adjacent to the tumor for a finite period of time before it is removed. Tandem and ovoid placement for carcinoma of the cervix is typically a temporary brachytherapy application. A (2) permanent brachytherapy application is placed permanently and, over time, the radioactive source decays. Injecting radioactive Au198 seeds into a bronchogenic carcinoma for palliation of bronchial obstruction by tumor is an example of a permanent implant.

Yet, a third way we can think about the forms of brachytherapy is by the speed with which the radiation is administered in cGy/minute. Three types are generally described. (1) Low–dose rate (LDR) brachytherapy typically administers its dose over a period of days. For example, administering 1,000 cGy/day to point A in a Cs 137 tandem and ovoid application would be a classic

example of LDR brachytherapy. (2) High–dose rate (HDR) brachytherapy delivers the dose in a few minutes. The use of a robot referred to as a remote HDR remote afterloader to pump high-activity Ir-192 into and out of a series of Teflon catheters in the tumor bed for the postoperative treatment of a high-risk soft tissue sarcoma is an illustration of HDR brachytherapy. Finally, there is so-called (3) intermittent HDR brachytherapy or pulse–dose rate (PDR) brachytherapy. This usually refers to fractionating the HDR brachytherapy several times during the day, but the term is used by some physicians to refer to once per day or once every other day insertion of the HDR sources in the Teflon catheters. In either situation, a HDR remote afterloader machine is used.

When LDR brachytherapy is used for cancer treatment, we must give due consideration to its particular radiobiologic effects. We can think of LDR brachytherapy as the ultimate form of fractionation, being equivalent to an infinite number of small fractions with no interfraction intervals devoid of irradiation. What are the implications of this infinite fractionation on tumor cell killing and normal tissue tolerance?

The first point to consider is that much of the value of brachytherapy has less to do with biology than it has to do with physics. Brachytherapy is typically highly localized irradiation. The radiation beam in external beam radiotherapy comes “from the outside in” and passes through a block of normal tissue on its way to the tumor volume and, in the case of uncharged beams like photons and neutrons, passes through normal tissue on its way back out of the body after passing through the tumor. In contrast, the radiation beams in brachytherapy come “from the inside out” and are generally within or directly upon the tumor with the dose falling off rapidly as the square of the distance as one moves away from the radioactive source(s). Long before computer modeling of external beam irradiation and multileaf collimators for external beam treatment, brachytherapy was, to some extent, the first form of “dose painting” or “intensity-modulated radiation therapy.” The ability to confine the radiation dose to a small area with brachytherapy, with the avoidance of exposing large areas of normal tissue, allows the treating clinician to safely give doses sometimes unimaginable with external beam treatment.

Perhaps, the ultimate clinical example of the volume effect of brachytherapy is the treatment of choroidal melanoma or retinoblastoma with a I-125 or Ir-192 or Co-60 or Ruthenium plaque sewn to the choroid and overlaying the tumor bed. In some cases, 40,000 to 70,000 cGy will be administered to a small area of the outer surface of the choroid with an acceptable long-term ill effects on

normal tissue profile. This is only possible by the use of highly localized brachytherapy. This had led some wags to observe that “this isn’t really radiotherapy as we know it. It is nuclear warfare.”

It is also worth remembering that the dose in the tumor volume created by brachytherapy is often highly heterogenous. In the treatment of carcinoma of the cervix, for example, generations of radiation oncologists have prescribed and described the dose administered to “point A” and “point B,” both located lateral to the cervix. Radiation dose, however, falls off as the square of the distance. Therefore, the dose at the surface of the tumor-containing cervix from a Cs137 tandem and ovoid application is much higher and more tumoricidal than the dose at point A.

The author has had the occasion to treat vaginal rhabdomyosarcoma in very young girls with intracavitary pulsed HDR brachytherapy and custom-built lead shields to both push uninvolved normal tissue away from the brachytherapy catheters and partially shield this tissue with lead. It is difficult to imagine achieving more exquisitely conformal radiation dose distributions by any means other than brachytherapy.

The second point to consider is the fundamental series of effects of LDR on cell death. We can think of the radiation damage to mammalian cells as divisible into (1) lethal, irreversible, and irreparable lethal damage; (2) PLD whose injurious effects can be either exacerbated or ameliorated by the postirradiation environmental conditions of the irradiated cells; and (3) SLD which, under normal circumstances, can be repaired unless additional SLD is heaped upon existing damage and converts it to lethal damage. Here’s a simple way to think about SLD mathematically. Assume that A% of cells are killed by dose X of external beam irradiation. If you take dose X and split it into two equal fractions, then each fraction is X/2. Now, instead of giving all of the radiotherapy dose X at once, give X/2 today and the remaining X/2 tomorrow. What will happen? Instead of *A*% of cells dying as a result of radiation, A − B% will die. The improvement in the probability of cell survival, represented by B, is repaired SLD.

Let’s turn our attention back to PLD. By definition, PLD is influenced by the conditions the cells find themselves in after being irradiated. Let’s assume we do something to the cells, which prevents them from moving forward in the cell cycle. We might achieve this by lowering the ambient temperature or allowing the cells to be packed in closely so that density inhibition of growth occurs or by using a culture media, which starves the cells of nutrients. If we keep the cells

from moving forward in the cell cycle, then we will inhibit the ability of radiation-induced DNA injury to manifest itself by causing cell death when the cells try to divide. Cell survival will rise compared to allowing the cells to vigorously march through the cell cycle into M phase. This diminution in cell mortality represents PLD.[394]

With LDR, several things happen simultaneously, which influence cell killing. The relative importance of these factors will vary based on the specifics of whether you are thinking about normal tissue tolerance to radiotherapy or the tumor type, the tumor's growth environment, and, for normal or tumor tissue, the dose rate. The factors are:

(a) Repair: As the dose rate slows, some cells will endeavor to repair the radiation injury as it occurs. The cell's ability to survive may gain the upper hand if the dose rate is low enough and the cell's intrinsic radiation repair functions can handle the injury as it occurs. Imagine you are sitting in a rowboat in the middle of a lake and the boat springs a pinhole-sized leak. If the rate of the water entering your boat is slow enough, you can bail the boat fast enough to get yourself back to shore. If the rate of the water entering the boat becomes too fast, you and your boat are going to find yourselves seated on the bottom of the lake. The hole in your boat is analogous to the rate of induction of radiation injury.

(b) Repopulation: Some cells will be killed by the radiation. For those that survive, they no longer have to compete with their adjacent newly dead neighbor for oxygen and other nutrients. They will start to grow faster and, to varying extents depending upon the type of tissue or tumor, repopulate the neighborhood with new cells.

(c) Reoxygenation: Oxygen is the most powerful radiosensitizer. To the extent that LDR kills cells, the "neighborhood effect" as described just above in (b) also applies to oxygen. The continuous reoxygenation will render the remaining cells, which have survived the initial onslaught or radiation more sensitive to subsequent radiation injury.[395]

(d) Reassortment: As a general principle, reassortment refers to the progression of cells through the cell cycle during the interval between split doses. To the extent that cells move into the more radiosensitive phases of the cell cycle, they are more likely to be killed by radiotherapy. To the extent that they move into less radiosensitive phases of the cell cycle, they are more likely to be spared. There is a paradoxical form of reassortment, which occurs in some cell lines during LDR. It is called the "inverse dose rate effect." When the inverse dose rate effect occurs, cells

march through the cell cycle but become arrested in G2. G2 is a highly radiosensitive phase of the cell cycle, and the cells are more likely to be mowed down by radiation.[103]

Let's put all these factors together and think about what the net effect will be of LDR.

To the extent that cells repair SLD more effectively then the lower the dose rate, the better the cell survival. The magnitude of the effect will be dependent upon the efficacy and speed of SLD repair in an individual cell line.

To the extent that cells are redistributed into a more sensitive phase of the cell cycle, then the lower the dose rate, the worse the survival unless the dose rate is so low that the cells progress right on through into more resistant phases of the cell cycle. Then, their survival will rise.

To the extent that cells become better oxygenated as a result of LDR, then the worse the cell survival.

On net, from most mammalian cell lines, LDR produces a decrease in cell killing via a "flattening" of the cell survival curve and a "loss of the survival curve shoulder."

Brachytherapy is often a highly effective treatment for solid tumors as a result of its conformal dose distribution and radiobiologic effects on killing tumor cells and sparing normal tissue. Brachytherapy requires technical expertise, patience, access to a procedure room or operating room, and due attention to radiation safety and radiation protection. Catheters and seeds can be misplaced and there are risks of bleeding and infection. Practice makes perfect, and, unfortunately, many radiation therapy treatment centers do not do brachytherapy procedures frequently enough to develop local expertise and confidence with the techniques. It is not surprising that in the United States, inadequate brachytherapy experience is a common citation against radiation oncology residency programs. I am reminded of the words of wisdom of one of his beloved professors at the Massachusetts General Hospital in the early 1980s, Leonidas Harisiadis: "Brachytherapy is a highly effective form of treatment, but doing it can be a pain in the neck."

The radiation dose rate may significantly influence the biologic response, particularly for sparsely ionizing radiations such as x-rays and γ-rays. Three main biologic processes are involved in the dose rate effect (Figs. 1.23 and 1.24).[89,162]

With the advent of moderate– and high–dose rate remote control afterloading

devices, increased emphasis has been placed on the biologic effects of dose rate. Many *in vitro* and *in vivo* experimental observations indicate variations in cell killing and repair of sublethal or PLD with varying dose rates. The so-called dose rate effect is most dramatic between 1 cGy/minute and 1 Gy/minute.[193] The biologic effect achieved by a given irradiation dose decreases as the dose rate diminishes, chiefly as a result of the increase in cell repair that occurs during continuous prolonged irradiation, because cell proliferation is virtually negligible in the range of treatment times used in LDR brachytherapy.[194]

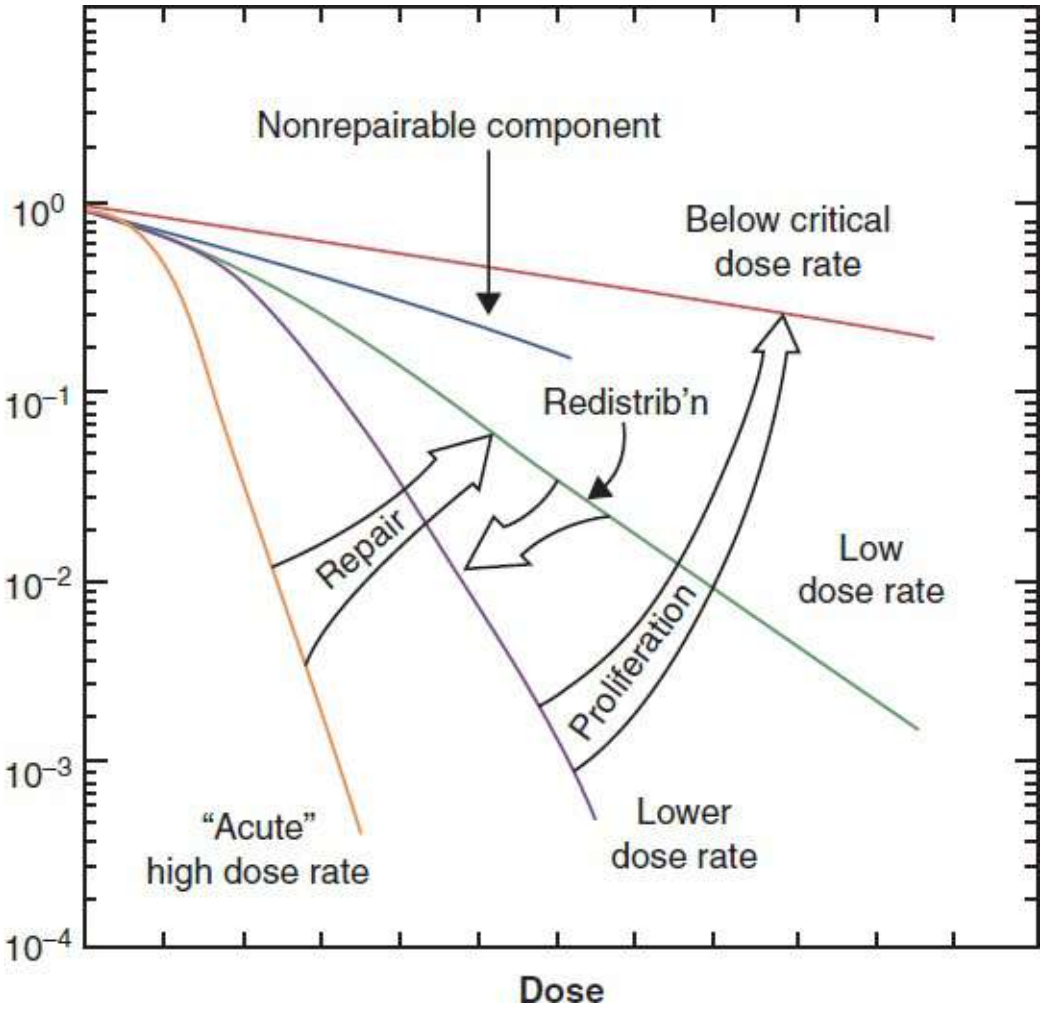

FIGURE 1.23. The dose rate effect as a result of repair of sublethal damage, redistribution in the cycle, and cell proliferation. The dose–response curve for acute exposures is characterized by a broad initial shoulder. As the dose rate is reduced, the survival curve becomes progressively shallower as more and more sublethal damage is repaired, but cells are "frozen" in their positions in the cycle and do not progress. As the dose rate is lowered further and for a limited range of dose rates, the survival curve steepens again because cells can progress through the cycle to pile up at a block in G2, a radiosensitive phase, but still cannot divide. A further lowering of dose rate allows cells to escape the G2 block and divide; cell proliferation then may

occur during the protracted exposure, and survival curves become shallower as cell birth from mitosis offsets cell killing from the irradiation. (Based on the ideas of Dr. Joel Bedford, and from Hall EJ. *Radiobiology for the radiologist*. 4th ed. Philadelphia: J.B. Lippincott, 1994, with permission.)

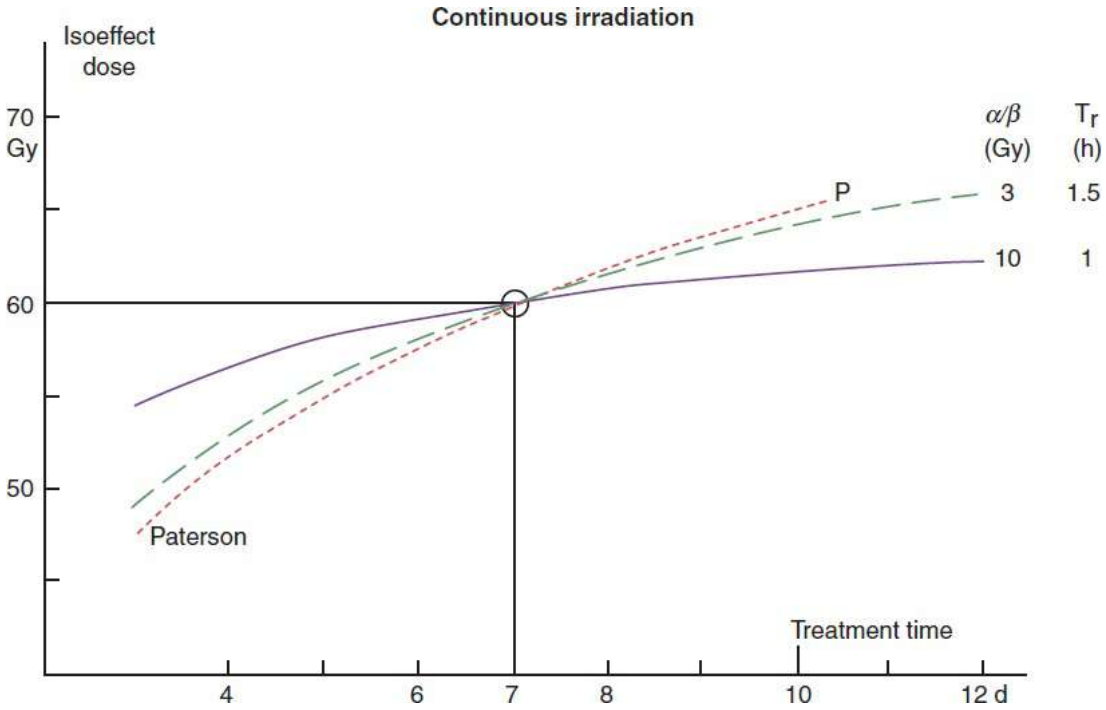

FIGURE 1.24. Low–dose rate irradiation. Isoeffect dose equivalent to 60 Gy in 7 days. Two sets of parameters have been considered for the computation, which would presumably correspond to skin and mucosa early reactions and to the effect on the epithelioma (α/β = 10 Gy, Tr = 1 hour) and to late reactions (α/β = 3 Gy, Tr = 1.5 hour). (Reprinted from Dutreix J. Expression of the dose rate effect in clinical curietherapy. *Radiother Oncol* 1989;15[1]:25–37. Copyright © 1989 Elsevier Ireland Ltd. With permission.)

In some experiments, a bending of the cell survival curve at very low dose rates has been noted, instead of the expected exponential result, possibly because of cell redistribution[388] or a decline in the repair capacity with large doses.[195] At a very low dose rate, because the cell killing is caused only by direct lethal events that are considered independent of the dose rate, cell repair is also negligible. The induction of sublethal injury is relatively slow compared with the rate of repair, and cell killing, by accumulation of sublethal injury, remains minimal. Variation of the isoeffect dose occurs mainly in the range of medium dose rates (1 to 10 Gy/hour), and it vanishes at very high dose rates because the cell repair is negligible during the short treatment time.[194]

The dose rate effect in clinical brachytherapy was described initially by Green and Paterson and reiterated by Ellis and Orton.[80,160,196–198] The historic isoeffect

curve showed a significant increase in dose when time was increased from 2 to 7 days. However, the validity of Paterson's curve was questioned by Pierquin et al.,[199] who used the same dose of 70 Gy with treatment times ranging from 3 to 8 days for the treatment of head and neck tumors with Ir-192 implants and did not observe any difference in the control rate or incidence of necrosis. The agreement with Paterson's curve is acceptable when the α/β value equals 3 Gy and repair half-time (T_r) equals 1.5 hours, but the curve is shallower when α/β equals 10 Gy and T_r equals 1 hour. One should expect Paterson's curve to correspond to late reactions and to overestimate the variation for early reactions and control of squamous cell carcinoma.

Several important concepts should be considered regarding the clinical relevance of dose rate[189,193,200]:

- At ultra-high doses and instantaneous dose rates (i.e., 10 Gy pulsed in nanoseconds), the rapid deposition of energy consumes oxygen too quickly for diffusion to maintain an adequate level of oxygenation, and dose–response curves are characteristic of hypoxia.
- Based on laboratory data, it may be possible to design schedules with a pulse width of several minutes and a pulse interval of about 1 hour to achieve cell killing equivalent to that obtained with a continuous 30 Gy in 60 hours (0.5 Gy/hour).
- Using the LQ equation, it is possible to estimate the equivalency of HDR and LDR exposures with a variety of fractionation schedules (remembering that a lower number of fractions may result in enhanced late effects).

Special consideration should be given to the effect of HDR brachytherapy on normal tissues. The tumor dose must be decreased 30% to 50% in comparison with that delivered with conventional low dose rates.[201,202] (For further discussion, see Chapters 22 to 25.)

In the past, there was some interest in continuous LDR irradiation with external cobalt units.[203] Pierquin et al.[204] used a modified ^{185}Co unit with a small industrial source (activity 45 Ci). Radiation was delivered at 1 to 1.39 Gy/hour to administer daily tumor doses of 8 to 10 Gy in 7 to 8 hours. A minimum of five treatments was given per week, although occasionally weekends and holidays caused schedule modifications. Patients were given short rest periods every 1 or 2 hours. Tumor doses of approximately 63 Gy were delivered in 8 to 11 fractions, with the volume reduced to 8 by 10 cm after 45 Gy. Nineteen patients with advanced tumors of the mouth and pharynx were

treated; 15 had no evidence of tumor 3 months after treatment. Only three patients developed recurrences. Of 19 patients, two developed moist desquamation and six developed dry desquamation; the others had only erythema. No significant late effects on the skin or the subcutaneous tissues were noted; 16/19 patients developed severe mucositis. Seven patients developed necrosis, six in large areas of the oral cavity and pharynx and, in several instances, at the tumor site.

The Target Theory of Radiobiology and How It Has Shaped Our Understanding of the Cell Survival Curve

We hold a dart in our hand and toss it at the dart board. What is our goal? To hit the target; to make a "bull's-eye." We go to a pistol range and, similarly, aim at the target. We try to "hit the target," whether it is a series of concentric circles or a paper outline of a man. A hunter stalks his or her prey in the woods with a rifle or a bow and arrow. They, similarly, want to cause a lethal injury and "bag the game."

A dart, a bullet, and an arrow are all physical modalities, not chemical, either used to inflict injury or death or show a person's ability to shoot straight and true. It is not much of a leap to envision how the early students of ionizing radiation's ability to kill cells envisioned that the physical modality of radiation would kill cells by hitting a target. Because many of these original investigators came from the world of physics, they sought to reduce the description of radiation's killing effect on viruses, bacteria, and cells to a series of mathematical equations, which described the cell survival curve. Furthermore, the empirical data, which were derived from radiation survival curves from the exposure of viruses and bacteria, could be fit to these equations.

The target theory is based on the concept that the biologic end product of cell death is related to the initial physical events, which occur upon irradiation. The fundamental principle of target theory is that inactivation of the target inside a cell or a bacteria or a virus results in its death.[200,238] The target is considered a unit of biologic function. The theory implies that the exact site where an ionizing event occurs, such as a double-strand DNA break, is the place where the primary ionizations responsible for that event occurred. Radiation-induced cell death can occur, in simplest terms, when there is a single hit of sufficient power to inactivate a single target and that target is sufficiently important that, when inactivated, the cell dies. This is called the single-hit/single-target model. One can also envision that some cells might not die unless multiple targets are

inactivated. This is called the multiple-hit/multiple-target model. All manner of variations might be imagined such as a stubborn single target that required repetitive assaults to be inactivated (multiple hit/single target).[205,381,385]

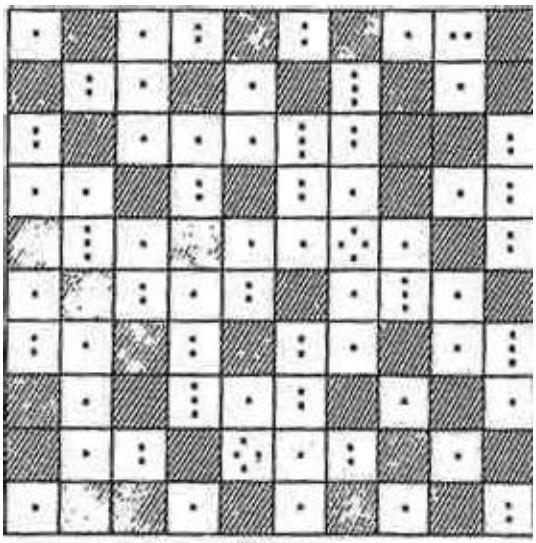
With low–linear energy transfer (LET) radiation, ionizations occur in clusters and sporadically along the path traveled by the particle. The radiation survival of most bacteria and viruses is a constant exponential function of dose. To kill them, it would seem to require inactivation of at least one target per bacteria or virus. At this point, however, we need to rethink our metaphor of the dart, the bullet, or the arrow. Darts, bullets, or arrows are very consciously and with great intent aimed at a specific target. Radiation beams, however, while they are aimed at tumors, are not aimed at individual cells, and they certainly are not aimed with any knowledge of where, at any moment, the important target is located. The target, the DNA, is moving within the cell. This brings us to a crucial point: The deposition of ionizations from radiation and the production of radiochemical injury to the cell are random events. To better understand this concept, careful study of Figure 1.25 is recommended.[396,401]

Unlike the straight line survival curves of many bacteria and viruses, when you plot the cell survival curve of most mammalian cells on a semilog plot, you see a “shoulder” in the low-dose region indicative of a decreased efficiency of cell killing and then a straight or “exponential” component of the curve.

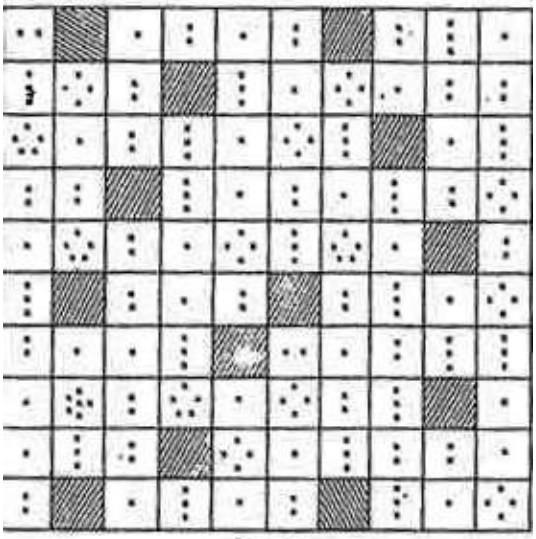
If we think about a strand of DNA as containing some regions that are essential to maintain the reproductive ability of the cell, then these regions are the specific targets for radiation damage. As we have pointed out, straight survival curves are usually found for the inactivation of bacteria and viruses and some very sensitive normal and malignant human cells, for the radiation response to low-LET radiation at very low dose rates and the response to high-LET radiation.

In Figure 1.25, we described how the dose D_0 is that dose of radiation, which gives an average of one hit per target and reduces the probability of cell survival from 1 to 0.37 or e−1. Using Poisson statistics, and understanding that the probability of the next hit occurring in any given cell is small, then the probability of a given cell surviving is the same as the probability that a cell suffers zero hits = $\exp(-D/D_0)$. (For a brief description of the Poisson distribution, see Box 1.7.) We could also look at the situation, mathematically, this way[396,398,399]:

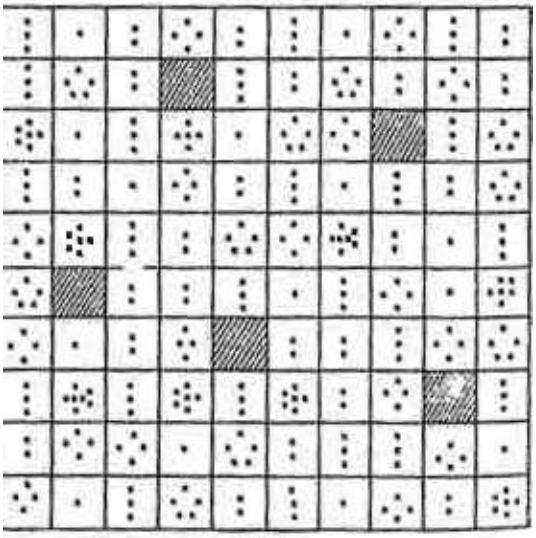
If there is one target per cell, then the probability of that cell surviving (S) an average of one-hit per cell for a large number of cells is



$\lambda = 1$



$\lambda = 2$



$\lambda = 3$

FIGURE 1.25. Let us assume that there are 100 equally sized tumor cells. Any individual cell will be killed if a crucial single target is hit at least once. This is a single-hit/single-target model. We fire a radiation beam capable of producing 100 lethal hits/ionizations at the 100 cells in the upper panel, and the deposition of ionizations occurs along the beam bath in clusters and randomly. Any individual cell's target is struck zero to four times with lethal ionizations. Any cell's target, which is struck at least once, is killed. Sixty-three cells die. Thirty-seven survive. The probability of any one cell surviving the onslaught is 37% which is e^{-1}. In the next panel, in the middle, we fire a radiation beam capable of producing 200 lethal hits/ionizations at the same 100 cells. The targets of some cells are completely missed. Others are hit up to six times. Eight even cells die. Thirteen survive. Thirteen is 37% × 37% or e^{-2}. In the lowest panel, we fire a radiation beam capable of producing 300 lethal hits/ionizations at the same 100 cells. How many cells survive? 37% × 37% × 37% or e^{-3} = 5 cells or 5% of the 100. It is the mathematical result of this random deposition of ionizing energy, which is part of target theory, helps us understand the derivation of the equations, which give mathematical representation to the cell survival curve, and helps define the concept of D_0. (Reproduced with permission from Withers HR, Peters LJ. Biologic aspects of radiotherapy. In: Fletcher GH. *Textbook of radiotherapy*. 3rd ed. Philadelphia: Lea and Febiger, 1980:103–180.)

$$P(1) = S = e^{-1}$$

If we gave a dose, which caused an average of two hits per cell, for a large number of cells, then the probability of any individual cell surviving is

$$P(2) = S = e^{-2}$$

If we gave a dose, which caused an average of X hits per cell, for a large number of cells, then the probability of any individual cell surviving is

Box 1.7

How the Poisson Distribution Helps Us Understand the Equations for the Radiation Cell Survival Curve

The Poisson distribution is named after the French mathematician Siméon Denis Poisson (1781–1840). A Poisson distribution expresses the probability of a given number of events occurring in a fixed interval of time and/or space if these events occur with a known average rate and independently of the time since the last event.

Let's think of some examples in order to understand this concept. Assume that a person receives an average of 50 text messages on their personal electronic device (cell phone or pad) every day from a very wide variety of sources. If the receipt of any particular email message does not affect the probability of getting the next email message, then some days the person will get 49 emails, some days they will get 51, some days they will get 100, and if enough time elapses then there will be a day when they get zero. While the average number of emails that arrive per day is 50, on any particular day the number of emails received will vary. Most days, the number of emails will cluster close to the number 50, but there will be a wide

variation.

We can think of the deposition of ionizing events in cells and inactivating targets as following a Poisson distribution. If you look back at the panel at the top of Figure X-Y, the average number of hits per cells is 1, but the actual number of hits per cell varies from zero to four. If you plot the number of hits per cell, they'll follow a Poisson distribution. Most cells will have one hit, but they'll be a wide variation.

A Poisson distribution is not the same as a normal distribution (sometimes called a "bell-shaped curve") although, at first glance, they look somewhat similar. These two statistical concepts come from two different principles. A Poisson distribution is one example for discrete probability distribution, whereas normal belongs to the idea of a continuous probability distribution.

$$P(X) = S = e^{-X}$$

Because the typical radiation cell survival curve for normal and malignant mammalian cells has a "shoulder" and then an exponential component, it can be fit to a multitarget model. The initial slope of the curve, D_1, is the result of single-hit killing and has a slope, which represents the dose that is required to reduce the number of surviving cells from 100% to 37%. The final slope of the curve is the dose that is required to reduce survival from 0.1 to 0.037 or from 0.01 to 0.0037.

We can represent this "two-sloped" curve in the multitarget model by

$$P(X) = S = 1 - (1 - e^{-xD})^n$$

S is the probability of survival. *D* is the dose that causes a mean of hit per cell. *X* is the number of hits per cells. *N* is the number of targets that must be hit in an individual cell to cause cell death.

If we use the term D_0 for the slope of the exponential part of the curve, then

$$S = [1 - (1 - e^{-D/D_0})^n]^m$$

In this equation, *S* is the probability of survival, *D* is the dose of radiation administered, D_0 is the dose that causes a mean of one hit per cell, *N* is the heterodiploid number so that 1 is haploid, 2 is diploid, and 3 is triploid, and m is the number of targets that must be hit in an individual cell to cause cell death.

For a diploid cell with a average of one target per cell, the equation becomes

$$S = 1 - (1 - e^{-D/D_0})^2$$

Although there may or may not be discrete and identifiable target areas within DNA, the multitarget model does a pretty good job of predicting many cell

survival curves, and the concepts of DQ, D_0, and n are understandable tools in describing radiation sensitivity.[396,400] There are radiation cell survival curves, which are not well represented by the target model, and the LQ theory was developed to be a more general concept (Fig. 1.25).

IMPORTANCE OF TREATMENT PLANNING IN RADIATION THERAPY

The predicted consequences of EBRT are based on the precision with which the dose and the irradiated volume are defined. An imprecise treatment system could lead to a high incidence of necrosis with, paradoxically, a low probability of tumor control (Fig. 1.26).[112] Decreasing irradiation doses to avoid complications will further reduce the probability of achieving tumor control if such action is based on the wrong assumption that the tumor control/complication ratio is related only to radiation dose levels. The ICRU recommends a ±5% accuracy for dose delivery computations.[42,206] However, every effort should be made to develop accurate dose calculation algorithms, including methods to correct for inhomogeneities in tissue density and the shape of the patient's body, and to develop practical treatment planning capabilities to obtain the highest possible dose optimization in the irradiated volume (tumor and normal tissues). There are benefits of reducing the treatment volume in an effort to deliver higher doses of irradiation. This may improve the quality of tumor control without excessively irradiating surrounding normal tissues, thereby decreasing treatment-related morbidity.

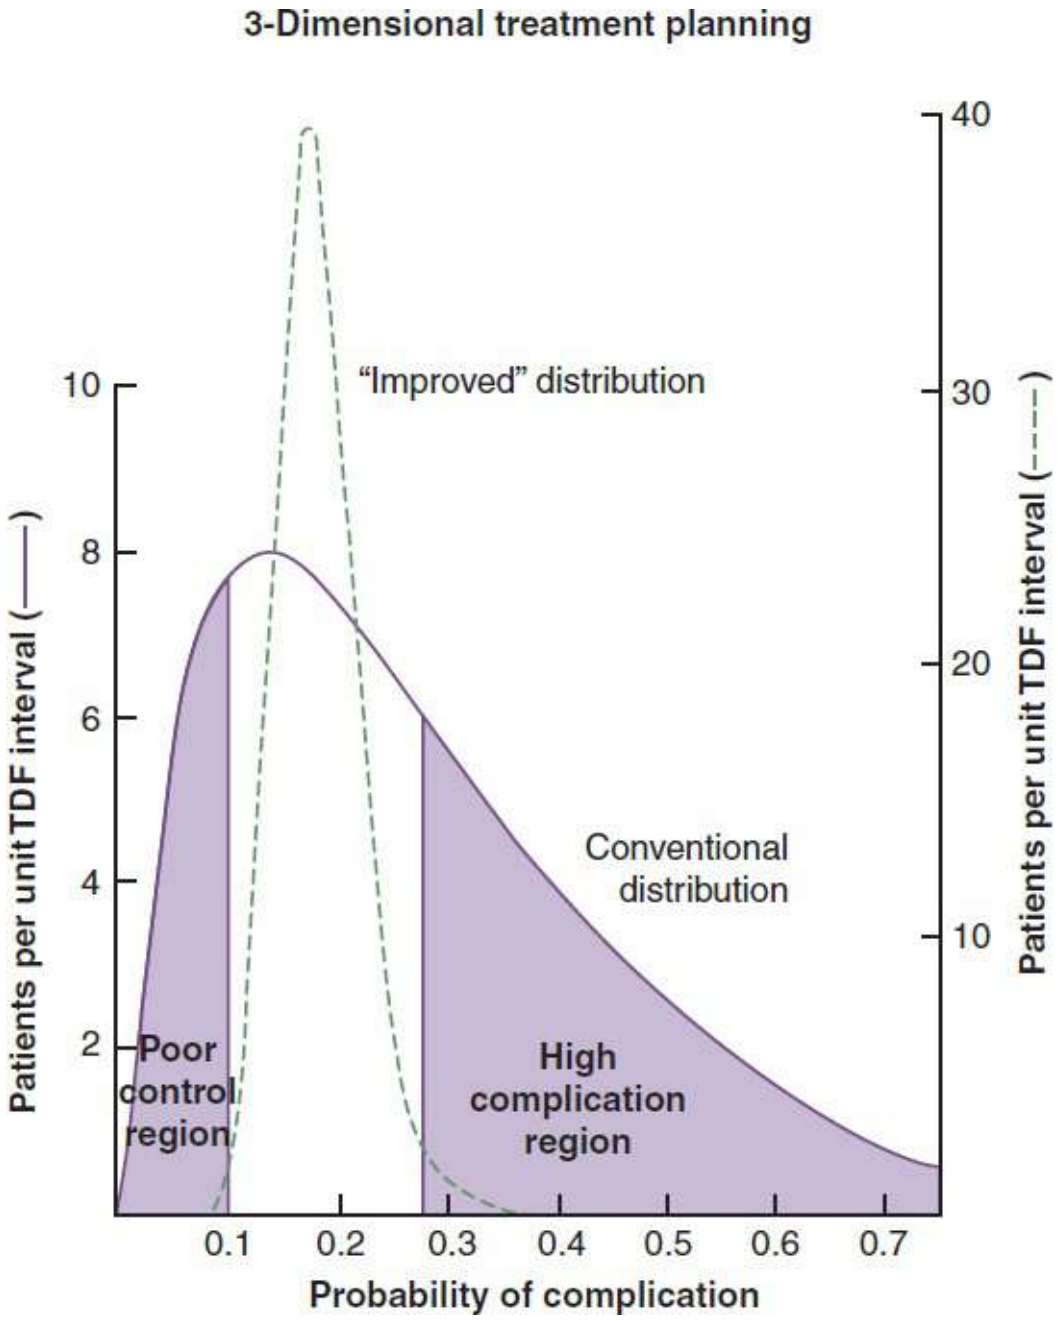


FIGURE 1.26. Frequency distribution of patients treated to different probabilities of complication. (From Orton CG. Other considerations in 3-dimensional treatment planning. In: Bagne F, ed. *Computerized treatment planning systems*. HHS Publication FDA 84–8223. Washington, DC: U.S. Government Printing Office, 1984:136–141.)

Various steps can be taken to decrease toxicity in normal tissues, including precise treatment planning and irradiation techniques, selective decreased volume receiving higher doses dictated by estimated cell burden, and maneuvers to exclude sensitive organs from the irradiated volume. With the emphasis on

organ preservation, treatment planning is critical to achieve maximum TCP and satisfactory cosmetic results.

Optimal dose distribution may be achieved by a combination of multiple stationary beams or by moving beam therapy, such as in arc or full rotational techniques or IMRT. In addition, the optimal dose distribution in many tumors requires access to more than one modality or beam energy particle type. A combination of external beams and intracavitary or interstitial therapy also may be required, depending on the location of the tumor.

Three-Dimensional Treatment Planning

Advances in computer technology have augmented accurate and timely computation, display of 3D radiation dose distributions, and DVHs.[207,208] These developments have stimulated sophisticated 3D treatment planning systems, which yield relevant information in evaluation of tumor extent, definition of target volume, delineation of normal tissues, virtual simulation of therapy, generation of digitally reconstructed radiographs, design of treatment portals including the use of multileaf collimators and aids (e.g., compensators, blocks), calculation of 3D dose distributions and dose optimization, and critical evaluation of the treatment plan.[209–211]

The potential benefits of 3D planning and delivery systems are great. It is, however, not clear which specific disease sites and treatment situations will be benefited by 3D planning.[212] With advanced computerized and display technologies, contiguous CT and/or MRI and/or PET slices are used to define anatomic structures and target volumes. External radiation beams of any possible orientation are simulated. A significant feature of these systems is the so-called beam's eye view, in which patient contours are viewed as if the observer's eye is placed at the source of radiation looking out along the axis of the radiation beam.[213] These systems allow simulation of the geometric setup; evaluation of the plan for dose optimization still is made on the merits of volumetric dose distributions.

Quantitative treatment planning evaluation is crucial in selection of the best portals and radiation beams to deliver an optimal dose to the tumor with relative sparing of normal tissues. The ICRU Report 50 and its supplement G2 define 3D volumes for the prescription and reporting of EBRT.[42] The GTV is defined as the gross demonstrable extent and location of malignant growth; the CTV allows a margin around the GTV for subclinical disease; the PTV allows margins on the CTV for variation in position, size, and shape so that the prescribed dose is

received by the CTV; and the treated volume is that area receiving a dose considered appropriate to the purpose of treatment such as tumor eradication or palliation.

The DVH is useful as a means of dose display, particularly in assessing several treatment plan dose distributions.[214] A DVH provides a complete summary of the entire 3D dose matrix, showing the amount of target volume or critical structure receiving more than a specified dose level. Because a DVH does not provide spatial dose information, it cannot replace the other methods of dose display; it can only complement them.

Models for optimization of 3D dose distribution using biologic models of tumor and normal tissue responses correlated with physical radiation doses have been described. Mohan et al.,[172] in a theoretical analysis, concluded that for certain clinical situations, it is not sufficient to specify objectives of optimization purely on the basis of pattern of irradiation dose and that dose–volume effects and biologic indices also must be incorporated into the formulation.

Niemierko et al.[144] described a technique for optimization of 3D conformal radiation therapy plans with biologic models of tumor and normal tissue response to irradiation as well as with scores based on physical dose. Optimization programs attempted to minimize dose gradient across the target volume, match specified isodose contours to the target and critical organs, match specified dose–volume constraints, minimize integral dose to the entire volume of patient treated, minimize maximum dose to critical organs, and constrain dose to specified normal tissues below a TD level. The solutions were based on TCP, NTCP, various dose levels given to specified volumes of the patient, discrete or continuous values of beam parameters, number of beams, and logical combination of any constraints.

Intensity-Modulated Radiation Therapy

An increasingly popular approach to 3D treatment planning and conformal therapy optimizes the delivery of irradiation to irregularly shaped volumes through a process of complex inverse (or forward) treatment planning and dynamic delivery of irradiation that results in modulated fluence of photon or proton beam profiles and a more conformal dose to the target volume(s), with enhanced sparing of surrounding normal tissues.[185,215]

Treatment planning begins with the determination of the GTV and the CTV, which contains the GTV, and an estimate of where the tumor may spread. CT, MRI, and fluorodeoxyglucose positron emission tomography (FDG-PET)

imaging along with image fusion have enhanced the possibilities for determining the target more accurately. The PTV accounts for inaccuracies in positioning patients and organ motion.

In “forward” planning, software calculates the dose distribution, displays it with a 3D anatomic model, and provides analytical and graphical metrics for assessing the adequacy of tumor treatment and normal tissue avoidance. The physician decides if the plan is acceptable. If not, an alteration is made in the beam arrangement, and the process is repeated.[271]

Computerized optimization techniques have led to “inverse” planning. Goals of an acceptable treatment plan are delineated, and the inverse planning algorithm searches through many thousands of possibilities to find a plan that best satisfies the goals. In IMRT, the beams are broken up into “beamlets” (on the order of 0.5 by 0.5 or 1 by 1 cm) that can each have a different intensity. IMRT may improve the ability to treat with a high radiation dose while minimizing dose to nearby critical structures.

There are a variety of forms in which IMRT can be administered:

- A linear accelerator and multileaf collimation, with a variety of beam configurations at various angles, may be used; the MLC determines the portal shape of each of the portals. Photon-modulated fluency may be obtained (a step-and-shoot method). Analogous techniques may be used with protons.
- Dynamic computer-controlled IMRT is delivered when the configuration of the beams outlined with the MLC is changing at the same time that the gantry or the accelerator is changing positions around the patient.
- In helical TomoTherapy, the photon fan beam continually rotates around the patient as the couch transports the patient longitudinally through the ring gantry. The verification processes for helical TomoTherapy are enabled by the use of the ring gantry; the geometry of a CT scanner allows tomographic processes to be reliably performed. Dose reconstruction is a key process of tomography; the treatment detector sinogram computes the actual dose deposited in the patient. The length of the beam is 40 cm at the central axis and has a width that can vary between 0.5 and 5 cm. The lengths of the MLC in helical tomography are temporarily modulated or binary in the sense that they are rapidly driven either in or out by air system actuators rather than beam slowly pushed by motors driving lead screws as in the conventional MLC.
- The robotic IMRT system consists of a miniaturized 6-MV photon linear accelerator mounted on a highly mobile arm and a set of ceiling-mounted x-ray cameras to provide near real-time information on patient position and target exposure during treatment.

The majority of the IMRT systems use 6-MV x-rays, but energies of 8 to 10 MV may be more desirable in some anatomic sites (to decrease skin and superficial subcutaneous tissue dose). Higher energies will increase neutron contamination of the therapeutic beam(s). The dose distribution and field-shaping parameters are based on inverse 3D planning using a specially defined minimal dose to target and dose constraints for surrounding normal tissues.[216–218] Inverse planning starts with an ideal dose distribution and finds through trial and error or multiple iterations (simulated annealing) the beam characteristics (fluence profiles) and then produces the best approximation to the ideal dose defined in a 3D array of dose voxels organized in a stack of two-dimensional (2D) arrays.[7,219]

A back-projection technique through careful choice of filters, beam placement, and shaping of the portals conforms the irradiation dose to the shape of the tumor, minimizing dose to critical adjacent structures. When this technique is used, it is critical to adhere to basic concepts of treatment planning and evaluation of the pathobiology of malignant disease. Well-designed treatment plans based on radiographic imaging (CT or MRI or PET), which in most instances demonstrates gross disease, are necessary to minimize the risk of missing or underirradiating adjacent microscopic or subclinical tumor.

Given the added time and labor involved in IMRT, numerous issues require study:

- Can the tumor be localized with sufficient accuracy to take advantage of the improved dose localization?
- Treatment plans that produce a rapid drop in dose between the edge of the tumor and the normal tissue require more exact patient positioning; otherwise, there is a high risk of underdosing the tumor or overdosing normal tissue.
- Some IMRT plans treat the center of the tumor with a very high dose to achieve an acceptable dose at the edge. This may not be optimal.
- Many IMRT techniques spread a low dose over a larger volume or normal tissue. This may increase the risk of secondary malignancies years later.

HEAVY PARTICLE BEAMS

One can imagine two possible mechanisms by which one could improve on therapeutic x-rays with an alternative particle. First, the alternative particle could have energy deposition characteristics that lead to a superior dose distribution. A beam, conceivably, could have more skin sparing than x-rays, better stopping

characteristics, and/or less side scatter. This might allow a more conformal therapy. Second, the alternative particle could have advantageous radiobiologic properties. It might be more toxic than x-rays to hypoxic cells or cells in the late S-phase of the mitotic cell cycle. Such a particle would have, perhaps, a lower oxygen enhancement ratio (OER) and a higher RBE than x-rays. These two possible mechanisms of improving on x-rays are not mutually exclusive. A particle could have both superior physical dose distribution and radiobiologic properties.

The effort to identify improved alternatives to x-rays has focused on the group of particles called hadrons. These are particles constituted of strongly interacting particles called quarks and gluons. The hadrons include the mesons and the baryons. The latter include protons, neutrons, negative pions, and the nuclei of heavier atoms such as He^{2} (helium), C^{6} (carbon), O^{8} (oxygen), Ne^{10} (neon), and Ar^{18} (argon). All of these forms of radiation are distinguished from x-rays and electrons by their greater masses. These alternative radiation modalities are relatively difficult to produce, are expensive, and are considerably more difficult to control.

Proton, heavy ion, and hadron beams have attracted radiation oncologists because they offer interesting and potentially beneficial dose distribution characteristics. Radiobiologically, their properties are not significantly different from x-rays. When a heavy particle beam traverses tissue, the dose is deposited in an approximately constant rate. The rate of energy loss (also called the “stopping power”) of a heavy charged particle is proportional to the square of the particle charge and inversely proportional to the square of its velocity. As a proton or heavy ion slows down, its rate of energy loss increases and so does the ionization or absorbed dose to the tissue. Near the end of the proton’s range, the deposition of energy rises very sharply before dropping to almost zero. This peaking of dose near the end of the particle range is called the Bragg peak. As a result of the Bragg peak effect and minimal scattering, the proton offers the potential advantage and the ability to concentrate dose inside and immediately adjacent to the tumor volume and minimize dose to surrounding normal tissues. There are multiple proton treatment facilities operational and under construction throughout the world.

For a thorough discussion of proton and neutron radiation, as well as a consideration of pi meson therapy and charged nuclei therapy such as helium ions and neon ions, the reader is referred to Chapters 19 and 20 of this volume.

BORON NEUTRON CAPTURE THERAPY

The fundamental concept of boron neutron capture therapy (BNCT) is the production of high–LET particles ($^{7}Li^{3+}$ and $^{4}He^{2+}$) when one "tags" or "labels" a tumor cell with a compound having a large cross-section capable of capturing a "slow" (thermal) neutron. After the compound captures the neutron, it goes into an excited state. The excited fission of the ^{9}B nucleus will release energy, which drives the heavy ion products over short distances comparable to the dimensions of one cell. A 0.48-MeV photon is also produced in 94% of the fission events. This is useful for monitoring the reaction but is of little consequence for cell killing.

The neutron has a mass of 0.782 MeV, more than that of the proton. Neutrons were identified in 1932 by Chadwick[120,384] at Cambridge University's Cavendish Laboratory. Subsequently, Fermi[220] discovered that neutrons react most efficiently with a number of elements after they are slowed by passage through a hydrogen-rich substance such as paraffin. Chadwick and Goldhaber,[120] Taylor and Goldhaber,[221] and Burcham and Goldhaber[222] showed that slow neutron bombardment of specific stable isotopes of boron, lithium, and nitrogen yields charged particle tracts in photographic plates. The tracts from boron's interaction with neutrons were short and straight and were consistent with the formation of two particles traveling in opposite trajectories. In photographic gelatin, their average travel distance was 7.6 μm. The boron neutron capture process is highly localized. In principle, one could kill a tumor cell containing boron while sparing an adjacent normal cell that does not contain boron. Box 1.8 provides a glossary of terms related to neutron capture therapy.

The complete chemical reaction is as follows:

$$^{10}B + ^{1}n \rightarrow ^{7}Li + ^{4}He + \gamma + 2.4\ MeV.$$

The attraction of BNCT, for many clinicians, has been the notion of the "magic bullet." The idea that one could specifically label tumor cells with a compound with an enlarged cross-sectional area, not label surrounding normal tissue, and therefore deposit radiation only in the tumor is most attractive. Unfortunately, reality is far different from the ideal.

Box 1.8

A Glossary of Terms Pertinent to Neutron Capture Therapy

Epithermal neutrons: Energetic neutrons pass through an intermediate energy range on the way to becoming slow or thermal neutrons. This intermediate energy range is called epithermal.

Fast neutrons: Fast neutrons are highly energetic and travel quickly.

Moderation: Neutrons generated from the fission process or from particle bombardment of materials have significant energy. They lose that energy by colliding with atoms in their environment and create energetic recoil atoms. After a sufficient number of collisions, the neutrons lose essentially all of their energy and become thermal. This process of energy loss is called moderation. The material that provides the atoms the fast neutrons collide with is called a moderator. Water is the usual moderator.

Slow neutrons: Slow neutrons have little energy. They also are referred to as thermal neutrons because they have the same average kinetic energy as gas molecules in their environment.

Thermalize: Epithermal neutron beams, as they penetrate tissue, become additionally moderated. This is called becoming thermalized.

From Yanch JC, Shefer RE, Busse PM. Boron neutron capture therapy. In Fletcher GH, ed. *Science Med*. 1999; January/February:18–27.

Fast neutrons differ from x-rays in the mode of their interaction with tissue. Whereas x-ray photons interact with the orbital electrons of atoms via the Compton or photoelectric process and set fast electrons in motion, neutrons interact with the nuclei of the atoms of the absorbing tissue. Neutrons put fast recoil protons, α-particles, and heavier nuclear fragments in motion. At energies above about 6 MeV, inelastic scattering by neutrons takes place.[99] A neutron may interact, for example, with a carbon or an oxygen nucleus to produce α-particles. These lead to nuclear fragments called spallation products. The LET is considerably higher for neutrons than for x-rays. Because the LET of neutron radiation is higher, the slope of the cell survival curve becomes steeper and the size of the initial shoulder gets smaller. This produces a beam with a lower OER than x-rays—neutrons are considerably more toxic to hypoxic cells than x-rays. Also, neutrons are more toxic to cells in phases of the cell cycle that are relatively radioresistant to x-rays. Thus, the RBE of neutrons is higher than x-rays.

In 1936, Locher[223] published a theoretical account of the possible biologic effects and therapeutic possibilities of boron neutron capture. In a prescient comment, he wrote:

> The possibility of destroying or weakening cancerous cells, by the general or selective absorption of neutrons by themselves and particularly there is the possibility of introducing small quantities of neutron absorbers into the

> regions where it is desired to liberate ionizing energy. A simple illustration would be the injection of a soluble non-toxic compound of boron, lithium, or gold into a superficial cancer followed by bombardment with slow neutrons.

In 1950, Conger and Giles[224] from Oakridge National Laboratories reported that the trace amounts of boron normally present in lily bulbs were responsible for most of the radiation changes in the plants following exposure to slow neutrons. This demonstrated the biologic fact clearly and led William H. Sweet[225] and others to see if the normal brain could exclude enough boron and if tumor tissue could take up enough boron to produce an appropriate therapeutic ratio.

Sweet began work at the Brookhaven National Laboratory in New York with a 20-MW nuclear reactor in 1950.[226] He initially treated 10 glioblastoma multiforme patients who had undergone gross total resection of their tumors at the Massachusetts General Hospital in Boston. Sweet described the initial clinical work:

> A portion of the shielding atop the reactor was removed to permit placing the lateral aspect of the patient's intact scalp and skull at the specially designed portal. To prevent scalp damage, we tied off the external carotid arteries and covered the entire scalp with tight elastic bandages in an attempt to prevent boron-containing blood from entering the scalp. These tactics, however, did not prevent the development of several large radiation erosions of the scalp. Five patients received a single radiation dose and the remaining 5 were given the treatment in 2 to 4 fractions. Although there were no life threatening complications of therapy, all of the patients died from 6 to 21 weeks after the first session of neutron capture therapy, which was usually the case in the 1950s for glioblastoma patients treated by any means. Postmortem studies done in 6 of the patients showed abundant viable tumor. Their painful scalp lesions together with the inadequacy of the radiation dose lead us to attempt to deliver the thermal neutron beam directly to the grossly normal but microscopically tumor-infiltrated brain. The Rockefeller Foundation made this approach possible with a $500,000 gift to the Massachusetts Institute of Technology [MIT] to provide additional features to a nuclear reactor that was then being constructed. Included was a surgical operating room immediately beneath the reactor core. This permitted us to turn down the scalp, bone, and dural flap used in

> the prior removal of gross tumor. At reopening the cerebrospinal fluid replacing tumor was also drained away to give maximally unimpeded access of the thermal neutrons through sterile air to the tumor-infiltrated brain.[225]

Sweet treated 18 patients at MIT. They died from 10 days to 11.5 months after radiation. In every patient, the cause of death was cerebral, and extensive irradiation necrosis of the brain was induced in nine cases. In two cases, only recurrent tumor was seen, and in one patient, there was extensive radiation necrosis and tumor.

Some of the initial work with BNCT was highly controversial and, decades later, led to investigations concerning the nature of informed consent for these human experiments. President William J. Clinton created, by executive order, a commission to study the ethics of cold war–era medical experimentation using radiation. One of the collateral effects of this commission's report was that Sweet and his colleagues were sued for malpractice 40 years after the BNCT experiments. Although the plaintiffs were awarded substantial damages at trial, the decision was eventually overturned on appeal.[227]

Lack of progress in BNCT may be attributed to two primary factors: inadequate tumor specificity of the boron compounds used to localize in the tumor and poor penetration into tissue of the thermal neutrons. In addition, the thermal and antithermal neutron beams produced by nuclear reactors have considerable contamination with γ-rays and fast neutrons. These can cause normal tissue damage even in the absence of boron concentration in tissues. In addition, there are a number of compounds in normal tissue that can interact with thermal neutrons and have capture events of their own, producing biologic damage even to non–boron-containing tissue.

The development of suitable boron-carrying agents remains a stumbling block to clinical programs. The ideal agent will be nontoxic, will have a high tumor-to-normal tissue ratio, and will have a high absolute boron concentration.

Investigations of improved ways of delivering thermal neutrons have centered on two areas: the use of nuclear reactors and useful alternatives to reactors.

The most intense way to generate a neutron beam is with a nuclear reactor. Despite the high neutron intensities available from these reactors, it is widely recognized that alternative neutron sources will be necessary for BNCT to be performed. First of all, there are few suitable nuclear reactors in operation. A patient would have to travel a long distance for treatment. Second, nuclear

reactors, for political and social reasons, are not likely to be sited near major population centers in the future. A major reactor facility located far from a population center would have to be provided with its own clinical infrastructure, and it is not obvious that the target patient population would be large enough to support the operation of more than a few medical reactors. Therefore, some investigators have been pursuing nonreactive sources of thermal and epithermal neutrons with a sufficiently high flux to be used for BNCT.[225,228–230]

An alternative to the reactor would be a neutron source from radioactive decay such as californium-252 (^{252}Cf). However, production of a neutron beam with sufficient intensity for BNCT would require more than the entire present annual supply of ^{252}Cf. Another alternative source is a particle accelerator. Accelerator-based neutron beams are created when light ions such as protons or deuterons are accelerated in an electric field and are made to bombard target materials. Several accelerator techniques now exist that may be capable of producing intense beams for BNCT.

GENES AND THE BIOLOGY OF CANCER

The infectious nature of some cancers was demonstrated by Francis Peyton Rous (1879–1970) in a 1910 experiment showing that defined, submicroscopic, filterable agents (viruses) isolated from a chicken sarcoma could induce new sarcomas in healthy chickens. Rous and his work languished in obscurity before being rediscovered and recognized with the Nobel Prize in Physiology or Medicine in 1966 (Fig. 1.27).[84] In his Nobel Lecture, "The Challenge to Man of the Neoplastic Cell," Rous considered the possible existence of growth-promoting genes—what he called oncogens and what are now called oncogenes.

> Tumors destroy man in a unique and appalling way, as flesh of his own flesh which has somehow been rendered proliferative, rampant, predatory and ungovernable. They are the most concrete and formidable of human maladies, yet despite more than 70 years of experimental study they remain the least understood. This is the more remarkable because they can be evoked at will for scrutiny by any one of a myriad chemical and physical means which are left behind as tumors grow. These had acted merely as initiation. Few situations are more exasperating to the inquirer than to watch a tiny nodule form on a rabbit's skin at a spot from which the chemical agent inducing it has long since been gone, and to follow the nodule as it grows, and only too often becomes a destructive epidermal cancer. What can be the why for these happenings?
>
> Every tumor is made up of cells that have been so singularly changed as to no longer obey the fundamental law whereby the cellular constituents of an organism exist in harmony and act together to maintain it. Instead the changed cells multiply at its expense and inflict damage that can be mortal. We term the lawless cells neoplastic because they form new tissue, and the growth itself is a neoplasm; but on looking into medical dictionaries, hoping for more information, we are told, in effect, that *neoplastic* means "of or pertaining to a neoplasm," and turning to *neoplasm* learn that it is "a growth which consists of neoplastic cells." Ignorance could scarcely be more stark.
>
> The chemical and physical initiators ordinarily are called *carcinogens*; but this is a misleading term because they not only induce the malignant

> epithelial growths known as carcinomas but also other neoplasms of widely various kinds. In this chapter the less often used term oncogenes will be used, meaning “thereby capable of producing a tumor.” It hews precisely to the fact….
>
> What can be the nature of the generality of neoplastic changes, the reason for their persistence; for their irreversibility; and for the discontinuous, steplike alterations that they frequently undergo? A favorite explanation has been that oncogenes cause alterations in the genes of the body—somatic mutations as these are termed. But numerous facts, when taken together, decisively exclude this supposition.[84]

Rous, it turned out, was unequivocally wrong about oncogenes. Theodor Boveri[256] was right. In 1914, he used his studies of normal mitosis in sea urchins and worms as a platform for suggesting that cancer might be caused by the abnormal gain or loss of chromosomes and their function. In a 1929 English translation of his 1926 book, *The Origin of Malignant Tumors*, Boveri wrote:

> The unlimited tendency to rapid proliferation in malignant tumor cells [could result] from a permanent predominance of the chromosomes that promote division…. Another possibility [to explain cancer] is the presence of definite chromosomes which inhibit division…. Cells of tumors with unlimited growth would arise if those “inhibiting chromosomes” were eliminated … [since] each kind of chromosome is represented twice in the normal cell, the depression of only one of these two might pass unnoticed.[256]

FIGURE 1.27. Peyton Rous won the Nobel Prize in 1966 for experiments he began in 1910. He demonstrated that a sarcoma could be transmitted from one chicken to another via a very small carcinogenic agent—a virus. **A:** Rous as a young investigator. **B:** At the time of the receipt of the Noble Prize. (Courtesy of Rockefeller Archives Center.)

Boveri predicted that the genetic abnormalities leading to the development of cancer are of two sorts: growth-promoting genes and growth-suppressing genes. If the growth-promoting genes are excessive in number or activity, they lead to cell proliferation. If, however, the growth-suppressing genes are defective in amount or activity, they fail to halt cell proliferation and lead to unbridled cell replication (Fig. 1.28). These growth-promoting genes are called *oncogenes.* The growth-suppressing genes are called *tumor suppressor genes.*

We may think of oncogenes and tumor suppressor genes as analogous to the accelerator pedal and the brake pedal of an automobile. The car can move forward when it is idling with the transmission in drive either by pushing on the accelerator pedal, by taking pressure off the brake pedal, or by doing both simultaneously. Similarly, cell growth and proliferation, leading to cancer, can occur either by the activity of the oncogenes or inactivity of the suppressor genes.

There are clearly a wide variety of physiologic conditions that call for the effective use of growth-promoting and growth-suppressing genes. There must be

a mechanism to cause the fetus to grow and then, at the appropriate time, to restrain growth. There must be a way of causing fibroblasts to proliferate to heal a wound and then, at the appropriate time, halt the fibroblasts (except in the case of keloid formation). Uncontrolled cell growth, or cancer, may be thought of as a set of physiologic controls of cell growth gone awry.

Oncogenes

The experiments that initially identified oncogenes were based largely on transformed retroviruses in transplantable tumors in chickens, mice, and rats.[191] Oncogenes were described as the genetic material carried by RNA tumor viruses that resulted in rapid malignant transformation of target cells.[366,367] The name oncogene was given to virus-encoded single genes that alone or in combination with other genes induced a transformed phenotype in affected cells.[43,390,391]

The word oncogene derives from the Greek *onkos*, a "mass" or "tumor." Many oncogenes are those found in retroviruses. However, not all cellular genes capable of transforming cells have been identified within the genome of known retroviruses. It is accepted that an oncogene is a gene capable of contributing directly to the conversion of a normal cell to a tumorigenic one and that a proto-oncogene is a cellular gene convertible to an oncogene by various molecular mechanisms: sequence mutations, gene amplification, chromosomal translocation, viral transduction, and insertional mutagenesis. In general, these perturbations result in two net effects: altered regulation or augmented expression of an oncogene through mutation or rearrangement of the nucleotide sequences that constitute signals for control of transcription, messenger RNA (mRNA) processing, and stability via insertion of a strong foreign promoter or by increased gene dosage and altered biochemical function or ectopic expression of a protein product as a result of a mutation or translocation within the protein-coding region of the oncogene. Proto-oncogene products are involved in the regulation of normal cellular growth and differentiation.

A large number of viral oncogenes have been identified. In addition, oncogenes have been identified that are not associated with RNA tumor viruses but are recognized either by their activity in transformation or by their association with chromosome translocations.[257] When DNA probing techniques were used, it was found that sequences homologous to the oncogene region of the virus were present in the DNA of all tissues of virus-free chickens. The normal cellular sequences are proto-oncogenes. The oncogene carried by a virus is referred to as *v-onc*, whereas the proto-oncogene is referred to as *c-onc*. In the

normal cell, the expression of proto-oncogene is well controlled and appears to play a role in the growth and development of the organism. The function of some of these genes has been determined, whereas for others, a close association between cell proliferation and gene expression has been established.

Stimulation of a nonmalignant cell into a proliferative state often depends on an external signal, which is received by a receptor on the cell membrane and transferred through the membrane into the cytoplasm and ultimately to the nucleus where DNA synthesis is initiated. Proto-oncogenes have been found that function at each step of this pathway. The *erb*-B oncogene is homologous to the gene encoding for cell membrane receptor of epidermal growth factor (EGF). The interaction of EGF with this receptor reduces the proliferation of epidermal cells such as breast epithelium.

Strong evidence suggests that malignancy induction may be associated with genetic changes in the cell. Examples of this are the finding of specific chromosome abnormalities in malignant cells, association of tumor development with DNA-damaging agents such as ionizing irradiation and chemical carcinogens, and increasing incidence of cancer in hereditary diseases such as xeroderma pigmentosum. It is recognized that oncogenes are normal cellular genes that may contribute to the development of the malignant cell if their expression is altered through mutation, translocation, amplification, or some other mechanism. Evidence suggests that several genetic changes are needed to produce a cancer cell, and oncogene studies support this concept.

Chromosome translocations occur at a high frequency in some types of tumors, suggesting that they may play a role in their development. Examples of translocations are the t(9;22) Philadelphia chromosome in chronic myelogenous leukemia (CML), the t(15;17) in promyelocytic leukemia, and several translocations involving chromosome 8 seen in lymphatic malignancies. Common sites of translocations in malignant cells are frequently near an oncogene. Those translocations such as the t(9;22) in CML can result in the formation of a new protein that is intimately involved in the tumorigenic transformation of the cell. In the CML example, the *ber*-gene is translocated next to the *abl*-oncogene, forming the new *bcr-abl* gene. The proteinaceous product of this newly formed gene is a hyperactive protein kinase that provides permanent growth signals to the cell.

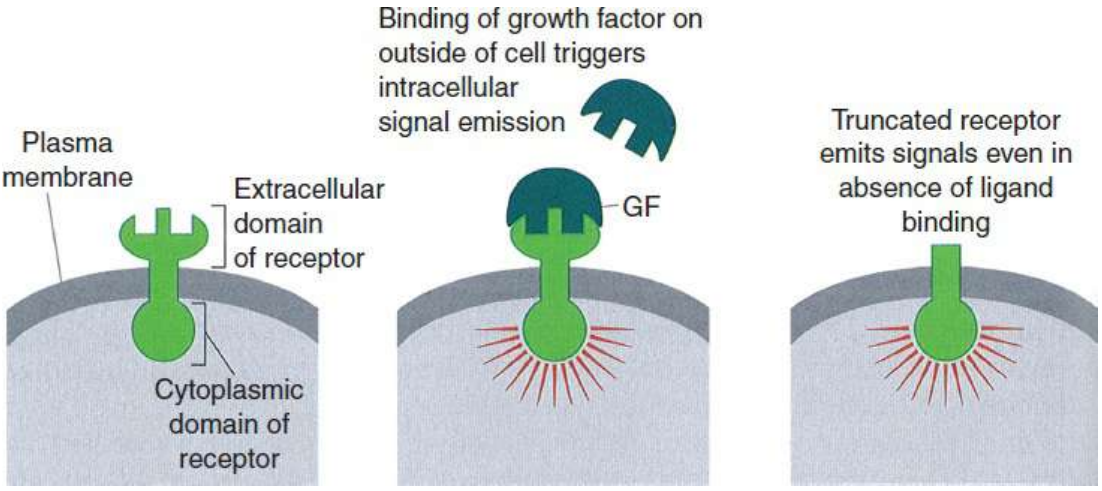

FIGURE 1.28. Oncogenes can act in multiple ways. One method is for a growth factor receptor, which ordinarily is only active when it binds to a ligand, to become active all the time even in the absence of a growth factor binding to it. This is called "being constitutively active" and is the result of an oncogenic mutation. (From Weinberg RA. *The biology of cancer*. New York: Garland Science, Taylor and Francis Group, 2007. Copyright © 2007 by Garland Science, Taylor & Francis Group, LLC. Used by permission of W. W. Norton & Company, Inc.)

Role of Proto-Oncogenes in Normal and Transformed Cells

Proto-oncogenes are genes with oncogenic potential, and because they are apparently present in all animals, some kind of activation of proto-oncogenes is likely to be associated with the initiation and progression of neoplasia. Activated oncogenes are detected in a large percentage of human tumors, suggesting a prominent role of these genes in their development; association between activated oncogenes and neoplastic diseases must have some kind of specificity for both the oncogene and the tumor.

Proto-oncogenes can be activated by genetic changes that affect either protein expression or structure. As succinctly stated by Weinberg:

> The somatic mutations that caused proto-oncogene activation could be divided into two categories—those that caused changes in the structure of encoded proteins and those that led to elevated, deregulated expression of these proteins. Mutations affecting structure included the point mutations affecting ras proto-oncogenes and the chromosomal translocations that yielded hybrid genes such as bcr–abl. Elevated expression could be achieved in human tumors through gene amplification or chromosomal translocations, such as those that place the myc gene under the control of immunoglobulin enhancer sequences….

> Gene amplification occurs through preferential replication of a segment (the amplicon) of chromosomal DNA. The result may be repeating end-to-end linear arrays of the segment, which appear as homogeneously staining regions (HSRs) of a chromosome when viewed under the light microscope. Alternatively, the region carrying the amplified segment may break away from the chromosome and can be seen as small, independently replicating, extra-chromosomal particles (double minutes). Gene amplification does not always result in overexpression of the gene….[382]

A variety of structural changes in proteins can also lead to oncogene activation. Examples include alterations in the structure of growth factor receptors (such as the EGF receptor) and translocations that fuse two distinct reading frames to yield a hybrid protein (such as Bcr-Abl). Both types of alterations deregulate the proteins, causing them to emit growth-promoting signals in a strong, unremitting fashion.[258]

Oncogene protein products can be grouped into several classes depending on their location and reactivity: nuclear, cytoplasmic, and membrane protein kinases; cytoplasmic guanosine triphosphate–binding proteins; growth factors; and others. The protein products of the proto-oncogenes *src*, *abl*, and *ras* are cytoplasmic in location. The proto-oncogene products of *myc*, *fos*, *ski*, and *myb* are nuclear in location and are believed to play an important role in the control of cell division. The expression of these genes may be responsible for the entry of the cell into DNA synthesis. Growth factors are proteins that act at the cell surface to stimulate cell growth.

Current evidence suggests that *ras* oncogenes contribute to both initiation and progression of human neoplasia. The incidence of proto-oncogene amplifications in biopsy specimens from tumors, although highly variable, is usually low. However, there may be a tendency toward association of amplification of specific proto-oncogenes and particular types of tumors. Amplifications of the c-*erb*-B-2/*neu* proto-oncogene (also referred to as *her*-2) may be involved in the etiology of human breast, salivary gland, and ovarian cancers and might serve as a useful prognostic marker for these malignancies.[327] The *erb*-B-2/*neu* locus is amplified in 30% of primary breast carcinomas and that amplification is associated with a worse prognosis.[183]

Amplification of another proto-oncogene, C-*myc*, occurs mainly in adenocarcinomas, squamous cell carcinomas, and sarcomas but not in hematologic malignancies, whereas N-*myc* amplification occurs most frequently

in neuroblastomas and occasionally in retinoblastomas and a few small cell lung carcinomas.

Tumor Suppressor Genes

The concept that a gene product could inhibit or suppress proliferation of cells in a tumor was derived from experiments using somatic cell genetics.[259] Different chromosomes from normal human cells carry tumor suppression genes that are able to block tumor formation by the cancer cell. The cancer cells must sustain mutation in both alleles of these genes to develop the ability to produce tumors.[260,392,393]

These somatic cell genetic experiments relied on cell fusion. In the first type of experiment, a cancerous cell that was able to form a tumor in an animal was fused with a normal cell. The hybrid cell no longer produced tumors in animals. One could conclude that there was an element in the normal cell that was able to suppress the tumorigenic potential of the cancerous cell. It was found that, on occasion, one of the hybrid cell lines produced by fusion of cancerous and normal cells was tumorigenic. Why? These malignant cell lines were missing genetic material supplied by the normal parent cells. Further investigation identified the presence of tumor-suppressing genes from the normal parent. Eventually, several specific tumor suppressor genes were identified and named.[383,384]

The next important part of the story of tumor suppressor genes comes from studies of the ocular tumor of infancy—retinoblastoma. Retinoblastoma can be either unilateral and unifocal or bilateral and multifocal. The disease also can be heritable or nonheritable based on the presence of a positive family history. Alfred Knudson[261] noted that heritable retinoblastoma was more often bilateral and multifocal and occurred in younger children rather than nonheritable unilateral retinoblastoma, which occurred in older children (Figs. 1.29 and 1.30). Knudson postulated that there was a gene that renders children susceptible to retinoblastoma. Patients with early-onset bilateral, multifocal disease inherit one defective copy of this gene and one normal allele. With a very high frequency, mutations develop in the normal allele, and children develop the tumor. However, patients with nonheritable retinoblastoma inherit two normal alleles. Only if two independent mutations develop in the same gene, completely obliterating the function of that gene, will a cancer arise.

Knudson concluded that it requires two genetic injuries in two alleles to produce retinoblastoma. This is called the “Knudson two-hit” hypothesis. The

hypothesis predicts that if only one of the two gene copies remains active, there is sufficient growth suppression activity to keep the cell normal. Only if both copies are inactivated is there sufficient loss of genetic activity to allow unbridled cell proliferation. The retinoblastoma gene, *Rb*, was isolated on the long arm of chromosome 13. Because the short arm of chromosomes is abbreviated as p and the long arm as q, the deletion of the *Rb* gene is abbreviated as 13q-.

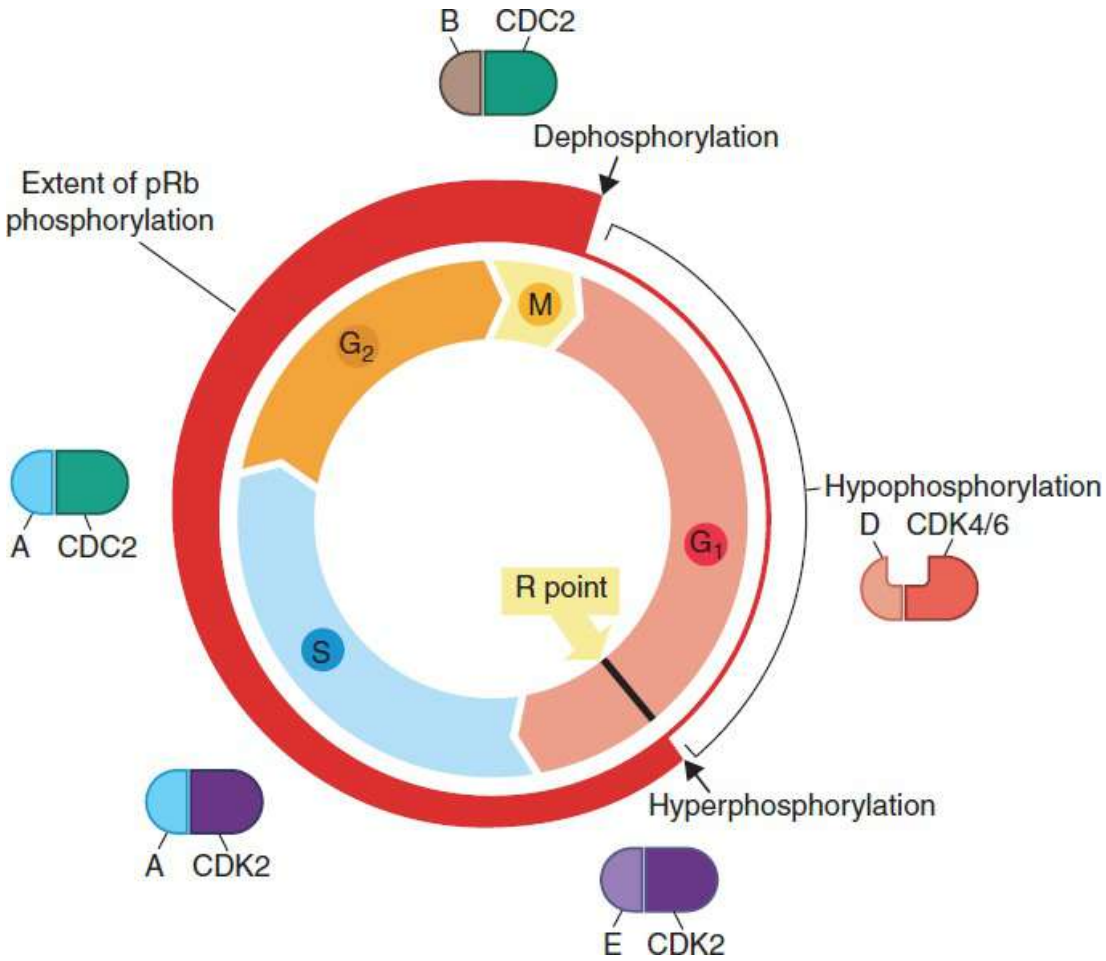

FIGURE 1.29. The phosphorylation of the retinoblastoma gene product protein, depicted as the red circle, helps to control the cell cycle. As the cell moves from M to G1, the protein is unphosphorylated; as the cell progresses through G1, the protein is hypophosphorylated; and after passing the R point (the restriction point), it is hyperphosphorylated. This process of phosphorylation is controlled by cyclins. (From Weinberg RA. *The biology of cancer*. New York: Garland Science, Taylor and Francis Group, 2007. How could one find tumor suppressor genes when their existence was most apparent by their absence? Robert Weinberg explains:

> The dominantly acting oncogenes, in stark contrast, could be detected far more readily through their presence in a retrovirus genome, through the transfection-focus assay, or through their presence in a chromosomal segment that repeatedly undergoes gene amplification in a number of independently arising tumors….
>
> A more general strategy was required that did not depend on the chance observation of interstitial chromosomal deletions or the presence of a known gene … that, through good fortune, lay near a tumor suppressor gene on a chromosome. Both of these conditions greatly facilitated the isolation of the Rb gene. In general, however, the searches for most tumor suppressor genes were not favored by such strokes of good luck[258].

The tendency of tumor suppressor genes to undergo LOH (loss of heterozygosity) during tumor development provided cancer researchers with a novel genetic strategy for tracking them down. Because the chromosomal region flanking a tumor suppressor gene seemed to undergo LOH together with the tumor suppressor gene itself, one might be able to detect the existence of a still-uncloned tumor suppressor gene simply from the fact that an anonymous genetic marker lying nearby on the chromosome repeatedly undergoes LOH during the development of a specific type of human tumor.

The use of more powerful mapping techniques allowed geneticists to plant polymorphic markers more densely along the genetic maps of each chromosomal arm. Within a given chromosomal arm, some markers were found to undergo LOH far more frequently than others. Clearly, the closer these markers were to a sought-after tumor gene (i.e., the tighter the genetic linkage), the higher was the probability that such markers would undergo LOH together with the tumor suppressor gene. Conversely, markers located further away on a chromosomal arm were less likely to undergo LOH together with the tumor suppressor gene. Genetic analyses of DNAs prepared from various types of human tumors have revealed a large number of chromosomal regions that frequently suffer LOH. A subset of these regions have yielded to the attacks of the gene cloners, resulting in the isolation of many tumor suppressor genes.[258]

A number of distinctions separate the oncogenes from the tumor suppressor genes. It is almost certain that, in most human cancers, there is a multistep pathway to tumor development, which involves the accumulation of mutations in a series of oncogenes and suppressor genes.[260]

Many tumor suppressor genes have been cloned. The suppressor p53 gene resides in 20 kilobase (kb) of DNA located in chromosome 17p13.1. The gene is a nuclear phosphoprotein composed of 393 amino acid residues in humans.[260] p53 mutations have been detected in a wide variety of malignant human tumors. The p53 gene encompasses 16 to 20 kb of DNA on the short arm of human chromosome 17. Loss of normal p53 function is associated with cell transformation *in vitro* and development of neoplasms *in vivo.* Abrogation of the normal p53 pathway is a common feature in human cancers, and it appears to be critical in the pathogenesis and progression of these tumors.[117] In some cases, candidate tumor suppressor genes have been identified based on an association between loss or inactivation and tumor development, the causal connection being only inferred.

FIGURE 1.30. Alfred Knudson (1922–2016) received a B.S. degree from California Institute of Technology (Caltech) in 1944, an M.D. from Columbia in 1947, and a Ph.D. from Caltech in 1956. He served in the Navy during World War II and the Army during the Korean war. In 1971 he published his “two hit” hypothesis for the etiology of some forms of cancer. We now know this to be the result of the disabling of a tumor suppressor gene.[397] (Photo courtesy of Fox Chase Cancer Center Archives, Philadelphia, PA.)

Cell Cycle Control

The cell cycle, which consists of four phases (G1, S, G2, and M), regulates the duplication of genetic information and distribution of duplicated chromosomes to daughter cells. The phrases “cell cycle control” or “cell cycle clock” are used to describe the cell’s molecular circuits operating in the nucleus that process and integrate afferent signals and decide if the cell will actively proliferate or remain quiescent. If the “go/no-go” decision is to “go” into proliferation, the circuitry is engaged to launch the biochemical changer necessary to allow the cell to double its contents and divide into two daughter cells. Key providers of the afferent information are tyrosine kinase receptors, G-protein–coupled receptors, transforming growth factor-*b* receptors, integrins, and the cell’s nutritional status[258].

The Nobel Prize in Physiology or Medicine for 2001 was awarded to Leland H. Hartwell, R. Timothy Hunt, and Sir Paul M. Nurse for their discoveries regarding the control of the cell cycle. The Nobel presentation speech by Professor Anders Zetterberg succinctly describes the important controls of cell replication elucidated by these three scientists:

> Cell division is a fundamental process of life. All living organisms on earth are descended from an ancestral cell that appeared about 3 billion years ago, and which has undergone an unbroken series of cell divisions since then. Each human being also began life as one single cell—a cell that divided repeatedly to give rise to all one hundred thousand billion cells that we consist of…. Every second millions of cells divide in our body.
>
> The cycle of events that a cell completes from one division to the next is called the cell cycle. During the cell cycle the cell grows in size, duplicates its hereditary material—that is, it copies the DNA molecules in the chromosomes—and divides into two daughter cells.
>
> This year’s Nobel Laureates have discovered the key regulators of the cell cycle—cyclin dependent kinase (CDK) and cyclin. Together these two components form an enzyme, in which CDK is comparable to a “molecular engine” that drives the cell through the cell cycle by altering the structure and function of other proteins in the cell. Cyclin is the main switch that turns the “CDK engine” on and off. This cell-cycle engine operates in the same way in such widely disparate organisms as yeast cells, plants, animals, and humans.

How were the key regulators CDK and cyclin discovered? Lee Hartwell realized the great potential of genetic methods for cell-cycle studies. He chose baker's yeast as a model organism. In the microscope he could identify genetically altered cells—mutated cells—that stopped in the cell cycle when they were cultured at an elevated temperature. Using this method Hartwell discovered, in the early 1970s, dozens of genes specific to the cell-division cycle, which he named CDC genes. One of these genes, CDC28, controls the initiation of each cell cycle, the "start" function. Hartwell also formulated the concept of "checkpoints," which ensure that cell-cycle events occur in the correct order. Checkpoints are comparable to the program in a washing machine that checks if one step has been properly completed before the next can start. Checkpoint defects are considered to be one of the reasons behind the transformation of normal cells into cancer cells.

Paul Nurse also used the genetic approach in his cell-cycle studies but in a different kind of yeast. In the late 1970s and early 1980s he discovered the gene CDC2, which could be mutated in two different ways. Either the cells did not divide, or they divided too early. From this he correctly concluded that CDC2 controls cell division. He later discovered that CDC2 not only controls cell division, the final event of the cell cycle; it also has a key regulatory function for the whole cell cycle, including that described for CDC28 in baker's yeast. This key function was shown to be that of CDK in the cell-cycle engine. By moving human genes into yeast cells, in 1987 Nurse isolated a human CDC2 gene. This human CDC2 gene functioned perfectly in yeast cells. Thus, the CDK function in the cell-cycle engine had been conserved through more than 1 billion years of evolution—from yeast to man.

Tim Hunt discovered the other key component of the cell-cycle engine, the protein cyclin, which regulates the function of the CDK molecule. Working with sea urchin eggs as a model organism, in 1982 he discovered a specific protein that increased in amount before cell division but disappeared abruptly when the cells divided. Because of these cyclic variations, he named the protein cyclin. These experiments not only led to the discovery of cyclin, but also demonstrated the existence of periodic protein degradation in the cell cycle—a fundamental control mechanism. Hunt also

showed the existence of cyclins in other, unrelated species. Thus cyclins, like CDK, had been conserved during evolution.[263]

Since the structure of the DNA molecule—the double helix—was discovered, we have a molecular explanation of how a gene can make a copy of itself. With the discoveries of CDK and cyclin, we are now beginning to understand, at the molecular level, how the cell can make a copy of itself.

To ensure that the daughter cells possess a full complement of genetic information, checkpoints exist to ensure fidelity of DNA duplication and accuracy of chromosome segregation.[48] Checkpoint pauses permit editing and repair of genetic information so that each daughter cell receives a full complement of genetic information identical to the parent cell. In some cells, there are checkpoints for initiation of mitosis. Mutation of the checkpoint genes allows the cell to enter mitosis after x-irradiation.[264] For example, the rad-9 gene is a G2/M checkpoint gene because it responds to two different types of signals.[265] Experimental observations suggest that the p53 gene, shown to be a transcriptional activator,[118] may be critical for G1 checkpoint control. p53 has been shown to induce transcription of p21, which in turn inhibits the association of CDK 4,6 with proliferating cell nuclear antigen and cyclin D. As a consequence, the retinoblastoma protein cannot be phosphorylated and stays in complex with the transcription factor E2 F, effectively blocking the transcription of cell cycle–promoting proteins and causing a cell cycle arrest.

Checkpoints are signal transduction systems that must receive a signal, amplify it, and transmit it to other components that regulate the cell cycle. Double-strand DNA breaks, unexcised ultraviolet light-induced dimers in DNA, and centromeres not engaged by the spindle are potential signals.[139,266] Checkpoints ensure the fidelity of genomic replication and segregation. Biologically significant levels of spontaneous damage require checkpoint control for cells to maintain a high fidelity of chromosome transmission. Therefore, restoration of compromised checkpoints could slow cancer cell evolution even in the absence of exogenous sources of DNA damage.[266] Many signal transduction systems, including checkpoint controls, exhibit adaptation; that is, in the presence of a constant stimulus, the response diminishes with time. As a consequence, the cell may proceed through the cell cycle, although the original perturbation has not been removed or cannot be repaired. Checkpoint activation may induce a variety of cell responses, including cell death. The checkpoint controlling entry into S-phase in mammalian cells includes p53. One function

under the control of this pathway is apoptosis. Restoration of defective checkpoints could restore the apoptotic response of cancer cells and increase their sensitivity to DNA-damaging agents. It may be possible to achieve specificity for certain types of cancer cells because not all cells respond to the same apoptotic signals.[237,238,267,268]

Growth Factors and Signal Transduction

Transmission of biochemical signals to the cellular nucleus leads to altered expression of a wide variety of genes involved in microgenic and differentiation responses.[138] A number of growth factors exert their effects through receptors possessing intrinsic protein tyrosine kinase activity. On activation, these receptors phosphorylate both themselves and other intracellular proteins on the amino acid tyrosine. Among the receptors for growth factors are EGF, platelet-derived growth factor, insulin, nerve growth factor, and macrophage colony stimulatory factor. The mitogenic signaling pathway activated by protein tyrosine kinase receptors involves the activation of ras proteins. Ras undergoes conformational change and interacts with additional downstream targets. A protein kinase cascade is activated, which conveys the growth factor–initiated signal to the nucleus via the raf, mek, map kinase, and other proteins.

Telomeres

Human chromosomes are linear. At each end of the chromosome are structures known as telomeres, from the Greek *telo* for “end” and *mere* for “structure.” Telomeres are composed of specialized DNA and DNA-binding proteins. As chromosomes are replicated, telomeres shorten each time during the process of cell division. Continued cycles of cell division result in shortened telomeres. The telomeres, for example, in the fibroblasts of older adults are shorter than those in children. Normal human cells senesce when the telomeres shorten to a critical length.

Stem cells and cancer cells must maintain their telomere lengths to prevent senescence. Two mechanisms of telomere maintenance have been identified: expression of the telomerase enzyme and the recombination of telomeres.

The telomere hypothesis states that critical telomere shortening prevents somatic cells from dividing. In contrast, the maintenance of telomere length allows cancer cells to continue to divide. An increasing body of experimental evidence supports the telomere hypothesis and its association with cancer.

The capacity of cells to respond to ionizing radiation is determined by

multiple factors. There are a variety of syndromes associated with molecular defects that are characterized by clinical radiosensitivity. These include ataxia, telangiectasia, Nijmegen breakage syndrome, and ataxia telangiectasia–like disorder. These syndromes all have defective telomere maintenance in common. It has been hypothesized, therefore, that the radiosensitivity phenotype and the telomere dysfunction phenotype may be linked. A variety of experimental models suggest that telomere maintenance and radiosensitivity are associated, and this may offer the opportunity for a therapeutic target.

Apoptosis

Apoptosis or programmed cell death, a phenomenon distinct from necrosis, was described in 1972 by Kerr et al.[240] Apoptosis is programmed by specific signals in the cell that cause an endonuclease to cleave DNA at internucleosomal sites.

Apoptosis is detected by histologic evaluation of membrane blebbing and chromatin condensation, by flow cytometry using fluorescent nucleotides and terminal transferase to detect fragmented DNA, by detecting apoptotic cells that are usually very small with characteristic profiles of right-angle and forward light scattering, or by using DNA fluorochrome to detect a decrease in fluorescence as small DNA fragments diffuse from the cell that is undergoing apoptosis.[237,269,270] An early change in apoptosis, the flip-flop of the phospholipid phosphatidylserine (PS) from the inner to the outer leaflet of the bilayer membrane, also can be detected using a fluorescently labeled annexin V protein that has a high binding affinity to PS. Several oncogenes, cytokines, and growth factors have been reported to play a role in promoting or reducing radiation-induced apoptosis.[233]

Most radiation-induced cell lethality (loss of reproductive integrity) for dividing cells appears to be caused by mitotic-linked death resulting in loss of genetic information as cells with chromosomal aberrations divide. Apoptosis, frequently seen within 4 to 6 hours after irradiation, occurs spontaneously and is enhanced by radiation as observed *in vivo* in the intestinal crypt and salivary and lacrimal glands with nondividing cells and nondividing lymphocytes. Apoptotic cells are eliminated rapidly *in vivo*, making it difficult to quantify. In contrast, this cell death mechanism is easy to quantify *in vitro* because apoptotic cells persist in culture for many hours. However, cell division of nonapoptotic cells complicates quantification.[233] In cell lines susceptible to apoptosis, this process sometimes occurs early before cells enter mitosis or later after the cells divide. Late apoptosis may be associated with mitotically linked death and, in fact, may

be triggered by chromosomal aberrations. Apoptosis may be quite important for clinically relevant doses of fractionated irradiation, even if it causes a relatively small reduction in clonogenic survival. However, this requires that cells be recruited into the apoptotic-susceptible fraction after each dose fraction.

It appears that with progression of certain tumors, spontaneous and therapy-related apoptosis occurs less frequently. The apoptotic response to irradiation can be modified by cytokines to protect normal tissues[170] or to induce tumor cell killing.[271–273] Tumor necrosis factor increases apoptosis after irradiation in some tumors while protecting the hematopoietic compartment, possibly by blocking apoptosis. Irradiation prevents extensive cellular proliferation by increasing differentiation in both tumors and normal tissues. Also, irradiation appears to increase the aging of normal cells. Another mechanism of reversible loss of proliferative capacity induced by irradiation is necrosis, which occurs with high doses of irradiation and is a major mechanism seen with large-dose fractions such as in stereotactic irradiation.

GRID Therapy, Bystander Effects, Abscopal Effects, REAP, and DAMP

Early in radiotherapy's history, some clinicians tried to improve normal tissue sparing, particularly the skin, by creating a shielding block which resembled a checkerboard. Imagine a checkerboard in which the black squares are lead and the white squares are open. This would permit radiation to travel through the open squares while the black squares would shield the patient, the patient's normal tissue, and the tumor from radiation. If a single-photon field was used to deliver the grid pattern of radiation, there would be a dose distribution of peaks and valleys across the normal tissue and the tumor because of penumbra and side scatter. A radiation dose, which is delivered to a continuous region, induces greater damage than the some dose fractionated in space. This concept is generally called GRID radiation therapy. It can now be performed with TomoTherapy, multileaf collimators, and/or a proton beam. In three dimensions, the GRID or "checkerboard" is probably better thought of as a honeycomb.

Spatially fractionated radiotherapy causes irradiated tumor cells to engage to cell-to-cell signaling. Neighboring unirradiated cancer cells are clearly affected. One observes cells undergoing a stress response, activation of repair enzymes, and antioxidant gene expression. It is as if the irradiated cells are sending a "Mayday…mayday…I am under attack" message to neighboring cells. Furthermore, in some experimental models, the irradiated cells provoke an

immune response, which can kill irradiated and unirradiated cells. It appears that the radiation causes the emission of antigens and cell signals, which activate an immune reaction. The phenomena of the irradiated cells have an effect upon neighboring unirradiated calls is called “the bystander effect.”[274]

The abscopal effect is a phenomenon where the localized treatment of a tumor causes not only a shrinking of the treated tumor but also a shrinking of tumors outside the scope of the localized treatment. Imagine, for example, an experimental mouse with a tumor implanted in the left thigh and a tumor of the same histology implanted in the right thigh. If a highly localized external radiation beam were directed against the tumor of the left thigh and it regressed and, in addition, the unirradiated tumor of the right thigh regressed, then the behavior of the tumor of the right thigh is called an abscopal effect. In a 1953 paper in the British Journal of Radiology, R.H. Mole proposed the term “abscopal” (“ab,” away from; “scopus,” target) to refer to radiation’s effects “at a distance from the irradiated volume but within the same organism.”[275]

A current active area of research addresses the idea that irradiation may augment the immunogenicity of tumors and accentuate the cytotoxic effects of radiotherapy both on the irradiated tumor and on distant tumors—a form of the abscopal effect. In combination with immunotherapeutic agents, an irradiated tumor might be able to act as an autologous *in situ* tumor vaccine. The mechanism of action might involved radiation-enhanced antigen presentation (REAP), damage-associated molecular patterns, or danger-associated molecular patterns (DAMP), by which host molecules initiate and perpetuate a noninfectious inflammatory response, immunomodulation of tumor cell surface molecules, and the modulation of cellular infiltrates in the tumor microenvironment.[276,277]

Stick the following references where they go, alphabetically, in the reference section of Chapter 1 but do not number them.

THE BIOLOGY OF METASTASIS

The prefix *meta* is of Greek origin and is defined as “after,” “beyond,” or “over.” It is used to denote change or transformation. The word *stasis* means “stand” or “stationary.” Thus, when the two words are combined to form *metastasis*, the new word is used to represent a change in location of a disease or its manifestations. It also means the transfer of a disease from one organ or body part to another organ or body part not directly connected. The oncologist uses

the term *metastasis* to refer to the manifestation of malignancy that arises from the primary growth but is now in a secondary site.

It is clear that the pattern of metastatic spread of cancer is not random. The distribution of some secondary tumor deposits can be explained on mechanistic grounds (i.e., that the tumor cells are shed into the bloodstream and lodge in the first narrow capillary network that they encounter downstream). This would explain, for example, why the liver is the most common site for secondary tumors in patients with primary cancer within the catchment area of the hepatic portal vein, such as gastrointestinal malignancies. Similarly, the lung would be a favored site in patients with primary tumor spilling into the systemic veins. There can be no doubt that vascular drainage patterns influence the distribution of secondary tumor deposits from some types of primary cancer.

It is also clear, however, that the distribution of some metastatic tumors cannot be explained solely by patterns of encountering and lodging in the nearest narrow capillary bed. This is called “metastatic tropism”: Carcinomas form detectable metastases in only a limited subset of possible distant organ sites. The seminal paper addressing the problem was metastatic tropism by Stephen Paget (Fig. 1.31). Paget was the fourth and youngest son of the famous British physician Sir James Paget. James Paget was one of the founders of modern pathology and is the nanesoke of Paget’s disease. Stephen Paget worked as an assistant surgeon at the West London and Metropolitan Hospitals in England. Later in life, he devoted himself to public health issues and became a highly regarded biographer and essayist.[278] Writing in the *Lancet* on March 23, 1889, on “The Distribution of Secondary Growth in Cancer of the Breast,” Paget wondered:

FIGURE 1.31. Stephen Paget (1855–1926). (Reprinted by permission from Nature: Fidler IJ. The pathogenesis of cancer metastasis: the 'seed and soil' hypothesis revisited. Nat Rev Cancer 2003;3[6]:453–458. Copyright © 2003 Springer Nature.)

The question ought to be asked, and if possible answered: "What is it that decides what organs shall suffer in a case of disseminated cancer?" If the remote organs in such a case are all alike passive and, so to speak, helpless —all equally ready to receive and nourish any particle of the primary growth which may "slip through the lungs," and so be brought to them— then the distribution of cancer throughout the body must be a matter of chance. But if we can trace any sort of rule or sequence in the distribution of cancer, any relation between the character of the primary growth and the situation of the secondary growths derived from it, then the remote organs

> cannot be altogether passive or indifferent as regards embolism…. Every single cancer cell must be regarded as an organism, alive and capable of development. When a plant goes to seed, its seeds are carried in all directions; but they can only live and grow if they fall on congenial soil.[281]

Paget observed, in a large number of autopsies of women with breast cancer, that the lymph nodes, liver, lung, bone, and brain commonly were involved. However, he found that the kidney and spleen rarely were involved despite receiving a significant amount of blood flow. He was struck by the discrepancy between the relative blood supplies and the relative frequencies of metastatic tumors in various organs. From his data, Paget expounded his "seed and soil hypothesis." He argued that metastasis required both a willing seed (intrinsic cellular factors) and hospitable soil (host organ). There must be intrinsic cellular factors that lead to a satisfactory interaction between the tumor cell and the host organ resulting in successful metastasis. In contemporary terms, we understand this to mean that the tumor cell must have favorable adhesion molecules, and the host organ must be accepting receptors on its endothelial cells, which results in appropriate sites for the circulating tumor cells to bind, migrate into the organ, and subsequently grow, or, perhaps, that tumor cells promote upregulation of adhesion receptors in specific stromal cells.

As they grow, tumors almost certainly release large numbers of malignant cells into the blood and lymphatics continuously. It is clear, however, that the mere presence of tumor cells in the bloodstream does not always lead to the formation of distant metastases. A. J. Salisbury of the Brompton Hospital in London is credited as being one of the first to emphasize that the metastatic process is highly inefficient. The overwhelming majority of malignant cells released in the blood die.[282] They are battered in the circulation, assaulted by the immune system, and fail to reproduce. Irving Zeidman and Isaiah J. Fidler, at that time working at the University of Pennsylvania, injected mouse melanoma cells labeled with radioactive iodine into a peripheral vein of an experimental mouse. Within a few minutes, the melanoma cells had lodged in the nearest, narrowest capillary bed: the lungs. Most tumor cells died there. A day later, about 1% of the injected cells were still alive.[283,284]

The fact that only a small fraction of a tumor's cells can successfully form metastatic colonies implies that the survivors are, indeed, specially adapted cells. One might think of them in evolutionary terms. These successfully metastasizing cells must represent the survival of the fittest: the most hardy, most resilient, and

most able to fend off the body's attempt to kill them. Isaiah J. Fidler performed an experiment with B16 melanoma cells in mice wherein he injected them into a peripheral vein, harvested the ones that grew in the lungs, grew them in a tissue culture environment, and repeated the process over and over and showed that he could create increasingly efficient cancers, which became better and better of metastasizing to the lung. He shown that they truly were "the fittest" when he came to metastatic potential.

A long period of tumor growth leads to progressive changes in a tumor's structure, blood supply, oxygenation status, antigenic characteristics, doubling rate, growth properties, and metastatic potential. Several investigators have performed variations of the following experiment: Unselected tumor cell suspensions were divided into two parts. One part was injected intravenously into a group of mice. The other part was subdivided into separate cultures. From each culture, a single tumor cell was isolated and grown to produce a large number of different clones, that is, cells with identical genetic composition. Then, these clones were injected into groups of mice.[225,285]

If the metastatic potential of tumor cells was homogenous, then you would expect that the number and location of tumor colonies in injected mice would be similar in the mice receiving the unselected tumor cell suspensions and the mice receiving the cloned lines. If different cloned subpopulations gave rise to widely different numbers of colonies compared to the uncloned cells, it would indicate that the tumor was heterogenous—that the tumor contained cells with a variety of metastatic potential. The result was that there were widely different numbers of metastatic colonies. This implies the intrinsic heterogeneity of metastatic potential in a growing tumor.

As Stephen Paget suggested, there really a tendency for particular types of primary tumors to preferentially metastasize to particular organs. Can we show, experimentally, that this is true and that it really is not about "the nearest, narrowest capillary bed trapping the tumor cells"? Garth L. Nicholson and Isaiah J. Fidler took highly metastatic melanoma cells serially passed so that they were quite efficient at metastasizing to the lungs and injected some into the tail vein of mice where the first narrow capillary bed they would encounter was the lung and, in other animals, they injected the cells into the left ventricle, just beyond the lungs, where they would be more likely to be disseminated throughout the body. Initially, the animals who had cells injected into the tail vein had far more tumor cells in the lungs. One day after injection, there was no difference in the number of cells in the lungs irrespective of the site injection. After two weeks,

the same number of lung tumors were found for the two sites of injection. Tumor cells destined to form metastases in a particular organ appear capable of detaching from their first home and recirculating until they come to rest at their preferred site of ultimate metastases.[285]

Metastasis formation is an inefficient process. Fidler and colleagues[286] injected melanoma cells into the peripheral vein of a mouse whose DNA had been labeled with radioactive iodine. They found that, shortly after the injection, most of the injected cells rested in the lung (i.e., the nearest narrow capillary bed). Most of the tumor cells, however, went on to die in the lung. Only a few live cells continued to circulate. Within a day, only 1% of the injected cells were alive, and after 2 weeks, no known metastasis could be seen in the lungs. Only 0.1% of the cells originally injected were still alive.[286] Blood-borne metastasis must be a highly selective process. Only a very small proportion of malignant cells that enter into the bloodstream are able to survive and grow.

There are three major pathways of metastasis. They are:

- Across body cavities such as the peritoneal cavity or within the cerebrospinal fluid. This is the way, for example, that medulloblastoma disseminates via the leptomeninges or that ovarian tumors form on the peritoneal surface of the intestine.
- Via the lymphatic system. Axillary masses following breast cancer, which are easily palpable, would be a common example.
- Hematogenously, usually via veins rather than arteries. The spread of a limb sarcoma to the lungs would be an example (Fig. 1.32).

The molecular mechanism of tumor metastasis is a multistep process involving many tumor cells—host–cell interactions as well as cell–matrix associations.[312,338] This process is sometimes called the invasion–metastasis cascade. The crucial processes are as follows:

- Tumor cell adhesion to other tumor cells at the site of the primary malignancy, host cells, or components of the extracellular matrix
- Proteolysis of the extracellular matrix during invasion
- Tumor cell motility through the extracellular matrix to reach the vascular or lymphatic endothelium
- Intravasation into the lumina of blood vessels or lymphatics—this is facilitated by molecular changes that promote the ability of carcinoma cells to cross the pericytes and endothelial cell barriers
- Embolism into the lymphatic system and/or the blood circulation
- Tumor cell survival despite both the mechanical trauma endured by the cell in

transit in the vascular system as well as the body's immunologic assault directed against the circulating tumor cell (insofar as most tumor cells have a diameter of 20 to 30 μm and capillaries have a diameter of approximately 8 μm; most tumor cells in circulation are probably quickly trapped in capillary beds)

- Adherence to the endothelium when the tumor cell comes to rest at the metastatic site in the secondary organ
- Dissolution of the cell–cell junction and the basement membrane of the blood vessel or lymphatic into the organ parenchyma
- Survival in the new host organ microenvironment and interaction with that new microenvironment in the host organ to permit growth of the tumor deposit
- Tumor cell proliferation in the new organ and angiogenesis to achieve metastatic colonization

Only if all of these steps can be negotiated successfully can the tumor cell ultimately "set up shop" as a metastatic focus. The fact that only a small fraction of tumor cells survive and successfully establish a metastasis would suggest that the ultimately successful cells must be quite unusual. It would be reasonable to believe that they represent a subpopulation of tumor cells that are endowed with particular characteristics that make for successful metastasis. As the population of tumor cells evolves, it is likely that aggressive subpopulations, having diverse properties, will arise and that their frequency in the population increases under selective pressure of the host immune defenses. This will lead, ultimately, to the emergence of cells with enhanced malignancy.[287] Many people believe that tumor cells evolve via a Darwinian selection. Genetic variation continuously occurs in the tumor population and clones with a survival advantage become overrepresented. These cells have "metastasis virulence genes" enabling their spread. The successful metastatic cells will possess characteristics of neoplastic transformation—the ability to turn on an angiogenic switch, an invasive phenotype, and the capacity to evade the immune response—as well as favorable cell adhesion and motility characteristics.[258,288–290]

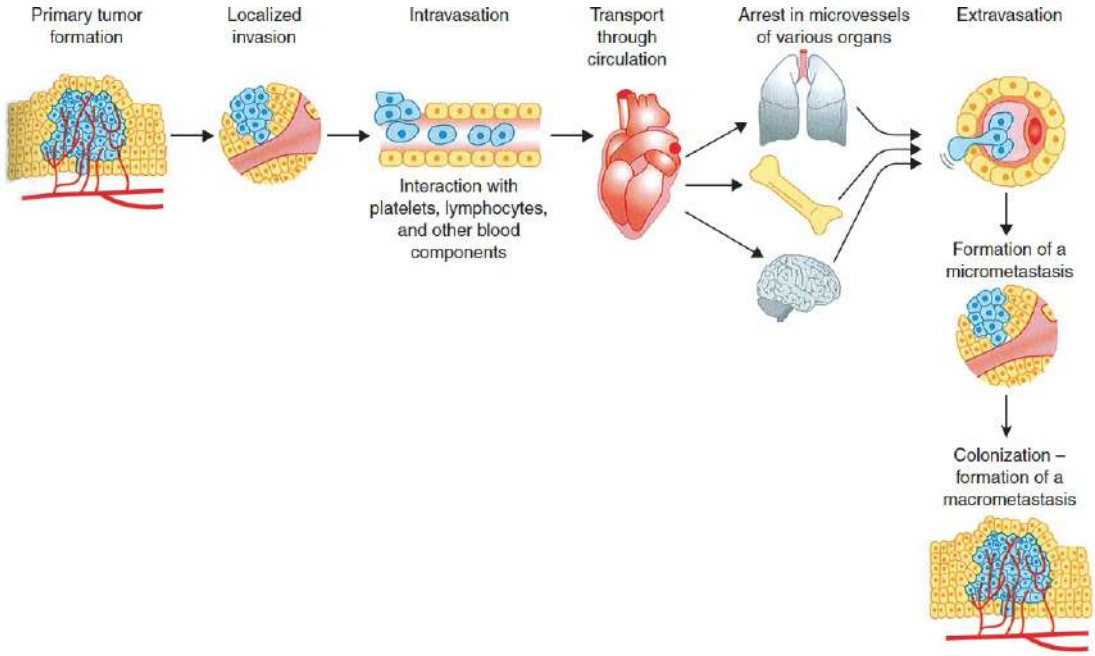

FIGURE 1.32. The development of metastasis is a multistep process that is highly inefficient. In order to form a metastasis, the tumor must breach the basement membrane and enter either a blood vessel or a lymphatic, travel through the bloodstream or the lymphatics and not be destroyed either by attack of the immune system or mechanical trauma, adhere to the endothelium at a distant anatomic site, invade the organ parenchyma, draw a blood supply into the metastatic deposit, and colonize the new organ. (From Weinberg RA. *The biology of cancer*. New York: Garland Science, Taylor and Francis Group, 2007. Copyright © 2007 by Garland Science, Taylor & Francis Group, LLC. Used by permission of W. W. Norton & Company, Inc.)

Metastatic progress involves not only the tumor's cells but also those cells' ability to recruit the aid of stromal cells. As tumors progress, the stroma becomes increasingly "reactive"—akin to the tissue of wound healing or chronic inflammation.

THE MOLECULAR BIOLOGY OF THE METASTATIC PHENOTYPE AND ANGIOGENESIS

Tumor progression is the acquisition of permanent, irreversible, qualitative changes in one or more characteristics of neoplasm that ultimately will lead to the tumor becoming more autonomous and malignant.[291] A genetic analysis of the stages of tumor progression has led to the formulation of the multistep theory of tumorigenesis. The multistep theory involves activation of oncogenes, inactivation of tumor suppression genes, and identification of many tumor-associated molecules. The metastatic phenotype appears to require cells to have

the additive effect of positive modulators (oncogenes) as well as the loss of negative effectors (tumor suppressor genes, invasion- and metastasis-suppressor genes). Thus, the molecular biology of a metastatic cell is clearly a multistep process of diversification and clonal selection for aggressive cells.

The mutated *ras* oncogene sequences, when transfected into mouse embryo–derived fibroblasts (NIH 3T3 cells), cause those transfected cells to produce numerous metastases. This finding has been confirmed in both fibroblasts and epithelial cells of human and rodent origin. A number of other metastasis-associated genes have been described. These include NM23-1 and stomelysm-3 (ST-3). NM23-1 has features similar to a transcription factor and may play a role not only in *c-myc* expression but also in the response of cells to transforming growth factor-β. ST-3 is a member of the matrix proteinase family.[292]

It would be far too simplistic to conclude that the metastatic phenotype arises only from genetic alterations associated with the acquisition of aggressive tumorigenicity. Cells clearly can be transformed by oncogene transfection, but not all cells acquire a metastatic phenotype after this oncogene transfection. Simply stated, we must bear in mind that there is separation between the genetic changes that drive tumorigenicity and the metastatic phenotype. Invasion and metastasis will require the activation of additional effector genes or loss of suppressor local inhibitors above those genetic changes required for uncontrolled growth alone.

The successful development of a metastatic focus requires new blood vessel growth. There are angiogenesis promoters and inhibitors that may be modified or removed during the tumor-induced angiogenic response. Tumor angiogenesis in the nascent metastasis is a tightly regulated process in a delicate balance between the pro- and antiangiogenic factors.[293]

Angiogenesis

The success of growth of a tumor is, in part, governed by a complex interplay between the tumor cells and the surrounding normal tissue. A dramatic example of this interplay is the process of tumor angiogenesis (also called tumor neovascularization).

The growth of the tumor depends on the tumor’s access to nutrients and oxygen as well as its ability to eliminate metabolic waste and carbon dioxide. In very small tumors, these requirements are addressed by diffusion. As the tumor enlarges, however, diffusion is inadequate. The growing tumor requires direct access to the circulatory system.

Tumor access to the circulatory system is secured through angiogenesis, through which the tumor cells encourage the ingrowth of capillaries and larger vessels from the adjacent normal tissue. The tumor cells recruit these vessels through the release of angiogenic factors. These cause the proliferation of endothelial growth factor and, almost certainly, tissue growth factor-β. The generation of tumor vessels is the result of a delicate balance between angiogenesis-promoting factors and angiogenesis-inhibiting factors. These factors have now provided a growing body of therapeutic targets in the treatment of cancer.

Some authorities encourage us to think about the tumor as a structure composed of varied compartments including the actual clonogenic cells, a connective structure, and the blood vessels. Utilizing this way of thinking about tumors, we envision cancer treatment as striking at different components of the tumor (i.e., antiangiogenesis agents directed against the vasculature and anticlonogenic agents directed against proliferating cells). Experimental evidence suggests that, in certain tumor systems, the combination of radiation and antiangiogenic agents is a fruitful way of treating cancer. We may expect to see an increasing body of evidence for the use of combinations of radiation, chemotherapy, hormonal therapy, and antiangiogenesis agents in the coming years.

The hallmark of an invasive cancer is its ability to disrupt the epithelial basement membrane and the presence of cancer cells in the stromal compartment. It makes sense, therefore, that two broad classes of molecules have been implicated repeatedly in contributing to the metastatic ability: Cell–cell adhesion molecules and motility molecules play a crucial role in the development of metastatic potential.[294] The ability of tumor cells to adhere to other tumor cells, cells of the host, or components of the extracellular matrix affects multiple components of the metastatic cascade. These interactions depend on several classes of molecules expressed on the cell surface. Cadherins are calcium-dependent molecules that mediate homophilic cell–cell adherence. Integrins are heterodimeric transmemory proteins that are formed by the noncovalent association of α- and β-subunits. The binding of the extracellular matrix ligands to integrins is known to initiate similar transduction pathways. These pathways lead to cell proliferation, differentiation, migration, or cell death. Selectins act through a terminal calcium-dependent lexon domain. They are prominently involved in heterotypic cell–cell adhesion between blood cells and endothelial cells.[295]

Tumor adherence to the extracellular matrix and cell motility are the next crucial component of the metastatic cascade. Tumor cells are able to attach to a specific lipoprotein of the extracellular matrix such as fibronectin, collagen, and laminin. These adherences are formed either through integrin or nonintegrin cell surface receptors. CD44 is a crucial transmembrane glycoprotein with a large echo domain and a single cytoplasm domain. CD44 is involved in cell adhesion to hyaluronan[291] (Box 1.9).

Box 1.9

Antiangiogenesis Therapy of Cancer

Tumor vessels are fundamentally different from normal blood vessels insofar as they are usually irregular and disorganized. In vessels that are leaky, hemorrhagic, or torturous or in those containing poorly oxygenated blood that may flow backward and forward in the same vessel, tumor vasculature may provide an interesting therapeutic target. The general public and the scientific community have recently experienced a wave of considerable excitement associated with the possibility that antiangiogenesis agents may be employed clinically to disrupt tumor angiogenesis. This form of therapy may complement existing cancer treatments. Vascular endothelial growth factor (VEGF) is a key element in the stimulation of angiogenesis. VEGF binds to a receptor on endothelial cells (VEGFR), which stimulates tyrosine kinase activity, which in turn stimulates downstream signaling and activation of endothelial cells. The drugs in the therapeutic pipeline may be categorized as follows:

- Anti-VEGF agents: Some drugs prevent the binding of VEGF to its receptors. *Bevacizumab (Avastin)* is a monoclonal antibody that binds to VEGF, prevents it binding to VEGFR, and inhibits VEGFR activation. It is being utilized in the therapy of a variety of human malignancies.[262]
- Anti-VEGFR agents: Several receptors bind to VEGF: VEGFR1, VEGFR2, NRP-1, and NRP-2. VEGR2 is thought to mediate most of the angiogenic properties of VEGF and is expressed at high levels on the endothelial cells of tumor vasculature. Several monoclonal antibodies are under investigation in animal models to target the VEGF receptor.
- Receptor tyrosine kinase inhibitors: An antiangiogenesis strategy is to target the downstream activity of the binding of the VEGFR by inhibition of tyrosine kinase activity. The following drugs, now in human clinical trials, fall into this category: cediranib or recentin (AZD2171), pazopanib, BIBF 1120, sorafenib, and sunitinib (SU11248).

The potentially metastatic cell must overcome a series of tissue barriers. These include the basement membrane and connective tissue. These must be traversed by the tumor cells during the metastatic process. Five classes of naturally occurring proteinases have been associated with aggressive tumor cells

and implicated in metastases. These include members of the gene family of matrix metalloproteinases. These enzymes, each of which is secreted by a proenzyme that subsequently requires activation, may be divided into three general subclasses: interstitial collagenase, type 4 collagenase (gelatinases), and stromelysins. Once having dissolved barriers, active tumor cell motility is required for the penetration of the basement membrane and the interstitial stoma. Successful migration of metastatic cells requires transition of propulsive force from the extracellular matrix to the cytoskeleton. Tumor cells exhibit amoeboid movement, which is characterized by pseudopod extension. For the protrusion and retraction of pseudopods, the network of intracellular polymerized cross-linked filaments must be disassembled and then reassembled.[287]

MANAGEMENT OF THE PATIENT WITH CANCER

The optimal care of cancer patients is a multidisciplinary effort that may combine two or more disciplines: surgery, radiation therapy, and chemotherapy. Many professionals, including physicians, physicists, laboratory scientists, nurses, rehabilitation staff, sociologists, and social workers, are intimately involved. Pathologists, radiologists, clinical laboratory physicians, and immunologists are integral members of the team that renders the correct diagnosis. Biology, biochemistry, and pharmacology have contributed greatly to the advancement of methods used to evaluate and treat cancer patients (e.g., biomarkers, cell kinetic indicators, oncogenes).

The radiation oncologist, like any other physician, must assess all conditions relative to the patient and the tumor under consideration for treatment and systematically review the need for diagnostic and staging procedures as well as the best therapeutic strategy. This has been well illustrated in a series of “decision trees” designed by the Patterns of Care Study Group for radiation therapy.[296] In several instances, a clear relationship existed between compliance with guidelines for diagnostic or therapeutic procedures (best current management consensus) and therapy outcome, as defined by survival, recurrence patterns, or complications of treatment.

Emphasis on screening and early diagnosis of cancer, as well as improvements in therapeutic strategies, has had a significant positive impact on the survival of patients with cancer. In the United States, results of the Surveillance, Epidemiology, and End Results program have shown a small but steady improvement in survival for a variety of tumor sites. Relative survival of

patients with cancer at various times after diagnosis has improved substantially since 1960.

Combination of Therapeutic Modalities

Irradiation and Surgery

The rationale for *preoperative radiation therapy* relates to its potential ability to eradicate subclinical or microscopic disease beyond the margins of the surgical resection, to diminish tumor implantation by decreasing the number of viable cells within the operative field, to sterilize lymph node metastases outside the operative field, to decrease the potential for dissemination of clonogenic tumor cells that might produce distant metastases, and to increase the possibility of resectability. The disadvantages of preoperative irradiation are that it may interfere with normal healing of the tissues affected by the radiation, it delays surgery, and it may disrupt surgical staging of the tumor and/or the expression of histologic or immunohistochemical prognostic factors.

The rationale for *postoperative irradiation* is based on the fact that it is possible to eliminate subclinical foci of tumor cells in the tumor bed (including lymph node metastases). By delivering higher doses to the volume of high-risk or known residual disease than can be achieved with preoperative irradiation, a greater tumor control may be obtained.

The potential disadvantages of postoperative irradiation are related to the delay in initiation of radiation therapy until wound healing is completed. Theoretic and experimental evidence suggests that the radiation effect may be impaired by vascular changes produced in the tumor bed by surgery (Fig. 1.33).

Irradiation and Chemotherapy

Tumor or *normal tissue enhancement* describes any increase in effect greater than that observed with either chemotherapy or irradiation alone.[297] Agents used in chemoirradiation include those with cytotoxic activity against the tumor, which may show additive, subadditive, or supra-additive effects, such as 5-fluorouracil or mitomycin C in anal carcinoma; agents with minimal or no significant activity against a specific tumor, which may, however, enhance the irradiation effect; radiation hypoxic cell cytotoxins or bioreductive agents; and radioprotectors.

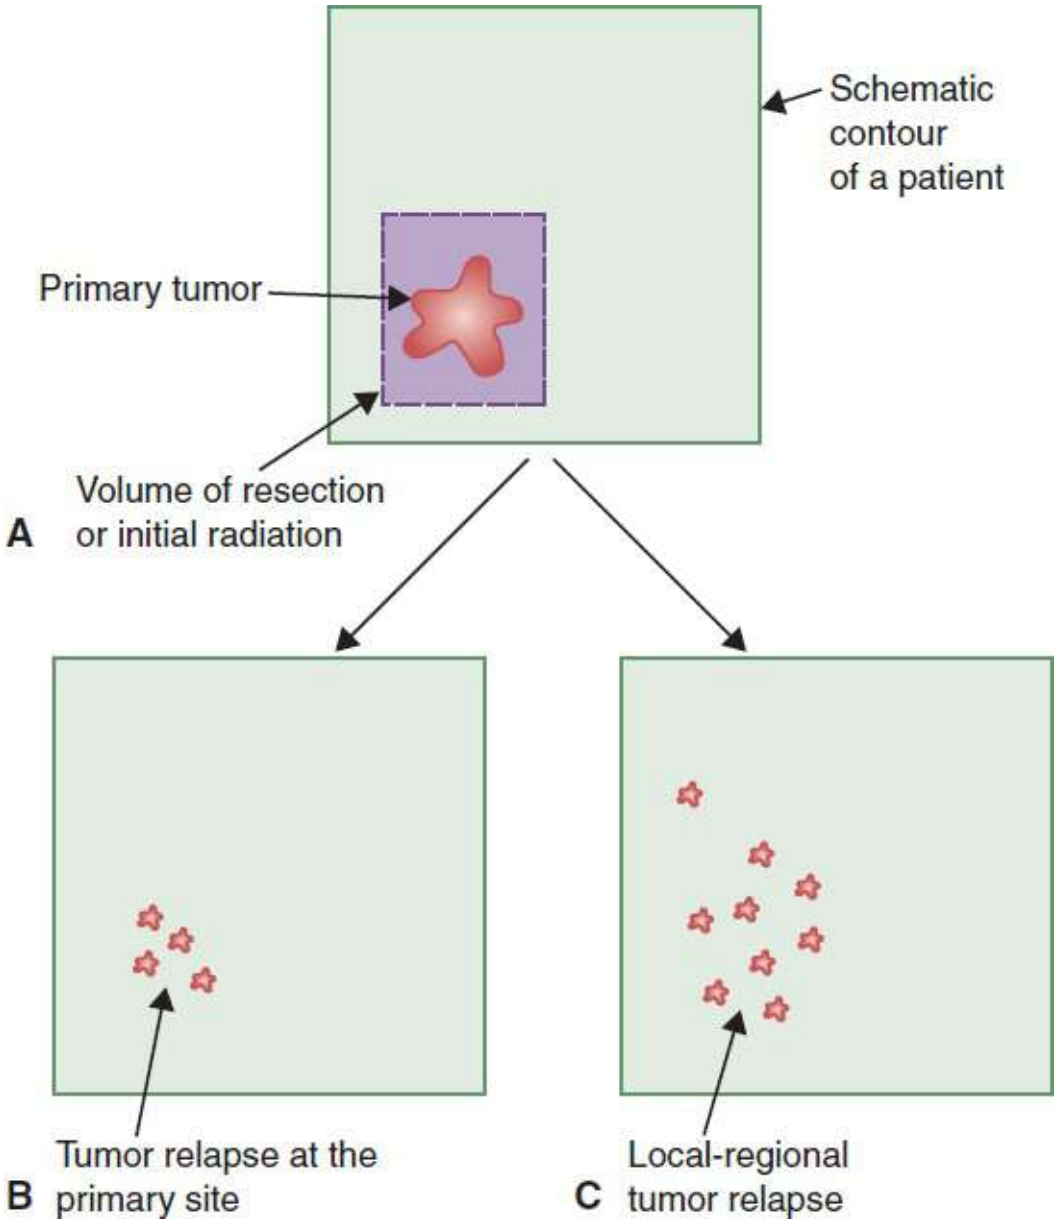

FIGURE 1.33. **A:** A pattern of failure analysis is useful to improve treatment of malignancies. **B:** If the tumor after surgery and/or radiotherapy tends to relapse at the primary site within the volume treated, it would suggest that the local therapy is insufficiently intense. **C:** If, however, there is a locoregional tumor relapse, it would suggest that the initial surgery or radiotherapy field size is insufficient to cover microscopic extension of disease that has the potential to be controlled. A pattern of failure as shown in panel **C** is not, by itself, sufficient to make the case for extended-field radiation. One must have a pattern of failure such as that which is seen in panel **C** and also be able to show that intervention with large field irradiation can alter that pattern in a favorable manner.

Chemotherapy alone or combined with irradiation may be used in several settings.[298] *Primary chemotherapy* is used as part of the primary lesion treatment

(even if later followed by other local therapy) and when the primary tumor response to the initial treatment is the key identifier of systemic effects. *Adjuvant chemotherapy* is used as an adjunct to other local modalities as part of the initial curative treatment. The term *neoadjuvant chemotherapy* is used when this modality is used in the initial treatment of patients with localized tumors, before surgery or irradiation.

The effects of combined radiation therapy–chemotherapy can be independent, additive, or interactive. Chemotherapy and irradiation can be administered sequentially or concomitantly. Sequencing of treatment at the appropriate time is significantly related to the residual tumor cell burden at the point of introduction of each new treatment program.

Administration of chemotherapy before irradiation may produce cell killing and reduce the number of cells to be eliminated by the irradiation. Use of chemotherapy concurrently with radiation therapy has a strong rationale because it could interact with the local treatment (additive and even supra-additive action) and also could affect subclinical disease early in treatment. However, the combination of modalities may enhance normal tissue toxicity. When agents with added toxicity are used, lower tumor control may result because the added morbidity requires lowering the doses of the effective agents or prolonging overall irradiation treatment time. When fatal toxicity from chemotherapy occurs, it prevents some dying patients from demonstrating tumor response that could have been observed had they survived. Overall patient survival may be compromised as well.

Biologic Considerations in Combinations of Chemotherapy and Irradiation

Many experimental animal studies have shown therapeutic benefit from a combination of irradiation and drugs, but most are phenomenologic. Therapeutic benefit requires differential properties on tumor and normal tissues, which may be exploited for therapeutic gain. These include genetic instability of tumors compared with normal tissues, differences in cell proliferation (particularly cell repopulation during fractionated radiation therapy), and environmental factors such as hypoxia and acidity (which usually are confined to tumors). There are variations in sensitivity or resistance to irradiation or drugs. The mechanisms for resistance to these agents may be shared in some tumors and different in other tumors. Resistance to anticancer drugs may have implications for resistance to radiation therapy; many drug mechanisms for resistance are multifactorial, such

as in cisplatin, in which this phenomenon may be the result of decreased drug uptake, increased repair of DNA, increased expression of sulfhydryl compounds such as glutathione and metallothionein, and increased expression of glutathione-*S*-transferase. Combined treatment with radiation and drugs might result in an improved therapeutic index if mechanisms of resistance are independent.[299]

Oxygen, pH, and nutrient supply can play an important role in the combined effects of chemotherapy and irradiation on tumor cells.[300] Hypoxic cells are less radiosensitive and chemosensitive to many drugs, and chronic hypoxia can alter cell cycle age distribution and proliferation rate—both important modifiers of cellular response to ionizing radiation and drugs. In addition, chronic hypoxia can affect cellular ability to repair radiation- and drug-induced DNA damage. Bioreductive drugs such as mitomycin C are activated to toxic species and affect solid animal tumors under hypoxic conditions. DNA repair, cell cycle age distribution, and the activity and stability of some chemotherapeutic drugs may be pH dependent; thus, this factor plays a role in the sensitivity of cells to irradiation and cytotoxic agents.

Hypoxic conditions, which commonly exist in tumors, may lead to amplification of genes. Under hypoxic conditions, hypoxia-inducible factor 1 (HIF-1) occur, levels rise, and functional HIF-1 transcription factor complexes induce angiogenesis, erythrocytopoiesis, glycolysis, and glucose transport into cells—all techniques to allow the cell to survive hypoxia. HIF-1 induces the genes encoding vascular endothelial growth factor (VEGF), platelet-derived growth factor, and transforming growth factor.[258] Some cytokines such as tumor necrosis factor-α or interleukin[235] and growth factors such as platelet-derived and fibroblast growth factors are seen in malignant and normal human cells after irradiation.[301] These cytokines and growth factors enhance the cytotoxic effects of irradiation and chemotherapy in tumor cells[302] or offer radioprotection in normal cells.[303]

Possible molecular or cellular mechanisms of interaction of chemotherapy and irradiation include:

- Modification of the slope of the dose–response curves, such as has been shown with actinomycin D, cisplatin, doxorubicin, mitomycin C, 5-fluorouracil, and other agents.
- Decreased accumulation or inhibition of repair of SLD, as induced by actinomycin D, cisplatin, bleomycin, hydroxyurea, and nitrosoureas.[304–307] Doxorubicin and other DNA intercalators decrease the shoulder widths but do

not decrease the slope or suppress the repair of lethal damage in *in vitro* studies.[308]

- Inhibition of repair of PLD, as has been shown with actinomycin D, doxorubicin, and cisplatin.[107,309]
- Perturbation of cell kinetics, for example, after treatment with hydroxyurea, which kills cells in the S-phase, when cells may become partially synchronized and blocked at the G1/S-phase of the cell cycle. If irradiation is delivered during this sensitive phase, as the cells subsequently emerge from the block, an enhanced cytotoxic effect may be expected.
- Selective cytotoxicity and radiosensitization of hypoxic cells, which have been reported with mitomycin C and cisplatin.[310]
- Inhibition of cell repopulation.
- Decrease in tumor bulk leading to improved blood supply, reoxygenation, and cell cycle recruitment, resulting in increased radiosensitivity and chemosensitivity.

A possible danger in the administration of cytotoxic drugs before radiation therapy is accelerated cell proliferation or repopulation. Because some tumor regression is induced by the cytotoxic agent (drugs or irradiation), the distance between the tumor cells, and decreases in adjacent functional capillaries, this may induce tumor cell proliferation so that higher doses of irradiation would be required to produce a given tumor control. This may occur because, during radiation therapy, tumor cells surviving neoadjuvant chemotherapy may be stimulated to repopulate at a faster rate. Because of this effect, the initial advantage in cell killing by drugs is lost, and the survival curves for fractionated radiation therapy may come together or even cross over. Although this mechanism is hypothetical, it suggests caution in the use of induction chemotherapy and explains why an initial tumor response may not necessarily translate to a therapeutic advantage with combined modality treatment given in this fashion. For example, three courses of induction chemotherapy might reduce tumor cell numbers from 10^{10} to 10^{8} (from 10 g to about 0.1 g), which is considered a complete clinical tumor regression. Even a pathologic complete response has limited long-term implications; a complete pathologic regression is consistent with the presence of about 10^{6} tumor cells per gram, a substantial biologic cell burden (Fig. 1.34).

Integrated Multimodality Cancer Management and Organ Preservation

Combinations of two or all three of the classic modalities frequently are used to improve tumor control and patient survival. Steel and Peckham[311] postulated the biologic basis of cancer therapy as spatial cooperation, in which an agent is active against tumor cells spatially missed by another agent, addition of antitumor effects by two or more agents, and nonoverlapping toxicity and protection of normal tissues. Large primary tumors or metastatic lymph nodes must be removed surgically or treated with definitive radiation therapy. Regional microextensions are eliminated effectively by irradiation without the anatomic and at times physiologic deficit produced by equivalent medical surgery. Chemotherapy is applied mainly to control disseminated subclinical disease, although it also has an effect on some larger tumors.

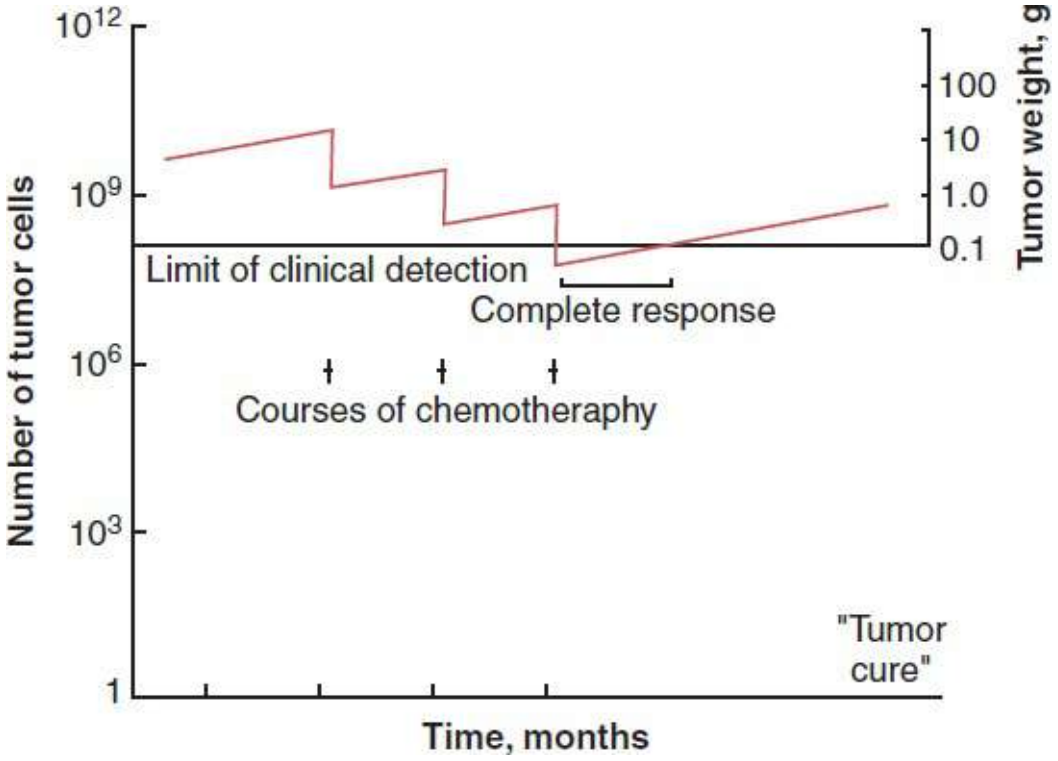

FIGURE 1.34. Relationship between clinical remission and cure. A 10-g tumor containing 10^{10} cells is treated with three courses of chemotherapy, each of which kills 90% of the tumor cells present. After three courses, the number of viable tumor cells is $<10^{8}$ (<0.1 g) and the patient is judged to be in clinical and radiologic complete remission. Note that this is a small step toward tumor cure. Moreover, additional chemotherapy may not be helpful if drug-resistant cells have been selected after three courses of chemotherapy. (Reprinted from Tannock IF. Combined modality treatment with radiotherapy and chemotherapy. *Radiother Oncol* 1989;16[2]:83–101. Copyright © 1989 Elsevier Ireland Ltd. With permission.)

Organ preservation is being vigorously promoted because it enhances the

quality of life and psychoemotional feelings of patients with excellent tumor control and survival. In some types and stages of head and neck tumors, breast cancer, gastrointestinal malignancies, genitourinary tumors, soft tissue sarcomas, and pediatric tumors, studies have shown that less radical surgical procedures combined with chemotherapy and radiation therapy yield the same local tumor control at the primary site and survival as did radical procedures. Advances in reconstructive surgery have greatly improved our ability to repair defects of radical surgery.

CANCER PREVENTION

Cancer is a largely preventable disease. Epidemiologic studies have identified the causative agents for a significant proportion of adult cancers. Approximately 30% to 35% of cases of cancer in the United States are associated with tobacco use.[402] Another 30% to 35% of cases are associated with excessive dietary fat and obesity. Approximately 5% of cancer is related to alcohol use. Another 5% is associated with exposure to viral agents.[312] Among the other causative factors of cancer, each responsible for a small percentage of malignancies, are occupational exposures, a family history of cancer, environmental pollution, ionizing and ultraviolet irradiation, prescription drugs, and medical procedures (Table 1.6, Figs. 1.33–1.36).[280]

There are two general approaches to cancer prevention. They are referred to as *primary prevention strategies* and *secondary prevention strategies.* A primary preventive strategy may be invoked when there is an explicit and indisputable behavior that should be avoided or adopted because of its association with a predictable and certain reduction in cancer risk for an individual. A secondary prevention is distinguished from primary prevention in that it is an intervention focused on altering the natural history of a disease and thus avoiding disease-related adverse outcomes.[72] The most commonly used secondary prevention strategy is broad-based or targeted population screening.

The principal primary prevention strategies are directed against cancers that have been associated with certain behaviors. They begin with avoidance of tobacco. Tobacco is the single largest preventable cause of death in the Western world today. Tobacco use, either in the form of cigarette, pipe, or cigar smoking or the use of snuff or chewing tobacco, is strongly associated with carcinoma of the lung, larynx, pharynx, oral cavity, and esophagus. Tobacco also appears to be an important contributing factor in cancer of the pancreas, bladder, kidney,

stomach, colon, and uterine cervix. In addition to its role in the etiology of cancer, tobacco also is associated with coronary heart disease, chronic lung disease, stroke, and other maladies.[388]

In recent years, we have come to understand the role of excessive fat consumption and obesity in the etiology of cancer.[387] Studies suggest a direct correlation between average dietary fat intake in various countries and the incidence of breast cancer. Classic studies have shown that the incidence of stomach cancer among the Japanese decreases when Japanese individuals migrate to Hawaii. Second-generation Japanese residents of Hawaii have an incidence of stomach cancer equivalent to that of the White population.[313] Clearly, a more healthy diet could reduce the incidence of cancer.[297]

Excessive alcohol consumption also is associated with cancer. Alcohol consumption is particularly harmful among cigarette smokers. It appears that smoking acts as an initiator, producing injurious mutations, and alcohol acts as a promoter in cancer of the oral cavity, oropharynx, pharynx, larynx, and esophagus.

A variety of occupational exposures also are associated with specific cancers. These include cancer in asbestos miners and workers, various forms of cancer in workers in the chemical industry, cancers associated with pesticide exposure in agricultural workers, and radiation-associated cancers in uranium miners. An obvious preventive strategy is to minimize or eliminate such harmful exposures in the workplace.

In recent years, scientists have become increasingly aware of various genetic syndromes associated with the etiology of cancer. These include the multiple endocrine neoplasia syndromes and their association with medullary cancer of the thyroid, susceptibility genes that increase the risk of colon cancer, and the association of the BRCA1 and BRCA2 genes with carcinoma of the breast and ovary. For some of these genetic susceptibility traits, the best that the physician can offer is close follow-up. There are certain situations where the avoidance of a potentially lethal cancer may lead an individual to consider prophylactic surgery.

An exciting development in cancer prevention is the development of a vaccine capable of reducing, by about 70%, the incidence of human papillomavirus (HPV)-associated cervical cancer. The U.S. FDA approved this vaccine for clinical use in summer 2006. This vaccine, along with the use of routine Pap testing, has the potential to make invasive cervical cancer an exceedingly rare event.

Cancer screening is the most frequently considered secondary preventive strategy. A cancer screening procedure should lead to the early detection of an asymptomatic or unrecognized disease by the application of simple, inexpensive tests or examinations in a targeted population. For cancer screening to be appropriate and successful, several criteria should be met. These include the following:

- The cancer for which one is screening should have a substantial morbidity and/or mortality rate that warrants the screening procedure.
- The cancer for which one is screening should have a sufficiently high prevalence in a detectable, preclinical state to warrant screening.
- Once the cancer is detected by a screening procedure, there should be an effective treatment related to early detection. This criterion is quite important because there is little value in screening for an untreatable malignancy.
- The screening test should have a high sensitivity and specificity.
- The screening test should be of low cost such that the expense of screening a large population would be more than offset by the reduced cost to society of treating early rather than advanced malignancy.
- Individuals screened should suffer little inconvenience and discomfort.

There is no perfect screening test. Those tests currently used generally meet most, but not all, of the aforementioned criteria.[314,315]

There are several examples of currently used screening tests. For breast cancer, these include self-examination, examination by a trained health practitioner, and mammography, augmented, when appropriate, by ultrasound and MRI. The value of these tests in various populations of women is currently highly disputed. In screening for colorectal cancer, the tools available to the clinician include testing for fecal occult blood, sigmoidoscopy, colonoscopy, and barium enema studies and the developing field of virtual colonoscopy. There is a general consensus that screening for fecal occult blood and, in the appropriate aged population, screening colonoscopy are worthwhile. Among the most controversial areas for cancer screening is the role of screening in the detection of early prostate cancer. There was rapid general acceptance of the use of physical examination and prostate-specific antigen (PSA) testing to ascertain the presence of early prostate cancer. On further consideration, however, many investigators fear that we have, as a society, successfully identified large numbers of men who would never have been diagnosed with symptomatic prostate cancer in their remaining lifetime or required treatment. The appropriate role of screening for prostate cancer has generated as much controversy as the

debate over mammography in breast cancer. A considerable amount of anxiety has been generated in asymptomatic men compulsively watching their PSA levels. The US oncology community has engaged in a very public debate over the recommendation of the U.S. Preventive Services Task Force ("USPSTF") to rescind a recommendation in favor of the widespread use of PSA for screening. The task force report in 2012 advised that healthy men should no longer receive the PSA blood test to screen for prostate cancer because the test does not save lives overall and often leads to more tests and treatments that needlessly cause pain, impotence, and incontinence in many.

The draft recommendation was based on the results of five clinical trials and had the potential to substantially change the care given to men aged 50 years and older. There are 44 million such men in the United States, and 33 million of them have already had a PSA test—sometimes without their knowledge—during routine physicals. As further evidence became available, the USPSTF revised its recommendations and, in 2018, recommended that men between 55 and 69 years discuss with the doctor the risks and benefits of PSA screening and make a decision based on personal values and risk factors. The USPTF does not recommend screening for men ≥70 years of age.[316]

It is likely that, in the future, efforts will be expended to identify that subset of men with biologic markers suggesting that they might benefit from PSA screening and, if diagnosed, treatment compared to those who are "best left alone."

Far less controversial, however, has been the use of the Pap test for early detection of carcinoma of the cervix. Where properly used, the test appears to have resulted in a decrease of mortality from this malignancy.

Cancer chemoprevention is defined as a pharmacologic intervention with specific nutrients or other chemicals intended to suppress or reverse carcinogenesis and to prevent the development of invasive cancer. Trials involving chemopreventive therapy require large numbers of individuals who are at high risk for malignancy because of family history, carcinogenic exposure, or the presence of a mutated gene. The ideal chemopreventive agent would have minimal side effects because it would be given to a considerable number of people, none of whom have cancer. Chemoprevention trials differ from other types of cancer prevention studies and from therapeutic studies in important ways. The participants are healthy volunteers, and one seeks to measure a reduction in morbidity and mortality in the long run. Chemoprevention trials are, by definition, large. There are strict enrollment criteria that reflect the group of

interest. These studies are often long term and expensive. To date, the best-studied agents in human preventive trials are retinoids (the natural derivatives and synthetic analogs of vitamin A) and one member of the carotenoid class, *β*-carotene. A number of randomized cancer prevention trials involving carotenoids and retinoids have been completed. Some of these trials have reported chemopreventive effects for various retinoids and for *β*-carotene, particularly in oral premalignancy. Other trials have been negative or even have suggested cancer promotional effects by *β*-carotene.[317]

CLINICAL TRIALS

These studies have been classified as phase I (toxicity), phase II (dose/efficacy), and phase III (efficacy and toxicity of a new drug compared with an established standard). Randomized phase III clinical trials and meta-analyses are the two most accepted sources of scientific information in evidence-based medicine. These randomized clinical studies, with sometimes complicated treatment schemas, large numbers of patients, defined endpoints, and rigorous statistical testing, which are increasingly required by the U.S. FDA to document the efficacy and safety of new drugs (and, I believe should add, should be required for medical devices), are logistically difficult and expensive to conduct. Cooperative clinical trial groups have been a major contributor, along with the participating institutions, investigators, and associated staff, to clinical investigation centered on the application of ionizing radiations, alone or combined with surgery or cytotoxic agents, hormones, and so forth, to improve the management of patients with cancer.

It is the responsibility of practicing radiation oncologists in academic and community centers to be active contributors, with both scientific input and encouragement of their patients to participate in many of these trials.

RADIATION-INDUCED SECOND PRIMARY MALIGNANT TUMORS

Patients cured of cancer have a significant probability of developing other cancers. Many publications document the frequency of second malignant neoplasms, associated with radiation therapy, in cancer survivors.[160] Several principles characterize radiation-induced cancers:

. A wide variety of histologic types of cancers can be induced by radiation

therapy. The current state of knowledge does not allow us to distinguish these tumors, morphologically, from “naturally” occurring cancers. In the future, it may be possible to identify specific genetic changes associated with radiation-induced malignancy. This future technology, termed *molecular forensics*, may, ultimately, affect our understanding of attributable risk of radiation-induced malignancies.[318,319]

- The dose incidence curve for carcinogenesis generally rises more steeply with high-LET radiation doses than with low-LET doses, especially at low dose rates (Fig. 1.37).[96] In a liver cancer model in mice, neutron irradiation produces a greater incidence of hepatomas than gamma irradiation.[320] Low-LET radiation becomes less effective at carcinogenesis per cGy as the dose falls. High-LET radiation, however, does not.[321]
- When one compares the frequency of second malignant neoplasms over time, it appears that orthovoltage radiation therapy is more likely to be carcinogenic than megavoltage therapy. This may be a dose-related phenomenon insofar as orthovoltage irradiation gives a higher dose to bone. It is also possible that the longer-term follow-up available for survivors of orthovoltage irradiation may, somewhat artifactually, lead to a higher reported incidence of tumors.[317,322,323]
- The sensitivity of tissues to radiation-induced malignancies is not uniform. Current evidence indicates that the thyroid gland and the breast are sensitive to cancer induction at relatively low doses of radiation; lymphoid tissue, lung, and liver require moderate doses; and bone requires the highest dose. It also seems likely that the relationship between dose and response may vary according to the type of induced tumor. One can estimate the cancer risk from radiation either per unit dose measured in Gy or per unit dose equivalent measured in sievert. When one measures in sieverts, a quality factor (Q) is used to take account of the varying biologic effectiveness of the different forms of radiation. For example, for a conventional γ-ray or x-ray, $Q = 1$. For neutron irradiation, $Q = 20$. A review of the available literature indicates that the lifetime cancer mortality risk for a working population of both sexes is 0.008 per Sv for high doses and 0.004 per Sv for low doses.[324] The cancer mortality risk for the general population after whole-body exposure is 0.0001 to 0.0004 per cGy per person.
- One of the most puzzling aspects of radiation-induced cancer concerns the issue of the relation of low radiation dose to carcinogenesis. Most of the data we have concern relatively high doses. Much of the public debate, however, concerns exposure to relatively low doses. Because we have few exact data regarding low doses, extrapolation is, for the most part, used to predict risk at low doses. This can be a particularly vexing problem in litigation where a

plaintiff sues for an alleged radiation-induced malignancy following relatively low-dose exposure to radiation.

- Any assessment of the radiation dose–response curve for the production of second malignant neoplasms has to take into account the fact that neoplasms also can be induced by agents other than radiation. These include chemotherapy, environmental exposures, and hereditary disposition.
- Because the risk of radiation-induced carcinogenesis is very small, a large denominator of irradiated patients followed for a long period with thorough follow-up would be necessary to calculate risk with any reliability.
- Latent periods for the production of radiation-induced tumor vary according to the type of induced tumor. One type of latency is exemplified by the risk of leukemia in survivors of the atomic bomb. This consisted of an early pulse of increased risk followed by a gradual decline to baseline levels. The second pattern of occurrence, more typical of solid tumors, is an increase in the relative risk of second malignant neoplasms over many years that remains constant over time thereafter. It is important to remember, therefore, that the duration of follow-up for any study population is very likely to influence the frequency of tumors seen.
- Age is a critical factor in determining radiation risk. In children, second cancers would be more likely to occur in tissues undergoing rapid proliferation such as the bone and thyroid tissue.

There are several classically cited episodes of human radiation carcinogenesis. These include:

- Individuals who are treated with radiation for ankylosing spondylitis suffered from an increase in leukemia. Mortality from colon cancer, which is associated with spondylitis through a common association with ulcerative colitis, was increased in irradiated patients. Mortality for patients with cancers other than leukemia or colon cancer also rose.[325]
- Diagnostic x-rays of the abdomen and pelvis taken of a pregnant woman to ascertain the size of the pelvic outlet before delivery are associated with an increased risk of malignancy in the offspring.
- A large number of immigrants entered the State of Israel following its founding in 1948. X-ray epilation was used to treat tinea capitis. There was an increased incidence of brain and nervous system tumors (1.8 excess risk per 10,000 persons per year) in 10,834 children irradiated for tinea capitis compared with the same number of nonirradiated matched controls and 5,392 siblings. There were 12 malignant brain tumors in the irradiated patients versus five and one suspected in nonirradiated people. The average dose

received was 4 Gy in 5 consecutive days. Irradiation doses of 1 to 2 Gy significantly increased the risk of neurologic tumors.[12]

- The United States dropped atomic bombs on Hiroshima and Nagasaki in Japan in August 1945. Radiation-related risks among bomb survivors show that the incidence of leukemia rose. The increased risk appeared 1 to 3 years after the bombing and peaked at 6 to 7 years. In solid tumors, excess tumor risk was manifest only after exposed individuals reached the age at which the cancer was normally prone to develop.
- Uranium miners suffered an increase of lung cancer as a result of inhalation of radon gas. Workers who painted luminous radium dials on watch faces developed bone sarcomas because of the habit of shaping the paintbrush in the mouth and ingesting bone-seeking radium.[326]
- In the past, thorotrast was used as a contrast medium in diagnostic radiology. This material is a colloidal suspension of the α-emitter thorium dioxide. The compound was associated with the late development of angiosarcoma.
- Canadian studies of women with tuberculosis who were fluoroscoped repeatedly for monitoring of an induced pneumothorax demonstrated an increased incidence of breast cancer.
- The Chernobyl Nuclear Power Plant accident of April 26, 1986, is associated with an increased risk of thyroid cancer in Belarus and Ukraine.

An important review of radiation-induced sarcomas was published by Cahan et al.[327] in 1948. Cahan's criteria, which were used to define a radiation-induced sarcoma, have wide applicability and are used, by some investigators, as the standard for demonstration of any alleged radiation-induced malignancy. The Cahan criteria,[327] modified from his original definition, are:

a. A radiation-induced malignancy must have arisen in an irradiated field.
b. A sufficient latent period, preferably longer than 4 years, must have elapsed between the initial irradiation and the alleged induced malignancy.
c. The treated tumor must have been biopsied. The alleged induced tumor must have been biopsied. The two tumors must be of different histologies.
d. The tissue in which the alleged induced tumor arose must have been normal (i.e., metabolically and genetically normal) prior to radiation exposure.

QUALITY AND SAFETY

Quality and safety are important topics in radiotherapy. The issue of patient safety for radiation therapy and diagnostic imaging has been pulled to the

forefront by press reports and associated congressional hearings. A number of misadministrations described in a series of *New York Times* articles triggered increased interest in improved patient safety in radiation oncology.[255,328] These articles have highlighted some of the risks inherent to advanced radiation therapy treatment planning and delivery systems and techniques. Many new patient safety initiatives, meetings, and other efforts have been organized to address the need to continue to enhance the safety of patients undergoing radiation therapy.

Safety and quality are different but related concepts. Safety generally relates to preventing errors that can have major therapeutic implications (e.g., treatment of the wrong patient, treatment with the wrong plan, incorrect placement of a block or wedge, failure to correctly transfer electronic data between the various computer systems). In contrast, quality often relates more to somewhat subjective issues such as ensuring that the defined volumes, doses, beams, and so forth are clinically appropriate and that the treatment is delivered as prescribed within acceptable clinical tolerance limits. To reconcile these concepts, in 2011, ASTRO sponsored the Intersociety Council to review and update previously published guidelines concerning the role of radiation oncology in integrated cancer management. In this updated document, entitled “Safety Is No Accident,” every facet of patient evaluation, treatment planning, and treatment delivery was described with the specific goal of maximizing patient safety.[329] The process of care, the roles and responsibilities of staff, staff training and maintenance of competency, requirements for facilities and equipment, and the management of quality assurance (QA) were formally recognized as inextricably linked to the provision of safe, efficient, and effective radiation therapy. These ASTRO initiatives have involved cooperation with other organizations, including the American Association of Physicists in Medicine (AAPM), the American Brachytherapy Society, the American College of Radiology (ACR), the American College of Radiation Oncology, the American Board of Radiology, the American Society of Radiation Technologists, and the Society of Radiation Oncology Administrators.

Modern radiation therapy is complex and rapidly evolving. The safe delivery of radiation therapy requires the concerted and coordinated efforts of many individuals with varied responsibilities. Thus, all team members need to work together to create a *safe*, *high-quality*, and *efficient* clinical environment and workflow.

THE PROCESS OF CARE IN RADIATION ONCOLOGY

The "process of care" in radiation oncology refers to a conceptual framework for ensuring the appropriateness, quality, and safety of all patients treated with radiation for therapy. Each of the aspects of the process of care in radiation oncology requires knowledge and training in the natural history of cancer and certain benign diseases, radiobiology, medical physics, and radiation safety that can only be achieved by board certification in radiation oncology (or equivalent training) to synthesize and integrate the necessary knowledge base to safely and completely deliver care. This high level of training and board certification apply as a recommendation for all of the specialists on the radiation oncology team. The medical therapeutic application of ionizing radiation is irreversible, may cause significant morbidity, and is potentially lethal. Use of ionizing radiation in medical treatment, therefore, requires direct or personal physician management, as the leader of the clinical team, as well as input from various other essential coworkers.

The radiation oncology process of care can be separated into five categories:

- Patient evaluation
- Preparing for treatment
- Therapeutic simulation
- Treatment planning
- Pretreatment QA and plan verification
- Radiation treatment delivery
- Radiation treatment management
- Follow-up care management

A course of radiation therapy is composed of a series of distinct activities of varying complexity and is a function of the individual patient situation. All components of care involve intense cognitive medical evaluation, interpretation, management, and decision-making by the radiation oncologist and other members of the clinical team. Each time a procedure is approved and reported, its level of effort/complexity should be appropriately documented in the patient record.

The clinical team, led by the radiation oncologist, provides the medical services associated with the process of care. Other team members involved in the patient's planning and treatment regimen include the medical physicist, dosimetrist, radiation therapist, and nursing staff. Many of the procedures within each phase of care will be carried to completion before the patient's care is taken

to the next phase. Others will occur and recur during the course of treatment, and they are by necessity repeated during treatment because of patient tolerance, changes in tumor size, need for boost fields or port size changes, or protection of normal tissue, or as required by other clinical circumstances (i.e., certain procedures may need to occur multiple times during the treatment course). Each phase of care involves medical evaluation, interpretation, management, and decision-making by the radiation oncologist as well as other team members.

Patient Evaluation

Patient evaluation is a service provided by a physician at the request of another physician, the patient, or an appropriate source to either recommend care for a specific condition or problem or to determine whether to accept responsibility for ongoing management of the patient's entire care or for the care of a specific condition or problem. The physician as part of this process will review the pertinent radiologic and pathologic studies, the patient's complaints, and physical findings. This initial visit can also be used for patient counseling, coordinating care, and making recommendations about other aspects of oncologic management or staging.

Preparing for Treatment

The selection of a comfortable and appropriate patient position for treatment is an important part of the simulation processes. The selected position should consider the location of the target and anticipated orientation of the treatment beams. Appropriate immobilization devices provide comfort, support, and reproducibility. Immobilization of the patient in a comfortable position for treatment might involve the construction or selection of certain treatment devices for helping the patient remain in position during treatment. This step must consider the potential treatment planning considerations so that the treatment aids do not restrict the treatment techniques.

Simulation is the process of determining critical information about the patient's geometry, to permit safe and reproducible treatments on a megavoltage machine. Simulation for external beam radiation treatment is always image based. Simulation procedures have shifted away from the direct use of the treatment beam to using diagnostic x-rays, CT, or MRI. In general, this part of the overall process of care determines the relationship between the position of the target or targets and the surrounding critical structures. When a simulator of conventional design is used that mimics the geometry of the treatment unit or

when direct simulation is performed on the treatment machine, this relationship is often determined indirectly through observation of skeletal anatomy that can act as a surrogate for the target position. Conventional simulators, like the CT simulator, can include the ability to produce volumetric data in addition to 2D images.

The preparation for external beam treatment can also depend on other imaging modalities that are directly or indirectly introduced in the simulation process. MRI, ultrasound, and/or PET is now available, and treatment planning systems that include image registration capabilities allow combining of information from other imaging modalities with the standard CT dataset obtained during simulation in appropriate situations. It is now possible to produce image datasets that quantify the motion of structures and targets because of respiration, cardiac motion, and physiologic changes in the body.

For most brachytherapy, treatment preparation is similar to the procedure described earlier for EBRT. The simulation process is also image based. Multiple imaging modalities may be important for some brachytherapy procedures, and these studies can be obtained as part of the preplanning imaging process. For clinical situations where therapy is delivered by unencapsulated radionuclides, a separate and distinct treatment planning process is necessary because of its multidisciplinary execution.[330]

Clinical treatment planning is a comprehensive, cognitive team effort performed under the direction of the radiation oncologist for each patient undergoing radiation treatment. The radiation oncologist is responsible for understanding the natural history of the patient’s disease, knowing the extent of the disease relative to the adjacent normal anatomic structure, and integrating the patient’s overall medical condition and associated comorbidities. A detailed understanding of the integration of chemotherapeutic and surgical treatment modalities with radiation therapy is also essential.

The skills of the trained and appropriately credentialed dosimetrist relate to the efficient and effective use of the complex treatment planning system hardware and software. This individual must also understand the clinical aspects of radiation oncology in order to interact with the radiation oncologist during the planning process. The role of the medical physicist is to guarantee proper functioning of the hardware and software used for the planning process, consult with the radiation oncologist and dosimetrist, check the accuracy of the selected treatment plan, and perform measurements and other checks aimed at ensuring accurate delivery of the plan.

For either EBRT or brachytherapy, treatment planning starts with a complete, formally documented, and approved directive. Details including total dose to all targets and OARs, fractionation, treatment modality, energy, time constraints, normal tissue constraints, and all other aspects of the radiation prescription in a written or electronic format must be provided by the radiation oncologist prior to the start of treatment planning. In some cases, this prescription can require modification based on the results of the treatment planning process.

Clinical treatment planning for either EBRT or brachytherapy is an important step in preparing for radiation oncology treatment. This planning includes the following components: determining the disease-bearing areas based on the imaging studies and pathology information, identifying the type (brachytherapy, photon beam, electric particle beam, other) and method of radiation treatment delivery, specifying areas to be treated, and specifying the dose and dose fractionation. In developing the clinical treatment plan, the radiation oncologist may use information obtained from the patient's clinical evaluation as well as any additional tests, studies, and procedures that are necessary to complete treatment planning. Studies ordered as part of clinical treatment planning may or may not be associated with studies necessary for staging the cancer and may be needed to obtain specific information to accomplish the clinical treatment plan. Review of imaging studies and laboratory tests must be performed to determine treatment volume and critical structures in close proximity to the treatment area.

At various steps in the treatment planning process, the radiation oncologist is presented with one or more treatment plans for review and selection. This process is often iterative and requires additional treatment planning. The radiation oncologist is responsible for selecting and formally approving the plan to be used for treatment.

The QA steps taken after completion of treatment planning and before the start of treatment are critical for guaranteeing patient safety. In the past, treatment verification consisted of field aperture imaging using radiographic film. These images are referred to as portal images or port films. With the introduction of IMRT, imaging of individual apertures is no longer practical. However, the traditional method of verifying the plan isocenter position using orthogonal imaging is often used for both 3DCRT and IMRT. For IMRT, this important QA technique is not considered to be sufficient to guarantee patient safety. In addition to this isocenter check procedure, for IMRT and other complex delivery techniques that use inverse treatment planning, patient-specific QA measurements are also required. In terms of clearly organizing the different

steps in the process of care for radiation oncology, a blurring of the separation between the verification and treatment delivery occurs on the first day of treatment and whenever the treatment plan is changed.

Radiation Treatment Delivery

The physician is responsible for verification and documentation of the accuracy of treatment delivery as related to the initial treatment planning and set-up procedure. Image guidance (IGRT) may be performed to ensure accurate targeting of precise radiation beams. IGRT requires a target that is expected to move from day to day and can be reliably identified by the selected imaging modality. The physician is responsible for the supervision and review of these images and prescribing necessary positional shifts to ensure the therapy delivered conforms to the originally planned dosimetric constraints. Similarly, management of organ motion during treatment delivery is the responsibility of the treating physician.

Radiation Treatment Management

Radiation treatment management encompasses the radiation oncologist's overall management of the course of treatment and care for the patient as well as checks and approvals provided by other members of the radiation therapy team that are necessary at various points in the process. For the radiation oncologist, radiation treatment management requires and includes a minimum of one examination per week of the patient for medical evaluation and management. The professional services furnished during treatment management typically include:

- Review of portal images in a format appropriate to the technique of radiotherapy delivery
- Review of dosimetry, dose delivery, and treatment parameters
- Review of patient treatment setup
- Patient evaluation visit

Not all of these elements of treatment management are required for all patients for each week of management (except for the patient evaluation visit) because the clinical course of care may differ due to variation in treatment modality and individual patient requirements. Examinations and evaluations may be required more often than once weekly.

Follow-Up Care

Continued follow-up care of patients who have completed radiation therapy is

necessary to manage acute and chronic morbidity resulting from treatment as well as to monitor the patient for tumor recurrence.

THE RADIATION ONCOLOGY TEAM

The radiation oncology team ensures every patient undergoing radiation treatment receives the appropriate level of medical, emotional, and psychological care before, during, and after treatment, through a collaborative multidisciplinary approach.

The radiation oncology team consists of but is not limited to radiation oncologists, physicists, dosimetrists, oncology nurses, and radiation therapists. The process of care in radiation oncology involves close collaboration of a team of qualified professionals. On-site or by consultation services can be provided by nonphysician providers, including nurse practitioners, clinical nurse specialists, advanced practice nurses and physician assistants, dentists, clinical social workers, psychologists/psychiatrists, nutritionists, speech pathologists, physical therapists, occupational therapists, genetic counselors, integrative medicine specialists, and pastoral care providers.

Board certification is the primary consideration for establishing proper qualifications and training for any professional working in radiation oncology. The relevant professional societies will establish the eligibility requirements to sit for a board exam. This may include education and training requirements such as a clinical residency. In addition, in some jurisdictions, professionals must meet additional requirements for obtaining appropriate licensure.

The applications, technologies, and methods of radiation oncology continue to expand and develop. Lifelong learning is vital to ensure incorporation of new knowledge into clinical practice. Therefore, each member of the interdisciplinary radiation oncology team should participate in available Continuing Education (CE) and Maintenance of Certification (MOC) programs. Each facility should have a policy regarding orientation, competency, credentialing, and periodic competency evaluations of all team members.

Staffing Requirements

Starting in 1986, the Intersociety Council for Radiation Oncology published a set of guidelines in a small pamphlet titled “Radiation Oncology in Integrated Cancer Management,” often referred to as the “Blue Book.”[331] This subsequently has been updated several times sought to improve it.[332] The

document offers guidelines for staffing requirements and equipment utilization. The staffing needs of each facility are unique based on the patient mix and complexity of the services offered. The patient load, number of machines, and satellite clinics and affiliated treatment centers will influence the demand on management and clinical staff (Figs. 1.35 and 1.36). The minimum personnel requirements for a radiation oncology facility specify the need for one medical director (radiation oncologist), chief medical physicist, and department manager per program.[329]

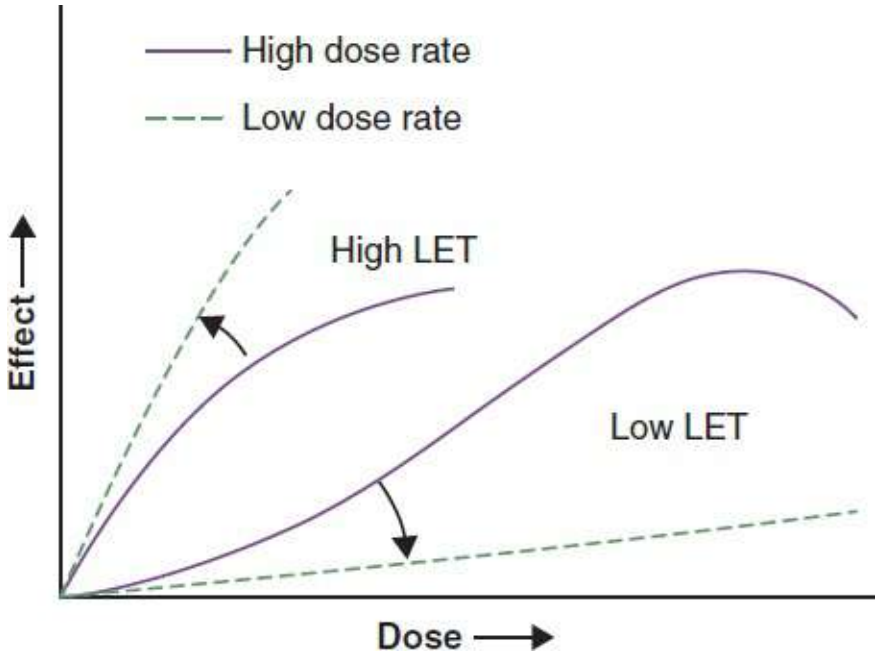

FIGURE 1.35. Dose–response curves for incidence of tumors in relation to dose and dose rate of high–linear energy transfer (LET) and low-LET irradiation. (From Upton AC. Biological aspects of radiation carcinogenesis. In: Boice JD, Fraumeni JF, eds. *Radiation carcinogenesis: epidemiology and biological significance*. New York: Raven Press, 1984:9. With permission.)

MANAGEMENT AND QUALITY ASSURANCE IN RADIATION ONCOLOGY

Quality assurance in radiation oncology is a set of processes and procedures designed to improve the practice of radiation therapy by confirming that radiation therapy will be or was administered appropriately and safely and documented properly. The overall goal of a QA process is the delivery of high-quality radiation oncology treatment to all patients.[272] Note that QA is an all-encompassing term that is often used to describe some or all of the different

elements involved in quality management (QM) and a culture of safety. Cost and value are important in determining the quality of care.[268] To prove that technology adds value to patients, patients' reported outcome should be included.

A radiation oncology facility must satisfy numerous requirements[329]:

- A department must provide adequate clinic space, exam rooms and equipment, patient waiting and changing space, convenient patient parking, treatment rooms, simulation and imaging space, brachytherapy source preparation and storage space, dosimetry/treatment planning rooms, office space for professional staff, and medical physics laboratory and equipment storage space. The extent of facilities should be appropriate for the volume of patients seen and treated (Fig. 1.36).
- Treatment rooms must be carefully designed for radiation shielding, environmental conditions, adequate storage space for spare parts, testing and dosimetry equipment, and patient access and safety (Tables 1.8 and 1.9).
- There must be access to CT, MRI, and PET imaging for treatment planning.
- Rooms used for brachytherapy procedures require special attention to the specific radiation protection requirements associated with the particular brachytherapy modalities to be used. If the brachytherapy procedure load warrants it, a brachytherapy suite should be available, including patient waiting space, procedure rooms, recovery rooms, and brachytherapy source preparation and storage areas.
- Each department must have electronic access to the hospital or clinic information system for medical records and picture archiving and communication.

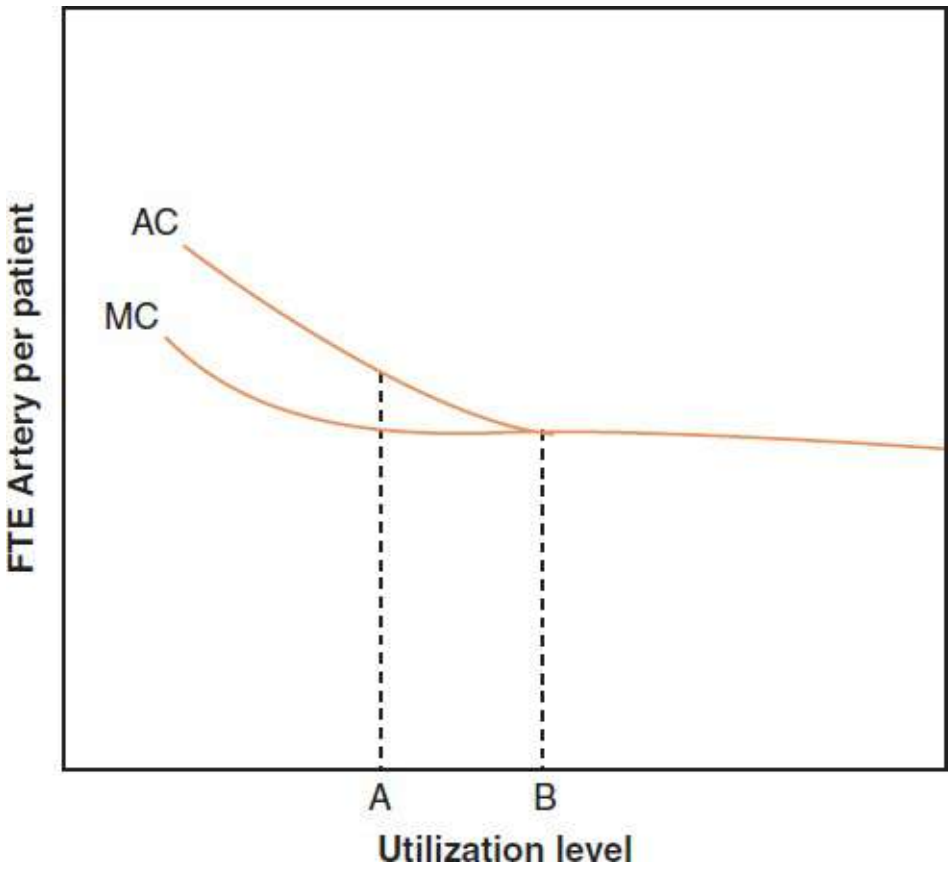

FIGURE 1.36. The theoretical relation between the cost per patient and rate of use of a linear accelerator for cancer therapy. As the rate of use of a linear accelerator increases, the average cost (AC) of treatment per patient declines until all economies of scale have been achieved (*point B*). The average cost of a radiotherapy treatment will fall as long as any additional patients can be treated at a marginal cost (MC) lower than the AC. It is important to remember that point B represents only the minimized cost of operating the linear accelerator. If you add in costs such as the travel time for a patient to go a considerable distance to reach the linear accelerator, the lost time from work for the patient and anyone traveling with him or her, child care costs, and stress, then the total societal expenditure for a linear accelerator will not be minimized at point B. It will, instead, be reached at point A. We are, however, quite poor at accounting for costs such as travel, loss of work time, and stress, so it is difficult to determine point B and, in turn, the need for a new linear accelerator. If you wish to persuade a government regulatory agency to grant a certificate of need for a piece of radiotherapy equipment at a moderate distance from an existing facility, then you will have an economic incentive to inflate the importance of travel and inconvenience. In the United States, this behavior is increasing as institutions try to justify the need for linear accelerators, radiosurgery, and proton therapy units. The corporations that manufacture and market these units have a vested interest in contributing to this exaggeration of need. (Modified from Suit HD, Urie M. Proton beams in radiation therapy. *J Natl Cancer Inst* 1992;84[3]:155–164. Reproduced by permission of Oxford University Press.)

TABLE 1.8 ESTIMATED NEW CANCER CASES AND DEATHS,

UNITED STATES, 2017

	Estimated New Cases	Estimated Deaths
All sites	1,688,780	600,920
Oral cavity and pharynx	49,670	9,700
Digestive system	310,440	157,700
Respiratory system	243,170	160,420
Bones and Joints	3,260	1,550
Soft tissue (including the heart)	12,390	4,990
Skin (excluding	95,360	13,590
Breast	255,180	41,070
Genital System	279,800	59,100
Urinary system	146,650	32,190
Eye and orbit	3,130	330
Brain and other nervous system	23,800	16,700
Endocrine system	59,250	3,010
Lymphoma	80,500	21,210
Myeloma	30,280	12,590

The following specific capabilities and methods for various aspects of the radiotherapy process are considered essential[329,333]:

- Calibration of treatment machines, CT and MRI scanners, treatment planning systems, and brachytherapy sources is to be carefully accomplished according to the appropriate protocols described by scientific/professional organizations.
- A safety program designed to monitor patient safety, avoid radiation incidents, and prevent errors in the treatment process should be in place and subject to periodic review and update.
- A system for documenting radiotherapy treatment and other aspects of the patient's medical care should be rigorous and be subject to periodic review and update.
- High-quality and comprehensive treatment planning, using 3D computerized treatment planning for dose calculations, imaging, and other aspects of the planning process.
- A comprehensive QM program, including QA, quality control (QC), and other quality improvement tools.
- Radiation monitoring of simulators and treatment machines. A system to

carefully control and monitor all radioactive sources in accordance with the requirements of regulatory agencies.

- A program for maintenance and repair of equipment.
- Staff training that is comprehensive, ongoing, and well documented.
- A well-developed process for continuous peer review. This should include a mechanism for peer review of the entire department and its procedures as well as for individual clinical care decisions.
- Access to medical oncology, surgical oncology, and other physician and nonphysician specialists involved in the multidisciplinary care and follow-up of the patient.
- Each department must implement careful and well-described policies and procedures for every aspect of patient care, for QA of the patient care process, for staff behavior, and for any issues that may impact the safety of patients and/or staff. Each specific treatment modality (e.g., IMRT, IGRT, stereotactic body radiation therapy [SBRT], etc.) should have detailed documentation of its treatment planning and delivery process including a description of the roles and responsibilities of each team member in that procedure, QA checklists, and a plan for continuous quality improvement and safety.

TABLE 1.9 STAFFING LEVELS FOR RADIATION ONCOLOGIST, MEDICAL PHYSICIST, DOSIMETRIST, AND RADIATION THERAPY TECHNOLOGIST

Clinical FTE[a]	Approximate Maximum # of Patients Treated per FTE per Year
Radiation oncologist	250
Physicist	250
Dosimetrist	250
Therapist	90
Nurse	250
Treatment machine	300[b]
Therapists/treatment machine	3.5[c]

[a]It is recommended that a minimum of two qualified individuals be present for any external beam patient treatment.
[b]Each treatment machine is assumed to be operational for 9 hours a day.
[c]The number of therapists per treatment machine is the ratio of the total number of therapists and the number of treatment delivery machines, not including the simulator.
FTE, full-time equivalent.

One of the most crucial activities in a quality radiation oncology department

is the organized review and monitoring of all aspects of safety, errors, and outcome. Creating a “culture of safety” depends on guidance, direction, and financial support from the leadership of the institution and of the radiotherapy department, on individual effort by every member of the department, and on organized support for quality and safety at every level in the institution.

Each department should have a department-wide review committee that monitors specific quality metrics including near misses and errors in treatment, diagnosis, patient care, or other procedural problems that might lead to errors. This committee should organize the collection and analysis of such events, work to identify potential problems in devices or processes, and then try to mitigate these problems by modifying processes or adding new checks or actions to minimize the likelihood of further problems. Radiation oncology departments should hold regularly scheduled rounds to review patient morbidity and mortality, dose discrepancies, and any incident reports that involved an accident or injury to a patient. Morbidity and mortality include unusual or severe complications of treatment, unexpected deaths, or unplanned interruptions of treatment. Staff included should represent all the team members, including radiation oncologists, nurses, physicists, dosimetrists, therapists, and administrators.

Equipment and Device Quality Management

Radiation therapy is employed for treatment in a broad spectrum of human malignancy (Figs. 1.37 and 1.38). The delivery of radiation therapy relies on computer-controlled treatment machines, interconnected imaging, delivery and planning systems, and complex ancillary devices. Any new radiotherapy system should go through the following processes as it is prepared for clinical use:[330,334–336]

FIGURE 1.38. Ten leading cancer types for the estimated new cancer cases and deaths by sex, United States, 2017. Estimates are rounded to the nearest 10 and cases exclude basal cell and squamous cell skin cancers and *in situ* carcinoma except urinary bladder. (From Siegel RL, Miller KD, Jemal A. Cancer Statistics, 2017. *CA Cancer J Clin* 2017;67[1]:7–30. Copyright © 2017 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.)

- Each system should be carefully specified before acquisition, purchase, or development, including design, expectations, capabilities, tolerances, hazards, necessary training, usability, and technical specifications.
- To prevent data communication errors and clinical efficiency issues, each system must be interoperable and connectable with other systems in the clinic.
- Acceptance testing must be performed to document that the new system satisfies the specifications. Often, the acceptance criteria and/or testing methods should be documented as part of the specification for the system.
- Clinical commissioning includes all the activities that must be performed to understand, document, characterize, and prove that a given system is ready to be used clinically. Standard operating procedures, training, and hazard analysis should be part of the commissioning process.

- Each new system, device, and process must be formally released for clinical use after clinical commissioning has been completed.

Clinical use of a device, system, or process must involve the creation and application of a safety- and quality-oriented program designed to ensure that the machine or device is functioning in accordance with accepted standards[330,334–336]:

- Quality management (QM) is defined as the overall program to organize the oversight of the use of any system or process in radiation oncology. The QM program should include hazard analysis, QC, QA, training and documentation, and ongoing quality improvement efforts.
- Hazard analysis is the active evaluation of the potential for failures that will cause incorrect results or harm to the patient and should be performed for any new system.
- QC checks on the data that are input into a decision or process and is designed to prevent the propagation of error.
- QA is the typical shorthand term for the entire QM program and addresses quality checks that confirm that a given process is reasonable and generates appropriate results. QA checks, along with QC, are essential parts of the QM process for most devices and systems, as they can check the output of potentially very complicated decisions or actions performed by the system.
- Training of staff in goals, methods, results, operation, and evaluation of the quality of the output is important for the proper use of any system.

Patient-Related Quality Management

Within the complex and many-step process with which radiotherapy patients are treated, patient-specific issues must be carefully and comprehensively analyzed, documented, and verified. Each radiation oncology facility, regardless of its location or size, must appropriately manage and adhere to high-quality standards of practice for general medical issues,[337] including:

- Drug allergies
- Medication reconciliation
- Do-not-resuscitate codes
- Cleanliness and efforts to reduce infection
- Patient confidentiality and security of protected health information

Modern oncology patient care very often involves multiple modalities and requires the review and discussion of experts in various oncology-related

disciplines. It is critical that the management of most cancer be addressed by the appropriate mix of disciplines. Regular presentation of these cases to a multidisciplinary tumor board is the standard of care and should be performed for most cancer cases to determine the appropriate combination (and coordination) of therapies for each individual case.

The details of the patient care process in radiation oncology vary from institution to institution. However, maintenance of the safety and quality of the radiotherapy process for most patients requires that a number of procedures be performed.[329] These include:

- A new patient conference that consists of a brief presentation of the details of each patient's history and physical examination, disease status, and plan for therapy to the other physicians and staff involved in patient care is used as an initial peer review for the basic treatment decisions and plan.
- The physician must obtain a clear, accurate, and detailed description of the patient's chief complaint and pertinent history in conjunction with an appropriate physical examination as part of the decision process for radiation therapy.
- Many patients who receive radiation therapy should receive a CT, PET/CT, or MRI-based simulation.
- After the physician defines target volumes and other normal tissues (contouring), this should be peer reviewed and confirmed before treatment planning begins.
- After treatment planning is complete, the physician and members of the planning team should review the plan and verify that it satisfies the clinical requirements and prescription(s) from the physician and that it can be carried out accurately.
- On-treatment visits of the patient by the physician are essential for continuity of care and monitoring of tumor response and normal tissue toxicity. Typically, this occurs every five fractions, but some situations may require more frequent visits.
- Patient chart rounds are an important peer review procedure used involving weekly review of all patients under treatment by the radiotherapy team, including physicians, therapists, nurses, dosimetrists, and physicists.
- Follow-up visits are a critical component of care for the radiotherapy patient. The frequency of follow-up visits will vary in accordance with the type of cancer, stage, degree of tumor response, normal tissue reactions, and other factors.
- Documentation is required of all the relevant details of patient care.

Maintenance and continuous improvement of the quality and accessibility of the treatment record are essential.

The overall performance status of the patient prior to treatment should be recorded. Assessment of tumor response and normal tissue toxicity should occur both during and after treatment. Clinical assessment of patient response is a valuable independent check on the success of the overall QM system as unexpected outcomes may identify issues related to technique or equipment performance.

External Beam Quality Assurance

Nearly all external beam treatment requires the following steps, each of which must be carefully confirmed as part of the patient-specific QA process: determination of patient set-up position and immobilization; cross-sectional imaging (CT, PET/CT, or MRI simulation); creation of the anatomic model (contouring); specification of the treatment intent; creation of the planning directive and treatment prescription by the physician; computerized treatment planning and dose calculation; monitor unit calculation and/or IMRT leaf sequencing; plan and (electronic chart) preparation; plan evaluation; download to treatment management system (TMS); patient-specific QA as typically performed for IMRT, stereotactic radiosurgery (SRS), or SBRT; patient setup and delivery; plan verification checks; plan adaptation and modifications; chart checks; and more.[335,336,338,339]

Brachytherapy Quality Assurance

The QA process for brachytherapy is similar to that of external beam and involves several components that must be confirmed as part of the patient-specific QA management: treatment planning; treatment delivery systems; applicator commissioning and periodic checks; cross-sectional imaging (CT simulation); specification of the treatment intent, planning directive, and treatment prescription by the physician; plan preparation; plan evaluation; download to TMS; plan verification checks; plan modifications; and chart checks.[339–345]

LEGAL PRINCIPLES CONCERNING MALPRACTICE IN RADIATION ONCOLOGY

A plaintiff initiates a radiation oncology malpractice lawsuit by filing papers

with the court claiming that he or she was harmed by the radiation oncologist and is entitled to legal redress. The claim of malpractice must be set out in the plaintiff's *prima facie* case. This will include a statement of the facts and legal theories that establish that the plaintiff believes he or she is legally entitled to enforceable claims against the physician.

There are four essential elements to a *prima facie* case of medical malpractice. They are the establishment of duty, breach, causation, and damages. To demonstrate medical malpractice, a plaintiff–patient must show that the radiation oncologist had a duty to provide nonnegligent care to the patient, that the provider breached that duty by providing negligent care, and that this breech caused the patient injury or damage.[261,295]

To establish a *duty*, the plaintiff must have facts that demonstrate a legal relationship between the radiation oncologist and the patient. It is a basic rule of Anglo American law that there is no duty to another person unless there is a legally recognized relationship with that person. The plaintiff–patient must demonstrate the existence of a physician–patient relationship.[346]

To establish a *breach*, the patient–plaintiff must demonstrate facts that illustrate the radiation oncologist breached the legal duties implied in the physician–patient relationship or duties that would be generally imposed on members of society. The plaintiff must establish that the appropriate standard of care was violated. Although, in theory, the establishment of the standard of care and the breach of that standard are legally separate, in reality, unless there is a factual question about what the radiation oncologist actually did, the proof of the standard of care also would demonstrate the defendant's breach. Most commonly, in law, the definition of *standard of care* is how similarly qualified radiation oncologists would have managed the patient's care under the same or similar circumstances. In most medical malpractice cases, both the standard of care and the breach are established through the testimony of expert witnesses.[347]

Negligence is defined as "the omission to do something which a reasonable man guided by those ordinary considerations which ordinarily regulate human affairs would do, or the doing of something which a reasonable and prudent man would not do." The person who brings a malpractice claim is asserting that he or she is owed some duty by the defendant physician and that the violation of that duty by the physician must have caused injury. The court will make a determination concerning the propriety or impropriety of the defendant physician's performance on the basis of "the reasonable man" had he or she been in the same situation as the individual being judged. Negligence may derive

from the physician's lack of training or experience. It may also result from the physician's carelessness or inadvertence[348] (Box 1.10).

To understand the concept of an expert witness, we must consider the legal doctrines of the *school of practice*, the *locality rule*, and the concept of the *qualifications of an expert*.[376] The legal doctrine of the school of practice is designed to deal with the historic problem of the competing interests of physicians. Physicians generally do not want to testify against their colleagues, but they often are tempted to try to run their competitors out of business. Allopathic physicians were happy to label homeopathic physicians as quacks, and many medical doctors would be happy to dispute the competence of a chiropractor. To deal with the problem, the courts use the legal doctrine of the *school of practice* in which they refuse to allow physician experts to question a different school based on philosophic or psychological beliefs.[346] The school of practice rule now generally is used to differentiate physicians in the self-designated specialties (we use the term *self-designated* because few state licensing boards recognize specialties or limit physicians' rights to practice the specialties in which they have been trained).

Box 1.10

The New York Times Investigates Radiation Therapy

Radiation therapy practice was severely shaken when *The New York Times* published an article on June 21, 2009, titled "At V.A. Hospital, a Rogue Cancer Unit" and a second article on January 23, 2010, titled "Radiation Offers New Cures, and Ways to Do Harm." Both articles were authored by Walt Bogdanich.[255,328]

The first article described allegations that the prostate brachytherapy program at the Philadelphia V.A. Medical Center was "a rogue cancer unit at the hospital, one that operated with virtually no outside scrutiny and botched 92 of 116 cancer treatments over a span of more than six years—and then kept quiet about it…." The article described allegations of repetitive misplacement of prostate brachytherapy seeds, the changing of treatment plans to cover up the alleged errors, lack of peer review and quality assurance procedures, and the development of severe complications in patients.

The second article focused on the death of a 43-year-old man who had been irradiated at St. Vincent's Hospital in Manhattan for a tongue carcinoma and a 32-year-old female breast cancer patient treated at the State University of New York Downstate Medical Center. In the former case, the multileaf collimator was left fully open during intensity-modulated radiation therapy. In the latter case, a wedge was left out of the linear accelerator. Both patients were significantly overdosed and the tongue cancer patient died of radiation injuries. Bogdanich explores the causes of the errors: possible software malfunctions, human error, and lack of quality assurance and safety check procedures. Furthermore, the reporter raised the serious question of whether or not governmental oversight was sufficient to ensure the safety of clinical radiation therapy.

The articles made the safety of radiation therapy a national concern and have produced considerable soul searching in the medical physics and clinical radiation therapy communities. Efforts are under way at many levels to understand what can go wrong in radiation therapy, what can be done to prevent these errors, how much can be done to engineer procedures to prevent machine and human error, and what types of oversight are necessary to minimize error. We must never forget the Hippocratic admonishment *primum non nocere:* "First do no harm."

The *locality rule* refers to the concept that a physician's competence should be determined by comparison with other physicians in the community or in similar neighboring communities.[346] However, with the development of national standards for the practice of radiation oncology, there is no justification for rules that shelter substandard medical decision-making by using an excuse that it is the norm for a given community. A radiation oncologist, for example, could not be held at fault for failing to treat a patient with an unusual or exotic technology if that technology were not available in his or her local community. However, physicians are required to inform the patients of the limitations of the available facilities and recommend prompt transfer if indicated. Failure to refer patients when a provider lacks the experience to appropriately treat may create malpractice liability. Furthermore, if a radiation oncologist does not give a patient information about the potential result associated with not seeing a subspecialist able to use a specific technology, then the initial radiation oncologist may be held liable. Physicians must recognize when a particular medical problem is beyond their capacity for diagnosis or treatment. They are responsible for obtaining timely and adequate consultations when indicated and for referring the patient to an appropriate specialist or facility whenever the requirements for the appropriate or specialized care cannot be satisfied at the available facilities. The continued expansion of knowledge in radiation oncology and the increasingly specialized training of physicians make it essential that the radiation oncologist be able to recognize any limitations in his or her capabilities or ability to treat a given patient with what is perceived to be standard of care. Failure to obtain an appropriate consultation or make an appropriate referral may denote negligence.[192,349,350]

Qualified experts sometimes disagree as to the standard of care. When alternative schools of thought exist, the physician defendant is entitled to be judged by the tenants of the school he or she follows. In such states, this is called the *minority practice doctrine.* With this doctrine, also called the *respectable minority rule*, the physician may show that although the course of therapy followed was not the same as other practitioners would have followed, it was

one that was accepted by a respectable minority group of practitioners.[351]

A problem that is increasingly facing physicians in the United States has been the pressure radiation oncologists face from their employers or from insurance companies to conform their proposed care to a predetermined regimen. Despite legislative initiatives to hold such organizations accountable, the radiation oncologist will, for the most part, carry a significant portion of the risk of liability in cases where the patient asserts that he or she was unable to obtain the most accurate and appropriate diagnostic and therapeutic measures. It is essential that the radiation oncologist come to his or her own conclusions about the standard of care irrespective of any pressures applied by an employer or an insurance company. In litigation, the radiation oncologist's best defense against a claim of malpractice is if he or she can demonstrate action only in the interest of the patient, regardless of any financial consideration or bureaucratic restraint imposed by an insurance company, an HMO, or any other financial consideration. If a conflict arises between the radiation oncologist's recommendations for the best course of treatment and the level of care authorized by his/her employer, or insurance company, or an HMO, the physician must give the best care to the patient even if it means he or she will not ultimately be compensated.[352]

Radiation oncologists will, on occasion, be called on to serve as expert witnesses in malpractice cases. Physicians, trained to give opinions, may find the give and take of the court room off-putting. For an expert witness, the foremost qualifications are effective presentation and teaching ability. The radiation oncologist, serving as an expert witness, must educate the attorneys, judge, and jury. Once there is a perception of understanding, the radiation oncologist may be able to convince the judge and jury that they can make an independent decision that his or her testimony is correct.

Both the plaintiff's attorney and the defense attorney will retain expert witnesses who will be persuaded to "take sides." The expert witness will be asked to swear, under oath, what influence the radiation dose, volume, or technique had on the risk of an ill effect of radiation therapy on normal tissue or alleged failure to control the tumor. This expert witness system troubles many physicians who feel that they can bring a dispassionate and scientific view to such cases and come to a reasonable conclusion about whether or not malpractice occurred outside the process of litigation.[352] Whatever the wishes of the physician, a trial is an adversarial process. The physician is best advised, therefore, to state his or her opinion about the case frankly and not attempt to

predict or handicap how a trial will turn out. The physician should do his or her best to provide an opinion and then step aside to let a system, in which he or she has little expertise, run its course in the hands of the attorneys and judge. Although often frustrating and distressing, the physicians will find themselves out of their league if they attempt to act as attorney or judge.

Each physician must make a determination as to whether he or she feels comfortable participating in the legal process as an expert witness. Some radiation oncologists accept employment as expert witnesses in both plaintiffs' actions and in defense. Some only choose to participate as expert witnesses for the defendant physicians or simply wash their hands of the matter and will have nothing to do with the process. The lure of money is strong and serving as an expert witness can be quite lucrative. Each physician must, however, determine for him- or herself whether the financial compensation for serving as an expert witness outweighs the considerable effort and troubling aspects of the process.

It is important that radiation oncologists understand that the concept in malpractice law of *res ipsa loquitur*,[346] roughly translated as "the thing speaks for itself," is used to deal with cases in which the actual negligent act may not be proved, but it is clear that the injury was caused by negligence. In law, this doctrine was first recognized in the case of a man who was injured when a barrel rolled out of a second-story window of a warehouse. The defense attorney argued that the plaintiff did not know what events preceded the barrel rolling out of the window, and, therefore, it could not be proven that an employee of the warehouse was negligent. The plaintiff, however, countered that barrels do not normally fall out of second-story warehouse windows. The simple fact that the barrel fell from the window and caused an injury "spoke for itself" and demonstrated that someone must have been negligent.

In medical malpractice law, *res ipsa loquitur* is used to shift the burden of proof to the defendant's position regarding causation. *Res ipsa loquitur* can be invoked if the patient suffers an injury that is not an expected complication of medical care, the injury does not normally occur unless someone has been negligent, and the defendant was responsible for the patient's well-being at the time of the injury. Examples in which this concept has been invoked include the dislocation of a patient's shoulder while aligning it for a chest x-ray, knocking out a patient's tooth while the patient was under anesthesia for a tonsillectomy, nerve injury because of a hypodermic injection, leaving a sponge in the abdomen during an operation, or fracturing a patient's jaw while extracting a tooth.[346]

An *intentional tort* is an action that can result in harm to the plaintiff. The

classic intentional tort in medical malpractice law is forcing unwanted medical care on a patient. Even if care clearly would benefit a patient, if that care were refused and the radiation oncologist had no state mandate to force care on the patient, but did so anyway, the patient might sue for intentional tort. The most common intentional tort is *battery.* The legal standard for a battery is "an intentional unconsented touching."[347]

Battery is not the same, in law, as *assault.* Assault is the act of putting a person in fear of bodily harm. Most battery claims against physicians are based on real attacks. However, battery claims also can be created by the circumstances of the medical treatment. The legal standard of care is that male health care providers do not examine female patients without a female attendant present. Although the standard frequently is ignored, it should not be. An attorney representing a plaintiff–patient may attempt to demonstrate that allowing an unattended examination of a female patient by a male radiation oncologist is concrete evidence that, at the very least, the physician has very poor judgment.

Of particular concern to radiation oncologists, in the realm of malpractice, is the concept of *loss of chance.* This usually is evoked in circumstances where physicians failed to diagnose a terminal illness. The loss of chance stems from the failure to diagnose in time for the patient to have a chance of cure. Not all states recognize this standard. In those states that do, however, the patient must show that the loss of chance is statistically significant.[346]

It is generally viewed that any patient injured by exposure to a defective x-ray machine will be compensated as a matter of law.[348] If, however, the radiation oncologist did not know or could not have reasonably been expected to know that a machine was defective, he/she will generally not be held liable if they used the machine properly.[353] Radiation oncologists are bound by the usual standards of skill, knowledge, and appropriate diligence that apply to the specialists within the field.

If a patient is hypersensitive to radiation therapy, and in the absence of any reasonable way to predict this, the radiation oncologist will not be expected to predict or prevent it.[354–356] There is, however, the possibility that the plaintiff's attorney will invoke *res ipsa loquitur* in certain circumstances.[357] For example, in a patient who received radiation therapy for a benign condition and suffered a severe radiation cutaneous reaction that required bilateral amputation, the radiation oncologist was found to be negligent.[358] In the employment of diagnostic radiation, minimal exposure is involved, and it is not expected that a skin reaction will be produced. Thus, if a skin reaction does ensue, many courts

would infer negligence.[359] If a part of the body is unintentionally irradiated and injured, liability will generally follow. For example, a patient who is undergoing radiation therapy to the head and neck was compensated when he suffered severe injury to the arms.[360] A patient given radiation therapy to the ear suffered reaction of the head, face, and neck. Liability was also imposed.[361] It is reasonable to expect that patients give informed consent for radiation therapy and will accept a certain risk of ill effects. This does not mean that the patient assumes a risk of negligent care.[362,363]

In a case where a patient with carcinoma of the rectum was given radiation therapy at a dose above that recognized as proper and suffered severe ill effects, the radiation oncologist offered a defense that such dosage had been given in accordance with the recommendation of a recently delivered scientific paper. The court rejected this claim. In the court's view, this was not a generally accepted course or program of therapy, and the patient's specific consent to the variance in therapy had not been obtained.[364]

One must be particularly cautious in dealing with a woman of childbearing age concerning the possibility of pregnancy before exposing her to radiation therapy. Because the fetus might be injured, producing birth defects or necessitating an abortion, the patient has a right to refuse or at least should be given the full chance of providing informed consent.[282]

One must also be wary of injury through other forms of negligence involving radiation therapy. Injuries of this type include allowing the patient to fall, unstrapped, off the couch of a treatment machine as it is being moved into the correct position, being struck by a fluoroscopic screen or other equipment from a treatment machine or a simulator, being shocked or burned, or being permitted to come in contact with high-tension electrical wires.

There are some data concerning the types of malpractice claims brought in radiation oncology. From 1975 through 1994, a total of 18,860 malpractice suits were brought in Cook County, Illinois, naming at least one codefendant physician; 8% named a radiation oncologist as one of the defendants. The number of suits directed against radiation oncologists fell sharply in Cook County after 1982. At that time, allegations that thyroid cancer in adults developed from tonsillar irradiation administered in childhood for benign disease halted when such suits proved unsuccessful. The most common complaints initiating radiation oncology suits in recent years relate to:

a. Alleged complications of radiation therapy
b. Alleged administration of radiation therapy for inappropriate indications

c. Alleged inappropriate withholding of radiation therapy[365]

An interesting survey of 107 radiation oncology lawsuits conducted by the Fletcher Society found that 59% of the plaintiff patients were female. The four most common organ sites involved in the suits were gynecologic (17%), breast (16%), head and neck (14%), and urologic (12%). The actuarial probability of a radiation oncologist remaining free of a lawsuit after 30 years in practice was 35%.[366]

From 1985 to 2007, I reviewed 20 cases of alleged malpractice involving radiation oncology in the capacity of an expert reviewer employed by an attorney—almost always for the defense. When there was sufficient information to determine intent of treatment, it was always curative rather than palliative. A few themes have emerged from an analysis of the primary complaints of the plaintiffs. In six of the 20 cases, the plaintiff alleged that a delay in diagnosis other than the radiation oncologist adversely affected the prognosis and/or increased the risk of adverse late effects of radiotherapy. In four of the 20 cases, the plaintiff alleged a breach of the standard of care caused radionecrosis, cognitive injury, or second malignant neoplasm induction. In two cases, the plaintiff alleged that the treating radiation oncologist should have obtained a second surgical pathology or cytology opinion and that failure to do so resulted in unnecessary ill effects of treatment.[367]

Marshall et al. reviewed 362 closed malpractice claims filed against radiation oncologists collected by a US liability trade association from 2003 to 2012. Of the 362 claims, 102 (28%) were paid, totaling $38 million or an average of $372,468/paid claim. The most common alleged error leading to a paid claim was improper performance of radiation therapy (18%). Examples include misplaced prostate brachytherapy seeds rectal toxicity, or forgetting a spinal cord block and causing radiation myelitis. Errors in diagnosis accounted for 12% of paid claims. Examples include failure to diagnose a new comer on a follow-up imaging study, stimulating a patient for prostate radiotherapy and not recognizing the presence of a colon cancer, or failure to diagnose appendicitis or an aortic aneurysm.

Death-related claims had a lower average payment and lower percentage of paid claims than claims for radiation injury. Why? It may be more difficult to blame a radiation oncologist for the death of a new comer patient than for radiation toxicity in a living patient.[368]

The National Association for Insurance Commissioners conducted an

extensive study of medical liability claims and insurance indemnity. It was published yearly between 1977 and 1980. The final report was based on data collected from over 70,000 medical liability claims arising from over 62,000 alleged injuries or incidences that were closed with payments to the plaintiffs by insurers. These data show that 4% of paid claims were related to EBRT.[369]

Brachytherapy as the origin of a malpractice action poses particular problems for the radiation oncologist. Brachytherapy procedures are relatively rare. Therefore, expertise is often limited and the individual experience of the practicing radiation oncologist may be minimal. The existence of postimplant films, which document the location of the radioactive material, can be used to challenge the quality of the implant procedure. Brachytherapy complications can take years to occur and, because brachytherapy is often employed in treatment of carcinoma of the prostate, cervix, and uterus, the development of fistulas in long-term survivors can be the cause of a malpractice action.

Radiation oncologists conduct their practice with the assistance of others: physicists, dosimetrists, nurses, and therapists. It is necessary, therefore, for radiation oncologists to understand *vicarious liability.* In general, employers are responsible for the actions of their employees. This is called *respondent superior* —also called the master–servant relationship.[215] The fundamental issue that determines whether a person is legally treated as an employee is the extent to which the person hiring the worker may control the details of that work. Nurses, physician assistants, radiation therapists, and other physician extenders are professionals, but in most states in which they are licensed, they generally have a limited license. The extent to which they make medical decisions is determined by state law, but they usually must work under the supervision of a practicing physician. The physician's license, however, is unlimited. The physician, for example, may perform nursing tasks without violating nursing practice laws. Injury caused by extenders may, ultimately, lead to a malpractice claim against the physician. Physician liability for the actions of hospital employees is particularly problematic for radiation oncologists. Many radiation oncologists practice in hospital-based clinics. In general, the *doctrine of the borrowed-servant* or the *captain of the ship doctrine* states that all actions of hospital employees are attributable to the patient's attending physician. Under such a doctrine, the radiation oncologist may be found liable for the actions of a nurse, dosimetrist, or radiation therapist who the physician can neither hire, fire, nor otherwise directly control.[347]

When radiation oncologists are directors of clinical services, they also should

be aware of the fact that they may be vicariously liable for the behavior of employees if they tolerate inappropriate activity or do not properly screen employees for dangerous tendencies. If, for example, a therapist has assaulted persons in the past and the radiation oncologist was negligent in discovering this, the radiation oncologist could be held liable under the theory of negligent hiring. The radiation oncologist also could be held liable for negligent retention if there were complaints about the behavior of the therapist and the physician failed to act on them.[346]

The captain of the ship doctrine means that physicians may have responsibility for the mistakes of their radiation therapists, dosimetrists, physicists, nurses, and fellow practicing physicians allegedly under their supervision or control. It is, therefore, incumbent upon the responsible radiation oncologist to take care in staff selection, training, and supervision. There is a risk in delegating such matters to an office manager. Ultimately, the physician must maintain an active role in ascertaining that he or she can fully trust the person selected to assist in all aspects of patient care. This means that the radiation oncologist must protect against allegations of sexual misconduct or abuse, alcohol or drug impairment, or mental illness potentially affecting patient care; because the physician is ultimately liable for the care given to a patient, the radiation oncologist must play an active role in ongoing training and professional development of his or her staff.

If an accident or allegation of misconduct occurs, the radiation oncologist must have a thorough, efficient, and adequate means of investigation of the matter and, if necessary, discipline or dismissal. Adequate employment records must be maintained.[352]

One of the most vexing problems now facing the practicing radiation oncologist is the matter of substance and alcohol abuse in the workplace and potential criminal records of employees. Some practices are instituting mandatory pre-employment screening for alcohol and drug abuse and criminal background checks. These issues, however, are extremely complicated, and it is not yet clear which drugs should be tested for, when the testing should occur, who should be evaluated for a potential criminal background, which positive criminal background checks merit a decision not to employ an individual or to dismiss the person, under what circumstances a person can be felt to have paid his or her debt to society in a way that allows the individual to practice in a health care environment, and to what extent a radiation oncologist can be held liable for failure to exercise due caution in this process. Obtaining sound advice

from an expert in personnel relations and legal counsel is advisable.[365]

It is well recognized that no radiation oncologist can be available at all times and in all circumstances. A physician may arrange, during his or her absence for vacation or ill health, for practice coverage by another physician. When one radiation oncologist "covers" for another, there are risks to patient safety, and possible susceptibility to malpractice claims, if clinical care "falls through the cracks." To minimize the risk of malpractice claims, the following guidelines should be followed:

- When you are away from your practice, you should select a covering radiation oncologist who possesses knowledge and skill at least equal to yours.
- Inform and obtain consent from those patients who will be affected.
- Apprise your covering physician of any important clinical information pertaining to patients he or she will see in your absence.
- The covering physician is expected to do more than just "fill in." He or she must apply the same degree of medical skill and care as the regular radiation oncologist.
- When the regular radiation oncologist returns, he or she should receive a report of any noteworthy patient care events, laboratory tests or diagnostic imaging results that deserve follow-up, and any other "loose ends."[370]

It cannot be overemphasized that well-maintained medical records are crucial to a satisfactory legal defense in malpractice claims in radiation oncology. In law, the concept of *spoliation* refers to the destruction of evidence of significance or a meaningful alteration of a document. In medical malpractice cases, this would refer to the absence or disappearance of medical records. One radiation oncologist wisely counseled: Now and then look over an old chart, see if you can trace all of your steps in making decisions and executing treatments. Would this chart be sufficient to defend yourself against a malpractice claim?[366]

The Nature of Grievances, Malpractice Claims, and Insurance Disputes in Radiation Oncology

Dissatisfied patients might ignore their physician's advice or seek a new physician. Assertive patients may confront their physician. It is also commonplace for patients to discuss their complaints about physicians with friends and relatives.

In Anglo American law and custom, patients whose dissatisfaction prompts formal action have several options. These include bringing a malpractice claim and seeking redress in courts. Other options include filing a complaint with a

government medical board; filing a complaint with the “patient relations office” of a hospital or group practice; directing a complaint to a hospital’s chief of medical staff or credentials office; or submitting a grievance to the local, state, district, or national medical society. Why some dissatisfied patients do nothing and others take formal action is not well studied.[181] The general nature of patient grievances against physicians, however, has been evaluated by several authors.[371,372] Complaints fall into several broad categories:

- Alleged failure of physicians to fulfill the patient’s expectations for examination and treatment (i.e., inadequate therapy, failure to obtain informed consent prior to a procedure, inadequate physical examination, or lack of prompt attention following hospitalization)
- Alleged failure to make a prompt diagnosis
- Alleged rude or discourteous behavior
- Alleged unacceptable practice behavior, such as producing excessive pain or practicing outside an area of expertise
- Alleged inappropriate behavior related to billings and collections
- Alleged physician’s use of alcohol or drugs
- Alleged sexual misconduct
- Alleged errors in prescribing
- Alleged insurance fraud

Formal complaints, including malpractice suits, represent only the tip of the iceberg of patient dissatisfaction. Patients far more often deal with their dissatisfaction by complaining to family and friends or switching doctors than by submitting a written complaint. A study by the Harvard Medical Practice Study Group, for example, found that <2% of patients who had adverse events because of medical malpractice ever filed malpractice claims.[373] Patients pursued medical malpractice claims for a variety of reasons. The four most common include an attempt to hold the offending caregiver accountable, to seek a more complete or satisfying explanation for the adverse event, to stop similar events from occurring to other patients, and to obtain financial compensation[368,372,373] (Boxes 1.11 and 1.12).

A disagreement between a patient and his or her radiation oncologist may cause the patient to have diminished trust in the physician, to be dissatisfied with the clinical results, to change physicians or health plans, to file a complaint, or to undertake litigation. For physicians, however, disagreements with patients may result in frustration, anger, a feeling of loss of control, and career dissatisfaction.

It is important to document your explanation of the risks and benefits of

radiation therapy and to obtain the patient's written authorization to proceed, with a full understanding of those risks. In discussing any procedure or treatment with the patient or his or her guardian, the radiation oncologist should endeavor to explain all of the risks in sufficient detail to permit the patient to make a well-educated decision. Written informed consent should be obtained. But simply having the patient sign a standard form is not the end of the matter. The forms need to be easily understood and written in clear language. It is unwise for a physician to adopt standard printed forms without giving them proper scrutiny. Radiation oncologists must also be sure that the consent form is properly filled out. If, for example, there are blanks for explanations of particular risks involved for the procedure, they should be properly filled in.[352]

Box 1.11

Systematic Radiation Therapy Overdose and Underdose: Events in the United Kingdom

It was discovered in 1998 at Exeter that 207 patients were given a radiation dose >25% than that generally deemed appropriate for the treatment of breast cancer. Some patients had more marked radiation reactions than appropriate. When this became known, adverse publicity appeared in the press. At Stafford approximately 1,000 patients received approximately 25% underdosing over a 20-year period. An investigation concluded that in approximately 500 patients, there was a real possibility that underdosage may have affected the outcome of treatment and, in a small number of patients, produced a cancer recurrence higher rate than that expected.[279,280]

The causes of these two incidents were analyzed in great detail and may have been related to inadequate medical physics staffing. A Royal College of Radiologists survey showed that radiation oncologists in many UK radiotherapy departments were seeing ≥600 new patients per year as compared to the usual 250 to 300 patients seen in France, Germany, and the United States.

Box 1.12

The RAGE Campaign

In 1991, a group of women formed an organization in the United Kingdom called RAGE (Radiation in Action Group Exposure). Their campaign began when a patient developed serious brachial plexus damage following surgery and radiotherapy for breast cancer. The patient wrote a letter to several newspapers describing these events and criticizing the medical and legal processes. This produced an outpouring of concern from other patients who claimed to have suffered from the same side effects. RAGE called for significant changes in the use of radiotherapy for the treatment of breast cancer.[374] The group successfully applied to the legal aid board for funds to undertake research toward a group legal action and, in 1995, constituted a group of plaintiffs in a malpractice case. Publicity associated with the litigation prompted the

Royal College of Radiology to establish a multidisciplinary working party that made recommendations to ensure that patients with symptoms that might be due to radiation-associated brachial plexus injury had access to a network of health care professionals and cancer centers with the necessary skills for diagnosis, functional assessment, and treatment. The case highlighted the risks of high-dose-per-fraction radiation therapy used in the 1970s and 1980s. When the case eventually came to judgment, Justice Ebsworth concluded that there was no negligence and costs were directed against the plaintiffs. The justice commented that "it was unfortunate that litigation in terms of medical negligence was felt to be the only mechanism available," particularly in view of the fact that the cost of litigation exceeded £4 million. The case is instructive on several grounds:

1. The ill effects of radiation therapy may take a long time to become manifest.
2. Communication with patients concerning the causes and treatment of an injury is crucial.
3. The cost of litigation is quite high, and one would certainly hope that in the future society can derive alternative mechanisms to costly malpractice actions to allow patients to understand how and why injuries occur.[280,374,375]

It is essential that radiation oncologists use fundamental communication skills to avoid grievances and malpractice claims, understand the patient's worries and concerns, express empathy, actively discuss care options, negotiate differences of opinion, and allow time for adequate conversation. The challenge for radiation oncologists is to recognize patients' unfulfilled expectations and to engage patients in a discussion with the goal of identifying and avoiding dissatisfaction while building a trusting therapeutic relationship.[389]

Insurance disputes involving radiation oncology typically centered on one or more of the following questions: Is the recommended course of radiotherapy covered under the patient's insurance contract? Is the proposed treatment standard of care or experimental? Is the proposed course of treatment likely to be more beneficial than alternatives? What are the supporting references from the medical literature underpinning the doctor or the insurance company's decisions?

I was asked, between 1995 and 2007, to review 69 radiation oncology insurance disputes. Overwhelmingly, these disputes were about a radiation oncologist's desire to employ and bill for the use of an expensive technique of external become radiotherapy and the insurance company's response that the technology was not standard of care. Examples include Gamma Knife or Cyber Knife treatment of metastatic corner or proton therapy for prostate cancer or

vestibular schwannian or IMRT for localized breast cancer.[367]

Health Insurance Portability and Accountability Act

Because the Health Insurance Portability and Accountability Act of 1996 (HIPAA) has come fully into effect, considerable changes have occurred in the area of health care fraud and abuse. HIPAA created new criminal offenses and brought civil remedies while strengthening existing ones. More important for the practicing radiation oncologist, however, HIPAA is part of a larger political initiative in which health care fraud and abuse became a top law enforcement priority. Large numbers of civil investigations have been brought regarding alleged abuses of Medicare and Medicaid. Many physicians and organizations have been excluded from federally funded health care programs, and there have been criminal convictions and collection of large amounts of money in criminal fines.

RISK MANAGEMENT IN RADIATION ONCOLOGY

In an era of increasing litigation and, unfortunately, a growth in adversarial situations between physicians and patients, it is critical for the radiation oncologist and staff to make every effort to decrease professional liability risks.

The origins of medical malpractice suits include[100]:

- Medical accidents that may not be adequately understood by the patient or explained by the treating physician.
- Less than successful or unexpected adverse results of treatment.
- Poor results from previous treatment elsewhere and ill-advised comments by other physicians or health care personnel.
- Rejection of a plan of therapy without appropriate documentation that the physician has advised the patient of the consequences of declining treatment. Some physicians document this discussion in the chart and send a certified letter advising the patient of the consequences of rejection of treatment.
- Complaint of experimentation when the patient has not been appropriately informed of the nature of the therapy to be administered.
- An angry patient who may find this a way to vent anger or frustration about any events surrounding treatment, including lack of communication, discourteous treatment by the physician or staff, or the amount of the medical bill.

The best prevention against a lawsuit is good rapport with the patient and

relatives, effective communication and QA programs in all activities related to patient management, and clear and accurate documentation of all procedures, discussions, and events that take place before, during, and after treatment.

After appropriate clinical assessment, the histologic diagnosis of the patient must be confirmed at the treating institution; this often includes review of outside pathologic slides. Rationale of therapy and any changes in treatment plan should be duly explained and documented in the record. All procedures performed on the patient should be recorded in the chart, including details of daily treatments, such as use of special treatment aids (i.e., bight blocks, testicular shields, eye shields, immobilization devices), and any problems related to equipment operation. All treatment parameters and calculations should be accurately recorded and verified by a physicist or dosimetrist, in addition to the radiation oncologist. We should remember that, as professional liability attorneys say, “If it is not recorded on the chart, we may assume it never happened.”

The physician and staff may help in their own professional liability defense in case a lawsuit occurs. It is extremely important for the physician to understand and, at an appropriate time, identify early warning signs of an impending malpractice suit. The physician should promptly contact his or her attorney, risk management office, and insurance carrier.

The physician should prepare an incident report in anticipation of potential litigation, describing the potential liability, including dates when events took place and actors and witnesses to be identified by name, affiliation, and status. Incident reports are confidential information between the physician and the attorney, risk manager, or insurance carrier. The report should be prepared while the facts are still fresh so that documentation will be optimal.

TABLE 1.10 POSSIBLE SPECIFIC SEQUELAE OF THERAPY DISCUSSED IN INFORMED CONSENT

Anatomic Site	Acute Sequelae	Late Sequelae
Brain	Earache, headache, dizziness, hair loss, erythema	Hearing loss Damage to middle or inner ear Pituitary gland dysfunction Cataract formation Brain necrosis
Head and neck	Odynophagia, dysphagia, hoarseness, xerostomia, dysgeusia, weight loss	Subcutaneous fibrosis, skin ulceration, necrosis Thyroid dysfunction Persistent hoarseness, dysphonia, xerostomia, dysgeusia

		Cartilage necrosis Osteoradionecrosis of mandible Delayed wound healing, fistulae Dental decay Damage to middle and inner ear Apical pulmonary fibrosis Rare: myelopathy
Lung and mediastinum or esophagus	Odynophagia, dysphagia, hoarseness, cough Pneumonitis Carditis	Progressive fibrosis of lung, dyspnea, chronic cough Esophageal stricture Rare: chronic pericarditis, myelopathy
Breast or chest wall	Odynophagia, dysphagia, hoarseness, cough Pneumonitis (asymptomatic) Carditis Cytopenia	Fibrosis, retraction of breast Lung fibrosis Arm edema Chronic endocarditis, myocardial infarction Rare: osteonecrosis of ribs
Abdomen or pelvis	Nausea, vomiting Abdominal pain, diarrhea Urinary frequency, dysuria, nocturia Cytopenia	Proctitis, sigmoiditis Rectal or sigmoid stricture Colonic perforation or obstruction Contracted bladder, urinary incontinence, hematuria (chronic cystitis) Vesicovaginal fistula Rectovaginal fistula Leg edema Scrotal edema, sexual impotency Vaginal retraction or scarring Sterilization Sexual impotence Damage to liver or kidneys
Extremities	Erythema, dry/moist desquamation	Subcutaneous fibrosis Ankylosis, edema Bone/soft-tissue necrosis

Clear and well-kept records with notes documenting every discussion and procedure that is performed on the patient should help in case of a lawsuit. A full discussion with the patient and relatives regarding planned therapy, particularly side effects of irradiation, and a well-documented informed consent form are valuable in risk management.

Informed Consent

The need to obtain informed consent for treatment is based on the patient's right to self-determination and the fiduciary relationship between the patient and physician.[376] The law requires that the treating physician adequately apprise every patient of the nature of the disease requiring treatment, recommended

course of therapy and details regarding it, alternative treatments available, benefits of recommended treatment, and all minor and major risks (acute and late effects) associated with the recommended therapy (Table 1.10). If the plan of therapy is modified, this should be discussed with the patient, and, if warranted, a second informed consent may be required. It is advisable to discuss the informed consent contents in the presence of a witness and have that person sign an informed consent form or the chart verifying that the information was discussed with the patient.

Informed consent is a process, not a form. A consent form documents and codifies the process but does not substitute for clear and appropriate provision of information to the patient with adequate time for questions, answers, and free discussion and exchange. Ultimately, the competent adult patient or a legal representative must agree to the treatment and give approval. For unemancipated minors or legally incompetent adults, informed consent must be signed by the parents, adult brothers or sisters, or a responsible near relative or legal guardian. For incompetent adults, spouses may be allowed by the state to sign. Emancipated minors may provide their own consent. It is extremely important for the radiation oncologist and the staff to spend as much time as is needed to ensure that the patient and, if necessary, relatives understand all aspects of the radiation therapy, particularly the specific description of the various potential deleterious effects of this modality.[221] Many physicians indicate which situations may require surgery to treat a complication and, specifically, when a gastrostomy, colostomy, ileal bladder, or other organ-substituting operation may be necessary to correct sequelae of therapy.

The radiation oncologist is always balancing a full disclosure of risks and options without overwhelming the patient with data and causing distress. It is reasonable to expect the patient to come away from a meeting with the treating radiation oncologist with a general realistic hope regarding the proposed course of treatment and honest understanding of the side effects and a sense of trust for the physician and the organization.[352] Good documentation is crucial and, if a malpractice action were to occur, liability may hinge on who said what to whom at what point of the treatment process. Absent or lost records will reflect extremely poorly on the radiation oncologist.[352]

It must be stressed that in dealing with children or mentally incompetent adults, a thorough discussion of the plan of therapy and sequelae should be held with the parents, relatives, or legal guardian of the patient. Also, they must sign the informed consent.

Although, in case of a lawsuit, having a properly executed informed consent form in the record is helpful, more important is the incontrovertible documentation in the chart of the pertinent discussion held with the patient. Table 1.10 describes many of the specific sequelae in several anatomic sites that should be included in the informed consent. Radiation oncologists also should be aware of court decisions that place a greater burden on the physician to disclose statistical life expectancy information to critically ill patients as part of the informed consent and as an affirmation of patient-centered decision-making (regarding treatment) in the context of a physician–patient relationship based on trust.[377]

Cancer Biology

CHAPTER 2

Molecular Cancer and Radiation Biology

Michael Baumann, Ina Kurth, Nils Cordes, Mechthild Krause, and Annett Linge

During the last three decades, molecular cancer research has become a rapidly growing branch of the biomedical sciences. Many advances in our understanding of cancer are closely related to innovations in biotechnology—for example, gene editing techniques to modify the specific gene of interest, experimental maneuvers to manipulate temporal and spatial gene expression, the utilization of high-throughput methods to study the entire genome and proteome of cancer cells, and a vastly growing methodology to specifically interfere with signal transduction. Because of the rapidly expanding knowledge in molecular cancer and radiation biology, this chapter can only provide an introductory overview on selected topics.*Cell biology* approaches contribute to modern radiobiology and help to better understand effects of ionizing radiation on cells, tumors, and normal tissues. Knowledge in molecular cancer biology is important for clinical decision-making in oncology and the development of novel biology-driven strategies in the multidisciplinary clinical environment.[1–4] *Molecular pathology* of tumors increasingly supplements classic histopathology and immunohistochemistry, thereby providing the basis for improved treatment stratification in oncology.[5–7] *Molecular pathophysiology* describes mechanisms leading to a characteristic microenvironment of tumors or that eventually manifest radiation sequelae in normal tissues.[8] *Molecular imaging* has become important not only for staging but also for biologic characterization of tumors and for determination of target volumes in radiation oncology, including approaches such as dose painting.[9–12] *Molecular targeting* in radiotherapy may either increase the tumor response or protect normal tissues, thereby enhancing the therapeutic gain of the treatment.[13–17]Radiotherapy appears to be particularly promising to integrate molecular targeting approaches.[15,17] First, the radiobiologic mechanisms of the response of tumors and normal tissues to radiotherapy are well characterized, and the molecular pathways involved in

these responses are increasingly known. Second, similar to conventional chemotherapeutic drugs, the novel drugs developed are not necessarily curative by themselves. In contrast, radiotherapy in itself is extremely efficient in eradicating cancer stem cells (CSCs), and recurrences often occur from only one or a few surviving CSCs.[18–20] Thus, even if novel drugs have the potential to kill only a limited number of CSCs, this might be sufficient to increase local control when combined with radiotherapy. The same argument applies when these drugs increase the radiosensitivity of tumor cells or when normal tissues are specifically protected. Third, in contrast to systemic chemotherapy, radiotherapy can be modulated in dose, time, and space. This allows individual tailoring of the effects of combined treatments in consideration of the spatial distribution of CSC burden as well as with consideration of normal tissues. Preclinical data and early clinical results corroborate these arguments[18,19,21–26] and support further translational research on biologically enhanced radiotherapy.

THE HALLMARKS OF CANCER

During carcinogenesis, neoplastic cells are gaining several biologic capabilities, which enable tumor growth and metastatic dissemination. Molecular biology of cancer can be summarized by a simplified concept based on a small number of underlying principles. In their seminal articles, Hanahan and Weinberg described these principles, which are being shared by most human tumor types, as the six core "*hallmarks of cancer,*" as well as "*emerging hallmarks*" and "*enabling characteristics*" facilitating tumor promotion.[27,28] These hallmarks are the consequence of specific genetic alterations or modifications in important oncogenes and tumor suppressor genes and are briefly outlined below.

Sustaining Proliferative Signaling

Mitogenic signals from growth factors, cytokines, extracellular matrix, and cell–cell adhesion molecules are transferred into the cell by different classes of transmembrane receptors.[27,28] Malignant cells acquire the capability to escape from the tightly regulated dependence on extracellular growth signals. The molecular mechanisms include overexpression of growth factors as well as growth factor receptors (autocrine and paracrine stimulation), receptor mutations leading to constitutive receptor activation without ligand binding, and molecular aberrations in the intracellular signal transduction pathways.[27,28]

Evading Growth Suppressors

Normal cell division is tightly regulated by stimulatory and inhibitory growth signals. Growth signaling involves interaction of diffusible growth factors or cytokines with transmembrane receptors, as well as regulation of growth by components of the extracellular matrix and by cell–cell interactions. Once a resting cell receives a sufficient growth stimulus, it enters the cell cycle by passing the restriction point and four distinct phases of cytokinesis and mitogenesis: gap-1 (G1), deoxyribonucleic acid (DNA) synthesis (S), gap-2 (G2), and mitosis (M).[29] The passage through the restriction point and the entry into S and M (G1/S and G2/M checkpoints) are governed by several proto-oncogenes and tumor suppressor genes such as *TP53* and *RB1* encoding for p53 and the retinoblastoma protein (pRb), respectively (Fig. 2.1).[27,28,30,31] Inactivation of tumor suppressor genes by genetic mutations or epigenetic mechanisms will ultimately lead to sustained cell proliferation.[27,32–34]

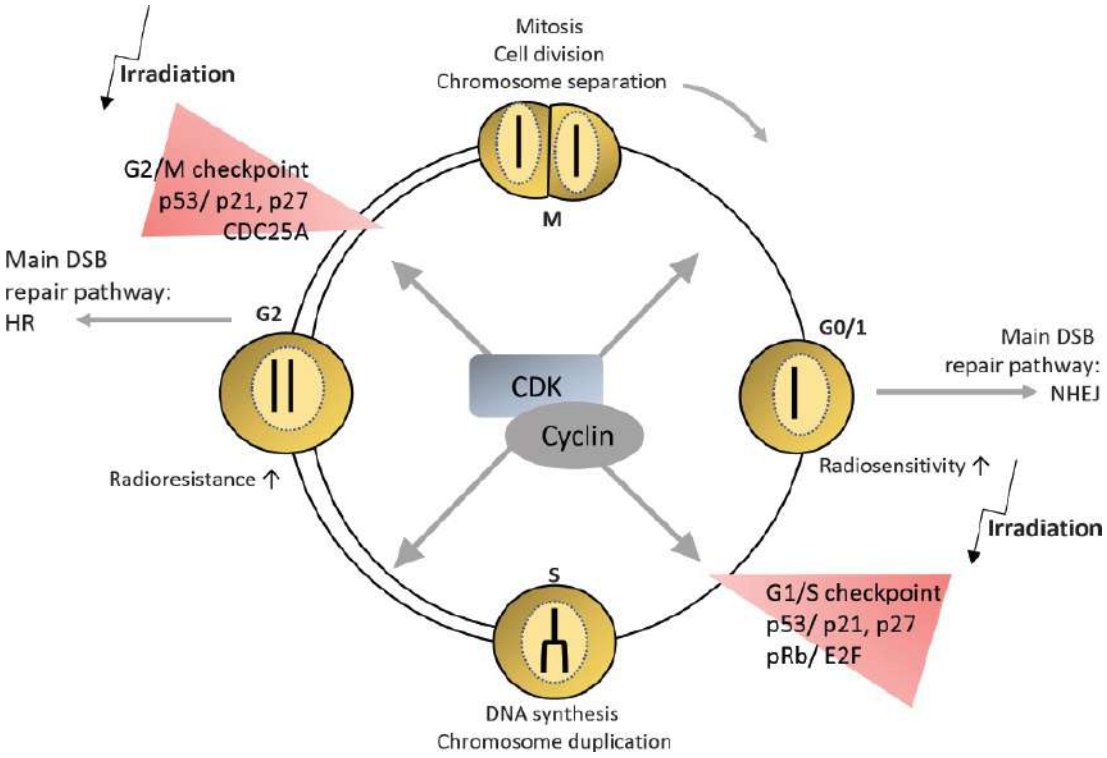

FIGURE 2.1. Cell cycle and checkpoints. The cell cycle is the backbone process that facilitates duplication of the DNA and cell division in order to generate two daughter cells. The distinct phases of the cell cycle are differently susceptible to irradiation damage. The highest radiation sensitivity is in early S and late G2/M phase. The cell cycle checkpoints in Gap 1 (G1) and Gap 2 phase ensure that the cell is ready for DNA synthesis (S-phase) or mitosis (M). If the DNA is damaged, the cell stops cycling and either the damage will get repaired and the cell continues with the cycle or the cell undergoes apoptosis and dies. Many types of cancer arise from mutations that lead to checkpoint misregulation or skipping of those. Cell cycle progression is governed by various cyclins and cyclin-dependent kinases (CDKs). Different cyclin–

CDK complexes determine targeted downstream proteins that for example promote DNA replication and degrade S-phase inhibitors. NHEJ, nonhomologous end joining.

Activating Invasion and Metastasis

Locoregional and distant spread of tumor cells requires detachment from the primary tumor, invasion into surrounding tissues, intravasation into blood or lymphatic vessels, anoikis resistance, adhesion to endothelial cells at distant sites, extravasation, and eventually colonization in distant organs.[28,35] The acquired capability of cancer cells to grow invasively and to metastasize is associated with multiple genetic and biochemical alterations of the cell–cell and cell–matrix interactions.[27,28] Tissue invasion and metastasis require, at different steps, contrary capabilities—for example, detachment from the primary tumor versus adhesion at the metastatic site—suggesting that rapid adaptations, genetic instability, and clonal selection play an important role.[35] Also, the intratumoral microenvironment plays a key role; for example, hypoxia is described as one possible activator of metastasis.[36] In order to effectively metastasize, several critical steps are necessary, which involve epithelial to mesenchymal transition (EMT), extracellular matrix modulation, intravasation, circulation, extravasation, homing, forming the premetastatic niche for organotropic colonization and mesenchymal–epithelial transition (MET).[37,38]

Enabling Replicative Immortality

Loss of growth control and resistance to cell death are not sufficient for the development of macroscopic tumors. Normal cells have the capacity for a finite number of cell divisions, which results in a limited replicative potential. Thereafter, either cells stop proliferating and enter the process of senescence, which is a viable but nonproliferative state, or they die.[28,39] During tumorigenesis, some premalignant cells become immortal by circumventing senescence, that is, by acquiring a capability of limitless replicative potential.[27,28] Of importance, malignant tumors consist of heterogeneous populations differing in their replicative potential. Although most cancer cells have a limited replicative potential, a small subpopulation (i.e., CSCs) have an infinite replicative capacity and the capability to reconstitute the tumor.[40] Thus, this subpopulation represents the target for curative cancer therapy, that is, all of these stem cells have to be inactivated by therapy or by host-related mechanisms to achieve cure.[18] It remains to be clarified whether CSCs represent distinct tumor cell subpopulations or whether they can switch between different stages in response to stress or environmental conditions.[41–43]

The molecular mechanisms underlying the escape from senescence and other modes of cell death include loss of tumor suppressor proteins such as p53 and pRB as well as telomere maintenance.[28] Telomeres are chromatin segments located at the ends of the chromosomes that protect these regions from recombination and degradation.[44] As telomeres are incompletely replicated, they become progressively shorter during cell divisions, subsequently resulting in loss of chromosomal protection, which in turn triggers senescence. Cancer cells generally have shorter telomeres than do normal cells but are able to perpetuate their replicative potential by expressing telomerase, a complex including DNA polymerase, which reconstitutes the telomeres.[44]

Inducing Angiogenesis

To grow beyond microscopically sized cell aggregates of around 1 mm, tumors depend on angiogenesis. Proliferating cells require appropriate oxygen and nutrient supply, which is physiologically limited to a distance of 100 to 200 μm from the next blood vessel. Therefore, malignant cells must induce and sustain their own vascular system to form tumors and metastases.[45] The process of the *angiogenic switch* during tumorigenesis (i.e., the transition from the avascular phase to the vascular stage) is governed by different molecular changes in tumor cells and in cells of the surrounding stroma.[27,28,46] The major event of the angiogenic switch is that proangiogenic factors—mostly growth factors such as vascular endothelial growth factors (VEGFs), fibroblast growth factors, and platelet-derived growth factors (PDGFs)—outbalance antiangiogenic factors, such as thrombospondin (*TSP-1*), *angiostatin*, and *endostatin*. Hypoxia promotes tumor angiogenesis via the hypoxia inducible factor 1, which transcriptionally regulates many angiogenic molecules.[47,48]

TABLE 2.1 TYPES OF RADIATION-INDUCED CELL DEATH AND THEIR CHARACTERISTICS

Type of Cell Death	Important Morphologic Characteristics	Important Molecular Mechanisms
Mitotic catastrophe	During or after mitosis, missegregation of chromosomes, cell fusion, micronuclei, giant cell formation	Lethal chromosome damage, caspase independent
Apoptosis	Chromatin condensation, nuclear fragmentation, blebbing of cell membrane	Damage to DNA, and/or membranes, and/or alterations of intracellular signaling, caspase dependent (intrinsic pathway via

		caspase 9)
Senescence	Metabolically active but nondividing, functionally differentiated cells	Damage to DNA and/or alterations of intracellular signaling, generally p53-dependent terminal growth arrest, increased senescence-associated β galactosidase
Autophagy	Partial chromatin condensation, cell membrane blebbing, increased number of autophagic vesicles	Protein degradation characterized by double-membrane vesicles in the cytoplasm, possibly related to DNA protein kinase (DNA-PK) activity
Necroptosis	Early plasma membrane permeabilization, translucent cytosol, swollen mitochondria	Damage to DNA, and/or membranes, and/or alterations of intracellular signaling, caspase independent
Necrosis	Increased vacuolation, swelling of organelles and cells, rupture of cell membranes, formation of necrotic mass	Unregulated traumatic cell destruction; after irradiation as consequence of, for example, mitotic catastrophe or vascular damage

Adapted from Brown JM, Wouters BG. Apoptosis, p53, and tumor cell sensitivity to anticancer agents. *Cancer Res* 1999;59:1391–1399; Okada H, Mak TW. Pathways of apoptotic and non-apoptotic death in tumour cells. *Nat Rev Cancer* 2004;4(8):592–603.

Resisting Cell Death

Under physiologic conditions, tissue homeostasis results from the balance of cell division and cell loss. This balance is disturbed in most tumors by an increased cell division rate due to the molecular mechanisms previously described and by a reduced rate of cell death, such as by apoptosis and senescence[27,28,49,50] (Table 2.1).

Deregulating Cellular Energetics and Metabolism

The sustained cell proliferation of cancer cells requires modifications and adjustments to their energy metabolism.[28] Under aerobic conditions, normal cells are processing glucose to pyruvate, and only under anaerobic conditions they are switching to glycolysis. Cancer cells were shown to favor glycolysis, also under aerobic conditions, and this has been termed “aerobic glycolysis” or Warburg effect.[28,51–53] Glutamine and lactate have also been shown to serve as metabolic fuel in cancer cells.[54–56] The deregulated cellular metabolism is an “emerging hallmark,” because it is significantly independent from the main (initial) hallmarks.[28]

Evading Immune Destruction

During the development of cancer, antitumor responses are presenting a barrier that has to be overcome. The exact engagement of the immune system still remains to be determined and is therefore being referred to as an emerging hallmark.[28] It has been shown that many types of tumors utilize different strategies to evade immune destruction. Tumor cells change, for example, surface expression of antigens renders them invisible to cytotoxic T cells, or secrete immunity inhibitory proteins.[57]

Tumor-Promoting Inflammation

Immune cell infiltration can be seen in most neoplastic tissues, but to a varying extent.[58] Inflammation has been shown to be involved in a number of hallmark capabilities by supplying growth and survival factors, proangiogenic factors, and extracellular matrix–modifying enzymes.[28,59–61] Furthermore, inflammation can drive the progression of cancers from incipient neoplasias.[28,61] The release of reactive oxygen species (ROS) can also act mutagenic in surrounding cancer cells.[28,60] However, the immune system is also capable of evoking an antitumor response.[62]

Genome Instability and Mutation

Genomic alterations or modifications of neoplastic cells are largely necessary to acquire the hallmarks outlined above. During tumor progression, mutations and epigenetic modifications but also nonmutational gene expression changes are leading to the accumulation of more favorable genotypes and clonal expansion of cells.[28] The identification of driver mutations leading to malignant progression is important also in terms of therapeutic targeting. For the detection of epigenomic changes, more comprehensive analyses such as histone modifications and DNA methylation are necessary.[28,63]

PRINCIPLES OF MOLECULAR CANCER BIOLOGY

Carcinogenesis describes the transformation of normal cells into cancer cells and the subsequent development of a tumor. This multistep process includes accumulating changes on the cellular, genetic, and epigenetic level and is also characterized by abnormal cellular proliferation. However, these changes can differ between tumor cells within the same tumor leading to intratumoral heterogeneity and also between patients causing intertumoral heterogeneity.

Genetic changes include point mutation, deletion, insertion, gene amplification, chromosomal instability, loss of heterozygosity, and translocation.

Silencing of tumor suppressor genes by promoter hypermethylation, histone modifications, and microRNA (noncoding RNA) expression represents important epigenetic mechanisms of tumorigenesis.[32,34,64] Chemical agents, radiation, and errors during DNA replication and also infection with oncogenic viruses can contribute to the development of human cancer (e.g., human papillomaviruses [HPVs] in cervical or head and neck cancer, hepatitis B viruses in hepatocellular carcinoma, and human immunodeficiency viruses in Kaposi sarcoma).[65,66] The hostile micromilieu in solid tumors, particularly hypoxia, further promotes progressive genomic alterations and clonal selection.[67] Consequently, cells gain advantage in proliferation and survival, which eventually results in malignant transformation, a prerequisite for the development of cancer and metastatic spread.

Conceptually, two classes of cancer genes can be distinguished. First, *oncogenes* are activated in cancer cells by genetic alterations resulting in a gain of function. Mutations in proto-oncogenes acting in a dominant fashion (i.e., a genetic alteration in one of the alleles) are sufficient for gene activation. Typical oncogene functions are stimulation of cell proliferation (e.g., by activation of Ras) and increase in cell survival (e.g., by activation of PI3K/Akt signaling). Disorders in the second class of cancer genes, *tumor suppressor genes*, cause a loss of function. Mutations in one allele of a tumor suppressor gene are recessive because they can be functionally compensated by the second, nonmutated (wild-type) allele. Although some cancers can be attributed to single genetic alterations, most sporadic solid tumors exhibit a wide range of disorders in numerous cancer genes. Simplified mathematical modeling of the increasing incidence of common cancers as a function of age suggests that four to seven somatic gene alterations are required for carcinogenesis.[68,69] A typical example for multistep tumorigenesis is the adenoma–carcinoma sequence in colorectal cancer.[70]

Inherited cancer predisposition can be divided into the rare group of inherited cancer syndromes and familial cancers (strong predisposition) and the more frequent group of predisposition without evident family clustering (weak predisposition).[71] The first group includes syndromes caused by germ-line mutations affecting DNA repair, genomic stability, and cell cycle control, for example, *TP53* (Li-Fraumeni syndrome), nucleotide excision repair genes (xeroderma pigmentosum), *ATM* (ataxia telangiectasia), DNA mismatch repair genes (hereditary nonpolyposis colorectal cancer), and *BRCA 1/2* (familial breast cancer). An example of a familial cancer syndrome related to oncogene

activation is neurofibromatosis type I, in which the mutated *NF1* gene results in activation of the Ras oncogene.[71] Germline mutations causing inactivation of the cell–cell adhesion molecule E-cadherin can be found, for example, in familial diffuse gastric carcinoma.[72] A debate is ongoing on the question how close the risk of cancer depends on the number of normal stem cell divisions in contrast to the influence of environmental factors.[73,74] This issue is highly relevant for public health considerations as it points to the "bad luck" hypothesis versus a cancer risk importantly effected by external influences.

MOLECULAR RADIATION BIOLOGY

Biologic Consequences of Irradiation

The effects of ionizing radiation on cellular target molecules may lead to various functional consequences. These functional effects can be broadly categorized into cell death, repair, cell cycle effects, altered gene expression, modification of signal transduction, mutagenesis, and genomic instability (Fig. 2.2). These categories are not exclusive.

Cell Death

Among the functional consequences of ionizing radiation, cell death is the most important one for radiation oncology. Cells can die in several ways[75]—by apoptosis, mitotic catastrophe, senescence, necrosis, necroptosis, and autophagy (Fig. 2.3; Table 2.1). Most important for the effect of radiotherapy of solid tumors is the *mitotic catastrophe*, which is caused by lethal chromosome damage.[76] After irradiation, cells can pass through one or few mitotic cycles before missegregation of chromosomes or cell fusion leads to the loss of their replicative potential (or clonogenicity). Often micronuclei, containing nonrepaired chromosome fragments, can be detected. Those micronuclei, and hence essential genetic information, will be lost during the following cell cycle, which results in cell death. Frequent multinucleate giant cells reflect a radiation-induced failure of cytoplasmatic separation on cell division.

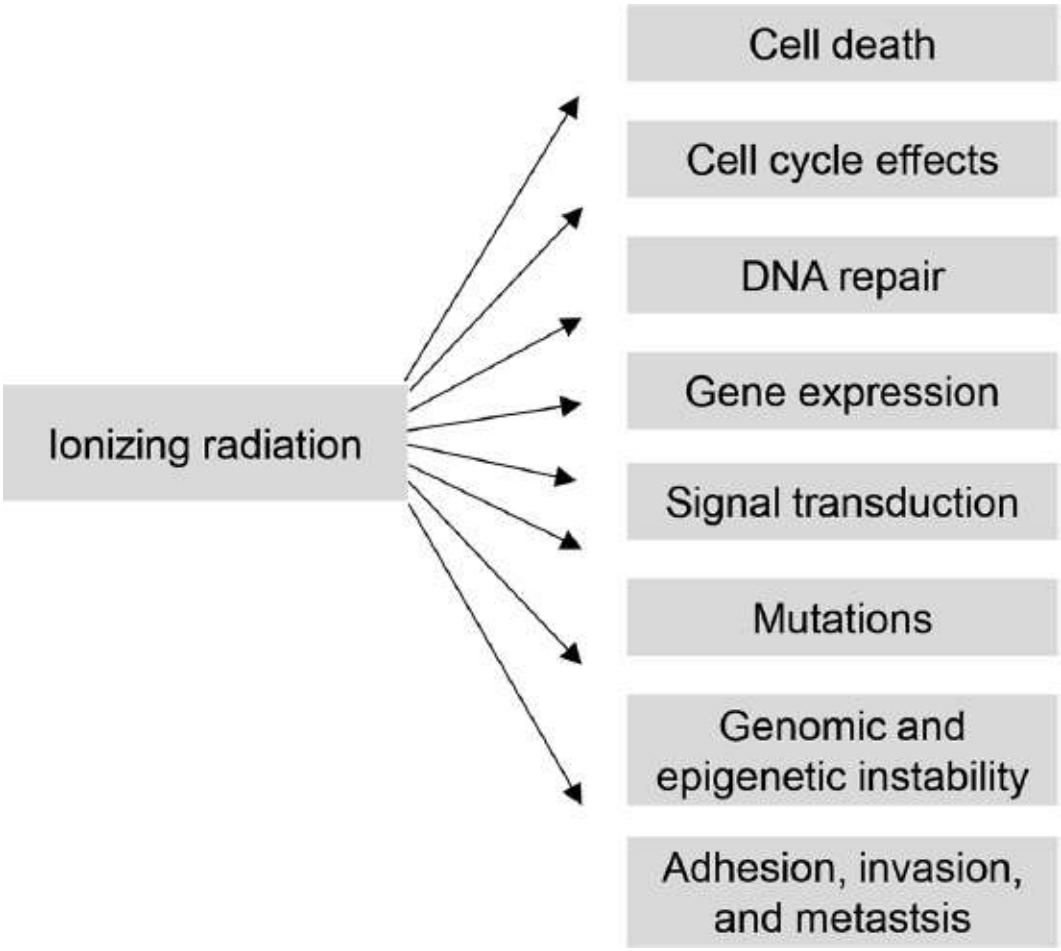

FIGURE 2.2. Illustration of cellular effects upon ionizing radiation.

Neoplastic hematopoietic or lymphatic cells often die from radiation-induced *apoptosis* via the intrinsic, caspase 9–dependent pathway. Two different forms of radiation-induced apoptosis can be distinguished—early or premitotic versus late or postmitotic apoptosis.[77] Early apoptosis is p53 dependent, occurs within few hours after irradiation before the cells enter mitosis, and is primarily a consequence of DNA damage. Early apoptosis represents a distinct mode of radiation-induced cell death. In contrast, secondary apoptosis occurs after mitosis and is one of several possible manifestations of radiation-induced lethal chromosome aberrations. In most cancers, particularly in solid tumors, apoptosis appears not to be the main mechanism of radiation-induced cell death.[78] No clear evidence exists that either apoptotic index or levels of p53, Bcl-2, or other Bcl-2 family members are predictive of the response of solid tumors to radiotherapy. For example, overexpression of Bcl-2 was shown to significantly decrease the apoptotic fraction in response to irradiation. However, this did not translate into a change of clonogenic cell survival after irradiation.[79]

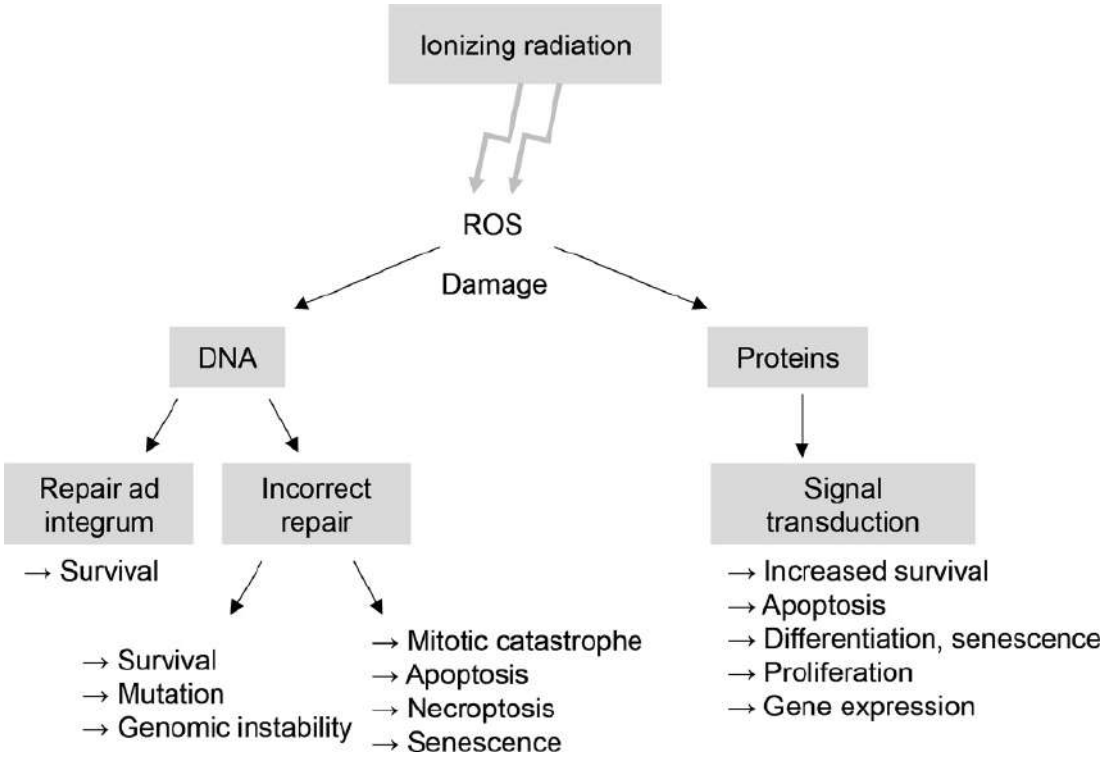

FIGURE 2.3. Simplified illustration of cellular ROS effects. The generation of reactive oxygen species (ROS) causes DNA and non-DNA damage and results in different cellular effects.

Radiation-induced *senescence* plays an important role for development of normal tissue damage—for example, fibrosis[80]—but occurs also in response to nonlethal stress as in tumor cells.[81] Cells survive and are metabolically active but lose their replicative potential. *Necrosis* is an unregulated process of cell destruction by the release of intracellular components. This is usually the consequence of pathophysiologic conditions such as ischemia and inflammation.[75] It is well known that tumors often show massive necrosis after neoadjuvant radiotherapy or radiochemotherapy, which in some tumors correlates with improved prognosis.[82,83] It is likely that this radiation-induced necrosis is explained by several factors, including mitotic catastrophe of tumor cells and the effects of irradiation on tumor vessels leading to changes in the microenvironment, which consequently cause cell death.

Necroptosis, the prototype of regulated necrosis, is a caspase-independent form of programmed cell death and kills apoptosis-deficient cells. It is stimulated by death receptor ligands of the tumor necrosis factor receptor subfamily such as TNF-alpha (TNF-α), CD95 ligand, or tumor necrosis factor–related apoptosis-inducing ligand (TRAIL), but also by other receptors such as

ectodermal dysplasia receptor.[84] Necroptosis can also be induced by other stress-inducing factors such as ionizing radiation, DNA-damaging agents, as well as ROS.[85] Recent experimental data show that knockout of necroptotic genes leads to significantly enhanced radiosensitivity and reduces tumor formation in mice.[86] Other reported forms of regulated necrosis are ferroptosis, oxytosis, ETosis, NETosis, cyclophilin D (CYPD)-mediated regulated necrosis, parthanatos, pyroptosis, and pyronecrosis.[85]

Autophagy is a form of nonapoptotic and nonnecrotic cell death that is related to lysosomal degradation of proteins and cell organelles that are then utilized for the production of new cells.[75] This mode of programmed cell death is triggered by growth factor withdrawal, differentiation, and developmental stimuli. Although the molecular regulation is not completely understood, data suggest that a high rate of autophagy contributes to radiation resistance and that autophagy is regulated through different hypoxia-dependent pathways, thereby facilitating survival during metabolic stress.[87,88]

Target Molecules of Radiation Damage

Radiation effects may occur as direct ionizations in an organic molecule or indirectly via free radical processes. As cells consist mostly of water, most ionizations produced by irradiation occur in water molecules. Within only 10^{-10} seconds, radiolysis of water leads, among other entities, to e^-aq, H·, and OH·. About 60% to 70% of cellular DNA damage produced by ionizing radiation is caused by OH·.[89] The radiation-induced ROS undergo further reactions—for example, production of H_2O_2 from two hydroxyl radicals. Aerobes have evolved antioxidant defenses to protect themselves against the oxygen-derived species generated *in vivo* or from external sources. These defenses include enzymes (such as superoxide dismutases, catalase, and glutathione peroxidase), low molecular mass agents (such as α-tocopherol and ascorbic acid), and proteins that bind metal ions in forms unable to catalyze the generation of free radicals. In contrast to those defensive mechanisms, the oxygen molecule has a high affinity to free radicals, which may give rise to further cascades of radical production and thereby to the fixation of free radical damage to important macromolecules of the cell (e.g., DNA). This is one explanation of the oxygen effect of radiation damage, that is, the fact that well-oxygenated cells are more radiosensitive than are hypoxic cells.[90,91]

By far the most important target for the biologic effects of ionizing radiation is the DNA (Fig. 2.3). This is obvious for the induction of mutations but has also

been consistently demonstrated for the killing of cells in a number of different experiments. Irradiation of the cytoplasm of cells with short-range α-particles only leads to cell kill at very high doses, whereas 1,000-fold lower doses to the nucleus are sufficient to kill the cell.[92] Radioactive isotopes with short-range emission effectively kill cells when incorporated into the DNA but not when predominantly incorporated in cell membranes.[93] Modification of radiation-induced cell kill by different measures, including hypoxia, high–linear energy transfer radiation, or hyperthermia, is linked closely with a change in the induction and repair of DNA double-strand breaks (DSBs). Exposure of cells to about 1 Gy causes approximately 3,500 DNA injuries, 1,500 to 2,500 of which are damaged bases, 1,000 single-strand breaks (SSBs), 40 DSBs, and an estimated 100 to 200 local multiple-damaged sites, where one or several DSBs occur in close proximity to SSBs and base damage.[94] Most radiation-induced DNA damage is recognized and very efficiently repaired by the cell (*vide infra*). Importantly, it also has to be considered that different types of radiation treatment can cause different extent of damage to the DNA in a tumor cell. In contrast to photon therapy, particle therapy causes more severe DNA damage.[95]

Besides effects on DNA, ionizing radiation also evokes biologically important responses on proteins (e.g., transmembrane receptors) and on lipids (e.g., ceramides) (Fig. 2.3). Radiation-induced activation of receptors will be discussed later in this chapter. Ionizing irradiation induces rapid sphingomyelin hydrolysis by acid sphingomyelinase to generate ceramide, an inductor of apoptosis.[96]

Recognition of Radiation-Induced DNA Damage

DNA damage, in particular DSBs, is sensed by different proteins that trigger an ataxia telangiectasia–mutated (ATM)–dependent or, in some cases, ataxia telangiectasia and Rad3-related (ATR)–dependent signaling cascade (Fig. 2.4).[97] ATM activation requires the telomeric protein TRF2 and the MRN complex consisting of Rad50, meiotic recombination protein 11 (Mre11), Nijmegen breakage syndrome protein 1 (NBS1), mediator of DNA damage checkpoint protein-1 (MDC1), and 53BP1.[98] In addition to proper activation of downstream DNA repair proteins, histone H2AX molecules need to be phosphorylated in the vicinity of the DSB. All of these proteins assemble at the site of the breaks and presumably control the choice of one of several repair pathways. In addition to its role in repair, ATM is involved in the regulation of multiple cell cycle checkpoints (G1/S, S, G2/M) after DNA damage.[99] ATM, ATR, and DNA-

dependent protein kinase catalytic subunit (DNA-PK_{CS}) phosphorylate p53 and a number of proteins involved in cell cycle delay, apoptosis, and induction of DNA repair. ATR appears to be important for sensing ultraviolet-related and other types of bulky lesions, as well as damage that induces a replication block, whereas ATM seems to be the sensor for DSB induced by ionizing radiation.[97] ATR may serve in some cases as a backup for ATM.

DNA Repair

Genome integrity is essential to the survival of cells and organisms. It is estimated that about 10^4 DNA lesions occur in a single human cell every day.[100] Most of the damage is caused by endogenous sources such as oxygen free radicals, replicative errors, and spontaneous deaminations. To cope with the plethora of permanent damage, a repair system was developed during evolution that also acts on external challenges such as radiation or chemical DNA damage. To enable repair of massive DNA damage, the cells stop proliferation. This may prevent replication or segregation of damaged genetic material. If repair is not possible, the cells either die or, in case of survival, may propagate mutated DNA (Fig. 2.4). When the DNA replication machinery meets damaged DNA, replication may continue despite the damage by translesion synthesis, which requires DNA polymerase with low fidelity. Different mechanisms are involved in DNA repair.[97,101]

Base Excision Repair

The mechanism of base excision repair (BER) is responsible for the repair of various kinds of base damage (abasic sites, oxidized bases, deaminated bases, and alkylated bases) and SSB. Base damages and SSB are the most frequent types of DNA damage after irradiation.[102,103] The major BER pathway is the short-patch pathway, which involves excision of only one base. The minor pathway—the long-patch repair—excises 2 to 10 nucleotides.

DSB Repair

Spontaneous DSBs either occur on topoisomerase failure during recombination and are forced by replication errors or are due to thermodynamic fluctuation. In germ cells, DSBs are produced during meiotic crossover in T- and B-lymphocytes during a site-specific DNA recombination of variable diversity and joining genes (VDJ) on maturation of T-cell receptors and antibodies. Radiation-induced DSBs are, despite their relatively low induction frequency (40 per Gy

per cell), biologically much more important than base damage and SSB. Two major pathways—homologous recombination (HR) and nonhomologous end joining (NHEJ)—have evolved to repair DSB (Fig. 2.5).[104,105] Whereas NHEJ occurs in all phases of the cell cycle, HR is particularly important in the S/G2 transition of the cell cycle.

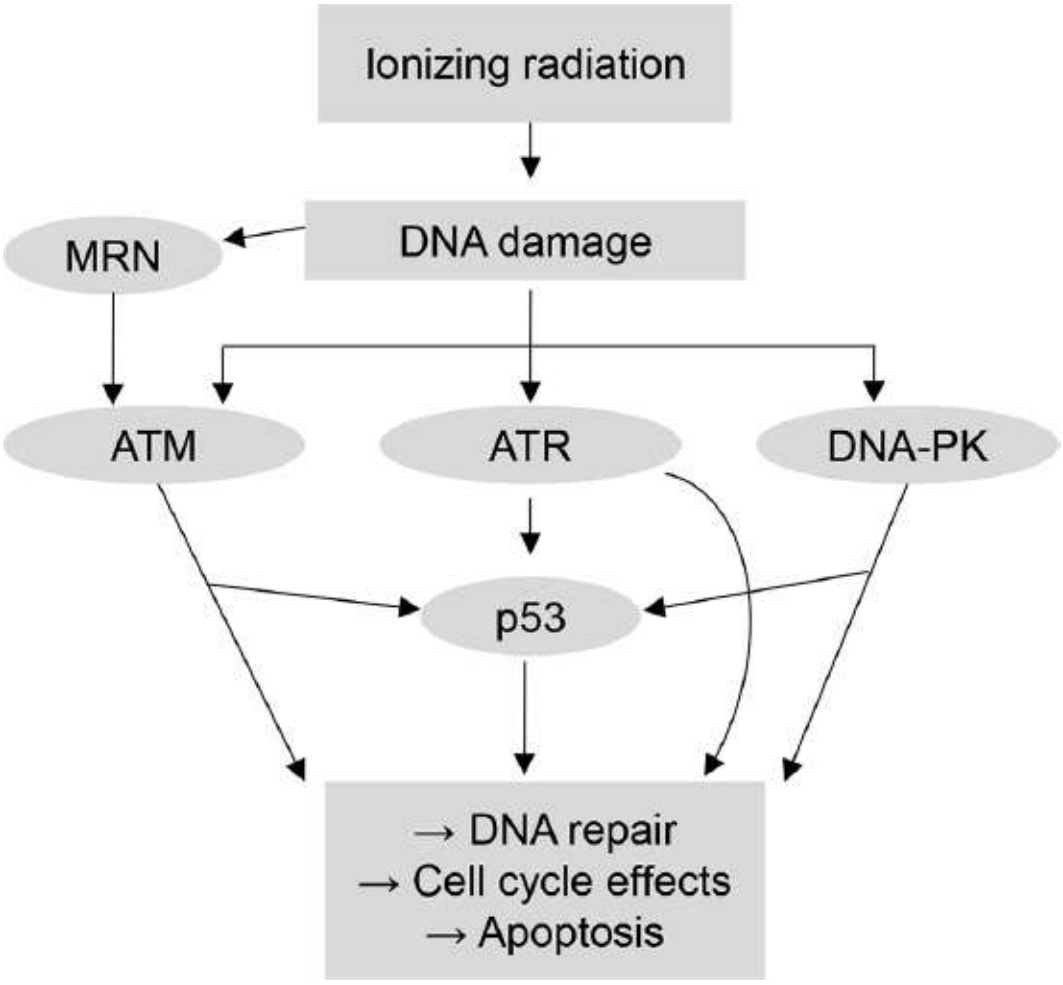

FIGURE 2.4. Simplified pathways of radiation-induced DNA damage recognition.

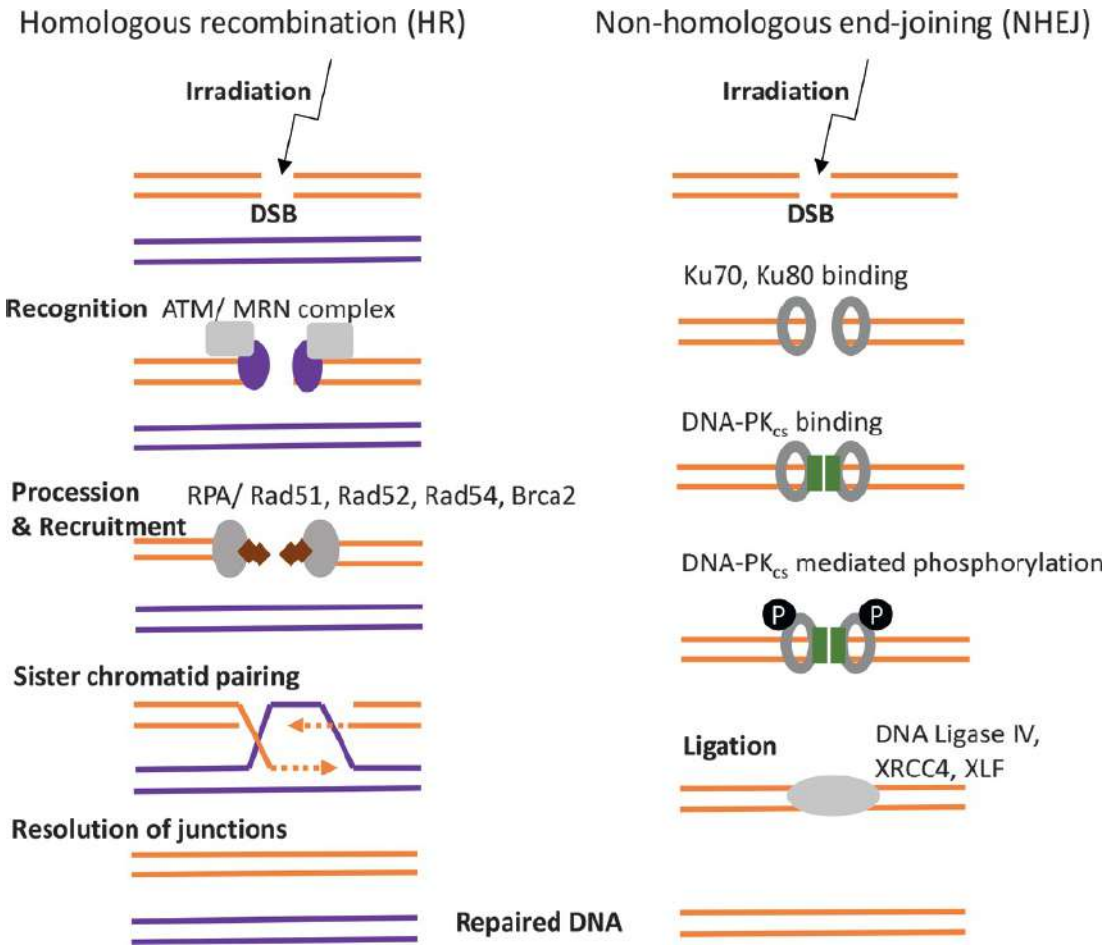

FIGURE 2.5. Main DNA double-strand break damage repair mechanisms. The more error-prone nonhomologous end joining (NHEJ) is active throughout the whole cell cycle. For homologous recombination (HR), an identical DNA strand is necessary and used as template for precise repair.

HR is a slow, high-fidelity repair pathway. Regions of DNA homology—usually the sister chromatid—are used as the template. During HR, activated ATM recruits endonucleases that process broken ends, which ultimately creates single-stranded 3′ ends. For the processing, the MRN complex is required. In concert with BRCA1, BRCA2, and Rad51 paralogues (XRCC2, XRCC3, Rad51B, Rad51C, Rad51D, Rad52, Rad54), the Rad51 protein binds to single-stranded DNA with the aid of replication protein A and searches for a homologous sequence on the sister chromatid. On strand invasion, Rad51 enables the formation of a temporary triple helix. Once the complementary strands have paired, the 3′ end of the damaged DNA will be elongated by polymerases (not yet identified) beyond the position of the former DSB. When the 3′ single strand of the second end of the DSB also invades the structure, a quadruple helix is formed called a *Holliday junction*, which can be extended in

both directions. After the gap has been safely bridged (usually about 50 base pairs will be copied), the Holliday junction is resolved, and the remaining nicks are sealed by a DNA ligase.[106,107]

NHEJ is a fast but error-prone, and thus potentially mutagenic, repair pathway that rejoins DNA ends, usually after removal of a limited number of base pairs. NHEJ is initiated by the Ku70/Ku80 heterodimer, which binds to DNA ends and recruits the DNA-PK_{CS}. DNA-PK_{CS} can phosphorylate a variety of repair proteins such as Ku, x-ray cross-complementation protein 4 (XRCC-4), Artemis, p53, or replication protein A. However, only the autophosphorylation has been identified as being essential for repair. Artemis, in concert with DNA-PK_{CS}, trims the DSB ends for subsequent processing. After release of DNA-PK_{CS} from the DNA, the end will be bridged by the complex of ligase IV/XRCC-4–/XRCC-4–like factor (XLF), which also performs the final ligation step. It has been observed that NHEJ can, to some extent, occur in the absence of several core proteins. This gave raise to the idea of a backup pathway that only operates when the DNA-PK–dependent NHEJ fails.[108] Besides the genuine repair proteins, the tumor suppressor p53 is involved in controlling the repair. P53 appears to suppress both HR and NHEJ in case an error-free repair is not possible and thereby reduces the mutagenic risk of error-prone repair.[109]

Despite our molecular knowledge about DSB repair, chromatin organization has also been shown to impact DSB induction and repair.[110–113] Chromatin is organized as euchromatin and heterochromatin, representing loose and condensed DNA areas, respectively. Whereas DSBs in euchromatin are easily accessible for repair proteins, DSBs in heterochromatic DNA regions need to be moved to less condensed areas for efficient repair.[111,113] Key molecules involved in these differential chromatin-dependent processes are ATM in association with heterochromatic marker proteins like KAP-1 and 53BP-1 and certain types of histones.[110,112]

Radiation-Induced Cell Cycle Delay

It has long been recognized that radiation-induced DNA damage is associated with delay in the cell cycle, which has been interpreted as allowing additional time for the cells to repair. Furthermore, DSBs can be found in all cell cycle phases, suggesting incomplete repair before entering the next phase. For example, tracking of radiation-induced γ H2AX foci, representing DSBs, revealed transfer of DSBs induced in the G1 cell cycle phase to daughter cells.[114]

G1 Phase

The G1 cell cycle checkpoint prevents damaged DNA from being replicated and is the best understood checkpoint in mammalian cells.[115] Radiation-induced G1 phase cell cycle arrest is regulated by p53 (Fig. 2.1). Loss of p53 function, which is found in the majority of tumors, leads to a lack of G1-phase arrest. Instead, these cells exert a dose-dependent blockage in the G2 and M phases of the cell cycle. Central to the G1 checkpoint is the accumulation and activation of the p53 protein, which is controlled by the ATM and ATR kinases. These kinases, together with DNA-PK, are activated by and recruited to radiation-induced DNA lesions. Physiologically, p53 expression levels are low because of interaction with its negative regulator MDM2, which targets p53 for nuclear export and proteasome-mediated degradation in the cytoplasm.[116] Following radiation-induced DNA damage, ATM activates the downstream cell cycle checkpoint kinase Chk2 by phosphorylation, leading to p53 phosphorylation and finally resulting in p53 accumulation. Moreover, ATM exerts p53 stability and thereby prevents p53 nuclear export to the cytoplasm for degradation. P53 target genes include several genes that are involved in the DNA damage response (e.g., MDM2, GADD45a, $p21^{Cip1}$). Accumulation of the cyclin-dependent kinase inhibitor $p21^{Cip1}$ blocks G1/S-phase progression by binding to the cyclinE/cdk2 complex, reducing cdk2 activity, which has an important function in phosphorylation of pRB. The retinoblastoma protein is an important regulator of cell cycling and cell differentiation.[117] Loss of pRB function is often found in malignant cells and leads to an uncontrolled G1/S transition, genomic instability, and loss of differentiation. Hypophosphorylated pRB binds to several proteins, including the E2F transcription factors and histone deacetylases.

S-Phase

After irradiation, the rate of DNA synthesis is decreased via ATM- and NBS1-dependent pathways.[118] Radiation-induced DNA damage activates ATM for Thr68 phosphorylation of Chk2.[119] Activated Chk2 targets CDC25A phosphatase for ubiquitination. As a result, Cdk2/cyclin E and Cdk2/cyclin A complexes remain inactive, which prevents completion of DNA synthesis and G2 entry. Alternatively, radiation-activated ATM phosphorylates several downstream substrates, including BRCA1, NBS1, and SMC1.[119,120] ATR phosphorylates the cell cycle checkpoint kinase Chk1. Subsequently, Chk1 phosphorylates CDC25A, which results in cytoplasmic sequestration and thereby in inhibition of S–G2 transition.[121]

G2 Phase

In contrast to the G1 checkpoint, all mammalian cells, normal or transformed, undergo cell cycle arrest in G2 after radiation-induced damage.[122] The G2 cell cycle checkpoint is the essential final determinant allowing cells to divide. The entry into mitosis is regulated by the activity of the cyclin-dependent kinase Cdk1[123] (Fig. 2.1). Phosphorylation of Cdk1 blocks cell cycling into G2. These phosphorylations are removed by the phosphatase CDC25C. After irradiation, ATR and ATM activate the downstream checkpoint kinases Chk1 and Chk2, which phosphorylate CDC25C.[124] This results in binding of 14-3-3 proteins. The CDC25C/14-3-3 protein complex is translocated into the cytoplasm for sequestration. As a consequence of this CDC25C degradation, Cdk1 remains phosphorylated, thereby preventing entry into mitosis. ATM appears to be more dominant at the early stage of G2/M checkpoint activation, whereas ATR seems to contribute mainly to sustained checkpoint events.[125]

Molecular Targets

Radiation Effects on Signal Transduction

Ionizing radiation affects intracellular signaling.[126] The general mechanisms of radiation-induced signal transduction activation involve the dose-dependent production of ROS and reactive nitrogen species (RNS), which stimulate, for example, cytoplasmic protein kinases, phosphatases, and cell membrane receptors or disturb, for example, lipid and protein metabolism.[127] Many signaling pathways are simultaneously activated in a dose- and cell-type–dependent manner, which may contribute to different radiation responses in different cell types. In addition, distinct radiation qualities such as photons or particles trigger different molecular signaling pathways.

Cooperative and mutual cross talk occurs between parallel and upstream and downstream signaling routes.[128] Examples of important intracellular signaling pathways and their modulation by ionizing radiation are discussed in the following paragraphs.

Receptor tyrosine kinases (RTKs) represent a group of oncogenic, transmembrane receptors consisting, if complete, of an extracellular ligand-binding domain, a transmembrane part, and an intracellular catalytic domain with tyrosine kinase activity.[129] On ligand binding and receptor homo-/heterodimerization, the protein kinase is subsequently activated, resulting in phosphorylation of tyrosine residues of the receptor itself (autophosphorylation) or target proteins. Depending on the cellular context, this triggers an intracellular

signaling cascade that eventually leads to proliferation, survival, differentiation, and migration. Among the known human RTKs are the epidermal growth factor receptors (EGFRs), the platelet-derived growth factor receptors (PDGFRs), the vascular endothelial growth factor receptors (VEGFRs), the fibroblast growth factor receptors, the ephrin receptors, and tyrosine kinase receptor. This RTK signaling involves several distinct molecular pathways that are often deregulated in cancer cells. Prime examples of such deregulated pathways are the Ras–Raf–mitogen-activated protein kinase (MAPK) pathway, the phosphoinositide 3′ kinase (PI3K)/Akt pathway, the Jak/Stat molecules, and protein kinase C. Cooperative and mutual cross talk between the different transduction pathways forms a complex signaling network.

The *EGFR family* consists of four distinct members (EGFR/ErbB-1, HER2/ErbB-2, HER3/ErbB-3, and HER4/ErbB-4) that are dimerized after ligand binding to the extracellular domain.[130,131] The receptor ligands, such as epidermal growth factor (EGF), tumor growth factor-*α* (TGF-*α*), and neuroregulin-1, as well as their cognate receptors, are abundantly expressed in a large variety of human cancers, including lung, breast, head and neck, and gliomas, and have been related to poor prognosis.

The EGFR is being activated through its natural ligands such as EGF, TGF-*α*, or amphiregulin and can be transactivated by cell adhesion molecules such as integrins or immunoglobulin-like receptors.[132] In addition, ionizing radiation is able to stimulate EGFR.[133] Radiation doses of 1 to 2 Gy activate the EGFR and its downstream signaling cascades with similar efficiency as physiologic EGF concentrations of 0.1 to 1 nM. Radiation-dependent production of ROS/RNS seems to play a critical role in EGFR activation and downstream signaling via MAPK.[127,134] It was shown that protein tyrosine phosphatases contain ROS-/RNS-sensitive cysteine residues at a site essential for phosphatase activity. Thus, the radiation-dependent activation of EGFR could be controlled by ROS-/RNS-regulated protein phosphatases. In addition, paracrine and autocrine activation of the EGFR can also result from radiation-induced release of TGF-*α* from irradiated cells or by release of growth factors stored in the extracellular matrix as result of activation of matrix-degrading proteases.[135–137]

EGFR signaling via Ras–Raf–MAPK after irradiation has been implicated in increased proliferation,[138] which corresponds to observations that EGFR overexpression is associated with repopulation during fractionated irradiation.[139–141] In addition, EGFR-dependent signaling via PI3K/Akt has been associated with increased cellular survival and cell cycle progression.[142,143]

After radiation-induced activation, the EGFR is internalized and may function as a nuclear transcription factor.[144] In addition, internalized EGFR can activate DNA-PK that is involved in cell cycle repair (see paragraph “DNA repair”). Pharmacologic inhibitors can block EGFR signaling at different levels and thereby influence several mechanisms of radioresistance, such as DNA repair, repopulation, antiapoptotic signaling, and tumor hypoxia.[24] The specific mutational status of the cells—for example, Ras mutations[136,145]—and the class of drugs[146,147] may modify effects of EGFR inhibition on radiation response. The concept of EGFR inhibition to improve outcome of radiotherapy has been proven in a phase III clinical trial.[23] However, considerable intertumoral heterogeneity has been observed, which is mechanistically only partly understood.[21]

RTK-Initiated Signal Transduction

Ras–Raf signaling

An important signal transduction route within EGFR signaling represents the Ras–Raf–MAPK pathway. The *Ras proteins* (H-Ras, K-Ras4A, K-Ras4B, and N-Ras) are GTPases and are attached in their active state (GTP bound) to the inner surface of the cell membrane. The Ras proto-oncogene, predominantly K-Ras, is mutated in about one-third of human cancers. Activating mutations are frequent in adenocarcinomas of the pancreas (up to 90%), the colorectum (about 50%), and the lung (about 30%).[148] The processing and membrane attachment of the functional Ras are governed by farnesyltransferases, which are the molecular target for specific pharmaceutical inhibitors of activated Ras.[149]

Activated Ras has an effect on various downstream molecules, including *PI3K*.[150] Signaling mediator molecules of PI3K include phosphoinositide-dependent kinase 1, Akt, protein kinase C, and subsequently the nuclear transcription factor NFκB. The cellular responses on activation of the PI3K pathway are cell-type specific and include changes in gene expression, cell cycle progression, survival, and apoptosis. The tumor suppressor protein *PTEN* negatively regulates the PI3K/Akt pathway. Akt overexpression or hyperactivity and PTEN mutations are found in numerous human malignancies.[151]

PDGF-Mediated Signaling

Radiation-induced autocrine and paracrine PDGF signaling plays an important role in fibroblast and endothelial cell activation and proliferation *in vitro*.[152] Combination of irradiation with PGDFR tyrosine kinase inhibitors resulted in

decreased clonogenic survival of endothelial cells and fibroblasts *in vitro*.[152] PDGFR signaling may attenuate development of radiation-induced pulmonary fibrosis.[153]

VEGFR-Mediated Signaling

Transmembrane receptors for VEGF and related ligands include VEGFR-1 (Flt-1), VEGFR-2 (KDR/Flk-1), VEGFR-3 (Flt-4), neuropilin-1, and neuropilin-2.[154] On irradiation, VEGF is up-regulated via the EGFR/STAT signaling and released by tumor cells and exerts, via VEGFR/PI3K/Akt signaling, prosurvival stimuli on tumor and endothelial cells.[155] Up-regulated VEGFR expression has been found after ionizing irradiation.[156,157] Besides normalizing the tumor micromilieu,[158] inhibition of radiation-induced VEGF/VEGFR signaling represents the rationale for combining anti-VEGF strategies with radiotherapy. Besides, targeting immunomodulatory drugs to VEGF have recently been shown to reduce toxicity and increase local tumor control in the preclinical setting.[159]

Cytokine Receptors

A large number of growth-stimulating hormones, growth factors, and cytokines such as the interleukins, erythropoietin, and prolactin bind to the class of cytokine receptors that are structurally different from the previously described RTKs.[160] The intracellular signaling in response to cytokine receptor activation includes the *JAK* and *STAT* kinases. In addition to the cytokine receptors, also, many RTKs can activate the JAK/STAT pathway. In malignant cells, the autonomy of growth signaling can be associated with mutations in cytokine receptors (e.g., in the erythropoietin receptor) and constitutively up-regulated activity of the JAK/STAT pathway. Cancer cells can also evade drug-induced cell death by the secretion of cytokines leading to autocrine receptor stimulation.[161]

Wnt Signaling

Wnt proteins are diffusible growth factors that bind to specific surface receptors (Frizzled) and trigger distinct intracellular pathways leading to cell growth.[162] Wnt signaling involves the tumor suppressor protein adenomatous polyposis coli (*APC*) and regulates by phosphorylation the steady-state levels of cytosolic β-catenin. An increased level of β-catenin facilitates its transit into the nucleus, activation of transcription factors, and subsequently transcription of β-catenin target genes, including *MYC*, *JUN*, *CCND1*, and *ALDH1A1*.[163,164] The aberrant activation of Wnt signaling caused by mutations in the β-catenin and APC genes

are typical findings in colon cancer and melanoma but also have been identified in a large variety of other human cancers. Wnt signaling has been shown to play an important role in tumorigenesis and in CSC self-renewal and differentiation and thus provides a promising target for anticancer treatment.[165,166]

Integrin-Mediated Signaling

Cross talk between tumor cells and tumor stroma emerges as an important determinant for tumor response to radiation and as a potential target for novel therapeutic combinations. Interactions between cells and ECM proteins are facilitated mainly by the integrin family of cell adhesion molecules.[167] Besides the influence of growth factors and cytokines, the cells' adhesion resistome adds further facets to the network of microenvironmental factors that modulate the cellular behavior on exposure to ionizing radiation.[168] Chemotherapeutic compounds, molecular-targeted compounds, and ionizing radiation showed less cytotoxic efficacy in cells adherent to ECM compared to cells growing in suspension or on plastic surfaces.[169] Resistance-promoting effects by integrin-mediated adhesion to ECM were found in cell lines from solid tumors of the lung,[170,171] breast,[172] liver,[173] colon,[174] pancreas,[169,175,176] ovary,[177] prostate,[178] brain,[179] and leukemia cells.[180] Certain integrins seem to communicate increased radiation and drug resistance, which is cooperatively influenced by RTKs like EGFR.[181,182] For example, $\alpha 5\beta 1$ integrin, the "classic" fibronectin receptor, acts as a major antagonist of cell death induced by doxorubicin or melphalan in multiple myeloma,[183] by paclitaxel in breast cancer or small cell and non–small cell lung cancer,[184,185] or by cisplatin or mitomycin C in non–small cell lung cancer.[184] Additional studies underscored the important role of $\beta 1$ integrins in promoting resistance against ionizing radiation.[186,187] Further regulatory cytoplasmic cascades downstream of $\beta 1$ integrins that exert survival advantage on treatment with genotoxic agents include regulation of the Akt1/FoxO cascade and the antiapoptotic Bcl-2–like proteins or Bcl-2/Bax.[180] In addition to regulating cell survival, cell–matrix interactions affect radiation-induced cell cycle arrest, that is, adhesion of cells to matrix proteins prolongs the G1 and G2 cell cycle blockage in parallel with enhanced activation of DNA repair pathways involving the checkpoint kinases Chk1, Chk2, and Cdk1, p53, and diverse cyclins.[184,188–190]

Following radiation exposure, the expression of several integrin subunits, including $\beta 1$, $\beta 3$, $\alpha 5$, and αv, is up-regulated in human skin and lung fibroblasts,[169] endothelial cells, and keratinocytes,[191] as well as in tumor cells of

the colon,[174] hematopoietic cells,[192] prostate,[193] lung,[194] brain,[195] and melanomas.[169] Generally, integrin-mediated adhesion to matrix proteins confers chemoresistance and radioresistance.[180,181,196,197]

Nonreceptor Kinases

Cytoplasmic, nonreceptor kinases are often activated in malignant disease. For example, the *Bcr/Abl* fusion protein kinase is a typical molecular finding in chronic myeloid leukemia and represents the molecular target for small molecule inhibitors such as imatinib.[198] This drug also inhibits KIT, a cytoplasmic tyrosine kinase, that has been shown to be activated by mutation in gastrointestinal stroma tumors, thus providing another molecular targeting approach.[199,200]

Transcription Factors

Transcription factors bind to the DNA and activate the expression of specific genes. Oncogenic transcription factors are overactive in most human cancers and contribute to the autonomy of growth signaling. Based on their mechanism of activation, three groups can be separated.[201] First are the *steroid receptors*, which are found in hormone-sensitive breast or prostate cancer. The second group of transcription factors resides in the nucleus, is governed by kinase signals, and consists of various members, including *myc*, *activator protein 1* (AP-1), and *E2F.* Myc transcription factors are induced in cancer by different mechanisms, including translocation and gene amplification. For example, c-myc is activated by the chromosomal translocation t(8;14), which results in a constitutive c-myc expression in 80% of Burkitt lymphomas. N-myc and L-myc amplifications are found in neuroblastoma and small cell lung cancer, respectively. AP-1, consisting of *JUN*, *FOS*, *ATF*, and *MAF*, can exhibit oncogenic or antioncogenic effects depending on the cellular context.[202] The third group of oncogenic transcription factors—the latent transcription factors—is activated by ligand–receptor interactions and includes the STATs (see previous discussion), the WNT–β-catenin pathway (see previous discussion), NFκB, and the stemness-related molecules Notch and Hedgehog. NFκB levels have been shown to be constitutively active in lymphomas, leukemias, and breast and colon cancer.[201]

Cancer Stem Cells

As described above, malignant tumors are composed of genetically and phenotypically heterogeneous cells in various differentiation states. Within this

pool, CSCs are considered as the major cell population responsible for tumor initiation, growth, and relapse as well as for metastasis formation and therapy resistance.[203] Evidence shows that CSCs, which comprise a rather small fraction of the tumor mass, are often stunningly resistant to cytotoxic therapies as compared to the bulk tumor cells.[204] Therefore, the reduction of tumor mass is not an adequate measure of therapy success.[18] The identification of CSC populations within a tumor represents a promising strategy for prognosis, prediction, and also targeting of aggressive tumors (also see paragraph on "Molecular stratification in personalized radiotherapy"). However, identification and targeting of CSC is challenged by the high inter- and intratumoral diversity of different putative stem cell populations and CSC plasticity during cancer evolution and treatment. The CSC phenotype does not describe a static subpopulation but rather a highly dynamic intrinsic property of a tumor cell. This means that the CSC pool might be re-established by non-CSC tumor mass cells, and cancer therapy can only be effective when eradicating both tumor mass and CSC simultaneously.[205]

Targeting the signaling axes of CSC alone and in combination with cytotoxic drugs and/or radiotherapy is one approach. Those CSC signaling pathways often shared with normal stem cells include Notch, Hedgehog, and Wnt/β-catenin signaling.[206] Activated Wnt/β-catenin signaling, for instance, is one of the key pathways during embryonic development and is described for carcinogenesis, EMT, and radiation resistance. One target comprises the Wnt receptor Frizzled by blocking the association of Wnt with its receptor. First clinical studies with such an inhibitor ipafricept (FZD8-Fc, *OMP-54F28*) were just completed (clinicaltrials.gov, NCT01608867, NCT01345201). Another promising example for CSC signaling pathway targeting is the small molecule MK0752 that inhibits the Notch signaling pathway and is currently tested for treatment of advanced breast and pancreatic cancer (NCT00106145, NCT01098344). The combination of cytotoxic drugs with CSC inhibitors is tested for advanced stage small cell lung carcinoma and recurrent small cell lung carcinoma by using cisplatin and etoposide in combination with the Hedgehog inhibitor GDC-0449 (NCT00887159).

Metastatic spread is caused by disseminated tumor cells with CSC characteristics that leave the primary tumor and settle and grow at distant for them hostile places in the body. The transport phase of those cells, then called circulating tumor cells (CTCs), through the blood system represents another attractive diagnostic and therapeutic target. However, there is no standard

definition of those CTC. To date, the magnetic bead–mediated CELLSEARCH system is the only FDA-approved method for the enrichment of epithelial cell adhesion molecule (EpCAM) expressing CTCs. Counts of EpCAM-positive cells show significant prognostic relevance for breast and prostate cancer patients.[207,208] Further biomarkers for the identification of CTCs are currently under investigation.

The CSC niche as a tumor-supporting microenvironment resembles another potential target for anti-CSC therapies. The niche maintains and sustains CSCs and orchestrates their fate decisions via extracellular matrix molecules (ECM), cell-to-cell contacts, pH value, vascularization, hypoxia, etc., that may induce for instance stem cell–related signaling cascades.[36] Thereby, the niche also provides a protective microenvironment for CSCs; for example, hypoxia can induce quiescence of the cells.[42] Thus, the cells escape chemotherapy, which mainly attacks rapidly proliferating cells. However, the ECM and their cognate receptors on the CSC surface represent potential drugable targets. The CSC metabolism, in parts intrinsically regulated also dependents on the microenvironment and the given nutrition supply, comprises a targetable CSC feature.

Epigenetics

Accumulating evidence suggests that a variety of epigenetic mechanisms contribute to tumor heterogeneity and to the initiation and maintenance of CSC traits. Per definition, epigenetics defines stable heritable changes in gene expression that are not caused by changes in the underlying DNA sequence.[34] Chromatin and histone modifications and DNA methylation are epigenetic key mechanisms that are influenced by cancer risk factors such as chronic inflammation, aging, and environmental changes. Replication of DNA methylation is highly error prone, and it is contemplated that not only genomic but also epigenetic instability drives tumorigenesis and heterogeneity.[63,209,210] Epigenetic alterations can silence or activate genes and thereby offer tumor cells two possible choices to rapidly evolve under therapy pressure, which can lead to therapy resistance and tumor relapse.[34] Epigenetic therapeutics can reverse those epigenetic changes and resensitize tumor cells. Epigenetic drugs such as enhancer of zeste homolog 2 (EZH2), isocitrate dehydrogenase (IDH), and bromodomain and extraterminal (BET) inhibitors are currently under investigation in clinical trials.[211] IDH1 mutations lead to DNA and histone hypermethylation. The IDH1 R132 mutation is of special interest as it may also serve as so-called neoantigen (*vide infra*). Peptide vaccines that capture this

mutated region are currently under development and testing.[212] Epigenetic changes such as the IDH1 R132 mutation can directly affect tumor immune evasion because DNA hypermethylation and promoter methylation can regulate the expression of cancer antigens and foster the evolvement of neoantigens. Therefore, epigenetic inhibitors also play an important role in immunotargeting.

Antitumor Immunity

Mutagenesis as well as genomic and epigenomic instability in the tumor can lead to the expression of tumor-specific mutant proteins (neoantigens) that are not present on normal cells.[213] Neoantigens are short peptides expressed on the tumor cell surface and thereby become recognizable to T cells as foreign antigen. Because of their tumor-selective expression, those neoantigens resemble attractive immune targets with minimal risk of autoimmunity and immunotolerance. Also, virus antigens expressed by tumors with a viral etiology (such as HPV-caused cancers of the cervix and the oropharynx) are representing an example of neoantigens. However, neoantigens arise in most cases from unique mutations, which complicates identification and needs individualized targeted immunotherapy. Current advancements in proteomics, genomics, and sequencing coupled with epitope prediction algorithms will speed up the future development of such therapy approaches. The development of immune checkpoint inhibitors targeting cytotoxic T-lymphocyte–associated protein 4 (CTL4) and programmed cell death protein 1 (PD1) was recently shown to provide clinical benefit in melanoma[214] and non–small cell lung cancer and is expected to be efficient in subsets of a wide variety of tumor entities.[215] Also, antibody-based therapies, including engineered bispecific T cells and chimeric antigen receptor (CAR) T cells, have been shown to be therapeutically active in several cancers, for example, leukemia.[216,217]

Human Papillomavirus

Oncogenic viruses such as the HPV are contributing to carcinogenesis and are driving malignant progression. Papillomaviruses are small, nonenveloped, double-stranded circular DNA viruses. To date, more than 200 HPV genotypes have been identified, including low-risk and high-risk subtypes.[218] Especially the high-risk subtypes HPV16 and HPV18 are known to cause a variety of carcinomas such as cervical cancer, oropharyngeal cancer, and anal cancer. In contrast to most viral infections, where virions are produced directly in the target cell, the syntheses of new HPV virions occur only after the target cell has

undergone mitosis, followed by differentiation of one of its daughter cell.[219] HPV infects proliferating cells in the basal layer of stratified squamous epithelia following microtrauma and leads to the establishment of the HPV genome as extrachromosomal elements or episomes. Because these HPV genomes do not contain enzymes for viral replication, they depend on the DNA replication machinery of their host to mediate viral DNA synthesis.[220] Also after undergoing differentiation, virus-infected cells are remaining active in the cell cycle. In the suprabasal layers, some cells are still able to re-enter the S-phase in order to replicate HPV genomes and synthesize virions. When the epithelial cells are reaching the outer layer, the HPV virions are released.[219]

The proliferation of HPV-infected epithelial cells is independent from cellular differentiation. The HPV E7 oncoprotein binds to proteins of the Rb family and targets them for degradation. This leads consequently to the release and activation of the E2 transcription factors (E2F), which are driving the expression of S-phase genes and thereby initiating cell cycle progression.[221] The Rb-E2F protein normally acts via a negative feedback loop and inhibits gene transcription of CDKN2A, which encodes for p16. In contrast, the functional inactivation of the pRb pathway by the HPV E7 oncoprotein leads to loss of this negative feedback loop and thus to p16 overexpression[222] (Fig. 2.6).

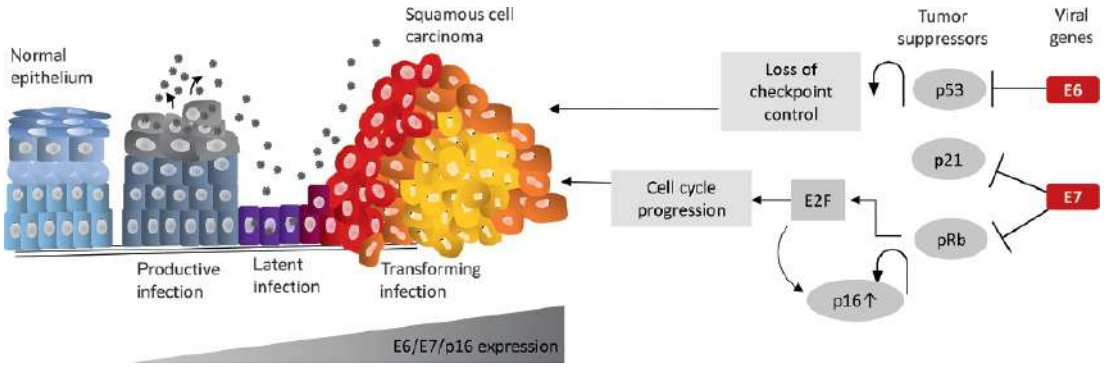

FIGURE 2.6. Human papillomavirus (HPV) infection and activation: Microtraumas allow the entrance of HPVs to the epithelial basal cell layer. This is followed by the coordinate expression of different viral genes. E6/E7 cause viral genome amplification and shedding of the newly produced viral particles. Persistent expression can lead to malignant dysplasia, once the HPV infection is established and evaded from immune recognition. Malignant transformation is characterized by loss of differentiation, high E6/E7 level, and no viral replication. The expression of the viral genes E6 and E7 inhibit the expression of the tumor suppressor genes p21, pRb, and p53, respectively. E6-triggered inhibition of the tumor suppressors p53 and p21 leads to loss of checkpoint control and with this to uncontrolled growth of squamous carcinoma cells. The E7 oncoprotein inactivates pRb, the effector protein of p16, via pRb/E2F degradation. This results in overexpression of p16 and cell cycle progression.

It is important to note that especially HPV E7 oncoprotein of high-risk HPV subtypes is binding strongly to the members of the Rb family. This efficient binding would then lead to the inhibition of cell growth and to apoptosis, via p53. To overcome this, the HPV oncoprotein E6 initiates ubiquitination and subsequent degradation of the p53 protein including disruption of the p53 pathway. The loss of the tumor suppressor gene p53 leads to defective control at the G1/S and G2/M checkpoints and subsequently to uncontrolled cell cycle progression.[223]

HPV-driven head and neck squamous cell carcinoma (HNSCC) are more radiosensitive than non–HPV-driven carcinoma, which is due to their cell cycle dysregulation (*vide supra*) including impaired DNA DSB repair capacity.[224]

Radiation-Induced Gene Expression

Radiation may significantly modify gene expression.[225] Many of the transcriptionally activated proteins have been shown to be centrally involved in the pathogenesis of radiation damage or to modulate the effect of radiation on tumor cells. Early responses may occur within hours after irradiation and involve mostly transcription factors such as the proto-oncogenes *JUN*, *FOS*, *JUNB*, and early growth response gene 1 (*EGR1*).[226] Sustained activation of early radiation response genes such as NFκB may contribute to late radiation damage.[227] Other examples of radiation-induced genes that may occur early and/or late after irradiation include TGF-β, TNF-α, bFGF, PDGF, and interleukin-1 (IL-1).[228]

Gene expression and DNA-binding activity of *NFκ B* are induced soon after ionizing radiation.[229] NFκB is a sequence-specific DNA-binding protein complex that binds to DNA as a dimer. According to its multiple functions, NFκB can also be activated by a variety of agents, like membrane receptors such as TNFR or toll-like receptors and oxidative stress. Radiation-induced activation of NFκB is mediated by IKK.[230] This response does not depend on a nuclear signal, as it also occurs in enucleated cells.[231] However, it has been shown that ATM is required for chronic activation of the transcription factor NFκB.[232] NFκB acts in an antiapoptotic way and mediates radioresistance.[233]

Radiation exposure induces immediate and sustained *TGFβ1* gene expression, as well as activation of this cytokine.[234] On transcriptional activation, TGF-β is produced as an inactive latent form and secreted. Latent TGF-β is stored in the extracellular matrix and proteolytically activated in irradiated tissues.[235] Active TGF-β1 binds and activates the TGF-β1 type I receptor, resulting in TGF-β1–dependent gene expression, inducing, for example, p21, p27, collagen, and tissue

inhibitors of metalloproteinase (TIMP).[15,236] This is most likely responsible for the cellular effects of TGF-*β*, such as modulation of proliferation, differentiation, and radiation sensitivity of fibroblasts, and for the biochemical events (e.g., collagen deposition, characteristic of radiation-induced fibrosis). In addition, TGF-*β* secreted by tumor cells on irradiation contributes to the development of radiation-induced fibrosis[237]. Intervention of TGF-*β*–mediated effects (e.g., by TGF-*β*1–neutralizing antibodies and superoxide dismutase) offers a promising strategy to prevent radiation-induced fibrosis. Moreover, a recent preclinical study showed that combined inhibition of TGF-*β* and PDGF with small molecules is a promising approach in diminishing radiation-induced lung toxicity.[238] Aside from fibrosis, TGF-*β* has been demonstrated to reduce latency, promote aggressive tumor growth, and increase estrogen receptor–negative breast cancers.[239] Moreover, the radiosensitivity of cancer cells can be enhanced by TGF-*β*–directed treatments.[240,241]

TNF-α belongs to the group of proinflammatory cytokines involved in radiation-induced normal tissue damage, such as pneumonitis and lung fibrosis. Immediately after irradiation, TNF-*α* is transcriptionally up-regulated and released by the bronchiolar epithelium. TNF-*α* enhances phagocytosis and cytotoxicity by neutrophilic granulocytes and modulates the expression of other cytokines such as IL-1 and IL-6.[242] Experimental data show that also tumor lines, particularly pediatric sarcomas, may produce large quantities of bioactive TNF-*α* after irradiation, which is of potential importance for tumor response and for normal tissue reactions after radiotherapy.[243]

Tracking of genetic changes during and after ionizing radiation will further elucidate the molecular and basic impact of how cancer and normal cells respond to radiation and may serve as predictors for therapy response.

Genome Instability and Mutation

Cells may survive radiation despite unrepaired or misrepaired DNA damage, that is, with mutations or chromosomal aberrations. These may remain silent or result in radiation-related secondary primary cancers or, as germline mutations, cause hereditary disease.[244–246] In addition to directly induced mutations, radiation may induce a heritable, genome-wide process of instability (i.e., genomic instability) that leads to an enhanced frequency of genetic changes occurring among the progeny of the original irradiated cell, which is transmissible over many generations of cell replication.[247] Whereas most mutations induced directly by radiation involve loss of large parts of the tested gene, leading to a

loss of heterozygosity, most mutations resulting from radiation-induced genomic instability involve point mutations and small deletions.[247,248] While some studies, particularly on thyroid cancer in children after the Chernobyl fallout, suggest a nonrandom pattern of chromosomal damage, generally no fingerprint alterations have been identified that would unequivocally indicate radiation-induced cancer.[246]

Radiation exposure induces immediate and sustained *TGF-β1* gene expression, as well as activation of this cytokine.[234] On transcriptional activation, TGF-*β* is produced as an inactive latent form and secreted. Latent TGF-*β* is stored in the extracellular matrix and proteolytically activated in irradiated tissues.[235] Active TGF-*β*1 binds and activates the TGF-*β*1 type I receptor, resulting in TGF-*β*1–dependent gene expression, inducing, for example, p21, p27, collagen, and TIMP.[15,236] This is most likely responsible for the cellular effects of TGF-*β*, such as modulation of proliferation, differentiation, and radiation sensitivity of fibroblasts, and for the biochemical events (e.g., collagen deposition, characteristic of radiation-induced fibrosis). In addition, TGF-*β* secreted by tumor cells on irradiation might contribute to the development of radiation-induced fibrosis.[237] Intervention of TGF-*β*–mediated effects (e.g., by TGF-*β*1–neutralizing antibodies and superoxide dismutase) offers a promising strategy to prevent radiation-induced fibrosis. Aside from fibrosis, TGF-*β* has been demonstrated to reduce latency, promote aggressive tumor growth, and increase estrogen receptor–negative breast cancers.[239] Moreover, the radiosensitivity of cancer cells can be enhanced by TGF-*β*–directed treatments.

TNF-α belongs to the group of proinflammatory cytokines involved in radiation-induced normal tissue damage, such as pneumonitis and lung fibrosis. Immediately after irradiation, TNF-*α* is transcriptionally up-regulated and released by the bronchiolar epithelium. TNF-*α* enhances phagocytosis and cytotoxicity by neutrophilic granulocytes and modulates the expression of other cytokines such as IL-1 and IL-6.[242] Experimental data show that also tumor lines, particularly pediatric sarcomas, may produce large quantities of bioactive TNF-*α* after irradiation. This may be of potential importance for tumor response and for normal tissue reactions after radiotherapy.[243]

Induction of genes by ionizing radiation has been experimentally exploited for therapy. For example, the early-response gene *EGR1* was inserted upstream to TNF-*α*, which may act as a radiosensitizer. This provides a strategy for spatial and temporal control of the biologic effect by radiotherapy.[225,249]

Molecular Stratification Toward Personalized Radiotherapy

The treatment decision for patients with malignant tumors is clinically based on anatomical location and histopathologic features. To verify the anatomic extent of the disease, the TNM classification has been introduced, which considers the size of the primary tumor, the lymphatic spread (lymph node metastases), as well as distant metastases. The cell type and histopathologic features are being assessed based on the WHO classification. With recent advances in molecular pathology, implementation of DNA or RNA sequencing of cancer and normal tissue genomes, and biologic imaging techniques, a better understanding of the tumor and radiation biology is being gained and is leading toward molecular subclassification of tumors and, thus, to molecular stratification of patients along with clinically established biomarkers.

In patients with HNSCC and specifically in those with oropharyngeal carcinomas, the HPV infection status has been found to be associated with improved prognosis. Preclinical studies showed that HPV infection leads to increased radiosensitivity in HNSCC cell lines.[224,250] A prospective multicenter study including patients with HNSCC who received radiotherapy alone revealed that the HPV status is a strong independent parameter for locoregional tumor control, disease-specific survival, and overall survival.[251] A retrospective multicenter study showed that patients with locally advanced HNSCC who received postoperative or primary radiochemotherapy could be stratified according to their HPV status.[252,253] After postoperative radiochemotherapy, patients with HPV-positive HNSCC showed an excellent locoregional control of nearly 100%,[252] suggesting that these patients may benefit from de-escalation therapy, for example, by reducing the radiation dose. Such a de-escalation strategy is expected to reduce radiation-induced side effects while achieving an unchanged tumor control probability and is being currently tested in clinical trials. Patients with HPV-negative tumors could be further stratified by CSC marker expression as well as tumor hypoxia, which is in line with radiobiologic knowledge. Patients with HPV-negative, low hypoxic, and low CSC marker–expressing tumors also showed a superior locoregional control, whereas patients with hypoxic, CSC marker–overexpressing tumors showed a poor locoregional control and might benefit from intensified therapy regimens.[254] In contrast to the patients receiving postoperative radiochemotherapy, where only a few remaining tumor cells may have been left, the tumor volume is an important parameter for patients who are undergoing primary radiochemotherapy. The tumor volume is associated with the CSC number and is therefore important for local control.

CSC marker expression reflecting CSC density varies widely between different tumors and can further enhance the powerful predictor tumor volume. Also, patients receiving primary radiochemotherapy could be stratified for their risk of locoregional failure based on their HPV status, tumor hypoxia, and CSC marker expression levels within the tumors.[253]

An important issue in research on biomarkers for radiotherapy is that parameters reflecting tumor response may change during treatment. For example, hypoxic tumors may reoxygenate during treatment, and it has been demonstrated that this is associated with improved local control compared to tumors with residual hypoxia.[255] Therefore, more extensive investigation into biomarker dynamics, by imaging, repeat tumor biopsies, or liquid biopsies, appears promising to improve their predictive value.

The identification of predictive biomarkers for the development of normal tissue toxicity in the individual patient is also a relevant issue in terms of personalized radiotherapy. It is well recognized that the degree of radiation-related toxicity varies between patients, which may be partly due to genotypic variation. The study of germ-line genotypic variations and the large clinical variability associated with the response to radiotherapy is also termed *radiogenomics*.[256] The overall aim of radiogenomics is to identify patients with common genetic variants who are very likely to develop normal tissue toxicity following radiotherapy. A recent meta-analysis of genome-wide association studies in prostate cancer identified two SNPs, which are associated with late toxicity following radiotherapy in patients with prostate cancer: rs17599026 on 5q31.2 with urinary frequency and rs7720298 on 5p15.2 with decreased urine stream.[257]

CHAPTER 3

Biologic Basis of Radiation Therapy*

William H. McBride, H. Rodney Withers, and Dörthe Schaue

INTRODUCTION

Clinically Relevant Physicochemical Events

Ionizing radiation (IR) interacts with biologic matter in many different ways, but in essence, high-energy photons produce electrons that directly ionize atoms and can break chemical bonds. Subsequently, free radical and other reactive species are generated whose actions can be heavily influenced by the intracellular milieu. For low linear energy transfer (LET) x- or γ-rays, there is about 1,000 ionization tracks per gray (Gy), and most of the free radicals, such as hydroxyls, singlet oxygen, superoxide, and hydrogen peroxide, come from ionization of water, a cell's major (about 90%) constituent. These oxygen-containing molecules are often collectively, although not totally accurately, referred to as reactive oxygen species (ROS) and have half-times generally of <1 ms. They cause oxidative damage by virtue of their unpaired valence shell electrons and are particularly relevant for low LET radiation (perhaps 70%). This indirect mechanism has numerous implications for the biologic effects of radiation therapy (RT) and is a major reason why biologic dose differs from physical dose. The type (quality) of radiation also determines the biologic effect. For all IRs, the density is especially high at the end of the electron tracks, but for high LET radiations, such as α-particles, ionization is dense all along and close to tracks, which number about 4 per Gy. As a result, more energy is deposited directly in biologic molecules, resulting in more direct than indirect damage.

The interaction between free radicals and the biologic microenvironment is complex but critical for the outcome of RT. Oxygen, and other electron affinic molecules,[1] participates in free radical cascadic reactions, but probably, its major effect is to "fix" chemical damage within biologic molecules, limiting their chemical repair. Oxygen is therefore a potent radiosensitizer, whereas hypoxia limits radiation damage and is a possible cause of failure of cancer RT.

Considerable effort has gone into the search for oxygen-mimetic drugs that might penetrate tumor hypoxic regions and radiosensitize tumors. Some, such as the imidazoles, have been used successfully in the context of RT and for imaging hypoxia. Conversely, antioxidants such as glutathione, which is present in millimolar amounts in cells, protect cells by scavenging free radicals.

In general, IR is an oxidative stress forming numerous oxidative adducts, lowering antioxidant levels, and changing redox status. Numerous redox-sensing proteins are altered with biologic consequences. For example, Keap1 controls transcriptional activation of the nuclear factor (erythroid-derived)-like 2, also known as NFE2L2 or Nrf2. This pathway is highly dysregulated in several human cancers, most notably non–small cell lung cancer,[2] and strongly impacts cellular anabolic metabolism, tumor aggression, and response to IR.[3] Cell lineages also vary naturally in these pathways. For example, quiescent stem cells generally have high levels of free radical scavengers and antioxidants that confer relative radioresistance.[4]

The first wave of radiation-induced free radicals is amplified by further oxidative stress reactions that generate more ROS/RNS (reactive nitrogen species). One outcome is inflammation that plays a major role in physiologic and pathologic events, causing cell death, perpetuating damage, and producing even more ROS/RNS from biologic sources, most notably mitochondria, activated cation membrane channels, NADPH and other oxidases, and nitric oxide synthase induction. Radiation-induced inflammation in the form of skin burns was the earliest radiobiologic observation. Recently, interest has been revived in radiation-induced inflammation because of radiation-induced vascular changes, bystander effects, and immune cell infiltration into normal tissues and tumors. As early as 1916, roentgenologists were asking, “is the effect of radiation merely the result of the reaction between the rays and the cells they happen to hit, or do the rays in some way exert an indirect action over the entire organism.” It was concluded that the systemic effects of radiation were important in RT and attributable in part to “radiovaccination,” that is, systemic immune activation.[5] These concepts were swamped by mathematical models relating dose to direct target killing, only to be recently resurrected.[6]

DNA as a Biologic Target in RT

All cellular organelles are damaged by IR, but the biggest footprint relevant to RT is in DNA. Complex or clustered DNA double-strand breaks (DSBs), also referred to as multiply damaged sites, are most significant for radiation lethality

and carcinogenesis, as opposed to “simple” DSBs and other forms of damage. These form in both cycling and noncycling cells as multiple lesions involving 15 to 20 base pairs clustered within about 1 helical turn of the DNA. They are a direct consequence of the characteristic and unique way that IR spatially deposits energy in dense “packets” and are the reason why IR is a powerful cytotoxic therapy. Low LET IR generates about 30% of DNA DSBs of this form, whereas for α-particles, it is >90%. By way of contrast, few complex lesions result from everyday, “natural” oxidative and chemical DNA damage. As many as 70,000 DNA lesions are produced per cell per day, mainly as single-strand break (SSB) and base damage that are readily repaired, although one study estimates that about 1% of such lesions are converted into DSBs as they encounter replicative DNA polymerase, forming 50 DSBs every cell cycle that may have larger consequences.[7]

Safeguarding the integrity of DNA is a biologic imperative that is achieved through highly efficient DNA repair mechanisms, each with a focus on a type of DNA lesion. The mechanisms are discussed in more detail in Chapter 2, but defective DNA repair mechanisms can account for many differences in the response to cancer RT. The two major DSB repair pathways are nonhomologous end joining (NHEJ), which is error prone, efficient, and not cell cycle phase specific, and homologous recombination (HR), which operates only in late S/G2 cell cycle phase, uses the sister chromatid as a template, and has slow kinetics. These have different functions and have been honed by evolution to deal with physiologic DSBs produced during meiosis (HR), DNA replication (HR), and the generation of specific immune receptors (NHEJ). The key proteins required for both NHEJ (Ku70, Ku80, DNA-PKcs, XRCC4, XLF, DNA ligase IV) and HR (Rad51, Rad52, Rad54, BRCA2, RPA) have been identified by a combination of genetic experiments and the use of fluorescent antibodies to examine the composition of IR-induced foci (IRIF) that form at sites of DSBs. The proteins MRE11, Rad50, and NBS1 act as a complex (MRSN) and participate in both HR and NHEJ. Simpler DNA SSBs and base damages formed by IR (1,000 per cell per Gy) are rapidly repaired largely by base excision repair (BER).

DNA repair mechanisms face considerable challenges partly because of diversity of the lesions. Complex DNA damage is especially difficult and slow to resolve, whereas repair in heterochromatin is slower than in euchromatin. Further, SSBs may be converted into DSBs at replication forks, making BER relevant to RT outcome in cycling cells. One consequence of this diversity is that

the time taken for DNA repair varies substantially. “Fast” and “slow” components are a minimum consideration, with the latter having estimated half-lives of up to 4 hours and with “residual” unrepaired DNA damage often being most relevant to outcome. Estimates of “repair” rates within a tissue are therefore very uncertain. Note that when clinical fractionated treatments are discussed, the interfraction time interval left to allow “repair” really refers to tissue recovery rather than DNA repair *per se*.

The way cells respond to DNA damage is very important in RT. In general terms, DNA damage is recognized by “sensor” molecules that activate “transducer” protein kinase cascades to trigger downstream effectors of the DNA damage response (DDR). The protein mutated in ataxia telangiectasia (ATM) is one such sensor, whose loss results in extreme radiosensitivity and a complex human syndrome. Another sensor is ATR (ataxia telangiectasia and Rad3-related) that recognizes and repairs DNA replication complexes that have stalled at sites of DNA damage. IRIF form at DNA DSBs and signal the initiation of the DDR. IRIF are complex in composition and number depending on, for example, whether the DSB is in euchromatin or heterochromatin and the cell cycle phase irradiated.

In one early IRIF event, histone 2A subtype, H2AX, is phosphorylated by one of several phosphoinositol 3-kinase–related protein kinases (PIKKs), such as the ATM, DNA-PK, and ATR. The resulting gamma-H2AX molecules bind to DSB over several megabases along the flanking chromatin and can easily be detected using specific antibody. This highly sensitive assay has become the popular way to measure DSB formation and repair.[8] The histone provides interaction surfaces for IRIFs enrolling repair and checkpoint molecules to activate further kinase-dependent pathways leading to coherent downstream DDRs. The classic DDR pathway, which is a hallmark of radiation damage, is through ATM, which then phosphorylates various downstream substrates, including p53, the checkpoint kinase CHK2, p21, BRCA1, NBS1, and Bak and Bax to effect DNA repair, cell cycle progression, and cell death by apoptosis. Not surprisingly, defects in molecules in DDR and DNA repair, especially HR, are major causes of impaired IR-induced G_1-S, intra-S, and G_2-M cell cycle checkpoints, as well as radiosensitivity, genomic instability, increased mutational load, chromosomal abnormalities, and cancer predisposition, and are targets for therapeutic intervention.

The cell cycle phase restriction of HR repair to S and G2 has ramifications for cancer biology and treatment. Those chemotherapies that target proliferating

cells will engage HR, which may be especially critical for chemo-RT combinations. Also, mutations in the BRCA1 or BRCA2 tumor suppressor genes compromise the ability of cells to perform HR and makes them especially sensitive to PARP-1 inhibitors, which block BER. This process, where a failure in either of two genes is not lethal but failure of both results in cell death, is known as synthetic lethality. DNA repair can therefore provide opportunities for therapeutic intervention, for example, targeting HR through iPARP or iATR with RT.[9]

Finally, DNA DSBs breaks may rejoin to form chromosome/chromatid aberrations, and their frequency can serve as an indicator of radiation dose received. Lesions take many forms, but deletions can result in acentric fragments (chromosome fragments lacking a centromere) and micronuclei or chromosomes that have difficulty migrating with the rest during anaphase and yet may persist through several divisions. The relevance of DNA fragments to cell signaling is discussed later. Exchanges can form symmetric translocation or inversions, or dicentrics or rings. The latter are generally lethal, whereas inversions are one of the mutational signatures of radiation-induced cancers.[10]

Radiation-Induced Cell Signaling

IR directly damages cellular structures other than DNA that rapidly trigger primary genetic programs (also known as immediate early response) in the absence of *de novo* protein synthesis. These evolve along with DDR pathways into more restricted secondary gene programs. The doses and times at which these different pathways “kick in” to trigger their downstream effects after RT are not well known, but they form an integral part of the overall response to IR.

Redox changes are one way primary programs can be generated, but are complex, for example, low ROS levels can activate molecular responses, whereas high levels can cause cell death. Redox changes can also activate transcriptional programs. In addition to Nrf2 mentioned earlier, NF-κB, AP-1, HIF-1α, PPARγ, p53, Sp1, c-abl, and STAT3 are redox sensitive, as are phosphatases that control activation of various pathways, for example, through epidermal growth factor receptor (EGFR).

One result of this signaling is the production of proinflammatory cytokines, such as members of the tumor necrosis factor (TNF) family (e.g., TNF-α, fasL, Trail), interleukin-1, type I interferons, etc. These can be induced through ROS/DDR p53–mediated pathways, or through activation of early growth response gene 1 (EGR1), or through pattern recognition receptors (PRRs)—a

system for innate immune recognition of pathogen- and damage-associated molecular patterns (PAMPs and DAMPs).[11,12] RT releases numerous DAMPs to trigger PPR signaling, but the radiation-induced micronuclei and cytoplasmic DNA fragments, most likely left behind at mitosis, are of particular interest. The sensor is cyclic GMP-AMP (cGAMP) synthase (cGAS) that produces cGAMP upon activation and, with the adaptor molecule STING, triggers IRF3, STAT6, and NF-κB pathways to produce type 1 interferon, IL-6, and TNF family members, respectively. The cGAS-STING pathway also assists in the generation of tumor-specific CD8-mediated immunity. Interestingly, high single radiation doses, through nuclease controls, seem less effective than moderate fractionated doses at generating these responses.[13] Activation of this pathway is probably modified by proliferative status and/or mode of cell death and is likely to be more important days after exposure, whereas immediate early pathway responses are initiated within minutes to hours. The cGAS-STING pathway also responds to intracellular pathogens leading to potent immune activation, so it is not surprising that aberrant activation by self DNA can lead to autoimmune and inflammatory disease. Inflammation is therefore tightly integrated within responses to RT at multiple different levels. For example, TNF molecules may be on the cell surface or released, the latter contributing to mechanisms of IR-induced bystander effects; the former may be more involved in cell death, vascular responses, and proliferative responses to RT.[14] It is worth noting that some clinical symptoms are probably because of radiation-induced TNF-α and other proinflammatory cytokines rather than cell death, for example, nausea or vomiting within hours of RT involving the upper abdomen, acute erythema and edema associated with vascular leakage, fatigue in patients receiving RT to a large volume, and somnolence within a few hours of cranial irradiation. Radiation-induced proliferative responses such as gliosis or certain forms of fibrosis may also cause symptoms unrelated to cell depletion.

Cellular Damage Responses after Irradiation

The final cellular outcome of RT will depend in part upon how cells and tissues "perceive" damage through internal and external "sensors." Sensors in addition to those already mentioned include hypoxia, cytokines, cell–cell and cell–matrix interactions. Cancer-related mutations in DNA repair, cell cycle, and cell death pathway molecules and cell metabolism will inevitably alter the clinical response to RT. It is easy to see why "biologic dose" differs considerably from "physical dose."

A major and desired cellular outcome of RT is cell death. This can occur in several different ways that can change with dose[15] and can determine the outcome of RT.[16]

Mitotic death after irradiation was observed first in 1956 by Puck and Marcus,[17] who made the critical observation that “cells in which the ability to reproduce has been destroyed by doses below 800r can still multiply several times. At higher doses, even a single cell division is precluded.” They were observing mitotic death, which is the most common form of cancer cell death caused by IR. So, mitotic death can be delayed at low dose, and the length of delay is inversely dose dependent. After around 8 Gy, the number of divisions and perhaps the persistence of damage may decrease, as may the number of mutations generated and the likelihood of radiation-induced genomic instability and cancer. The mode of death also may change.[15]

Mitotic death can be due to any of several molecular mechanisms, but in the M phase, chromothripsis can occur, which is a single catastrophic shattering event followed by the stitching of genomic fragments into derivative chromosomes that might generate numerous rearrangements, further genomic instability, fragmented genetic material, and cause cGAS-STING activation.

Apoptosis, by way of contrast, was first[18] seen as interphase death occurring within 4 to 6 hours of low dose IR in certain cell types, including many lymphocytes, and some cells in the endothelium, salivary gland, thyroid, intestinal crypt, and hair follicles. Radiation-induced apoptosis is often, although not always, “intrinsic” through the DDR involving p53 with Bax and Bak as primary downstream effectors.[19] Mitochondrial membranes are disrupted and factors released that activate a cascade of proteolytic caspases and an endonuclease that cleaves DNA between nucleosomes, producing DNA fragments that are multiples of a defined size. So, cells commit “suicide.” Alternatively, TNF family members can trigger an “extrinsic” pathway through cell membrane receptors of the TNFR family that contain “death domains.” This extrinsic TNFR-driven death pathway utilizes caspase-8 but overlaps mechanistically with the intrinsic mitochondrial factor pathway that activates caspase-9, and both converge on the same final executioner caspase-3–dependent pathway to complete apoptosis. Many cell types are protected against apoptosis. Only cells that have their internal molecular “rheostat” on a proapoptosis setting are susceptible. For the intrinsic pathway, Bcl-2 and Bcl-XL are important antiapoptotic factors. The TNF pathway is also controlled. For example, mice lacking TNFR2, which counters the TNFR1 death pathway, are

particularly sensitive to late effects of brain irradiation.[20] IR increases the frequency of apoptosis but does not change the rheostat settings, that is, it does not convert an inherently antiapoptotic phenotype into one that is proapoptotic. In clinical terms, tumors that have a high proportion of cells with a proapoptotic phenotype, such as lymphoma, tend to be radiosensitive. They respond rapidly to RT because of rapid cell loss. They may also regrow fast. The same general principles generally hold for normal tissues, where rapid apoptosis is often associated with proliferating sites.

Necrosis is a form of cell death most frequently seen in pathologic tissue injury settings. Cell membrane integrity is lost, cells swell, lysosomal enzymes are released, vasculature is damaged, and inflammatory responses are generated. It may be caused either directly by IR or indirectly by immune infiltrating cells that have infiltrated in response to radiation damage. Necrosis is often considered unregulated, but regulated forms exist, called necroptosis and pyroptosis, that differ primarily in their usage of proinflammatory cytokines, the former involving TNF-α and the latter IL-1β and IL-18.

Autophagy is another alternative death style that can follow IR. This is a primordial survival response in which cells internalize their cellular organelles within vacuoles and recycle them; it is most often seen in nutrient deprivation. Cells can be rescued from autophagy, although they die when the process is taken to excess. Again, death is delayed.

Senescence is another very delayed response of many proliferating cell types to IR that is relevant to many pathologic situations, including aging. It is akin to a permanent DDR with cell cycle arrest through activation of cell cycle checkpoint activators such as p21 and p16 and production of antiproliferative cytokines, such as IL-6 and transforming growth factor beta (TGF-β).[21] Cytoplasmic DNA and the cGAS pathway mentioned earlier may be essential.[22] Because senescence-associated cytokines drive collagen production, IR-induced senescence may be a reason for the fibrosis[23] that is so often seen as late damage in irradiated tissues. The relevance of senescence to “bystander” effects may be considerable because it is a long-lived secretory phenotype.

Mitotic death, apoptosis, necrosis, autophagy, and senescence may all remove damaged cells from the reproductive pool, decreasing the risk of radiocarcinogenesis, but the differences in timing may have additional consequences, apart from fibrosis and bystander effects. Some cells may resist death and checkpoint arrest and reenter the cell cycle precociously with persisting DNA damage or may reprogram into stem/progenitor cells.[24] The

mechanisms of cell death are therefore likely critical to late as well as acute radiation effects, genomic instability, tissue regeneration, tumor regrowth, and antitumor immunity after RT.

TISSUE DAMAGE RESPONSES

Molecular and Cellular Aspects

Tissues can generally be classified as having either high or low turnover, that is, rate of cell loss and regeneration. This is important in RT because it determines the response to changes in the size of dose per fraction.

For example, the small intestine has the highest turnover rate in the body, with epithelial cells traveling from the crypt, up the villus, to be shed in about 5 days. Slow cycling columnar Lgr5+ stem cells intermingle with Paneth cells at the base of crypts to maintain the procession but easily apoptose after RT. Directly above, at position 4+ from the crypt base, is a population of some controversy.[25] It seems to contain radioresistant stem cells that regenerate rapidly in response to IR but also are sufficiently plastic to replace the lost Lgr5+ stem cells at the base of the crypt.[26] In any event, the microcolony assay[27] showed that loss of >90% of surviving regenerating crypts at 3.5 days is lethal for mice. In contrast, in the colon, which is more radioresistant, radiation-induced apoptosis in Lgr5+ stem cells is not so marked and proliferative recovery is slower. These differences have been ascribed to less precocious entry of cells into the cell cycle in the colon compared with small intestine.[28]

In the thymus, about 98% of the cells generated die by apoptosis under normal conditions. Not surprisingly, IR causes a strong DDR and massive rapid, p53-dependent cell death in the thymic cortex. Similar responses are seen in most lymphoid tissues, in the small intestine, in hair follicles, and in the ependyma. In contrast, some normal tissues, in response to IR, up-regulate p53 without apoptosing, whereas others show neither radiation-induced p53 nor apoptosis, for example, liver, skeletal muscle, and brain.[19] The functional significance of apoptosis may depend upon the location and whether it is part of a natural process that removes excess proliferating cells or is more integral to lineage development. In humans, acute parotitis can develop within the first 24 hours in patients receiving head and neck RT, which is due to rapid death of serous cells.[29] Hence, xerostomia (dry mouth) occurs early, before acute mucositis.

A case has recently been made for a critical role of radiation-induced

endothelial cell apoptosis through ceramide activation in both normal tissue and tumor responses.[30–32] The role of the vasculature in radiation responses is however a long-standing controversy best viewed in a wider context. There is little doubt that IR causes vascular damage, most obviously observed as microvascular "pruning," which may diminish a tissue's reserves following IR and possibly cause some hypoxia. An additional factor may be radiation-induced inflammation that activates vasculature to promote extravascular egress of neutrophils and other immune cells from the circulation and impacts endothelial cell viability and thrombus formation. RT can be thought of as generating a hub of oxidative stress reactions and danger signals leading to proinflammatory chemokines and cytokines, with consequential up-regulation of proteases, cell adhesion molecules, and extracellular matrix materials. The vasculature is part of this, but *in toto,* it is a regulated acute tissue reaction that has its evolutionary roots in fighting infection with cell death and inflammation and is normally resolved through tissue regeneration and remodeling. IR doses above approximately 6 to 7 Gy are especially proinflammatory[12] and are required for ceramide-mediated vascular responses.[30–32] Hypofractionation may favor these responses, although conventional fractions may also generate them over a longer time period.

Inflammation and danger signaling can extend the influence of RT outside the radiation field.[14,33] In addition to bystander effects, systemic tumor-specific immunity may be generated by RT promoting inflammatory microenvironments that are permissive for innate immune recognition. DAMPs and inflammatory cytokines further promote maturation of antigen-presenting dendritic cells to better stimulate adaptive immunity that may manifest systemically as "abscopal" distant antitumor responses that impact overall survival or assist in local tumor cure.[34] A key aspect of this response has come to the fore through the recent demonstration that many human tumors are immunogenic because of mutations caused by chemical or viral exposure that can be recognized as nonself by the adaptive immune system.[35] Defective DNA repair mechanisms increase the mutational load, as might RT.[10] It seems that dose, dose per fraction, and radiation quality are important to radiation-induced immunity as in other aspects of RT, with moderately hypofractionated SBRT perhaps showing some superiority.[13,36] In any event, these scenarios form the rationale behind combining immune checkpoint inhibitors (ICIs) with RT, which is currently the subject of numerous clinical trials.[33] It should be noted that ICIs also disrupt normal tissue homeostasis and, although less toxic than conventional therapies,

come with added risk of inflammation and autoimmunity that could exacerbate radiation toxicities.

In the longer term, a train of events is initiated after RT that may in fact not resolve the disturbance in tissue homeostasis, but perpetuate it. Dose-related oscillating waves of inflammatory responses and further DNA damage have been observed in preclinical models for months after tissue exposure that likely have clinical relevance. These waves presumably reflect continual failed attempts at tissue recovery and remodeling.[12,14] Late complications of RT therefore come to resemble chronic inflammation, which raises hope that better understanding may lead to some treatments for these debilitating diseases. The disturbances because of cancer itself, such as high local and systemic levels of TGF-β, may additionally critically impact outcome.

Kinetics of Normal Tissue Radiation Injury

As has been said, the rate of tissue turnover, that is, rate of cell loss and regeneration, is important in defining the response to RT, including changes in the size of dose per fraction. It has been known since the time of the Curies that it takes varying amounts of time for tissues to express radiation injury (*latency*), leading to use of the terms *acute*, *subacute*, and *late* effects. Note that these refer to symptoms not tissues *per se*, as any one tissue can express acute and late endpoints at different times. Acute and late effects appear largely independent of each other, although a severe acute radiation injury can lead to nonspecific late (consequential) changes, such as stenosis consequent to mucosal ulceration of the bowel, or fibrosis or necrosis of skin or oropharynx consequent to desquamation and acute ulceration.

Acute Responses

Acute responses to RT are defined as occurring during a standard 6- to 8-week course of RT and are seen in tissues that turn over rapidly (gastrointestinal, oropharyngeal and esophageal mucosa, bone marrow, skin). Such tissues are organized hierarchically, generally with a small number of relatively quiescent stem cells that proliferate slowly to produce highly proliferative progenitor cells that differentiate into mature, nonproliferative, functional cells. The functional population is little affected by RT, and the time it takes for an acute effect to become apparent (latency) is the time to the natural loss of functional cells without replacement. In contrast, IR generally depletes the more radiation-sensitive proliferating cell pool, often causing death by apoptosis. If depletion is

sufficient, the functional pool is not replaced, and serious, even fatal, consequences may ensue.

The timing and extent of regeneration is classically assessed experimentally by giving two doses of IR and varying the time in between by days, weeks, or months. These assays have been invaluable guides for more modern studies into the *in vivo* effects of RT on stem/progenitor populations using biomarkers such as Lgr5. Remarkably, the depleted stem/progenitor pools are often dramatically expanded before functional recovery is initiated, although this varies with the tissue. A useful way to think of the impact of regeneration is that under normal steady-state circumstances, tissues have, by definition, a cell loss factor (φ) of 1. The only requirement for tissue growth is a decrease in (φ) to <1, as for embryos and fetuses, tissue regeneration, and malignancy. After IR exposure, some tissues (e.g., jejunal crypts) appear to reduce (φ) to zero and regenerate quickly; others (e.g., skin) may reduce it to about 0.5 and regenerate less quickly, continuously producing some functional cells; others such as seminiferous epithelium show little change in (φ) and mostly continue in steady state, producing sperm in numbers that are reduced for months or years in direct proportion to the extent of stem cell depletion.

It follows from the above that leukocyte and platelet numbers in blood drop quickly after bone marrow irradiation because they have a fast turnover rate, whereas anemia is not so obvious because red cells turn over slowly. In the testis, each spermatogenic stem cell produces more than 1,000 sperm through successive divisions of a small number of radiosensitive spermatogonia and spermatocytes—a process that in humans takes more than 60 days. So, sperm counts remain normal for several weeks after RT, falling steeply only when the progeny of the irradiated spermatogonia would normally have reached the seminal vesicles. In the small intestine, crypt stem/progenitor cells are lost within days of exposure, and the nonproliferative villus is unaffected initially but shortens as cells are shed into the lumen and not replaced. So, symptoms take about 2 weeks to appear in patients undergoing abdominal RT.

The *severity* of acute radiation injury increases with dose. Providing the reserve does not fall below a critical value, symptoms will be transient and recovery can be complete. Dose fractionation can lessen the severity of acute effects by allowing the stem/progenitor cell compartment to regenerate during the course of RT. The *latency* for acute injury, on the other hand, is relatively independent of dose because it is determined primarily by the physiologic turnover rate, that is, the kinetics of cell loss. Having said that, as dose increases,

latency for an acute effect does decrease, but only by a few days, so the time, for example, to mucosal reactions seems fairly similar between individuals. For late effects, the inverse dose–time relationship is more marked.

Subacute Responses

Certain tissues may display subacute reactions several months after RT that are associated with cell loss and inflammation. Symptoms are often reversible, although in some instances, they may progress to severe damage and even death. Lhermitte syndrome after spinal cord irradiation is an example of a transient subacute reaction that is most likely because of diffuse demyelination and reversible by remyelination. Similarly, subacute pneumonitis can be seen by chest x-ray or CT scans 2 to 3 months after the start of lung RT with symptoms such as dyspnea, nonproductive cough, and poor lung function. The incidence depends on the dose and volume irradiated, as well as on smoking, and additional treatment. Loss of type I pneumocytes is associated with increased microvascular permeability, and host cell infiltrates, especially myeloid cells activated to secrete proinflammatory cytokines. It may resolve but can progress into chronic consolidated late pulmonary disease.

Late Responses

Late reactions to RT in normal tissues can be severe and with limited recovery. Because they occur after completion of treatment, dose adjustment is obviously not an option. Severity and latency are both dose dependent, with the latency increasing markedly with decreasing dose. This means that some late effects, such as atherosclerosis and heart disease, can occur decades after RT, which is becoming an increasing problem as patients survive longer. Late effects are generally considered to result from depletion of slowly proliferating “target” cells that are lost from the tissue at a slow rate or senesce after IR. However, chronic inflammation is also often present and is a hallmark that cannot be ignored. Pathologic findings are often variable and indicate more than one “target” mechanism. For instance, late demyelination after brain irradiation has often been ascribed to loss of oligodendrocytes, and subsequently of neurons, but proliferation and activation of astrocytes and microglial cells are common, as are vascular lesions with edema, hemorrhage, and inflammatory infiltrates. The more chronic and debilitating nature of late reactions may be because of their relative inability to be readily repopulated from a stem cell pool, but regeneration may be additionally compromised by inflammation and fibrosis that

is part of an ongoing alternative healing response for slow-responding tissues.

In late-responding tissues, proliferative cells may also be functional. When stimulated to proliferate, they may therefore also lose function, initiating a vicious “avalanche” effect. By the same token, late effects may be precipitously increased by insults such as surgery, chemotherapy, infection, or physical trauma. Depleted cellular reserves may also have an impact, as may expression of latent DNA damage. Latency decreases with dose as a result; however, late effects are complex and the critical cell type may change with time, making time–dose relationships and histopathology important when comparing responses.

An issue of growing clinical importance is the extent to which late radiation effects can be reversed. It has been shown recently that certain agents given after RT can modify injury in tissues. For example, captopril, an angiotensin-converting enzyme inhibitor, slows the development of radiation-induced nephritis and lung fibrosis in rats.[37] It is however clear that late effects are a reflection of dysregulated homeostasis that is in many cases linked to chronic inflammation. Reestablishing immune homeostasis may be required for full treatment.

Tolerance Doses and Functional Subunits

Generally accepted tissue tolerance doses exist and vary widely from tissue to tissue. Tolerance is determined by intrinsic radiosensitivity, capacity for regeneration, and many other factors. One factor is tissue organization. Tissues can be thought of as being composed of functional subunits (FSU), each FSU being defined as the tissue unit able to recover from one surviving clonogen. For example, epilation requires lower doses than desquamation, primarily because a smaller number of clonogenic cells are present in each hair FSU. Similarly, hair is depigmented by lower doses than epidermis because each hair follicle contains a smaller number of melanocytes, sometimes only one. In the kidney, each nephron is an FSU. If a tubule is completely de-epithelialized, it is lost permanently because it is not repopulated from adjacent nephrons. Therefore, the tolerance dose for the kidney is determined more by the number of tubule stem/progenitor cells per nephron than the number of nephrons. For example, if a kidney contained 10^{11} clonogenic tubule cells distributed as 10^4 cells in each of 10^7 nephrons, then most tubules should regenerate after a dose that reduced survival to 10^{-4}. From Poisson statistics, 37% of nephrons would be eliminated. If on the other hand, the 10^{11} clonogenic tubule cells were distributed as 10^7 in

each of 10^4 nephrons, the dose required to eliminate 37% of the nephrons would have to reduce survival to 10^{-7}. In a multifractionated dose regimen with a logarithmic decline in cell number, a 7/4 (1.75) times higher dose would be needed. Tolerance doses can therefore vary greatly among tissues and organs even having the same intrinsic radiosensitivity. In mouse skin, the survival of about 10 out of approximately 10^6 basal stem/progenitor cells per cm^2 is required to prevent overt desquamation. Therefore, an FSU is about 1/10 cm^2.

Organs with more tubular architecture (e.g., salivary glands, pancreas, sweat glands, testis, mammary epithelium, spinal cord, nerve tracts, and central lung) may resemble the kidney in having better-defined FSUs organized “in series,” whereas in dermis, mucosa, gut epithelium, and epidermis, FSUs may be considered to be organized “in parallel.” The latter lack restricting physical barriers to cell migration, which may assist tissue regeneration. A tumor behaves as one FSU, as one surviving stem/progenitor cell can lead to recurrence, whereas a larger number of small metastatic deposits will be cured with lower radiation doses than a small number of larger metastases even if the total cell number is the same in the two cases. The FSU concept has some implications for “volume” effects.

Volume Effects

Traditionally, radiation oncologists reduce total dose when treating large volumes of normal tissue. In fact, the now widespread use of 1.8 rather than 2 Gy had its origin in a volume effect; the longer treatment duration enhanced mucosal tolerance in large head and neck treatment fields. A reduction in dose with increase in volume was generally recommended in the orthovoltage era, but this became less of an issue with the advent of skin-sparing megavoltage beams. In the modern era, dose–volume histograms (DVHs) are generated during intensity-modulated radiation therapy (IMRT) treatment planning. These are useful for avoiding excessive dosing to too high a volume for certain organs, but limited by the lack of spatial information and as a result do not predict toxicity very well.

In reality, the concept of decreasing dose with increasing treatment volume has little radiobiologic basis in cell kill, except in specific circumstances. For example, if FSUs are arranged in series, as in tubular structures, the loss of one FSU may result in injury regardless of the state of the other FSUs. The probability of injury increases with volume (number of FSUs exposed) (Fig. 3.1). Such a volume effect has been demonstrated clinically for small bowel

obstruction and experimentally for myelitis.

The relationship between the number of FSUs irradiated (n) and the probability of a complication (P) can be quantified by:

$$P = 1 - (1 - p)^n ,$$

where p is the probability of the loss of one FSU. This relationship is illustrated in Figure 3.2. When the average number of surviving cells per FSU is reduced to almost one, increasing the volume (number of FSUs exposed) reduces the dose necessary to produce a complication and increases the steepness of the dose–response curves.

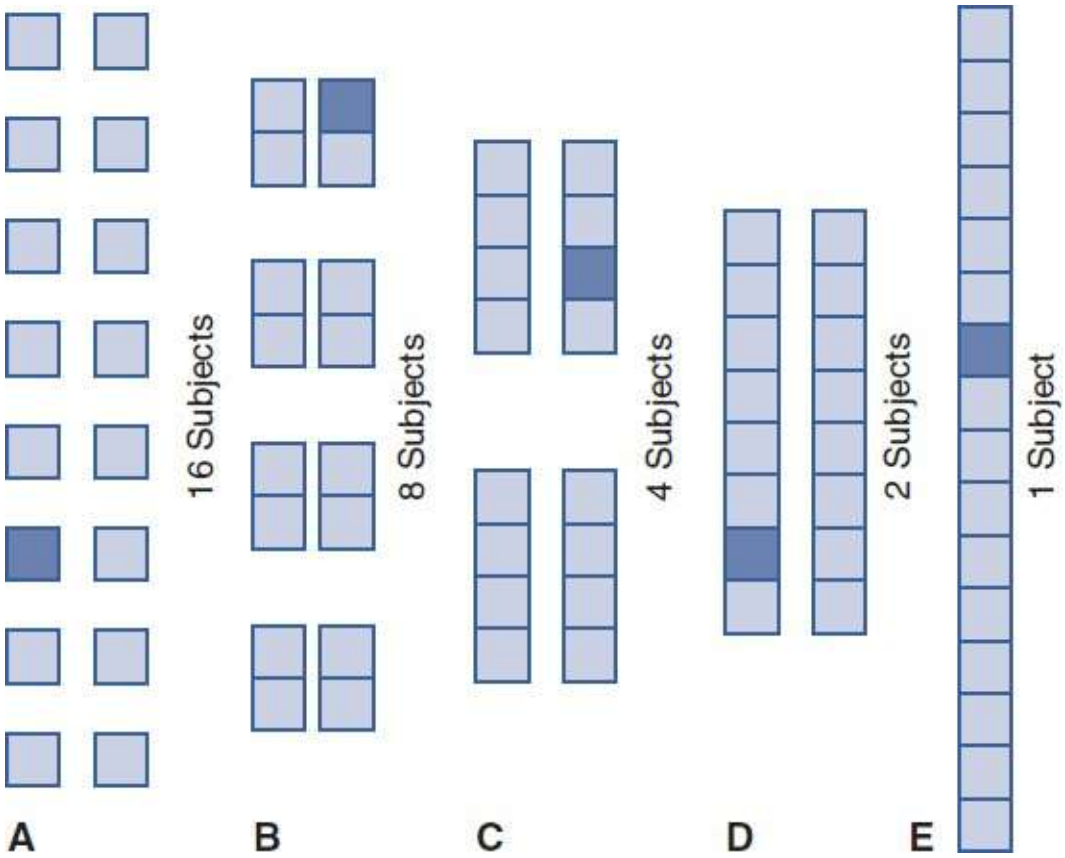

FIGURE 3.1. Diagrammatic representation of the influence on the probability of a complication from increasing the treatment volume in a tissue where FSUs are arranged serially. The average survival of FSUs was 1 in 16, with sterilized FSUs being denoted by the *dark blue squares*. With the small volumes (*A*), the probability of myelitis was 6% (1/16), whereas it would approach 100% if 16 FSUs in one patient were exposed (*E*). The actual probabilities can be calculated using the equation in the text. (Reprinted from Withers HR, Taylor JM, Maciejewski B. Treatment volume and tissue tolerance. *Int J Radiat Oncol Biol Phys* 1988;14[4]:751–759. Copyright © 1988 Elsevier. With permission.)

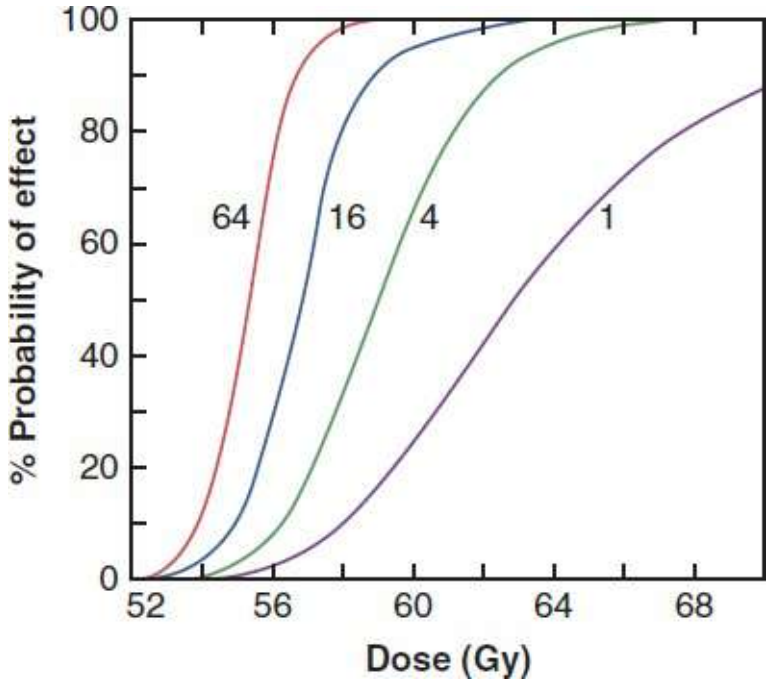

FIGURE 3.2. Curves illustrating how the probability of producing a complication increases with increase in the number of serially arranged FSUs included in the treatment volume. The curves were positioned by assuming that 58 Gy in 2-Gy fractions sterilized 10% of FSUs and that for a series of 2-Gy fractions, the effective D_0 for the target cells was 4 Gy. The curves are shifted to the left and are steeper with increase in number of FSUs exposed; however, this effect becomes less obvious once large numbers of subunits are involved. (Reprinted from Withers HR, Taylor JM, Maciejewski B. Treatment volume and tissue tolerance. *Int J Radiat Oncol Biol Phys* 1988;14[4]:751–759. Copyright © 1988 Elsevier. With permission.)

Spinal cord has been a favored model for volume effects. Experimental studies in spinal cord of rats have indicated a steep volume effect at <10 mm of length and an interesting "bath-and-shower" effect[38] for small fields with high tolerance for IR-induced paralysis. An additional modest "bath" dose (about 4 Gy) administered to 4-mm segments of the spinal cord surrounding a targeted "shower" 2 mm in size dramatically decreases the effective dose for 50% paralysis (ED_{50}) from 88 to 61 Gy. Proposed mechanisms are inhibition of angiogenesis or cell migration. Another recent study[39] showed IR-induced motor deficits in pigs to be independent of the irradiated volume in the lateral direction. This is of clinical relevance because it suggests that even partial spinal cord irradiation can have deleterious effects. However, in general, preclinical spinal cord dose–volume studies indicate that dose distribution may be more critical than the volume, suggesting that neither DVH analysis nor absolute volume constraints will be fully effective in predicting complications.

There is no evidence that direct cell kill after RT is affected by an increase in

treatment volume. The radiosensitivity of skin epithelial clones is constant over a 5,000-fold range of treatment area. On the other hand, “volume effects,” which are not related to cell death, can be seen when:

- A small area of injury is tolerated better than a large area of the same severity. Pain, fluid leakage, and inflammation may be worse, and healing may be slower with more consequential contraction and scarring.
- As volume increases, so does dose heterogeneity across the field. A tumor dose prescribed at the 80% level may be 25% higher dose at D_{max}, which could produce a marked increase in the incidence of complications, which would be further compounded for late effects by the “double trouble” of increased physical and biologic dose.[40] In addition, large fields may have large variations in contour that could cause a high dose region where tissue thickness is less than that measured at the midplane, as, for example, in the spinal cord at the thoracic inlet in thoracic irradiation and in tangential fields for treatment of the breast.
- If organ “reserve” is obliterated as volume is increased (e.g., lung, salivary gland). This is not a true volume effect because sequelae are determined by the volume and functional status of the tissue *excluded* from the treatment volume, not the volume irradiated.

Regeneration (Repopulation)

As has been said, the latency and extent of regeneration after RT can be measured experimentally by a split-dose technique with two doses separated in time. The size of the second dose necessary for a constant level of effect (isoeffect) increases with time after the first dose because of regeneration/repopulation.

In acute-responding tissues, repopulation starts early because cell loss is rapid. In the irradiated jejunal mucosa, the lag time may be <24 hours. In the colon and stomach, it is slightly longer. In mouse renal tubules, there is no histologic evidence of cell depletion for many months after irradiation; there is a long lag period, and it takes more than 12 months to reconstitute a tubule.[41] The rate of repopulation has not been well quantified in tissues. In mice, some approximate doubling times for clonogenic cells are 8, 12, and 22 hours for jejunum, colon, and skin,[42] respectively.

In humans, tissue turnover kinetics are slower than in mice. Mucositis begins 14 to 21 days after the start of a regimen of 2 Gy given five times per week, but repopulation begins at about 10 to 12 days. The lag period may be shorter after

high initial doses, but only by 1 or 2 days. Repopulation can increase the tolerance of the mucosa to a conventional regimen by an *average* of at least 1 Gy/day, which is equivalent to approximately a doubling of clonogenic cell numbers every 2 days, and it may be faster.[43] If daily irradiation is suspended (e.g., a 10- to 14-day break during an accelerated regimen), clonogenic cells may repopulate at two or three times this rate.[44] Figure 3.3 shows estimates for lengths of lag time and repopulation rates. The critical point is that there is a lag period followed by a phase of rapid exponential growth. In general, the lag period is shorter for chemotherapy, hyperthermia, and surgery because of more rapid cell loss.

The importance of repopulation is implicit in the history of RT. The current standard protracted overall treatment times confer a benefit by allowing regeneration of acute-responding tissues, which reduces toxicity. When attempts are made to accelerate therapy, acute responses become more severe and dose limiting.

Growth factors may shorten the apparent lag phase and accelerate recovery in irradiated tissues. Hematopoietic growth factors such as G-CSF, GM-CSF, erythropoietin, and IL-11 can accelerate proliferation of hematopoietic cells. In doing so, they minimize the danger of infection. In epithelial tissues, keratinocyte growth factor (KGF), which is specific for epithelial cells, has similar potential. It protects the oral mucosa, small intestine, lung, and hair follicles against chemo- or radiation injury in preclinical models.[45] In addition, mitigators of radiation damage have been developed[46–48] that can be given at least 24 hours after exposure.

“Remembered” Dose: Tolerance to Retreatment

According to conventional wisdom, heavily irradiated tissue cannot be retreated because of irreversible vascular damage. Although prior RT may decrease tissue tolerance, retreatment is often possible and may be better tolerated than expected. Factors that determine the limits include the tissue at risk, the amount of initial cell depletion, and the time elapsed since treatment and therefore the extent of regeneration. High prior doses, a short interval, and slow regeneration will reduce retreatment tolerance.

Data for experimental radiation myelitis in Figure 3.4 show the effect of size of a preceding dose on the dose required to produce a 50% incidence of myelitis. Recovery is complete after low doses but is progressively compromised as the initial dose approaches tissue tolerance.[50] It should be remembered that clinical

"tolerance" doses for the spinal cord of 45 to 50 Gy in 1.8- to 2-Gy fractions are lower because the extent of injury tolerated is lower. The rate of recovery is not accurately known; however, in rats, at 100 days recovery is about 50% from what it would be at 200 days.[51] In monkeys, there was extensive recovery from 44 Gy in 2.2-Gy fractions by 2 years.[52]

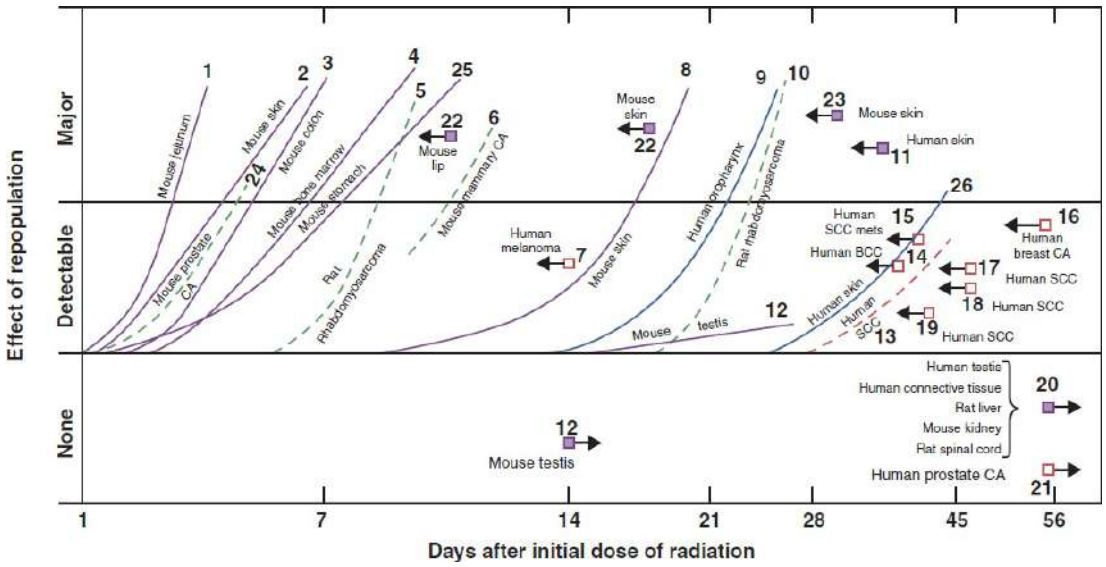

FIGURE 3.3. Representation of the approximate kinetics of regeneration of irradiated normal tissues (*solid lines*, *solid symbols*) and tumors (*dashed lines*, *open symbols*). Curves are based on measurements or estimates of regeneration; symbols denote times at which an effect of regeneration has already appeared (*left-pointing arrow*) or has not yet appeared (*right-pointing arrow*). The logarithmic abscissa is for convenience of presentation only and has no biologic rationale. In general, the human data are displaced to the right of experimental animal data, reflecting a slower initiation of repopulation. Because human tissues proliferate more slowly than do their rodent counterparts, they were exposed to protracted dose regimens, and less-sensitive end points were used to detect onset of repopulation in humans. Numbers on the curve and symbols refer to different sources of data. These come from many sources. Further details are in the previous editions of this book.

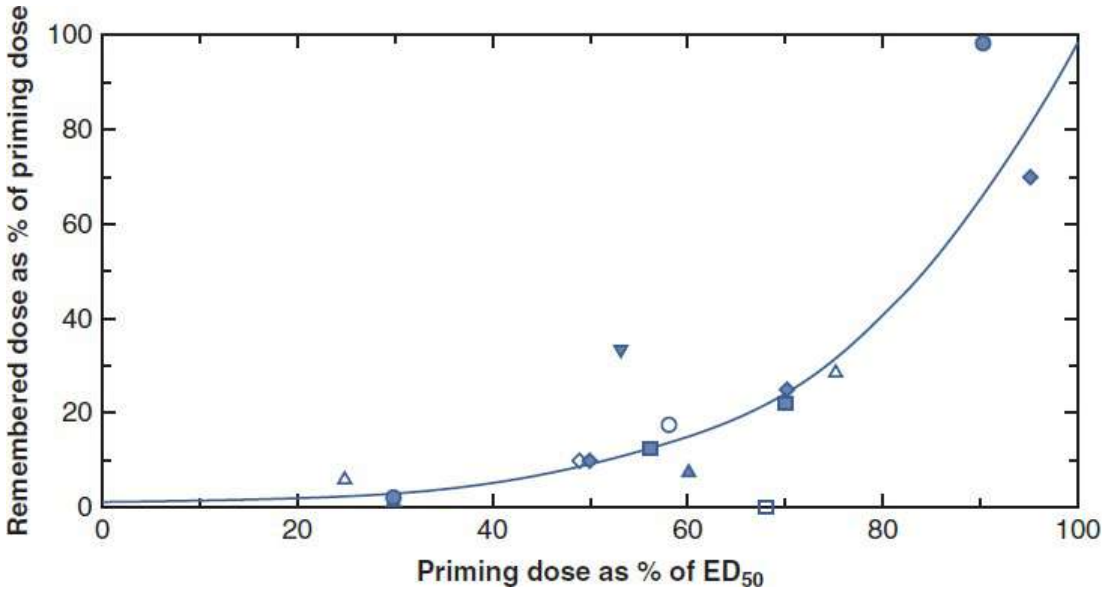

FIGURE 3.4. The dependence of remembered dose on size of priming dose (as a percentage of the ED_{50}) is shown for a variety of animal species at long periods (6 months to 2 years) after the initial radiation treatment: O, adult rhesus monkey; Δ, 12-week-old rat(49); ◊, 1-day-old guinea pig; ●, young adult mouse; filled ▲, 8-week-old guinea pig; filled ▼, 8-week-old guinea pig; filled ■, 3-week-old weanling rat; ♦, young adult rat. (Reprinted from Mason KA, Withers HR, Chiang CS. Late effects of radiation on the lumbar spinal cord of guinea pigs: re-treatment tolerance. *Int J Radiat Oncol Biol Phys* 1993;26[4]:643–648. Copyright © 1993 Elsevier. With permission.)

Not all tissues or structures within tissues recover at an equal rate or extent after RT. Epithelial and hemopoietic tissues generally recover quickly and demonstrate a high tolerance to retreatment. However, the fibrovascular support structures in skin and mucosa and bone marrow respond more slowly. Kidney function shows poor retreatment tolerance in mice.[53] Retreatment tolerance is inversely related to the initial dose and decreases significantly with increasing interval between treatments, suggesting progression rather than recovery from the initial damage.

Because different tissues show different levels of tolerance to retreatment, caution should be exercised in the application of these concepts to the clinic. In addition, the experimental studies deal with well-defined end points within a limited time scale. If different end points in the same tissue are examined or the time is extended, the same guidelines may not apply. It should also be noted that if slowly proliferating cells involved in late responses are extensively or functionally inhibited, recovery may be permanently incomplete and the organ will be vulnerable to further injury, whether from radiation, trauma, cytotoxic drugs, or otherwise. For example, hyperthermia can precipitate myelitis in a

patient who has had high but otherwise tolerable doses of x-irradiation, and trauma from dental intervention frequently precipitates mandibular necrosis.

Reproducible differences in tolerance of acute- and late-responding normal tissues, and between different types of tumors, to the same physical dose of IR are important because they define the basis of the biologic advantage of dose fractionation in conventional RT. This radiobiologic rationale has been encapsulated in the 4 “Rs” (repair, repopulation, redistribution, and reoxygenation).[49]

TUMOR RADIOBIOLOGY

Kinetics

Tumor Cell Death and Survival

As is obvious from clinical practice, the doses of RT required for control of human tumors vary widely. Heterogeneity in radiosensitivity comes from many sources, not the least being cancer-related mutations that affect pathways integral to DNA repair, cell proliferation, and death. Hierarchical organization is as relevant in tumors as it is in normal tissues. For example, in normal breast, undifferentiated estrogen receptor–negative mammary tissue, stem cells maintain themselves through self-renewal while differentiating into committed progenitors that ultimately give rise to mature ductal and alveolar luminal epithelial cell lineages that line the mammary gland and the surrounding mature myoepithelial cells. Breast cancer, like other cancers, is a heterogeneous disease with subtypes that express luminal, mesenchymal or claudin-low, and basal-like phenotypes with distinct blocks imposed by BRCA1 loss and HER2 amplification. So most hierarchically organized tumors have more differentiated cells with limited proliferative potential and a cancer stem cell (CSC) compartment that maintains the tumor and contributes to RT resistance owing to its unique biologic properties. The importance of this concept is that tumor cure and regrowth are dependent on what may be a small minority of relatively quiescent cells that in several tumor types have been shown to be often very radioresistant and aggressive, which impacts how one thinks of the 4Rs related to cancer.[54] It also means that *in vitro* clonogenic assays are generally not good surrogates for *in vivo* radioresponse.

The mechanism of cell death may be important for radiocurability. The most radiocurable tumors have a tendency to apoptose, that is, lymphocytic > carcinomas > melanomas, sarcomas, astrocytomas. Importantly,

the proportion of cells that undergo apoptosis tends to be regenerated between fractions.[55] In addition, genetic modification of cells to introduce a proapoptotic phenotype frequently, although not always, radiosensitizes.[56] Despite these findings, studies specifically designed to find relationships between molecular markers of apoptosis and radiocurability of human tumors have yielded mixed and sometimes contradictory results. This may be because the CSCs do not often express a proapoptotic phenotype. In contrast, cells that senesce or undergo autophagy or go through several mitotic divisions after RT may have a greater chance of surviving and of undergoing CSC reprogramming.

In Vivo Kinetics of Tumor Responses

Tumors that regress during a course of RT have a rapid turnover rate and are considered analogous to acute-responding normal tissues in their radiation dose–fractionation responses. In contrast, some tumors, such as melanoma, soft tissue sarcoma, and liposarcoma,[57] prostate,[58] and breast cancers[59] often have a slow turnover rate, regress slowly, and are like late-responding tissues.

Tumor Regression after RT

Regression of a tumor after RT reflects the *rate* of cell loss, which is determined by turnover kinetics. A cell loss factor (φ) of <1 is required for tumor growth. Most head and neck carcinomas have a φ close to 1, which is why their growth rate (on average, volume doubling times of about 60 days) is slower than one would think from their mitotic or labeling indices (LI), which indicate a potential doubling time (Tpot) of about 3 to 7 days. So, tumor with a high proliferative capacity does not necessarily grow rapidly, though they may regenerate fast. A classic example is the slow-growing basal cell skin carcinoma, in which numerous mitotic figures are commonly visible. They have a high φ owing to extensive apoptosis.[60] Tumor growth rate therefore does not equate with proliferation index, cell loss, or regrowth rate.

For standard RT, tumors with a high φ will regress rapidly during and after RT, regardless of pretreatment growth rate, and generally have a good prognosis. On the other hand, rapid regression would be expected if tumors have a high rate of cell production and high growth fraction, even if φ is low, but prognosis may be poor. Rapid regression is therefore not a universal prognostic indicator,[60] although it is usually a favorable prognostic sign.

Similar arguments can be applied to tumors that regress slowly, such as prostate carcinoma, some cases of nodular sclerosing Hodgkin disease,

teratocarcinomas of testis, some soft tissue sarcomas, choroidal melanomas, meningiomas, pituitary adenomas, chordomas, or glomus tumors. Slow regression may reflect slow proliferation, low cell loss factor, or a high stroma content.

A practical implication of the complexity underlying tumor response to RT is that total dose should not be reduced just because a tumor regresses rapidly. In addition, tumors that are well-differentiated and grow slowly because of high cell loss factors may initiate an early repopulation response, and local control may be prejudiced by protraction of treatment time beyond normal, just as it is for fast-growing tumors.[61]

Potential Doubling Time

Repopulation with a decrease in φ occurs in all tumors and tissues as a homeostatic response to cell depletion. The potential regeneration rate of tumors after RT is better predicted by the pre-RT proliferative activity than by pre-RT tumor growth rate. The Tpot, which is the time required for clonogenic cells to double in number if the cell loss factor were zero, is a measure of this.[60] It can be estimated from the average duration of the S phase (Ts) and the fraction of cells in S phase, measured by LI:

$$\mathrm{Tpot} = \mathrm{l}\mathrm{Ts}/\mathrm{LI},$$

where l is a correction factor for the cell cycle distribution of the population.

Tpot is a logical predictor of the kinetics of a regenerative response, and attempts were made to use it clinically to predict which tumors would benefit from treatment acceleration aimed at minimizing repopulation. Early results indicated that it might be of some value, although later analyses indicated otherwise.[62] This may be because the cell cycle time in a tumor alters from before to during and after treatment.

Growth Fraction

The distinction between tumor and normal tissue is in a sense false, though convenient. In reality, perhaps 50% of cells in a tumor are host immune and stromal cells. The vasculature is obviously host derived. In addition, as in normal tissues, many cells in a tumor will be noncycling for a number of reasons; the most important are probably differentiation, hypoxia, and catabolic insufficiency. CSCs, for instance, are generally in a quiescent state. As a result, the *growth fraction*, which is simply the fraction of cycling cells in solid tumors,

may be quite small (e.g., 20%). As tumors enlarge, they grow more slowly and the growth fraction may decrease even further (see control curve, Fig. 3.5). This changing growth rate can be approximated by a Gompertz equation. In contrast, after RT, the growth fraction may increase as CSCs are recruited to the proliferative pool and contribute to accelerated tumor regrowth, although other factors, such as hypoxia and necrosis, may be an influence. Of particular importance after RT may be an influx of tumor-associated macrophages that in many cases have been found to stimulate cell growth and metastasis.

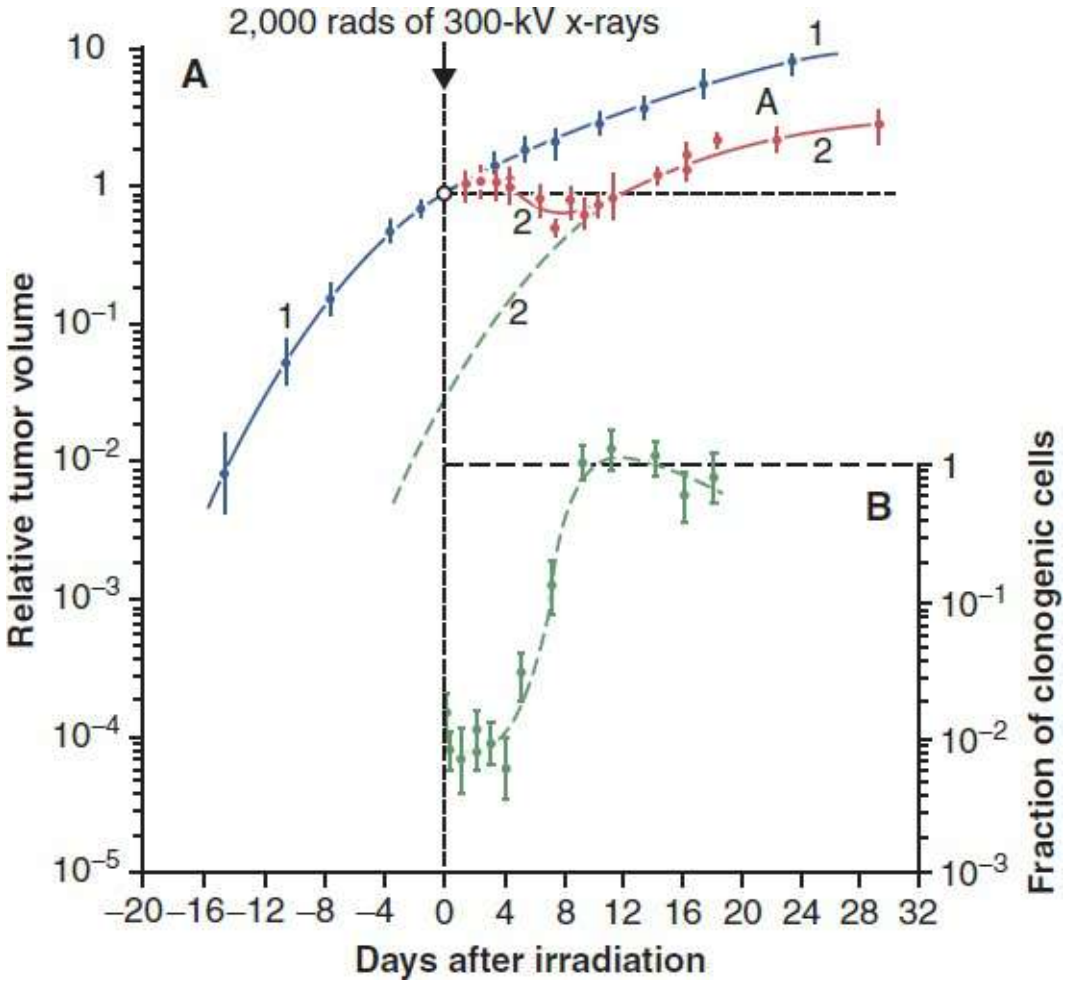

FIGURE 3.5. **A:** Growth curves for a rat rhabdomyosarcoma and its constituent clonogenic cells after a dose that reduced survival to 1%. The upper curve (*1*) shows unperturbed growth of tumors; the middle curve (*2*) shows regression and regrowth of tumors irradiated on day 0 with a dose that reduced cell survival to 1%; the lower curve **(B)** traces the repopulation of the tumor by surviving clonogens. Exponential regrowth of the surviving clonogenic cells occurs, whereas the gross tumor is regressing. (Reprinted from Hermens AF, Barendsen GW. Changes of cell proliferation characteristics in a rat rhabdomyosarcoma before and after x-irradiation. *Eur J Cancer* 1969;5[2]:173–189. Copyright © 1969 Elsevier. With permission.)

Regeneration in Experimental Tumors

Regeneration in tumors is similar to that found in normal tissues (liver, dermis) and largely involves rapid recruitment of resting, G0-phase cells. Hermens and Barendsen[63] showed a rapid exponential increase of surviving clonogenic tumor cells in a rat rhabdomyosarcoma several days after RT. Because only 1% of the initial clonogens survived, tumors did not visibly enlarge; rather, the tumor mass was still regressing when repopulation began (Fig. 3.5). This was later confirmed in other experiential tumors, and the same probably occurs during regression of clinical tumors. *In vitro* fractionated, daily irradiation can select for a small proportion of CSCs[64] and also promote reprogramming from more differentiated tumor cells.[65]

Regeneration in Human Tumors

Clonogen regeneration in human tumors can be assessed by the effect of increased treatment duration on the dose required for tumor control or the decrease in tumor control rate. Accelerated tumor regrowth occurs during standard RT for head and neck cancer[66,67] and is likely to occur in all but slow-growing tumor types with a low ϕ. The concept of accelerated repopulation in human tumors during and after a course of fractionated RT is supported by several observations.

- *Time to Tumor Recurrence*
  If 10^4 head and neck cancer cells survived RT, they would have to undergo 15 doublings to present as a recurrence. Because most local recurrences are detectable within 12 months of RT, the *average* doubling time would have to be about 2 weeks, in contrast to about 2 months before RT, so the growth rate must accelerate following unsuccessful RT. Similar rapid regrowth was seen in pulmonary metastases after subcurative RT.[68]
- *Split-Course Treatment*
  Split-course regimens for head and neck squamous cell carcinomas (SCCs) give lower local control rates than continuous regimens of the same total dose.
- *Protracted Treatment*
  Protraction of treatment time decreased the rate of locoregional control for head and neck cancer,[66] which is consistent with accelerated tumor regeneration. Three analyses were done:

  a. *Scattergram analysis*. Protracting treatment time for oropharyngeal cancers led to worse outcome[66] (Fig. 3.6). For treatment durations of 30 to 55 days, every day required total dose to be increased by about 0.6 Gy to achieve a

constant rate of tumor control. Assuming that 1.8 to 2.4 Gy reduces cell survival by 50%, an increase of 0.6 Gy/day is consistent with clonogens doubling every 3 to 4 days. Because tumors at presentation have a doubling time of about 2 months, there must be a dramatic change in growth rate during RT. The same pattern (Fig. 3.6) was seen in 11 other subsets of patients with oropharyngeal cancers and carcinomas of the supraglottic larynx[67] and for SCC of tonsil.[69] The latter is important because differences in overall treatment duration predominantly reflected institutional policy in this multicenter study. Because an increase in the tumor control dose 50 (TCD_{50}) was clearly noticed across all participating institutions with the extension of overall treatment time, any bias for worse tumors was unlikely.

b. *TCD_{50} analysis*. Figure 3.7 presents TCD_{50} values for SCC of head and neck calculated from the literature.[67] They are independent of treatment duration up to about 28 days, after which they increase rapidly (consistent with 0.6 Gy/day). The suggestion is that *on average*, head and neck SCCs exhibit a lag period of 3 to 4 weeks before beginning to repopulate, with an average doubling time of 3 to 4 days.

c. *Analysis of primary tumor control rate*. When a standard prescription (e.g., 50 Gy in 20 fractions in 4 weeks) is extended in time, the control rate decreases, commonly by 1% to 2% per day for head and neck and cervix cancer (Fig. 3.6B).

It should be noted that a lag period of up to 4 weeks and thereafter a 0.6 Gy/day increase in the "isocontrol" dose are *not* evidence that RT for head and neck cancer should be given in 4 weeks. Repopulation of mucosa begins at about 10 to 12 days and is more rapid than tumor. Thus, a therapeutic gain in mucosal tolerance relative to tumor control is still achieved by extending treatment beyond 4 weeks. Late-responding tissues, which do not benefit from repopulation, are unaffected by treatment prolongation, only by the size of dose per fraction and total dose. It follows that the overall therapeutic differential will be greatest if the tolerance dose for the critical late-responding tissue is delivered in the shortest overall time that is acceptable for acute responses, and without compromising the total dose delivered to the tumor, assuming the tumor has a high turnover rate.

. *Accelerated Treatment*

If accelerated tumor growth contributes to treatment failure, it may be offset by accelerated RT. In nonrandomized studies, shortening the overall duration

of treatment improved the local control in inflammatory breast cancer,[70] melanoma metastases to the brain,[71] and head and neck cancer.[72] Randomized studies of accelerated treatment of head and neck cancer validated the benefit.[73] Exceptions may be cancer of the prostate, which has slow turnover rate, although hypofractionation with stereotactic body radiation therapy (SBRT) for prostate cancer has shown promise.[74] Dose-intensity studies suggest that chemotherapy also accelerates tumor regrowth.[75] As a result, two or three cycles of chemotherapy before the start of RT for head and neck cancer are rendered of little value because of accelerated regrowth.

FIGURE 3.6. A: Scattergram with TCD_{50} and TCD_{90} curves for 3-year local control of SCC of the tonsil (*1*, local control; *2*, recurrence; *3*, persistence of detectable disease). For a given total dose, local control decreased with protraction of overall treatment time. For a given overall time, local control improved with increase in dose. The total doses were normalized to be equivalent to the total dose in 2.5-Gy fractions using the LQ isoeffect curve (Fig. 3.22). An α/β value of 2.5 Gy was used, being the best estimate from these and other data. (Reprinted from Maciejewski B, Withers HR, Taylor JM, et al. Dose fractionation and regeneration in radiotherapy for cancer of the oral cavity and oropharynx: tumor dose-response and repopulation. *Int J Radiat Oncol Biol Phys* 1989;16[3]:831–843. Copyright © 1989 Elsevier. With permission.) **B:** Pelvic control as a function of treatment time for 621 patients treated with a total dose of 85 Gy. (Reprinted from Fyles A, Keane TJ, Barton M, et al. The effect of treatment duration in the local control of cervix cancer. *Radiother Oncol* 1992;25[4]:273–279. FIGURE 3.7. Estimated TCD_{50} values as a function of treatment duration from published results of RT for squamous carcinomas of the head and neck excluding nasopharynx and true vocal cord. TCD_{50} values are expressed as $LQED_{2Gy}$ (the equivalent dose given in 2-Gy fractions calculated using the LQ model). Total doses for an isoeffect increase steeply with protraction of treatment duration, implying accelerated repopulation by surviving tumor clonogens, consistent with the 3- to 4-day average doubling time calculated from scattergrams (Fig. 3.6A). The relatively constant TCD_{50} value for treatments lasting up to 4 weeks is consistent with an average time of onset of accelerated growth at about 4 weeks. Growth of clonogens at the average preirradiation doubling rate of 2 month would have little detectable effect on TCD_{50} values (about 2.5-Gy increase in 8 weeks). (From Withers HR, Taylor JM, Maciejewski B. The hazard of accelerated tumor clonogen repopulation during radiotherapy. *Acta Oncol* 1988;27[2]:131–146. FIGURE 3.8. Radiation dose–survival curves for one line of mammalian cells (V-79 Chinese hamster) synchronized in four positions in the division cycle. Significant differences occur in the survival of cells at different ages, with the differences relative to absolute survival being greatest at lower doses. The survival ratio between late S and G_2M cells after 2 Gy is approximately 5. (From Withers HR, Peters LJ. Biological aspects of radiation therapy. In: Fletcher GH, ed. *Textbook of radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger, 1980.)

Cell Cycle Redistribution after Radiation Therapy

Cells change in their radiosensitivity as they traverse the cell cycle[76] (Fig. 3.8). Irradiation will partially synchronize cells in relatively radioresistant cycle phases (e.g., S). When they resume cycling, they will move into more sensitive phases. If they were to be perfectly synchronized, this could be exploited by fractionation.[77] Unfortunately, synchronization is not perfect. Nevertheless, fractionation will still enhance the therapeutic ratio among tumor cells versus late-responding normal tissues by permitting redistribution. Radiosensitive cells in G2M will be eliminated by the first fraction and by the time the next fraction is given those originally in S phase will have moved into G2M, becoming more radiosensitive. This was the initial rationale for clinical trials of hyperfractionation, before intrinsic differences in response to low dose fractionation between late- and acute-responding tissues were appreciated.

The effect of cell cycle redistribution on tumor responses to multifraction RT is difficult to demonstrate. This may be because of intratumoral heterogeneity or because few cells are in radiosensitive G2/M phase. Also, CSCs are believed

mainly to cycle slowly in niches, of which there are several, for example, glioma CSCs residing in both perivascular and hypoxic niches.[78,79] Most CSCs are negative for the proliferation marker Ki-67, but multiple fractions of IR may promote their recruitment from the niche and increase the proportion of cycling cells,[78,79] with a possible concomitant increase in radiosensitivity. Therefore, for CSCs, redistribution following RT may be tied to their mobilization into the cell cycle and thus regeneration.

The Oxygen Effect

In 1909, Schwarz reported that restricting the blood flow to a tissue decreased its radiation response, but it was not until 1952 that Read[80] showed that oxygen was a radiosensitizer. The relationship between oxygen tension and radiosensitivity varies, but about 3 to 10 mm Hg achieves a radiosensitivity halfway between that of hypoxic and euoxic (aerobic) cells (the k value[5]) (Fig. 3.9). Cells can survive at lower oxygen concentrations than this, so hypoxic radioresistant cells can retain viability. The inset in Figure 2.9 shows how survival curves are modified by oxygen concentration. The ratio of doses required to produce the same level of effect (e.g., cell survival) in hypoxic and euoxic conditions is the oxygen enhancement ratio (OER), which is between 2.5 and 3 for high doses of x- or γ-rays and slightly lower at low doses or low dose rates. This may be because at low doses, most damage comes from the densely ionizing component at the ends of electron tracks that are less affected by oxygen.

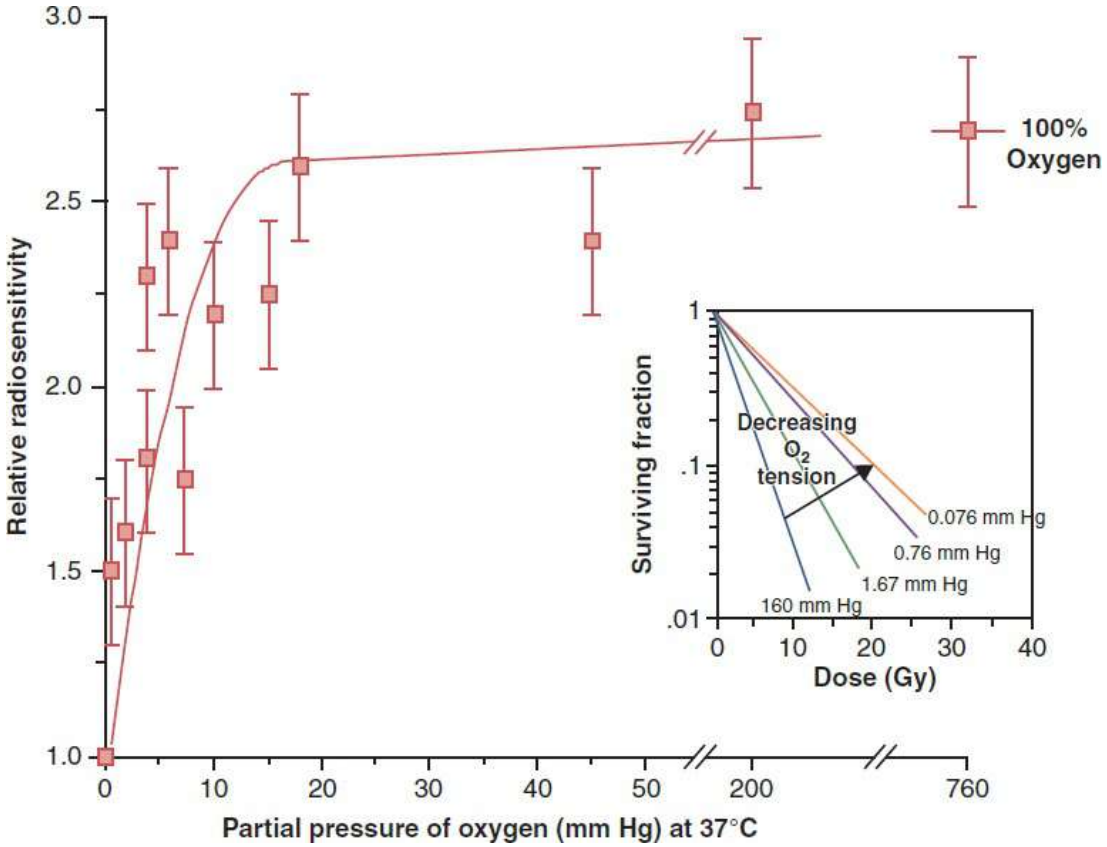

FIGURE 3.9. Curve relating cellular radiation sensitivity to partial pressure of oxygen at the time of irradiation. Data were obtained by scoring anaphase aberrations in Ehrlich ascites tumor cells, although similar curves have been obtained for killing of bacteria. About 50% of the total sensitization by oxygen is seen at a partial pressure of approximately 4 mm Hg at 37°C. The *inset* shows survival curves for different levels of oxygenation.

The electron affinity of oxygen is critical to radiosensitization. After this was realized, radiochemists developed electron-affinic drugs that could mimic the radiosensitizing effect of oxygen and that had more favorable properties, like being easier to administer, less rapidly metabolized, and able to diffuse further into hypoxic regions. The nitroimidazoles were most promising, for example, metronidazole, misonidazole, etanidazole, and nimorazole. Recently, other drugs have been developed, such as tirapazamine, that are selectively toxic to hypoxic cells and may radiosensitize.[81] Toxicity has somewhat limited the use of all of these drugs, but there is evidence of clinical efficacy.

Relevance of Hypoxia to Clinical Radiation Therapy

Tissue oxygenation is critically dependent on capillary blood flow, which is sluggish in solid tumors that develop hypoxic foci[82] because of poor blood supply, necrosis, shunts, or temporary occlusions. Temporary occlusion and

blood shunting cause acute transient hypoxia that may be more important in RT than chronic hypoxia, which generally results from limited oxygen diffusion.[83] Chronic hypoxia may even radiosensitize as it decreases RAD51-mediated HR.[84]

Hypoxia has been linked with poor clinical outcome. Hyperbaric oxygen[85] or correction of anemia may help, although erythropoietin can support tumor CSC proliferation and survival, and so has the opposite effect.[86] Poor local control and survival rates have been correlated with hypoxia in head and neck and cervix cancer treated with RT.[82] However, outcome of surgical treatment alone in patients with uterine cervix cancers also correlated with hypoxia,[87] which can be explained by hypoxia selecting for more aggressive tumors.[88]

Despite the likely existence of hypoxic cells within many, if not all, solid human tumors, the importance of hypoxia as a predictor of individual response to RT has yet to be established, probably because the causes of tumor radioresistance are multifactorial and very complex. It is hard to routinely differentiate between acute and chronic hypoxia, and the status may change after RT as vascular damage preferentially eliminates acute hypoxia.[32,89] RT may also inhibit angiogenesis,[90] forcing the tumor to rely more on vascular supply through vasculogenesis. How common these radiation-induced alterations in the tumor microenvironment are in clinical reality, their intertumor variation, and their relationship to tumor cure has yet to be fully established, but higher than conventional doses may be required for vascular damage, directly[32] or indirectly through proinflammatory cytokines,[91] so they may be especially important in highly accelerated hypofractionated regimens.

Tumor Reoxygenation

Reoxygenation can occur during fractionated RT. The rate and extent seem variable, but if 30% of tumor cells were hypoxic and 70% euoxic and there was no reoxygenation during a course of conventional RT, most surviving cells would be hypoxic after the first few fractions and 70 Gy would be noncurative reducing survival to only about $<10^{-4}$. These are large assumptions and probably incorrect; however, they indicate the relevance of reoxygenation to tumor control. The possible effect of reoxygenation on the response to multiple dose fractions can be appreciated from Table 3.1. For example, the dose to a tumor that repeatedly returns to an 80 to 20 euoxic-to-hypoxic ratio would need to be 15% higher than if all tumor cells were euoxic. Where large dose fractions are given as a single exposure, outcome may be more compromised by hypoxia, but

the high control rates achieved experimentally and clinically with brachytherapy and SABR suggest that reoxygenation is either adequate or not critical. In hyperfractionation, where the dose per fraction is small, responses will be little affected by 10% to 20% hypoxia. Reoxygenation should be a rapid process, but tumor cells may need to be reduced in number or interstitial tumor pressure decreased, which may take time. It should be noted that free radicals generated during reoxygenation may be particularly toxic to cells, which may be why CSCs that resist considerable redox fluctuations can exist in a perivascular niche.[54] This could contribute to some of the vascular effects of RT mentioned above.

TABLE 3.1 Ratios of Dose for Isosurvival Equivalent to That From 2 Gy in OXIC Conditions[a]

Ratio of Euoxic to Hypoxic Cells	Dose Modification Factor
100/0	1.0
90/10	1.07
80/20	1.15
70/30	1.23
60/40	1.35

[a]Assuming a constant OER of 2.5 at all doses.

QUANTITATIVE RADIOBIOLOGY AND DOSE FRACTIONATION

Random Nature of Cell Killing

Our earliest understanding of dose–response relationships for irradiated cells came from studies with bacteria,[92] where survival decreases geometrically. In other words, the dose that reduces the survival rate to 50% will, when doubled, reduce it to 25%, and so forth, resulting in a straight line semilogarithmic plot, reflects random cell kill. Poisson statistics indicate that if 100 lethal lesions are distributed randomly throughout 100 equally radiation-sensitive cells (mean lethal dose = 1), 37 cells will be spared, 37 will have one lethal lesion, 18 will have two, etc. (Fig. 3.10), and all with >1 lesion will be dead. The 37% survival rate will recur for each additional mean lethal dose.

The mathematic bent of early radiation biologists, many of whom were also physicists, caused them to describe the slope of survival curves in terms of the

mean lethal dose (D_{37} or D_0), which reduces survival by one natural logarithm (e^{-1}). D_{10}, which reduces it by one common logarithm ($\log_{10}$), is an easier term to think in with D_{10} about 2.3 times D_0.

Mammalian Cell Survival Curves

Puck and Marcus[17] published the first survival curve for mammalian cells in 1956. In general, cell survival decreases logarithmically with dose, but D_0 values are one-tenth of those for bacteria, generally between 0.75 and 2 Gy, largely because of differences in DNA target size. Also, mammalian cell survival curves most often have a shoulder before the logarithmic decline (Fig. 3.11). The biologic basis for the shoulder is not firmly established; however, it is consistent with the views of Lea,[93] Catcheside,[92] and Read[94] who quantified biologic responses to irradiation in terms of linear, single-hit, α-type killing term plus a quadratic, multihit, β-type killing term. At clinical doses of around 2 Gy, most killing is single hit. At higher doses, additional multihit lesions accumulate, which are the result of interactions between lesions caused by different electron tracks (intertrack). This “sublethal” injury can be converted into additional lethal injury.

Additional complexity comes from the fact that some systems show hypersensitivity to very low radiation doses (<20 cGy), and a plateau of radioresistance from about 30 cGy to 1 Gy, before the usual curve that bends down with increasing dose.[95] This phenomenon is not universal; only some human cell lines display it *in vitro* and only some tissues, for example, mouse skin, kidney, and lung. The precise mechanisms are still unclear, although low dose hypersensitivity may be due to a failure to activate G2-phase cell cycle checkpoints.[96] Obviously, many things can affect radioresponsiveness and therefore the dose–response curve. Mathematical models are derived to fit existing data, and their limitations must be considered when applying them in the clinic.

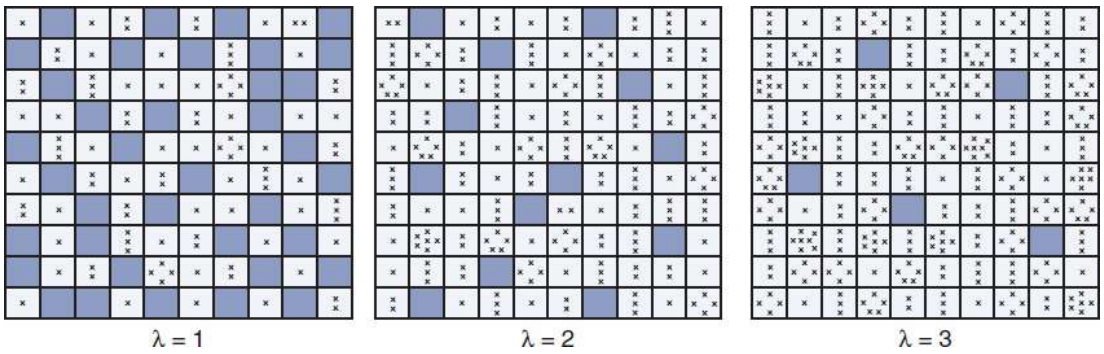

FIGURE 3.10. Random distribution in 100 equal-sized "targets" of 100, 200, or 300 "hits." The probability that any one of the 100 targets will not be struck when 100 hits are delivered randomly is e^{-1}, or 37%. The same probability of survival applies for each equal increment in the number of hits: 200 hits would result in a probability of survival of e^{-2}, or 0.37 × 0.37. Even after 300 hits are delivered, there is still a chance of e^{-3} = 5% that any one target will survive. This proportionate, or geometric, decrement in survival rate may be plotted as a *straight line* on semilogarithmic coordinates. (From Withers HR, Peters LJ. Biological aspects of radiation therapy. In: Fletcher GH, ed. *Textbook of radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger, 1980.)

Linear Quadratic Formula

Assuming a linear dose coefficient (α) and a coefficient (β) for the square of the dose, the effect (E) is proportional to $\alpha D + \beta D^2$, which can be used to fit a continuously bending curve to cell survival data.[97] The linear component (αD) is of major significance for conventionally fractionated RT (Fig. 3.12). Its importance was largely ignored in the 1960s but was "rediscovered" in the early 1970s when Dutreix et al.[98] demonstrated that acute effects in human skin were not spared by decreasing fraction sizes below 3 Gy, that is, when the multihit component has become negligible and the effective survival curve is linear and has reached the slope of the α component in the single-dose curve. Now, it is accepted that single lethal hits are required for low dose rate brachytherapy or standard fractionated RT to eradicate cancer.[99]

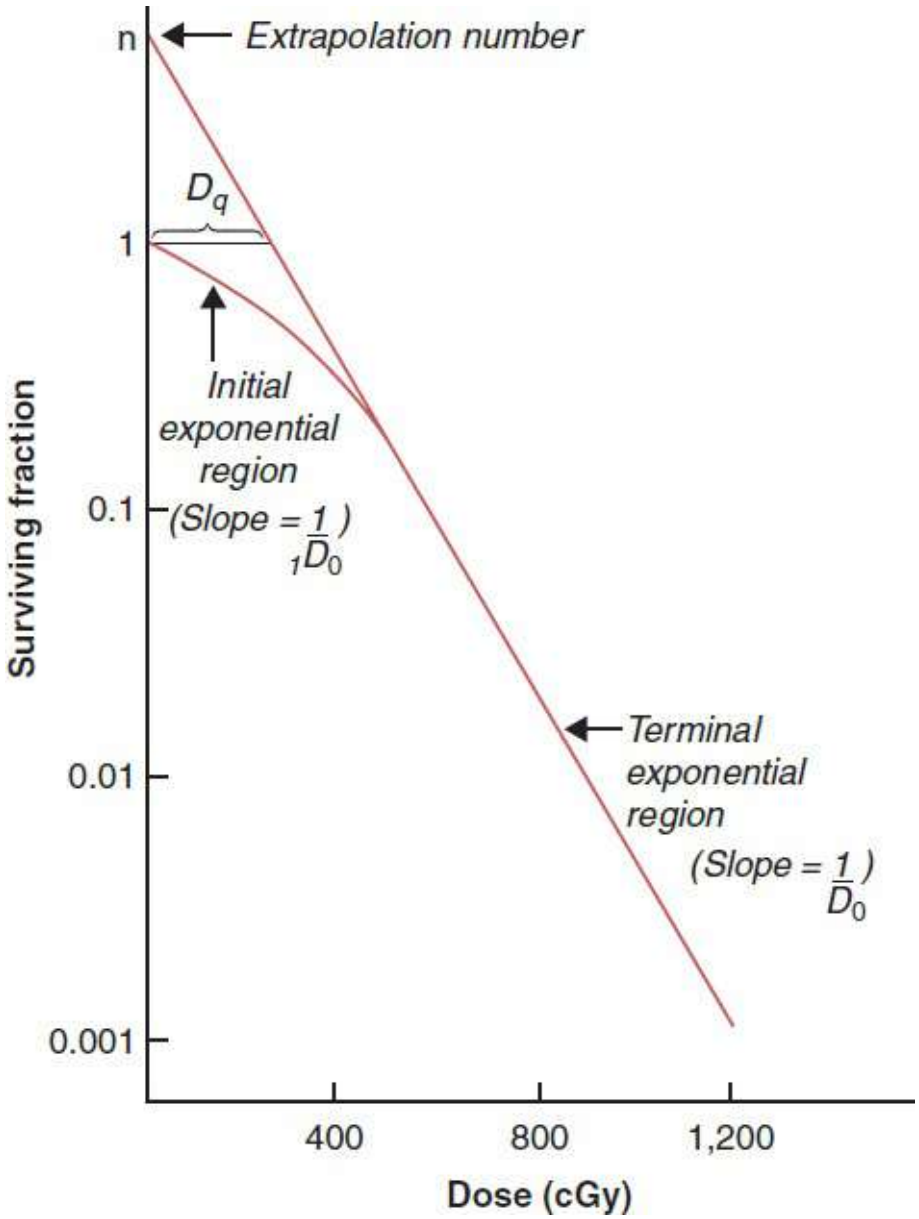

FIGURE 3.11. A TC survival curve for mammalian cells is characterized by a "shoulder" followed by a terminal exponential region, the slope of which is defined by a D_0 value (slope = $1/D_0$). The position of the curve on the radiation dose axis can be fixed by the intercepts of the terminal exponential region extrapolated back to the zero dose axis (*n*) or to the 100% survival level (D_q): *n* is termed the extrapolation number, and D_q the quasi-threshold dose. Although *n* and D_q are parameters that define the width of the shoulder on the survival curve, they do not indicate its shape, which is of prime importance in RT. The survival curve shoulder can be considered to consist of an initial exponential region (the slope of which is defined by ${}_1D_0$), followed by a downward-bending segment that merges asymptotically into the final exponential region of the survival curve. (From Withers HR, Peters LJ. Biological aspects of radiation therapy. In: Fletcher GH, ed. *Textbook of radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger, 1980.)

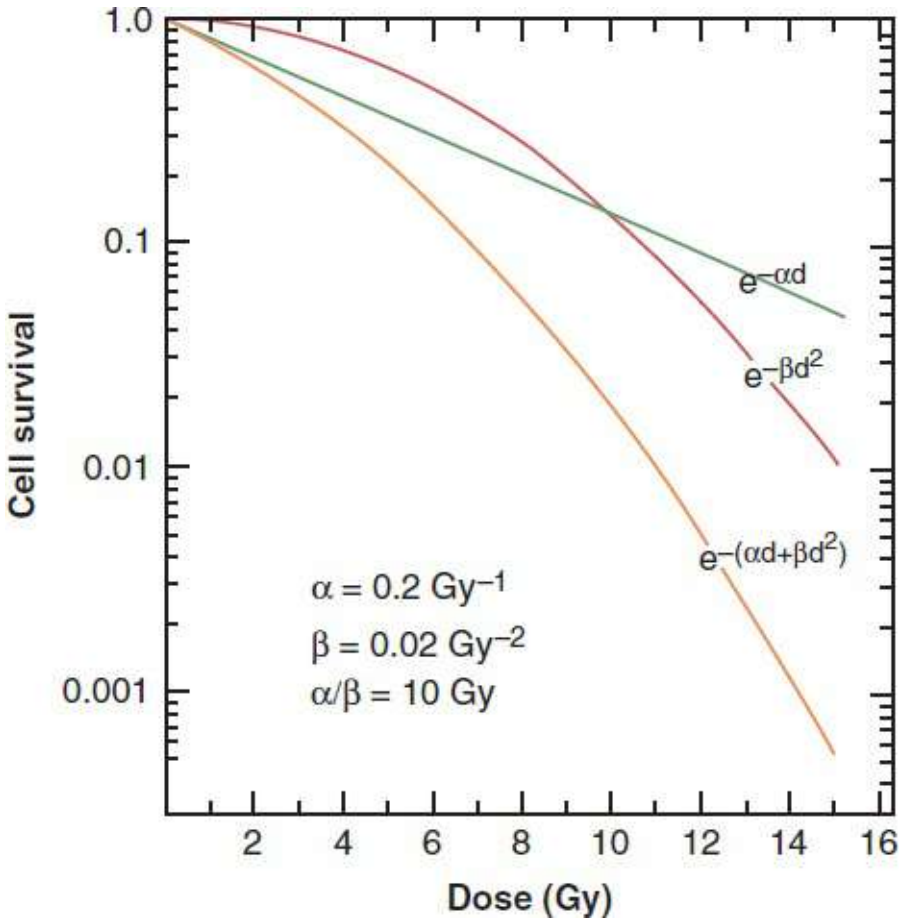

FIGURE 3.12. Model dose–survival curves for mammalian cells showing that the experimentally determined curve for acute exposures (lowest curve) is the product of two mechanisms: single-hit injury described by an exponential curve ($e^{-\alpha d}$), and multihit, or cumulative, injury described by a continuously bending curve related by a coefficient, β, to the square of the dose. At doses of clinical relevance, cell death from the single-hit mechanism predominates. The rate at which the survival curve bends from an initial, essentially exponential region depends on the ratio (α/β) of the coefficients for single-hit and multihit killing: the lower the value, the sooner and more steeply the curve bends. The value of α/β is the dose at which single- and multihit mechanisms contribute equally to cell killing. In these curves, α/β = 10 Gy, which is a value characteristic of acutely responding tissues. Target cells in late-responding normal tissues are characterized by low α/β values; hence, their survival curves are curvier. The flexure dose, D_f, is the dose at which deviation from the initial exponential part of the curve is difficult to detect and, for available biologic assay systems, is about one-tenth of α/β. When doses in a multifraction regimen are less than D_f, further dose fractionation does not produce detectable "sparing" (because cell killing is essentially all the result of single-hit events, the lesions potentially contributing to multievent killing being completely repaired during the fractionation intervals). The lower the α/β value, the lower the dose at which multihit mechanisms cause cell death, the lower the value of D_f, and the lower the dose per fraction below which a sparing effect of dose fractionation is lost. The curve for single-hit killing ($e^{-\alpha d}$) can be measured experimentally using very small dose fractions or a continuous low dose rate exposure; however, the curves for multihit killing ($e^{-\beta d2}$) can be determined only

indirectly from a knowledge of the other two curves.

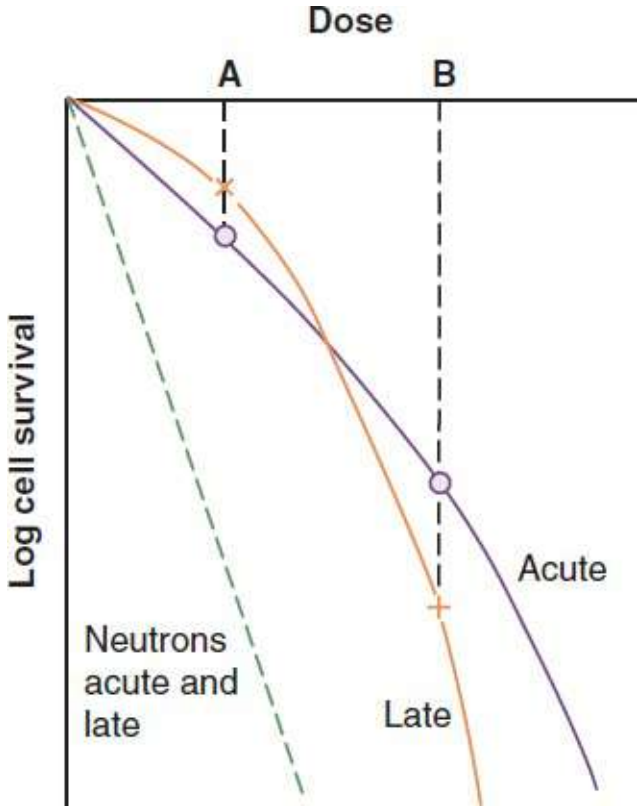

FIGURE 3.13. Hypothetical survival curves for the target cells for acute and late effects in normal tissues exposed to x-rays or neutrons. The *α/β* ratio is lower for late effects than for acute effects in x-irradiated tissues, resulting in a greater change in effect in late-responding tissues with change in dose. At dose A, survival of target cells is higher in late-effect than in acute-effect tissues; at dose B, the reverse is true. Increasing the dose per fraction from A to B results in a relatively greater increase in late than acute injury. For neutrons, the *α/β* ratio is high, with no detectable influence of the quadratic function (βd^2) over the first two decades of reduction in cell survival, implying that accumulation of sublethal injury plays a negligible role in cell killing by doses of neutrons of clinical interest.(Reprinted from Withers HR, Thames HD, Jr, Peters LJ. Biological bases for high RBE values for late effects of neutron irradiation. *Int J Radiat Oncol Biol Phys* 1982;8[12]:2071–2076. Copyright © 1982 Elsevier. With permission.)

$$\text{S.F. (survival fraction)} = e^{-(\alpha D+\beta D^2)}$$

The dose range over which the linear component dominates depends on the relative values of *α* and *β*. The *α/β* ratio defines the dose at which cell killing by linear and quadratic components are equal. The higher the *α/β* ratio, the more linear and steeper is the dose–response curve and the less sensitive it is to dose fractionation. The lower the *α/β* coefficient, the “curvier” is the survival curve, bending down only after an initial linear region and allowing a marked sparing

effect of dose fractionation (Figs. 3.13 and 3.14). The parameters can be estimated from multifraction data if the reciprocal of the total dose $1/nd$ is plotted against dose per fraction (d) (Fe plot).[100] The intercept on the ordinate is $\alpha/\log_e S$, and the slope is $\beta/\log_e S$. The ratio of the intercept to slope gives the α/β ratio. Fowler[101] also introduced the biologically effective dose (BED), which is the total dose multiplied by its relative effectiveness and changes linearly with a slope dependent on the α/β value of the tissue.

TABLE 3.2 α/β Values

Early-Responding Tissues	α/β (Gy)	Late-Responding Tissues	α/β (Gy)
Skin (desquamation)	9.4–21.0	Spinal cord (paresis)	1.6–5
Skin—pig (desquamation)		—Cervical	2–3.4
—Time ≤16 d	8.7	—Lumbar	4–5
—Time >16 d	0.9	Brain (LD_{50}/10 mo)	2.1
Lip mucosa (desquamation)	7.9	Kidney (multiple endpoints)	0.4–5
Jejunal mucosa (clones)	7–13	Lung (pneumonitis)	1.6–4.5
Tongue mucosa (ulceration)	11.6	Lung (fibrosis)	2.3
Colonic mucosa (clones)	7–8.5	Heart failure	3.7
Hair follicles (epilation)		Liver (clones)	2.5
—Anagen	7.5	Bladder (frequency)	7.2
—Telogen	5.5	Bladder (contraction)	5.8–11.0
Testis (clones)	13.9	Bowel (stricture/perforation)	3.5–5
Spleen (clones)	8.9	Bowel (fistula/obstruction)	10.7
Bone marrow (clones)	9.0	Bowel (rectal stenosis, <5 d)	6.2
Melanocytes (depigmentation)	6.5	Bowel (rectal stenosis, >5 d)	1.1
Tumors (cure)		Dermal contraction	1.5–3.5
Experimental tumors	10–35	Dermal wound healing	2.5
Most human tumors	6–25	Eye cataracts	1.2
Human prostate cancer	1.5	Bone (human fracture)	2.2
		Cartilage and submucosa	1–4.9
		Total body irradiation (LD_{50}/1 y)	5.1

These values represent a synthesis from many sources. Individual values are means from one study. Where a range is given, it represents mean values from multiple studies.

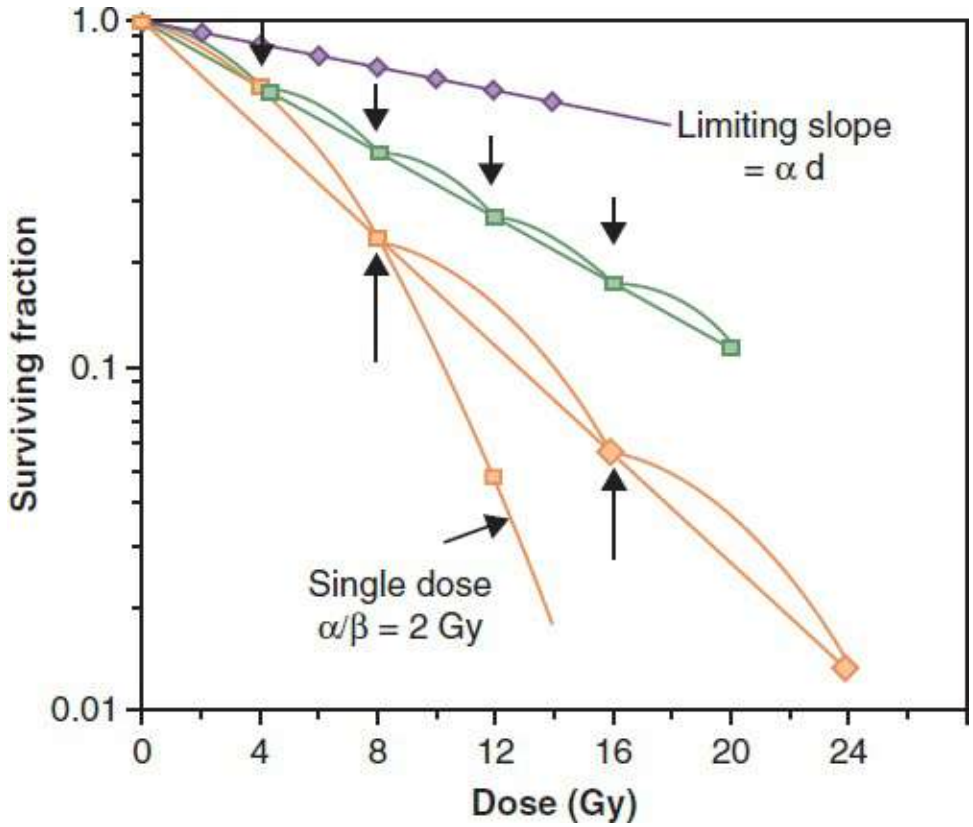

FIGURE 3.14. Multifraction dose–survival curves compared with a single-dose curve. Effective survival curves for multifraction regimens that produce an equal (proportionate) decrement in survival from each dose are linear, with shallower slopes than the single-dose curve at the same dose. Slopes of the multifraction curves become less steep with a decrease in fraction size until the dose per fraction is so low that multihit killing contributes negligibly and the slope is the limiting one determined by single-hit killing (and $_eD_0 = 1/\alpha$). The dose per fraction below which the effective survival curve becomes no shallower is a function of the curviness of the single dose–survival curve and is lower than the α/β value.

The α/β ratio is a measure of how sensitive different tissue responses are to changes in size of dose fraction. Importantly, it is not a measure of radiosensitivity *per se*. Late-responding, slow turnover tissues generally have a low α/β ratio and a large fractionation effect. Acute-responding, high turnover tissues generally have a large α/β ratio, as do many tumors, although melanoma, soft tissue sarcoma, liposarcoma, prostate, and breast tend to have low α/β ratios (Table 3.2). Variation observed within any one tumor type may indicate lineage differences. The linear quadratic (LQ) model is simple and useful in part because α/β ratios can be determined from *in vivo* multifraction experiments even though the absolute values of each coefficient are unknown.

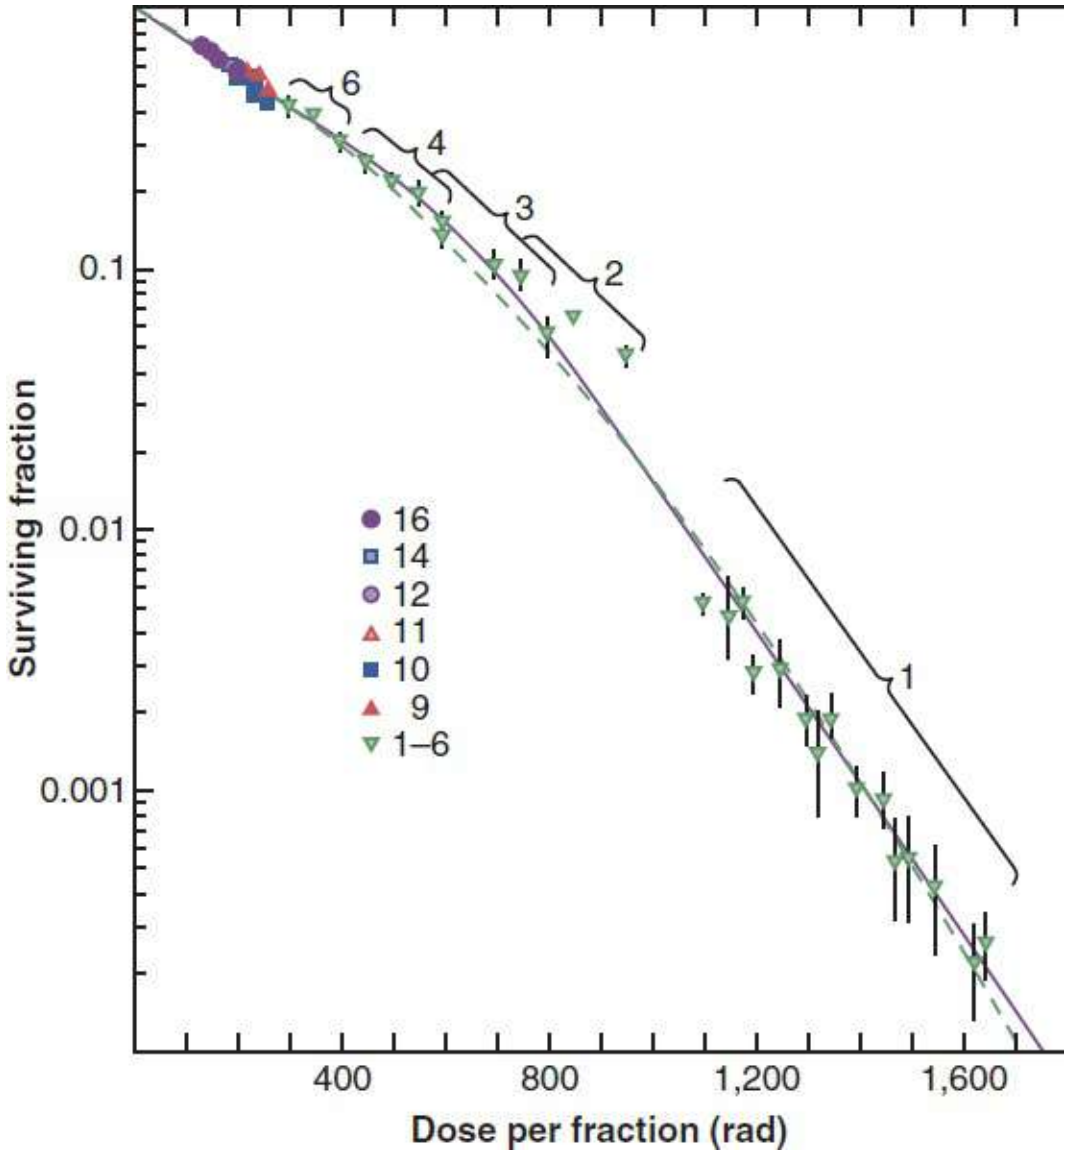

FIGURE 3.15. Effective single dose–survival curves for clonogenic cells of jejunal crypts fitted to multifraction data using LQ (*broken curves*) and TC (*solid lines*) models. Numbered brackets illustrate that the data were from experiments using that number of fractions. Mean survival curve parameters are as follows: for LQ model, n α = 0.23 Gy, β = 0.018 Gy^{-2}; for TC model, $_1D_0$ = 3.57 Gy, D_0 = 1.43 Gy, $_nD_0$ = 2.37 Gy, and n = 20.4. (Reprinted from Thames HD, Jr, Withers R, Mason KA, et al. Dose-survival characteristics of mouse jejunal crypt cells. *Int J Radiat Oncol Biol Phys* 1981;7[11]:1591–1597. Copyright © 1981 Elsevier. With permission.)

Two-Component Model

Dose–survival curves can be well fitted by formulas other than the LQ formula. The two-component (TC) model combines a single-hit component $e^{-D/_1D_0}$, where $_1D_0$ is the dose required to reduce survival to 0.37(e^{-1}), with a multiple-hit $e^{-(1-e-D/_nD_o)^n}$, where $_nD_o$ is the dose needed to reduce survival to e^{-1} in the final

region of the curve and *n* is the extrapolation number (Fig. 3.11).

$$S.F. = e^{-D/D_1} \cdot (1 - [e^{-D_n/D_0}]^n)$$

Comparison of the Linear Quadratic and Two-Component Survival Models

Over a limited dose range (e.g., 2 to 8 Gy), relevant to most RT, both the TC and LQ models "fit" data similarly (Fig. 3.15). Outside this range, many experimental isoeffective curves are not very linear, and use of either model is unlikely to give realistic equivalent doses,[102] although there are other opinions.[103] The models differ significantly at predicting isoeffective doses at fractions of <2 Gy. The differences may appear small but are amplified if, for example, a dose of 1.15 Gy were to be repeated 70 times or more, as could happen in a hyperfractionated RT regimen (Fig. 3.16).

Multifraction Survival Curves

In 1959, Elkind and Sutton[77] showed recovery from sublethal damage (SLD) within a few hours, which can be estimated by split-dose experiments, that is, by increasing time between two dose fractions over a 24-hour period or by the increase in total dose necessary to achieve the same level of cell survival, or isoeffect (D2 to D1) (Fig. 3.17). If repair of SLD is complete, survivors of the first dose behave as though they had not been irradiated. So, if 2 Gy reduces survival to 50% ($S.F._{2Gy} = 0.5$), two doses of 2 Gy would reduce it to $(0.5)^2$ and *n* doses to $(0.5)^n$. Complete repair and no effect of redistribution, regeneration, or reoxygenation between doses are unlikely, but each dose fraction having an equal effect is a sufficient assumption for modeling purposes, and the multifraction dose–survival relationship gives a straight line when plotted on semilogarithmic coordinates (Fig. 3.18), extrapolating to 1 ($n = 1$) with a slope that is shallower the smaller the dose per fraction (Fig. 3.14). If the effects of the 4Rs were constant, the resulting survival curve would be linear and the slope would vary depending on the extent to which each phenomenon affected the response. More likely, their influence varies with time. In some normal tissues (e.g., oropharyngeal mucosa), regeneration of surviving clonogenic cells late in a course of 1.8- to 2 Gy fractions may outstrip the cytocidal effect of treatment and the net survival curve will have a positive slope, as may happen to tumors on treatment. Despite these uncertainties, models of dose–response relationships can be useful.

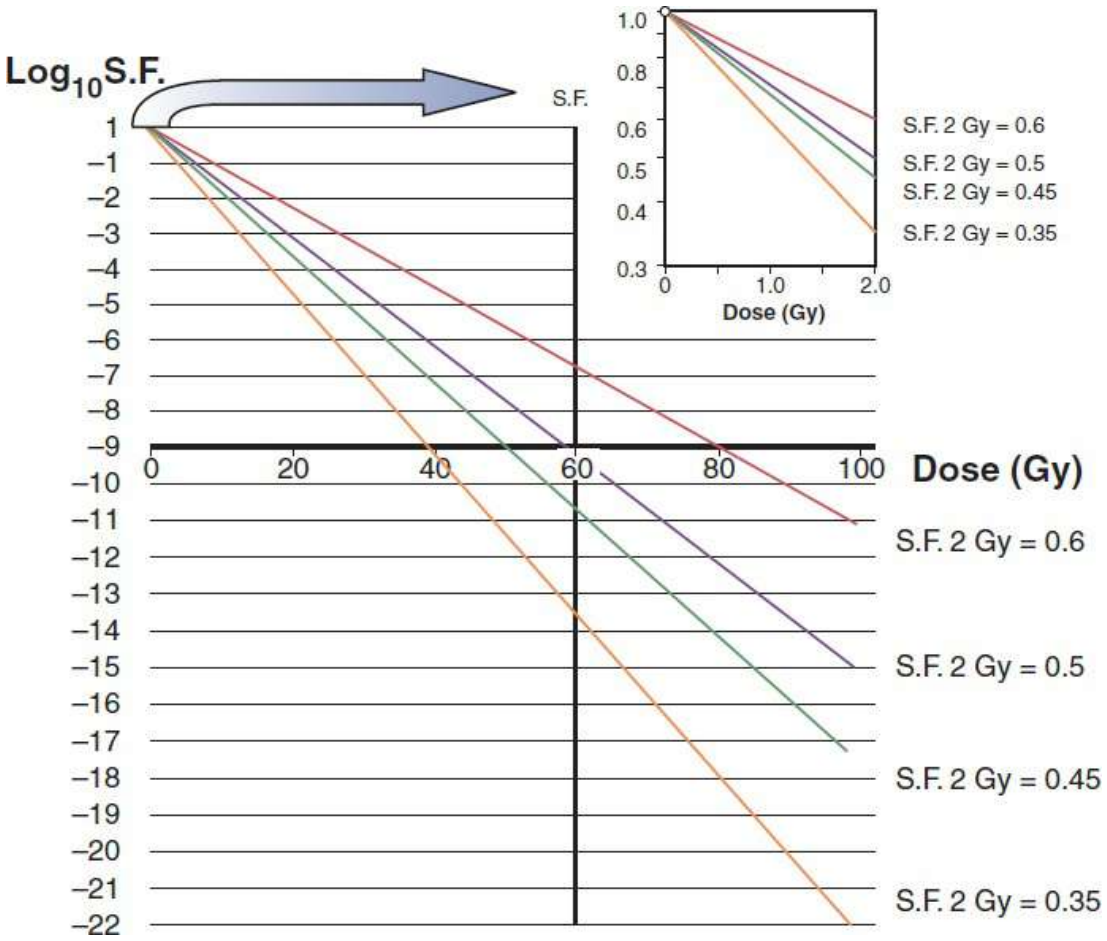

FIGURE 3.16. Effective multifraction dose–survival curves for cell populations, the survival of which from 2 Gy varies from 0.65 to 0.35. When survival from 2 Gy is 0.5, survival from 30 × 2 Gy is $(0.5)^{30}$ = approximately 10^{-9}. When this figure was constructed, this survival value was taken as an arbitrary standard against which the relative survival of other populations exposed to 30 × 2 Gy was plotted. The abscissa at the standard survival shows the total doses in 2-Gy fractions necessary to achieve that standard survival level in different cell populations. In all cases, an equal effect per dose fraction was assumed. The ratios of cell survival after a total dose of 60 Gy illustrate the exponential amplification of survival differences with increasing dose. Thus, dose fractionation can transform small differences in response at low doses (2 Gy) to large ultimate differences; measurements must be made accurately after a dose of 2 Gy to predict accurately the ultimate outcome of high dose multifraction irradiation. (Reprinted from Withers HR. Predicting late normal tissue responses. *Int J Radiat Oncol Biol Phys* 1986;12[4]:693–698. Copyright © 1986 Elsevier. With permission.)

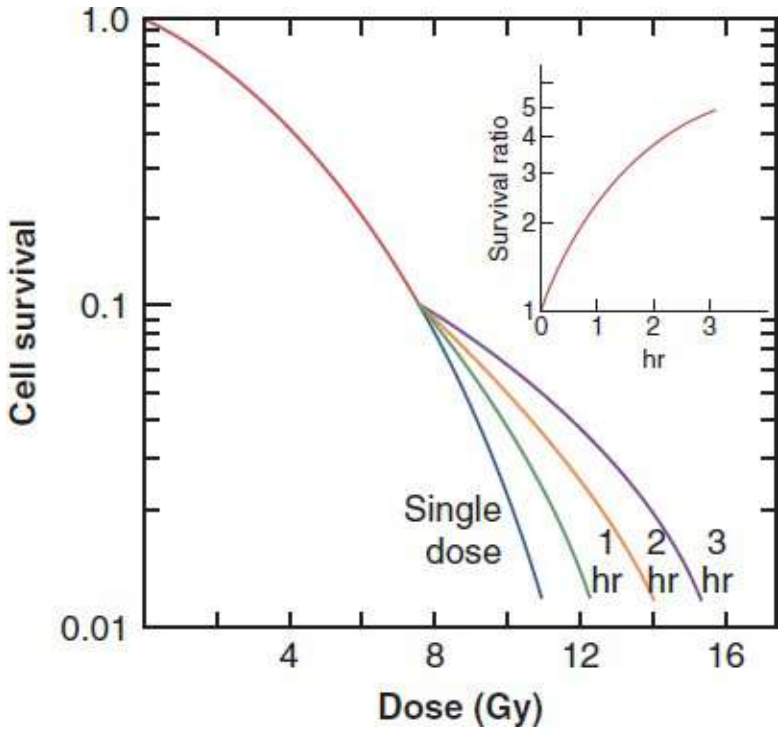

FIGURE 3.17. Recovery curves of the type first described by Elkind and Sutton.[77] The repair of sublethal injury begins immediately and can be measured in terms of survival ratio (*inset*) or the increment in dose to achieve isosurvival. (Reprinted by permission from Nature: Elkind MM, Sutton H. X-ray damage and recovery in mammalian cells in culture. *Nature* 1959;184:1293–1295. Copyright © 1959 Springer Nature.)

The slope of a multifraction survival curve can be described by an "effective D_0" ($_{eff}D_0$, or $_eD_0$) that reduces survival to e^{-1}. If $S.F._{2Gy}$ were 0.5, the corresponding $_eD_0$ value for a series of 2 Gy fractions would be 2.9 Gy ($S.F. = e^{-D/_{eff}D_0}$). If the $S.F._{2Gy}$ values ranged from 0.45 to 0.67, the $_{eff}D_0$ values are from 2.5 to 5.0 Gy. In mice, $S.F._{2Gy}$ values for jejunal crypt and spermatogenic stem cells are about 0.6 and for colonic cells about 0.65, giving $_{eff}D_0$ values for 2 Gy fractions of about 3.9 and 5.0 Gy, respectively. It can be calculated, in two ways, that 30 fractions of 2 Gy would reduce survival of jejunal crypt cells to 2×10^{-7}:

$$\text{S.F. after } 30 \times 2 \text{ Gy} = (\text{S.F.}_{2\text{ Gy}})^{30} = (0.6)^{30} = 2 \times 10^{-7} \text{ or}$$

$$\text{S.F. after 60 Gy in 2-Gy fractions} = e^{-60/_{eff}D_0} = e^{-60/3.9} = 2 \times 10^{-7}$$

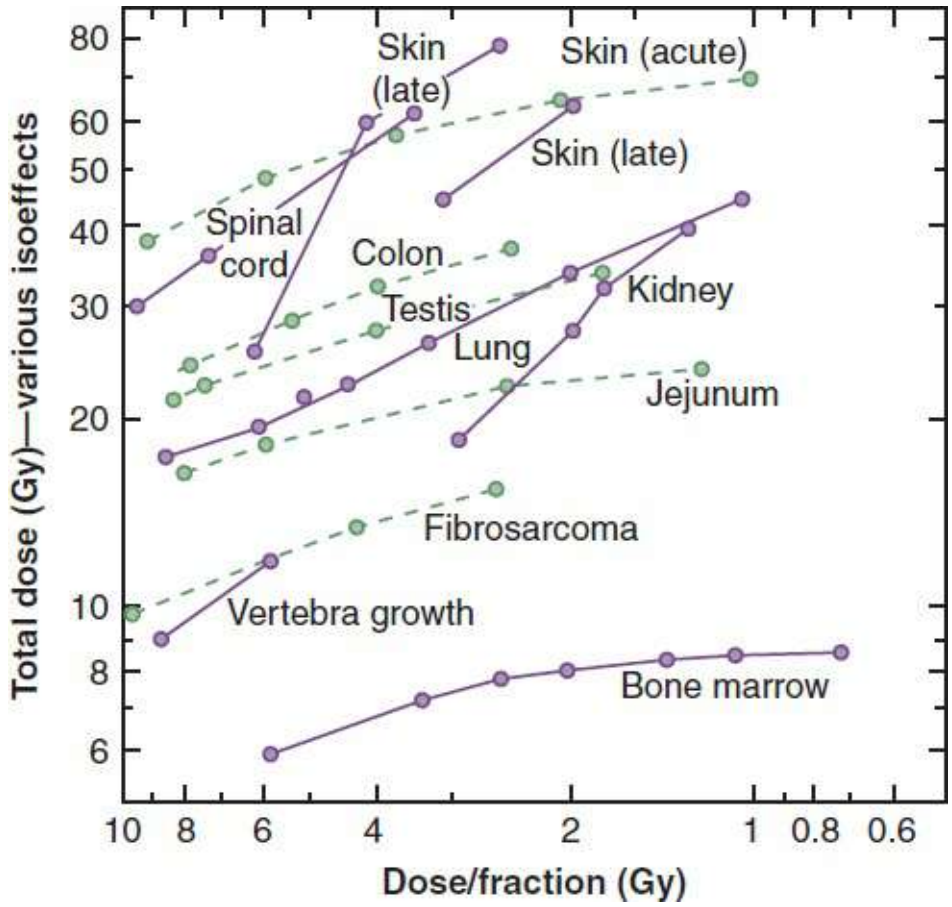

FIGURE 3.18. Isoeffect curves in which the total dose necessary for a certain effect in various tissues is plotted as a function of dose per fraction (late effects, *solid lines*; acute effects, *broken lines*). Data were selected to exclude an influence on the total dose of regeneration during the multifraction experiments. The isodoses for late effects increase more rapidly with decrease in dose per fraction than is the case for acute effects. (From Withers HR. Biologic basis for altered fractionation schemes. *Cancer* 1985;55[9 Suppl]:2086–2095. Copyright © 1985 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.)

Small differences between cell types in intrinsic sensitivity amplify after many 2 Gy fractions. For example, if $S.F._{2\ Gy}$ in one tissue were 0.6 and in another 0.5, the ratio of cell survival after 30 doses of 2 Gy would be $\left(\frac{0.6}{0.5}\right)^{30}$, or 237-fold. For 35 doses, the difference would be 590-fold. The effect of differences in $S.F._{2Gy}$ ranging from 0.35 to 0.6 on outcome after 30 fractions is shown in Figure 3.16. These very large differences can be judged from the ratios of cell survival rate (on the ordinate) or the range of total doses needed to achieve the same level of cell survival ($\sim 10^{-9}$) (abscissa).

Common Logarithms and $_eD_{10}$

If $S.F._{2Gy}$ is about 0.5, $_{eff}D_0$ values are around 2.9 Gy, and $_eD_{10}$ is 6.7 Gy. Remember that about 10^9 tumor cells tightly packed would have a volume of about 1 cm^3 and that 10^{10} cells in an average T3 tumor would form a sphere about 2.2 cm diameter. Assuming an $_eD_{10}$ of 7 Gy, treating a T_3 tumor with 70 Gy would reduce surviving clonogens by 10^{-10} ($10^{-70/7}$), that is, on average of 1 clonogen per tumor, with the 37% that have 0 clonogens being eliminated. If $_eD_{10}$ were 6.5 Gy, then 65 Gy would cure 37% of tumors containing 10^{10} cells, and a dose of (65 + 6.5) = 71.5 Gy would reduce cell survival to 10^{-11}, resulting in a 90% local control rate.

Tumor Control Probability

Tumor Control Probability for Clinically Detectable Disease

The probability of tumor control increases as radiation dose increases, with success or failure depending on killing the last clonogen, so control is achieved abruptly. A plot of tumor control probability (TCP) versus dose therefore shows no response until a certain dose is reached, then a rapid increase to 100% following a Poisson distribution. If cell survival is reduced to an average of one clonogen per tumor, there would be, on average, 37% cured. The probability of tumor control with cell survival rate is given by:

$$P_{\text{cure}} = e^{-x} = e^{-(SF \cdot M)},$$

where x is the average number of surviving clonogens per tumor, which in turn is the product of S.F. (fraction of cells surviving) and M (initial cell number). For example, if a tumor contains 10^{10} clonogens, doses that reduce survival to 10^{-10} would give an average cell survival of 1 and P_{cure} to $e–(10^{10} \cdot 10^{-10}) = e^{-1} = 0.37$, or 37%. If the total dose were increased by two $_{eff}D_0$ values, cell survival would be further reduced by two natural logarithms, from 1 to $1 \times e^{-2}$, that is, to an average of 0.135 cells per tumor, and $P_{\text{cure}} = e^{-0.135} = 0.87$, or 87%. It can be calculated that an increase in dose by three $_{eff}D_0$ values is sufficient to increase the probability of cure from 10% to 90%. If $P_{\text{cure}} = 10\% = 0.1 = e^{-x}$, then $x = 2.3$. In other words, at 10% local control rate, there is an average of 2.3 clonogens per tumor. After an increase in dose by three $_{eff}D_0$ values, $P_{\text{cure}} = e^{-(2.3.e-3)} = e^{-(0.115)} = 0.89$, or 89%.

This relationship between probability of cure and dose, above a certain threshold, is described by a sigmoid curve (Fig. 3.19). It is obvious from the above that the slope of the curve is a function of the $_{eff}D_0$ values for the last few

surviving tumor clonogens. It is steeper for neutrons or for single-dose x-ray treatments than for multifraction x-ray exposures and steeper (by the OER) for euoxic than for hypoxic cells. The dose that yields a 50% control rate for experimental studies is known as the TCD_{50}, which is in a steep part of the TCP curve and sensitive to small changes in the effectiveness of therapy. A higher rate is usually sought in clinical practice.

TCP curves from experimental data are steep but shallow for human tumors.[104–106] This reflects heterogeneity in tumor characteristics and RT prescriptions. RT is often individualized by physicians prescribing higher doses for larger tumors, which is not accounted for and flattens TCP curves. Even when variation has been minimized, TCP curves are fairly shallow, indicating a need for even better molecular profiling and examination of factors that impact their intrinsic radiosensitivity, redistribution, repopulation, and reoxygenation. The effect of constructing TCP curves for a series of tumors nonhomogeneous only in volume (T-stage) is illustrated in Figure 2.19. If tumors are stratified into three sizes varying in diameter by factors of 2, three distinct steep TCP curves would be obtained with a flatter overall TCP curve. It would not be appropriate to include a 64-fold volume range in a clinical TCP analysis, although the range in CSC numbers in human cancers of similar T-stage may be of this magnitude. The effect of CSC number would be further magnified by differences in repopulation kinetics during RT.

Normal tissue dose–response curves for the incidence of a certain complication are also sigmoid above a certain threshold, and probit analysis is used for estimating LD_{50} or ED_{50} values. Because normal tissues are more homogeneous than tumors, complication probability curves are steeper than those for tumor control, especially late effects.[107] The art of RT can be quantified in a risk–benefit analysis as a balance between the TCP and the probability of complications, NTCP (both represented by sigmoid curves illustrated in Fig. 3.20), with many factors involved. Different points illustrate this:

- If there is to be a therapeutic gain, RT must be more effective against the tumor than normal tissues, that is, normal tissues must be preferentially spared.
- In the steep midrange of TCP or NTCP, a small change in biologic effect can give a substantial change in clinical outcome. Conversely, if a change in RT produces a modest difference in TCP or NTCP, the change in biologic effectiveness may be small. It is better to quantify effectiveness as a change in dose to achieve a certain isoeffect, that is, the lateral shift of the TCP or NTCP curve. The ratio of isoeffect doses is the dose modification factor (DMF).

- At incidences of less than about 10% and greater than about 85%, changes in biologically effectiveness may not be demonstrable or useful. For example, if the TCP is 90%, any gain to be had would be minor and may be of disadvantage if there was a risk of complications.
- Because TCP and NTCP curves are generally close together, it is usually inappropriate to produce no complications (a.k.a. no pain, no gain). Within the treatment volume, a certain incidence of injury to normal tissues that is sufficient to be defined as a complication may be a prerequisite to good curative RT.
- If the TCP is to the right of the NTCP curve, tumor control without a high incidence of complications is unlikely and other modalities should be considered. For example, a therapeutic gain might come from prior tumor excision or chemotherapy. However, 50% or even 90% debulking is of modest value. A 90% reduction in tumor volume may represent only a one-decade decrease in cell number, equivalent to about 6.5 to 7 Gy in 2 Gy fractions.
- It defies scientific and ethic rationale to deny a patient the potential benefit from maximizing dose merely because TCP curves appear to be shallow in retrospective studies, as long as there is a finite chance of tumor control.

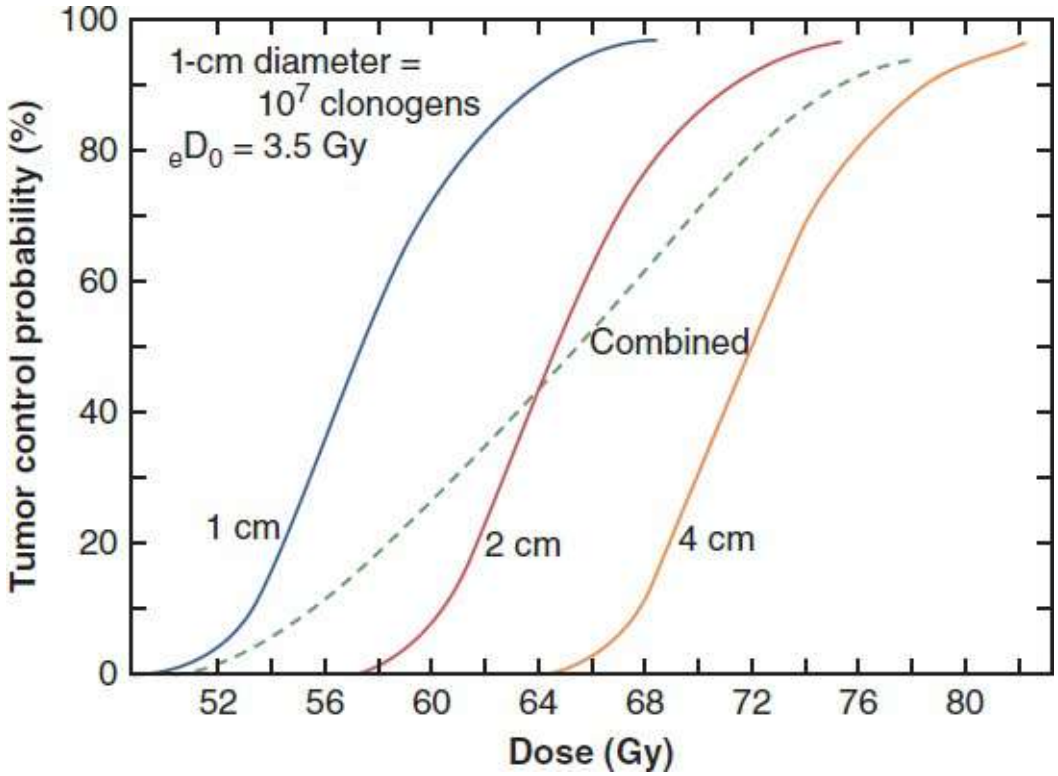

FIGURE 3.19. Theoretic TCP curves for three sizes of spherical tumors (*solid lines*) and one that would result from a study incorporating into the dose–response analysis all three tumor sizes in equal proportions (*broken line*). They were calculated on the

assumptions that the dose was given in 2-Gy fractions, that the $_eD_0$ value for 2 Gy/fraction was 3.5 Gy, and that a 1-cm diameter spherical tumor contained 10^7 clonogens. As tumor volume increases, so does the dose required for a certain probability of control. The cell number increases by 8 times and 64 times as the spherical tumor increases from 1-cm diameter to 2 and 4 cm, respectively. An exponential increase in clonogen number is related to a linear increase in dose for an isoeffect. Heterogeneity of even one factor, initial clonogen number, causes the TCP curve to be shallower (*broken line*). Retrospective clinical studies incorporate a large number of causes for heterogeneity of response.

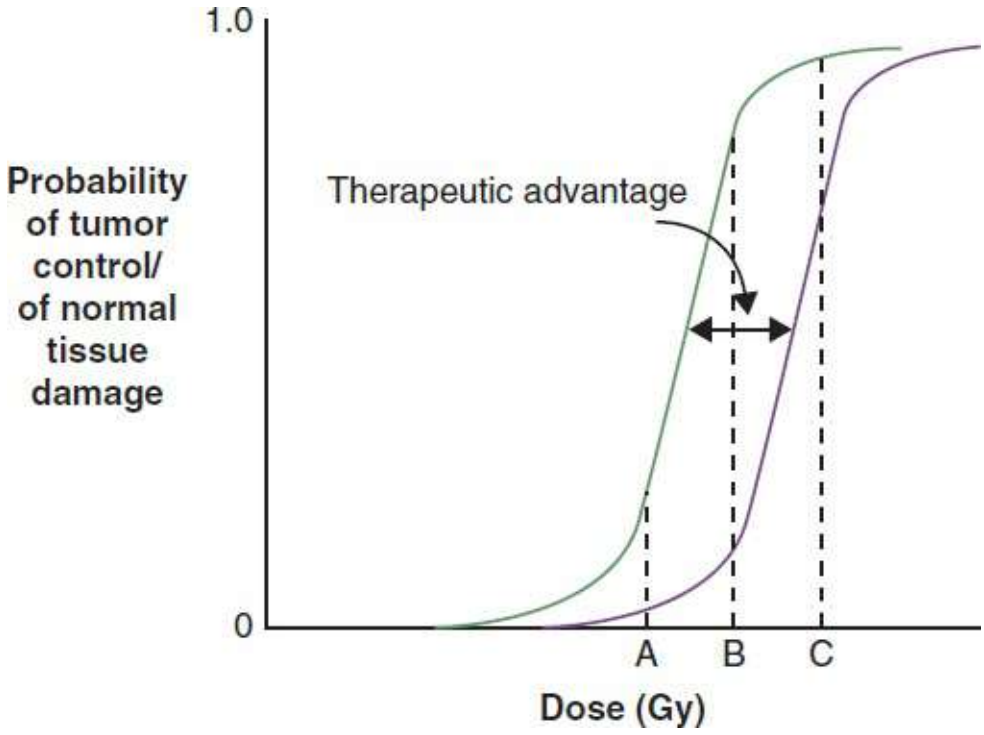

FIGURE 3.20. Theoretical curves showing the probability of tumor control and normal tissue complications. Both curves have a threshold and are log sigmoid in nature. The art of radiotherapy is to increase the distance between these two curves, that is, to derive a therapeutic benefit. If the normal tissue damage curve is to the left of that for TCP, tumor control is unlikely without unacceptable normal tissue complications.

Tumor Control Probability for Subclinical Disease

The threshold–sigmoid TCP curve for clinically detectable tumors is not appropriate for subclinical metastases. If 10^n clonogens represent the upper limit of clinical undetectability of metastases, then patients who harbor subclinical metastases have a tumor burden of between 1 and 10^n cells. Given that micrometastases grow exponentially, it is reasonable (as a working hypothesis) to assume an even distribution of the logarithm of metastatic clonogens (between 1 and 10^n cells) within a series of patients.[108] If a reasonable value for n is 9, the assumption is that there will be the same number of patients with between 1 and

10 metastatic clonogens as between 10 and 10^2, and so forth, with 11% in each cohort. Although not completely accurate, this is a reasonable assumption, and TCP curves will generally exhibit no threshold and be shallow. The model in Figure 3.21A illustrates these concepts. Although the distribution could be modified by many factors, the analysis is generally consistent with results for RT of subclinical metastases (Fig. 3.21B) and suggests that relatively low doses could cure a percent of patients with micrometastatic disease.

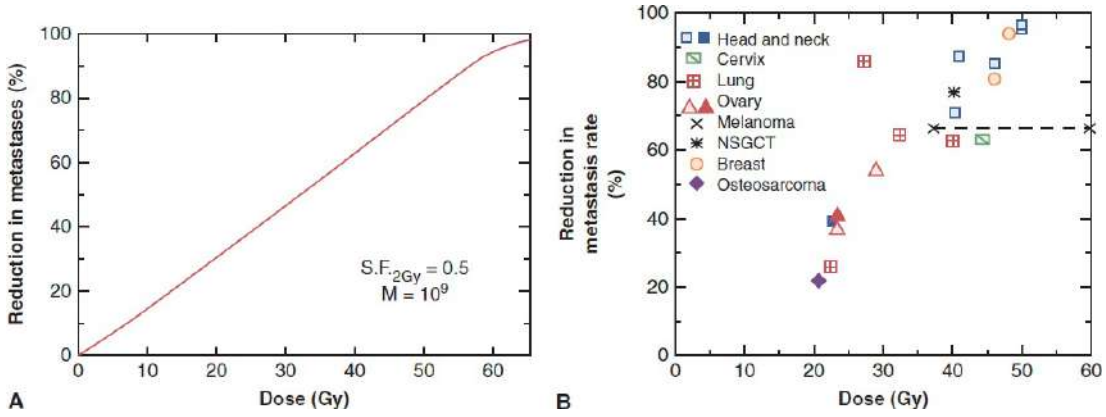

FIGURE 3.21. Percentage control rate as a function of dose for subclinical metastases. **A:** Modeling on the basis of a uniform distribution of the logarithm of numbers of metastatic tumor cells per patient ranging between 1 and 10^9. An $S.F._{2\ Gy}$ value of 0.5 was used. The intercept of this theoretic curve is displaced slightly from zero because of the random statistical chance that any cell will survive any dose of radiation. In addition, at high doses, the probability of sterilizing all tumor cells approaches 100% asymptotically for the same reason. **B:** Percentage reductions in recurrence as a function of dose from reports in the literature for various tumor types. Solid symbols represent data from prospective randomized trials. Other data are retrospective comparisons between control rates with and without elective irradiation. TIME–DOSE ISOEFFECT FORMULAS AND DOSE FRACTIONATION

History

Early isoeffect curves by Strandquist related the total dose required to produce certain skin reactions, or to achieve a certain TCP, to the treatment time over which the dose regimen was delivered.[109] Fowler and Stern[110] varied the number of fractions (N) and overall time (T) experimentally and showed that they were independent variables. Ellis[111] developed the nominal standard dose (NSD) formula to incorporate these two variables into an isoeffect curve that was used

clinically for decades until the LQ model became popular, with or without modification for parameters related to the 4Rs.[112] In fact, there can be no single universally applicable isoeffect equation or curve because tissues (and tumors) differ greatly in characteristics that determine fractionation responses and kinetics that cannot be readily quantified.

Acute- Versus Late-Responding Tissues

The most clinically important biologic phenomenon influencing fractionated RT is differences between late- and early-responding tissues and tumors on changing the dose per fraction.[113] The exact reason is unknown but is entwined in differences in mechanisms of DNA repair and the mode of cell death that determine tissue turnover and recovery following RT. So, as the size of dose per fraction is reduced, the dose for an isoeffect increases more rapidly in late- than early-responding tissues, as is reflected in the slopes of isoeffect dose–survival and dose–function curves in Figures 3.18 and 3.22. Those in Figure 3.22 are constructed using the LQ formula to correct the total dose (normalized to 1) to that which would be given if the dose per fraction were a standard 2 Gy. Shown for comparison is a plot based on the NSD formula where the correction for time is ignored, that is, where $D = \text{NSD} \times N^{0.24}$.

Some specific clinical implications of the differences in fractionation responses between acute- and late-responding tissues are as follows:

- For the same level of acute effects, large dose fractions are relatively more harmful to late-responding tissues than small dose fractions.[113]
- Because of this therapeutic differential, the smallest practical dose per fraction should give the best therapeutic gain.[114] For example, for a hyperfractionated regimen, if two fractions of 1.15 Gy are isoeffective for 2 Gy in a late-responding tissue while 1.05 Gy is isoeffective for the tumor, the therapeutic gain would be 1.15/1.05 = 1.1, increasing the biologically effective tumor dose by 10% with no increase in late complications, although acute-responding normal tissues will receive an increased biologic dose.
- To maximize the potential therapeutic gain from hyperfractionation, repair of SLD in late-responding tissues must be complete, implying fractionation intervals of at least 6 hours.[107,115] For the spinal cord, a longer interval may be prudent.[116]
- The relative biologic efficiency (RBE) for high LET radiations is greater at low doses than high doses for late effects because the comparison is with x-rays that have a large sparing effect at low doses (Fig. 3.13).

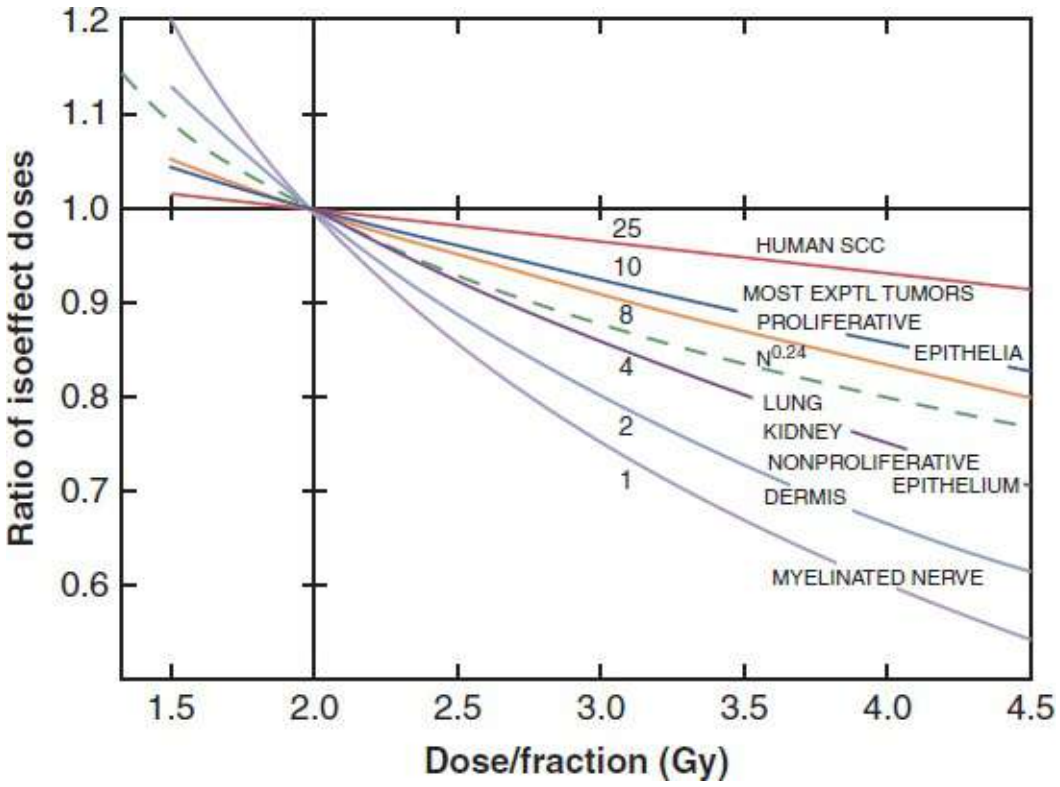

FIGURE 3.22. Isoeffect curves relating total dose to dose per fraction, with total dose being expressed as a ratio of that necessary in 2-Gy fractions (i.e., the $LQED_{2\ Gy}$). *α/β* ratios (in Gy) are shown on the curves. Although the *α/β* ratios are not yet established accurately or even precisely for most normal tissues, especially late-responding ones (Table 2.2), the likely order of fractionation sensitivities is as shown. The *broken line* traces the change in dose, as it would have been predicted by a factor $N^{0.24}$ in the NSD formula. Phenomena other than repair of sublethal injury, specifically repopulation, are not accounted for by these curves. (From Withers HR. "Failla Memorial Lecture, Contrarian Concepts in the Progress of Radiotherapy." *Radiat Res* 1989;119:395–412. Reused with permission from Radiation Research. Using the LQ Formula for Calculating Isoeffect Relationships

The LQ formula can be used to change the size of dose per fraction (within limits)[117,118]:

$$D_{new}/D_{ref} = (\alpha/\beta + d_{ref})/(\alpha/\beta = d_{new}),$$

where D_{new} is the new total dose for dose per fraction of d_{new}; D_{ref} is the previous total dose in fractions of d_{ref}; and *α/β*, in Gy, is for the tissue in question. For example, if d_{new} were 4 Gy and d_{ref} were 2 Gy, the ratio of total doses to achieve the same effects in a tissue with an *α/β* value of 2 Gy would be 0.66. For a tissue with an *α/β* value of 10 Gy, it would be 0.85. This calculation

was used to derive the data in Figure 3.22.

The following caveats apply to this use of the LQ isoeffect formula:

- The LQ response model does not apply equally at all dose levels. It fits well between about 1.5 to 8 Gy; however, its validity and precision above or below that range is in doubt.
- Using uncertain values for α/β ratios affect late-responding tissues more and carry more risk. For tissues with α/β values of 10 Gy or more, isoeffect curves change little for different dose per fraction regimens, but this is not true for tissues with α/β values of around 2 Gy (Fig. 3.22).
- The possible errors in dose corrections are greater at low doses per fraction. Using the isoeffect formula presented earlier, or the curves in Figure 3.22, compare the ratios of isoeffect doses for a tissue characterized by an α/β value of 2 Gy when the dose per fraction is changed from 2 to 1 Gy (a 33% increase) and from 2 to 3 Gy (a 20% decrease).
- The basic LQ model has no time parameter. This is not so important for late-responding tissues that turnover slowly as it is for tumors and acute-responding tissues. Factors can be added to correct for incomplete repair, reoxygenation, and redistribution[112] and to the time to (kickoff time) and the extent of regeneration,[118] but the values are uncertain. The LQ formula should therefore be used cautiously.

Influence of Regeneration (Repopulation)

Normal Tissues

The influence of overall time on fractionated RT comes largely from differences in the time to (kickoff time) and extent of regeneration among various normal and neoplastic tissues (Fig. 3.3). As a result, simply adding a constant exponent for overall treatment time in an isoeffect formula without regard to tissue type is dangerous. For example, early regeneration in intestinal mucosa or bone marrow makes a major contribution to the net RT response if treatment is over several weeks, whereas it provides little or no benefit in spinal cord, kidney, or dermis.

Tumors

As with acute-responding normal tissues, tumors accelerate their growth in response to injury. Some clinical implications are:

- Protracting treatment longer than necessary is likely a disadvantage, especially as it is difficult to predict the accelerated repopulation response of individual tumors. As an example, using 1.8 Gy rather than 2-Gy fractions given five

times per week extends overall treatment time by about 10% and should be reserved for situations in which acute responses are likely to be limiting or where there may be substantial inhomogeneities in dose distribution that can lead to “double trouble,” where the increase in physical dose has an added biologic component that will especially compromise late-responding tissues (Fig. 3.23).

- If a treatment break is essential because of acute toxicity, it should be kept as short as tolerable.
- Planned split-course therapy is inadvisable unless part of an accelerated protocol that ultimately shortens the overall treatment duration.
- Breaks in therapy for nonmedical reasons (machine breakdown, holidays) may merit “catch-up” treatments, for example, by treating twice on some remaining days.
- Obviously, rapidly growing tumors must be treated rapidly. Also, it is reasonable to accelerate treatment of tumors with a high proliferative index, regardless of their growth rate, because they are likely to reduce their rate of cell loss and regenerate earlier and faster during RT.

MODIFICATION OF DOSE FRACTIONATION PATTERNS

Standard RT regimens of about 2 Gy/day 5 days/week were developed empirically over decades and serve as a good overall regimen for dose fractionation. However, it should be obvious that it will not fit all clinical situations and that it is certainly inappropriate in some (e.g., obviously rapidly growing tumors).

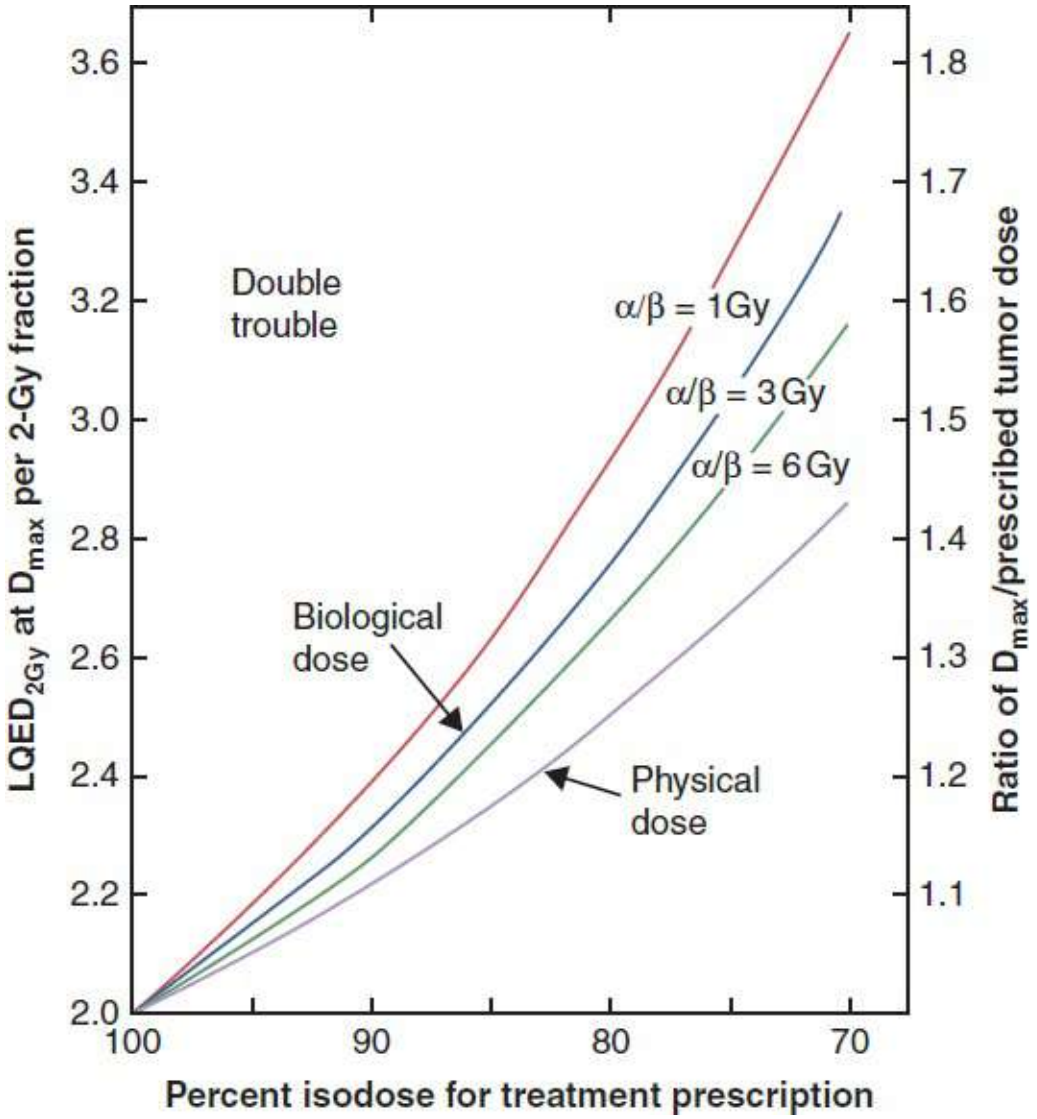

FIGURE 3.23. Influence of dose heterogeneity on physical and biologic doses as a function of the isodose line chosen for defining the tumor dose and of *α/β* ratio of the tissue located at D_{max}. The divergence of biologic and physical doses reflects the change in biologic dose that results from change in dose per fraction that derives from the heterogeneity of dose distribution. The lower the *α/β* ratio, the greater the divergence between biologic and physical doses. This "double trouble" is not reflected in physics isodose distributions and not only may explain a spurious volume effect but also may contribute to low values of tolerance doses that have appeared in the literature from time to time.

Some biologic factors relevant to modified dose fractionation are as follows:

- Tissue-related factors have to be taken into account (Figs. 3.14, 3.18, and 3.22).
- Acute-responding normal tissues have an enormous capacity for repopulation (Fig. 2.3).

- Tumors can show accelerated repopulation (Figs. 3.5–3.7). There is probably great variability from tumor to tumor, but on average, the lag time is longer and its rate slower than for acute-responding normal tissues.
- Cell cycle redistribution produces net sensitization in proliferative tissues but not in nonproliferative, late-responding tissues.
- Hypoxia has less effect at low doses, and the kinetics of reoxygenation are probably rapid, so it may be a factor only for treatments employing single or a few large doses.
- Slow-responding tissues "repair" better than acute-responding tissues.
- Repopulation in normal tissues, and possibly in tumors, may be rapid during a treatment break.
- The lag time to the onset of repopulation may be shortened to a limited extent by causing injury faster, for example, by increasing dose intensity or by concomitant chemotherapy.
- Some tumors are similar to late-responding tissues in having a low α/β ratio and slow turnover.
- True "stem" cells and CSCs are often relatively quiescent and have different characteristics from the bulk of the normal tissue and tumor. For example, long-term repopulating hematopoietic stem cells have a low α/β ratio[119] even though most bone marrow responses including lethality have a high α/β ratio. The target population for an endpoint therefore has to be carefully considered.

Accelerated Treatment

Accelerated treatment may be defined as a shortening of the overall treatment duration without a comparable reduction in total dose. However, in practice, for fraction sizes >2 Gy, lower doses are generally given (e.g., 50 to 55 Gy in 3 to 4 weeks), with an exception being continuous hyperfractionated accelerated radiotherapy (CHART) that gave 1.5 Gy three times per day, 7 days per week.[61,120] The essential aim is to minimize tumor regeneration during therapy. The importance of accelerated repopulation during tumor treatment can be visualized by thinking that two to three doublings of surviving clonogens should increase tumor burden to an equivalent of a one-step increase in T-stage. The difficulty is to avoid excess toxicity in acute-responding normal tissues, which may decrease the benefit from its repopulation. Hypofractionation accelerates treatment; however, this should be reserved for specific circumstances, as discussed later. In practice, accelerated regimens are often given as conventional or even reduced doses per fraction given more frequently (i.e., six or more times per week). This was tested in phase III clinical trials in head and neck SCC in

the 1970s, planned using the LQ formula. The meta-analysis[73] showed a modest, but significant, 2% increases in local control without total dose reduction and 1.7% with dose reduction at 5 years. Various other approaches to modestly increase the intensity of dose accumulation have been tried.

- *Continuous standard 2 Gy fractions per day:* A course lasting <2 weeks resulted in good local control rates but a high frequency of severe complications.[121]
- *Relative hypofractionation:* About 50 Gy given in 15 fractions in 3 weeks or 20 fractions in 4 weeks have been adopted as standard in a number of centers.
- *Concomitant boosting:* A second boost dose is given on several days to a reduced volume "concomitantly" with treatment of the initial larger volume, with an interfraction interval of at least 6 hours, and preferably during the later stages of treatment.[122] Concomitant boost with accelerated fractionation was part of a clinical trial that showed significantly improved locoregional control of head and neck cancer.[123]
- *CHART:* With CHART, 51 to 54 Gy is given as 1.4- or 1.5-Gy fractions, three times daily at 6-hour intervals for 12 consecutive days.[61,124] In a large prospective, randomized CHART trial, tumor control rates were increased with acceptable acute morbidity. Some permanent sequelae (e.g., xerostomia, fibrosis) were reduced, although myelopathy was more likely when the spinal cord was treated three times per day.
- *Split-course accelerated treatment:* Head and neck tumors were given about 38 Gy over about 10 days as 2 fractions of 1.6 Gy/day; after a break of 12 to 14 days, an additional 28 Gy (approximately) was delivered, with the total treatment lasting about 6 weeks. The results were better than in historic controls.[125,126]

Because accelerated tumor regrowth has its greatest effect late in a standard regimen, even a 1-week shortening could be advantageous (Figs. 3.5 and 3.6). However, excessive shortening to less than the lag time (e.g., to <3 to 4 weeks in head and neck cancer) is unlikely to improve tumor control rates, especially if the total dose is reduced to maintain acceptable acute toxicity.

Although modifying and individualizing fractionation patterns may improve the outcome for some patients, accelerated tumor growth, repopulation in acute-responding tissues, and differences in response between late-responding normal tissues and tumors have important implications for everyday conventional treatment. Consideration should be given to whether it is wise to complete RT on a Monday after a weekend break, start a course on a Friday, or to counter breaks

in treatment (public holidays, patient demands, etc.) by delivering more than five fractions in at least one week of treatment b.i.d. Chemotherapy given before the start of RT may initiate accelerated repopulation and compromise local tumor control. It is best during or after RT when surviving tumor clonogens are actively proliferating.

Hyperfractionation

Hyperfractionation uses smaller-than-standard doses per fraction. It can be achieved without extending the overall treatment duration by treating once a day for 6 or 7 days per week but is usually given as 2 fractions per day, 5 days per week. It aims to increase the therapeutic differential between late-responding normal tissues and acute-responding tumors by exploiting differences in response to dose fractionation. It may also exploit cell cycle redistribution in the tumor and absent in late-responding normal tissues, and the OER being lower at low doses. When 2 fractions are given per day, the interfraction interval should preferably be not <6 hours, and longer if CNS tissue is involved. Hyperfractionation is unlikely to be advantageous for slowly proliferating tumors with a low α/β ratio.

Clinical evidence suggests that to stay within comparable toxicity constraints in fibrovascular tissues (late responding), one fraction of 2 Gy/day should be replaced with two fractions of about 1.2 Gy, whereas for acute-responding tissues and tumors, it is about 1.05 Gy, giving a therapeutic differential of 1.2/1.05 = 1.14, a 14% benefit. Hyperfractionation has improved tumor control rates but also increased acute toxicity. A meta-analysis of randomized trials treating mostly cancer of the oropharynx and larynx and comparing conventional RT with hyperfractionated RT with or without total dose reduction showed increased survival benefit of 8% at 5 years.[73]

Hypofractionation, SBRT, SRS, SABR

Classically trained radiation oncologists often fear giving high dose fractions because they have been associated with increased vascular injury, chronic inflammation, and severe late effects that can drastically affect quality and length of life of patients. However, these biologic disadvantages can sometimes be overcome. The advances in physics, particularly related to the use of IMRT, along with better imaging, and gating techniques to account for body motion, allow dose to be distributed to better avoid organs at risk and minimize tumor margins. Major issues remain as to what dose to give and how to fractionate.

From the radiobiologic perspective, if the fractionation response of the tumor is similar to that of late-responding normal tissues (low α/β ratio), there is little therapeutic advantage to be gained from conventional dose fractionation and, instead, moderate hypofractionation should be considered. Accelerated tumor repopulation would not be expected in tumors with low α/β ratios, so this is unlikely to be a factor. Acute toxicity may be increased, as might the risk of geographic miss and "cold spots," and tumor cure compromised by poor reoxygenation, but these may be countered by giving enough fractions. A recent SBRT analysis in low- and intermediate-risk prostate cancer (low α/β ratio), giving 36.25 Gy in 4 to 5 fractions, indicated PSA relapse-free survival rates comparable with other definitive treatments.[74] Fraction sizes of up to 8 Gy are convenient because they do not deviate much outside the limitations of the LQ model, but there are other reasons for thinking fractions around this size might be useful. Dose distributions optimized by IMRT mean less normal tissue receives high radiation doses, and although the integral body dose may be greater,[127] the rapid dose falloff outside the tumor may generate gradients of cytokines and chemokines that spatially organize infiltrating host immune cells. Such doses may also generate more "danger" signals for tumor immunity and abscopal effects, which could assist in combating micrometastatic disease. Preliminary data suggest that moderately high hypofractionated doses may be superior in this respect and in fact superior to even high single ablative doses.[36,128] The RT may cause more intratumoral vascular damage and prevent cells going through a single cycle and instead opt for a mode of rapid cell death. These factors will surely vary greatly with the tumor and are not easily investigated in the clinic, but they provide rationales for moderate hypofractionation under certain circumstances, especially in combination with ICIs.[33]

Single and high dose fractions, as used in stereotactic radiosurgery (SRS) or stereotactic ablative radiotherapy (SABR), are a separate consideration from moderately high doses used in hypofractionation. Leksell[129] introduced SRS in the late 1960s to treat inaccessible cerebral lesions and in particular small arteriovenous malformations with single-dose treatments, leading to development of the gamma knife. This was followed by the use of linear accelerators to give single dose SRS or stereotactic radiotherapy (SRT) in a small number of fractions. These approaches have proved clinically effective in treating a variety of benign and malignant brain diseases,[130] in particular well-defined metastatic masses. SRT has been extended to extracranial sites in the

form of SBRT that may employ hypofractionation as above or SABR, which uses a small number of high dose fractions, such as three fractions of 15 to 20 Gy.[131,132] There is growing evidence that it dramatically improves outcome in medically inoperable early-stage non–small cell lung cancer patients[133] and may be of use against oligometastatic disease.[131,132] These findings, together with reports of excellent outcomes from high dose rate afterloading brachytherapy,[134] have prompted some re-evaluation of how traditional radiobiologic concepts apply to these new clinical procedures.[135]

SABR has a very different aim from conventional RT and aims at tumor ablation. Using the LQ formula, 3 × 20 Gy is equivalent to around 275 Gy in 2 Gy fractions to late-responding tissues with an α/β ratio of 3 Gy.[135] This extrapolation is probably not valid, but under any circumstances, the doses can be considered ablative. The normal tissue trade-off for SABR comes by minimizing the treatment volume and more consideration being given to tumor location. As discussed earlier, radiobiologic advantages of a high dose to a small volume may include allowing angiogenesis and stem cell migration from surrounding normal tissue to effect better normal tissue recovery and limit vascular damage and normal tissue hypoxia. As for location, SABR doses are moderated for tumors that are centrally located in the lung where serial structures are present. In the lung, loss of peripheral tissue function in small areas is not clinically important because there is ample residual lung function, which is not the case for all tissues and sites. Site and volume therefore appear to be the main SABR constraints, and provided they are adhered to, SABR appears to be well tolerated, with the caveat that there are not yet sufficient patients treated in this fashion to allow long-term effects to be properly assessed.

Low Dose Rate Continuous Irradiation

Low dose rate continuous irradiation, as in low dose brachytherapy, has the same biologic advantages as hyperfractionation. Additionally:

- Proliferative cells may be delayed in their progression through the cell cycle,[136] in particular in late G2 phase. Such a skewed redistribution could self-sensitize proliferative tissues and tumors without affecting late-responding normal tissues.
- The overall duration of therapy is shortened.
- The high dose regions near the radioactive sources have a probability of being sterilized.
- The volume of normal tissue receiving a high dose is minimized. Not only is

the total dose beyond the treatment volume lower, the dose rate is as well, boosting further the sparing of late-responding tissues. This can be considered an inverse dose rate effect, that is, an inverse double-trouble effect or a double advantage.

- Potential biologic disadvantages are the relatively rapid falloff in dose beyond the treatment volume and “cold spots” resulting from seed misplacement or movement. These could decrease the probability of tumor eradication if the tumor lay beyond the specified minimum tumor isodose (geographic miss).
- Permanent implants of low dose rate radioisotopes with long half-lives (e.g., ^{125}I) may give late-responding normal tissues high doses, and if the total dose is delivered over a long time, the initial dose rate may have to be so low that CSCs “escape.”

In contrast to low dose rate, the advantages of high dose rate brachytherapy come from improved logistics and staff protection and that some normal tissues can be tolerably displaced from the high dose field. Its biologic disadvantages may be loss of therapeutic differential between late-effect tissues and tumors endowed by the 4Rs.

Optimal Dose Rate

A change in dose rate, even 10 Gy/minute to 1 Gy/minute, can affect the response of tissues by allowing more SLD repair.[136] However, sparing of late-responding tissues is most pronounced with even lower dose rates, such as are characteristic of low dose rate brachytherapy, that is, between about 10 and 0.1 Gy/hour. In acute-responding tissues, and presumably also in a proportion of tumors, repopulation may be more important than repair at very low dose rates.

In late-responding tissues, such as rat spinal cord and lung,[137] a large dose rate effect is seen with change from 4 to 2 Gy/hour. If the 2 Gy per hour data are compared with multifraction data, the potential for substantial sparing with a further decrease in dose rate below 2 Gy/hour is indicated.[138] Such a large sparing effect of the reduced dose rate is to be expected in late-responding tissues.

Low Dose Rate Total Body Irradiation

Because proliferative bone marrow populations and leukemia cells are characterized by a high α/β ratio (Table 2.2), it is reasonable to prepare patients for bone marrow transplantation using either multiple small dose fractions or continuous low dose rate exposure. Between about 1 and 7 Gy/hour has been

chosen for various continuous total body irradiation regimens, which is the dose where biologic effectiveness changes rapidly and even lower dose rates may provide better therapeutic differential.[139] Because the time to deliver the dose at such low dose rates is so long, many transplant centers give multifraction exposures. In general, low doses per fraction and low dose rates provide the best therapeutic differentials, provided the overall treatment duration is kept short in relation to the growth rate of the leukemic and normal stem cells.

Spatial Dose Considerations

Geographic Underdosage of Tumor

The impact of geographic underdosage (cold spots) of areas within tumor on the TCP depends on the number of CSCs in that area and the extent of the underdosage. This can be modeled under the assumption that cells and radiosensitivity are distributed uniformly. Each tumor can be regarded as being composed of a large number of "tumorlets," each receiving a specified, although variable, dose. The overall TCP can be estimated by summing the TCPs for all the tumorlets. As illustrated in Figure 3.24, the TCP decreases with the number of underdosed tumorlets (volume) and the larger the decrement in dose. (Note that physical dose inhomogeneities are amplified by "biologic" dose to an extent that will depend on the α/β ratio, that is, 2Gy + 2 Gy is not always 4 Gy, especially when the α/β is low.)

Figure 3.24 traces the decline in TCP as a function of volume and magnitude of tumor underdosage. The magnitude of the underdose is shown as multiples of D_{10}, the dose that would reduce the number of surviving clonogens to 10% of the initial number—about 7 Gy for a standard regimen of 2 Gy fractions. From Figure 3.24, it can be seen that a 7 Gy ($1 \times D_{10}$) underdosage to 10% of the tumor would reduce TCP from 90% to 83%, whereas a 14 Gy underdosage to only 5% of the tumor would reduce TCP from 90% to 55%; that is, the extent of underdosage is more important than the volume underdosed.

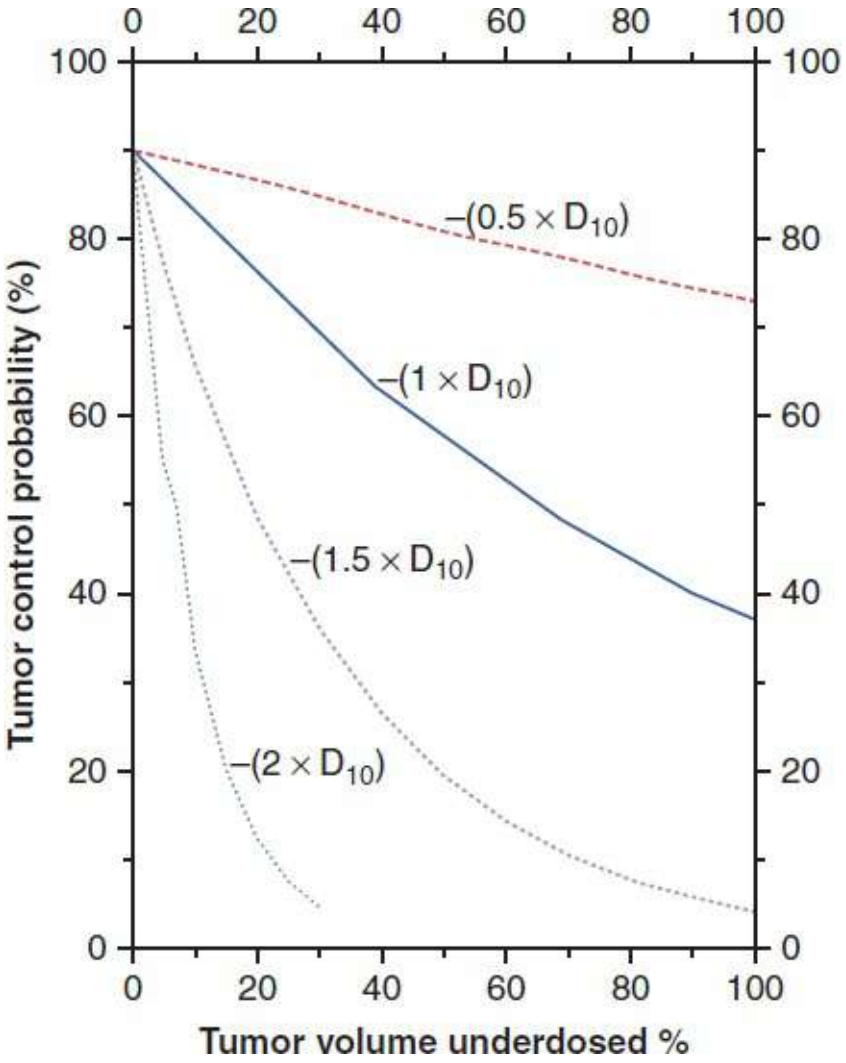

FIGURE 3.24. Effect of varying degrees of underdosage (in terms of D_{10} values) on TCP as a function of tumor volume underdosed. Note that the most important determinant is the magnitude of the underdosage.

Theoretical DVHs are presented in Figure 3.25. The smallest deviation from 100% dose to 100% tumor is outlined by a-e, showing 5% of the tumor being underdosed by about 5% ($0.5 \times D_{10}$). Underdosage by 10% ($1 \times D_{10}$), 15% ($1.5 \times D_{10}$), or 20% ($2 \times D_{10}$) in a 70-Gy regimen is shown by b-e, c-e, and d-e, respectively. The impact on TCP of the four levels of underdosage depicted by the DVHs in Figure 3.25 can be read from Figure 3.24. Assuming that 70 Gy in 2-Gy fractions yields a TCP of 90%, then the effect of underdosing 5% of the tumor by 5% ($0.5 \times D_{10}$), 10% ($1 \times D_{10}$), 15% ($1.5 \times D_{10}$), or 20% ($2 \times D_{10}$) would be a decline in TCP by 1%, 3.5%, 12.5%, and 35%, respectively (Fig. 3.24).

It is obvious that most of the DVH is irrelevant to TCP, but that small increments in the indentation along the *x*-axis in the upper right-hand corner may be critical, signifying that moderate to large reductions in dose to even small volumes are dangerous. The DVHs b-e, b-f, and b-g in Figure 3.25 illustrate a 10% underdosage to 5%, 10%, and 20% of the tumor, respectively. From Figure 3.24, it can be seen that this 10% underdosage would decrease the calculated TCP by 3.5%, 7%, and 14%, respectively, much less of a loss than associated with the smaller indentations along the x-axis. Again, the extent of underdosage is a more important determinant of TCP than the volume of tumor underdosed unlike overdosing.

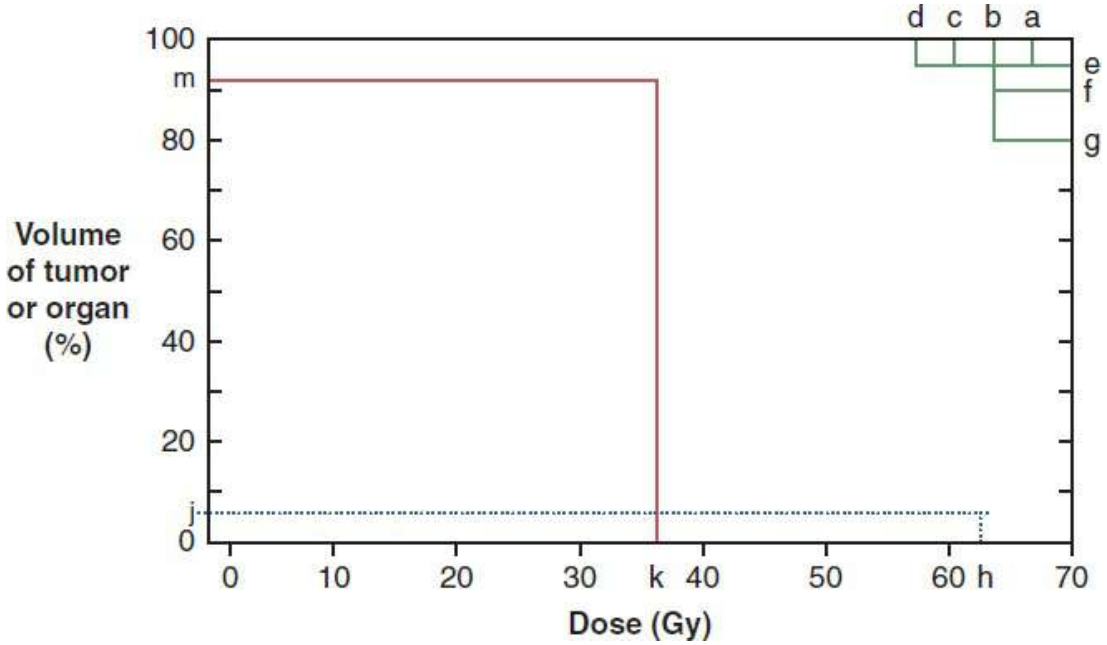

FIGURE 3.25. Multiple theoretical DVH. By reference to Figure 3.24, the impact on TCP of indentations in the upper right corner of the DVH can be estimated (see text). The underdosage (*a*-*e*, *b*-*e*, *c*-*e*, *d*-*e*) is the most important determinant of TCP. The histogram *h*-*j* depicts a dangerous DVH for an organ with serially arranged FSUs such as spinal cord but benign for lung, liver, kidney, and so forth. Histogram *k*-*m* depicts danger for liver, lung, and kidney, although not for spinal cord.

Geographic Overdosage of Tumor

Small areas of elevated dose, or hot spots (e.g., in ≤30% of the tumor), produce a negligible change in overall TCP, especially if the TCP from the homogeneous dose is already high (Fig. 3.26). Obviously, the larger the volume of tumor included in the overdosed region, the greater the potential for an increase in TCP, especially if the TCP was low to begin with (lower curves, Fig. 3.26). In general, dose-painting subvolumes offer little advantage, whereas elevating the dose to

the whole tumor could be of great value. For example, an escalation of dose to 30% of the tumor by 1 × D_{10} could raise the TCP from 10% to nearly 18%, whereas the same increment to the whole tumor could raise the TCP from 10% to 80%.

A significant advantage would only derive from hot spot dose painting if the targeting was accurate and in areas of substantially and consistently greater radioresistance (e.g., a nidus of hypoxic cells, or a CSC niche) that would not be cured by a standard homogeneous dose. At present, there are no proven ways of localizing tumor foci that are consistently radioresistant. Thus, with current levels of understanding and technical expertise, the largest and most certain benefits are likely to be achieved if the dose to the whole tumor is escalated. This is illustrated by the increasing slope of the curves in Figure 3.26 as the volume receiving the higher dose approaches 100%.

Effective Uniform Dose

The effects of inhomogeneous dose distribution on TCP can be quantified by the equivalent uniform dose (EUD).[140] An EUD produces a constant probability of tumor control for different volumes of tumor under- or overdosed. In Figures 3.24 and 3.26, a horizontal line for any chosen TCP would join EUDs for various volumes exposed to doses differing by various multiples of D_{10}, the relevant EUD value being the homogeneous dose that produced that TCP.

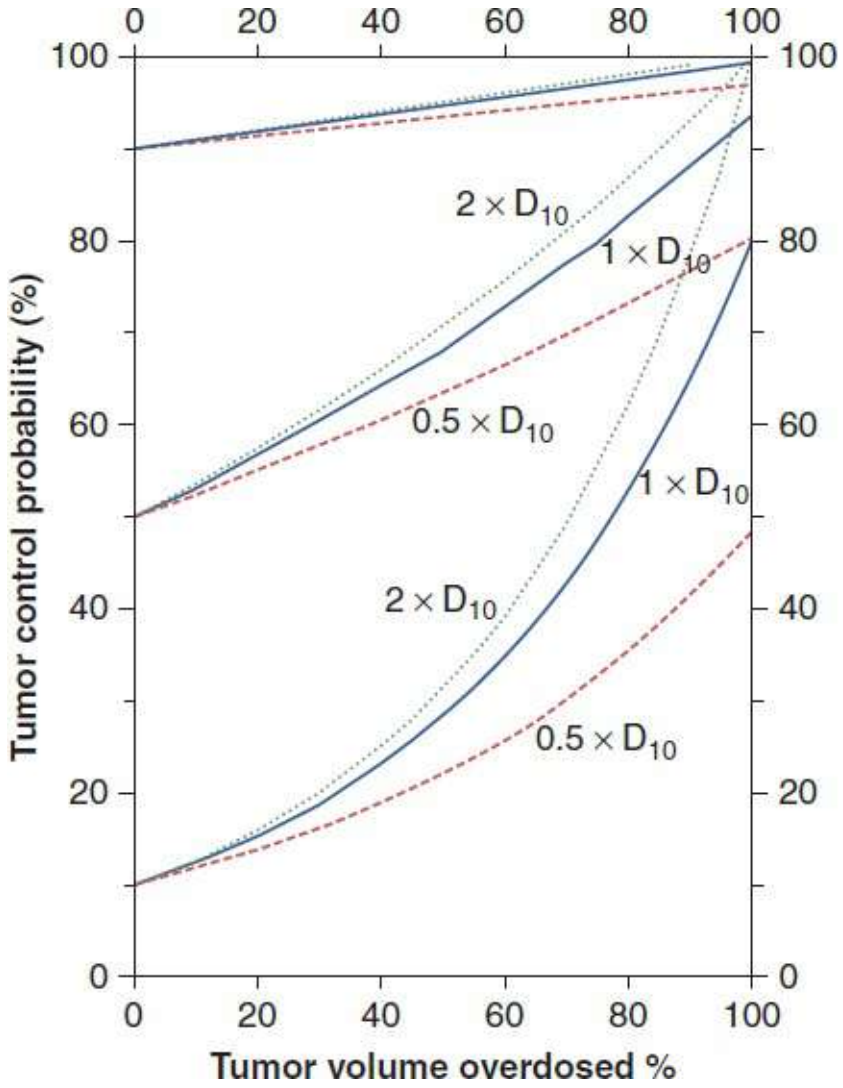

FIGURE 3.26. Modeling of the effect on TCP of increasing dose to increasing proportions of the tumor. Small hot spots are not very useful, especially if TCP is already high. The closer to 100% the tumor being "overdosed," the steeper the TCP curve.

Dose–Volume Histograms for Normal Tissues

Obviously, heterogeneity in dose will also result in different levels of injury, with an outcome heavily dictated by the structure and function of the organ. Spinal cord, where FSUs are in series, can be injured by a high dose to even a small volume (Fig. 3.25, h-j) but not by a low dose to a large volume (k-m). However, a large dose to a small volume (h-i) is of little consequence if the tissue has a large "reserve" volume of FSUs. Conversely, a relatively low dose to a large volume (e.g., k-m), could be devastating if applied to lung, liver, or kidney. Thus, DVH configurations should be viewed against an understanding of the structure and physiology of the specific tissue.

QUALITY OF RADIATION

Linear Energy Transfer and Relative Biologic Efficiency

The rate at which a charged particle, such as an electron or proton, deposits its energy along its track is described as its LET; the heavier the particle, the higher its LET. Thus, electrons are predominantly low LET, protons slightly higher, neutrons even higher, and heavily charged particles the highest LET of clinically used radiations.

The rate of energy transfer increases as particles slow down, which means that LET is only an average value. As LET increases, so does its biologic efficiency, although the increase is most rapid and peaks around 100 to 150 kv/μm. This is thought to represent the sweet spot where individual ionization events are spaced exactly so that they are most likely to hit both strands of DNA. It then decreases per unit of measured physical dose with further increase in LET (an "overkill" phenomenon). As LET increases, OER decreases inversely with biologic effectiveness (i.e., oxygen is not needed as much to cause damage), and the impact of variations in cell cycle–related radiosensitivity become less.[141] At high LET, single-hit, nonrepairable cell killing increases relative to that from accumulation of SLD; thus, the survival curve for neutrons or heavily charged particles is essentially linear over at least the first decade of cell killing, and there is little sparing from dose fractionation.[142]

RBE is a ratio of doses from two beams to produce the same effect:

$$\text{RBE} = \text{dose (standard beam)}/\text{dose (test beam)}$$

Historically, RBE is used to compare high and low LET radiations; however, it has wider applicability for comparing the effectiveness of treatment approaches such as high and low dose rate x-irradiation. Initially, the standard photon beam was 250 kVp x-rays, but now, at least from the viewpoint of RT, it is ^{60}Co (250 kVp x-rays are about 15% more efficient than ^{60}Co in killing mammalian cells). It is not widely appreciated that even at relatively high dose rates, photon beam effectiveness varies with dose rate and is an important determinant of RBE. This can only be measured accurately if the same effect is achieved by both radiations. These uncertainties are magnified further when considering radiations that have a Bragg peak, where the RBE can vary markedly and rapidly over small tissue areas.

---

*With the passing of H. Rodney Withers on February 25, 2015, the radiation oncology field lost its most pre-eminent clinically oriented thinker. The *in vivo* stem cell assays he developed over half a century ago were used by him and others to elucidate the biology behind many clinical radiation phenomena. The

general principles he developed are forever enshrined in his 4Rs that fundamentally shaped the way we conceptualize fractionated radiation therapy for cancer treatment. The quantitation he developed spawned the phase III clinical trials on altered fractionation in the 1990s. However, perhaps more than anything else, his clarity of thought and attention to critical issues pertaining to the biologic effects of radiation delivery in the clinic remain his most brilliant contribution. Some of these concepts he expressed in earlier versions of this chapter. Here, we have tried to retain the flavor of many of his ideas. Their relevance is unchanged, and they form part of his lasting legacy.

CHAPTER 4

Molecular Pathophysiology of Tumors

Rakesh K. Jain, John D. Martin, and Dan G. Duda

INTRODUCTION

A solid tumor is an organ-like structure containing neoplastic and stromal cells nourished by the tumor vasculature composed of endothelial cells (ECs), basement membrane, immune cells, and perivascular cells. All of these components are embedded in an extracellular matrix (ECM) (Fig. 4.1). The interactions between these cells, their surrounding matrix, and their local microenvironment influence the expression of various genes. The products encoded by these genes, in turn, control the pathophysiologic characteristics of the tumor. The tumor pathophysiology affects tumor growth, immune system evasion, invasion, and metastasis, as well as the response to radiation and other therapies. In this chapter, we will discuss various pathophysiologic parameters that characterize the vascular and extravascular compartments of a tumor as well as the molecular players involved in the formation and function of these compartments. Finally, we will point out some clinical implications of the findings and present a future perspective.

VASCULAR COMPARTMENT

Neoplastic cells, similar to normal cells, need oxygen and other nutrients for their survival and growth. Every reproductively intact normal cell in our body is located within 100 to 200 μm from a blood capillary so that it can receive adequate levels of oxygen and other nutrients by the process of diffusion. Likewise, cells undergoing neoplastic transformation depend on nearby capillaries for growth. These preneoplastic (i.e., dysplastic or hyperplastic) cells can grow as spherical or ellipsoidal cellular aggregates. However, once the size of the cellular aggregate reaches the diffusion limit for critical nutrients, the aggregate may become dormant. Indeed, human tumors may remain dormant for

a number of years despite active cell proliferation because of a balance between proliferation and cell death. However, once they have access to new blood vessels, the tumor may grow and metastasize. What triggers the growth of new vessels? What molecular and cellular players are involved? How do these vessels compare with normal vessels with respect to their structure and function? How do they impact immunosuppression that allows tumors to evade the immune system?

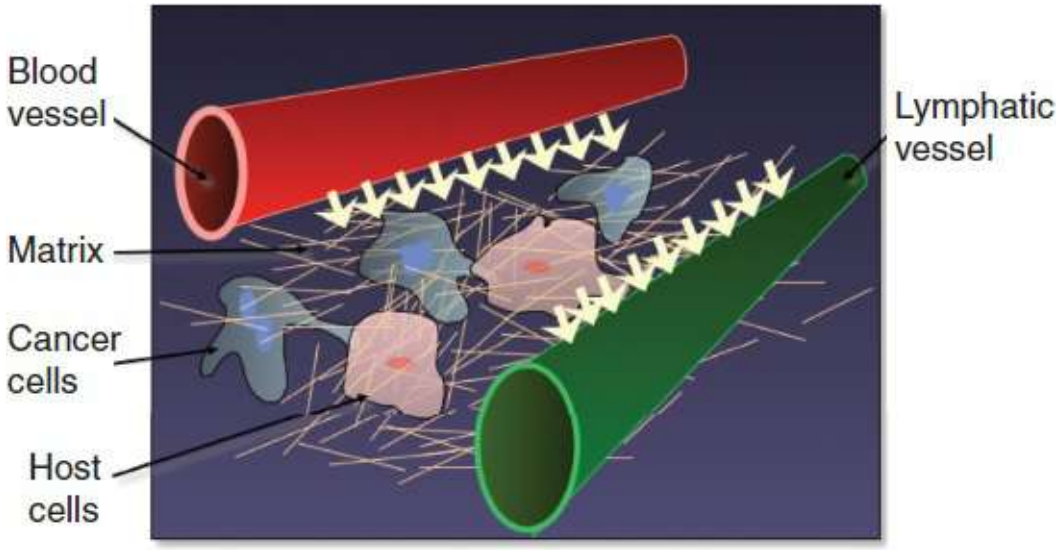

FIGURE 4.1. Schematic representation of a solid tumor—an organ-like structure. The key components include cancer cells, host cells, and blood vasculature made of endothelial and perivascular cells—all embedded in a matrix bathed in interstitial fluid. The lymphatic vasculature, present in most normal tissues, is often lacking or is dysfunctional in solid tumors.

Angiogenesis

The fact that the vascular system is associated with tumor growth in animals and humans has been known for more than a century.[1] Ide et al.[2] and Algire and Chalkley[3] provided powerful insight into the neovascularization of transplanted tumors using transparent window techniques (for reviews on this subject, see Refs.[4,5]). In 1968, Rijhsinghani et al.[6] and Ehrmann and Knoth[7] suggested the possibility that tumors produce an “angiogenic” substance. In 1971, Folkman[8,9] proposed the hypothesis that blocking angiogenesis should block tumor growth and metastasis. In 1978, Gullino[10] demonstrated that a tissue acquires angiogenic capacity during neoplastic transformation and proposed that antiangiogenesis approaches be used to prevent cancer. Both of these hypotheses have been validated in a number of preclinical studies.[11,12] A wide range of

antiangiogenic strategies are currently being evaluated in the clinic to prevent or treat a large number of diseases, including cancer.[11] Most importantly, antiangiogenic strategies have yielded overall survival benefits in patients with advanced colorectal cancer, non–small cell lung cancer, renal cell cancer, cervical cancer, gastric cancer, hepatocellular carcinoma, and gastrointestinal stromal tumors and have shown increased response rates and progression-free survival benefits in advanced breast, medullary thyroid, and ovarian cancer, pancreatic neuroendocrine tumors (PNETs), and glioblastoma (reviewed in Refs.[13–16]). This has led so far to U.S. Food and Drug Administration (FDA) approval for 12 antiangiogenic drugs in the treatment of these diseases (Table 4.1).

The net balance between pro- and antiangiogenic factors governs both normal and pathologic angiogenic processes.[11] This balance is spatially and temporally regulated under physiologic conditions so that the "angiogenic switch" is "on" when needed (e.g., during embryonic development, wound healing, formation of corpus luteum) and "off" otherwise. During neoplastic transformation and tumor progression, this regulation is deranged, which results in ectopically formed blood vessels to support the growing mass.[11]

Cellular Mechanisms

Several cellular mechanisms have been described in the vascularization of tumors: (a) co-option, (b) intussusception, (c) sprouting (angiogenesis), (d) vasculogenesis from endothelial precursors, (e) cancer cell lining of vessels (vascular mimicry), or (f) transdifferentiation to the EC (Fig. 4.2).[11] Tumor cells can co-opt and grow around the existing vessels to form "perivascular" cuffs. However, as stated earlier, these cuffs cannot grow beyond the diffusion limit of critical nutrients, and they actually may cause the collapse of the vessels as a result of the growth pressure (referred to as "solid stress").[17–20] Alternatively, an existing vessel may enlarge in response to the growth factors released by tumors, and an interstitial tissue column may grow in the enlarged lumen and partition the lumen to form an expanded vascular network. This mode of microvascular growth termed intussusception occurs during tumor growth and wound healing.[21,22]

TABLE 4.1 FDA-APPROVED ANTIANGIOGENIC DRUGS

Drug	Approved Indication	Improvement in RR (%)	Improvement in PFS (mo)	Improvement in OS (mo)

Bevacizumab	Metastatic colorectal cancer (with chemotherapy)	10	4.4	4.7
		0	1.4	1.4
		7.8	2.8	2.5
		14.1	2.6	2.1

	Thyroid cancer	28	7.2	5.5
	Unresectable HCC	5	1.1	2.2

GIST, gastrointestinal stromal tumor; HCC, hepatocellular carcinoma; NSCLC, non--small cell lung carcinoma; OS, overall survival; PFS, progression-free survival; PNET, primitive neuroectodermal tumor; RCC, renal cell carcinoma; RR, response rate.
Updated from Carmeliet P, Jain RK. Molecular mechanisms and clinical applications of angiogenesis. *Nature* 2011;473(7347):298–307.

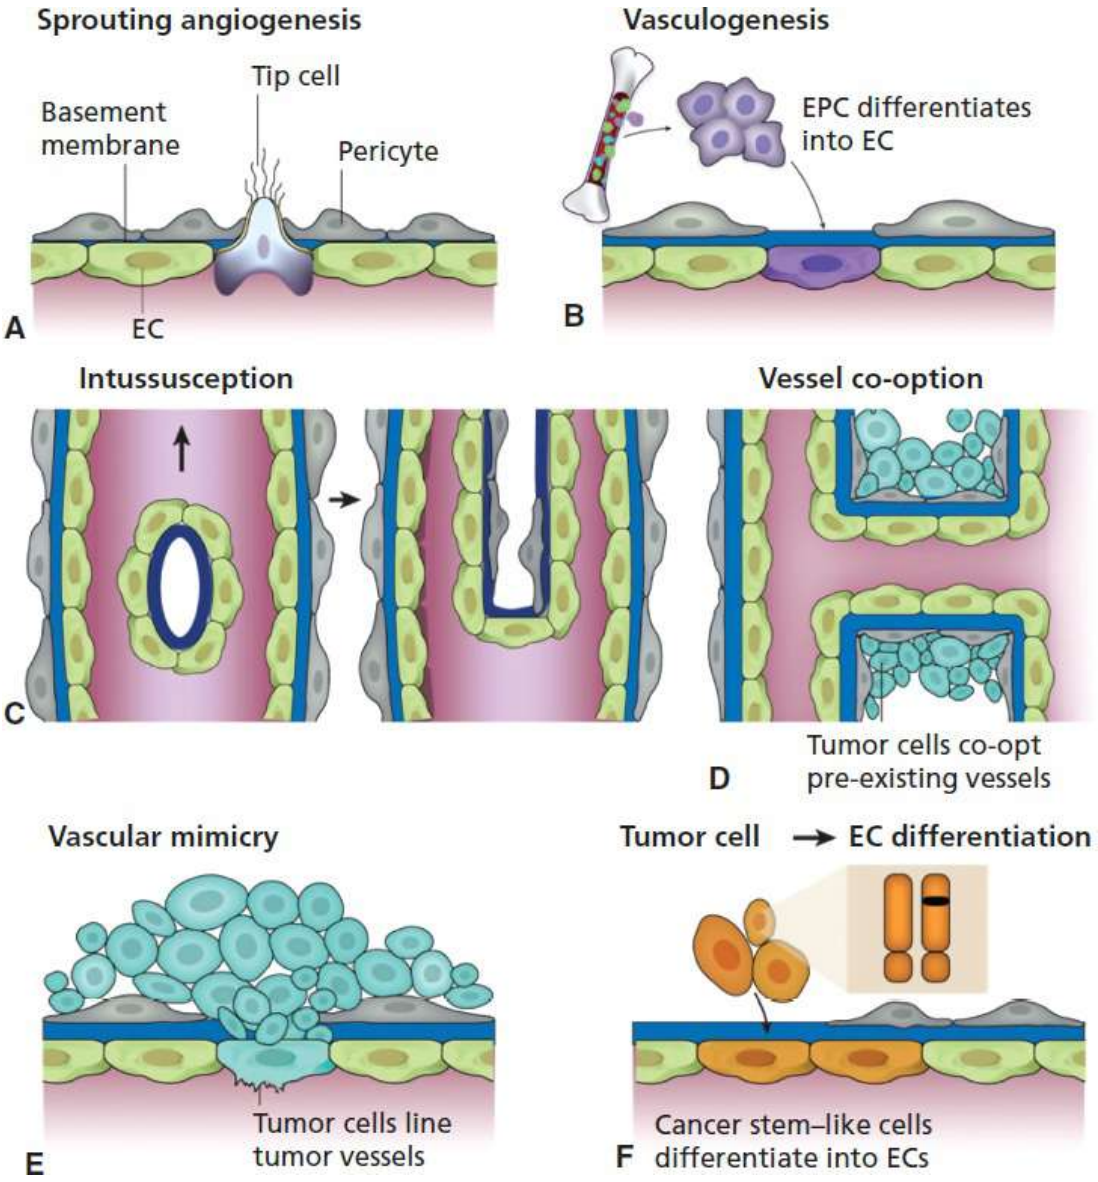

FIGURE 4.2. Modes of vessel formation in solid tumors. There are several known methods of blood vessel formation in normal tissues and tumors. **A–C:** Vessel formation can occur by sprouting angiogenesis **(A)**, by the recruitment of bone marrow–derived and/or vascular wall–resident endothelial progenitor cells (EPCs) that

differentiate into ECs **(B)**, or by a process of vessel splitting known as intussusception **(C)**. **D–F:** Tumor cells can co-opt preexisting vessels **(D)**, or tumor vessels can be lined by cancer cells (vascular mimicry; **E**) or by ECs, with cytogenetic abnormalities in their chromosomes, derived from putative cancer stem cells **(F)**. Unlike normal tissues, which use sprouting angiogenesis, vasculogenesis, and intussusception **(A–C)**, tumors can use all six modes of vessel formation **(A–F)**. (Reprinted by permission from Nature: Carmeliet P, Jain RK. Molecular mechanisms and clinical applications of angiogenesis. *Nature* 2011;473[7347]:298–307. Copyright © 2011 Springer Nature.)

"Sprouting" angiogenesis is the most widely studied mechanism of vessel formation. During sprouting angiogenesis, the existing vessels become leaky in response to growth factors released by cancer or stromal cells; the basement membrane and the interstitial matrix dissolve; the pericytes dissociate from the vessel; ECs migrate and proliferate to form an array/sprout; a lumen is formed in the sprout (referred to as canalization); branches and loops are formed by confluence and anastomoses of sprouts to permit blood flow; and, finally, these immature vessels are invested with basement membrane and pericytes. During physiologic angiogenesis, these vessels differentiate into mature arterioles, capillaries, and venules, whereas in tumors, they may remain immature.[5,11,23]

During mammalian embryonic development, a primitive vascular plexus is formed from angioblasts or endothelial precursor cells (EPCs) by a process referred to as vasculogenesis. Distinct signals specify arterial or venous differentiation.[24] Several studies showed that circulating EPCs mobilized from the bone marrow or peripheral blood also can contribute to postnatal vasculogenesis in tumors and other tissues.[25] Although debated, the repair of healthy adult vessels or the expansion of pathologic vessels can be aided by the recruitment of bone marrow–derived cells (BMDCs) and/or EPCs to the vascular wall.[26] The progenitor cells then become incorporated into the endothelial lining in a process known as postnatal vasculogenesis. Collateral vessels, which bring bulk flow to ischemic tissues during revascularization, enlarge in size by distinct mechanisms, such as the attraction and activation of myeloid cells.[26,27] However, this process appears to be of rather limited importance in tumor neovascularization.[28–32]

Tissues can also become vascularized by other mechanisms, but the relevance of these processes is not well understood. For example, tumor cells can line vessels—a phenomenon known as vascular mimicry. Putative cancer stemlike cells can even generate tumor endothelium.[33–36]

The challenge now is to discern the relative contribution of each of these mechanisms of new vessel formation in tumors to optimize antiangiogenic

treatment of cancer.[14,36,37]

Molecular Mechanisms

Various pro- and antiangiogenic molecules orchestrate different steps in vessel formation. Vascular endothelial growth factor (VEGF) is, perhaps, the most critical angiogenic molecule. Originally discovered in 1983 as the vascular permeability factor by Dvorak et al. and cloned in 1989 by Ferrara et al., VEGF increases vascular permeability, promotes migration and proliferation of ECs, serves as an EC survival factor, and is known to up-regulate leukocyte adhesion molecules on ECs.[38–40] During tumor progression, the variety and concentration of angiogenic molecules produced by a tumor can increase. Thus, if VEGF were blocked, tumor growth might continue as a result of the action of other angiogenic molecules, for example, basic fibroblast growth factor (bFGF), interleukin-8 (IL-8), and stromal cell–derived factor 1α (SDF1α).[37,41,42] Other positive regulators include angiopoietins (Ang-1 and Ang-2) that are involved in blood vessel maturation[43], various proteases involved in extracellular matrix remodeling and growth factor release,[11,23] and organ-specific angiogenic stimulators such as endocrine gland VEGF[40] (Fig. 4.3).

Angiogenesis inhibitors include soluble receptors of various proangiogenic ligands as well as molecules that down-regulate stimulator expression (e.g., interferons), interfere with stimulator release, or block binding of stimulators to their receptors (e.g., platelet factor 4). Thrombospondins are among the first and best characterized endogenous inhibitors that interfere with the growth, adhesion, migration, and survival of ECs. Other endogenous inhibitors include fragments of various plasma or matrix proteins, for example, angiostatin, fragment of plasminogen[44]; endostatin, fragment of collagen XVIII[45]; and tumstatin, fragment of collagen IV.[46]

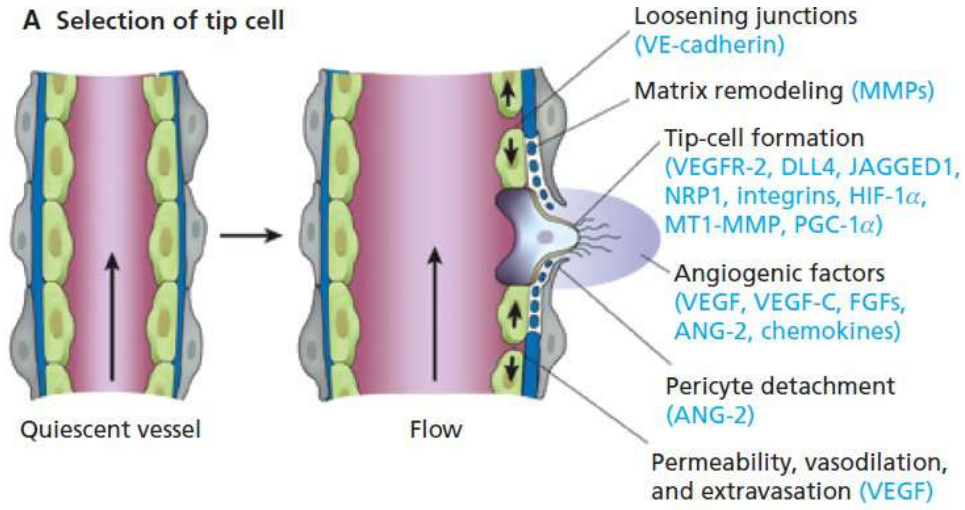
The generation of pro- and antiangiogenic molecules can be triggered by injury, metabolic stress (e.g., low partial pressure of oxygen [P_{O_2}], low pH, or hypoglycemia), mechanical stress (e.g., shear stress, solid stress), immune/inflammatory responses (e.g., immune/inflammatory cells that have infiltrated the tissue), and genetic mutations (e.g., activation of oncogenes or deletion of suppressor genes that control the production of angiogenesis regulators).[47–52] These molecules can emanate from cancer cells, ECs stromal cells, blood, and extracellular matrix[53–55] (Fig. 4.4). Because the host cells differ among organs, angiogenesis depends on host–tumor interactions.[54,56–60] Furthermore, because the tumor microenvironment is likely to change during

tumor growth, regression, and relapse after treatment, profiles of pro- and antiangiogenic molecules are likely to change with time and space.[61–70] The challenge now is to develop a unified theoretic framework to describe the temporal and spatial profiles of this increasing number of angiogenesis regulators to develop effective therapeutic strategies.[37,71]

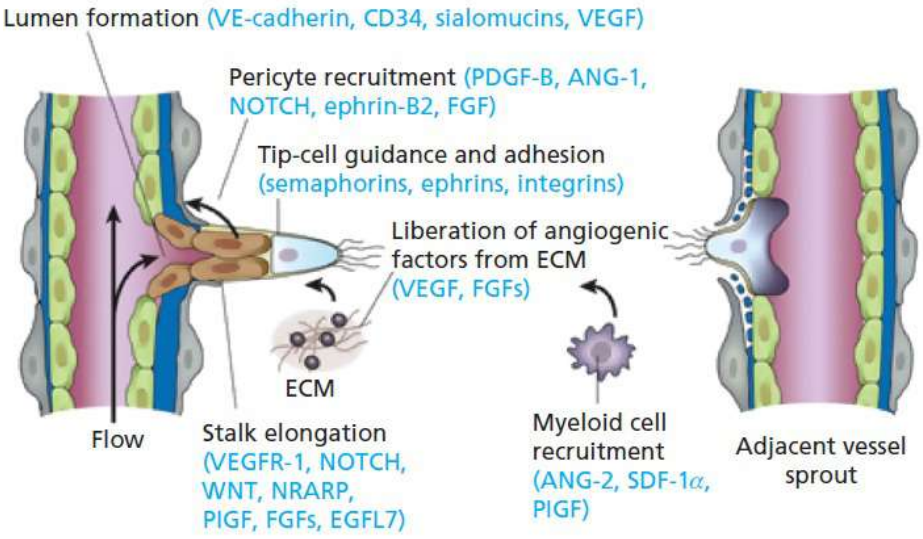
Vascular Architecture

In normal tissue, blood flows in a closed circuit from an artery to an arteriole to capillaries to venules to a vein. Although the tumor vasculature originates from these host vessels and the mechanisms of angiogenesis are similar, its organization may be completely different depending on the tumor type, its location, and whether it is growing, regressing, or relapsing.[72–74] In general, tumor vessels are dilated, saccular, tortuous, and chaotic in their patterns of interconnection. For example, whereas the normal vasculature is characterized by dichotomous branching, the tumor vasculature has many trifurcations and branches with uneven diameters.[75,76] The fractal dimensions and minimum path lengths of tumor vasculature are different from those of the normal host vasculature.[73,74,77]

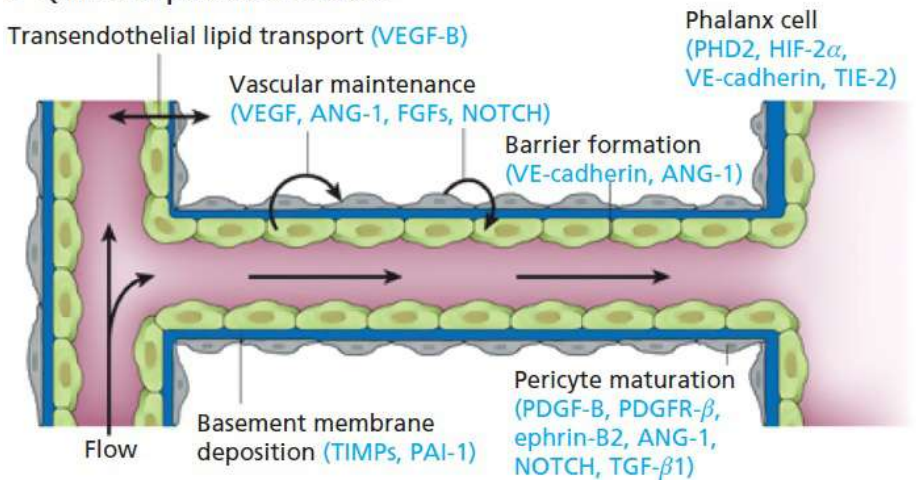
The molecular mechanisms of this abnormal vascular architecture are not entirely understood, but it seems reasonable to hypothesize that an imbalance of pro- and antiangiogenic molecules is a key contributor.[11,78] By extension, modulation of this angiogenic imbalance may allow for the correction of the tumor vascular abnormalities, leaving behind a more structurally and functionally normal vascular bed. Several observations support this "normalization" hypothesis.[78] Normalization of tumor xenograft vasculature is observed during therapies that lower VEGF (e.g., hormone withdrawal from a hormone-dependent tumor),[79] that interfere with VEGF signaling (e.g., treatment with anti-VEGF or anti–VEGF receptor-2 antibody or tyrosine kinase inhibitor[80–85] (Fig. 4.5A–D), or that mimic an antiangiogenic cocktail (e.g., trastuzumab treatment of a HER2-overexpressing tumor)[65]. Emerging clinical data from cancer patients treated with bevacizumab, an anti–VEGF antibody, or pan-vascular endothelial growth factor receptor (VEGFR) tyrosine kinase inhibitors AZD2171 (cediranib) or sunitinib lend even more compelling support to this hypothesis.[14,36,61,62,64,66–68,70,78,86,87] More crucially, the extent of vascular normalization directly correlates with the survival of patients with recurrent glioblastoma.[87] Moreover, the patients whose tumor blood flow increased most after cediranib treatment had the longest overall survival.[88,89]



A Selection of tip cell
Loosening junctions (VE-cadherin)
Matrix remodeling (MMPs)
Tip-cell formation (VEGFR-2, DLL4, JAGGED1, NRP1, integrins, HIF-1α, MT1-MMP, PGC-1α)
Angiogenic factors (VEGF, VEGF-C, FGFs, ANG-2, chemokines)
Pericyte detachment (ANG-2)
Permeability, vasodilation, and extravasation (VEGF)
Quiescent vessel
Flow



B Stalk elongation and tip guidance
Lumen formation (VE-cadherin, CD34, sialomucins, VEGF)
Pericyte recruitment (PDGF-B, ANG-1, NOTCH, ephrin-B2, FGF)
Tip-cell guidance and adhesion (semaphorins, ephrins, integrins)
Liberation of angiogenic factors from ECM (VEGF, FGFs)
ECM
Flow
Stalk elongation (VEGFR-1, NOTCH, WNT, NRARP, PIGF, FGFs, EGFL7)
Myeloid cell recruitment (ANG-2, SDF-1α, PIGF)
Adjacent vessel sprout



C Quiescent phalanx resolution
Transendothelial lipid transport (VEGF-B)
Phalanx cell (PHD2, HIF-2α, VE-cadherin, TIE-2)
Vascular maintenance (VEGF, ANG-1, FGFs, NOTCH)
Barrier formation (VE-cadherin, ANG-1)
Pericyte maturation (PDGF-B, PDGFR-β, ephrin-B2, ANG-1, NOTCH, TGF-β1)
Basement membrane deposition (TIMPs, PAI-1)
Flow

FIGURE 4.3. Molecular basis of vessel branching. The consecutive steps of blood vessel branching are shown, with the key molecular players involved denoted in parentheses. **A:** After stimulation with angiogenic factors, the quiescent vessel dilates and an endothelial cell tip cell is selected (DLL4 and JAGGED1) to ensure branch formation. Tip cell formation requires degradation of the basement membrane, pericyte detachment, and loosening of EC junctions. Increased permeability permits extravasation of plasma proteins (such as fibrinogen and fibronectin) to deposit a provisional matrix layer and proteases remodel preexisting interstitial matrix, all enabling cell migration. For simplicity, only the basement membrane between ECs and pericytes is depicted, but in reality, both pericytes and ECs are embedded in this basement membrane. **B:** Tip cells navigate in response to guidance signals (such as semaphorins and ephrins) and adhere to the extracellular matrix (mediated by integrins) to migrate. Stalk cells behind the tip cell proliferate, elongate, and form a lumen, and sprouts fuse to establish a perfused neovessel. Proliferating stalk cells attract pericytes and deposit basement membranes to become stabilized. Recruited myeloid cells such as TAMs and Tie2-expressing monocytes (TEMs) can produce proangiogenic factors or proteolytically liberate angiogenic growth factors from the extracellular matrix. **C:** After fusion of neighboring branches, lumen formation allows perfusion of the neovessel, which resumes quiescence by promoting a phalanx phenotype, re-establishment of junctions, deposition of basement membrane, maturation of pericytes, and production of vascular maintenance signals. Other factors promote transendothelial lipid transport. (Reprinted by permission from Nature: Carmeliet P, Jain RK. Molecular mechanisms and clinical applications of angiogenesis. *Nature* 2011;473[7347]:298–307. Copyright © 2011 Springer Nature.)

Mechanical stress generated by proliferating and contracting cancer and stromal cells and transmitted by dense extracellular matrix also leads to compressed or totally collapsed vessels in tumors.[18,20,90] Decompression of blood vessels by depleting cells or matrix supports this mechanical hypothesis.[19,20,91–96] Thus, the combination of both molecular and mechanical factors renders the tumor vasculature abnormal, and both must be taken into account when designing novel strategies for cancer treatment.

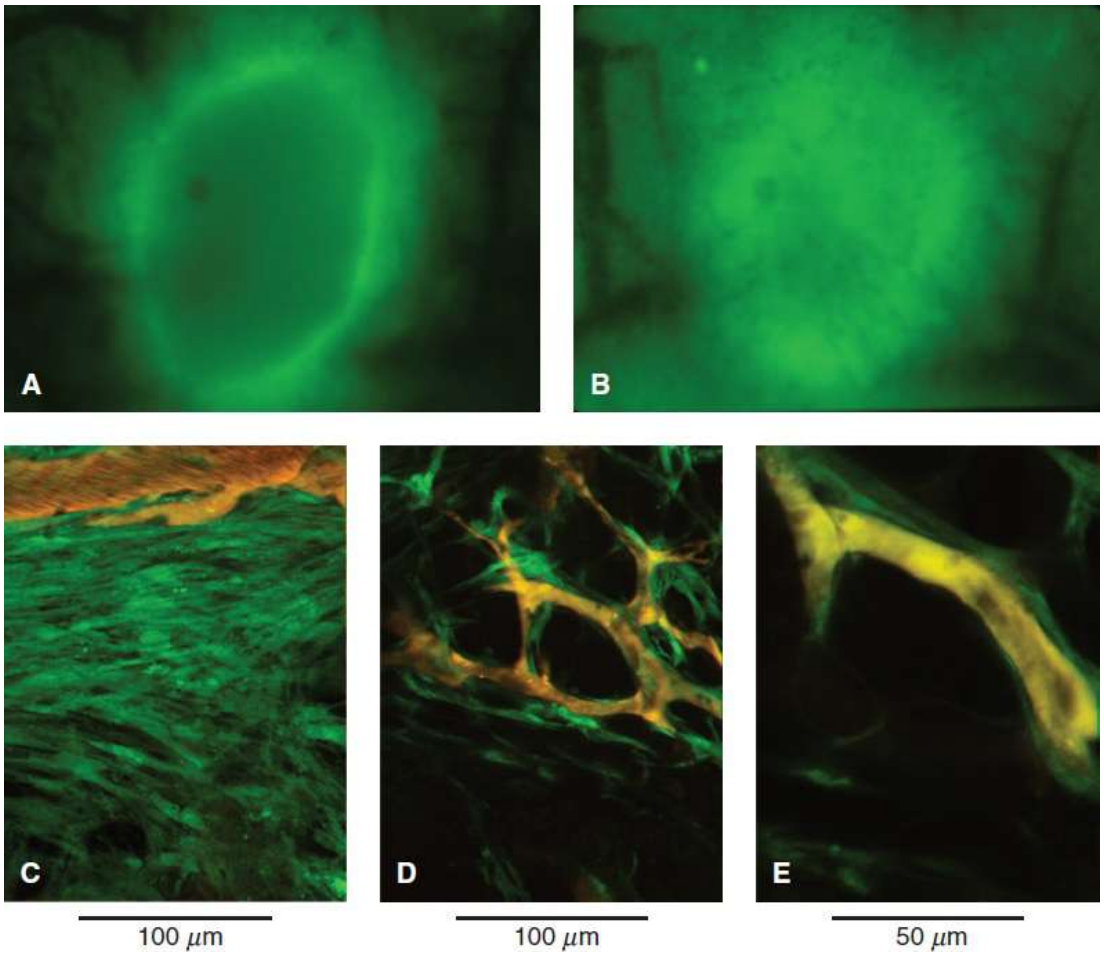


FIGURE 4.4. Tumor induction of host promoter activity in stromal cells. The expression of VEGF in host cells can be examined using transgenic mice expressing green fluorescent protein (GFP) under the control of the VEGF promoter. **A:** A murine mammary carcinoma xenograft shows host cell VEGF expression mainly at the periphery of the tumor after 1 week. **B:** After 2 weeks, the VEGF-expressing host cells have infiltrated the tumor. (Reprinted from Fukumura D, Xavier R, Sugiura T, et al. Tumor induction of VEGF promoter activity in stromal cells. *Cell* 1998;94[6]:715–725. Copyright © 2002 Cell Press. FIGURE 4.5. Normalization of tumor vasculature. **A:** Antiangiogenic therapies "normalize" the tumor vascular network. **B:** Tumor vessels are tortuous with increased vessel diameter, length, density, and permeability. **C:** Excessive pruning ultimately may reduce the vasculature to the point that it provides inadequate support for tumor growth. **D:** Normal vessels are well organized with even diameters. (Reprinted by permission from Jain RK. Normalizing tumor vasculature with anti-angiogenic therapy: a new paradigm for combination therapy. *Nat Med* 2001;7:987–989. Copyright © 2001 Nature; and Tong RT, Boucher Y, Kozin SV, et al. Vascular normalization by vascular endothelial growth factor receptor 2 blockade induces a pressure gradient across the vasculature and improves drug penetration in tumors. *Cancer Res* 2004;64[11]:3731–3736, with permission from AACR.) **E:** Causes and remedies of vascular compression in tumors. *Middle panel*: In solid tumors, proliferating cancer cells and activated fibroblasts deform the interstitial matrix, resulting in stretched collagen fibers, compressed hyaluronan, and deformed cells—all storing solid stress, a type of mechanical force transmitted by solid tissue components. This stress compresses intratumor blood and lymphatic vessels. Potential strategies to alleviate solid stress and decompress vessels involve depleting these components. Depleting cancer cells (*top left*) or fibroblasts (*top right*) relaxes collagen fibers, hyaluronan, and the remaining cells, alleviating solid stress. Depleting collagen (*bottom left*) alleviates the

stress that was held within these fibers while also relaxing stretched/activated fibroblasts and compressed cancer cells within nodules. Finally, depleting hyaluronan (*bottom right*) alleviates the stored compressive stress, allowing nearby components to decompress. Note that other stromal cells, such as pericytes, macrophages, and various immune cells that might also control production of collagen or hyaluronan, are not shown to simplify the schematic. Lymphatic vessels are also not shown for the same reason. (From Stylianopoulos T, Martin JD, Chauhan VP, et al: Causes, consequences, and remedies for growth-induced solid stress in murine and human tumors. *Proc Natl Acad Sci USA* 2012;109[38]:15101–15108.)

Blood Flow and Microcirculation

Blood flow in a vascular network—whether normal or abnormal—is governed by arteriovenous pressure difference and flow resistance. The flow resistance is a function of the vascular architecture and the blood viscosity.[97] Abnormalities in both the vasculature and blood viscosity increase the resistance to blood flow in tumors.[75,76,98–100] As a result, overall perfusion rates (blood flow rate per unit volume) in tumors are lower than in many normal tissues.[101–103]

Macroscopically and microscopically, tumor blood flow is temporally and spatially heterogeneous. Macroscopically, four spatial regions can be recognized in a tumor: an avascular necrotic region, a seminecrotic region, a stabilized microcirculation region, and an advancing front[12,104] (Fig. 4.6A). Microscopically, in normal tissues, red blood cell (RBC) velocity is dependent on vessel diameter, but there is no such dependence in most tumors.[56,60,105] Furthermore, the average RBC velocity may be an order of magnitude lower in some tumors compared to the host tissue.[60] In a given tumor vessel, blood flow fluctuates with time and can even reverse its direction.[104–106]

In addition to the elevated geometric and viscous (rheologic) resistance, other molecular and mechanical factors contribute to this spatial and temporal heterogeneity. These include imbalance between pro- and antiangiogenic molecules,[105] solid stress generated by proliferating cancer cells,[18–20,96] vascular remodeling by intussusception, and coupling between luminal and interstitial fluid pressure (IFP) via hyperpermeability of tumor vessels.[73,107–109] As discussed later, this heterogeneity contributes to both acute and chronic hypoxia in tumors—a potential cause of resistance to radiation and other therapies and increased metastatic potential.

Considerable effort has gone into modulating tumor blood flow to improve cancer treatment. This has been difficult to achieve reproducibly because the tumor vasculature consists of both vessels co-opted from the preexisting host vasculature and vessels resulting from the angiogenic response of host vessels to cancer cells. The former are invested with normal contractile perivascular cells,

whereas the latter either lack perivascular cells or are abnormally invested.[110–112] As a result, efforts to increase tumor blood flow and the delivery of cytotoxins, by pharmacologic or physical agents, have not always been successful.[97,113] In contrast, efforts to "starve" tumors by decreasing or shutting down tumor blood flow by "stealing" blood away from the passive component of the tumor vasculature by vasodilators[113] as well as by vascular targeting or intravascular coagulation have shown promise in experimental systems.[114] It also appears that judiciously applied antiangiogenic therapy may "normalize" the abnormal tumor vasculature, and the resulting "normalized" vessels might be more responsive to vasoactive agents[12,14,36,78,115] (Fig. 4.5A–D).

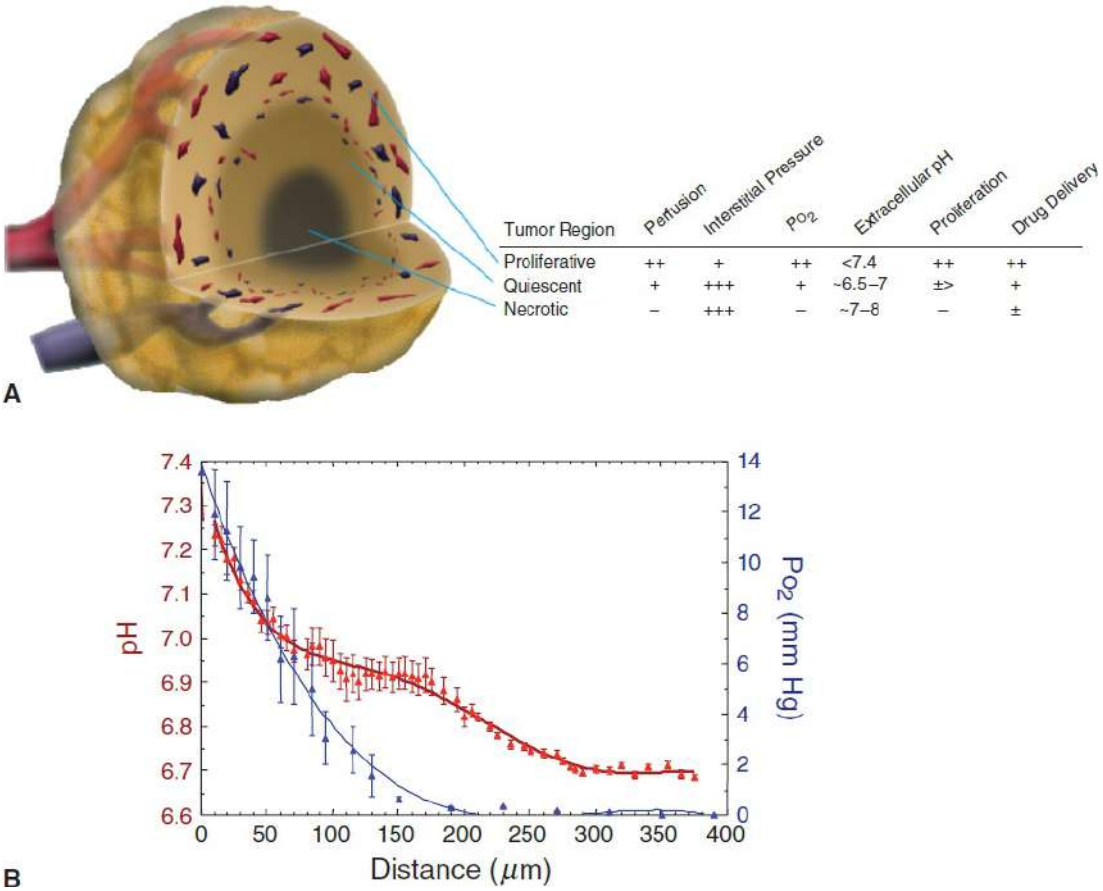

FIGURE 4.6. The tumor microenvironment is heterogeneous with proliferative, quiescent, and necrotic regions. **A:** These regions can be characterized in terms of various physiologic parameters. Decreasing magnitude of these parameters is indicated as + + +, + +, +, ±, and − in the adjoining table. (From Jain RK, Forbes NS. Can engineered bacteria help control cancer? *Proc Natl Acad Sci* USA 2001;98[26]:14748–14750, Copyright (c) 2001 National Academy of Sciences, U.S.A. With permission.) **B:** pH and Po_2 as a function of distance from a blood vessel in a tumor. The tumor environment becomes progressively more hypoxic and acidic farther away from a blood vessel. G, Yuan F, Dellian M, et al. Interstitial pH and pO_2 gradients in solid tumors in vivo: high-resolution measurements reveal a lack of correlation. *Nat Med* 1997;3[2]:177–182. Copyright © 1997 Springer Nature.)

Vascular Permeability

Once a bloodborne molecule has reached an exchange vessel, its extravasation occurs by diffusion, convection, and, to some extent, presumably transcytosis.[116] The diffusive permeability of a molecule depends on the size, shape, charge, and flexibility of the molecule as well as the size, shape, charge, and dynamics of the transvascular transport pathway. In normal vessels, these pathways include diffusion through the EC membrane (for lipophilic solutes), trans-EC diffusion, interendothelial junctions (<7 nm), open or closed fenestrations (<10 nm), and transendothelial channels (including vesicles or vesicovacuolar organelles [VVOs]).[117] Some of these pathways may be lined with glycocalyx on ECs, thus effectively reducing the size of the pathway. A basement membrane may retard further the movement of molecules. Ultrastructural studies show widened interendothelial junctions; an increased number of fenestrations, vesicles, and VVOs in tumor vessels; and a lack of normal basement membrane and pericytes.[38,58,117–119]

In concert with these ultrastructural findings, both vascular permeability to solutes and water permeability (referred to as hydraulic conductivity) of tumors, in general, are significantly higher than that of various normal tissues.[60,100,120–123] Furthermore, unlike normal vessels, tumor vessels lack selectivity for the size of extravasating molecules.[124] However, positively charged molecules have a higher affinity for the negatively charged angiogenic tumor vessels.[125] Despite increased overall permeability, not all blood vessels of a tumor are leaky. Even the leaky vessels have a finite pore size that is tumor dependent, and ultrastructural studies show that the larger pore size in tumors represents wide interendothelial junctions.[58,119] Not only do the vascular permeability and pore size vary from one tumor to the next but also within the same tumor they vary both spatially and temporally as well as during tumor growth, regression, and relapse.[58,65,79]

The local microenvironment plays an important role in controlling vascular permeability. For example, a human glioma (HGL21) is fairly leaky when grown subcutaneously in immunodeficient mice, but it exhibits blood–brain barrier properties in the cranial window.[60] Such site-dependent differences for other tumors have been observed in other orthotopic sites.[56,59,126] One possible explanation is that the host–tumor interactions control the production and

secretion of cytokines associated with permeability increase (e.g., VEGF) and decrease (e.g., Ang-1).[12,23,43,85,127] A better understanding of the molecular mechanisms of permeability regulation in tumors is likely to yield strategies for improved delivery of molecular medicine to tumors.[128]

Movement of Cells across Vessel Walls

Both cancer cells and immune cells frequently move across the walls of blood vessels—the former in the process of metastasis and the latter during immune response or cell-based immunotherapy. Both transendothelial and periendothelial pathways have been proposed as a route for intravasation and extravasation of cells. Very little is known about intravasation, except that a tumor may shed more than a million cells per gram per day and most of these are not clonogenic and that some may be shed as fragments along with stromal cells.[103,129–131] More is known about the molecular and cellular mechanisms of extravasation.[132–134] A cell within a blood vessel may continue to move with the flowing blood, collide with the vessel wall, adhere transiently or stably, and finally extravasate. These interactions are governed by both local hydrodynamic forces and adhesive forces. The former are determined by the vessel diameter and fluid velocity, and the latter by the expression, strength, and kinetics of binding between adhesion molecules and by the surface area of contact.[132,135–139] Deformability of cells affects both types of forces.[140]

Rolling of endogenous leukocytes is generally low in tumor vessels, whereas stable adhesion (≥30 seconds) is comparable between normal and tumor vessels.[141] However, both rolling and stable adhesion are nearly zero in angiogenic vessels induced in collagen gels by bFGF or VEGF, two of the most potent angiogenic factors. Whether the latter is due to a low flux of leukocytes into angiogenic vessels and/or down-regulation of adhesion molecules in these immature vessels is currently not known. Age may also play an important role in leukocyte–endothelial interactions.[142]

Further insight into the biology of cells that adhere to tumor vessels comes from studies on the localization of IL-2–activated natural killer (A-NK) cells in normal and tumor tissues in mice using positron emission tomography.[143,144] Immediately following systemic injection, these cells localized primarily in the lungs, whereas a nondetectable number of cells arrived in the tumor.[143] Increased rigidity caused by IL-2 activation may contribute to the mechanical entrapment of these cells in the lung microcirculation.[145,146] Constitutive expression of certain adhesion molecules in the lung vasculature also may

facilitate their localization in the lungs.[132] One approach to reducing lung entrapment is to reduce the rigidity of these cells.[140,144] Alternatively, entrapment in lung vasculature can be circumvented by injecting A-NK cells directly into the blood supply of tumors. In this case, A-NK cells, both xenogeneic and syngeneic, adhered to some blood vessels in three different tumor models[144,147,148] via CD18 and very late antigen-4 (VLA-4) on the A-NK cells and intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin on the activated endothelium of angiogenic vessels.[39,149,150]

These molecules can be up-regulated by a number of cytokines, including tumor necrosis factor-α (TNF-α) and a protein of 90-kD molecular weight (p90); secreted by some neoplastic cells;[39,136] and down-regulated by others, for example, transforming growth factor-β (TGF-β) also, presumably, secreted by cancer cells.[57,151] Surprisingly, the proangiogenic VEGF also can up-regulate these molecules, whereas another proangiogenic molecule, bFGF, can down-regulate these molecules.[39,54,81,152] The challenge now is to decrease nonspecific entrapment of immune cells in normal vessels and to increase their delivery to tumor vessels to improve various cell-based therapies, including gene therapy. Judicious doses of anti-VEGF agents that “normalize” tumor vasculature can potentially realize this goal.[153,154] Moreover, more recent work implicates vascular normalization as a key contributor to antitumor immunity and showed that interferon-γ (IFN-γ)+ Th1 cells directly mediate vascular normalization.[155] Others showed that while decreased hypoxia secondary to vascular normalization promotes immunostimulatory macrophage programming, heightened IFN-γ levels might also induce the expression of programmed cell death ligand-1 (PD-L1) in tumor ECs and confer immunosuppressive properties to tumor blood vessels.[156] These recent findings highlight the intricate relationship between tumor blood vessels and effector immune cells.[157]

EXTRAVASCULAR COMPARTMENT

Composition and Origin

The extravascular compartment of a solid tumor consists of neoplastic cells (parenchyma) and host cells (e.g., inflammatory cells, fibroblasts) residing in an interstitial subcompartment bathed by the interstitial fluid (Fig. 4.1). Depending on the tumor type and its stage of differentiation, neoplastic cells may be dispersed in the matrix as individual cells (e.g., lymphomas, melanomas) or as

clumps or nests (e.g., carcinomas). More than 80% of tumors are carcinomas arising from epithelial cells. The remaining 20% include sarcomas arising from mesenchymal cells (e.g., bone or muscle cells), lymphomas arising from lymphoid tissue, leukemias arising from hematopoietic cells, and hemangiomas arising from ECs. In a poorly differentiated carcinoma, the cancer cells may be loosely packed in clumps, whereas in a well-differentiated carcinoma, the cells may be connected with intercellular junctions and tightly packed in a nest enveloped by a basement membrane. With tumor progression, cancer cells may invade the basement membrane and spread to other regions.[38]

Unlike cancer cells, host cells must migrate into the tumor from normal tissue. Inflammatory cells may enter the tumor via blood vessels or may infiltrate from the adjacent tissue.[130] Other host cells, such as fibroblasts, may proliferate and migrate from the adjacent connective tissue[23,53,55,158,159] or from primary tumor to the metastatic site.[130] Increasingly, infiltrating host cells are being recognized as critical modulators of the tumorigenic process. For example, mesenchymal cells generically termed carcinoma-associated fibroblasts have been shown to promote tumor growth, metastasis, and angiogenesis, potentially through the secretion of SDF1α.[130,160–163] Furthermore, tumor-associated immune/inflammatory cells such as tumor-associated macrophages (TAMs), Tie2-expressing monocytes (TEMs), or Gr-1+ myeloid-derived suppressor cells (MDSCs) have been linked to both cancer immunosurveillance and suppression as well as to tumor promotion.[49,161,164–166] With the recent successes of immune therapy, a current challenge is promoting effector immune cell (e.g., T-lymphocyte) infiltration. Their limited infiltration can be attributed in part to the ECM providing a physical barrier[167] and to intratumoral hypoxia, which promotes an immunosuppressive phenotype of infiltrating cells.[168–171] The challenge now is to establish approaches for skewing immune cells (e.g., TAMs and T cells) toward a phenotype that promotes antitumor immune responses in cancer patients.[154,172,173]

The interstitial compartment of a tumor is bounded by the walls of the blood vessels on one side and by the membranes of cancer and stromal cells on the other. In normal tissues, the blood vessels are surrounded by a basement membrane, which is defective in tumors (see the Vascular Permeability section).[23,78] In addition, functional lymphatics may be confined to the tumor margin (see the Lymphatic Transport section).[174,175] Similar to normal tissues, the interstitial space of tumors is composed of a collagen and elastin fiber network that provides structural support to the tissue. Interdispersed in this

cross-linked structure are the interstitial fluid and macromolecular constituents (polysaccharides hyaluronan and proteoglycans [PGs]), which form a hydrophilic gel.

Compared with our understanding of blood vessel formation, our understanding of stroma generation is minimal. Dvorak has proposed that the extravasated plasma protein fibrinogen, a key component of the tumor interstitial fluid (TIF), clots to form fibrin, which serves as a major component of the provisional stroma.[38] This provisional stroma eventually is replaced by more mature connective tissue stroma. The TIF also contains several proteins including fibronectin, vitronectin, osteopontin, thrombospondin, decorin, and tenascin. These proteins are present in both free and bound forms and contain the amino acid sequence Arg-Gly-Asp (RGD). The RGD sequence provides a binding site for adhesion that assists in the migration of various cells, including stromal cells. In addition to extravasating from the leaky tumor vessels, these proteins, along with collagen and various PGs, also are synthesized by the stromal cells, albeit in a form that is different from that in the plasma or normal tissues.[38] TIF also may contain various growth factors that facilitate stroma formation. For example, *in vitro* studies suggest that platelet-derived growth factor-β is involved in the recruitment of fibroblasts to tumors, and TGF-β controls the production of collagen and other matrix molecules in tumors.[23,176] With the increasing interest in using the fragments of matrix constituents for controlling angiogenesis, our understanding of the molecular and cellular mechanisms of stroma generation in tumors is likely to increase.[158]

Interstitial Transport

Once a molecule has extravasated, its movement through the interstitial space occurs by diffusion and convection.[117] Diffusion is proportional to the concentration gradient in the interstitium, and convection is proportional to the interstitial fluid velocity, which, in turn, is proportional to the pressure gradient in the interstitium. Just as the interstitial diffusion coefficient, D (cm^2/s), relates the diffusive flux to the concentration gradient, the interstitial hydraulic conductivity, K (cm^2/mm Hg·s), relates the interstitial velocity to the pressure gradient.[117] Values of these transport coefficients are governed by the structure and composition of the interstitial compartment as well as by the physicochemical properties of the solute molecule.[125,177–181]

The value of K (interstitial hydraulic conductivity) for a human colon carcinoma xenograft (LS174 T), measured using two different methods,[182,183]

was found to be higher than that of a hepatoma,[181] which, in turn, was higher than that of the normal liver. Using fluorescence recovery after photobleaching, the diffusion coefficient (D) of various molecules in tumors was found to be about one-third that in water[184] and higher than the values in the host tissue.[178] Collagen content and structure have a significant effect on D in tumors.[180,182,185] This is surprising because hyaluronan and PGs, and not collagen, account for most of the resistance to transport in normal tissues. Because collagen is produced by the host-derived cells (e.g., fibroblasts), the penetrability of macromolecules into a tumor will depend on the host–tumor interaction. Thus, agents that interfere with collagen synthesis and/or organization (e.g., relaxin, bacterial collagenase, angiotensin system inhibitors) may increase interstitial transport in tumors.[177,186,187]

The time constant for a molecule with diffusion coefficient D to diffuse across a distance L is approximately $L^2/4D$. For diffusion of IgG (immunoglobulin G) in tumors, this time constant is on the order of 1 hour for a 100-μm distance, days for a 1-mm distance, and months for a 1-cm distance. So, for a 1-mm tumor, diffusional transport across the tumor would take days, and for a 1-cm tumor, it would take months. If the central vessels have collapsed completely as a result of cellular proliferation[18,19,19,96] and interstitial matrix rearrangement, the reduced delivery of macromolecules by blood flow would make diffusion the primary mechanism of delivery to this hypoxic center. Binding may further retard the transport in tumors.[184,188,189] The role of binding is illustrated clearly by comparing the rate of fluorescence recovery of a photobleached spot in tumor tissue injected with a nonspecific versus specific IgG. In addition to the heterogeneity of D in tumors, the most unexpected result of these photobleaching studies was the large extent (30% to 40%) of nonspecific binding.[184] These results collectively suggest that the interstitial compartment of a tumor can be a formidable barrier to the uniform delivery of therapeutic macromolecules (e.g., antibodies, genes using viruses, nanotherapeutics) in tumors, and strategies are needed to overcome this barrier.[91–94,116,125,186,187,190]

Lymphatic Transport

In most normal tissues, extravasated plasma and macromolecules are taken up by the lymphatics and returned to the central circulation. Although it is widely accepted that lymphatic vessels are present in the tumor margin and the peritumoral tissue, the hotly debated issue for nearly a century has been whether

anatomically defined lymphatic vessels are present within solid tumors and, if so, whether they function.[175,191] Currently, available immunohistochemical markers stain for structures in some tumors that resemble lymphatic vessels. However, because many of these markers lack specificity,[174,175,192] it is not clear whether they stain functional lymphatic vessels, ECs from remnant lymphatic vessels, or some other structures or cell types (e.g., preferential fluid channels.[182] It is likely that the stress induced by proliferating cancer cells compresses and impairs lymphatic vessels that are co-opted or formed in a tumor[18–20] and/or lymphatic valves are impaired by tumor growth.[193] The impaired lymphatic vessels, in turn, may contribute to the interstitial hypertension characteristic of animal and human tumors (see the Interstitial Hypertension section). In addition, invasion of the functional peritumoral lymphatics is considered to be a poor prognostic factor for a number of tumors, and lymphatic metastasis is a major cause of morbidity and mortality.

Our understanding of the mechanisms of lymphangiogenesis lags behind our understanding of the mechanisms of angiogenesis. However, considerable progress has recently been made toward identifying molecular players responsible for lymphangiogenesis. VEGF-C, acting through VEGFR-3, appears to play a central role in tumor-associated lymphangiogenesis. Several experimental[194–198] and clinical[199] studies have demonstrated a positive correlation between VEGF-C expression and peritumoral lymphatic vessel density, lymphatic metastasis, and, in some cases, poor clinical outcomes. Like in vascular angiogenesis, other positive and negative regulators, such as VEGF,[200,201] VEGF-D,[195] hepatocyte growth factor, platelet-derived growth factor-BB, and angiopoietins, are involved in lymphangiogenesis.[11,199] Furthermore, mechanisms analogous to co-option, intussusception, sprouting, and vasculogenesis may operate in lymphatic growth[11] (see the Angiogenesis: Cellular Mechanisms section). Similar to organ-specific angiogenic molecules (e.g., EG-VEGF)[40] and blood vascular EPCs,[25,202] there may be organ-specific lymphangiogenic molecules and lymphatic endothelial precursor cells that contribute to tumor-associated lymphangiogenesis.[203] Moreover, the proteolytic processing of lymphangiogenesis molecules, as well as the phenotype and function of the resulting lymphatics, may depend on the tumor type as well as on the host organ in which the tumor is growing.[23,81,174,199]

The precise roles for these lymphangiogenic molecules in the induction of lymphatic metastasis are imperfectly understood, even though phylogenetic tree analysis indicates that 35% of distant metastases arise from tumor-draining

metastases.[204] Recent data demonstrate that tumor VEGF-C overexpression induces peritumoral lymphatic hyperplasia through activation of VEGFR-3. Consequently, lymph fluid volumetric flow increases.[194] This results in increased tumor cell delivery to lymph nodes and a higher rate of lymphatic metastasis[194] (Fig. 4.7). It remains unclear how VEGF-C overexpression impacts tumor cell entry into lymphatic vessels; however, an attractive hypothesis is that the increased lymphatic surface area simply increases the probability of tumor cell entry and dissemination. Alternatively, VEGF-C may stimulate the release of a chemotactic factor that recruits tumor cells into lymphatic vessels. Of potential clinical importance, VEGFR-3 blockade was shown to inhibit VEGF-C–induced lymphatic hyperplasia, tumor cell delivery to draining lymph nodes, and lymphatic metastasis when treatment was started at the time of tumor initiation. However, lymphatic metastases were not significantly reduced if VEGFR-3 blockade was started after tumor cell seeding of draining lymph nodes.[194,205] These data suggest that anti–VEGFR-3 therapy may be effective in preventing, but not treating, lymphatic metastases—the more common clinical imperative—except in cases where a significant fraction of vascular ECs and/or cancer cells express VEGFR-3. The challenge now is to identify alternative strategies for treating lymphatic metastases, either through combination therapy (e.g., anti–VEGFR-2/anti–VEGFR-3) or modulation of other pathways.

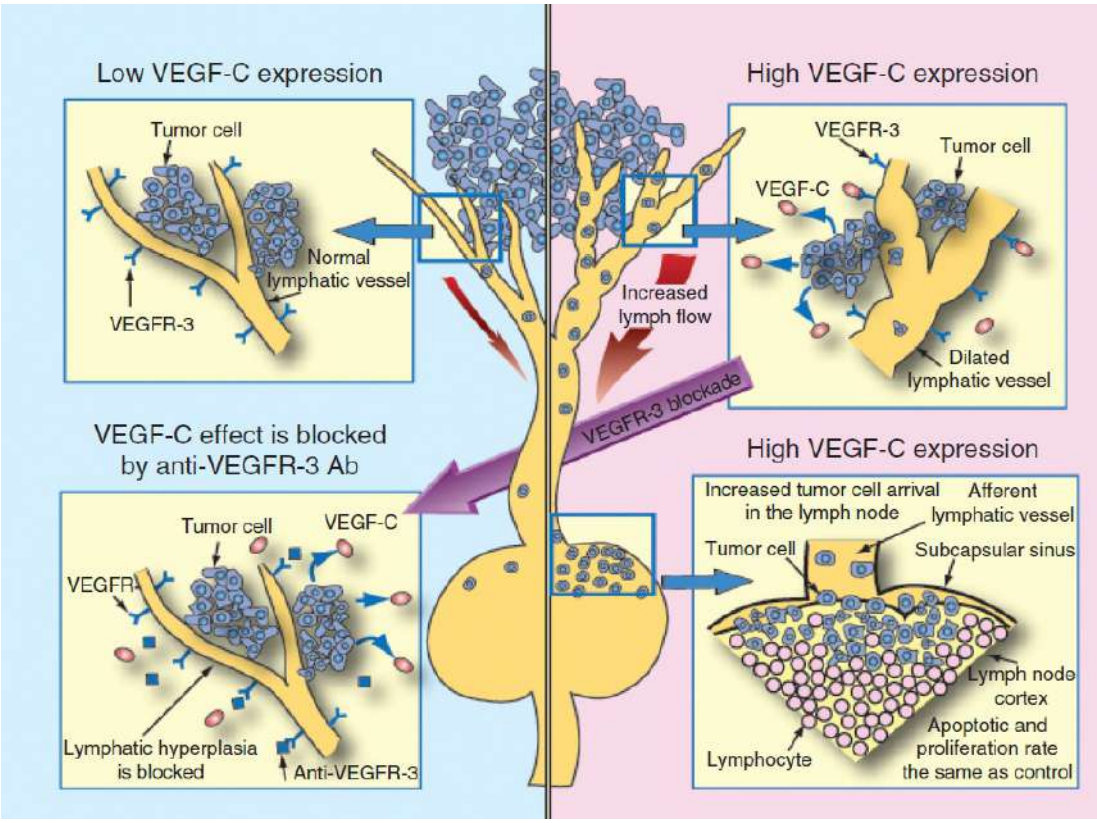

FIGURE 4.7. Schematic of lymphatics in low (*left*) versus high (*right*) VEGF-C–expressing tumors. VEGF-C secreted from tumor cells stimulates VEGFR-3 expressed in lymphatic ECs, inducing peritumor lymphatic hyperplasia (*top right*). An increase in lymphatic surface area may increase the opportunity for tumor cell entry into lymphatic vessels. Augmented lymph flow enhances tumor cell delivery to draining lymph nodes (*bottom right*). In the absence of VEGF-C overexpression, peritumor lymphatic hyperplasia is less pronounced and fewer tumor cells are delivered to draining lymph nodes (*left*). Anti–VEGF-C/anti–VEGFR-3 treatment inhibits VEGF-C–induced lymphatic hyperplasia and tumor cell delivery to draining lymph nodes (*bottom left*). (Reprinted from Hoshida T, Isaka N, Hagendoorn J, et al. Imaging steps of lymphatic metastasis reveals that vascular endothelial growth factor-C increases metastasis by increasing delivery of cancer cells to lymph nodes: therapeutic implications. *Cancer Res* 2006;66[16]:8065–8075. Mechanical signals that trigger the lymphangiogenic switch are unknown. Because lymphatic vessels help maintain the balance of fluid in tissues, hydrostatic pressure is a likely trigger.[205,206] Whether the lymphatic hyperplasia seen in tumor margins is, in part, a response to the elevated hydrostatic pressure in tumors and whether the newly formed lymphatics remain open and relieve this pressure are open questions. Techniques such as microlymphangiography,[4,174,175,194,197,207,208] fluorescence photobleaching lymph flow quantitation,[191,194,207,209–211] and optical frequency domain imaging

(OFDI)[212] will allow us to answer these important questions.

Interstitial Hypertension

Unlike normal tissues, where the IFP is around 0 mm Hg, both animal and human tumors exhibit interstitial hypertension.[64,66,68,117,175,183,213–224] The tumor IFP begins to increase as soon as the host vessels become leaky in response to angiogenic molecules such as VEGF.[225] Thus, IFP can be lowered by inhibiting the VEGF pathway using blocking antibodies.[64,66–68,83,226] The IFP increases with tumor size in some tumors[213,215,219] and remains independent of tumor size in others.[220]

Three mechanisms contribute to the interstitial hypertension in tumors. In normal tissues, lymphatics maintain fluid homeostasis; thus, the lack of functional lymphatics within tumors is a key contributor. Indeed, DiResta et al.[227] have shown that one could lower the IFP by placing "artificial lymphatics" in tumors. The second contributor is the leaky nature of tumor vessels. As a result, the hydrostatic and oncotic (colloid osmotic) pressures become almost equal between the intravascular and extravascular space.[77,83,214,228] At least two pieces of evidence support this hypothesis. First, lowering permeability by blocking VEGF signaling lowers IFP.[66,83,226] Second, IFP goes up and down with the microvascular pressure (MVP) within seconds.[229–231] The two mechanisms described so far can only explain hypertension up to 20 to 30 mm Hg—the MVP of most exchange vessels in our body—but IFPs as high as 94 mm Hg have been measured in human tumors.[223] Because the MVP is the driving force for IFP in tumors, these tumors must have a high MVP. Indeed, this is the case.[214] There are two possible explanations for the elevated MVP in tumors: (a) the tumor vessels have reduced arterial resistance so that the MVP becomes closer to arterial pressure, and/or (b) the tumor vessels have increased venous resistance as a result of compression and tortuosity so that the whole vascular network is under hypertension. Indirect evidence for the latter comes from the decrease in IFP following decompression of tumor vessels by drug-induced apoptosis of perivascular cancer cells.[19,96]

The elevated pressure can compromise the tumor microcirculation and delivery of therapeutics in three ways. First, reduced transmural pressure gradients resulting from equilibrium between MVP and IFP reduce convection across tumor vessels and thus compromise the transport of macromolecules.[77,83,97,214,230] Second, because IFP is nearly uniform throughout a tumor and drops precipitously in the tumor margin, the interstitial fluid "oozes"

out of the tumor into the surrounding normal tissue, carrying macromolecules with it.[30,129] Finally, transmural coupling between IFP and MVP as a result of high permeability of tumor vessels can lead to blood flow stasis in tumors without physically occluding the vessels.[107–109] Thus, decreasing vascular leakiness might restore the transmural pressure gradients and potentially resume/re-establish blood flow in the nonperfused regions of tumors.[154,232] Some direct and indirect antiangiogenic therapies may "normalize" the tumor vasculature through this mechanism[12,14,36,62,65,66,78,115,233] (Tables 4.2 and 4.3; Fig. 4.5).

Metabolic Environment

Hypoxia

A key function of the vasculature is to provide adequate levels of nutrients to the parenchymal cells and to remove waste products. Based on the anatomy of the capillary bed and a mathematical model of oxygen diffusion and consumption, the Nobel laureate August Krogh introduced the concept of a diffusion limit for oxygen of 100 to 200 μm nearly a century ago.[234] This unit of tissue—a single capillary surrounded by a 100- to 200-μm radius cylinder—is referred to as a Krogh cylinder in physiology. Nearly 50 years later, Thomlinson and Gray identified similar "cords" in human lung cancer and found necrotic cells beyond 180 μm away from blood vessels, presumably because of a lack of oxygen.[235] This is referred to as *chronic hypoxia* or *diffusion-limited hypoxia*. Although various hypoxia markers and microelectrodes have suggested these gradients, the first direct measurements of these perivascular P_{O_2} gradients, as well as perivascular pH gradients, became possible only with the development of phosphorescence quenching microscopy[236,237] (Fig. 4.6B).

As discussed earlier, blood flow in tumor vessels is intermittent, and, thus, some regions of a tumor are periodically starved for oxygen. The resulting hypoxia is referred to as *acute hypoxia* or *perfusion-limited hypoxia*. A necessary consequence of intermittent blood flow is the resumption of blood flow after shutdown, and the resulting production of free radicals can lead to *ischemia–reperfusion injury* or *reoxygenation injury*; thus, applying additional selection pressure on cancer cells can cause them to become more locally aggressive, metastatic, and resistant to therapy.[238]

Low pH

Another consequence of the abnormal microcirculation of the tumor is low

extracellular pH. There are at least two sources of H^+ ions in tumors—lactic acid and carbonic acid.[239] The former results from glycolysis, and the latter results from conversion of CO_2 and H_2O via carbonic anhydrase. However, the intracellular pH of cancer cells remains neutral or alkaline (≥7.2) despite the acidic extracellular pH. Because carbonic anhydrase-9 and various glucose transporters (GLUT-1, GLUT-3) and enzymes in the glycolytic pathway are up-regulated by hypoxia,[238] one would expect low extracellular pH and hypoxia to track each other and to colocalize with regions of low blood flow. It is surprising that there is a lack of spatial correlation among these parameters—a discovery made possible by recent developments in optical techniques that permit the simultaneous high-resolution mapping of multiple physiologic parameters.[236] A potential explanation for this lack of concordance is that some perfused tumor vessels carry hypoxic blood.[236] Thus, although they may not be able to deliver enough oxygen to the surrounding cells, they may be able to carry away the waste products (e.g., lactic acid).

Therapeutic Consequences

The presence of molecular oxygen during irradiation can "fix" biologic (e.g., DNA) free radicals, making radiation-induced damage irreparable (oxygen fixation hypothesis). Thus, hypoxia reduces the radiation sensitivity of neoplastic and normal cells both *in vitro* and *in vivo*. Similarly, hypoxia can compromise the efficacy of some chemo- and immune therapies. Independently, hypoxia can increase the metastatic potential of cancer cells.[238] Therefore, for nearly half a century, considerable preclinical and clinical effort has been focused on alleviating hypoxia through a multitude of interventions such as improving tumor perfusion with mild hyperthermia or drugs, increasing oxygen content of the blood via hyperbaric oxygenation, and increasing hemoglobin/hematocrit by transfusion or exogenous erythropoietin. Unfortunately, the clinical outcomes have not met expectations. Although early studies suggested a marked benefit of transfusion in anemic cervical cancer patients undergoing definitive radiotherapy, careful analysis suggests that these studies are confounded by selection biases that preclude the conclusion that anemia correction by transfusion impacts outcome.[240,241] Furthermore, erythropoietin (or analog) treatment showed encouraging survival results in anemic cancer patients receiving nonplatinum chemotherapy and in anemic lung cancer patients receiving chemotherapy.[242,243] However, subsequent trials in anemic head and neck cancer patients and mainly nonanemic metastatic breast

cancer patients actually suggested outcomes may be impaired by erythropoietic agents.[244,245] There are multiple possible reasons such interventions have yielded mixed results. These include the inability to increase tumor P_{O_2} as markedly as systemic P_{O_2},[246] the inability to increase P_{O_2} in all areas of a tumor to optimal levels because of abnormal vasculature,[77,115] and undesired "off-target" effects of interventions (e.g., immunosuppression with transfusion.[247–249] Furthermore, tumors may reoxygenate during radiation therapy with standard fractionation, potentially minimizing the impact of providing additional oxygen to the target tissue.

TABLE 4.2 STUDIES REPORTING ANTIANGIOGENIC THERAPY–INDUCED IMPROVEMENT IN TUMOR OXYGENATION

Antiangiogenic Therapy	Tumor Model	Effect on Oxygenation	Time Window of Improved Oxygenation
Antibody Therapy			
Bevacizumab	Melanoma, breast carcinoma, ovarian carcinoma	↑	2–4 d after start of therapy
Bevacizumab	GBM	↑	Up to 5 d
DC101	GBM	↑	2–8 days after start of therapy
Anti-PlGF Ab	Pancreatic carcinoma	No change	
TKI Therapy			
Sunitinib	Squamous carcinoma	↑	O_2 measured 4 d after start of therapy
Semaxanib	Melanoma	↑	O_2 measured 3 d after start of therapy
PI-103 (PI3 K inhibitor)	Fibrosarcoma, squamous carcinoma	↑	O_2 measured 10 d after start of therapy
Gefitinib (EGFR inhibitor)	Fibrosarcoma, squamous carcinoma	↑	O_2 measured 10 d after start of therapy
Erlotinib (EGFR inhibitor)	Squamous carcinoma, NSCLC	↑	O_2 measured 5 d after start of therapy

Endocrine Therapy			
Castration (androgen depletion)	Shionogi carcinoma	↑	O_2 measured 21 d after start of therapy
Metronomic Chemotherapy			
Low dose gemcitabine	Pancreatic carcinoma	↑	O_2 measured 28 d after start of therapy
Other Therapies			
FTIs (Ras inhibitors)	Prostate carcinoma, bladder carcinoma, glioma, fibrosarcoma, squamous carcinoma	↑	O_2 increased up to 7–10 d
Nelfinavir (AKT inhibitor)	Fibrosarcoma, squamous carcinoma	↑	O_2 measured 10 d after start of therapy
TNP-470	Breast carcinoma	↑	O_2 measured 9 d after start of therapy
Suramin	GBM	↑	O_2 measured 5–6 wk after start of therapy
Thalidomide	Liver carcinoma	↑	O_2 increased from day 2–4 after start of therapy
Thalidomide	Fibrosarcoma	↑	O_2 increased from day 2–3 after start of therapy
Genetic Models			
VEGF$^{-/-}$ (myeloid cells)	Lung carcinoma	↑	
nNOS$^{-/-}$ (tumor cells)	Glioblastoma	↑	
$\alpha_v\beta_3/\alpha_v\beta_5$ integrin–FAK–Rho knockdown (tumor cells)	Glioblastoma	↑	
SEMA3 A overexpression (transgene delivery)	Insulinoma	↑	O_2 increased after 4 wk

Rgs5$^{-/-}$ (stroma)	Insulinoma	↑
PHD2$^{-/-}$ (stroma or EC specific)	Melanoma, pancreatic carcinoma	↑
IFN-β overexpression (transgene delivery)	Glioblastoma, neuroblastoma	↑

EC, endothelial cell; EGFR, epidermal growth factor receptor; FAK, focal adhesion kinase; FTI, farnesyl transferase inhibitor; GBM, glioblastoma multiforme; IFN, interferon; nNOS, neuronal nitric oxide synthase; NSCLC, non–small cell lung cancer; PHD, prolyl hydroxylase domain protein; PI3 K, phosphoinositide-3-kinase; PlGF, placental growth factor; TKI, tyrosine kinase inhibitor; VEGF, vascular endothelial growth factor.

TABLE 4.3 STUDIES REPORTING THE IMPACT OF ANTIANGIOGENIC/VASCULAR NORMALIZATION STRATEGIES UPON DELIVERY OF THERAPEUTIC COMPOUNDS/SYSTEMICALLY ADMINISTERED MOLECULES INTO TUMORS

Systemically Administered Molecule	Normalization Strategy	Tumor Model(s)	Effect on Delivery
Conventional Cytotoxics			
Irinotecan	A4.6.1	Colon carcinoma	↑
Topotecan, etoposide	Bevacizumab	Neuroblastoma	↑
Temozolomide	Sunitinib	Glioma	↑[a]
Cyclophosphamide, cisplatin	TNP-470	Lung carcinoma	↑
Temozolomide	TNP-470	Glioma	↓
Cyclophosphamide	Thalidomide	Liver carcinoma	↑
Doxorubicin	PDGF-D overexpression	Breast carcinoma	↑
Topotecan	IFN-β overexpression	Neuroblastoma	↑
Doxorubicin	Anti–TGF-β antibody or overexpression sTβrII	Breast carcinoma	↑
Nanoparticles			
Liposomal doxorubicin	Anti–TGF-β antibody or overexpression sTβrII	Breast carcinoma	↑
Antibodies			
Nonspecific IgG, anti–E-cadherin Ab	Axitinib	Lung carcinoma, pancreatic tumor	↑ (per vessel)
Viral Particles			
Oncolytic virus	Cilengitide	GBM	↑

Other Molecules			
BSA	DC101	Breast carcinoma, colon carcinoma	↑
FDG	Bevacizumab	Rectal carcinoma	↑ (per vessel)[b]

BSA, bovine serum albumin; FDG, fluorodeoxyglucose; GBM, glomerular basement membrane; IFN, interferon; PDGF, platelet-derived growth factor; TGF, transforming growth factor.
[a]Increased delivery of temozolomide noted with sunitinib 20 mg/kg but not at 60 mg/kg.
[b]Study performed in human subjects.

Similarly, low extracellular pH can adversely (or favorably) affect the uptake and cytotoxicity of some therapeutics. The pH gradient difference between tumor and normal tissue may offer a tumor-specific target for nanomedicines or weak acid chemotherapeutics for the treatment of cancer.[250,251] The development of specific drugs that exploit this pH difference and strategies to modulate pH in tumors has not yet reached the clinic but are anticipated.[238]

Two broad strategies targeting the unique tumor metabolic environment are emerging: (a) exploit hypoxia to activate drugs or attract tumoricidal anaerobic bacteria and (b) dissect hypoxia-induced pathways to identify novel targets for drug development. The first strategy has led to the development of drugs such as tirapazamine and to renewed interest in bacteriolytic therapy[252]; both approaches are in clinical trials, but promising data are yet to emerge.[253,254] The second strategy has revealed several molecular players in the physiologic and pathophysiologic response to hypoxia.[238,255,256] The balance between hypoxia-induced apoptosis/necrosis on one hand and the increased resistance to cell death mediated by various hypoxia-induced pathways on the other determines whether a tumor can survive and even grow under hypoxic conditions. Ultimately, hypoxia selects for tumor cells that are more malignant, more invasive, and genetically unstable, rendering them resistant to various therapies. Therefore, certain players in the hypoxia-induced pathways now are being targeted in the development of diagnostic and therapeutic agents. Hypoxia-induced pathways include genes involved in oxygen delivery, glycolysis and glucose uptake, pH control, stress response pathways, growth factor signaling, angiogenesis, transcription, apoptosis, growth inhibition, and invasion and metastasis (Fig. 4.3 and Box 4.1).[11,255]

Of the various molecular players involved in sensing and responding to hypoxia, hypoxia-inducible factor-1 a (HIF-1α) has received the most attention.

This transcription factor is up-regulated in a number of human tumors.[255,264] Regulated by proline and asparagine hydroxylases, HIF-1*α* activates genes involved in an array of physiologic responses including angiogenesis, vasodilation, glycolysis, and RBC production by binding to the hypoxia-response element (HRE). Although HIF-1*α* is an attractive therapeutic target, its pleiotropic action may prove to be a major challenge for clinical exploitation. For example, teratomas arising from HIF-1*α*(−/−) embryonic cells grow more rapidly despite lower levels of VEGF and angiogenesis.[265] This counterintuitive finding may be a result of the ability of HIF-1*α*(−/−) cells to survive under hypoxic conditions, instead of undergoing apoptosis.[55] HIF-1*α* has also been shown to play an important role in determining tumor radioresponsiveness through the regulation of multiple, and sometimes opposing, processes.[266] Under some circumstances, HIF-1*α* inhibition *reduces* tumor cell radiosensitivity by protecting hypoxic cells from radiation-induced apoptosis and enhancing clonogenic survival potentially through reductions in adenosine triphosphate metabolism, cellular proliferation, and p53 activation.[266] Furthermore, HIF-1*α* serves a key function in inflammatory cell energy metabolism, and its inhibition results in profound immunodeficiency.[267] Consequently, molecular therapies that target HIF-1*α* or HRE, as well as more selective therapies that target key downstream effectors of HIF-1*α*, are under intensive investigation for cancer detection and treatment.[238,255,268] Nonetheless, although oxygen and cancer drugs fail to reach tumor regions that are far from perfused vessels in adequate concentrations, this delivery limitation is more important for these strategies that depend on hypoxia or target hypoxia-induced pathways.

Box 4.1

Hypoxia and Epigenetic Regulation of Angiogenesis

The prolyl hydroxylase domain (PHD) proteins PHD1–3 are oxygen-sensing enzymes that hydroxylate the HIF proteins HIF-1*α* and HIF-2*α* when sufficient oxygen is available. Once hydroxylated, HIFs are targeted for proteasomal degradation.[257] Under hypoxia, PHDs become inactive, and HIFs initiate broad transcriptional responses to increase the oxygen supply by angiogenesis, through the up-regulation of angiogenic factors such as VEGF.[258] HIFs are also activated in nonhypoxic conditions by oncogenes and growth factors, allowing tumor cells to stimulate angiogenesis before they become deprived of oxygen. In general, HIF-1*α* promotes vessel sprouting, whereas HIF-2*α* mediates vascular maintenance.[258] Reduced HIF-1*α* levels in mice impair embryonic vascular development, revascularization of ischemic tissues, and angiogenesis in injured tissues and tumors.[258] The use of HIF-1*α* inhibitors to block tumor or ocular angiogenesis has therefore received attention. Conversely, *Hif-1α* gene transfer in mice or activation of HIF-1*α* by pharmacologic blockade of PHDs promotes ischemic tissue

revascularization.

HIF-1α also regulates tumor angiogenesis indirectly, by releasing chemoattractants such as SDF-1α to recruit proangiogenic BMDCs.[259] Gene silencing of Phd2 in mouse tumor cells enhances vessel growth by similar mechanisms. Hypoxia also regulates the polarization and proangiogenic activity of TAMs by means of HIF-1α and HIF-2α with different effects.[257] That hypoxia and inflammation are closely intertwined is illustrated by the finding that signaling by HIF-1α and nuclear factor-κB cross-activates each other. In certain cases, hypoxic up-regulation of VEGF occurs independently of HIF-1α and is mediated by the metabolic regulator peroxisome proliferator–activated receptor gamma coactivator (PGC)-1α in preparation for oxidative metabolism once the ischemic tissue is revascularized.[260] Because HIF signaling contributes to acquired resistance against anti–VEGF therapy, the combined blockade of VEGF and HIF-1α is being explored as a cancer treatment strategy.

There is increasing evidence for epigenetic control of angiogenesis, particularly by noncoding microRNAs (miRNAs),[261] which induce messenger RNA degradation or block translation. Because miRNAs target multiple genes, they are well positioned to regulate complex processes such as angiogenesis. ECs express several miRNAs that are induced by hypoxia or VEGF. Most of those stimulate angiogenesis by hijacking proangiogenic cascades while suppressing angiostatic pathways.[262] The expression of miR-126 is induced by the mechanosensitive transcription factor KLF2A and integrates the mechanosensory stimulus of blood flow to shape the vascular system.[263] EC-specific loss of DICER, an exonuclease involved in miRNA biogenesis, impairs pathologic angiogenesis. Angiogenic miRNAs seem to offer significant pro- or antiangiogenic potential.

CLINICAL IMPLICATIONS

Two major problems currently plague the nonsurgical treatment of malignant solid tumors. First, physiologic barriers within tumors impede the delivery of therapeutics and oxygen (a key radiation sensitizer) at effective concentrations to all cancer cells.[36,78,269] Second, inherent or acquired resistance resulting from genetic and epigenetic mechanisms reduces the effectiveness of conventional as well as novel targeted therapies.[270,271] Can we take advantage of the unique pathophysiology of tumors to overcome these problems for better management of cancer? As discussed next, recent clinical data offer some hope.

Prognostic/Predictive Biomarker Implications

Multiple indices of tumor pathophysiology have been evaluated as potential predictors of treatment outcome including vessel density (reviewed in Refs.[37,272]), oxygen level (reviewed in Refs.[255,273]), interstitial pressure,[37,221,223,241] and blood or urine circulating molecules[68,86] (reviewed in Ref.[37]) Vessel density can be evaluated in biopsies and is measured either in “hot

spots" (i.e., regions of most active angiogenesis) or in the tissue as a whole. The former presumably provides a measure of a tumor's aggressiveness, and the latter reflects the status of global oxygenation. Most studies to date show that poor outcome of radiation therapy correlates with high vessel density in "hot spots" and/or low overall microvessel density. There are, however, several studies showing a lack of correlation or an opposite correlation. This discrepancy may be the result of the morphometric techniques used or of differences in tumor types or treatment schedules.

The oxygen level in a tumor also has a potential prognostic value, and it can be directly measured with microelectrodes. Alternatively, immunohistochemical analysis of tumor tissue for endogenous or exogenous hypoxic markers (e.g., HIF-1α, glucose transporter-1, carbonic anhydrase-9, pimonidazole) can be used as a surrogate for tumor oxygenation status. However, immunohistochemical assessments of hypoxia do not necessarily correlate with oxygen status measured directly with microelectrodes.[274] A concerted effort is under way to assess hypoxia using novel, noninvasive imaging techniques.[256,275,276] Several studies have shown that tumor hypoxia is a predictor of a poor outcome of radiation therapy when used alone or in combination with other therapies. These findings are consistent with *in vitro* and *in vivo* preclinical studies showing the adverse effect of hypoxia on radiation responses.

Because the IFP is a reflection of the global physiology of tumors, a correlation between tumor IFP and the response to radiation therapy has been suggested. One cervical cancer study has shown that elevated tumor IFP can, indeed, independently predict a poor outcome of radiation therapy.[241] In breast cancer, IFP was not related to response to chemotherapy.[277] Further studies are needed to evaluate the prognostic significance of IFP in tumors. However, one potential application of the steep rise of pressure at the tumor periphery is improved localization of tumors before their removal.

Finally, circulating biomarkers may provide information about tumor pathophysiology and its changes after treatment. Of note, some of the emerging biomarkers—such as circulating collagen IV or soluble VEGFR-1—may represent biomarkers of vascular normalization and, if validated, could be useful in treatment decisions.[86,87,277,278]

Although each of these approaches has advantages, key disadvantages include their invasiveness and their potential for sampling error. With rapid developments in the field of noninvasive imaging, it is likely that the measurement of various physiologic and molecular parameters in tumors will

become more refined and convenient for patients. Examples of such imaging approaches include blood oxygen level–dependent magnetic resonance imaging (BOLD MRI), electron paramagnetic resonance spectroscopy/imaging, and [^{18}F]-misonidazole positron emission tomography (FMISO-PET).[275,276,279–281] The promise of such imaging approaches has just started to be realized. FMISO-PET has been evaluated in a substudy of patients with stage III or IV squamous cell carcinoma of the head and neck randomized to concurrent radiotherapy with either tirapazamine and cisplatin or infusional fluorouracil and cisplatin. Pretreatment FMISO-PET–detected hypoxia was associated with a higher risk of locoregional recurrence among patients who did not receive the tirapazamine-containing regimen compared to patients who did receive tirapazamine.[281] This study suggests that FMISO-PET can provide clinically meaningful information about tumor physiology and simultaneously provides evidence that tirapazamine acts by specifically targeting hypoxic tumor cells. Furthermore, results from hypothesis-generating clinical trials involving noninvasive imaging approaches indicate that increased perfusion and oxygenation are potential predictive biomarkers of response to antiangiogenic therapy.[16,88,278,282–285] Such progress will continue, and physiologic/molecular profiles of patients' tumors will yield improved and better-tailored therapies for individual patients. Indeed, a current challenge is to verify increases in perfusion and oxygen as predictive biomarkers of response to antiangiogenic and solid stress–alleviating therapies.

Therapeutic Implications

Given the physiologic barriers to the delivery and effectiveness of various therapeutics, a strategy that is gaining increasing interest is destroying the tumor vasculature. This strategy has the advantage of targeting ECs that are easily accessible to a bloodborne drug and are presumably genetically stable. In addition, each EC supports multiple cancer cells, thus providing "therapeutic amplification." However, the inability to target *all* ECs in a tumor can reduce the effectiveness of antivascular therapy. Similarly, the dependence of ECs on multiple angiogenic molecules can limit the effectiveness of various antiangiogenic therapies when used alone.[36,78] Finally, destroying the stroma, including ECs, could promote disease progression.[286–289] These challenges may explain why currently available antiangiogenic agents, although demonstrating biologic activity, are usually unable to provide durable tumor control when used as monotherapy except in tumors that are highly VEGF-dependent (i.e., clear cell renal carcinoma, ovarian cancer, cervical cancer, and thyroid cancer) or

highly vascularized (i.e., neuroendocrine cancers and hepatocellular carcinoma).[15] However, it should be noted that the anti–VEGFR-2 antibody ramucirumab led to an OS advantage of 1.4 months in advanced gastric or gastroesophageal junction (GEJ) adenocarcinomas. This may reflect the dependence of GEJ tumor vascularization or immunosuppression on VEGFR-2 signaling.

Although of limited utility when used alone especially in desmoplastic carcinomas with cancer cells clustered in nests surrounded by stroma, the judicious combination of antiangiogenic therapies with conventional cytotoxic therapies has led to improved tumor control in mice and lengthened survival in certain types of human tumors[14–16,251,290–293] (see Table 4.1). For example, in two human tumor xenograft models, a VEGFR-2–blocking antibody decreased the dose of fractionated radiation required to control 50% of tumors (TCD_{50}) by 11 to 27 Gy without modifying infield skin reactions.[251] Thus, to maximize clinical gains, these agents must be employed in combination with radiation and chemotherapy. The challenge now is to optimally combine these therapies in patients. Destruction of tumor vasculature by antiangiogenic agents would only antagonize chemo- and radiotherapy by compromising the delivery of therapeutics and oxygen, respectively.[289] However, judiciously applied antiangiogenic therapy can prune inefficient tumor vessels and render the remaining vasculature more efficient (Fig. 4.5A–D).[12,36,78,115,233] This "normalization" of tumor vasculature has been demonstrated in various preclinical models (reviewed in Refs.[36,78]) and in HER2-negative breast cancer, non–small cell lung cancer, rectal cancer, hepatocellular carcinoma, ovarian carcinoma, and glioblastoma patients[61,62,64,66,68,70,277,278] (Fig. 4.8).

To be effective, vascular "normalization" should result in improved delivery of cytotoxic chemotherapy and radio- and immune-sensitizing oxygen, thereby improving tumor control. This principle has been rigorously tested in animal models[16,78,84,154,172,173,290,294–296] and investigated in large phase III trials and smaller hypothesis-driven trials. The lessons from these studies support the notion that optimally combining antiangiogenic therapies with radiation, chemotherapy, or immunotherapies will involve administering therapies in the window of maximized delivery of oxygen.[16] Furthermore, this window is dependent on the baseline vasculature, whether the vessels are fortified and whether vessel function is increased (Fig. 4.9A).[289]

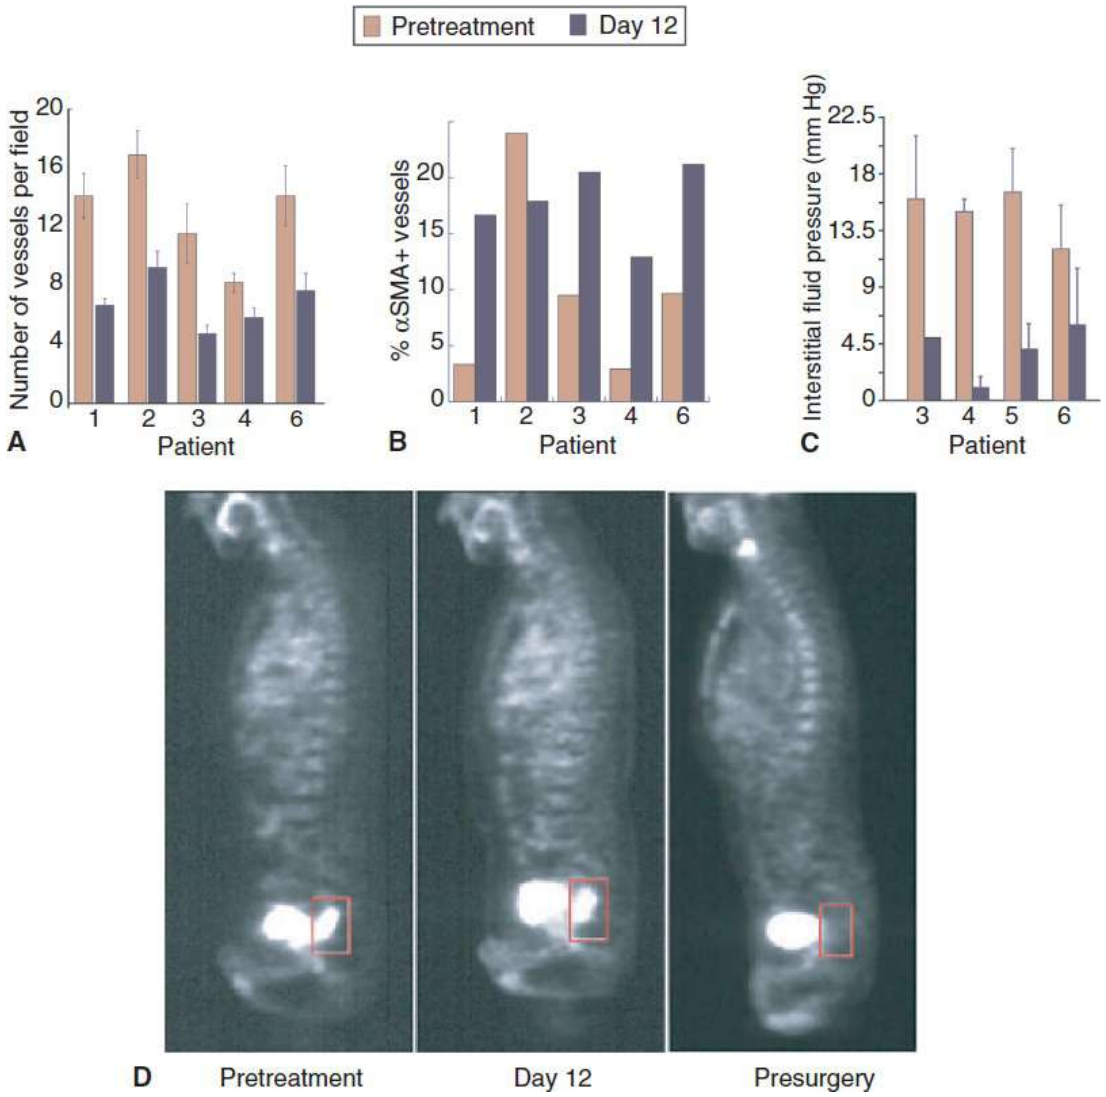

FIGURE 4.8. Vascular "normalization" in rectal cancer patients following treatment with the anti-VEGF antibody, bevacizumab. **A–C:** Tumor vessel normalization following a single injection of bevacizumab is suggested by the reduction of tumor microvessel density **(A)**, by the increase in fraction of tumor vessels with pericyte coverage **(B)**, and by the drop in IFP **(C)**. **D:** Positron emission tomography reveals no change in 18-fluorodeoxyglucose (FDG) uptake after a single dose of bevacizumab and complete resolution of FDG uptake following neoadjuvant chemoradiation (bevacizumab, 5-fluorouracil, pelvic external beam radiation therapy). The stability of FDG uptake following bevacizumab monotherapy, despite marked reductions in microvessel density, suggests the efficiency of residual tumor blood vessels after bevacizumab treatment is improved. (Reprinted by permission from Nature: Willett CG, Boucher Y, di Tomaso E, et al. Direct evidence that the VEGF-specific antibody bevacizumab has antivascular effects in human rectal cancer. *Nat Med* 2004;10[2]:145–147. Copyright © 2004 Springer Nature.)

In tumors that are hypovascular or hypoperfused, antiangiogenic treatments should be combined with solid stress–alleviating therapies to increase

oxygenation (Fig. 4.5E).[297] Indeed, TGF-β1 inhibition with angiotensin system inhibitors increases perfusion and reduces hypoxia in hypovascular murine cancer models and has demonstrated promise in increasing resection rates induced by chemoradiation in neoadjuvant pancreatic ductal carcinoma patients (Fig. 4.9B).[91,298] These prospective studies are consistent with retrospective studies each surveying hundreds of patients with non–small cell lung cancer, pancreatic ductal adenocarcinoma, and renal cell carcinoma that show repurposing angiotensin system inhibitors from treating hypertension to reprogramming the stroma of cancer might increase patient survival.[299–305] Furthermore, one retrospective study in hepatocellular carcinoma indicates that angiotensin system inhibitors and antiangiogenic agents in combination might increase survival.[304] Other strategies demonstrating potential in preclinical studies to decrease solid stress include vitamin D receptor agonism, antifibrotic medication losartan or tranilast, idiopathic pulmonary fibrosis medication pirfenidone, and diabetes medication metformin.[92–94,190] The current challenge is how to combine optimally antiangiogenic and solid stress–alleviating therapies particularly in tumors that are neither highly vascular nor highly desmoplastic.[297] Chemotherapy normalizes vessels when given metronomically, thereby complicating the task of optimizing treatment combinations.[306] Additionally, researchers must investigate how we can translate these lessons to treat patients with micrometastatic disease, which does not rely on sprouting angiogenesis.[307–309]

One emerging strategy to treat systemic disease could involve priming T cells with radiation locally administered to the tumor to promote immunogenicity of cancer cells and in turn immune response systemically against nonirradiated distant metastases.[310] This phenomenon, which is referred to as the “abscopal effect” of radiation, could potentially be used to increase the rate and duration of responses in patients treated with immunotherapy.[311] To progress, tumors must successfully resist immune rejection, even though they are continuously producing neoantigens that T cells can recognize.[312] If cancer cells undergo immunogenic cell death, epitopes can be transferred from cancer cells to dendritic cells that are required to activate tumor-specific T cells.[313,314] Indeed, ionizing radiation and some chemotherapies induce immunogenic cell death.

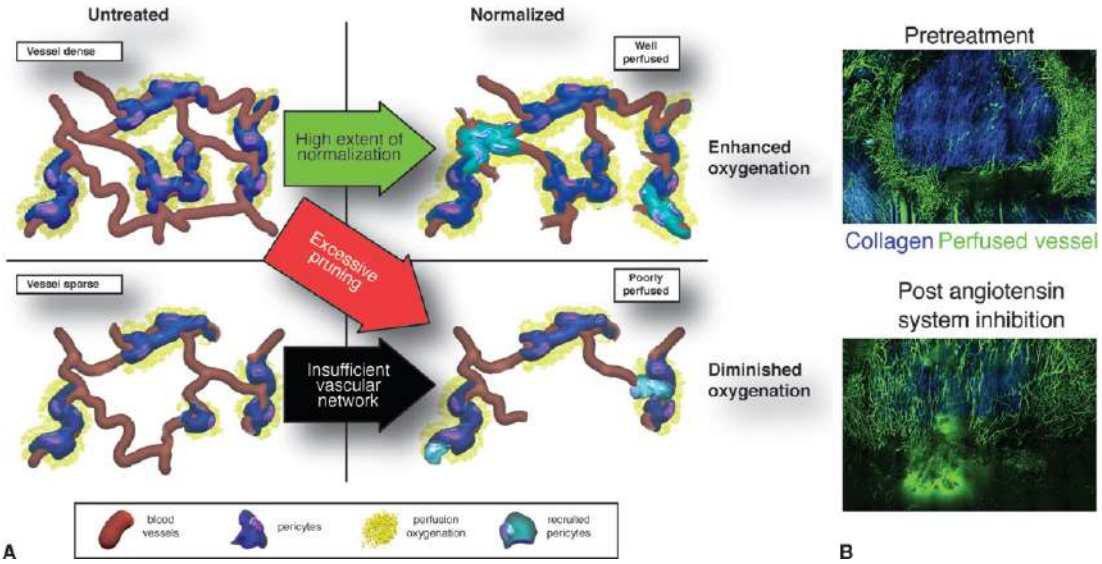

FIGURE 4.9. Vascular "normalization" in cancer patients. **A:** Preclinical and clinical studies support the hypothesis that the therapeutic effect of antiangiogenic therapies is best when vascular density is high and normalization fortifies rather than prunes vessels. The left quadrants depict tumor vessels (*red*) before antiangiogenic therapy. The right quadrants depict possible outcomes of antiangiogenic therapy. Tumors with low pretreatment vessel density do not respond to antiangiogenic therapy (*bottom left* to *right quadrant*), as the increase in vessel function from the recruitment of pericytes (teal) cannot overcome the paucity of vessels. In contrast, tumors with high baseline vascularity that recruit pericytes have better outcomes (*top left quadrant* to *top right quadrant*) than tumors with excessive pruning (*top left quadrant* to *bottom right quadrant*). (From Tolaney S, Duda DG, Boucher Y, et al. Role of vascular density and normalization in response to neoadjuvant bevacizumab and chemotherapy in breast cancer patients. *Proc Natl Acad Sci USA* 2015;112[46]:14325–14330.) **B:** Intravital microscopy images of a murine breast tumor before (*top panel*) and after (*bottom panel*) angiotensin system inhibition treatment to reduce solid stress. The treatment reduces the density of collagen fibers (*blue*) leading to a homogeneous distribution of perfused vessels (*green*, *bottom panel*). (Reprinted by permission from Nature: Chauhan VP, Martin JD, Liu H, et al. Angiotensin inhibition enhances drug delivery and potentiates chemotherapy by decompressing tumour blood vessels. *Nat Commun* 2013;4:2516. Copyright © 2013 Springer Nature.)

Recent work focused on defining optimal dose and fractionation to schedule radiation with various immunotherapies.[315] Preclinical evidence indicates that fractionated rather single-dose radiotherapy might be required to induce an abscopal effect in combination with the immune checkpoint blocker anti–CTLA-4 antibody.[316,317] Furthermore, radiation doses above a certain level attenuate immunogenicity and thus should be avoided.[318] The attenuated immunogenicity is mediated by the DNA exonuclease Trex1, which could be a potential biomarker to determine the radiation dose and fractionation in combination with immunotherapy. These hypotheses have been generated in proof of principle

clinical trials and require validation.[319,320]

In considering these disparate strategies together, several potentially synergistic combinations could be hypothesized to treat systemic disease. Antiangiogenic and solid stress–alleviating therapies could be administered in combination to alleviate hypoxia in tumors to potentiate subsequent fractionated, low dose radiotherapy. The resulting immunogenic cell death could lead to increased response through the abscopal effects when used in combination with immune therapy. One complementary pathway is TGF-β.[321] Inhibition of this pathway alleviates solid stress[91] and promotes radiotherapy-induced antitumor immunity.[322] Future studies should uncover mechanisms through which these strategies complement each other toward developing more effective combination schedules.[16]

CHAPTER 5

SMART Radiotherapy

C. Norman Coleman, Pataje G. Prasanna, Jacek Capala, Mansoor M. Ahmed, Jeffrey C. Buchsbaum, Bhadrasain Vikram, and Eric J. Bernhard

INTRODUCTION

On being asked to write a second edition of this chapter, we realized that there may have been a few different conclusions drawn from the previous version. It might have been wildly successful, not very good requiring a remedial effort, or largely ignored. This is a serious science-based chapter, and to bring a new level of SMARTs to how a book chapter is viewed—of which our chapter is 4.7% of the total number of chapters—we have included a mini-survey for the reader in the conclusion. We are pleased to be among the first five chapters and to serve as the linker between biology and physics. As stated in the previous version, we anticipate that the radiation biology chapter will include molecular aspects of radiation therapy and the basic aspects of tumor microenvironment, the physics chapter will include essential aspects of particle therapy, and the clinical chapters will include molecular characterization of tumors, the use of molecular and functional imaging, and the current studies with molecular targeted agents for the various diseases.

The goal of this chapter is to take a broad view of what are likely to be some of the innovative concepts, now entering the practice of oncology, that are relevant to radiation therapy researchers and practitioners. A first major point is that perhaps now more than ever, radiation oncology needs to be at the center of the science of cancer care. Our clinical expertise transcends all diseases; our technology has impact in the most expensive, high-technology, upper-income-country care but can also reach people in dire need of cancer care in lower/middle-income countries. Although not always recognized as such, in the evolving era of “precision medicine,” radiation is both “precision and accurate medicine” when one looks at radiation as a “drug.” We can control the

pharmacokinetics and pharmacodynamics of radiation by hitting specific physical targets and also by using doses and schedules that could be designed to activate molecular, cellular, and tissue pathways.[1] The term "focused biology" was coined 15 years ago,[2,3] and it is now increasingly relevant with image-guided radiation therapy, particle therapy, immune modulation, hypofractionation, and molecular targeted drug treatment.

Building from our definition of SMART radiotherapy from the previous edition, we will introduce new concepts *in italics*:

Science-focused clinical care based on cancer, molecular, cellular, and tissue biology—*radiation as a drug, as part of combined modality therapy, and as an immune modulator*

Multidimensional approach to all radiation issues facing society, including cancer treatment, prevention, and potential risk from radiation exposure —*normal tissue and biomarkers*

Access to care for all, including the underserved for whom radiation oncologists (often called clinical oncologists) are the primary oncology care provider—*progress in global health*

Responsible implementation of technology so that we control our destiny based on data—*particles, systemic radionuclides, and nano-based treatments*

Training and mentoring to ensure a broadly based, societal conscious next generation of clinicians, scientists, and educators—*radiation oncology as a key leader in cancer care*

By fortunate coincidence, our SMART components follow the same general organization as does this book. We start from the new biology, to the developing world, to physics and systemic radionuclides, and to education, training, and ethics.

SCIENCE-FOCUSED CLINICAL CARE BASED ON CANCER, MOLECULAR, CELLULAR, AND TISSUE BIOLOGY

Radiation as a Drug

A concept introduced in the previous edition of the chapter is radiation as a drug and immune modifier. Luo et al.[4] modified the "hallmarks of cancer" model of Hanahan and Weinberg[5] by targeting nononcogene addiction in addition to oncogene addiction. Logically, the biochemical and metabolic machinery of the

cell carries out the functions of the genes be they normal or abnormal so that the target of cancer therapy can be to disrupt the turning on and off of genes directly and also to disrupt the metabolic and biochemical pathways that they activate. Nononcogene pathways include the stress responses: metabolic, proteotoxic, mitotic, oxidative, deoxyribonucleic acid (DNA) damage, and evading immune surveillance. Notably, all these pathways can be modulated by radiation.

The initial work by Tsai et al.[6] that showed what we now call "multifraction-adaptive (MF-adaptive)" responses used ribonucleic acid (RNA) microarrays to study the effects of 10 Gy as a single dose or as multifractionated radiation, 2 Gy × 5, in three tumor cell lines—breast, prostate, and brain—*in vitro* and *in vivo*. There is a substantially different gene expression pattern with fractionation compared to single dose, with immune response genes being a pathway significantly up-regulated with fractionation. Fractionated radiation made the cell lines somewhat more alike (one of the hypotheses tested), and there was substantial difference between tumors treated *in vivo* versus *in vitro*, which might reflect the effects of radiation as well as the presence of a variety of cell types within a tumor.

John-Aryankalayil et al.[7] studied the molecular changes in prostate cancer cells exposed to 10 Gy as a single dose (SD) or multiple fractions (MF) using 2 Gy × 5 (MF2) and 1 Gy × 10 (MF1). The gene profiles are markedly different between SD and MF, and MF1 induces more changes than does MF2. Summarizing substantial work in this regard[3,7–9] includes the following: (a) An inflection point occurs after six to seven 1 Gy doses with immune response genes being a major pathway so that this MF-adaptive response may be missed in schedules using only 3 to 5 fractions; (b) changes occur in micro ribonucleic acid (miRNA), metabolomics, and protein expression, which are now being correlated; (c) 0.5 Gy × 10 will induce changes so that many tissues know they've been hit; (d) similar changes are seen in endothelial cells, including immune response genes; and (e) as a proof-of-principle, drugs targeting the Akt–mTor pathway were effective after MF but not before, demonstrating that radiation could stimulate drug susceptibility. The above studies indicate potential unique use of the radiation in the "focused biology" concept for molecular targeted therapy and emphasize the importance of investigating the molecular phenotype in cells that survive radiation.

The Tumor Microenvironment

The efficacy of radiotherapy is in part determined by tumor microenvironmental

factors, including, but not limited to, the extent of tumor oxygenation, the tumor pH, and the interaction of tumor cells with host stroma and with inflammatory cells. Tumors contain areas of poor vascular perfusion, low pH, and oxygen, which may provide regions in which both the delivery and activity of cytotoxic therapies is attenuated and in which cancer stem–like cells (CSCs) reside.[10,11] In addition, certain tumor environments may select for more aggressive or resistant tumor clonogens.[12] One factor that has received little clinical attention, but may provide an avenue for future advances, is the impact of mechanical force on transformation, progression, and treatment response of cancer cells.[13] Similarly, signaling originating from the interaction of stromal components with integrins on cancer cells can influence tumor survival and provide targets for intervention.[14,15]

The tumor microenvironment changes during radiotherapy.[16] Fractionated radiotherapy results in reoxygenation of the tumor due to elimination of well-oxygenated cells, thus increasing oxygen delivery to the previously hypoxic areas. Conversely, high-dose single fractions (over 13 Gy) have been shown to result in destruction of both tumor cells and vascular endothelium.[17] How and under what circumstances radiation-induced vascular injury impacts tumor responses continues to be a topic of investigation and is relevant to the current use of large fraction stereotactic radiosurgery or therapy.[18–21] Radiation also results in release of tumor antigens, and this release may be qualitatively and quantitatively modulated by fractionation schedules as discussed later.

Tumor Hypoxia

The longest-studied example of tumor microenvironment effects on cancer cell radiation survival is the impact of tumor oxygenation. Radiation under atmospheric oxygen conditions enhances killing by a factor of 2 to 3 compared to irradiation under anoxic conditions, which has been termed the oxygen enhancement ratio[22] (as reviewed by Horsman et al.[16]). In the clinical setting, hypoxia affects outcome after radiotherapy.[23,24] But hypoxia has also been shown to be a poor prognostic factor after chemotherapy[25] and surgery.[26,27] These findings were attributed to chronic hypoxia, and this has been studied under controlled oxygen concentrations *in vitro* or using electrodes or immunohistochemical staining to measure tissue oxygenation *in vivo*. Overcoming hypoxia by biochemical targeting of hypoxic regions in tumors has proven difficult to translate to the clinic.[28] Going forward, molecular targeting of hypoxic cells may prove more practicable and effective.[29] The approach of

reducing tumor oxygen consumption may also be more effective than either targeting hypoxic cells or trying to increase tumor oxygen.[30] Recent advances in noninvasive tumor hypoxia imaging may also come into play in the future, allowing precise definition of hypoxic tumors and tumor subregions through imaging with positron emission tomography (PET),[31] magnetic resonance imaging (MRI),[32–34] or electron paramagnetic resonance oxygen imaging (recently reviewed in Colliez et al.[35]). The resolution of these imaging modalities will be critical.[36]

More recent studies have shown that acute fluctuations in tumor oxygenation ("transient" or "cycling" hypoxia) interspersed with periods of reoxygenation may be even more effective in promoting tumor survival and progression than chronic hypoxia.[37] A third type of hypoxia, termed "longitudinal hypoxia," has also been proposed, which occurs as a gradient along the length of tumor vessels.[38] Defining the relative contributions of these hypoxia mechanisms to radiobiologic responses is ongoing; however, it is likely that all could contribute to resistance. It is clear that cycling hypoxia may complicate efforts to identify and target radiobiologically important hypoxic regions within tumors using approaches such as radiation dose painting to hypoxic tumor subregions.[39] Cycling hypoxia is more difficult to image using current methods, such as nitroimidazole markers, which are better suited to detecting chronic hypoxia. Developments in imaging hypoxia with MRI and electron paramagnetic resonance may facilitate real-time detection of transient hypoxia in the future.

Hypoxic Cell Sensitizers and Cytotoxins

Targeting hypoxic cells should improve outcome in frequently hypoxic tumors. Nimorazole, a nitroimidazole hypoxic cell sensitizer has shown promising results when used with radiotherapy in patients with hypoxic tumors.[40,41] However, testing and adoption of this drug in countries other than Denmark have been limited. The alternative approach of using hypoxic cell cytotoxins has also been tested. Tirapazamine (TPZ, 3-amino-1,2,4-benzotriazine-1,4-dioxide) undergoes reduction under hypoxia to form a highly reactive radical that causes DNA damage leading to cell killing.[42] Under normoxic conditions, the reduction of nitroimidazoles and TPZ is reversed, thus providing the specificity for hypoxic tissues.[43,44] Despite promising early results, phase III testing of TPZ in combination with chemoradiotherapy failed to demonstrate improvement in failure-free survival, time to locoregional failure, or quality of life among patients with head and neck cancers.[45] However, patients in this trial were not

selected for tumor hypoxia, and other treatment concerns were subsequently raised.[46] Development of new generation hypoxic cell cytotoxins with greater preclinical efficacy than TPZ is under way.[47] It will be crucial in future tests of hypoxia-targeting agents to select or stratify patients based on their tumor oxygenation status.[48]

The identification and selective treatment of hypoxic tumors may, in the future, enhance the results of radiotherapy. Novel imaging methods to identify hypoxia and new generation hypoxic cytotoxins and sensitizers will benefit this approach. In addition, hypoxia has been recently shown to impart susceptibility to DNA damage response inhibitors, as it down-regulates components of the homologous recombination (HR) DNA damage repair machinery.[49,50] Exploiting this finding in the context of radiotherapy with PARP or other HR inhibitors could prove effective for better elimination of otherwise resistant hypoxic tumor cells. The history and possible paths forward in exploiting hypoxia as a clinical target with a focus on lung cancer were recently reviewed.[51]

Tumor Angiogenesis and Antiangiogenic Approaches

Normal angiogenesis is a highly regulated process involving endothelial cells with differing functions (tip, stalk, and phalanx cells) under tight regulation of oxygen sensors (prolyl-hydroxylase-2 [PHD-2]), growth and maturation factors (vascular endothelial growth factor [VEGF], angiopoietins), and transmembrane receptors (Notch family) (reviewed in Carmeliet et al.[52]). Small changes or imbalance in the expression of these regulators can have a significant impact on vascular development and lead to the formation of abnormal tumor vessels that are inefficient in the transport of nutrients, oxygen, and metabolic wastes. Limited perfusion and convection also reduce the efficacy of chemotherapeutic delivery. Vascular endothelial cells, unlike tumor cells, are genetically stable and thus an attractive target. Antiangiogenic agents reduce or cut off tumor vascular flow by selective targeting of tumor vessel growth by blocking VEGF signaling. Targeting the tumor vasculature was originally proposed by Judah Folkman.[53] It is now clear, however, that this approach is complicated by the fact that development, structure, and the potential for recovery of tumor vasculature after treatment are influenced by bone marrow–derived progenitor cells in addition to the tumor and other stromal elements.[54] In addition, where tumor cell–derived vascular channeling (vasculogenic mimicry) plays a role in tumor circulation the effects of antiangiogenic strategies that target host vascular endothelial cells may not be as effective.[55]

VEGF can be induced in response to radiation, and inhibition of VEGF can increase tumor control after radiation in preclinical models.[56] VEGF receptor inhibition reduces endothelial cell proliferation *in vitro* after irradiation and also reduces microvessel density in irradiated tumors.[57] Clinical trials have suggested a potential benefit in combining radiation and antiangiogenic therapy in rectal cancer and sarcoma.[58,59] However, the toxicity of bevacizumab in combination with radiotherapy has been of concern in some tumors.[60]

Vascular normalization is a term coined to denote transient changes observed in tumor vessels after VEGF inhibition with a VEGF receptor-2 antibody.[60] Other antiangiogenic approaches have shown similar morphologic effects on tumor vasculature. Methylselenocysteine, which has antiangiogenic activity, has been shown to induce a more mature morphology in FaDu xenograft tumor vessels, accompanied by enhanced perfusion and a fourfold increase in doxorubicin delivery to treated tumors.[61] Normalization is characterized by a reduction in the chaotic branching and tortuosity of tumor vessels and is accompanied by a reduction in tumor hypoxia and enhanced radiosensitivity. The effects of vascular normalization may also involve reduction of tumor interstitial fluid pressure. High tumor interstitial fluid pressure has been shown to impact survival after irradiation and may also be influenced by the tumor stroma.[62] Tong et al.[63] have shown that blocking VEGF signaling results in decreased interstitial fluid pressure in tumor xenografts in mice. Although the normalization period offers an opportunity for improved response to radiation and chemotherapy, the period of normalization obtained with direct targeting of VEGF signaling in preclinical studies lasts less than a week, followed by vascular insufficiency. In addition, vascular normalization may not occur in all tumors and has not been observed in all studies (reviewed in Horsman and Siemann[64]). In the clinical setting, vascular normalization has been proposed as a predictive marker in patients undergoing cediranib (VEGF inhibitor) treatment for recurrent glioblastoma.[65] Elevated blood perfusion after cediranib treatment has recently been associated with increased survival in these patients.[66]

More durable normalization of tumor vasculature might be clinically achievable through growth factor or oncogenic signaling inhibition. Studies have shown changes in vascular morphology, function, and maturation accompanied by decreased tumor hypoxia after inhibition targeting epidermal growth factor (EGF) receptor, RAS, phosphoinositide (PI) 3-kinase, or AKT in human tumor xenografts and spontaneous mouse tumors that last up to 2 weeks.[67] Others have shown that blocking EGF signaling increased tumor uptake of cisplatin at the

same time that enhanced vascular function and oxygenation were seen in tumor xenografts.[68] Signaling inhibition in these studies decreased, but did not eliminate, VEGF production by tumors, which might account for the effects seen and their duration.

Other approaches to altering tumor vasculature are being investigated. Inhibition of $\alpha(v)\beta(3)/\alpha(v)\beta(5)$ integrin has been reported to cause effects similar to signaling inhibition on tumor vascular morphology.[69] Using another approach, investigators showed that shutting off NOS1 production in U87 glioblastoma tumors restored a nitric oxide gradient around the tumor vessels. This was accompanied by a normalized phenotype with less tortuous and more abundant vessels that had increased perivascular cell coverage.[70] Hypoxia in these tumors was reduced and their response to radiation increased as measured by both relative tumor volume and survival endpoints. Modulation of host PHD-2 can affect tumor vascular structure and maturity.[71] Inhibitors of PHD-2, such as dimethyloxaloylglycine (DMOG), might be developed for clinical application. More recently, the interaction between T cells and tumor vasculature has been studied in the context of immunotherapy. Interferon-beta (INF-β) produced by T-helper type 1 cells has been shown to promote vascular normalization, which in turn facilitates T-effector functions.[72]

Inhibition of Vasculogenesis

Vasculogenesis, unlike angiogenesis, recruits cells from distant sites, including the bone marrow, to participate in the formation of new blood vessels (reviewed in Patenaude et al.[73]). The process is thought to be an important contributor to the tumor vasculature, although the precise contribution of the different recruited cell types is still a matter of debate.[54] The CD11b-positive, matrix metalloproteinase-9 (MMP-9) expressing myeloid cells appear to be central to this process.[74] A neutralizing antibody to CD11b inhibited the recruitment of myeloid cells to tumors and prolonged radiation-induced regrowth delay. Additionally, mice with reduced CD11b expression showed enhanced xenograft radiosensitivity.[75] Stromal derived factor-1 (SDF-1) and the chemokine receptor CXCR4 also contribute to recruitment of endothelial cell precursors and could be targeted. Inhibition of the CXCR4/SDF-1 interaction reduced bone marrow–derived progenitor cell recruitment into irradiated glioblastoma orthotopic xenografts and slowed tumor regrowth.[76] An inhibitor of CXCR4 activation by SDF1, AMD3100 (plerixafor), is in clinical use for stem cell mobilization and could be quickly adopted for this purpose. This drug has been shown to have

promising effects in chemoradiotherapy for cervical cancer.[77]

Antivascular Therapy

Selectively destroying tumor vasculature with vascular disrupting agents (VDAs) is an approach that seeks to kill tumors by shutting off their blood supplies (reviewed in McKeage and Baguley[78]). This approach, however, acts primarily on the tumor core and does not eradicate host vessels that border the tumor and are in proximity of normal host vasculature. Tumor cells at the host–tumor interface can remain viable after this treatment to repopulate the tumor. Furthermore, vascular disruption could generate areas of hypoxia that still contain viable tumor cells, thereby selecting for more resistant clones.[12] Combining VDA treatment with a cytotoxic modality could overcome this problem. The effects of VDAs both alone and in combination with antiangiogenics, chemotherapy, radiation, or other modalities have been examined in a number of preclinical studies (reviewed by Horsman and Siemann[64]). VDAs are currently in phase II to III clinical trials alone or in combination with cytotoxic chemotherapies.[79]

Tumor Stroma and Extracellular Matrix

The tumor stromal compartment, including the extracellular matrix, host fibroblasts, and immune cells, is known to contribute to tumor progression and survival.[80,81] In certain tumors, like pancreatic cancers, activation of quiescent stromal cells, known as stellate cells, to myofibroblast-like cells involved in extracellular matrix production contributes significantly to tumor progression.[82] Activated fibroblasts deposit collagens, leading to changes in stromal rigidity. Stromal rigidity can impact both transformation and progression.[83] This mechanism of stromal-induced tumor promotion includes intercellular signaling initiation via integrins to prosurvival pathways, including PI3-kinase.[84]

There are multiple points at which stromal changes can be inhibited, including inhibition of fibroblast or stellate cell activation by angiotensin-converting enzyme (ACE) inhibitors or other antifibrogenic compounds such as halofuginone.[85] This class of agents can also protect from normal tissue fibrosis and inhibit tumor growth factor-β (TGF-β).[86,87] Signaling by the cytokine TGF-β strongly promotes fibrosis, both in response to tumor growth and in normal tissues in response to treatment with radiation. Direct inhibition of TGF-β in tumors can interrupt or mitigate desmoplasia and reduce tumor growth.[88] Angiotensin-II (Ang II) can promote stellate cell growth under pathologic

conditions, and ACE inhibitors act in part through blocking Ang II.[89] Angiotensin-(1-7), an endogenous 7 amino acid peptide antagonist of Ang II, has been shown to reduce TGF-β expression, block proliferation of cancer-associated fibroblasts, and inhibit tumor growth.[90] Inhibition of hedgehog pathway signaling is another approach that has been tested in pancreatic cancer mouse models.[91] but there is controversy surrounding the role of hedgehog signaling in pancreatic and other cancers.[92]

Integrin binding and signaling have been identified as a potential target for cancer treatment, as these receptors are involved in tumor growth and angiogenesis (reviewed in Desgrosellier and Cheresh[93]) as well as therapy resistance.[94] Cilengitide is a pentapeptide mimic of the RGD binding site that blocks $\alpha(v)\beta 3$ and $\alpha(v)\beta(5)$ integrin binding to extracellular matrix components.[95] In addition to its antiangiogenic activity, it inhibits focal adhesion kinase signaling.[96] Cilengitide is well tolerated and has some antitumor activity as a single agent.[97] It has been shown to be active in combination with radiation in several, but not in all reports.[98–100] However, questions remain about potential normal tissue toxicity in combined modality treatment because integrin signaling is required for normal cell function and survival.[98] A phase III trial of cilengitide with temozolomide radiotherapy for GBM saw no unanticipated toxicities but failed to meet its endpoints.[101] There are currently (2017) no open trials of this agent listed in Clinicaltrials.gov, but integrin targeting remains an active area of research.

Targeting Stem Cells

The CSCs model is currently used to as a framework for understanding cancer proliferation, growth, and treatment resistance (reviewed in Bednar and Simeone[102]). CSCs are thought to be a subset of cells at the peak of a developmental chain within a tumor with the capacity for unlimited self-renewal and lineage plasticity.[103] These cells give rise to more differentiated daughter cells with less replicative and tumorigenic potential that make up the bulk of the tumor cell population. The CSC may be more quiescent than the general population of cells in a tumor and relatively resistant to cytotoxic therapy.[104,105] Some studies have identified perivascular niches for these cells[106,107] and the conditions that promote their colonization and survival,[10] but the identification of both the stem cells and their niches in a disorganized and dynamic tumor environment remains challenging.[108] The perivascular niche and, in particular, the endothelial cells may both aid in tissue repair and promote tumor growth by

secreting “angiocrine factors.”[109] Targeting these factors could be an approach to cancer treatment. Disruption of the perivascular niche with VDAs or antiangiogenics might also reduce CSC numbers. The potential for CSCs as targets and potential biomarkers for radiotherapy has recently been reviewed by Krause et al.[110]

Recent work indicates a novel potential target within the tumor stroma, fibroblast activation protein, which has the potential to enhance innate antitumor immune responses. In a transgenic mouse model, the elimination (through genetic manipulation) of fibroblasts and pericytes expressing fibroblast activation protein enhanced antitumor immune responses. Activation of tumor-infiltrating T cells and the resulting increase in interferon-γ and tumor necrosis factor-α (TNF-α) promoted the antitumor immune response in a transgenic mouse model.[111] A possible pharmacologic approach to elimination of these activated fibroblasts is by inhibition of the matrix enzyme lysyl oxidase-like-2 (LOXL-2). Inhibition of this enzyme using a monoclonal antibody decreased desmoplasia and both primary and metastatic tumor growth[112]; small molecule inhibitors of this enzyme also exist. Targeting lysyl oxidase (LOX), which has been shown to promote tumor growth in orthotopic and spontaneous mouse tumor models, might also be a means of inhibiting tumor growth.[84]

Summary of Microenvironment

It is not possible to predict exactly how radiotherapy will evolve in its utilization of knowledge regarding the tumor microenvironment and host–tumor interactions. What appears clear is that increasing emphasis will be placed on these factors. Targeting changes specific to the microenvironment has the advantage of being largely tumor specific and potentially less toxic than cytocidal therapies. Future developments may allow for hypoxic tumor region dose painting. Alternatively, hypoxia-targeting drugs may finally reach clinical maturity. Inhibition of hypoxia in tumors may also arise from strategies that revert tumor vasculature to a more normal morphology and function. This strategy has the added advantage of reducing hypoxia selection for aggressive tumor clones and enhancing chemotherapy delivery. The impact of the immune response on tumors and in turn the effects of different radiotherapeutic interventions on immunity are now being exploited with the explosion of trials combining checkpoint inhibitors and radiation (see the next section). Findings relating to the impact of host stromal elements on tumor cell radiation survival through direct intercellular signaling, autocrine stimulation, or mechanical force

may also soon reveal new targets and interventions applicable to radiotherapy.

In addition to the host and tumor microenvironment, external environmental factors may also play a role in response to therapy. These have yet to be fully evaluated or exploited. Temperature (hyperthermia) is well known to impact radiation response,[113–115] but its evaluation and clinical application, at least in the United States, has lagged. Conversely, preclinical studies have shown that lower ambient temperatures can induce resistance to cytotoxic therapies[116] and influence both tumor growth and immune responses.[117] The impact of time of day of treatment and the role of circadian clock proteins is another understudied area that could be exploited.[118] Preclinical work points to the possibility that the clock proteins influence tumor radiosensitivity.[119] There are indications from clinical studies that both toxicity and treatment failure could be impacted by the time of irradiation, but the data are not yet conclusive.[120] At a minimum, the further study of these factors could inform preclinical study conditions and perhaps enhance translation and reproducibility of results.

Combining agents that alter the tumor environment with radiotherapy requires strong preclinical data demonstrating at least additive effect and acceptable toxicities. Careful preclinical testing, including normal tissue response evaluation, may avoid subsequent problems in many instances. Having markers and imaging that detect the targets of interventions, such as hypoxia, cancer-associated fibroblasts, or immune-infiltrating cells, and that can be used to assess intervention-mediated changes in the environment will be critical to fully exploiting this approach. Recent developments in the analysis of circulating tumor cells and cell-free DNA may revolutionize treatment monitoring as discussed later in this chapter.

Immunomodulating Events in Response to Ionizing Radiation

The surge in interest in immunotherapy for cancer offers an opportunity for radiation oncology and radiation biology to play central roles in the development and delivery of this aspect of precision medicine. The tumor microenvironment harbors clones that can escape from immune editing and surveillance processes. These processes are regulated by several cytokines and checkpoint proteins. Ionizing radiation (RT) causes changes in the tumor microenvironment that can lead to intratumoral as well as distal immune modulation (the so-called abscopal effect). Tumor-associated antigens (TAAs) are released by irradiated dying cancer cells triggering danger signals such as heat shock protein (Hsp), HMGB1, and calreticulin (“eat-me” signal for phagocytes). These TAAs and cell debris

are taken up by phagocytes such as macrophages, neutrophils, and dendritic cells for antigen processing and presentation. At the same time, RT can induce increased expression of tumor antigens and MHC class I molecules on tumor cells. Consequently, activated antigen-presenting cells (APCs) migrate to the draining lymph node, further mature upon encountering T helper cells, and release interferons (IFNs) and IL-12/18 to stimulate Th_1 responses that support the differentiation and proliferation of antigen-specific CTLs. Activated antigen-specific CTLs traffic systemically from the draining lymph node to infiltrate and lyse cells in primary as well as distal tumors. Concomitantly, tumor irradiation can also recruit immunosuppressive cells into the tumor microenvironment and induce expression of certain negative stimulatory molecules on T cells and tumor cells (CTLA-4, PD-1, PDL1) that can curtail the activation of T cells leading to an immunosuppressive environment. Other immunosuppressive function of radiation can occur through induction IL-10 and TGF-β (Fig. 5.1).[121–123] These immunomodulating events can also impact tumor growth at a distance from the irradiated tumor site, the "abscopal effect," that is mostly immune, and in certain instances, it can be non–immune mediated through ceramide signaling.

Harnessing Radiation Modulation of the Immune Response

Several factors can influence the ability of radiation to enhance immunotherapy, including (a) the dose of radiation per fraction and the number of fractions and (b) the volume of the irradiated tumor tissue and target location. However, the impact of these variables is not well understood. Historical evidence and recent literature point out that radiation doses at opposite ends of the dose spectrum induce robust immune activation.[124,125] For the sake of clarity, this section divides three dose ranges, low-dose RT (0.1 to 1 Gy), high-dose RT including ablation (8 Gy and above), and clinically relevant dose (1.8 to 2.2 Gy), to define immune modulation events and how these events can be harnessed with cancer immunotherapy.

Low-Dose Radiation

At low doses of radiation from 0.1 to 1 Gy, immune activation is achieved by increased Th1 response that attract naïve T cells and promote its differentiation and activation.[126] Because the D_{10} for CD4+/CD8+ lymphocytes ranges from 3.32 to 3.84 Gy,[127,128] low-dose chronic and acute irradiation stimulate enhanced immune function leading to in situ vaccination, trafficking, infiltration, and killing. Low-dose radiation at 0.5 Gy is associated with greatest number of

infiltrating T cells with a decline at >1 Gy, and this was accompanied with redirecting macrophage differentiation from a "tumor-promoting/immunosuppressive state" to one that enables cytotoxic T lymphocytes to infiltrate tumors and kill cancer cells.[129] Moreover, low-dose RT causes an increase in homing of activated T cells[129] in tumor milieu unlocking the barriers of cancer immunotherapy. Furthermore, tumor cells when irradiated with 1 Gy fractions can robustly activate immune gene program[130] that can be conducive for trafficking and homing of T cells that is similar to antimicrobial/inflammatory response. All these immune modulation conditions can be harnessed with drugs that augment dendritic cell maturation such as TLR or CD40 agonist or IFN-β to further intensify antitumor immunity effects.[125] Kinetics of immune gene activation in tumor cells treated with 1 Gy multifraction demonstrates that the opportunistic widow (inflection point) to exploit the maximal immune function for adjuvant immunotherapy is around 6 to 10 Gy total dose.[130] Cancer vaccines and adoptive T-cell therapy could boost radiation-induced in situ vaccination.[125] Furthermore, agonistic antibodies directed against costimulatory/coinhibitory molecules on T cells can synergize an increase in T-cell function.[125] Even though there are many preclinical studies to support the above low-dose RT combinations with immunotherapy, there is currently only one clinical trial that is opened by NCI CTEP utilizing 0.5 Gy bid fractions with dual checkpoint inhibitor in NSCLC and metastatic colorectal cancer (NCT02888743).

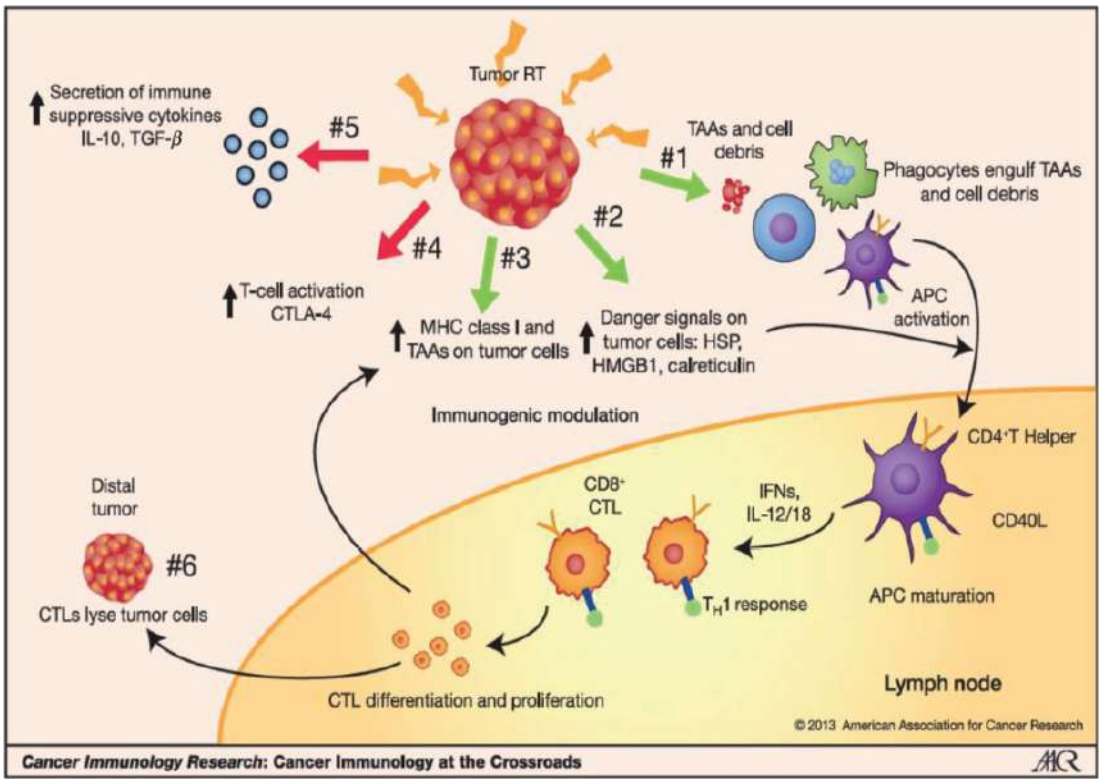

FIGURE 5.1. A schematic view of radiotherapy-induced immune modulations. #1, Tumor-associated antigens are released by irradiated dying cancer cells. TAAs and cell debris are engulfed in the tumor microenvironment by phagocytes such as macrophages, neutrophils, and dendritic cells for antigen processing and presentation. #2, Radiotherapy-induced cell death releases danger signals, including HSP, HMGB1, and calreticulin ("eat-me" signal for phagocytes). #3, Radiotherapy induces increased expression of tumor antigens and MHC class I molecules on tumor cells. #4, Radiotherapy-induced T-cell activation increases expression of negative stimulatory molecules such as CTLA-4. #5, Certain radiation doses may increase tumor production/secretion of immunosuppressive cytokines such as IL-10 and TGF-TGF-β. #6, Activated APCs migrate to the draining lymph node, further mature upon encountering TH cells, and release IFNs and IL-12/18 to stimulate TH1 responses that support the differentiation and proliferation of antigen-specific CTLs. Activated antigen-specific CTLs traffic systematically from the draining lymph node to infiltrate and lyse primary and distal tumors. RT, radiotherapy. (Reprinted from Ahmed MM, Hodge JW, Guha C, et al. Harnessing the potential of radiation-induced immune modulation for cancer therapy. *Cancer Immunol Res* 2013;1[5]:280–284. High-Dose Radiation

With radiation doses of 8 Gy and above in single or multiple fractions, TAAs initiate DAMPs to release IFNs to help mature T-cell differentiation and activation leading to immunogenic cell death and antitumor immunity with a potential to significantly increase the incidence of distal (so-called abscopal) effects.[131] These events lead to T-cell priming, trafficking, infiltration, *in situ*

vaccination, and immunogenic killing.[125] The immune modulation events by high-dose RT can be exploited to enhance immunotherapeutic efficacy by activating T cells using antibodies targeted against coinhibitory T-cell receptors/ligands such as PD-1/PD-L1 and TIM-3 and TGF-β and LAG-3 blockers.[125] In several preclinical tumor models, efficacy of immune checkpoint-targeted therapies improved when combined with high-dose radiation.[132] Significant downregulation of PDL-1 was observed in tumor cells treated with single fraction of 10 Gy but not with multifraction, and hence, anti-PDL1 combination can be effective with single high-dose treatment.[130] Similarly, vaccines or adoptively transferred CD8+ T cells combined with high-dose radiation demonstrated complete regression or significant growth delay.[133,134] Based on these promising preclinical data, there are nearly 50 clinical trials testing specifically targeting checkpoint inhibitor proteins with high radiation dose, mostly in phase 1 and 2 settings, and two open trials are there in phase 3 setting.[135]

Clinically Relevant Dose with Conventional Fractionation

Doses at 1.8 to 2 Gy in fractionated settings is standard of care for several solid tumors. Such fractionation extends several weeks to minimize toxicity to normal tissue, while lymphocytes are rapidly cleared from the irradiated field diminishing tumor antigen-specific T-cell populations through persistent site-specific cytotoxicity.[136] Such tolerogenic immunosuppressive events of radiation can be exploited by repletion of T cells in T-cell–deficient environment that can lead to proliferative expansion of T cells with activated phenotype and thus increase cytolytic activity to self and to tumor antigens.[136] Other immunotherapy combinations with 2 Gy fractions that can potentially partner for synergy include TLR and CD40 agonist, IFN-β, and cancer vaccines.[125] There are several open phase 1 and 2 clinical trials with EBRT plus checkpoint blockade therapy.[135]

Tumor Volume and Target Location

The size of the treatment field and radiation target can affect the exploiting potential of radioimmunomodulation. Larger treatment field tend to expose circulating lymphocytes that can impact proliferating T cells and T-cell priming in draining lymph nodes. This is similar to protracted RT regimens that are lymphotoxic, which may lead to T-cell clearance and lymphopenia.[137,138] To protect lymphocytes and T cells and reduce lymphopenia, one can adopt strategies such as reducing the treatment field size, shortening beam-on

treatment times, hypofractionation,[135] and lattice radiotherapy.[139,140]

Another important facet to consider when it comes to combining RT with immunotherapy is the site of radiation. As abscopal responses have been observed during irradiation of bone metastasis, there are reports to demonstrate that such abscopal events can result more from irradiation of visceral metastases.[141] This is supported by a recently failed phase 3 trial when single fraction of 8 Gy with anti-CTLA-4 to osseous metastasis.[142]

SMART Radiotherapy in Context of Immune Modulation and Immunotherapy

Current evidence indicates that either low-dose radiation or high-dose ablative radiotherapy can elicit immune stimulation more robustly than standard clinical regimens of fractionated radiotherapy. This is an area that requires further study and experimental validation. Based on the results to date, a potentially effective smart radiotherapy schema to boost immune response might be a preboost high-dose or ablative dose with single or less than three fractions directed toward partial treatment volume to trigger in situ vaccination, T-cell priming, trafficking, infiltration, and immunogenic killing. This would be followed by low-dose radiotherapy with 0.5 to 1 Gy fraction directed toward gross tumor volume to increase Th1-type response and facilitate the homing of activated T cells. At this time, dual checkpoint blockade immunotherapy can be effective in differentiation and proliferation of CTLs and to reactivate T-effector cells. Perhaps the most important point is that radiotherapy will best be used as a “drug,” which may mean varying the dose, fractionation, and target during a course of treatment to achieve the desired effect. The “one-size-fits-all” thinking is not an appropriate approach as it could lead to a lack of success by virtue of the wrong choice and not allow for the thoughtful development of the field. Biomarkers of response including circulating molecules or cells, imaging, and tumor sampling may be critical along the course of treatment to adapt to the changes in the tumor. This SMART radiotherapy approach will require validation in appropriate preclinical models and clinical trials prior to adopting as a standard of care for both highly and weakly immunogenic solid tumors.

MULTIDIMENSIONAL APPROACH TO ALL RADIATION BIOLOGY ISSUES FACING SOCIETY

Normal Tissue Injury and Biomarkers

Radiation risk to humans stems from a variety of complex radiation exposure scenarios, which include therapeutic and diagnostic medical exposures, occupational exposures, radiation accidents, nuclear weapons detonation, and terrorist events. Radiation exposure can cause acute, intermediate, late, and/or chronic injury. The severity of injury is dependent on radiation type, dose and dose rate, and volume of the tissue irradiated in addition to an individual's inherent sensitivity to radiation. In addition, different normal organs and normal tissues respond to radiation exposure in differing ways, influenced by, among other factors, intrinsic sensitivity to radiation, functional architecture, cellular turnover rate, and differences in damage response.

Acute exposure to total-body ionizing radiation in the dose range of 0.5- to 30-Gy can result in acute radiation syndrome (ARS), which is divided into organ syndromes based on the dose and cause of mortality.[143] The sequence of manifestation of ARS from lower to higher doses is as follows: hematopoietic, gastrointestinal, dermatologic, and cardiovascular and neurologic. However, syndromes overlap. For example, damage to the gastrointestinal or dermatologic systems can impact the outcome of hematologic syndrome at sublethal doses. Bioindicators or biomarkers of radiation exposure, even in the lower dose range, can reflect a response by multiple organs, all of which sense and respond to the radiation.[144]

At radiation doses below 0.5-Gy, acute effects are not observed but the probability of late effects such as cancer and hereditary effects begin to occur.[145] The possibility of exposure of a large number of people to radiation following a nuclear incident has raised the public's concerns about the increase in the chances of developing radiation-induced cancers.[146] However, public perception and "fear of radiation" appear to be well beyond the actual risk. This fear was elevated as a consequence of the Fukushima disaster, despite the lack of evidence for acute radiologic injury in the general population.[147] Quantifying the risk associated with low-level radiation exposures is problematic and uncertain because of the unresolved shape of the dose–response curve for radiation-induced cancer in the low-dose region.[148] For the purposes of radiation protection, it is assumed that there is a linear relationship between exposure and future cancer risk. A linear no-threshold (LNT) model is used to assess risk at doses below 100 mSv, recognizing that epidemiologic information in this dose region cannot unambiguously support or refute the model assumptions.[149] However, recent data from the Radiation Effects Research Foundation (RERF, Japan) seem to be more in line with a linear relationship between radiation dose

and cancer risk.[150] Evidence is also now emerging on the possibility of additional late developing effects on health following somewhat higher doses, such as cardiovascular[151] and respiratory disease,[152] premature senescence,[153] and damage to endothelial cells.[154]

A multidimensional approach is necessary to address the complexity of the radiobiologic issues facing society. Various agencies of the U.S. government have been conducting studies on radiation-induced normal tissue injury and developing medical countermeasures (MCMs) to mitigate a multitude of risks to individuals or populations associated with radiation exposures, addressing different dose ranges relevant to an agency's mission. Successful development of risk mitigation strategies requires a multidimensional approach with mechanistic scientific underpinnings to address the complex biologic variables. A summary of ongoing research efforts among various government agencies related to radiation-induced normal tissue injury is summarized in Figure 5.2.

The Department of Energy (DoE) under the Biological Systems Sciences Division studies radiation-related health risks from exposures to low levels of radiation. Exposures to low doses can occur in a number of scenarios including (a) around nuclear power plants, (b) during isolation of materials for nuclear weapons and nuclear power production and waste cleanup, (c) medical diagnostic exposures, (d) radiation terrorism incidents, etc. The DoE's low-dose program (now closed) focused on cellular and molecular responses to doses relevant to workplace exposure limits, radioadaptive responses, genetics of interindividual variation, low-dose and dose-rate effects, effects on immune system, and epigenetic regulations.

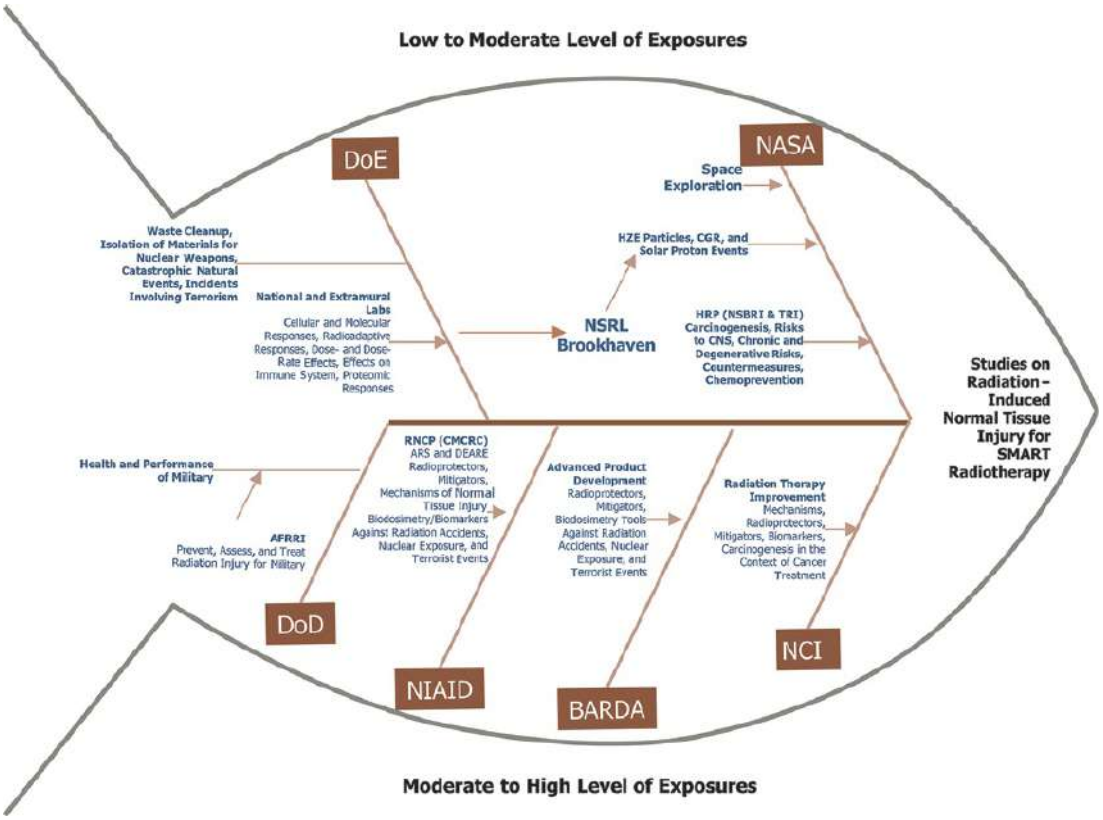

FIGURE 5.2. U.S. government research efforts among various government agencies related to radiation-induced normal tissue injury. AFRRI, Armed Forces Radiobiology Research Institute; ARS, acute radiation syndrome; BARDA, Biomedical Advanced Research and Development Authority; CMCRC, Center for Medical Countermeasures against Radiation Consortium; CNS, central nervous system; DEARE, Delayed Effects of Acute Radiation Exposure; DoD, Department of Defense; DoE, Department of Energy; GCR, galactic cosmic rays; HRP, Human Research Program; HZE, High (H) Atomic number (Z) and Energy (E); NASA, National Aeronautics and Space Administration; NCI, National Cancer Institute; NIAID, National Institute of Allergy and Infectious Diseases; NSBRI, National Space Biomedical Research Institute; NSRL, National Space Radiation Laboratory; RNCP, Radiation and Nuclear Countermeasures Program; SMART, **S**ocietal focused, **M**olecularly aware, **A**ltruistic, **R**esearch supportive, and wary of **T**echnological solutions to biologic problems; TRI, Translational Research Institute (also known as The Translational Research Institute for Space Health [TRISH]).

NASA's interest in radiation research focuses on space exploration including earth orbits and more recently potential manned missions to Mars and beyond. The duration of Mars mission necessitates understanding immediate health risks in the space radiation environment and long-term postmission quality of life. The Human Research Program (HRP) was developed to refocus the space program in early 2004. NASA identified major risk categories attributable to space radiation including carcinogenesis,[155] risks to central nervous system (CNS),[156] and chronic and degenerative tissue risks.[157] High charge and energy ion components

of galactic cosmic radiation (CGR) can cause genetic mutations,[158] inflammation, and CNS structural damage and dysfunction.[159] The HRP is focused on understanding the possibility of reducing these health risks by developing countermeasures for acute exposures of greater than one Gy associated with large solar particle events, and mitigators for lower-level exposures, particularly iron ions that will be encountered in the Mars mission. NASA's National Space Biomedical Research Institute (NSBRI) conducts integrated biomedical research to support long-term human presence during exploration of space and also on the enhancement of life on earth by applying these advances. The NASA Translational Research Institute was founded in 2016 to work in partnership with the HRP to translate cutting-edge terrestrial research into applications for space flight focusing on human risk mitigation strategies for exploratory missions. Teaming up with Department of Energy's Office of Science, NASA has established National Space Radiation Laboratory (NSRL) at the Brookhaven National Laboratory. NSRL makes use of the Brookhaven ion beam facilities to enhance understanding of the link between radiation and cellular damage and also seeks approaches to limit the damage to the healthy tissues by cosmic radiation in a simulated space radiation environment. NSRL uses beams of heavy ions extracted from Brookhaven's booster accelerator to simulate cosmic rays found in space environment. NSRL has a beam line dedicated to radiobiology research. These studies are also relevant in particle therapy research for cancer treatment.

The Armed Forces Radiobiology Research Institute (AFRRI), within the Department of Defense (DoD), conducts basic and applied research to identify and perform early development of measures to prevent, assess, and treat radiation injury in order to preserve and protect the health and performance of U.S. military personnel. The biodosimetry program has been developing rapid and precise methods to assess the severity of radiation injury as early as possible after the event to guide treatment decisions and also to aid in monitoring recovery from and the effectiveness of treatments for radiation injury.[160] AFRRI continues an intensive program on identification and development of radiation countermeasures to be used by the military and also civilian personnel.

The Department of Health and Human Services (DHHS) has two programs relating to normal tissue injury: (a) Medical Countermeasures Against Radiological and Nuclear Threats at the National Institute of Allergy and Infectious Diseases (NIAID) and (b) the Public Health Emergency Countermeasures Enterprise (PHEMCE), which includes research and advanced

development efforts in MCMs and biodosimetry including the Biomedical Advanced Research and Development Authority (BARDA) that deals with the full range of national security threats.[161] A key underlying principle of the entire radiologic or nuclear medical response program is that it is built on solid scientific underpinnings.[161] Research in normal tissue radiation biology received a substantial boost as the radiation biology community proactively responded to bringing the best science to help address the threat of radiologic and nuclear terrorism that became apparent following the September 11, 2001, terrorist attacks. Scientists from academia and the government conceptualized a research plan that distinguished modifiers of normal tissue injury into three time phases: (a) protectors that are administered before radiation, (b) mitigators that are used following radiation exposure but before the damage has been fully manifest, and (c) treatment that is given for established radiation injury.[162] Some agents may function in more than one role. The radiologic or nuclear incident research plan includes the broad categories of (a) MCMs, which are drugs or biologics developed as radiation mitigators, (b) biomarkers that can quantify an individual's radiation dose as a guide to treatment, and (c) agents that serve to reduce the exposure to internalized radionuclides by blocking uptake or enhancing excretion. The medical consequences of interest are those that result from a total-body exposure (or significant partial-body exposure) of a dose that can produce ARS.[144] A radiologic or nuclear incident will be a "no-notice" event, and for a large-scale nuclear incident, the requirement for an MCM is that it should be effective if started up to 24 hours after radiation.[163,164] A longer window of opportunity would be better given the chaos of the situation and that is part of the MCM development effort. What is not often appreciated is the concept of latency between exposure and clinical manifestation of radiation injury. To that end, there are two terms used to convey the concept: ARS and Delayed Effects of Acute Radiation Exposure (DEARE). The development of next generation of MCMs will exploit the evolving understandings on mechanisms by which radiation induces injury in normal tissue and its manifestation over time, from acute to DEARE to long-term late effects. The challenges to employing radioprotectors to reduce normal tissue injury during the course of radiotherapy are different. Here, a major concern is the protection of the tumor itself, which would result in a compromised therapeutic benefit.

NCI's Radiation Research Program (RRP) has been supporting studies of normal tissue injury in the context of radiation therapy for several decades. In the clinical context, a radioprotective drug might allow dose escalation to the

tumor, leading to a better tumor control or to same local control with less toxicity. Although many novel approaches of dose delivery to the tumor volume significantly reduce collateral normal tissue injury and improve the therapeutic ratio, location of the tumor within an organ of inherent sensitivity to radiation and the dose needed to cure the tumor can still result in normal tissue injury.[162] Many patients still suffer adverse effects from radiotherapy, largely due to the biologic variables influencing treatment outcome.[165,166] With improved survival come increases in treatment-related adverse late effects, such as pulmonary fibrosis,[167] cognitive damage,[168] and secondary cancers, especially among children.[169] Prevention of these late-occurring adverse effects warrants development of countermeasures for enhancing posttreatment health-related quality of life (HRQOL) for cancer survivors.

Synergy among government agencies in supporting drugs to reduce radiation injury ensures our investments are rational, viable, sustainable, and cost-effective. Academic and government research efforts can be leveraged by the NCI Small Business Innovative Research (SBIR) program through the Radiation Research Program (RRP) initiatives to test promising radiologic countermeasures for clinical applicability so that such products gain “dual utility”—use in cancer treatment and also use for accidental or intentional civilian exposure. Development of dual-utility agents will greatly reduce costs and risks of failure while enhancing the value of research.[170] The current RRP-SBIR effort for advanced development of radiation-effect modulators serves as a model to reduce risk for small businesses by providing government support.[171] Repurposed MCMs in the cancer treatment setting may help improve the treatment outcome by specifically protecting normal tissue during the course of treatment, reducing the acute adverse effects or mitigating late effects including therapy-induced secondary cancers thus improving HRQOL of patients. Some examples are discussed below.

Among patients undergoing radiation treatment for head and neck cancers, oral mucositis is a frequent and potentially serious symptomatic toxicity. Currently available treatment options could be augmented by innovative compounds that target underlying biologic pathways associated with mucositis.[172] Colby Pharmaceutical (Menlo Park, CA) via a fast-track contract from the NCI’s SBIR Development Center is formulating MnSOD as a mouthwash to prevent or reduce the severity of mucositis.[170] Similarly, radiation-induced lung damage is an intermediate to late-occurring side effect of radiotherapy in some patients after thoracic irradiation. Fibrogenesis, excessive

extracellular matrix and collagen deposition, and TGF-β are involved in the development and expression of lung and other forms of tissue fibrosis.[167] Humanetics Corp (Minneapolis, MN) is developing BIO300, a patented nanoparticle formulation of genistein as a postirradiation treatment option to prevent radiation-induced pulmonary injury.[170] BIO300 was originally developed as a medical radiation countermeasure with funding from US Department of Defense and BARDA. Radiation exposure is a core component in the treatment of brain tumors; however, many patients experience neurocognitive dysfunction, which is a late-occurring side effect. Chrysalis Biotherapeutics (Galveston, TX; formerly RADIX Therapeutics) proposed to accelerate the development of TP508 (Chrysalin) by repurposing it for mitigating the radiation effects on brain tissue.[170]

A nuclear accident or terrorist incident could potentially expose a large number of people to low to moderate doses of ionizing radiation and increase their lifetime cancer risk. There is an urgent need to develop low or nontoxic mitigators for this purpose. Current status, issues, and challenges regarding development of mitigators against radiation-induced cancers has recently been published.[173] These challenges include the long latency between exposure and cancer manifestation, limitations of animal models, potential side effects of the mitigator itself, potential need for long-term use, the complexity of human trials to demonstrate its effectiveness, and statistical power constraints for measuring health risks (and reduction of health risks after mitigation) following relatively low radiation doses (<0.75 Gy). Nevertheless, progress in the understanding of the molecular mechanisms resulting in radiation injury, along with parallel progress in dose assessment technologies, make this an opportune, if not critical, time to invest in research strategies that result in the development of agents to lower the risk of radiation-induced cancers for populations that survive a significant radiation exposure incident. Such mitigators will also be of immense value to counter late effects including secondary cancers after radiation therapy among cancer survivors.

Products that target the tumor promotion stage of a multistep carcinogenesis model, which involves initiation, promotion, and progression,[174] have largely come from the field of chemoprevention. Modifiers of radiation-induced transformation reported *in vitro* systems include the following classes of compounds: (a) vitamins (or vitamin-like compounds), their precursors (e.g., vitamin A, its precursor carotene and other carotenoids), and derivatives (e.g., retinoids), (b) protease inhibitors (e.g., the soybean-derived protease inhibitor,

Bowman-Birk inhibitor), (c) hormones (e.g., glucocorticoid hormones, testosterone, dihydrotestosterone), (d) modifiers of arachidonic acid metabolism (eicosanoids), (e) inhibitors of protein kinase C, and (f) antioxidants, including numerous products that scavenge free radicals.[173] Many cancer-preventive products recognized by Division of Cancer Prevention (DCP, National Cancer Institute) also may be useful as mitigators of carcinogenesis after exposures to carcinogens implying their potential to intervene in radiation-induced carcinogenesis at the promotion stage as exemplified by a Curcumin study in which dietary administration significantly reduced the incidence of mammary tumors in rats.[175]

However, testing MCM drugs for use after radiation accidents for effectiveness as well as mitigators to counter radiation-induced cancers are challenging. The Food and Drug Administration's Animal Rule provides a regulatory framework for obtaining regulatory approval for MCMs. Neupogen (filgrastim), a granulocyte colony–stimulating factor (G-CSF) and Neulasta has been approved by the FDA to counter radiation-induced neutropenia in the event of a radiation emergency. Regulatory challenges regarding mitigators have been even a greater challenge, given the uncertain relationship between low-dose exposures and late effects, lack of suitable models, and early predictive biomarkers.[173]

Biomarkers

Clinical Application of Circulating Cell-Free DNA and Circulating Tumor Cell DNA to the Assessment of Tumor Response and Evolution Under Treatment

One of the limiting factors slowing the integration of molecular therapies in the context of radiotherapy has been the lack of radiation biomarkers to monitor and predict clinical responses of both tumor and normal tissues. For monitoring tumor responses, the capacity to rapidly analyze cell free and circulating tumor DNA (ctDNA) promises to overcome this limitation. Analysis of free circulating DNA in plasma by droplet digital PCR (ddPCR) can reveal the presence of cancer in as little as 3 days compared to 4 weeks to obtain the results of next generation sequencing (NGS). In ddPCR, the purified plasma DNA is emulsified with oil into thousands of droplets containing at most one target DNA molecule that is PCR amplified and fluorescently labeled and then read in an automated droplet flow cytometer. Each droplet is individually scored based on fluorescent intensity for the mutant or wild-type allele of a target locus.[176] The high

sensitivity and specificity of this technology has been demonstrated in a prospective study of non–small cell cancer.[177] The limitations of this test are that it is useful only when the tumor sheds DNA into the bloodstream, it detects only known genotypes, and it cannot detect rearrangements and is difficult to multiplex.

NGS can detect a broad range of targetable genomic alterations with 100% specificity. The sensitivity of this technique is equivalent to that of ddPCR.[178] When assessing for the presence of a driver or resistance-associated mutation, this technique applied to circulating DNA could avoid biopsy when results are positive, but sensitivity limitations mean that it cannot rule out mutation with a negative result. Circulating tumor DNA (ctDNA) analysis can also be used to monitor the evolution of a tumor under treatment. Novel methods are being developed to use circulating tumor DNA analysis as a longitudinal diagnostic tool for patients with localized and metastatic cancers.[179–181] The mutation levels in patient plasma samples reflect the clonal hierarchy inferred from sequencing of tumor biopsies. Serial changes in circulating levels of subclone-specific mutations correlate with different treatment responses between metastatic sites. Comparison of biopsy and plasma samples in individual patients with metastatic breast cancer demonstrates that circulating tumor DNA provides a dynamic sampling of somatic alterations that reflect the size and activity of distinct tumor subclones. Analysis of ctDNA also mirrors the clonal hierarchy determined by multiregional tumor sequencing and tracks the variability of treatment responses by different metastases.

The identification of actionable somatic mutations or alterations that are known to confer resistance to specific therapies and their relative circulating levels in pretreatment plasma samples could inform an individualized choice of targeted treatments and represent a breakthrough for precision radiotherapy and cancer treatment in general.

The NGS-based approach of using Cancer Personalized Profiling by Deep Sequencing (CAPP-Seq) for analysis of ctDNA enhances both the sensitivity and specificity of ctDNA detection and mutation analysis.[182] This method uses labeled DNA oligonucleotides (selector) that target known DNA sequences mutated in the cancer of interest. The selector is applied to tumor or circulating DNA to identify, by hybrid affinity capture, a patient’s cancer-specific genetic aberrations (including driver mutations and rearrangements) and then used to quantitate their presence and change over time in circulating DNA. When combined with integrated digital error suppression (iDES), which eliminates

most technical artifacts observed in cell-free DNA (cfDNA) sequencing data,[183] CAPP-Seq can achieve the same sensitivity as the digital drop PCR (ddPCR) technique. CAPP-Seq can achieve the equivalent or better sensitivity to digital PCR techniques (down to 4 in 10^5 cfDNA molecules) but can test a much wider number of sites on the genome.

These new minimally invasive genomic analysis techniques can monitor response and minimal residual disease and give advanced warning of recurrence allowing for early changes in therapy. They may in the future be adapted to early detection, allowing for early-stage radiotherapy treatment of currently intractable diseases such as pancreatic and CNS malignancies. An example of this is the demonstration of the sensitivity of ctDNA in cases of new melanoma brain metastases.[184]

Biomarkers to Predict Normal Tissue Responses

The application of predictive biomarkers of radiation injury is another rapidly evolving area of research, with potential to integrate with SMART radiotherapy by (a) predicting individual differences in radiation sensitivity,[185] (b) predicting severity of normal tissue injury among patients,[186] and (c) assessing and monitoring tumor response to radiation therapy.[187] A biomarker-based test that can predict the risks of developing severe radiotherapy-related complications not only will allow the delivery of alternative treatment modalities and the use of mitigators and protectors but also may allow dose escalation to the tumor in less sensitive patients. This might improve the overall therapeutic benefit and improve outcomes among all cohorts of patients. A variety of radiation biomarkers have already been explored or are currently under development at different technology readiness levels in the context of their potential application for individual dose assessment in accidental exposures to radiation or malevolent use of radiation.[188] However, discovery, development, and validation of predictive biomarkers of radiation hypersensitivity are as challenging, if not more challenging, than radiation-effect modulators. This is due to the low prevalence of normal tissue complications in the clinic, a need for long-term studies for predicting late effects (e.g., radiation-induced cognitive damage),[168] and complexity related to the combination of chemotherapy with radiation as standard of care for most tumors.

Mitigating the risk of radiation-induced cancers will require the use of three categories of biomarkers: (a) radiation dose assessment biomarkers (biodosimeters), (b) genomic health predictors, and (c) cancer surveillance

biomarkers.[173] Diagnostic biomarkers for determining radiation dose of individuals following accidental exposures or therapeutic exposures may also be useful in assigning risk to the exposed population for developing delayed health risks including cancer. This would help identify "at-risk" individuals who may benefit from mitigators of late and/or enhanced cancer screening. In this context, well-established/validated cytogenetic assays, such as cytokinesis-block micronucleus assay[189] performed using peripheral blood lymphocytes for assessing "total genomic health risk,"[190] will be useful. There is also a need for using an enhanced cancer surveillance program for selected high-risk radiation-exposed cohort, especially following a radiologic mass casualty. The Early Detection Research Network of Division of Cancer Prevention at NCI, a consortium of laboratories, is focused on identifying, testing, and validating methods to noninvasively and accurately detect cancers at their earliest stages. Biomarker-based treatment decisions may eventually drive personalized medicine. Issues related to designing clinical trials with biomarkers have been discussed elsewhere.[191]

Several biomarker technologies are currently under development across government agencies, which have been reviewed.[188] The biomarker development and MCM development efforts complement one another. Commercial development and use of radiation risk mitigators will benefit from predictive biomarkers for radiation dose and genomic health concurrently, and these would help in the understanding of the impact of nutrition, repurposed drugs, or other interventions.

In summary, Figure 5.2 provides a glimpse of ongoing multidimensional efforts in radiobiology related to radiation-induced normal tissue injury at various government agencies. These efforts over the past decades has significantly advanced our understanding of mechanisms of radiation injury to normal tissue and its manifestation in different cell renewal and organ systems, allowing discovery and development of next-generation radiation countermeasures and biomarkers with foundational mechanistic radiobiology, which could be used to enhance SMART radiotherapy.

ACCESS TO CARE FOR ALL, INCLUDING THE UNDERSERVED FOR WHOM RADIATION ONCOLOGISTS (OFTEN CALLED CLINICAL ONCOLOGISTS) ARE THE PRIMARY ONCOLOGY CARE PROVIDER

At the time of writing this chapter, there is a major debate as to the future of health care in the United States. The Affordable Care Act (ACA) versus the American Health Care Act (AHCA) (so-called Obamacare vs. Trumpcare) issue is not likely to be resolved by the completion date of this chapter. Even more relevant is that entering this debate with the hope of a logical, scientific, and data-based outcome would not be SMART. As controversial as health care access and equity are for resource-rich countries, it is many times more dismal and complex for underserved people globally. This issue is covered in detail elsewhere in this book in the chapter "Radiation Oncology in the Developing World" by Timothy Hanna and Norman Coleman.

RESPONSIBLE IMPLEMENTATION OF TECHNOLOGY SO THAT WE CONTROL OUR DESTINY BASED ON DATA, … PARTICLES AS A SOCIETAL ISSUE AND SCIENCE

SMART Particles

Particle therapy is in many ways a paradox in terms of SMART. It is both very SMART, and it is not SMART at all. It has the most complex infrastructure of the external beam modalities in terms of physics support and costs. As such, it is relatively uncommon in most countries and is often considered the most specialized form of radiation. It has been touted as having fewer side effects and is often considered the first choice when treating pediatric tumors.[192] It also may be the most problematic on multiple levels. It is, in some sectors, the most promoted form of radiation therapy, and yet it is the most immature form of radiotherapy.[193]

Particle therapy can be divided into two major categories: protons and the so-called heavy ions, which include, typically, helium, carbon, and oxygen among others (although these are often termed "light ions" in the physics literature because of their position on the periodic table). Unlike photons that are generated from electrons hitting a target or from radioactive decay from isotopes such as cobalt-60, particles must be accelerated to near the range of the speed of light to do their work. To achieve this, large machines employing large magnetic fields are used to accelerate particles. Typical devices to do this include cyclotrons, synchrotrons, and other devices—areas of discussion in other chapters so we are only mentioning them here. This section applies to both of these subgroups unless otherwise stated explicitly.

To explore the concept of SMART particles, a number of interrelated domains

that will likely change simultaneously will be presented in this section. Although not exhaustive of all the possible changes to this type of radiation therapy, they are meant to be broadly reflective of the overall trends to be seen in particle therapy. What they have in common is that they are likely to reflect decreasing cost of the devices and a crucial, newfound willingness to treat particles as imperfect and in need of rigorous study. These changes are all based on financial change and increasing translational knowledge.

Hopefully, the field will conduct and complete prospective randomized trials to better define and develop where particle therapy has clear advantages and where is not only “less good” but perhaps “uniquely bad.” This is something we have needed in the field for a long time—with published articles at one point actually debating if trials were needed, in this case to evaluate protons, because of the fact that protons superiority was supposedly obvious and not up for debate.[194] Many things have conspired to make that supposedly obvious truth less obvious in the current space of using physical dose to prescribe dose in the case of proton therapy. We really don’t know if they have unique problems long term based on their biology to normal tissue.[195] We do think they are likely better if used carefully by those with experience, but with RBEs of higher than 1.1, how will doses that are 75 to 100 Gy equivalent affect normal tissues over time[196]? Conversely, if used poorly, they are at best likely to be far worse in that it is far easier to dosimetrically miss a tumor with particles. Plans with photons and standard planning target volumes (PTVs) are generally more robust making widespread use of particles, without widespread expertise in the subtleties of their use, a somewhat risky prospect moving forward for the field unless methods can be developed to make their use more robust and to contain the complexity in manageable planning interfaces.

Trials and the development of new tools are needed to address these issues and will generate a host of data to be incorporated prospectively into the field. Honest evaluation of planning skill and time spent in planning with outcome will need to be performed. The risks particle therapy presents to the field because of biologically incomplete planning will be one of the forces that may drive the inclusion of artificial intelligence into the planning process—as a means of giving patients more expertise wherever they are treated. The very earliest vestiges of this exist in the literature of autocontouring and expert training. In time, proper particle therapy will demand they be used as the number of users increases but patients who benefit remains about the same. Beam selection will need to optimize (a) not only Bragg peak location (b) but also all areas of high

linear energy transfer (LET) dose deposition such as the penumbra of each field, perhaps of each spot, (c) inherent geometric motion statistics for site in three and four dimensions, and (d) specific tissue data based on voxel-by-voxel beam data and situational awareness of other medical issues such as oxygenation of tissue, concurrent agent concentration, and prior tissue injury status.[196,197]

These changes due in the domain of particle therapy are a component of the parallel SMART radiation therapy concept of radiation as drug. It just becomes more unique to each particle because particles are biologically different. Each particle will finally be seen and considered as a different drug. Trials will be designed in this way. What we have done to date—allowing a mixture of photon and proton patients and looking at the results only after the fact—will no longer be a viable trial design. Trials will need to be powered for each "drug" used. What each particle does to DNA and even the normal components of cells like the membranes, organelles, and proteins are vastly different and may yield opportunities for therapeutic index gain. Each particle will be thought of as a new agent rather than just radiation therapy.[198] As such, agent mixes and even new agents designed to work specifically with our newly appreciated war chest of radiation "drugs" will allow further optimization of treatment and perhaps even cost savings. It might turn out that mixtures of particles of different types in specific sequences in time and space will be far superior than any monotherapy of particle or photon in use today.

These new data are likely to shed light on the reality of particle therapy and allow it to reach the level of promise many have envisioned for it from the beginning. To do this, the resulting new set of biologic data will be the basis of a major, global change in radiation oncology driven by particle therapy but affecting all modalities: biologic treatment planning. The software methodologies discussed above will collapse to classical photons as the control state much like classical mechanics is the default state of special relativity when one's velocity is far slower than the speed of light.[199] Plans for patients will move from physical energy dose prescription to this integrative form of a biologic dose prescription and organ at risk (OAR) risk tolerance mapping model. Computer models incorporation libraries of biologic data will be invoked to do this work. Imaging-based biomarkers will be used in real time to monitor biologic response to fit the models to actual host response. This new paradigm could be called adaptive biologic treatment planning.[200] It will be very labor intensive to build the models in ways that allow for real-time adjustment via the incorporation of biomarker data, but once built, what we do now with physical

dose will seem extremely crude in comparison. This is perhaps the most real form of SMART radiation therapy that is to come in the future. It will involve and allow for the use of all sorts of new agents and combinations of agents and the idea that radiation is very much biologically driven by the point in space and time it is being used rather and “a Gy is a Gy” will be the new paradigm.

Inexorably linked in time with more trials being performed will be a combination of decreasing cost of the devices, increasing availability of computing resources that can scale to these issues affordably, increasing numbers of particle treatment machines, more narrowly defined uses for radiation in general based on concurrent research expanding our biologic understanding, and likely decreased reimbursement. This is a metastable situation at best on several levels. The most profound level of which is the reality that everyone who wants one of these centers might not be able to support it with sufficient patient numbers where it is indicated to keep staff expert and bills paid. Financial uncertainty in radiation oncology is increasing, and these centers are likely to be the most uncertain financial component of any given center unless they are run with a “break-even at best” long-term business plan somehow supported by institutional commitment to the science involved despite risk of losses, the rare disease capacity, or development support.[201]

SMART Use of Visible Light and Related Technologies

Photodynamic therapy (PDT), where light is used to interact with chemical agents to deliver energy to tissue is currently in the midst of a large number of prospective trials as sponsored by several program project grants from the NCI and other support mechanisms. Areas of interest involve tumors of many regions, both from a definitive perspective in a postoperative setting and in a preventative setting. Additionally, some studies are evaluating the interplay between the immune system and PDT usage.[202–204] PDT is under intense investigation and its use may become more widespread if these trials define areas of significant therapeutic benefit. This active milieu of trials will be the contemporaneous environment of PDT for the reader of this text during the active period of this edition.

Much of the work described in the last edition[205] has progressed in terms of both molecular mechanistic understanding of how PDT therapy works and of new light plus photo agents that expand the use of the technology spatially.[206] These data will likely both inform the use of rationalized drug combinations with PDT, including checkpoint inhibitors,[203,207,208] and expand the spatial and

temporal use of the methodology to new clinical indications.

Beyond this natural evolution of PDT, there have been exciting, promising developments in the dimension of creating agents that interact with traditional ionizing radiation much like light does in PDT to make the range of action not just millimeters as in the case of light but centimeters.[209,210] This area may allow yet another way to use ionizing radiation with chemotherapy but with the agents being inert until radiated, that is, to be triggered with the radiation therapy like a mousetrap. This will move the scope of radiation therapy into a more diverse set of clinical situations as it opens up the ability to spatially constrain side effects further. Obviously, care will be needed to optimize this approach given the fact that radiation entry and exit doses may limit the ability to prevent damage to normal tissue in, at a minimum, entry dose regions. One could envision a mixture of old and new radiation modalities being used to harness these new agents' potentials.

The implications here are broad for radiation therapy departments globally. Orthovoltage optimization may become useful in this context again as could the use of heavy ions at low dose. If the agents can be designed to require a dosimetric threshold for action of say 0.25 Gy, one can imagine simple plans being very much able to address this with three-dimensional conformal radiotherapy at relative low doses, opening up the possibility of being able to avoid treating to normal tissue tolerance in the future routinely. This would better enable retreatment and would likely lower costs to society overall. Given radiation's unique capacity to be spatially delivered, this approach has promise. The biodistribution of these agents, like any chemical, will impact the success of these methods radically.

Combinatory Therapies

Systemic administration of therapeutic agents (TA) for cancer treatment is a common practice. However, their presence in normal tissue is generally not favorable as it could lead to adverse toxicities. The undue toxicity might be avoided if the TA remained encapsulated or inactive until exposed to an extremal stimulus within well-defiled volume. In addition, the time of activation could be adjusted so that concentration of the TA in the target volume reaches levels necessary for an effective treatment. The key criteria toward achieving effective and safe treatment include minimal invasiveness of the external stimuli and quantitative control of localized TA release or activation. Remote triggering mechanisms may include photodynamic, photothermal, photo-triggered

chemotherapeutic release, ultrasound, electrothermal, magnetothermal, x-ray, particle beam, and radiofrequency. Examples of three combinatory strategies using nanoparticles are presented in Figure 5.3.

Use of radiation or ultrasound to activate or release TA has been an active research front in many academic centers with fruitful results. Thermal release of drugs from liposomes has been in clinical practice for years. An example is ThermoDox (Cesion Corporation; http://celsion.com/thermodox/), which uses LTSL (lysolipid thermally sensitive liposome) technology to encapsulate doxorubicin, a proven and commonly used cancer drug. The heat-sensitive liposome rapidly changes structure when heated to 40°C to 45°C, creating openings in the liposome that release doxorubicin directly into and around the targeted tumor. Other "smart" systems that might release drugs or induce a toxic effect in response to an externally controlled stimulus promise unique clinical benefits over conventional systems that release their cargo passively or are activated internally. In combination with RT, x-rays might be used to stimulate local release of encapsulated drugs in tumor volume or the combination of x-rays with nanoscintilators producing light used in PDT would allow its extension to deep-seated tumors.

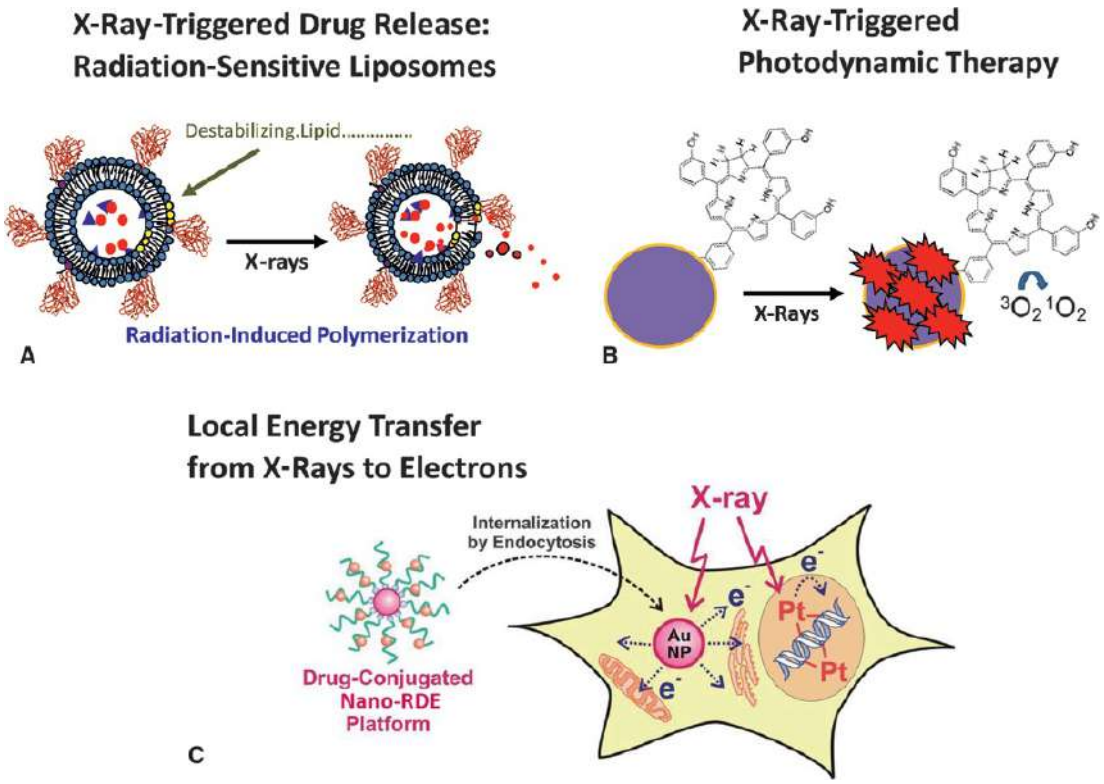

FIGURE 5.3. Examples of three combinatory strategies using nanoparticles. The top two panels utilize radiation to trigger liposomes and PDT. The lower panel uses

nanoparticles to internalize drugs/molecules that enhance effects of x-rays. Nano-RDE, nano-encased radiation dose.

Nanotechnology

Multifunctional nanoparticles allow simultaneous targeted delivery of diagnostic and TA to the tumor tissue giving rise to a new, fast-growing field of theragnostics that combines the modalities of diagnosis and therapy.[211]

Gold Nanoparticles

Over the last two decades, radiation dose enhancement by high atomic number elements such as iodine has been explored for cancer radiotherapy.[212] As a small molecule radiation dose enhancer (smRDE), iododeoxyuridine (IUdR) has been used because of its facile incorporation into cellular DNA.[212,213] The subsequent external irradiation of high-energy photons on the IUdR-containing target cells can trigger the secondary emission of photoelectric radiation (i.e., Auger/secondary electron emission or x-ray fluorescence).[214] The resulting triggered emission from smRDE can cleave the nuclear DNA double strands that can induce the radiosensitized cell death.[215] In this smRDE-mediated radiotherapy, several advantages have been demonstrated. The triggered emission from smRDEs generally decays in several millimeters, which is a typical length scale of a cell so that the resulting cytotoxicity is highly dependent on the cellular location of smRDEs. Therefore, only the smRDEs located inside the target cells can deliver high toxicity upon radiation, but their off-target toxicity can be reduced by virtue of their being outside of the cells.[216]

Although such smRDEs can improve the radiotherapeutic efficacy with reduced side effects, safe and effective delivery of smRDE to target tissue remains one of the major drawbacks to clinical applications.[216] As iodine-attached tumor-targeting antibodies were used to improve their biodistribution, their targeting and therapeutic efficacies were not satisfied because of the rapid dehalogenation mechanism in DNA as well as the heterogeneity and limited expression of target receptors on cancer cells.[217] Furthermore, the prolonged treatments with high dosages of iodine compounds should be avoided because of their toxic side effects to the host organs.

These limitations might be circumvented by development of a nano-encased RDE (nano-RDE) platform, based on functionalizable polymer-modified nanoparticles. Nano-RDE platforms can demonstrate several advantages: First, the biodistribution of nano-RDE can be highly improved by the “enhanced permeation and retention” effect in solid tumor tissue that allows for the

selective accumulation of nano-RDE at diseased sites (passive targeting).[218,219] Second, high amount of nano-RDE can be readily internalized in target cells by endocytic pathways, which are known as a completely different cellular internalization mechanism from that of small molecules.[220] In addition, the subsequent acidic endosomal environments can be used as a trigger for the pH-sensitive release of additional chemotherapeutic agents.[221]

In conventional chemotherapy, the rapid developments of multidrug-resistant characteristics in cancer cells cause a critical problem in clinical cancer treatments.[222] As such, it is obvious that a combinational therapy is more effective than a single modality treatment. To this end, anticancer drug-conjugated nano-RDE would be "smart-combined modality therapy" as a multimodal delivery platform for *both* radio- and chemotherapy.

Gold nanoparticles have been tested for improvement of both chemotherapy[223] and radiotherapy.[224] The TNF*α*-PEG-colloidal gold nanoparticle, CYT-6091 (CytImmune, Gaithersburg, MD), has been shown to selectively traffic to tumor tissue. This agent was evaluated in a phase I trial and shown to selectively deliver TNF-*α* to tumors with reduced toxicity compared to recombinant human TNF-*α* alone.[225]

In addition to its properties as a nanocarrier, colloidal gold, being a high-Z element, may also increase the radiation dose delivered specifically to the target cells. In this system, gold nanoparticles (AuNPs) are used as inorganic nano-RDEs for radiotherapy as well as a delivery platform for chemotherapeutic agents. Because of the K-edge of gold at 80.7 keV, x-ray radiation with the energy level of Au K-edge can trigger the secondary emission of photoelectric radiation from AuNPs.[226,227] The resulting radiation can induce the degradation of target molecules by ionization and can interact with surrounding water molecules to produce reactive oxygen species that can damage the target molecules.[228] As such, AuNP-sensitized degradations of plasmid DNA[229] and human proteins[230] upon x-ray radiation have been demonstrated in *in vitro* model systems. Additionally, when AuNP-containing tumor cells were irradiated, increased apoptotic cell death was detected because of the continuous stress on cytosolic organelles.[231] Furthermore, enhanced *in vivo* efficacy of AuNPs upon radiotherapy was also observed in human cancer-bearing mouse models.[224] However, these AuNPs have shown very poor pharmacokinetic results due in part to their limited surface functionality as a bare colloidal particle.

Recently, AuNPs have been used in a wide range of biologic applications

because of their biocompatibility and well-known surface chemistry. Using the known reactions, AuNPs can be readily modified with thiol-end–capped polymers[232] that can significantly alter the pharmacokinetics.[233,234] This functional polymer can be prepared by reversible addition–fragmentation chain transfer (RAFT) radical polymerization, which allows for copolymerization of a wide range of monomers.[235]

As the gold K-edge is at 80.7 keV and the enhancement is optimal in the photoelectric-dominated x-ray spectrum, irradiation conditions could be optimized by using monoenergetic x-rays. However, a significant enhancement of the treatment efficacy might also be obtained in standard megavoltage x-ray beams.[236] To track biodistribution of gold nanoparticles, these can be easily activated with thermal neutrons prior to administration to emit 411 keV gamma rays, which can be detected by SPECT.

Liposomes

Another alternative approach would be using radiation as a trigger releasing or activating drugs delivered to the tumor prior to irradiation. One option could provide radiosensitive liposomes. Liposomes have been explored as viable carriers for targeting, imaging, and delivery of payload of drugs for decades.[237] To date, various triggering modalities such as local hyperthermia and pH-triggered, tissue-associated enzyme, and light-triggered drug release have been developed.[238] Among these, electromagnetic radiation-triggered release of liposomal drugs appears a promising approach and includes strategically designed phospholipid molecules to initiate a light-induced trigger. These liposomes are based on the principle of photopolymerization of lipids,[239] photosensitization by membrane-anchored hydrophobic probes,[240,241] and/or photoisomerization[242] of photoreactive lipids. However, none of the formulations developed so far have been successful for *in vivo* applications presumably because of the lack of adequate photon energy produced by the radiation source(s) and/or inability of radiation to penetrate into biologic tissues.

Radiation-Activated Photodynamic Therapy

PDT is increasingly being recognized as an attractive and useful tool in the treatment of many diverse human diseases, including macular degeneration, several dermatologic disorders, and oncology.[243] PDT utilizes photosensitizers that can be preferentially localized in malignant tissues. The interaction of the photosensitizer and light results in the generation of cytotoxic species, including

singlet oxygen ($^1O_2$), free radicals, and peroxides, that attack key structural entities within the targeted cells. Those very toxic species are characterized by a short lifetime (<0.04 μs) and a short radius of action. Therefore, the damaged area is essentially confined to tissue that both contains the photosensitizer and is exposed to light.

Relative to current treatments, such as surgery, radiation therapy, and chemotherapy, PDT is also comparatively noninvasive, can be more accurately targeted, and is not subject to the total-dose limitations associated with radiotherapy; in addition, the healing process typically results in little or no scarring.[244] Despite these advantages, PDT has not yet gained general clinical acceptance. The photosensitizers that have been approved for routine PDT treatment absorb light in the visible spectral regions below 700 nm, thus preventing access to deeper residing tumors. As a result, even with the advent of more sophisticated light delivery systems, the clinical application of PDT is limited to superficial solid tumors, endoscopically accessible regions, or skin lesions. The development of photosensitizers with absorbance in the near-infrared region, which would help overcome the limitation on the penetration depth, is an active area of research. There is also still need for isomerically pure photosensitizers. Improving the efficiency of singlet oxygen production in the tissue microenvironment would permit reduction of the concentration of the photosensitizer necessary to treat the tumor. Finally, it would be helpful to develop better molecular targeting in order to improve the selectivity of the photosensitizers for the diseased tissue.

The combination of radiotherapy with PDT, exploiting the tissue penetration of ionizing x-ray radiation and the cell-level targeting of PDT, might provide a novel approach to overcome the problems with penetration depth and might help with the delivery and targeting of photosensitizing agents. It has been already observed that under certain conditions, some photosensitizers act as radiosensitizers. The combination of Photofrin, an FDA-approved photosensitizer, with radiation therapy led to significant enhancements in cytotoxic and apoptotic death of cancer cells.[245,246] However, the molecular mechanism for this effect is still unknown.

More recently, there has been interest in developing a nanoparticle-based photosensitizer delivery system for a combination of PDT with radiation therapy. Chen and Zhang[247] proposed using scintillating nanoparticles conjugated to photosensitizers; in response to irradiation with deeply penetrating x-rays, these nanoscintillators would produce light capable of activating the attached

photosensitizers, thereby producing toxic amounts of free radicals in any desired location of the body. These nanoparticles would overcome the limitations imposed on current PDT and expand its application to deeply located tumors. In addition, it might be possible to conjugate molecules for receptor-mediated internalization to the nanoparticles as well, ensuring delivery to the intracellular space; perhaps, delivery could even be targeted to vulnerable subcellular structures.

Several doped nanoparticles ($LaF_3:Ce^{3+}$, $LuF_3:Ce^{3+}$, $CaF_2:Mn^{2+}$, $CaF_2:Eu^{2+}$, $BaFBr:Eu^{2+}$) and semiconductor nanoparticles (ZnO, ZnS, and TiO_2) are potential light sources for use in a nanoparticle-PDT system. The emission spectra of these nanoparticles can be matched perfectly to the absorption spectra of Photofrin, fullerenes, and TiO_2 nanoparticles. For example, $BaFBr:Eu^{2+}:Mn^{2+}$ nanoparticles excited by x-ray have three emission bands, one peaking at approximately 400, 500, and 640 nm, respectively. The emission spectrum of these nanoparticles is well matched to the absorption spectrum of hematoporphyrin. Another example is the x-ray luminescence spectrum of $LaF_3:Ce^{3+}$ nanoparticles with maximum emission at 350 nm, tailing to 500 nm. This emission spectrum matches the absorption spectra of most photosensitizers as well. The rationale for this approach is to combine the effects of PDT and radiation therapy while reducing toxicity.

Boron Neutron Capture Therapy

Another example of combinatory treatment that in theory provides a way to selectively destroy malignant cells and spare normal cells is boron neutron capture therapy (BNCT). It is based on the nuclear capture that occurs when a stable isotope of boron, ^{10}B, is irradiated with low-energy thermal neutrons leading to fission reactions producing high LET alpha particles (^4He) and recoiling lithium-7 (^7Li) nuclei. Because the high LET particles have limited path lengths in tissue (5 to 9 μm), the destructive effects of these high-energy particles is limited to boron-containing cells. When a sufficient amount of ^{10}B accumulates in the tumor and enough thermal neutrons are absorbed by them to sustain lethal damage from the $^{10}B(n, \alpha)^7Li$ capture reaction, tumor cells dispersed in normal tissue can be selectively destroyed.

The development of BNCT began approximately 60 years ago. Since then, many research groups worldwide and 15 different neutron facilities using nuclear research reactors have been involved in development of BNCT. Only two boron delivery agents, the polyhedral boron anion, sodium

mercaptoundecahydro-*closo*-dodecaborate ($Na_2B_{12}H_{11}SH$), known as sodium borocaptate (BSH), and the boron-containing amino acid (L)-4-dihydroxy-borylphenyalanine known as boronophenylalanine (BPA) have been used in humans.[248] Clinical trials of BNCT have been focused primarily on high-grade gliomas[249,250] and head and neck cancers.[251] The lack of success of these trials could be attributed to slow progress in the development of compounds that would deliver adequate amounts of boron specifically to tumor cells and to the use of expensive and often obsolete nuclear reactors at physics laboratories apart from medical centers as the neutron sources. A positive development is the application of accelerator-based neutron sources, such as the one commercially available from Sumitomo Heavy Industries.[252] The new accelerator-based neutron sources will be more compact and their operation will be much less expensive than nuclear reactors. They might be located at a radiation department of any hospital, facilitating interactions with other departments, and particularly radiology that would improve diagnosis and treatment planning.

Development of new boron delivery agents characterized by low systemic toxicity and rapid clearance from blood and normal tissues, combined with high tumor uptake (at least ~20 μg ^{10}B/g tumor) and persistence in tumor during the BNCT procedure, is crucial for the success of future clinical trials. Special attention should be paid to targeting the CSCs known for efficient exocytosis that might be responsible for the failure of the clinical trials using BPA to deliver boron to cancer cells.[253] Promising new boron delivery agents based on peptides, purines, pyrimidines, porphyrin derivatives, thymidines, nucleosides, and nucleotides are being developed. In addition, monoclonal antibodies (MAb), liposomes, and nanoparticles are used to design high molecular weight BNCT agents.[254,255]

Targeted Radionuclide Therapy

Systemic targeted radionuclide therapy (TRT) is an evolving and promising modality of cancer treatment. It provides a unique means to efficiently eradicate disseminated tumors cells and small metastases before they are detectable by currently available methods. In combination with external RT, TRT might be used as a boost to deliver additional radiation dose specifically to the tumor.

The key characteristic of systemic targeted radiotherapy is its specificity. Using tumor-homing characteristics of a radioactive compound or conjugating therapeutic radionuclei with a tumor-targeting molecule (antibody, antibody fragment, or peptide), it can deliver higher amounts of a radionuclide to cancer

cells than to normal tissue. A number of antigens and receptors present on the tumor cell surface including CD20, CD45, PSMA, mucin 1 (MUC1), HER2, EGFR, tumor necrosis factor, as well as VEGF and avb3 abundant on the vascular endothelial cells within newly developed blood vessels have been advocated as potential targets for radioimmunotherapy (RIT) in patients.[256]

The targeting pharmaceuticals are radiolabeled with various radionuclides to deliver radiation directly to the target. In contrast to biologic targeted therapy, TRT does not require detailed knowledge of cancer phenotype signaling pathways. Rather than disrupting cancer-associated signaling, TRT directly kills tumor cells by radiation-induced DNA damage. Although DNA damage-induced tumor cell killing is also the mechanism used by chemotherapy, TRT is far less toxic because the radiation is delivered predominantly to cells that express a TAA. The fundamental and distinguishing aspect of TRT relative to other cancer therapeutics is the ability to select the radionuclide and, in particular, the type of radiation emissions that are delivered. The majority of TRT applications have used beta-particle emitting radionuclides such as ^{131}I, ^{90}Y, and ^{177}Lu. Beta-particle path length in tissue ranges from 0.8 to 5 mm; the energy deposited per distance traveled is approximately 0.2 keV/μm and has been characterized as low LET.

Medullary thyroid cancer treatment with targeted radionuclides illustrates the potential of molecular radiotherapy in a situation where few other treatment options exist. Treatment of indolent non-Hodgkin lymphoma (NHL) provides another example. There are two FDA-approved antibody-based molecular radiotherapeutics, Bexxar and Zevalin, for this disease. Both ^{131}I-tositumomab (Bexxar) and ^{90}Y-ibritumomab tiuxetan (Zevalin) are radiolabeled antibodies; they target different regions (epitopes) on the B-cell–associated CD20 antigen.

A lower molecular weight class of molecular radiotherapeutics, radiolabeled peptides (peptides are typically made up of less than 50 amino acids), has been the focus of European investigators. These peptides can achieve binding affinities in the low nanomolar range and have been found to be nonimmunogenic. One of the first of these, ^{111}In-DTPA-octreotide (Octreoscan) was approved by the FDA in 1994 for imaging/detection of neuroendocrine tumors with somatostatin receptors based on trials conducted exclusively outside the United States (in Europe). Although not as successful as the radiolabeled antibodies against lymphoma, radiopeptides have nevertheless demonstrated efficacy in patients with late-stage, refractory neuroendocrine tumors.[257] Such tumors are substantially more radioresistant than lymphomas. These agents clear

the circulation rapidly, reducing the bone marrow–absorbed dose and allowing greater administered activities and increased tumor-absorbed doses. The amount that can be administered in a single injection has been limited by renal toxicity.[257] Several interventions have been adopted to reduce uptake by the kidneys, the most prevalent one involves infusion of cationic amino acids. Over 400 patients with neuroendocrine tumors have been treated with radiolabeled peptides and overall response rates between 60% and 75% have been reported; only a small percentage of these, however, have been complete responses.[257] As in NHL, new promising peptide-based RPTs continue to be developed and comparative trials will be needed to determine how these will be used with current treatment against neuroendocrine tumors.

Metaiodobenzylguanidine (MIBG) is an aralkylguanidine analog of catecholamine precursors, structurally similar to norepinephrine that concentrates within secretory granules of catecholamine-producing cells. It has been labeled with ^{123}I for diagnostic imaging and with ^{131}I for therapy of neuroblastoma, pheochromocytoma, and, to a lesser extent, other neuroendocrine tumors.[258] Neuroblastoma constitutes approximately 8% to 10% of pediatric cancers at an annual incidence of 8 to 10 cases per million children. Approximately 600 new cases are seen in the United States each year. Once metastasized, the 5-year survival rate is only 30% to 40%. In these trials, ^{131}I-MIBG has demonstrated highly specific uptake and prolonged intracellular retention in tumor and not in normal organs. ^{131}I-MIBG has also been investigated in pheochromocytoma in adults.[259] In neuroblastoma treatment ^{131}I-MIBG has been investigated in progressive or recurrent neuroblastoma after conventional therapy or in combination with myeloablative therapy; it has also been applied prior to surgery in inoperable stage III and IV disease. In a very difficult to successfully treat patient population, a 40% to 60% rate of objective responses has been observed, including some complete responses. These responses are typically observed at doses that lead to high-grade hematologic toxicity.

The application of TRT for the treatment of solid tumors has been less successful than in patients with malignant lymphoma. There are several problems that should be addressed to improve its efficacy.[260] First, the cells in bulky solid tumors are generally less radiosensitive. Secondly, the delivery of therapeutic radionuclide to solid tumors might be less effective because of limited vascularization, elevated intratumoral hydrostatic pressure, and heterogeneous uptake of the radionuclide. Nevertheless, a recently completed

global phase III clinical trial (ALSYMPCA) with radium-223 chloride (Xofigo) in patients with castration-resistant prostate cancer and bone metastases showed that these limitations can be successfully circumvented and nuclear medicine may become an effective treatment modality for disseminated solid tumors as well.[261,262]

The success of ALSYMPCA leads to an increased interest in using alpha-particle–emitting radionuclides for TRT. Aside from the ability to target cells from within, targeted delivery of alpha-emitters provides the additional fundamental advantage of a more potent, cytotoxic type of radiation. Alpha particles are helium nuclei that deposit DNA damaging energy along their track that is 100 to 1,000 times greater than that of beta particles; the damage caused by alpha particles is predominately double-stranded DNA breaks severe enough to make the DNA repair mechanism ineffective. Therefore, a small number of tracks through a cell nucleus can sterilize a cell and alpha-particle radiation is not susceptible to resistance as seen with external radiotherapy (e.g., in hypoxic tissue). Animal and cell culture studies have shown that relative biologic effectiveness (RBE) of alpha particles is in the range of 3 to 7. Although one might expect that this high potency against targeted cells would also be accompanied by high toxicity to normal bystander cells, the short 50 to 100 μm range of alpha particles limits the amount of damage that is incurred by normal tissue.

In addition, the Big Pharma companies that have developed antibodies for targeted cancer therapies are interested in extending their application for delivery of therapeutic loads to the cancer cells. One example is Roche, which has recently introduced to the clinical practice trastuzumab emtansine (trade name Kadcyla), an antibody–drug conjugate consisting of the monoclonal antibody trastuzumab (Herceptin) linked to the cytotoxic agent DM1, and, in collaboration with AREVA Med, is currently developing ^{212}Pb-trastuzumab. The positive results of phase 1 clinical trials of this radioconjugate have been recently reported in the American Journal of Clinical Oncology.[263]

There are two different approaches that have been introduced into clinical practice including the use of direct conjugation of radioisotope tagged to mAb or pretargeting of the tumor. In the first case, the patient receives a diagnostic dose of an antibody labeled with radionuclide compatible with appropriate imaging modality (SPECT or PET). If the conjugate is stable and there is sufficient localization of an antibody at the site of disease, the patient can be injected with a therapeutic dose capable of inducing cytoreductive and potentially curative

effects. This approach, however, has some limitations. First, radiation dose delivered to solid tumors might be insufficient because of poor penetration of the large-size radioimmunoconjugate. Moreover, rather long serum half-life of mAbs together with long decay time of the radioisotope increases the radiation exposure to normal organs and can contribute to bone marrow toxicity.

In a pretargeting approach, the radionuclide is administrated separately from the antibody vehicle. There are two strategies; one involves the administration of radioactive biotin for selective localization on antibody–streptavidin conjugates. This approach takes advantage of the rapid pharmacokinetics of the small biotin molecule and the high affinity of avidin–biotin binding.[264] Alternatively, chelators of radioactive metals and multispecific antibodies that are capable to simultaneously bind to a TAA and a metal chelator could be used.[265]

The advance in imaging and radiation transport will allow new approaches to radionuclide therapy treatment planning. By administration of the dosimetric (trace-labeled) dose and determination of the patient's residence time (a measure of how long the radionuclide is retained in the body), the therapeutic dose can be precisely adjusted to maximize the therapeutic effect and minimize toxicity. The paradigm of a targeted drug with a patient-specific dose may become more routine as targeted therapies are further developed along with better assays to directly measure drug levels. For the present, whole-body dosimetry is routinely applied for RIT but in the near future, the patient-specific maximally tolerated therapeutic radiation dose will be used to maximize efficacy while minimizing organ and bone marrow toxicity.[266] The ability to access the radiation dose delivered to the tumor by TRT will enable its combination with external RT.

TRAINING AND MENTORING TO ENSURE A BROADLY BASED, SOCIETAL CONSCIOUS NEXT GENERATION OF CLINICIANS, SCIENTISTS, AND EDUCATORS

Contemplating the future requires careful scrutiny of the present and how we got here. That things that were "obvious truths"—more dose is better and protons must outperform photons—have had successes but also failures. Changing paradigms requires a willingness to look beyond conventional wisdom and embrace rather than fear change.

A number of prospective, randomized trials during the latter part of the 20 century showed that adding certain drugs to RT prolonged patients' survival (TMZ in GBM, cisplatin in H&N, cisplatin in cervix, cisplatin/etoposide in

NSCLC, cetuximab in H&N, ADT in prostate). For the most part, however, our understanding of why those drugs were successful whereas many others have failed remains poor. This has hampered industry investment. Exploiting for therapeutic gains, our growing knowledge about radiation response and (from initiatives such as TCGA) the vulnerabilities of specific subtypes of cancers is a high priority for the field.

Exploiting physics and engineering technology for escalating radiation dose to tumors for prolonging survival has unfortunately not been very successful so far (GBM, lung, prostate) and in some instances even counterproductive. One exception is tumor-treating fields wherein the application of low-energy electrical fields to the brain in conjunction with radiochemotherapy prolonged the survival of patients with GBM. The mechanism of action however remains poorly understood. Another bright spot is Radium 223 that prolonged the survival of patients with metastatic CRPC.[262,267] That has ignited interest in an area that had been ignored by radiation oncologists, namely, targeted radionuclide therapy (TRT). The knowledge gained from the human genome project, TCGA, etc., has led to the development of numerous molecularly "targeted" agents that can localize to the tumor or its microenvironment. Their ability to eradicate the tumor is limited however by the fact that (a) not all tumor cells may express the target and (b) tumor cells may develop secondary resistance. Adding a radioactive "payload" to such a drug may prevent the cell from developing secondary resistance. Furthermore, using beta particles of the appropriate energy may help kill even neighboring cancer cells that did not express the target.

Physics and engineering developments have had some success in decreasing adverse events (AEs). It must be pointed out however that these relatively expensive technologies (such as protons, SRT, and IMRT) in the United States have often been deployed in situations where no RT (or even no treatment at all) is a viable or even preferred alternative; examples include low-risk prostate cancer and breast cancer ductal carcinoma in situ (DCIS). Decreasing AEs is a laudable objective, but it must always be simultaneously demonstrated that it did not compromise tumor control. In that context, preliminary data showing decreased AEs should be supplemented by robust data showing at least noninferiority with regard to tumor control. Unfortunately, most studies reported to date fall short in that respect. Those concerns include worse tumor control after IMRT in H&N cancer, worse brainstem toxicity after proton RT for postfossa tumors, and worse intracranial tumor control after SRT for brain

metastases.

Drug companies routinely sponsor prospective, randomized trials for demonstrating the superiority of their products, but the device industry in general and the RO industry in particular do so rarely because they are usually not required to by the U.S. FDA. Why the latter has this double standard is beyond the scope of this discussion, but there is no reason why radiation oncologists, just like medical oncologists, should not demand robust evidence before paying millions, sometimes hundreds of millions, of dollars for what the manufacturer is trying to sell.

CONCLUSIONS

That there is so much new material to discuss in this second edition of this chapter is encouraging. There are improvements in the use of the existing technology including amalgamation of imaging and therapy to better hit the desired anatomic targets. Particle therapy is understood to be much more than better dose distribution. Indeed, it is time to begin to think of radiation in terms of the biologic changes it produces and future inverse planning will include biologic events rather than just physical dose. The era of precision medicine has already changed how cancer is diagnosed and classified and elucidated the remarkable heterogeneity in the cancer cells before and during treatment that makes drug targeting ever more challenging and exciting. Perhaps the focal stress response induced by radiation and/or the other new technologies described in this chapter can help homogenize and/or modify the cancer phenotype and make it susceptible to drug treatment or immunotherapy.

The introduction indicated that we would engage the readers in a SMART experiment. We would be interested in knowing how many people read this chapter, if there were any suggestions of what to include and if this would be useful as a journal publication in concert with this book that would ensure both broader and timely dissemination of this information as it is rapidly changing. Please send comments to ccoleman@mail.nih.gov and bernhardej@mail.nih.gov with the subject line SMART Rad (or something close to that).

To be a SMART radiation oncology health care provider requires the interest, ability, and dedication to stay current in one’s own field but also to remain aware of the rapid advances in cancer biology. Advances in imaging, machine learning, and computer-driven planning and treatment delivery may actually free us up to spend more time with patients and in creative activities. Knowing the limit of

one's toolkit provides incentive to reach into new domains and take on new challenges. Radiation oncology lives day-to-day at the interface of cancer biology, innovative technology, imaging, economics, long-term outcomes from many cured patients, societal fears of radiation, and an opportunity to bring care to the millions of underserved people. Be **S**ocietal focused, **M**olecularly aware, **A**ltruistic, **R**esearch supportive, and wary of **T**echnological solutions to biologic problems: Be ***SMART***.

PART B

Medical Radiation Physics

CHAPTER 6

Principles of Radiation Physics and Dosimetry

James A. Purdy and Sasa Mutic

A solid foundation in the principles of radiation physics, dosimetry, and treatment planning is essential for the practice of modern-day radiation oncology. This chapter discusses the basic concepts in radiation physics, radiation therapy treatment machines, and the dosimetry parameters used for photon external beam treatment planning and dose/monitor unit calculations methods. As this textbook is aimed at practicing radiation oncologists and physician residents, these topics are not treated in the detail required for medical physicists. More details on these topics can be found in the medical physics textbooks listed in the references.[1–3]

ATOMIC AND NUCLEAR STRUCTURE

The *atom* may be thought of as consisting of a centrally located core, the *nucleus*, surrounded by small orbiting particles called *electrons*. The overall dimension of an atom is about 10^{-10} m, and the nucleus is about 10^{-14} m. An electron has a rest mass (m_e) of 9.109×10^{-31} kg and has a negative electrical charge equal to 1.602×10^{-19} Coulomb (C). Most of the mass of the atom is contained in the nucleus, making it extremely dense (10^{15} kg/m^3). The nucleus is composed of two kinds of particles—*protons* and *neutrons*, known collectively as *nucleons*. A proton has a rest mass (m_p) of 1.673×10^{-27} kg and has a positive electrical charge equal in magnitude to the charge of the electron (1.602×10^{-19} C). Collectively, the protons constitute the electrical charge of the nucleus. A neutron is slightly more massive than a proton ($m_n = 1.675 \times 10^{-27}$ kg) and has no electrical charge.

Units used to describe atomic processes include the *atomic mass unit* (*amu*) for mass, *nanometer* (*nm*) for distance, *electron volt* (*eV*) for energy, and

electronic charge (*e*) for electrical charge. The amu is defined as 1/12 the mass of the neutral carbon-12 atom. Thus, 1 amu = 1.660×10^{-27} kg. In terms of amu, a proton's rest mass is equal to 1.00727 amu, a neutron's rest mass is equal to 1.00866 amu, and an electron's rest mass is equal to 0.000548 amu. The electron volt (eV) is defined as the kinetic energy acquired by an electron accelerated through a potential difference (voltage) of 1 volt (V). One electron volt is equal to 1.6×10^{-19} joule (J) of energy. One writes 1,000 electron volts (keV) as 10^3 eV, and 1 million electron volts (MeV) as 10^6 eV. The nanometer is defined as equal to 10^{-9} m, and the electronic unit of charge is defined as equal to 1.602×10^{-19} C.

The planetary model of the atom is attributed to Niels Bohr, who in 1913 theorized that the hydrogen atom consisted of an electron orbiting around a nucleus of equal and opposite charge. He extended his theory to multielectron atoms, requiring the electrons surrounding a nucleus to be arranged in distinct, concentric shells or energy levels as shown in Figure 6.1. Energy is released when an electron moves to an orbit closer to the nucleus, and energy is required to move an electron into a higher orbit. Historically, the shells are labeled, from innermost outward, by the letters *K*, *L*, *M*, and so forth. There are a maximum number of electrons that can be accommodated in each shell: 2 in the first shell, 8 in the second, 18 in the third, and so on. The maximum number of electrons allowed in each shell is given by $2n^2$, where n is an integer specific to each shell and is called the *principal quantum number*. Other properties of the electron also have discrete values specified by quantum numbers. These include the electron's angular momentum as it orbits the nucleus, denoted by quantum number l ($l = 0, 1, \ldots, n - 1$); its spin about its axis, denoted by s ($s = \pm 1/2$); and its magnetic moment, denoted by m_l ($m_l = 0, \pm 1, \ldots, \pm l$). Thus, each electron in an atom has an associated set of quantum numbers (n, l, s, m_l). This is the basis of the *Pauli exclusion principle*, which states that no two electrons can have the same set of quantum numbers within a particular atom.

Modern physics has replaced the simplistic orbiting electron model of Bohr with a complex quantum mechanical model of diffuse electron clouds that represent probability functions of the electron's position. However, for an understanding of radiologic physics, the simple Bohr model of a nucleus composed of protons and neutrons and surrounded by orbiting electrons in distinct orbits (energy levels) is sufficient.

The atom of an *element* is specified by its *atomic number*, denoted by the symbol *Z*, and its *mass number*, denoted by the symbol *A*. The atomic number is

equal to the number of protons in the nucleus, and the mass number is equal to the number of nucleons (protons and neutrons) in the nucleus. Hence, *A* minus *Z* is equal to the number of neutrons, denoted by the symbol *N*, within the nucleus. In addition, each element has an associated chemical symbol (e.g., Co for cobalt). When these definitions are used, the standard notation to specify an atom is ${}^{A}_{Z}\mathrm{X}$, as illustrated by ${}^{60}_{70}\mathrm{Co}$, which is a radioactive isotope of the element cobalt that has an atomic number of 27 (i.e., 27 protons) and a mass number of 60 (i.e., 60 nucleons, or 27 protons and 33 neutrons).

Isotopes of an element (e.g., ${}^{58}_{27}\mathrm{Co}$, ${}^{59}_{27}\mathrm{Co}$, and ${}^{60}_{27}\mathrm{Co}$) have the same atomic number but different numbers of neutrons and therefore different mass numbers. Isotopes have the same chemical properties but have different physical properties. Atoms such as ${}^{60}_{27}\mathrm{Co}$ and ${}^{60}_{28}\mathrm{Ni}$, which have the same mass number but different numbers of protons and neutrons, are called *isobars*. Atoms such as ${}^{57}_{27}\mathrm{Co}$ and ${}^{56}_{26}\mathrm{Fe}$, which have the same number of neutrons but different atomic and mass numbers, are called *isotones*.

Every atom has a characteristic atomic mass A_m (sometimes referred to as atomic weight). The *gram-atomic mass* of an isotope is the amount of isotope in grams that is numerically equaled to the isotope's atomic mass. For example, 1 g-atomic mass of carbon-12 is 12 g. One gram-atomic mass contains 6.0228×10^{23} atoms, a constant that is called *Avogadro number* (N_A). Useful parameters that can be calculated using Avogadro number are as follows:

$$\text{Number of atoms/gram} = N_\mathrm{A}/A_\mathrm{m}$$
$$\text{Number of electrons/gram} = (N_\mathrm{A}Z)/A_\mathrm{m}$$
$$\text{Number of grams/atom} = A_\mathrm{m}/N_\mathrm{A}$$

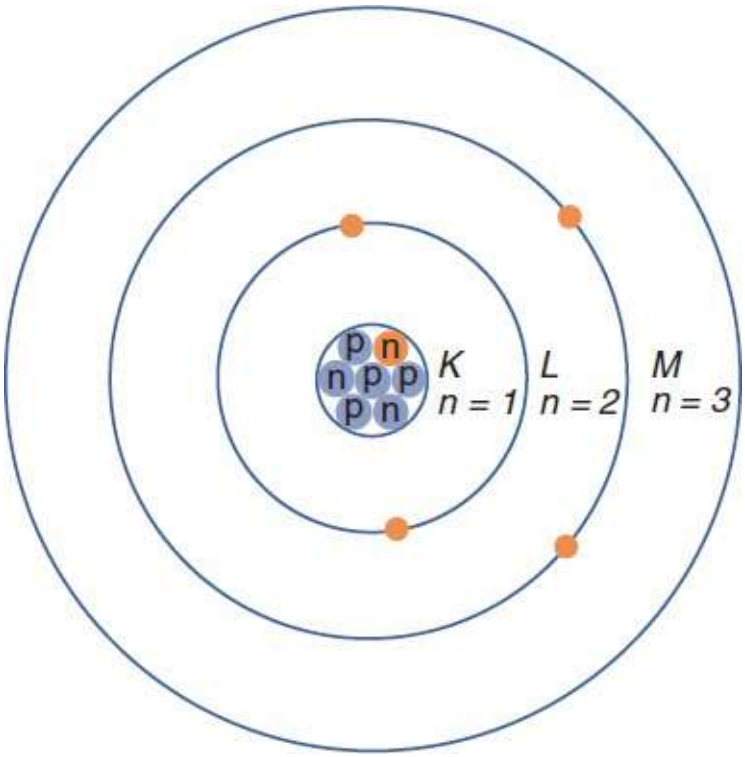

FIGURE 6.1. Schematic drawing of the Bohr model of the atom. The nucleus contains protons (p) and neutrons (n). Electrons revolve around the nucleus in specific orbits having discrete energy levels. By convention, the orbits (energy levels) are assigned either quantum numbers (n = 1, 2, 3, …) or letters (K, L, M,…).

The closer the electrons are to the nucleus, the more tightly bound they are to the nucleus. This results from the attraction between the negatively charged electrons and the positively charged nucleus and is referred to as the *Coulomb* or *electrostatic force*. To move an electron from an inner shell to an outer shell (*excitation*) or to remove it completely from the atom (*ionization*), energy must be supplied. The energy required to remove an electron completely from an atom is called the *binding energy* for the electron. Binding energies are considered negative because energy must be supplied to remove the electron from its orbit. Atomic shells often are described in terms of binding energy, as shown in Figure 6.2 for the tungsten atom. The binding energies for the K, L, and M shells are −69,500, −11,000, and −2,500 eV, respectively. The electrons in the outermost shells are called *valence electrons* and have a binding energy of only a few electron volts because they are very loosely bound. These electrons determine the atom's chemical properties.

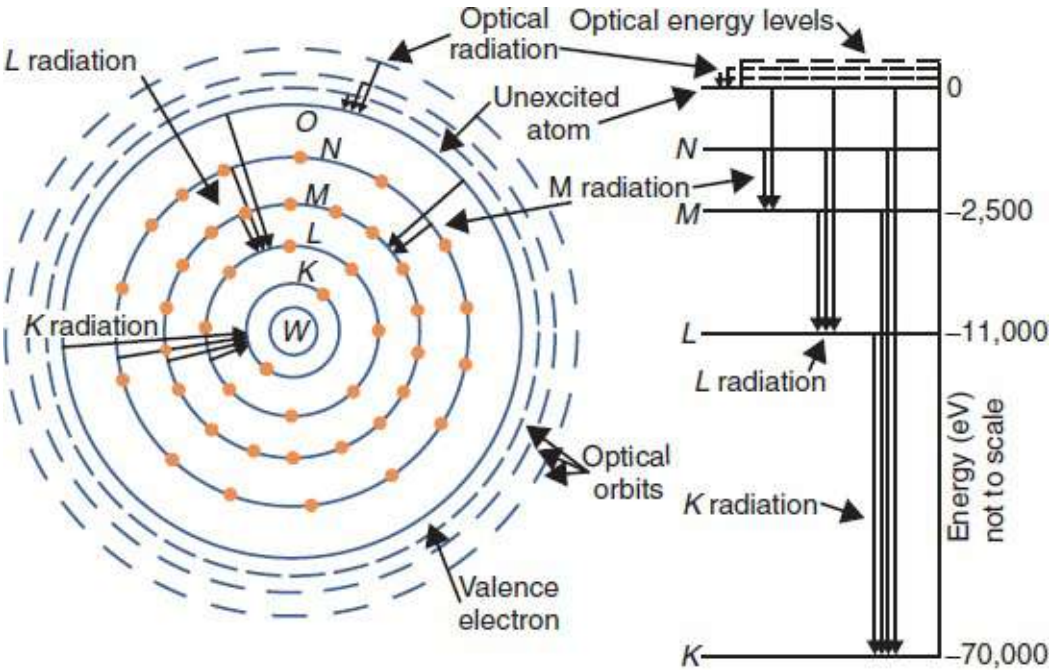

FIGURE 6.2. Schematic drawing of tungsten atom showing electron configuration and energy levels. (From Johns HE, Cunningham JR. *The physics of radiology*. 4th ed. Springfield, IL: Charles C Thomas, 1983:19. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, Illinois.)

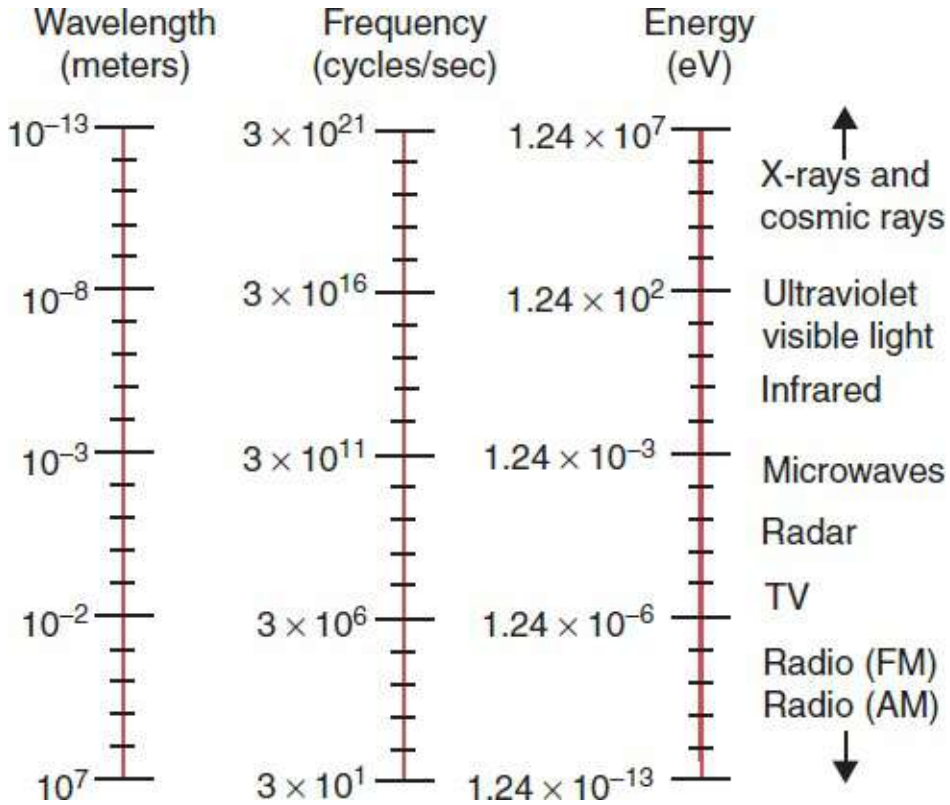

FIGURE 6.3. Electromagnetic spectrum extending over several orders of magnitude, with values of wavelength and frequency, and identifying values in some of the more

common regions of the spectrum.

ELECTROMAGNETIC RADIATION

Electromagnetic radiation can be represented by a varying electric and magnetic field that is conveniently described using a sine-wave model. The sine wave is characterized by two parameters: the *frequency*, represented by the Greek letter *v*, and the *wavelength*, represented by the Greek letter λ. The wavelength is the distance from one crest of the sine wave to another; the frequency is the number of complete cycles or oscillations per second and is measured in *hertz* (Hz). The product of the frequency and wavelength is the speed with which the wave is propagated, which in a vacuum is the speed of light ($c = 3 \times 10^8$ m/s).

Electromagnetic radiation wavelengths extend from approximately 10^7 to 10^{-13} m. The frequencies associated with these radiations are approximately 10^1 to 10^{21} Hz. The electromagnetic spectrum shown in Figure 6.3 includes the radio and television bands; radar and microwaves; the infrared, visible, and ultraviolet regions; and x-rays and cosmic rays.

Quantum physics allows electromagnetic radiation to be represented as waves and also as particles, called *photons*. This is referred to as the *wave–particle duality of nature*. The photon energy is directly proportional to the classic wave frequency and is related to it through a constant of proportionality known as *Planck constant* (*h*), which has a numerical value of 6.625×10^{-34} J-sec. The relationship between energy, *E*, and frequency, *v*, is given by the following equation:

$$E = hv$$

The relationship between photon energy and photon wavelength is given by the following equation:

$$E = hc/\lambda$$

in which *c* is the speed of light in a vacuum. These relationships show that as the wavelength becomes shorter or the frequency becomes larger, the energy of the photon becomes greater.

X-RAYS

Wilhelm Conrad Röentgen discovered *x-rays* on November 8, 1895.[4] He observed that a paper screen coated with fluorescent material glowed when

placed in the vicinity of a tube of gas at low pressure through which electricity was being passed. We now know that the x-rays were produced where the electron beam struck the anode. Energetic electrons that impinge on matter interact with either the orbital electrons or the nuclei of target atoms. The kinetic energy of the electrons then is converted into thermal energy or electromagnetic energy (in the form of x-rays).

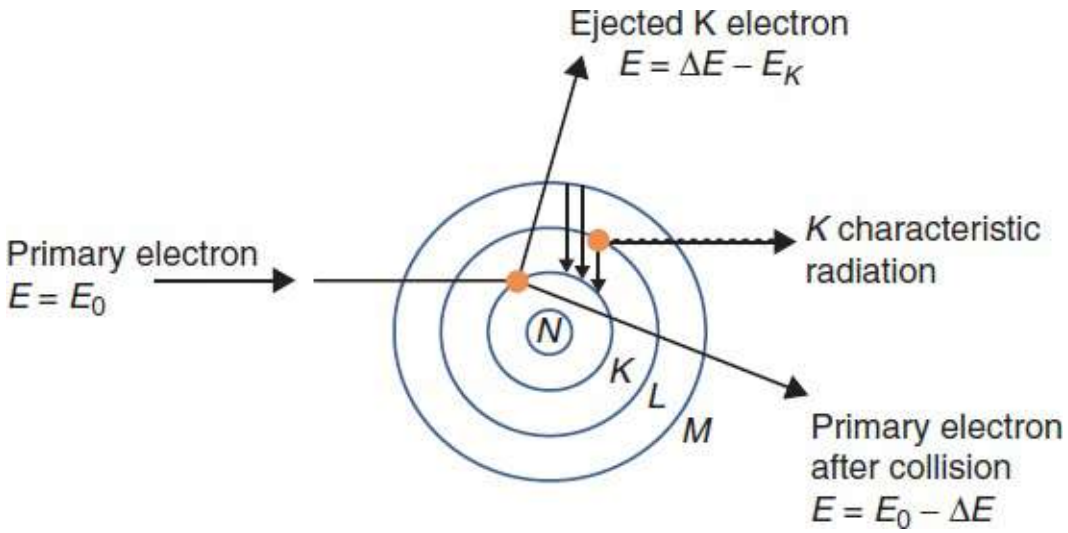

FIGURE 6.4. Schematic diagram illustrating characteristic x-ray production.

The impinging electron's kinetic energy is converted into thermal energy through interaction with an outer-shell electron of a target atom, which raises it to a higher energy level (referred to as *excitation*). The excited electron then returns to the normal energy level with the emission of low-energy electromagnetic radiation (*infrared*).

If the impinging electron's kinetic energy is high enough, the interaction can free an orbital electron (referred to as *ionization*), which then can result in the production of electromagnetic radiation (*characteristic x-rays*) when an outer orbital electron moves to the electron vacancy produced via ionization (Figure 6.4). The characteristic x-ray energy is equal to the difference in the binding energies of the two orbital electrons involved. Occasionally, this excess energy is transferred directly to another orbital electron, causing it to be emitted from the atom. Such electrons are called *Auger electrons*.

The impinging electron also can lose its kinetic energy via a process called *bremsstrahlung* (braking radiation), which occurs when the incident electron interacts with the electric field of the nucleus (rather than the orbiting electrons) and is deflected and loses energy. This loss of energy reappears in the form of an

x-ray photon. The impinging electron can lose any amount of its kinetic energy in the bremsstrahlung process. Thus, the x-radiation produced via the bremsstrahlung process is characterized by having a continuous range of energy values, unlike characteristic x-rays, which have only discrete energy values. A bremsstrahlung spectrum (i.e., a graph of x-ray intensity vs. energy) is shown in Figure 6.5. Superimposed on the continuous bremsstrahlung x-ray spectrum are the characteristic x-rays. The maximum energy of a bremsstrahlung x-ray is numerically equal to the maximum energy of the incident electrons. The direction of emission of the bremsstrahlung x-ray depends on the energy of the incident electron, with higher-energy electrons producing more-forward-directed x-rays.

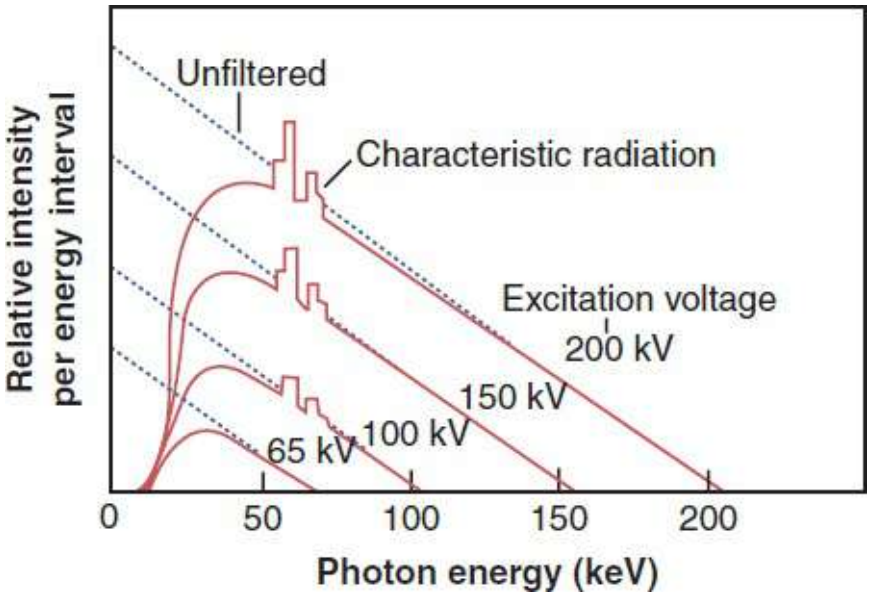

FIGURE 6.5. A bremsstrahlung x-ray spectrum calculated for a thick tungsten target extending from zero to the maximum energy of the electron. The *dotted lines* are for no filtration, and the solid curves are for a filtration of 1-mm aluminum. Note the superimposed characteristic x-ray emission spectrum. (From Johns HE, Cunningham JR. *The physics of radiology*. 4th ed. Springfield, IL: Charles C Thomas, 1983:271. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, Illinois.)

RADIOACTIVITY

In 1896, Henri Becquerel conducted experiments in which he wrapped a photographic plate in black paper to keep out the light and then placed pieces of various elements against the wrapped plate.[5] He discovered that the mineral pitchblende emitted x-rays. Other elements—such as thorium, actinium, and two new elements (polonium and radium) discovered by Pierre and Marie Curie[6]—

also emitted x-rays. Further experiments showed that the radioactive elements emitted three types of radiation: *α-particles*, having a positive electrical charge; *β-particles*, having a negative charge; and high-energy *γ-rays*, having no charge at all. We now know that an *α*-particle is a helium nucleus, *β*-particles are electrons, and *γ*-rays are electromagnetic radiation that is similar to x-rays except that they originate from within the nucleus of the atom.

Many other elementary particles have since been discovered and are important topics of current physics research, but they are not germane to our discussion of radiation oncology physics. Properties of the particles relevant to radiation therapy are listed in Table 6.1.

The radioactive decay processes are related to the forces involved. Huge electrostatic (Coulomb) forces of repulsion exist between the positively charged and closely spaced protons in a nucleus. However, a nuclear force of attraction (called the *strong nuclear force*) exists among the neutrons and protons, binding them together to form the nucleus. The strong nuclear force is much more complicated than the *electrostatic* (*Coulomb*) *force* and is still not completely understood. However, it is known that the strong nuclear force between nucleons depends on the distance between them and is effective only over a very short distance, whereas the electrostatic force decreases with the square of the distance. The strong nuclear force easily overcomes the repelling electrostatic force as long as the protons are very close together. However, for a large nucleus, the strong nuclear force binding the nucleons together may be weaker on opposite sides of the nucleus than the repelling electrostatic force. Therefore, a large nucleus is not as stable as a smaller nucleus.

Because neutrons interact through the attractive strong nuclear force and not the repelling electrostatic force, they can be considered stabilizing particles for the nucleus. For example, in light nuclei, only an equal number of neutrons and protons are required, but in heavier nuclei, the number of neutrons must be about 1.5 times greater than the number of protons to counteract the repelling electrostatic forces of the protons. A nuclide having too many more protons than neutrons is said to have an unfavorable *N*-to-*Z* ratio and thus undergoes *radioactive decay* to reach a stable configuration.

TABLE 6.1 PARTICLES OF INTEREST IN RADIATION THERAPY

Particle	Symbol	Charge	Mass
Photon	hν, γ	0	0

Electron	e, e^-, β^-	−1	0.000549 amu
Positron	e^+, β^+	+1	0.000549 amu
Proton	p, ^1_1H	+1	1.007277 amu
Neutron	n, ^1_0n	0	1.008665 amu
Alpha particle	α, $^4_2He^{++}$	+2	4.002604 amu
Neutrino	ν	0	<1/2,000 m_0
Pi mesons	π^+, π^-	+1, −1	273 m_0
	π°	0	264 m_0
Mu mesons	μ^+, μ^-	+1, −1	207 m_0
K mesons	K^+, K^-	+1, −1	967 m_0
	K^0	0	973 m_0

1 amu = 1.66043×10^{-27} kg. m_0, rest mass of an electron, 9.1091×10^{-31} kg.

The *decay constant* of a radioactive nucleus is defined as the fraction of the total number of atoms that decay per unit of time and is denoted by the symbol λ. The decay process can be represented mathematically. If N_0 radioactive nuclei are initially present in a particular sample, the number of radioactive nuclei, N, remaining at a particular time, t, is given by the following equation:

$$N = N_0 e^{-\lambda t}$$

Activity, which describes the radioactivity of a sample and is denoted by the symbol A, is defined as the total number of disintegrations per unit of time interval and is given by the following relationship:

$$A = \frac{\Delta N}{\Delta t} = -\lambda N$$

This decay-constant equation can be expressed in terms of activity:

$$A = A_0 e^{-\lambda t}$$

where A is the activity at time t and A_0 is the initial activity. The *curie* (Ci), a unit of activity, is equal to 3.7×10^{10} disintegrations per second, the approximate number of decays per second by 1 g of ^{226}Ra. The *becquerel* (Bq), the special name in the International System of Units (SI) for the measure of activity, is equal to one disintegration per second (Table 6.2).

The *half-life* of a radioactive nuclide is the time required for the number of atoms in a particular sample to decrease by one-half. The half-life, $T_{1/2}$, is related

to the decay constant by the following equation:

$$T_{1/2} = \frac{0.693}{\lambda}$$

The *average life*, T_a, of a radioactive nuclide is related to the decay constant and the half-life by the following equation:

$$T_a = \frac{1}{\lambda} = 1.44\, T_{1/2}$$

The average life represents the time period that a hypothetical source would need—if it retained its original activity for that time period and then suddenly decayed to zero activity—to produce the same number of disintegrations as produced over an infinite time period by the source if it decayed exponentially.

Gamma decay occurs when a nucleus undergoes a transition from a higher to a lower energy level. In this process, a high-energy photon, called a *γ-ray*, is emitted. These γ-rays are identical to the x-rays emitted by excited atoms, except that γ-rays originate from within the nucleus and x-rays originate from outside the nucleus. Half-lives for γ decay are usually very short, typically 10^{-15} second.

TABLE 6.2 INTERNATIONAL SYSTEM OF UNITS (SI UNITS) FOR RADIATION THERAPY

Quantity	SI Unit (Special Name)	Non-SI Unit	Conversion Factor
Exposure	C kg^{-1}	roentgen (R)	1 C kg^{-1} ≈ 3,876 R
Absorbed dose, kerma	J kg^{-1} (gray [Gy])	rad	1 Gy = 100 rad
Dose equivalent	J kg^{-1} (sievert [Sv])	rem	1 Sv = 100 rem
Activity	s^{-1} (becquerel [Bq])	curie	1 Bq = 2.7 × 10^{-11} Ci

Closely related to γ decay is the process called *internal conversion*. Instead of emitting a γ-ray, the excess energy from the excited nucleus is transferred to an electron in one of the inner atomic shells, causing ejection of the electron from the atom with emission of characteristic x-rays. The probability of internal conversion occurring increases as the atomic number increases.

In *β decay*, a neutron within the nucleus is converted into a proton, and an electron and an *antineutrino* are emitted, or a proton is converted into a neutron, and a *positron* and a *neutrino* are emitted:

$$\beta^- \text{ decay: } \mathrm{n} \rightarrow \mathrm{p} + \beta^- + \bar{v}$$
$$\beta^+ \text{ decay: } \mathrm{p} \rightarrow \mathrm{n} + \beta^+ + v$$

The positron was discovered in cosmic ray experiments in 1932. It is a positively charged particle with the same mass and spin as the electron and is considered the antiparticle of the electron. The neutrino and its antiparticle, the *antineutrino*, are massless particles (or at least have only a very small mass) having no charge that carry opposite spins and account for the conservation of energy and continuous energy spectrum observed for β decay. Particle–antiparticle pairs interact by annihilating each other, converting all their mass into electromagnetic energy (two γ-ray photons, each of 0.51 MeV). In β decay, the emitted particles may vary in the kinetic energy they possess, which is rarely >3 MeV. Half-lives for β decay are long compared with γ decay half-lives, varying from seconds to years. The forces responsible for the β decay processes are weak compared with both the *strong nuclear force* and the *electrostatic force* among the nucleons. Accordingly, the force responsible for β decay is referred to as the *weak nuclear force*.

Electron capture is an alternative to *positron decay*. In this process, an electron, usually in the *K* shell, is captured within the nucleus and combined with a proton to create a neutron. Electron capture most often is followed by γ decay to release any excess nuclear energy.

Alpha decay occurs in nuclides with atomic number >82 and where the ratio of neutrons to protons is low, thus resulting in the repulsive Coulomb force of the protons overcoming the attractive strong nuclear force. The emitted α-particle is a helium nucleus (two protons and two neutrons). The kinetic energy for a particular α decay is monoenergetic (i.e., the transition may be to an excited energy state with subsequent γ emission) and often 4 to 5 MeV. Half-lives range from 10^{-3} to 10^{10} years. The radioactive decay of radium to radon is an example of α decay, where the *Q* term represents the total energy release in the transition (called *transition energy*). For example,

$$^{226}_{88}\mathrm{Ra} \rightarrow {}^{222}_{86}\mathrm{Rn} + {}^{4}_{2}\alpha + \gamma + Q$$

The most recent version of the periodic table of the elements shows a grouping of 118 elements (elements 117 and 118 have not yet been observed but are included to show their expected positions). Only the first 92 occur naturally; the remaining ones have been produced artificially. In general, the elements with high atomic number tend to be radioactive; in fact, all but one of the elements

with atomic number >82 (lead) are radioactive; only Bi is stable.

The naturally occurring radioactive elements have been grouped into three radioactive series called the *uranium series*, the *actinium series*, and the *thorium series*, all of which terminate with a stable isotope of lead. The uranium series provides an example of radioactive nuclides undergoing successive transformations through α and β decay in which the parent nuclide produces a radioactive product called the *daughter nuclide*.

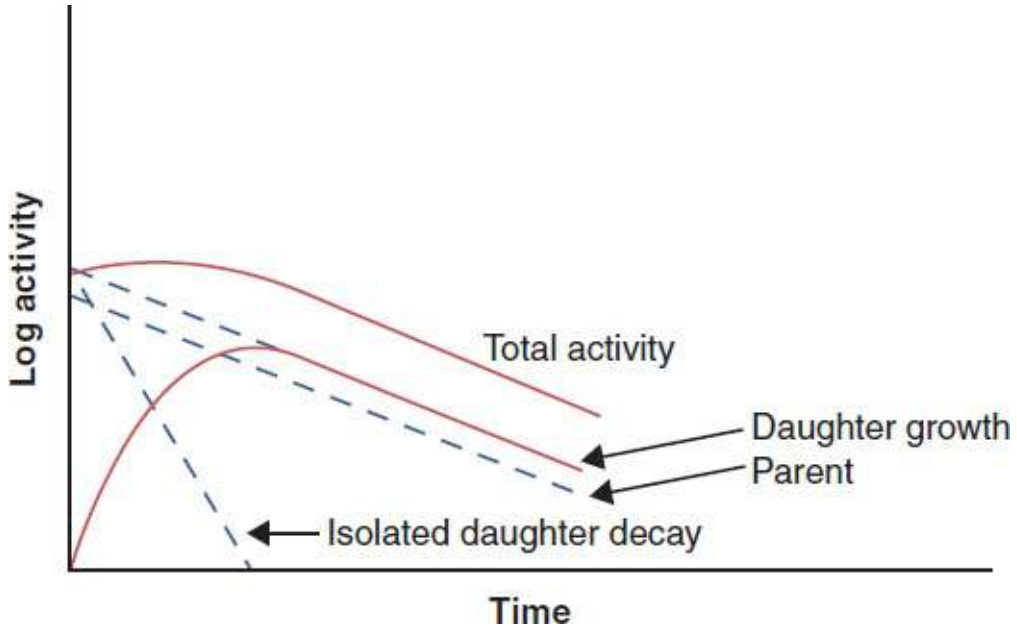

FIGURE 6.6. Transient equilibrium. Shown is a semilog plot of activity versus time for parent and daughter radionuclides illustrating conditions of transient equilibrium that may be achieved when the parent nuclide's half-life is not much greater than the half-life of the daughter nuclide. Once equilibrium is established, the daughter activity exceeds the parent activity, and both decay with the half-life of the parent.

When the half-life of the parent nuclide is longer than the half-life of the daughter nuclide, an equilibrium condition exists. When this occurs, the ratio of the activity of the daughter nuclide to the activity of the parent nuclide becomes constant, and the apparent decay rate of the daughter nuclide is controlled by the parent nuclide's decay rate. Two types of radioactive equilibrium conditions are defined: *transient equilibrium* and *secular equilibrium*. Transient equilibrium is established when the parent nuclide's half-life is not much greater than the daughter nuclide's half-life (Figure 6.6). In secular equilibrium, the half-life of the parent nuclide is much greater than that of the daughter nuclide (Figure 6.7). The two types of equilibrium are described mathematically by the following equations, in which A_P and A_D represent the activity of the parent and daughter

nuclides, respectively:

$$\text{Transient equilibrium: } \frac{A_D}{A_P} = \frac{\lambda_D}{\lambda_D - \lambda_P}$$

$$\text{Secular equilibrium: } A_D = A_P$$

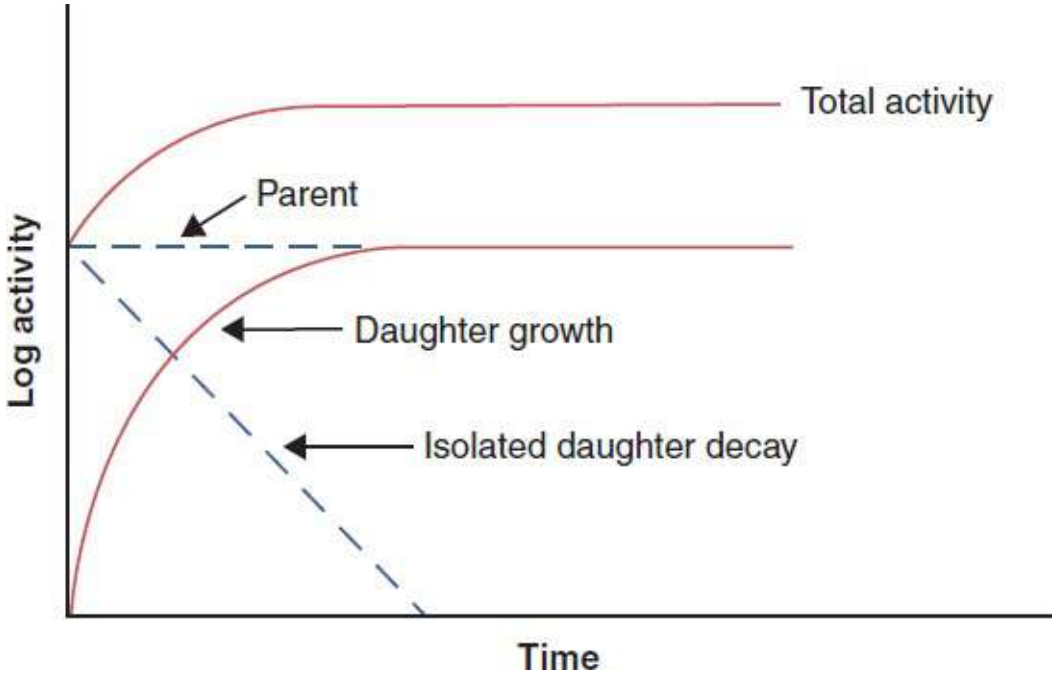

FIGURE 6.7. Secular equilibrium. Shown is a semilog plot of activity versus time for parent and daughter radionuclides illustrating conditions of secular equilibrium that may be achieved when the parent nuclide's half-life is much greater than the half-life of the daughter nuclide. Once secular equilibrium is established, activities of both parent and daughter are equal.

INTERACTION OF PHOTONS WITH MATTER

As stated previously, x-rays and γ-rays may be considered as bundles of energy called *photons*. If an x-ray photon enters a thin layer of matter, it is possible that it will pass through without interaction, or it may interact (usually with the atomic electrons, but sometimes with the atomic nuclei) in one of five different ways (*coherent scattering*, *photoelectric effect*, *Compton scattering*, *pair production*, and *photodisintegration*). The probability that a photon will interact when it traverses through a given thickness of material is the product of the individual interaction probabilities for each of these processes. The attenuation process can be described mathematically by the following equation:

$$N = N_0 e^{-\mu x}$$

where N_0 is the number of photons in the beam impinging on an absorber of thickness x, e is the base of the natural logarithms, and μ is the linear attenuation coefficient. The quantity μ is actually the sum of the individual attenuation coefficients for the five processes. Its numerical value depends on the energy of the photon and the type of attenuating material.

There are a variety of tabulated attenuation coefficients, including the *linear attenuation coefficient* (μ), the *mass attenuation coefficient* (μ/ρ), the *mass energy-transfer coefficient* (μ_t/ρ), and the *mass energy-absorption coefficient* (μ_{en}/ρ). Each type of coefficient is intended for use in the solution of different types of attenuation or energy-absorption problems; division by ρ, the physical density of the medium, makes the coefficient medium independent. Figure 6.8 shows the mass attenuation coefficient for lead and water as a function of incident photon energy. The discontinuities where the attenuation coefficient suddenly increases are called *absorption edges* and occur at photon energies just equal to the binding energy of a specific electron shell.

The thickness of material that reduces the number of photons transmitted to one-half the incident number is termed the *half-value layer* (*HVL*). The HVL is related to the linear attenuation coefficient by the following equation:

$$\text{HVL} = \frac{0.693}{\mu}$$

This parameter is used to describe the *quality* or *penetrability* of the radiation and is discussed later in this chapter.

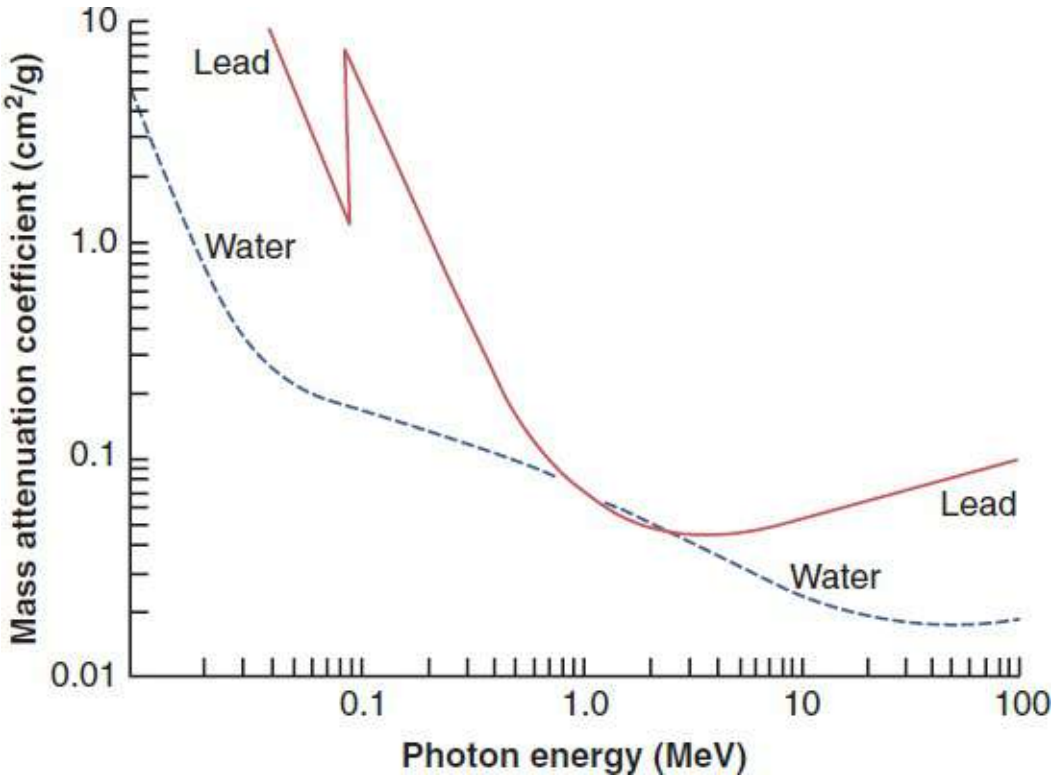

FIGURE 6.8. Mass attenuation coefficient for lead and water. Note sharp discontinuities, which are called *absorption edges*. (From Johns HE, Cunningham JR. *The physics of radiology*. 4th ed. Springfield, IL: Charles C Thomas, 1983:147. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, Illinois.)

Coherent or Classical Scattering

If the photon energy is low enough that the quantum effects of the interaction are unimportant and the bound electron(s) can be regarded as essentially "free," the interaction corresponds to the "classical scattering" situation (called *coherent scattering*), in which the incident electrical field accelerates one or more orbital electrons and causes them to radiate. There are two types of coherent scattering: *Thomson scattering*, in which a single orbital electron is involved, and *Rayleigh scattering*, in which the orbital electrons act as a single group. In coherent scattering, no energy is transferred; only the direction of the incident photon is changed. The coherent mass attenuation coefficient is denoted by σ_{coh}/ρ.

Photoelectric Effect

In the *photoelectric effect*, the total energy of the photon is transferred to an orbital electron, usually close to the nucleus, and the photon disappears. The electron then is ejected from the atom with an energy equal to the energy of the photon minus the binding energy of the electron (Fig. 6.9). The direction in

which the electron is emitted depends on the energy of the incident photon. For the low-energy photons (e.g., 50 keV), the photoelectron is ejected at a large angle with respect to the incoming photon's direction, increasing in the forward direction as the photon's energy increases. After ejection of the electron, the neutral atom becomes a positively charged ion with a vacancy in an inner shell that must be filled. The atom returns to a stable condition by filling the vacancy with a nearby, less tightly bound electron farther out from the nucleus, and characteristic x-rays or an Auger electron is emitted.

The probability that a given photon will interact by means of the photoelectric process (denoted by τ/ρ) is a function of both the photon's energy and the atomic number of the target atom. For the process to occur, the incident photon must have energy greater than the binding energy of the involved orbital electron. In general, the probability per electron that a photon will undergo a photoelectric interaction is inversely proportional to the third power of the photon's energy and directly proportional to the third power of the atomic number of the target atom.

Compton Scattering

In *Compton scattering*, the incident photon interacts with a loosely bound orbital electron in which part of the photon's energy is transferred to the electron as kinetic energy and the remaining energy is carried away by another photon (Fig. 6.10). The binding energy of the electron is insignificant compared with the incident photon's energy and thus can be ignored. The energy of the Compton-scattered photon is equal to the difference between the energy of the incident photon and the energy transferred to the electron. If the incoming photon's energy is low (e.g., 100 keV), very little energy is transferred to the electron. As the photon's energy increases, a greater proportion of the energy is transferred to the electron, so the scattered photon necessarily retains a smaller proportion of the incident energy. The photon may be scattered at any angle with respect to the direction of the incident photon, but the Compton electron is confined to angles between 0 and 90 degrees with respect to the direction of the incident photon. If the incoming photon's energy is low, the distribution of the scattered photons is isotropic (equal in all directions). The scatter angles decrease for photons and electrons as the incident photon's energy increases (e.g., at megavoltage photon energies, both are scattered predominantly in the forward direction).

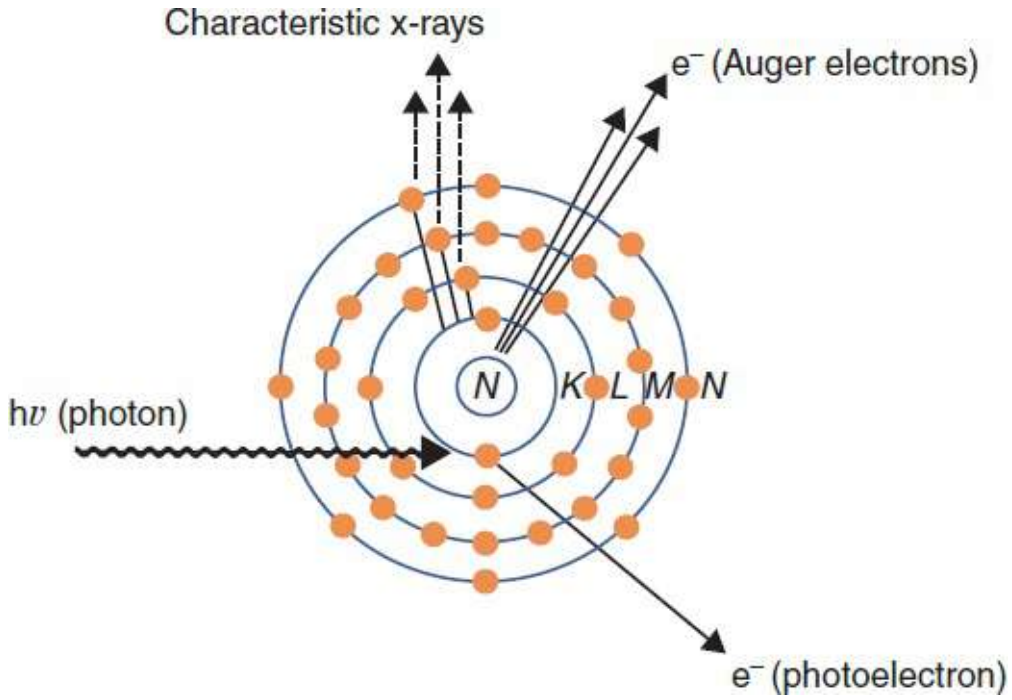

FIGURE 6.9. Photoelectric effect. In this type of photon interaction, the incident photon disappears, and an electron is ejected with kinetic energy equal to the incident photon's energy minus the binding energy of the electron. Characteristic x-rays and Auger electrons are emitted as the atom's electrons cascade to fill the vacancy created by the ejected electron.

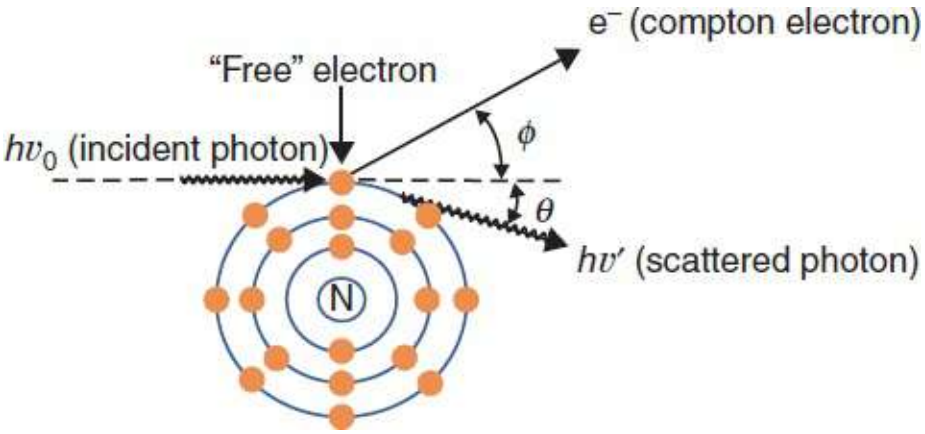

FIGURE 6.10. Compton effect. In this type of photon interaction, the incident photon interacts with one of the atom's outer electrons, and the energy is shared between the ejected electron and a scattered photon.

As a result of conservation of energy and momentum, the energies of the incident photon, $h\nu_0$; the scattered photon, $h\nu'$; and the scattered electron, E, are given by the following relationships:

$$E = h\nu_0 \frac{\alpha(1-\cos\theta)}{1+\alpha(1-\cos\theta)}$$

$$h\nu' = h\nu_0 \frac{1}{1+\alpha(1-\cos\theta)}$$

$$\cot(\varphi) = (1+\alpha)\tan(\theta/2)$$

where $\alpha = h\nu_0/m_0c^2$, and m_0c^2 is the rest energy of the electron (0.511 MeV). If $h\nu_0$ is expressed in MeV, then $\alpha = h\nu_0/0.511$.

The probability that a photon will interact with a target atom via the Compton process (σ_c/ρ) depends on the energy of the incoming photon, generally decreasing as the energy of the photon is increased. The probability of a Compton interaction is nearly independent of the atomic number of the absorber and is directly proportional to the number of electrons per gram.

Pair Production

Pair production (Fig. 6.11) is possible only with photons having energies >1.02 MeV. When such an energetic photon approaches closely enough to the nucleus of the target atom, the incident photon energy may be converted directly into an electron–positron pair. Energy possessed by the photon in excess of 1.02 MeV appears as kinetic energy, which may be distributed in any proportion between the electron and the positron. When the positron comes to rest, it combines with an electron, and both particles then undergo mutual annihilation, with the appearance of two photons with energy of 0.511 MeV traveling in opposite directions. The probability of pair production (π/ρ) occurring increases rapidly with incident photon energy above the 1.02-MeV threshold and is proportional to Z^2 per atom, Z per electron, and approximately Z per gram.

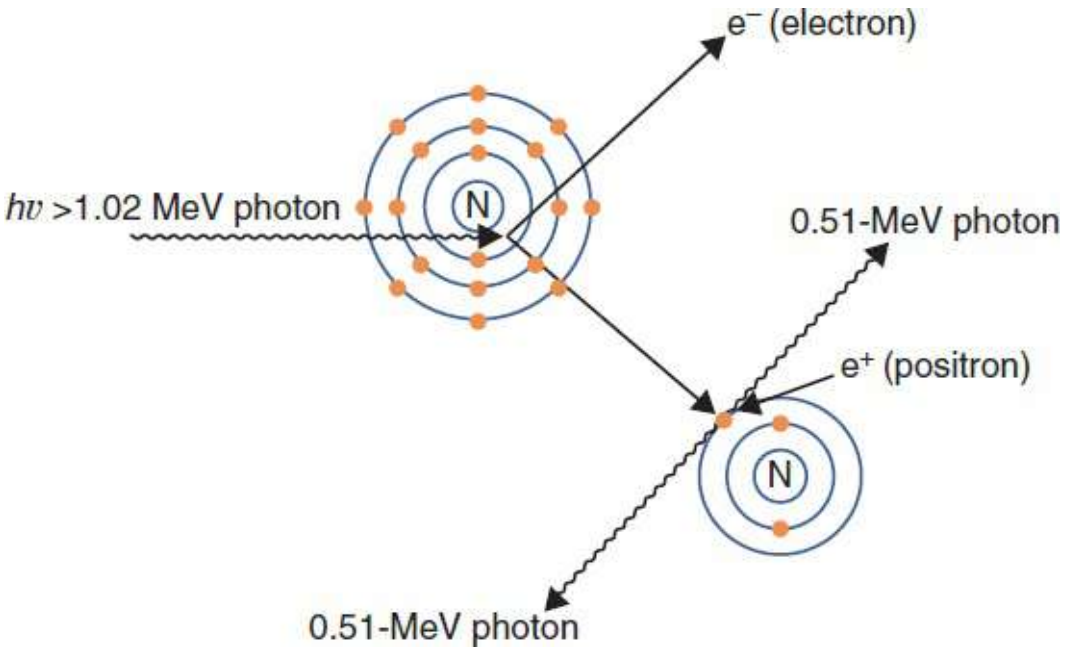

FIGURE 6.11. Pair production. In this type of photon interaction, the incident photon interacts with the electromagnetic field of the nucleus. The incident photon disappears, and two energetic electrons (a positron and a negatron) are produced. Two annihilation photons of energy 0.511 MeV then are produced when the positron interacts with its antiparticle, another electron.

Photodisintegration

In *photodisintegration*, a high-energy photon interacts with the nucleus of an atom, totally disrupting the nucleus, with the emission of one or more nucleons. It typically occurs at photon energies much higher than those encountered in radiation therapy. However, it is important to account for this in designing shielding around high-energy accelerators, as this interaction is a source of low-energy neutrons.

Relative Importance of Interaction Processes

Figure 6.12 illustrates the relative importance of the photoelectric, Compton, and pair-production processes—the three principal modes of interactions pertinent to radiation therapy—as a function of energy and atomic number of the absorber. For example, for an absorber with an atomic number approximately equal to that of tissue ($Z = 7$) and for monoenergetic photons, the photoelectric effect is the dominant interaction below about 30 keV. Above 30 keV, the Compton effect becomes dominant and remains so until approximately 24 MeV, at which point pair production becomes the dominant interaction. The total mass attenuation coefficient accounting for all the photon interactions discussed is given by the sum of the individual coefficients:

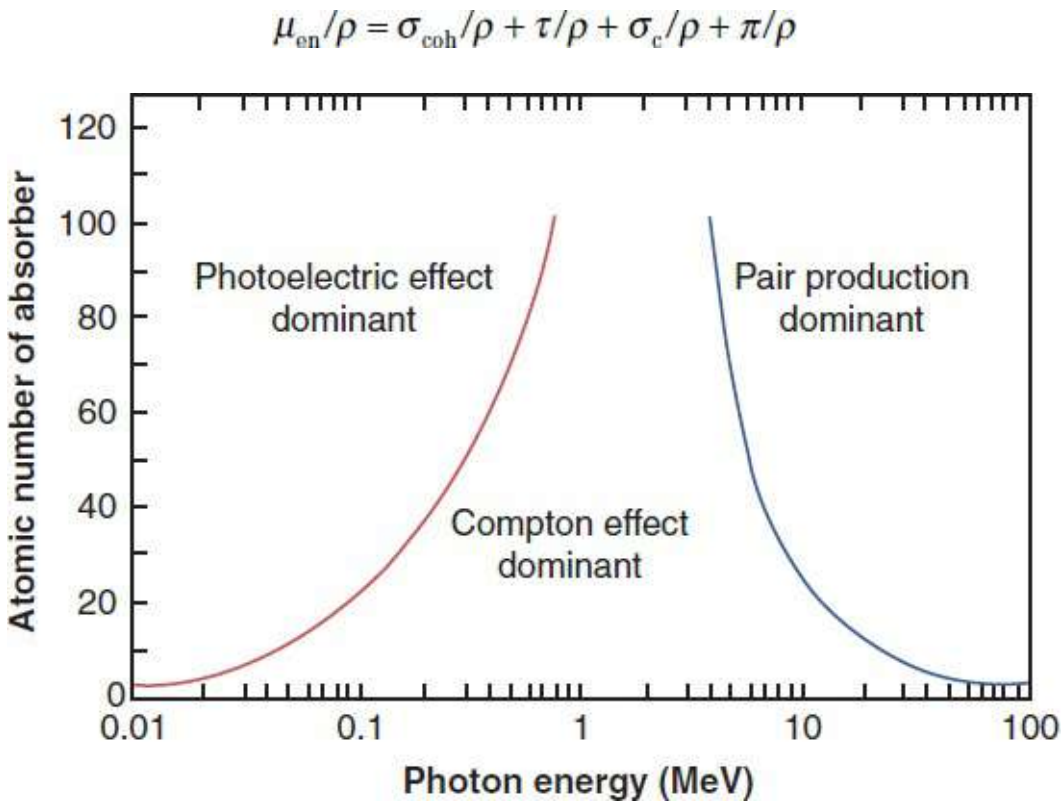

FIGURE 6.12. Relative importance of the three principal modes of interaction as a function of photon energy and atomic number of absorber. (Reprinted from Hendee WR, Ritenour ER. *Medical imaging physics*. 3rd ed. St. Louis: Mosby-Year Book, 1992. Copyright © 1992 Elsevier. With permission.)

INTERACTION OF PARTICLES WITH MATTER

Electrons

An electron loses its kinetic energy when traversing matter via interactions that can be either *elastic*, in which no kinetic energy is lost, or *inelastic*, in which some portion of the kinetic energy is changed into some other form of energy. The term *linear energy transfer (LET)* is used to describe how much energy an ionizing particle transfers to the material traversed per unit distance. Elastic collisions occur with either atomic electrons or with atomic nuclei and are characterized by a change in direction of the incident electron with no loss of kinetic energy. Inelastic collisions can occur with atomic electrons, resulting in *ionizations* and *excitations* of atoms, or inelastic collisions with atomic nuclei, which result in the production of bremsstrahlung x-rays (*radiative losses*). In the case of ionization, it is possible for the ejected electron to acquire enough kinetic energy to cause additional ionizations of its own. These electrons are called *secondary electrons* or *δ rays*, and they can go on to produce additional

ionizations and excitations. The typical energy loss in tissue for a therapeutic electron beam, averaged over its entire range, is about 2 MeV/cm in water.

The complete description of the energy and depth of penetration of the moving electrons at any point in the medium is complicated by the fact that the electrons are very much lighter than the atomic nuclei. As a result, the electron can lose a very large fraction of its energy in a single process and thus can be deflected by very large angles. This means that even if the electron beam is monoenergetic when first impinging on a medium, there will be a large variation among all the moving electrons as to where in the medium each will stop. This is referred to as *range straggling*.

Protons and Heavier Ions

Protons traverse relatively straight paths through matter, slowing down continuously by interactions with atomic electrons and with atomic nuclei. This results in depth–dose characteristics that show an approximately constant absorbed dose value over most of the beam range until near the end of the proton's range, where a very sharp increase in dose occurs (called the *Bragg peak*), as shown in Figure 6.13. Dose at the peak is approximately four times the dose at the surface, and the distal width of the peak is on the order of 1 cm, depending on beam energy and beam energy spread. Depth–dose characteristics customized for individual patients can be generated by superposition of multiple proton beams having different energies. This technique creates a *spread-out Bragg peak (SOBP)* that covers the target volume and decreases sharply to zero dose a few millimeters beyond the target. Protons are somewhat more effective biologically than photons, that is, a lower dose is required to cause the same biological effect. This concept of *relative biological effectiveness (RBE)* of protons is defined as the dose of a reference radiation (typically ^{60}Co) divided by the proton dose to achieve the same biological effect. Paganetti et al.[7] has shown that proton RBE varies (≅10%) along the Bragg peak, particularly at the distal end where LET is high. Current clinical practice and ICRU recommendations[8] advocate that an overall RBE factor of 1.1 be applied.

Heavier ions, such as carbon, are also being used in modern radiation therapy at a few medical heavy-ion facilities in Europe and Asia.[9–11] Because of the greater mass of carbon ions, multiple scattering and range straggling are much less than protons, resulting in a sharper lateral and longitudinal edge. Also, because the LET in the peak of a carbon beam is larger than that of proton beams, the RBE is far greater for carbon ions.

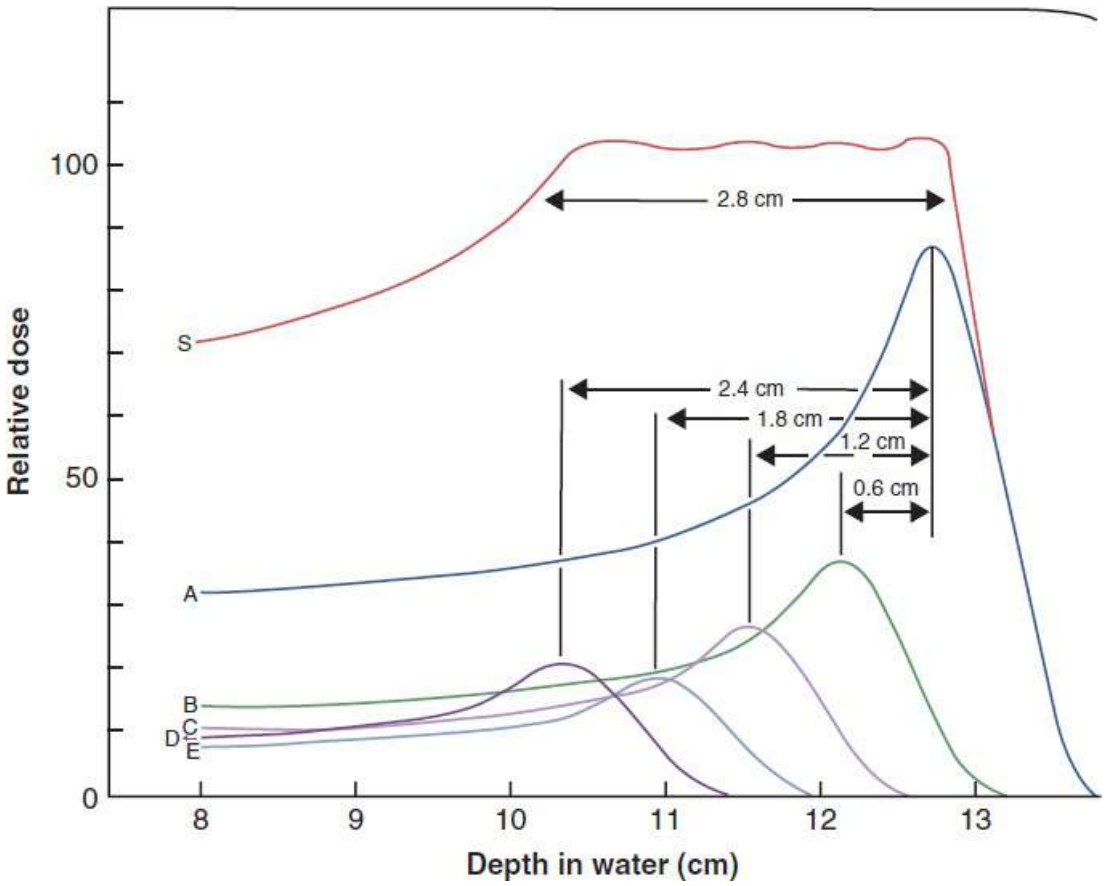

FIGURE 6.13. Drawing illustrating the way in which the Bragg peak for a proton beam can be spread out. Curve A is the depth–dose distribution for the primary beam of 160-MeV protons at the Harvard cyclotron. Beams of lower intensity and shorter range, as illustrated by curves B to E, can be added to give a composite curve, S, which results in a uniform dose of >2.8 cm. Neutrons

Neutrons, like photons, are uncharged and thus are an indirectly ionizing radiation, which are exponentially attenuated by matter. The interactions are through processes that are primarily nuclear. They include elastic scattering with nuclei that make up the body's tissues (hydrogen, oxygen, carbon, nitrogen, etc.). Neutron interactions result in recoil protons and charged nuclear fragments that have relatively low energy. The RBEs of these resultant particles are not fully known, thereby complicating the understanding of the relationship between clinical response and absorbed dose.

RADIATION THERAPY TREATMENT MACHINES

Kilovoltage Units

Before 1951, most radiation treatment units were kilovoltage x-ray machines capable of producing photon beams having only limited penetrability. Today, this type of machine is still used in some clinics for the treatment of skin cancer. In these machines, the electrons are accelerated by an electric field produced from a high voltage generated in a transformer that is applied directly between the filament (cathode) and the x-ray target (anode). A schematic diagram of a radiation therapy x-ray tube is shown in Figure 6.14. The potential difference (kVp) is variable on these machines, and metal filters can be added to absorb the lower-energy photons preferentially, changing the penetrability of the beam. The combination of variable kVp and different filtration provides the capability of generating multiple x-ray beams. The degree of penetrability is used to categorize the units as *contact*, *superficial*, and *orthovoltage* (deep-therapy) x-ray machines. A more detailed review of these type of treatment machine is provided by Biggs et al.[12]

Contact Units

A contact x-ray machine typically operates at potentials of 40 to 50 kVp and at a tube current of 2 to 5 milliamperes (mA). Attached cones are used for a source–skin distance (SSD) of typically 2 cm or less. Filters of 0.5- to 1.0-mm aluminum are used to give a typical HVL of 0.6-mm aluminum. The x-ray tube is rod shaped with an extremely thin mica–beryllium window, having an inherent filtration of 0.03-mm-aluminum equivalence, and the radiation is emitted axially. The primary radiation therapy application of a contact x-ray unit is for endocavitary irradiation of selected small rectal carcinomas.[13]

Superficial Units

A superficial unit is an x-ray machine that operates at potentials of 50 to 150 kVp and 5 to 10 mA. Added thickness of filtration (1-mm Al to 1-mm Al + 0.25-mm Cu) produces HVLs of 1.0 to 8.0 mm of aluminum. Attached cones typically are used; lead masks are used to define irregular fields. The SSD is typically 15 or 20 cm. These machines are used primarily to treat skin lesions.

Orthovoltage (Deep-Therapy) Units

Orthovoltage x-ray machines operate at potentials between 150 and 500 kV, with most operating between 200 and 300 kV, and with tube currents of 10 to 20 mA. HVLs of 1 to 4 mm of copper are common with the use of added filters, such as the *Thoraeus filter*, a combination of thin sheets of tin, copper, and aluminum arranged so that the highest–atomic number sheet is always closest to the x-ray

target, ensuring that the higher-energy characteristic x-rays are absorbed by the lower-*Z* metal. Treatment fields usually are defined using detachable cones. The SSD is typically 50 cm. Very few of these types of machines are still in clinical use.

Supervoltage and Megavoltage Photon and Electron Beam Treatment Units

X-ray treatment machines operated in the range of 500 to 1,000 kV were designated as *supervoltage therapy* machines.[14] The *resonant transformer x-ray machine* is an example of this type of kilovoltage machine. X-ray treatment machines that can produce beams 1 MV or greater have been designated as *megavoltage therapy* machines. One of the first megavoltage machines was the *Van de Graaff generator*, which operated at 1 to 2 MV. Another early type of megavoltage machine was the *betatron*, first developed in 1941 by Kerst.[15] Betatrons used in radiation oncology produced x-ray beams with energies of >40 MV. All of these early machines are now obsolete and no longer in clinical use. Details on the history and development of these early accelerators used in radiation therapy can be found in the textbook by Karzmark et al.[16]

Cobalt-60 Teletherapy

The first *cobalt-60* (^{60}Co) *teletherapy* machine was loaded with its ^{60}Co source

in August 1951 in the Saskatoon Cancer Clinic, Saskatoon, Canada, and the first patient was treated on November 8 of that year.[17,18] A very readable history of the development of the first cobalt-60 teletherapy machine in the United States is provided by Almond.[19] A technical review of ^{60}Co teletherapy machines is provided by Glasgow.[20] The advantages of a ^{60}Co teletherapy machine are its relative constancy of beam output, predictability of decay because of a well-defined half-life, and lack of day-to-day small-output fluctuations typically found in electrical machines. Disadvantages include the need for source replacement approximately every 4 to 5 years, poor field flatness for large fields and large penumbra, and lower depth dose compared with high-energy photons generated by medical linear accelerators and discussed later. Isocentric units with source-to-axis distance (SAD) of 80 or 100 cm were designed with maximum field sizes of 40 × 40 cm at the machine isocenter for the 100-cm SAD machine. Source activities vary from about 5,000 to 13,000 Ci in 1.5- to 2.0-cm-diameter sources and yield exposure rates from 150 to 250 R/min at 1 m. The radiation consists of 1.17- and 1.33-MeV γ-rays having a $d_{1/2}$ in tissue (the depth at which the dose has been reduced to 50% of the maximum dose value) of about 10 cm.

Cobalt teletherapy machines became a mainstay for radiation therapy for nearly three decades but are rarely used in US clinics today. Cobalt-based teletherapy machines do remain a valuable radiotherapy solution in developing countries, though there are several active programs to provide economical solutions which do not rely on radioactive materials.

Two exceptions for use of cobalt in modern radiotherapy machines are the Elekta Gamma Knife (Elekta AB, Stockholm, Sweden) stereotactic radiosurgery machines and the magnetic resonance (MR) guided radiotherapy machine by ViewRay (ViewRay Inc., Oakwood Village, OH).[21] Both of these technologies offer state-of-the-art radiotherapy solutions based on cobalt.

Gamma Knife

Elekta *Gamma Knife* is a dedicated stereotactic radiosurgical device that was developed in 1968 by Dr. Lars Leksell,[22] a Swedish neurosurgeon. This machine initially made it possible to deliver a single, large dose of highly conformal radiation (γ-rays) precisely to a number of intracranial sites using multiple fixed ^{60}Co sources aimed at a center point. As the field of cranial stereotactic radiosurgery evolved, Gamma Knife started offering solutions for fractionated treatments, named *stereotactic radiotherapy*. In stereotactic radiotherapy patients

are treated with several fractions of highly conformal doses without use of ring frames and relying on thermoplastic masks for immobilization. The Gamma Knife traditionally consisted of three basic components—a spherical source housing/gantry, four collimator helmets, and a couch with electronic controls. The source housing (models U, B, and C) contains 201 ^{60}Co sources distributed in a quasihemispherical arrangement. The γ-rays from each source converge to the *unit center point* (*UCP*), which is 40 cm away from each source. The UCP is analogous to the isocenter of a teletherapy machine and is the location where the target volume must be positioned during a treatment. This is accomplished by the three-axis coordinate system on the Leksell stereotactic frame. Each source has an activity of approximately 30 Ci when newly installed, and the 201 sources combined provide a dose rate of approximately 300 cGy/min at the UCP. Along the path to the UCP, the radiation beam from each source is collimated twice—once by a primary collimator and then by one of four secondary collimator helmets. For each helmet, 201 tungsten collimators define specified circular apertures (4, 8, 14, or 18 mm projected at the UCP). To conform the radiation dose to the shape of the target in the patent, various combinations of aperture diameters, aperture blocking (*plugging*), irradiation times, and head positions are used. A specific combination of these four parameters defines what is referred to as a *shot* in Gamma Knife terminology. Hundreds of thousands of patients have been treated using this type of treatment machine.

In 2006, Elekta introduced the Gamma Knife Perfexion, which was a major change in design from the previous models, with several advanced features, including an enlarged internal patient cavity for extended access to peripheral cranial anatomy. Unlike the earlier models, the Perfexion moves the entire patient on the couch to each stereotactic *x*, *y*, and *z* coordinate. The collimation was also placed within the source housing part of to the machine gantry, eliminating the external helmets. The sources are arranged radially and divided into eight moving sectors with 24 sources each. Each sector is independently selectable, thereby providing various sector combinations for aperture (collimation) size or blocking at each shot position during treatment. With the introduction of its associated Extend System accessory, the Perfexion has an increased reach to allow treatments to the upper cervical spine.

In 2015, Elekta introduced the Gamma Knife Icon (Fig. 6.15), which added image-guided radiation therapy (IGRT) imaging capability. The Icon enables cone beam computed tomography (CBCT)-based patient localization capability and intrafraction patient monitoring with infrared camera. CBCT isocenter is

placed away from the cobalt sources isocenter, but the two isocenters are linked in software and hardware and the Icon provides workflows for patient localization, treatment evaluation, and adjustments when need. In this sense the Icon offers modern IGRT capabilities in combination with cobalt radiotherapy.

Image-Guided Cobalt (ViewRay)

A concept of combining a linac-based radiation therapy treatment machine with a magnetic resonance imaging (MRI) scanner originated in 1990s, and several research groups worked on development of such system. ViewRay system (Fig. 6.16) was a parallel commercial effort, which concentrated on combining a 0.35-T split bore MRI, which straddles a radiotherapy gantry housing three cobalt heads spaced 120 degrees apart. Each head contains a nominally 15,000 Ci cobalt source mated to a multileaf collimator (MLC). The three sources contributed to the combined initial dose rate of approximately 600 cGy/min. The MRI scanner and radiotherapy gantry shared a common isocenter enabling MR-based treatment localization as well as intrafractional treatment monitoring with MRI. The first MR-guided radiotherapy treatment occurred at Washington University in St. Louis on January 15, 2014. The clinical system relied exclusively on Monte Carlo–based dose calculation and intensity-modulated radiation therapy (IMRT), 2D, and 3D treatment capabilities. While the ViewRay system relied on cobalt sources, which inherently have large penumbra than do linac-based systems, the doubly focused MLCs offered better collimation than did the contemporary linear accelerators resulting in equivalent treatment dose distributions between the two technologies.[23,24] The initial ViewRay system also enabled practical online adaptive radiotherapy where patients could be imaged, new plan generated, patient specific QA performed, and treatment delivered all within the time compatible with conventional radiotherapy treatment times.[25,26] This really also marked the initiation of the first practical online adaptive radiotherapy program, and Washington University treated the first online MR-guided adaptive radiotherapy treatment on September 8, 2014. This program quickly grew with several hundred adaptive treatments administered within the first 2 years of operation. The third key distinguishing functionality that the ViewRay system offered was intrafractional anatomy tracking and treatment control (gating). In this application, the ViewRay systems enabled acquisition of four sagittal orientated single image frames per second. On each of the acquired images, the system automatically contoured the tracked anatomy (target or organ at risk), determined if the object was within the treatment bounds or not, and

gated the treatment off when necessary. This functionality enabled treatment gating based on the actual anatomy rather than on surrogates. With the MR guidance, online adaptive radiotherapy, and MR-based gating, the ViewRay system offered state-of-the-art radiotherapy in combination with cobalt teletherapy. While this technology was adopted by several institutions around the world, ViewRay introduced a linac-based version of their system in 2016, which initiated the end of MR-guided cobalt-based machines.

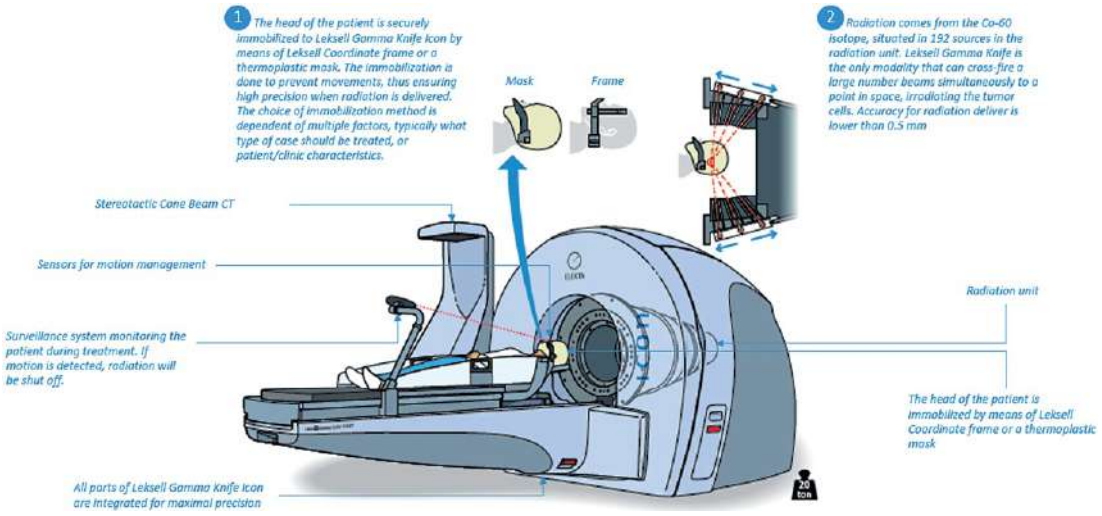

FIGURE 6.15. Elekta Gamma Knife (Elekta AB, Stockholm, Sweden) is a dedicated stereotactic radiosurgical device first developed in 1968 by Dr. Lars Leksell, a Swedish neurosurgeon, to provide highly accurate radiation ablative treatment of intracranial targets. Shown is the latest model, the Gamma Knife Icon, which now includes an integrated immobilization system and an integrated stereotactic cone beam CT system.

FIGURE 6.16. ViewRay system combines a 0.35 T split bore MRI, which straddles a radiotherapy gantry housing three cobalt heads spaced 120 degrees apart. The MRI scanner and radiotherapy gantry shared a common isocenter enabling MR-based treatment localization as well as intrafractional treatment monitoring with MRI.

Linear Accelerators

The first microwave electron linear accelerator (8 MV) for medical use became operational in 1953 at the Radiation Research Center of the Medical Research Council at Hammersmith Hospital in London.[27] The design for an isocentric gantry mount for the accelerator first was conceived by P. Howard-Flanders.[28] Shortly thereafter, Ginzton et al.[29] at Stanford University developed a 6-MV isocentric medical linear accelerator (*linac*). The history of the development of this first medical linear accelerator in the United States is provided by Jacobs.[30] Since then, there have been continued advances in accelerator design and construction, and today, medical linear accelerators account for most of the operational megavoltage treatment units in clinical use.[16,31]

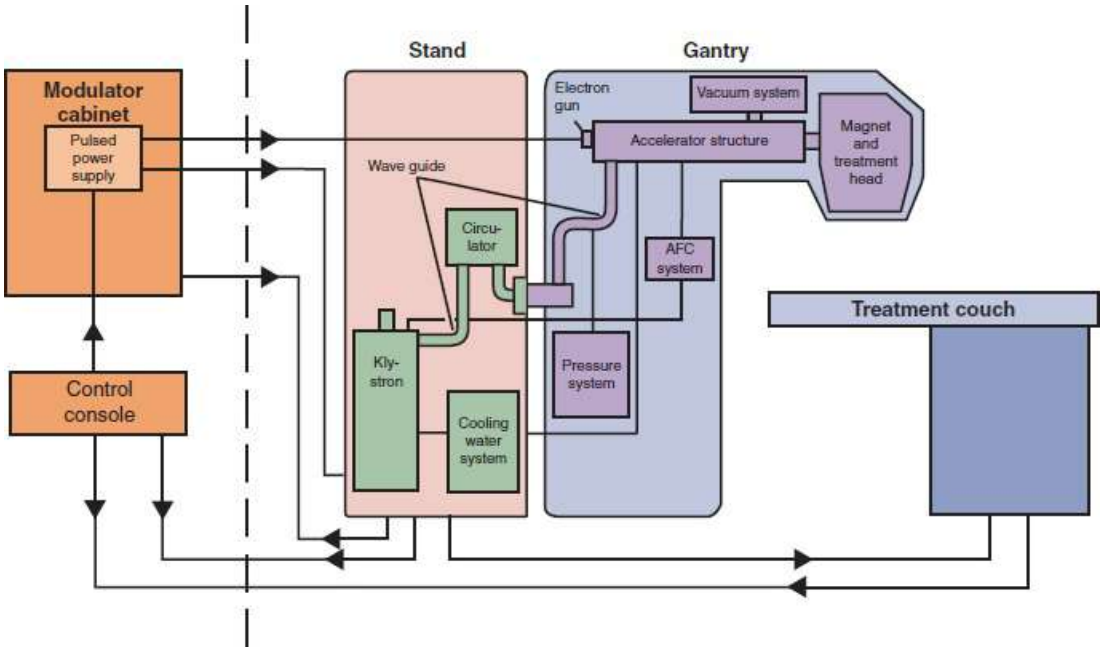

FIGURE 6.17. Schematic block diagram showing major components of a high-energy bent-beam medical linear accelerator. (Courtesy of Varian, Palo Alto, CA.)

Figure 6.17 is a block diagram of a high-energy, bent-beam medical linear accelerator showing the major components. The linac uses electromagnetic waves of frequencies in the *S-band* microwave region (2,856 megahertz [MHz]) to generate an electric field. The microwave radiation is propagated through a device called an *accelerator structure*, and the electrons injected into the structure are accelerated by the electric field in a straight line. The accelerator structure consists of a stack of cylindrical metal cavities having an axial hole through which the accelerated electrons pass. The accelerator structure's electric field produced by the microwaves can be either a *traveling wave* or *standing wave* design. In a traveling wave design, the electrons travel with the electric field as the field propagates through the structure with time, somewhat in the manner of a surfboarder riding the crest of an ocean wave. In a standing wave accelerator, the reflected microwave power is used to produce a standing wave electric field. In that case, the microwave power is coupled into the accelerator structure by side-coupling cavities rather than through the accelerator structure's axial cavity apertures.

The accelerator structure in low-energy (4 to 6 MV) linacs most often is mounted vertically in the treatment head collinear along with the components associated with producing, controlling, and monitoring the x-ray beam (Fig. 6.18, left). High-energy (15 to 18 MV) linacs use a horizontally mounted

accelerator structure with a beam-bending magnet system (Fig. 6.18, right). Accelerator structure technology now makes possible multiple high–dose rate photon beams of widely separated energies.

Other important components of a linac are the modulator, microwave power sources, electron gun, and the beam-handling components. The *modulator* is the source of pulsed direct current (DC) power, which is needed for the production of *microwave power*. Pulsed DC power is also supplied to the *electron gun* (a hot-wire filament that serves as the source of the accelerated electrons). The electrons are bunched before acceleration by a device called a *buncher*. The electron beam thus consists of pulses of bunched electrons in the form of a narrow pencil beam. The *magnetron* is a device that serves both as the source of the microwaves and as a power amplifier. The *klystron* is a device used to amplify the microwave power that is generated from a separate microwave source *(RF driver)*. The microwave power coming from the magnetron or klystron is transported to the accelerator structure by a metallic pipe called a *waveguide*. A device called the *circulator* is used to isolate the klystron/magnetron from the reflected microwave power.

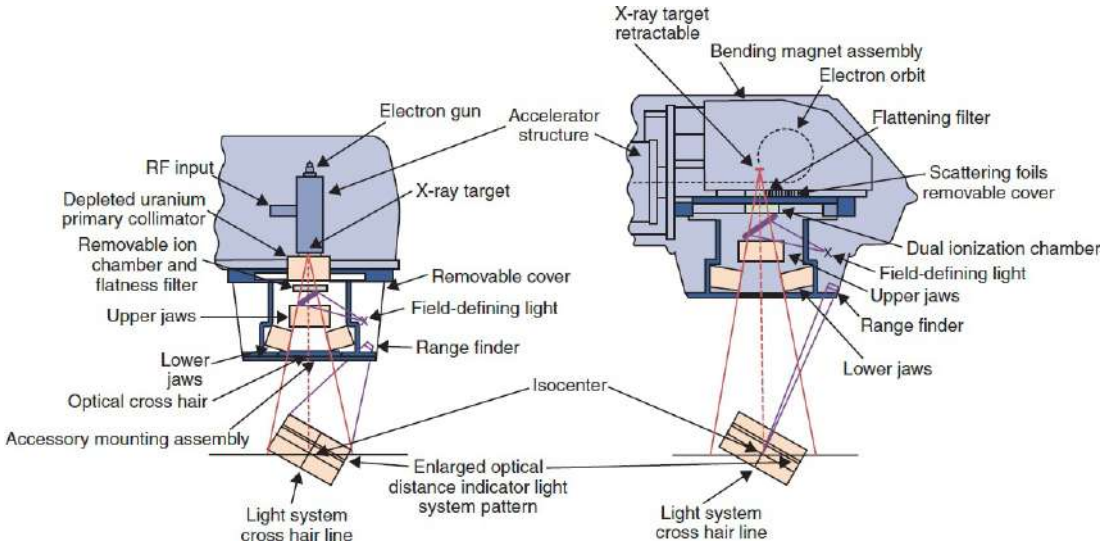

FIGURE 6.18. Schematic cutaway diagram of treatment heads for low-energy, straight-beam (*left*) and high-energy, bent-beam (*right*) medical linear accelerators. (Courtesy of Varian, Palo Alto, CA.)

Other important components in a linac are located in the treatment head. These include the *x-ray target*, *fixed primary collimator*, *scattering foils*, *flattening filter*, *monitor ion chamber*, *movable secondary collimator jaws and/or mulitleaf collimator*, *light field localizer*, and *optical distance indicator*.

In addition, the treatment head contains a significant amount of shielding material to minimize leakage radiation.

At the exit window of the accelerator structure, the high-energy electrons emerge in the form of a pencil beam of about 2 to 3 mm in diameter. In a low-energy (4 to 6 MeV) linac, the accelerated electrons proceed in a straight line and strike an x-ray target when in photon mode, producing bremsstrahlung x-rays. In high-energy linacs, because the accelerator structure is much longer and is placed horizontally or at some angle with respect to the horizontal, the electrons must be bent through a suitable angle, usually 90 or 270 degrees between the accelerator structure and the target. This is enabled by the beam transport system, which consists of an *achromatic focusing and bending magnet*, as well as *steering* and *focusing coils*.

The *primary collimator* is a fixed collimator located just below the x-ray target and is used to collimate the x-ray beam in the direction of the patient treatment and reduces the leakage radiation from the x-ray source. The angular distribution of the bremsstrahlung x-rays produced by megavoltage electrons incident on a target is forward peaked. To make the x-ray beam intensity uniform across the field, a conical metal *flattening filter* is inserted in the beam. Filters are constructed of lead, tungsten, uranium, steel, and aluminum (or some combination of these), depending on x-ray energy. The flattened x-ray beam then passes through a *monitor ionization chamber*. In most cases, this system consists of several transmission-type parallel-plate ionization chambers, which cover the entire beam. These ion chambers are used to monitor the field symmetry, dose rate, and integrated dose per monitor unit. In 2010s, several linacs offering flattening filter-free beams were commercially introduced. Some of these systems provided only flattening filter-free beams, whereas some provided dual capability with and without flattening filters.

After passing through the monitor chamber, the beam can be further collimated by continuously and independently movable x-ray collimators consisting of two pairs of lead or tungsten jaws and/or mulitleaf collimators consisting of a large number of tungsten leaves arranged in an opposing configuration. Conventional linacs typically provided rectangular field sizes ranging from 0 to 40 × 40 cm at a distance of 100 cm. The field size can be defined by a *light localizer* and a *mirror assembly*. The introduction of independently movable collimators allowed simplified patient positioning and improved safety by avoiding overlapping field abutments without the necessity of using heavy beam-splitting blocks.[32] Independent jaw technology in

conjunction with computer control of the dose rate can be used to create a wedge-shaped isodose pattern.[33]

Although the *multileaf collimator* (*MLC*) systems (Fig. 6.19)[34,35] were initially developed to simplify beam shaping for 2D- and 3D-based conformal radiotherapy, their ultimate purpose excelled in *intensity-modulated radiation therapy* (*IMRT*) making them a prerequisite capability on all modern radiotherapy machines. The MLCs offered ability to electronically and dynamically control beam shapes during treatment. IMRT can be delivered in various combinations of MLC and gantry motions. With respect to MLC motion, IMRT can be delivered by (a) delivering multiple field segments (called *segmental MLC* [*SMLC*] or *step-and-shoot IMRT*) or (b) having the leaf pairs move across the field at a varying rate with the x-ray beam on (called *dynamic MLC* [*DMLC*] or *sliding window IMRT*)[36] With respect to gantry motion, the VMAT capability involves continuous gantry motion during delivery of typically coplanar beams,[37–39] while 4Pi delivery involves complex combinations of gantry and couch rotations enabling highly conformal dose distributions with noncoplanar delivery.[40] Initial designs of MLCs relied on in-line opposing pairs of MLC leafs. Alternate MLCs arrangements have been a long-standing topic of interest and double focused and/or multilayer MLCs eventually became available. The double focused MLCs offer improved penumbra compared to inline MLCs by being able to match the leaf edge with the beam divergence across all field sizes. The inline MLCs require a compromise of the beam penumbra as a function of the MLC position. The multilayer MLCs offer greater flexibility in field shape resolution, reduced leakage, greater speed, and simplification of operation.

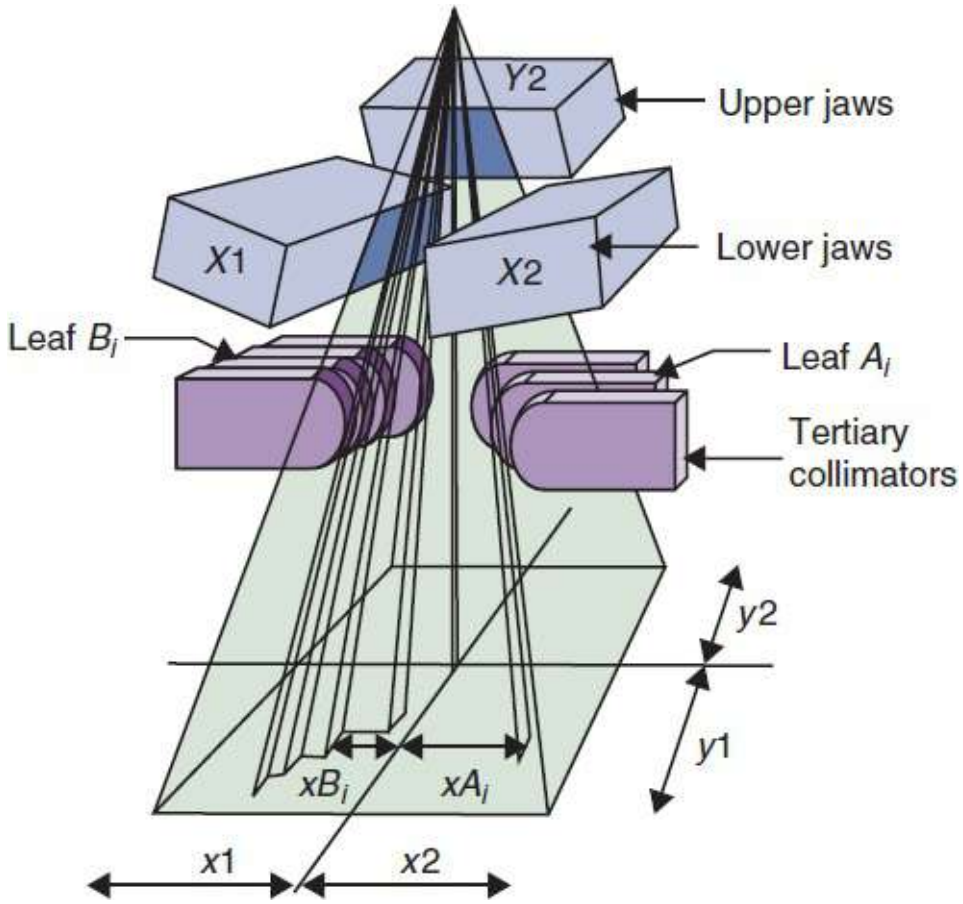

FIGURE 6.19. Schematic illustrating the geometry of a multileaf collimator for Varian linear accelerators. The *x*-direction is the field width across each leaf pair, and the *y*-direction is the field length. (Courtesy of Varian, Palo Alto, CA.)

In the electron mode, the accelerator's beam current is reduced 1,000-fold and the x-ray target is retracted. An *electron-scattering foil* is moved into place on the beam centerline so that the accelerated pencil electron beam strikes it in order to broaden the beam and produce a flat field across the treatment field. The scattering foil typically consists of dual lead foils. The thickness of the first foil ensures that most of the electrons are scattered with only a minimum of bremsstrahlung x-rays. The second foil is generally thicker in the central region and is used to flatten the field. The bremsstrahlung produced appears as x-ray contamination of the electron beam and is usually <5% of the maximum dose. An *electron applicator* is mounted below the movable collimator jaws to provide the final field collimation. A schematic diagram of all the treatment head subsystems for both x-ray and electron beams is shown in Figure 6.20.

In the early 2000s, conventional medical linacs integrated advanced imaging systems having *cone beam computed tomography* (*CBCT*) capability. Such

linacs are referred to as *image-guided radiation therapy* (*IGRT*) linacs. The first commercial CBCT IGRT linac was the *Elekta Synergy* (Elekta).[41,42] The other medical linac manufacturers have also embraced the IGRT concept and have offered a variety of CBCT-equipped machines. The Synergy IGRT system (referred to as XVI) consists of a retractable kilovolt x-ray source, an amorphous silicon flat-panel imager mounted on the linear accelerator perpendicular to the radiation beam direction, and a software module for processing the data and tools for registering the images (Fig. 6.21). The XVI system provides for planar, motion, and volumetric imaging capabilities. Registration software is provided to compare the daily patient setup image with the stored prescription computed tomography (CT)–planning image, after which table adjustments can be made prior to treating the patient.

Microtrons

The microtron, whose concept is credited to Veksler,[43] is an electron accelerator that combines the basic principles of the electron linear accelerator and the cyclotron. By using magnets to recirculate the electron beam through a microwave accelerator cavity (or cavities) one or more times, it is possible to achieve a high beam energy with a low-energy accelerating section. After each orbit in the magnet, the electron bunch must arrive in phase with the accelerator microwave field. Thus, the magnet system acts as an energy spectrometer, limiting the electron energy acceptance to a narrow energy width and consequently limiting to some extent the beam current.

This concept was developed further by Schwinger,[44] who proposed the *racetrack microtron*. It uses two D-shaped magnet pole pieces that are separated by a fixed distance, between which is a linac accelerator structure. A 50-MeV unit was developed for radiation therapy applications by the Swedish firm Scanditronics (Uppsala, Sweden) and was one of the first modern IMRT delivery systems described in the literature.[45] Only two of this type of microtron were installed in the United States, and both have been replaced.

Tomotherapy

Helical tomotherapy was first proposed by Mackie et al.[46] and became commercially available as the TomoTherapy HI-ART system (Accuray, Madison, WI).[47] A short, in-line, 6-MV linac (Siemens Oncology Systems, Concord, CA) rotated on a ring gantry at a source–axis distance of 85 cm. Figure 6.22 shows the unit installed at the University of California, Davis. The IMRT treatment is delivered while the patient-support couch is translated in the *y*-direction (toward the gantry) through the gantry bore in the same way as a helical CT study is conducted. Thus, in the patient's reference frame, the treatment beam is angled inward along a helix, with the midpoint of the fan beam passing through the center of the bore. Similar to helical CT, the treatment beam *pitch* is defined as the distance traveled by the couch per gantry rotation divided by the field width in the *y*-direction (typically between 0.2 and 0.5). The width of the beam in the *y*-direction is defined by a pair of jaws that is fixed for any particular patient treatment to one of three selectable values (1, 2.5, or 5 cm). Laterally, the treatment beam is modulated by a 64-leaf binary MLC, whose leaves transition rapidly between open and closed states. Each leaf has a projected width of 6.25 mm at the bore center, for a maximum possible open lateral field length of 40 cm. Intensity modulation is accomplished by varying

the fraction of time different leaves are opened. The individual modulation pattern can change with angle (divided into exactly 51 projections over a full revolution). During the treatment, the gantry rotates at a constant velocity with a period ranging between 10 and 60 seconds/rotation. The extent to which a treatment beam projection is modulated is characterized through what is called the *modulation factor*, defined as the ratio of the maximum leaf open time to the average leaf open time for the projection. Pitch and maximum permissible modulation factor are new parameters that need to be specified by the treatment planner. Highly modulated treatments achieve greater conformality but inevitably take longer to deliver. A helical MVCT image is acquired using the onboard xenon CT detector system and the 6-MV linac (detuned to 3.6 MV) with the leave fully opened when the patient-support couch is translated in the *y*-direction through the gantry bore. Registration software is provided to compare the daily patient setup image with the stored prescription CT planning image.

FIGURE 6.22. TomoTherapy HI-ART system installed at the University of California, Davis. A short, in-line 6-MV linac rotates on a ring gantry. Intensity-modulated radiation therapy treatment is delivered while the patient-support couch is translated through the gantry bore in the same way as a helical computed tomography study is conducted. The width of the beam in the patient-translated direction is defined by a pair of jaws that is fixed for any particular patient treatment, and laterally, the treatment beam is modulated by a 64-leaf binary multileaf collimator.

CyberKnife

The use of a small X-band (~10,000 MHz) linear accelerator mounted on an industrial robotic arm was first developed for radiosurgery.[48,49] The robotic arm provides the capability for aiming a narrowly collimated x-ray beam with any orientation relative to the target volume. The system uses two ceiling-mounted diagnostic x-ray sources and amorphous silicon image detectors mounted flush to the floor. The treatment is specified by the trajectory of the robot and by the number of monitor units delivered at each robotic orientation. During the patient's treatment, the CyberKnife system correlates live radiographic images with preoperative CT or MRI scans in real time to determine patient and tumor position repeatedly over the course of treatment.

New and Evolving Photon Treatment Machines

There are several other new photon beam treatment machine designs that show significant promise. For example, the four-dimensional IGRT system proposed by Kamino et al. has a unique, gimbaled x-ray head design that allows the linear accelerator head to be pivoted.[50] By easily allowing noncoplanar beams without couch rotations, new degrees of freedom are made available for IMRT optimization, and even more conformal dose distributions may be possible.

In May 2017, Varian Medical Systems announced their Halcyon machine (Figure 6.23), which was specifically designed to address challenges of deploying radiotherapy in low resource settings. Some of the specific features include lower power consumption, simpler installation process, easier serviceability, greatly simplified operation, and specific aim for higher throughput than conventional machines. The machine is also designed to benefit from a 100% IGRT treatment approach where all treatments require imaging guidance and imaging dose is included in the treatment dose. The Halcyon also has a double-layer MLC, which in early studies has shown to provide significant dosimetric advantages. It is worth noting that all of the features, which make this machine advantageous in emerging markets also, make it attractive in developed settings. As such, it is expected that this machine will play a role in a variety of settings and may have a significant impact on global access to radiotherapy. The machine does not offer electron beam treatment capability. Another noteworthy point is that the system has an "O" shape design, as opposed to the conventional "C" shape design for Varian, Elekta, Siemens, etc., machines. This design joins a host of other advanced machines with "O" shape (Tomotherapy, ViewRay, Elekta Unity) and potentially signals that this may become a more prevalent

approach to radiotherapy patient treatments.

FIGURE 6.23. Varian Medical Systems' Halcyon introduced in 2017, which is specifically designed to provide highly efficient IGRT treatments. Note that the system does not offer electron beam treatment capability and has an "O" shape design, as opposed to the conventional "C" shape design used for other Varian and Elekta medical linacs.

Several investigators have also pointed out the utility of very high-energy (VHE) electron beams (150 to 250 MeV).[51,52] Such high-energy beams are not yet available, and so only beam simulation software has been used to demonstrate the use of multi-VHE beams from opposed directions and the ability to modulated VHE beam intensity.[51,52] Such machines are clearly some time away, but these early studies show promise.

Proton, Light-Ion, and Neutron Beam Treatment Units

The first use of proton beams for radiation therapy is credited to Wilson,[53] who in 1946 pointed out the superior depth–dose characteristics provided by protons. Details on the history and development of proton beam radiation therapy (PBRT) machines are provided by Breuer and Smith[54] and Delaney and Kooy.[55] PBRT is seeing increasing interest worldwide because its depth–dose characteristics show advantages over those of photon beams.[56]

In most existing or proposed proton and light-ion particle treatment facilities, either a *cyclotron* or a *synchrotron* is used to accelerate proton beams to

sufficient energy (200 to 250 MeV) and beam intensity.

Cyclotron

The cyclotron (Fig. 6.24) was invented by Ernest Lawrence of the University of California in 1929. It accelerates charged particles such as protons, deuterons, and light ions using a high-frequency, alternating voltage (potential difference) applied across two conducting D-shaped evacuated half-cylinders (Ds). A fixed magnetic field, perpendicular to the top of the two Ds, forces the charged particles to travel in a circular path. The charged particles accelerate only when passing through the gap between the two Ds. The beam spirals out to the edge of the container as the particle speeds increase. At this point, the particle speed approaches the speed of light. Proton beam energies of 200 to 250 MeV are considered adequate for most radiation therapy applications. Beam intensity from the accelerator must be adequate to overcome losses in the beam delivery system and provide tolerable treatment times.

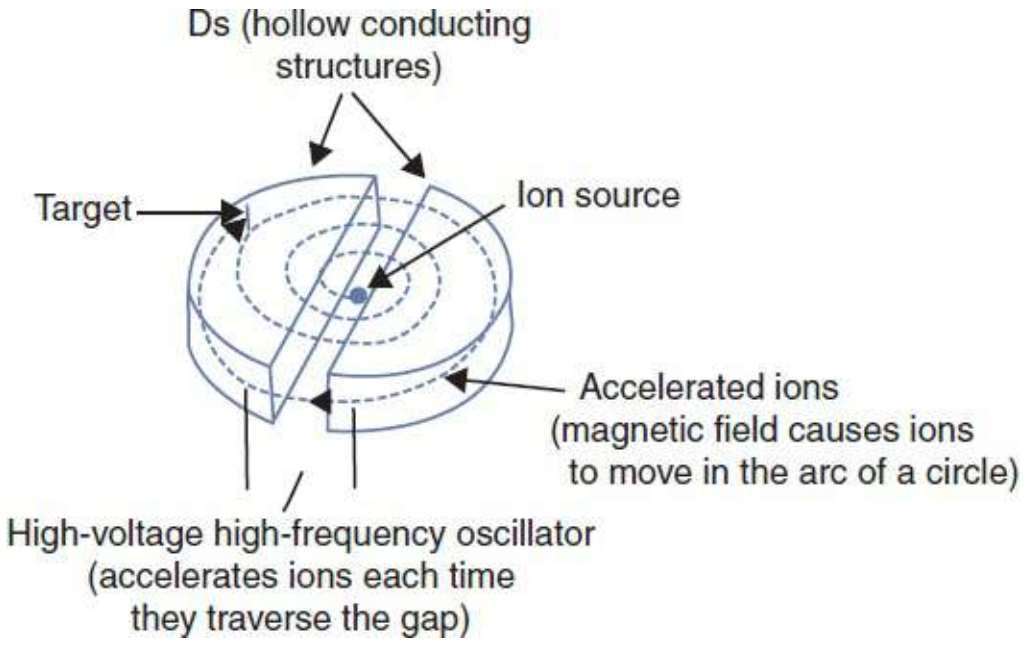

FIGURE 6.24. Schematic drawing showing principles of cyclotron operation. This machine is used for accelerating positive ions and is used clinically to produce proton and neutron beams. Metal half-disks (Ds) have an evacuated center through which the protons can travel. The protons are accelerated by an oscillating electric field operating between the half-disks. A magnetic field perpendicular to the plane of the half-disks confines the charged particles in the half-disks.

Synchrocyclotron and Synchrotron

A *synchrocyclotron* varies either the magnetic field or the frequency of the

applied electric field; a *synchrotron* varies both. By increasing these parameters appropriately as the particles gain energy, one can hold their path constant as they are accelerated. This allows the vacuum container for the particles to be a large, thin torus. In reality, it is easier to use some straight sections and some bent sections using multiple bend magnets, thus creating the shape of a rounded-corner polygon. The proton beam facility at Loma Linda University Medical Center (Loma Linda, CA) is an example of this type of accelerator.[57]

The synchrotron has the advantage of simple energy variability, whereas the cyclotron produces continuous beams with a fixed energy and higher beam intensity, making their design somewhat simpler. Beam-spreading mechanisms obtain suitable field sizes for radiation therapy by passive modulation (scattering foil) systems or by dynamic pencil-beam spot-scanning systems,[57] which allow dose conformation not only at the distal edge of the tumor but also at the proximal edge. Hall[58] pointed out that there is significant neutron leakage radiation for proton treatment machines that use a scattering foil and recommended moving to the pencil-beam scanning systems.

Size and Scope of Proton and Heavy-Ion Treatment Machines

The initial clinical proton systems involved either utilization of research system or commercial systems, which relied on multiroom solutions. Although the research systems enabled patient treatments, they did not allow broad scale deployment of this technology. The commercial multiroom solutions enabled broader deployment of this technology, but the significant initial cost and the size of the operation limited deployment of this type of technology. Single-gantry proton systems reduced the overall cost of proton facility and offered a scale that was easier to deploy. The first single room proton solutions included the MEVION S250 Proton Therapy System (Mevion Medical Systems, Littleton, MA) shown in Figure 6.25 and IBA Proteus One (IBA, Louvain-La-Neuve, Belgium). The first Proteus One treatment occurred at Willis-Knighton Cancer Center in Shreveport, Louisiana, in September 2014, and the first Mevion S250 treatment occurred at Washington University in St. Louis, Missouri, in December 2014. This system uses a superconducting synchrocyclotron that is gantry mounted and incorporates image guidance and robotic patient positioning. The first unit was installed at Washington University (St. Louis, MO) in late 2011.

Rendering of next-generation proton therapy system (MEVION S250 Proton Therapy System, Mevion Medical Systems, Littleton, MA; formerly Still River Systems). **A:** Outer gantry holds the proton accelerator in the center, pointing directly to the isocenter. Accelerator is a 250-MeV cyclotron specifically designed (uses superconducting magnets) for proton therapy (with intensity-modulated proton therapy capabilities, high dose rate, high reliability, and easy maintenance). **B:** Treatment room depicting inner gantry and six-degree-of-freedom robotic couch.

Several heavy-ion (carbon ion) radiation therapy facilities are now available

in several centers in Asia and Europe,[9–11,56,59] and the first such facility in the United States will likely start construction in the next few years. Heavy-ion radiation therapy requires beams at much higher energies than proton therapy. For example, a proton beam of 150 MeV can penetrate 16 cm in water. To achieve the same penetration with carbon ions, energy of 3,000 MeV or 250 MeV/nucleon is needed. Synchrotrons are the only available sources for such high-energy ion beams, and they are large, complex machines requiring large facilities and similarly large capital expenditures.

Interest in heavy-ion radiation therapy is due primarily to its combination of two important physical advantages: (a) its depth–dose characteristics and (b) high LET in the Bragg peak region of the beam. For its depth characteristics, the ratio of the Bragg peak dose to the entrance region dose is even larger than for protons. In addition, there is a large increase in the radiation LET in the Bragg peak region of the beam. The combination of these two characteristics results in a potentially unique advantage of providing a high LET region that can be closely conformed to the target volume.

Neutron Therapy Treatment Machines

Modern neutron therapy machines use cyclotrons to accelerate protons or deuterons to energies of about 50 MeV to produce neutron beams with depth–dose characteristics equivalent to those of about 6-MV x-rays. The p,Be (protons accelerated to strike a beryllium target) reaction is used most commonly because protons are much easier to bend around the gantry of an isocentric unit, and thus, the cyclotron can be much smaller and thus less expensive. The only exception is the superconducting cyclotron installed at Harper Hospital (Detroit, MI), which uses the d,Be (deuterions strike beryllium target) reaction.[60] With superconducting technology, the entire cyclotron is small enough to be rotated around the patient on isocentric rings, thus eliminating the need for bending the deuteron beam around a rotating gantry. In addition, the neutron yield for the d,Be reaction is about five times that for the p,Be reaction. More details on the history and development of neutron beam therapy machines are provided in the review by Maughan and Yudelev.[61]

SIMULATORS

Conventional Simulator

Details on the development of the *radiation therapy simulator* and the selection,

acceptance testing, and quality assurance of conventional radiation therapy simulators are provided in the review article by Van Dyk and Munro.[62] The conventional simulator mimics the functions and allowed motions of a therapy unit and uses a diagnostic x-ray tube to simulate the radiation properties of the treatment beam (Fig. 6.26). A simulator allows the beam direction and the treatment fields to be determined to encompass the projection of the target volume. Radiographic visualization of internal structures in relation to external landmarks allows special shielding devices (Cerrobend blocks) to be constructed to help minimize the dose to normal critical structures. Gantry arms are rigid enough to support heavy shielding blocks and simulated electron cones. Couch widths are similar to therapy-unit couch widths, and operating consoles feature digital displays of parameters and programmable settings for SAD, gantry angles, and field sizes. Older models of conventional simulators were equipped with an x-ray fluoroscopy system consisting of an image intensifier and video camera system to expedite field setup and beam angulations. Modern simulator design has replaced the image intensifier with amorphous silicon technology. The new imagers produce high spatial- and contrast-resolution images that approach film quality, facilitating the concept of filmless radiation oncology departments, and provide CBCT capability. Although this feature allows volumetric imaging on a conventional simulator, they have been virtually completely replaced with CT simulators.

The basic components and motions of a radiation therapy simulator. *A*: Gantry rotation. *B*: Source–axis distance. *C*: Collimator rotation. *D*: Image intensifier (lateral). *E*: Image intensifier (longitudinal). *F*: Image intensifier (radial). *G*: Patient table (vertical). *H*: Patient table (longitudinal). *I*: Patient table (lateral). *J*: Patient table rotation about isocenter. *K*: Patient table rotation about pedestal. *L*: Film cassette. *M*: Image intensifier. Motions not shown include field-size delineation, radiation beam diaphragms, and source–tray distance. (From Van Dyk J, Mah K. Simulators and CT scanners. In: Williams JR, Thwaites DI, eds. *Radiotherapy physics*. New York: Oxford Medical Publications, 1993:118. Reproduced by permission of Oxford University Press.)

CT Simulators

In the 1980s and early 1990s, research led to the integration of a diagnostic CT scanner with what was essentially a three-dimensional (3D) treatment-planning system, which led to the concept of *virtual simulation*.[63–65] Such a system is now referred to as a *CT simulator* and consists of a CT scanner, a flat-tabletop patient position–alignment system, including an orthogonal laser system, and a digital interface (DICOM) to a planning system that is equipped with virtual simulation software (Fig. 6.27). Modern CT simulation systems incorporate large-bore CT scanners especially designed for radiation oncology, with multislice capability,

high-quality laser patient positioning/marking systems, and sophisticated virtual simulation software features. Conventional diagnostic CT scanners are typically equipped with 70-cm-diameter bore, whereas large-bore scanners have openings 80 to 90 cm in diameter. While the CT scanners used for CT simulation tend to be specifically designed for radiation oncology, there has been a steady adoption of technology developed for diagnostic purposes to CT simulators. Most of this technology concentrates on ever-evolving image reconstruction improvements as well as improvements in image acquisition technology. For example, iterative image reconstruction techniques and dual kV acquisition have found application in radiotherapy. Details of the virtual simulation process are discussed in some detail in Chapter 9. More details on CT simulation can be found in the review article by Van Dyk and Taylor[66] and articles by Mutic et al.[67,68]

New and Evolving Simulation Machines

Positron emission tomography (PET)/CT simulators and MR simulators have been available for radiotherapy purposes for a while. The adoption of this technology has been relatively modest and is somewhat limited by reimbursement practices and generally good access to these modalities through diagnostic radiology departments. Recent developments in radiotherapy treatment planning based on functional imaging and monitoring of response to therapy may increase the presence of MR- and PET-based simulators. However, this will likely need to be facilitated by clinical evidence, which would result in modifications of reimbursement practices to allow broader use of multimodality scanners in radiotherapy departments.

QUALITY OF RADIATION

The penetrability of an x-ray beam, referred to as the *quality* of the beam, is completely specified by its spectral distribution curve (i.e., the relative intensities of photons of various energies), which is the result of fluctuations of tube potential, the bremsstrahlung radiation process, characteristic radiation, and multiple interactions of the incident electrons and the x-ray target. The distribution of the photon energies, including the peak photon energy, in the continuous spectrum is governed solely by the x-ray tube potential. However, the energy of the characteristic photons increases with increasing atomic number of the target element. All other factors being equal, the radiation intensity is proportional to the atomic number of the target element.

Spectral distribution of an x-ray beam can be modified by placing absorbing materials of various thicknesses (i.e., filters) in the beam. In general, a filter removes relatively more low-energy photons than high-energy photons, although photons of all energies are removed to some extent. For radiation in the orthovoltage region (except for the absorption edge effect), the lower the energy of the photons, the larger is the total mass attenuation coefficient and therefore the greater is the likelihood that the photon will be absorbed. Thus, the beam emerges from the filter with a larger percentage of high-energy photons than it had on entering the filter. The beam has a greater penetration power and is said to have been "*hardened*" by the filter. The quality of an x-ray beam improves with increasing tube potential and with increasing thickness and atomic number of the filter.

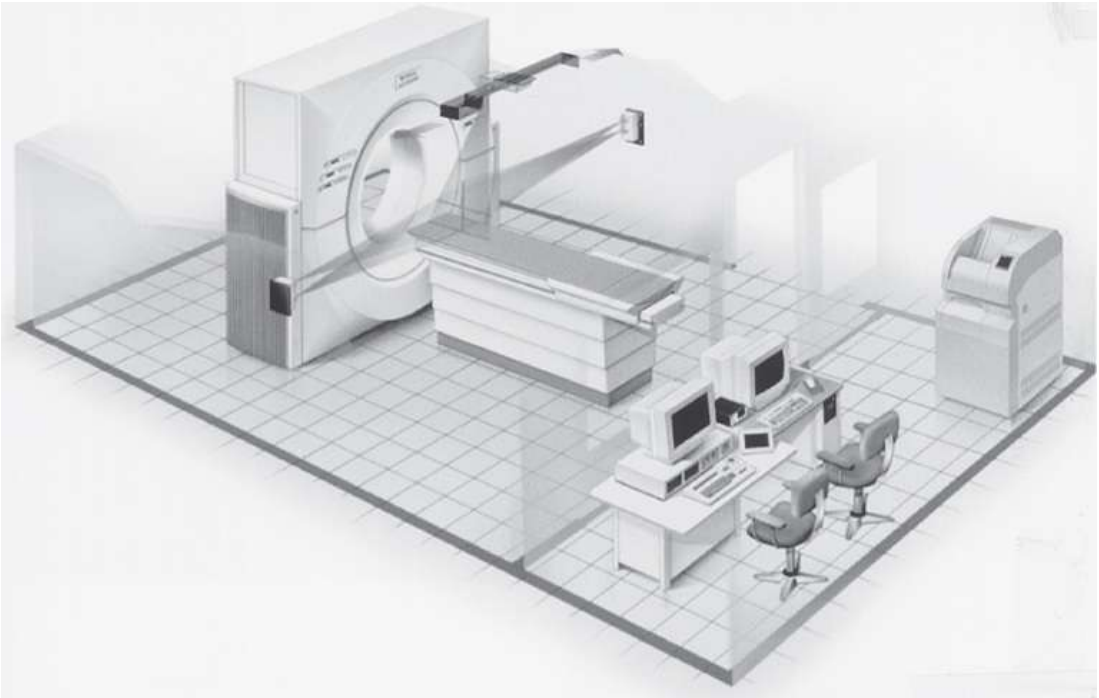

FIGURE 6.27. Typical computed tomography simulation suite showing the scanner, flat tabletop, orthogonal laser system, virtual simulation workstation, and hardcopy output device.

A specification of beam quality-based entirely on a spectral distribution is too cumbersome for radiation therapy. The usual method of specifying beam quality in superficial and orthovoltage therapy is to list the HVL and the accelerating potential. For megavoltage beams, only the maximum energy of the electrons striking the x-ray target typically is used. The *homogeneity coefficient* denotes how homogeneous an x-ray beam is with respect to its photon energies. It is

defined as the ratio of the first HVL to the second HVL. As the filtration is increased, the exposure rate decreases; therefore, there is a practical limit of filter thickness in orthovoltage therapy with a given combination of kilovolts, milliamperes, and treatment distance. In certain situations, it is convenient to express the quality of the x-ray beam in terms of an "equivalent energy," which can be derived from knowledge of the HVL. The type of x-ray beam that is used in radiation therapy is always heterogeneous; however, the x-ray beam can be considered to have an *equivalent energy* of a monoenergetic x-ray beam that has a HVL equal to the measured HVL of the heterogeneous beam.

RADIATION EXPOSURE

In 1928 at the Second International Congress of Radiology, the ionization of air, called *exposure*, was adopted as the measurable effect of radiation of a photon beam.[69] As the beam passes through a material, it creates ion pairs via the ionization process. In air, these ion pairs have some mobility and can be collected by applying an electric field across the air. The number of ion pairs collected is a measure of the quantity of radiation passing through the air.

The *roentgen* (R), the unit for exposure, also was defined at the 1928 Congress. The definition has been modified slightly by subsequent congresses, but the basic concept remains the same. The roentgen is that amount of x- or γ-radiation that causes the associated corpuscular emission per 0.001293 g of air to produce, in air, ions carrying one electrostatic unit of charge of either sign. The value 0.001293 g is the mass of 1 cm^3 of air at 0°C and 760 mm Hg pressure; "associated corpuscular emission" refers to the Compton and pair-production electrons set in motion by the interactions between the incident photons and the air molecules. By conversion of units, the roentgen can be expressed as follows:

$$1\,\mathrm{R} = 2.58 \times 10^{-4}\ \mathrm{C/kg\ of\ air}$$

With the advent of SI units, the roentgen no longer is used as a special name for a radiation unit, and the SI unit for exposure is Coulombs per kilogram (C/kg), which is equivalent to approximately 3,876 R (Table 6.2).

The condition of electronic equilibrium must exist for the definition of the roentgen to be satisfied (Fig. 6.28). According to the definition, the electrons produced in a specified volume must spend all of their energies by ionization in air, and the total charge must be measured. However, because some electrons produced inside the specified volume create ion pairs outside the volume and

some electrons produced outside the volume contribute ionization inside the specified volume, the gain and loss of ion pairs must be the same for the definition of the roentgen to be satisfied.

The free-air ionization chamber is used to measure exposure directly in roentgens.[1] It is designed to collect all the ions produced in a defined volume by the radiation beam and is used primarily by standards laboratories. Free-air chambers are bulky and too complicated to use for routine measurements. Instead, small ionization chambers called *thimble chambers* are typically used to measure exposure. The chamber gives a measure of the ionization produced, which then is converted to exposure in roentgens by use of an *exposure calibration factor,* N_x, traceable to the National Institute of Standards and Technology (Gaithersburg, MD). Thimble chambers are designed for use at specific energies; the thickness of the chamber wall is equal to the maximum electron range (electronic equilibrium established). If they are used at higher energies, at which the electron range is greater, an added wall thickness or *buildup cap* must be used.

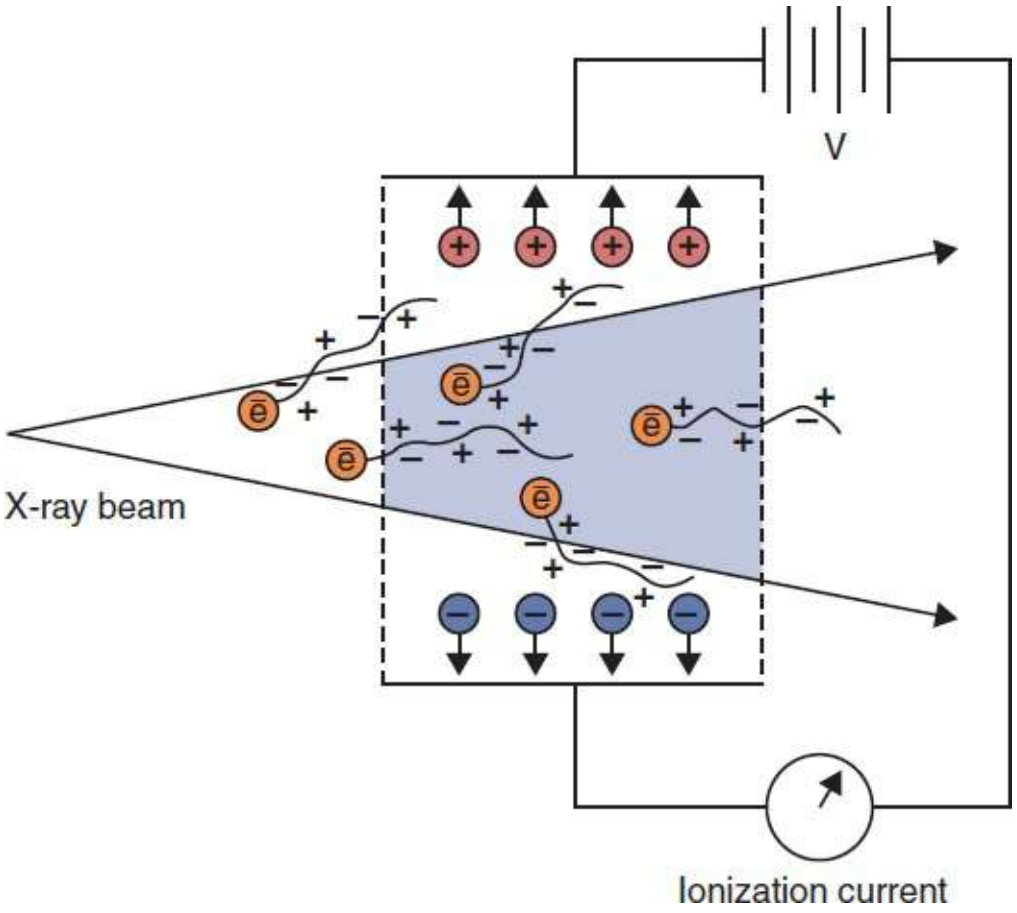

FIGURE 6.28. Schematic illustrating electronic equilibrium. (From Khan FM. *The*

physics of radiation therapy. 2nd ed. Baltimore: Williams & Wilkins, 1994. With permission.)

To determine the exposure rate from an x-ray or γ-ray machine, an exposure-calibrated thimble chamber (with appropriate wall thickness) and connected to an *electrometer* is placed at beam center, in air, at right angles to the beam's central axis and at the point where the exposure rate is to be specified. The field size for which the exposure rate is to be measured is set, and the radiation machine is turned on for a specified time, T, to achieve a reading, M, on the connected electrometer. The reading is corrected for *temperature and atmospheric pressure*, *timer error*, *stem effect*, and *ion-recombination effects*. The therapy machine exposure rate, $\dot{X}$, is given in roentgens per minute by the following equation:

$$\dot{X} = \frac{M \cdot N_x \cdot C_{tp} \cdot C_{st} \cdot C_s}{T + \alpha}$$

where M is the raw ionization chamber reading, N_x is the exposure calibration factor obtained from a standards laboratory, C_{tp} is the temperature and pressure correction factor, C_{st} is the stem effect correction factor, C_s is the ion-recombination correction factor, T is timer (minutes) or monitor unit setting, and α is the timer error. The temperature-pressure correction factor C_{tp} is given by the following equation:

$$C_{tp} = \left(\frac{t + 273.16}{295.16}\right)\left(\frac{760}{p}\right)$$

The timer error α is given by the following equation:

$$\frac{M_1}{T + \alpha} = \frac{M_2}{T + n\alpha}$$

where M_1 is the instrument reading for a single long exposure of T, M_2 is the instrument reading for n short exposures of total time T, and α is the timer error (monitor end effect for linacs) for a single exposure.[70]

Beyond 3 MeV, the roentgen cannot be measured accurately, and thus calibrations of radiation therapy machines at these higher energies are performed using an exposure-calibrated ionization chamber such as a Bragg–Gray cavity, and the ionization readings are converted to absorbed dose as discussed in the

following section.

ABSORBED DOSE

In 1953 the International Commission on Radiological Units and Measurements introduced the concept of *absorbed dose* and defined its unit, the *rad*.[69] Before its definition can be presented, the reader must understand the concept of dose absorption. As a beam of radiation passes through an absorbing medium, it interacts with it in a two-stage process. The first step occurs when energy carried by the photons—the indirectly ionizing particles—is transformed into kinetic energy of high-speed electrons; the second step occurs as these electrons—the directly ionizing particles—are slowed down and deposit their energy in the medium.

Kerma, an acronym for "kinetic energy released in the medium," represents the transfer of energy from the photons to the directly ionizing particles (step 1). The subsequent transfer of energy from the directly ionizing particles to the medium (step 2) is represented by the absorbed dose and is defined in terms of the energy deposited by the radiation beam as it passes through the medium. The relationship between kerma and absorbed dose is illustrated in Figure 6.29.

The *rad* represents the absorption of 0.01 J/kg of the absorbing material (1 rad = 0.01 J/kg). The rad now has been replaced with the SI unit for absorbed dose (1 J/kg) given the special name of *gray* (*Gy*) (Table 6.2). By conversion of units, the gray can be expressed as follows:

$$1\ \text{Gy} = 1\ \text{J/kg} = 100\ \text{cGy} = 100\ \text{rad}$$

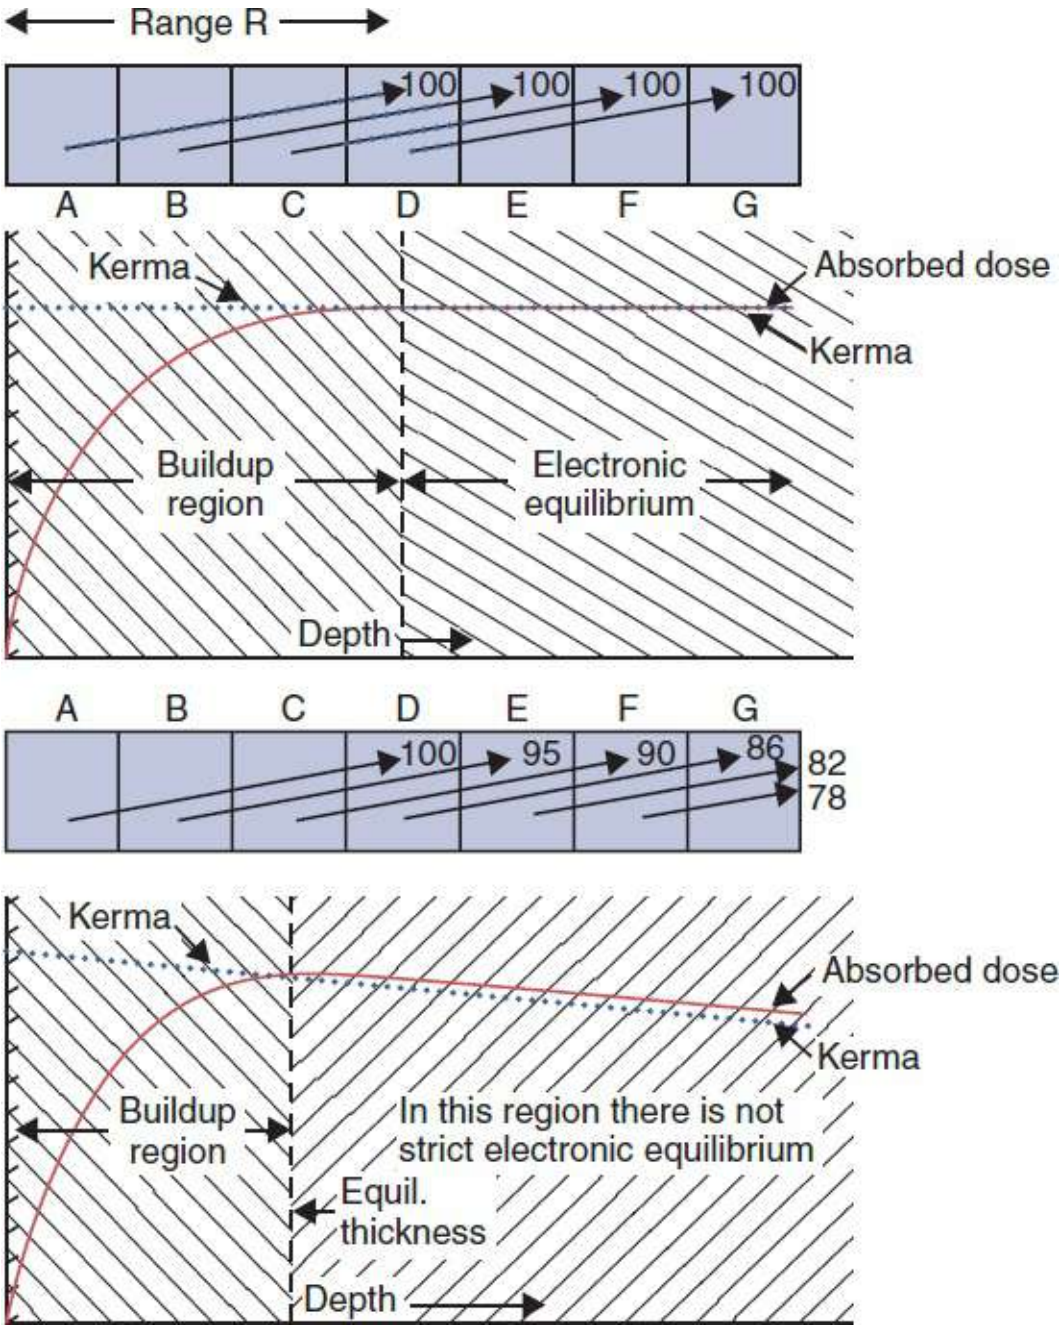

FIGURE 6.29. Graphs showing schematic relationship of kerma and absorbed dose. (From Johns HE, Cunningham JR. *The physics of radiology*. 4th ed. Springfield, IL: Charles C Thomas, 1983:222. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, Illinois.)

Determination of Absorbed Dose

It is difficult to measure absorbed dose directly, but two direct methods —*calorimetry* and *Fricke dosimetry*—are available in some laboratories. Neither method is particularly practical nor widely used, and the reader is referred to the

literature for more details.[71] Instead, a simpler, indirect method using an exposure-calibrated ionization chamber is used to determine absorbed dose.

Absorbed Dose Calculation from Exposure Measurement

For photon energies of ^{60}Co and lower, an ionization chamber having an exposure calibration factor assigned by an appropriate national calibration facility (e.g., a dosimetry calibration laboratory accredited by the National Institute of Standards and Technology or the American Association of Physicists in Medicine [AAPM; College Park, MD]) can be used to measure exposure in air as described in the section "Radiation Exposure." Absorbed dose then can be calculated from the exposure as explained here. The energy deposited in a fixed mass of air from a known exposure can be calculated because it is known that an exposure of 1 R creates a finite number of ion pairs per unit mass of air (i.e., 1.61×10^{15} ion pairs per kilogram of air) and that the mean energy required to create an ion pair in air (denoted by W) is equal to 33.97 eV per ion pair. When these values are used, the relationship between the exposure, X, and the dose to air, D_{air}, is given by the following expression:

$$D_{air}(\text{rad}) = 0.876\left(\frac{rad}{R}\right)\cdot X(R)$$

The *dose in free space*, D_{fs}, is defined as the dose at the center of a small mass of phantom-like material just large enough to provide electronic equilibrium (Fig. 6.30) and can be derived from D_{air} using the ratio of the mass energy-absorption coefficients (u_{en}/ρ) and an attenuation correction factor, A_{eq}, that accounts for the photon attenuation in the small mass of phantom-like material:

$$D_{fs} = \left[0.876\frac{\mu_{en}\rho_{med}}{\mu_{en}\rho_{air}}\right]\cdot X\cdot A_{eq}$$

The term in brackets is called the *f-factor* or the *roentgen-to-rad conversion factor* and is represented as f_{med}, giving the dose in free space as follows:

$$D_{fs} = f_{med}\cdot X\cdot A_{eq}$$

Values of f_{med} are shown in Figure 6.31 over the energy range commonly used in radiation therapy. Notice that the *f*-factor is a function of the medium and

the energy of the photon beam. Typical values of A_{eq} are 0.989 and 1.00 for ^{60}Co and 250-kV energies, respectively.

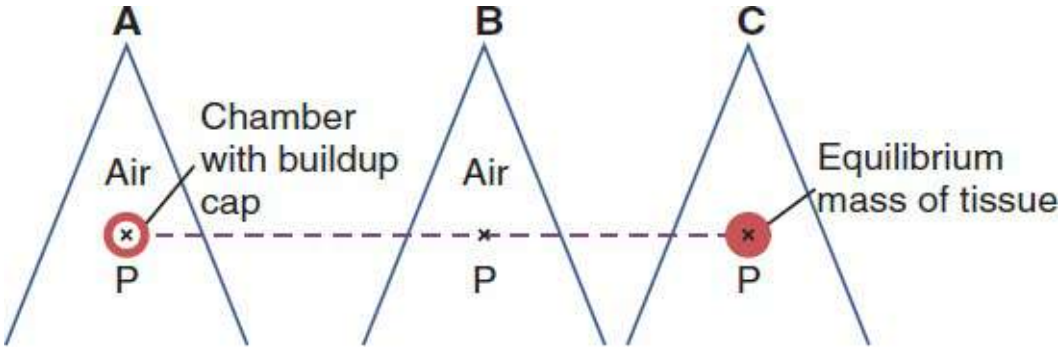

FIGURE 6.30. Schematic illustrating ionization measurement in air to determine dose in free space. (From Khan FM. *The physics of radiation therapy*. 2nd ed. Baltimore: Williams & Wilkins, 1994. With permission.)

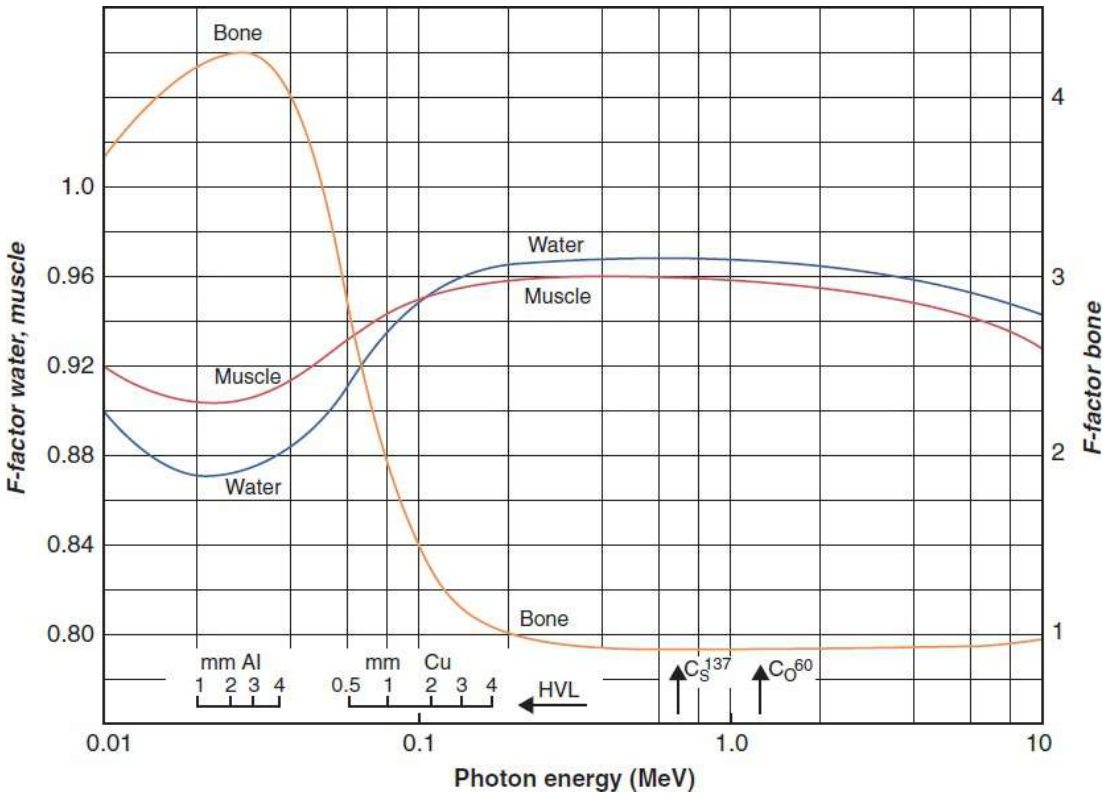

FIGURE 6.31. The roentgen-to-rad conversion factor for bone, muscle, and water as a function of photon energy. (From Johns HE, Cunningham JR. *The physics of radiology*. 4th ed. Springfield, IL: Charles C Thomas, 1983:287. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, Illinois.)

An in-air calibration procedure is performed as follows. The calibrated ion chamber (with wall thick enough to ensure electronic equilibrium) is placed in

air with its sensitive volume on the central axis of the beam and its stem at right angles to the beam direction. The center of the chamber most often is placed at a distance from the source (or target) equal to the nominal SSD of the machine plus the buildup depth. A standard field size is set, usually 10 × 10 cm, using either movable collimators or the standard treatment applicator. An exposure is made for a known time or number of monitor units. The ionization chamber reading is converted to units of Gy/min at the depth of the maximum dose within a phantom, d_{med}, using the following equation:

$$\dot{D}_{med} = \frac{M \cdot N_x \cdot C_{tp} \cdot C_{st} \cdot C_s \cdot A_{eq} \cdot f_{med} \cdot \mathrm{TAR}(d_{max})}{T + \alpha}$$

where M, N_x, C_{tp}, C_{st}, C_s, A_{eq}, f_{med}, T, and α are used as defined earlier. The term TAR(d_{max}) represents the tissue-air ratio at the depth of maximum dose (i.e., the *backscatter* or *peakscatter factor*) and converts the dose in free space to the dose in a phantom at the depth of maximum dose. This parameter is discussed in more detail later. The preceding equation can be rewritten as follows:

$$\dot{D}_{med} = \dot{X} \cdot f_{med} \cdot A_{eq} \cdot \mathrm{TAR}(d_{max})$$

and

$$\dot{D}_{med} = \dot{D}_{fs} \cdot \mathrm{TAR}(d_{max})$$

This method is also valid when the measurements are made with the exposure-calibrated ion chamber embedded within a medium, such as a water phantom. In that case, the TAR(d_{max}) term is not included in the calculation, and the A_{eq} factor is replaced by a displacement factor, A_m. The numerical value of A_m is very close to that of A_{eq}, and for exposure measurements made within a water phantom, the dose rate is given by the following expression:

$$\dot{D}_{med} = \dot{X} \cdot f_{med} \cdot A_m$$

Absorbed Dose Calculation from Bragg–Gray Cavity Ionization Measurement

For energies above the level of ^{60}Co, exposure calibration factors are not available from the standards laboratories because of measurement limitations. In 1983, the AAPM introduced a protocol for the calibration of high-energy photon and electron beams that was based on *Bragg–Gray cavity theory* and allowed

one to calculate dose directly from ion chamber measurements in a medium for energies above the level of ^{60}Co.[72] The protocol updated physical parameters and procedures for calibration and measurement and accounted for the different phantom materials (e.g., plastic and water) used for calibration and differences in ion chamber design and construction. The protocol introduced the *cavity-gas calibration factor*, N_{gas}, which is related to the ion chamber's ^{60}Co exposure calibration factor, N_x, and is used in conjunction with restricted stopping-power ratios, $\bar{L}/\rho$, for the radiation beam in question to convert the ionization reading to absorbed dose using the following expression:

$$D_{med} = M \cdot N_{gas} \cdot (\bar{L}/\rho)^{med}_{gas} \cdot P_{ion} \cdot P_{repl} \cdot P_{wall}$$

where M is the raw ionization chamber reading per monitor unit corrected for temperature and pressure, P_{ion} is the ion-recombination correction factor, P_{repl} is a correction factor for replacement of phantom material by the ionization chamber, and P_{wall} is a correction factor to account for ionization chamber wall composition.

In 1999, the AAPM published a new protocol (TG-51) for the calibration of high-energy photon and electron beams.[73] This protocol uses ion chambers with absorbed-dose-to-water calibration factors, $N^{Co\text{-}60}_{D,W}$, which are traceable to national primary standards via the ^{60}Co standard. The absorbed dose to water D^{Q}_{W}at the point of measurement of the ion chamber placed under reference conditions is given by the following equation:

$$D^{Q}_{W} = M \cdot k_{Q} \cdot N^{Co\text{-}60}_{D,W}$$

where Q is the beam quality of the clinical beam, M is the fully corrected ion chamber reading, and k_Q is the *quality conversion factor* that converts the calibration factor for a ^{60}Co beam to that for a beam of quality Q. The protocol is designed to be a simplification of the AAPM's TG-21 protocol in the sense that large tables of stopping-power ratios and mass energy-absorption coefficients are no longer needed, and the user does not need to calculate any theoretical dosimetry factors.[74–76]

Other Dosimetry Methods

Thermoluminescent Dosimetry

Certain crystalline materials exhibit a phenomenon known as *thermoluminescence*. When a crystal capable of thermoluminescence is

irradiated, a small portion of the energy absorbed is stored in the structure of the crystal lattice. If the material is heated, the energy is released in the form of visible light. Several thermoluminescent phosphors are available, but lithium fluoride, with an effective atomic number of 8.2, is the most commonly used.

The physical theory of thermoluminescent dosimetry can be explained as follows. In the individual atom, electrons occupy discrete energy levels. However, in the crystal lattice, the electronic energy levels are perturbed by mutual interactions between atoms, giving rise to energy bands, so-called *allowed energy bands* and *forbidden energy bands*. Impurities in the crystal create energy traps in the forbidden bands, allowing metastable states to exist; for example, when the phosphor is irradiated, some of the electrons in the valence band (ground state) receive sufficient energy to be raised to the conduction band. If there is an instantaneous emission of light, the phenomenon is called *fluorescence*. If an electron in the trap requires energy to get out of the trap and return to the valence band, the emission of light is called *phosphorescence*. If the emission of light is slow at room temperature but can be sped up with heating, the process is called *thermoluminescence*.

Thermoluminescent dosimeters must be calibrated before they can be used for measuring an unknown dose. Because the response of the thermoluminescent material is affected by its radiation and thermal histories, the material must be annealed to remove residual effects. The standard preirradiation annealing procedure for lithium fluoride is 1 hour of heating at 400°C and 24 hours at 80°C. More details can be found in the review article by DeWerd et al.[77]

Film Dosimetry

When an x-ray film is exposed to ionizing radiation, the exposed silver bromide crystals form a latent image. In the film development process, the affected crystals cause a darkening of the film, and the unaffected crystals leave the film clear. The degree of blackening of the film is proportional to the energy absorbed and is measured by determining the optical density with a densitometer. The optical density is defined as follows:

$$\mathrm{OD} = \log(I_0/I_T)$$

where I_0 is the amount of light detected without the film in place and I_T is the amount of light detected with the film in place. For radiation dosimetry, the net optical density is obtained by subtracting the densitometric reading for the base fog (clear portion of the film) from the measured optical density. Most films are

exposed to yield an optical density between 1.3 and 1.7 for optimal viewing.

A plot of net optical density as a function of radiation exposure or dose is called the *sensitometric curve* or the *Hunter–Driffield (H-D) curve*. If the curve is nonlinear, appropriate corrections must be applied to convert net optical density to absorbed dose.

The use of film is a relatively straightforward method of dosimetry for electron beams, but it must be done with extreme care in photon dosimetry. The problem is that the photoelectric effect depends on Z^3 ($Z_{\text{silver}} = 47$), and the film emulsion strongly absorbs radiation below 100 kV. A concise review of radiographic film dosimetry can be found in the article by Das.[78]

Radiochromic Film Dosimetry

Radiochromic film consists of a thin (7 to 23 mm), radiosensitive, colorless leuco dye bonded to a 100-mm-thick Mylar base. Radiochromic films are colorless before irradiation and turn deep blue when irradiated without physical, chemical, or thermal processing. The film is approximately tissue equivalent, integrates simultaneously at all measurement points, and has a high spatial resolution (>1,200 lines/mm). It shows a stable, reproducible response if protected from ultraviolet light, unstable temperatures, and humidity. Because radiochromic dye is an aromatic hydrocarbon, like plastic scintillators, it has an energy response superior to that of diodes and comparable with thermoluminescent dosimetry. Interest in radiochromic film as a quantitative dosimeter has been stimulated by the appearance of a fourfold-more-sensitive film (model MD-55), which extends its response down to the 5-Gy level. More details on radiochromic film dosimetry are given in the article by Soares et al.[79]

Diode Dosimetry

Semiconductor diodes offer many advantages for clinical dosimetry, including high sensitivity, real-time read-out, robustness, and independence of air pressure. Most semiconductor diodes are made from silicon, which is either *n* type (silicon doped with group V material, such as phosphorus) or *p* type (silicon doped with group III material, such as boron). To form a diode detector, a *p*-*n* junction must be created.

The physical theory of semiconductor dosimetry can be explained as follows. During irradiation, electron–hole pairs are created both within and outside the depletion region in the body of the diode detector. The charge carriers are swept across the depletion region and collected rapidly under the action of the electric

field that exists across it. In this way, a current is generated, flowing in the reverse direction to normal diode current flow, which can be measured and related to absorbed dose.

Dosimetry diodes are operated without an external reverse bias voltage and connected via cable to a simple electrometer. Details on their use for *in vivo* dosimetry are provided in AAPM Report 87.[80] Calibration of diodes typically is performed by comparison of readings against an ion chamber in a standard setup to establish a diode calibration factor for absorbed dose to water and the establishment of a series of correction factors to account for calibration differences when measurements are performed under various experimental conditions. Typical concerns are energy dependence, temperature sensitivity, directional dependence, and radiation damage. Each radiation therapy center should establish the responses of their diodes under the various conditions encountered and monitor them as the cumulative dose to the diodes increases. Frequency of checks should be adjusted according to the frequency of use of the diodes and the variability encountered. More details on diode dosimetry are given in the article by Zhu and Saini.[81]

Metal Oxide Semiconductor-Field Effect Transistor Dosimetry

Metal oxide semiconductor-field effect transistors represent another example of a semiconductor dosimeter. Originally developed for space dosimetry, the operation is based on the buildup of charge in the silicon oxide transistor gate created by ionizing radiation. The reader is referred to the article by Cygler and Scalchi[82] for more details on this type of dosimeter.

Polymer-Gel Dosimetry

Gel dosimetry is based on quantifying the effects of radiation-induced chemical changes occurring within some volume of material filled with an aqueous gel matrix. The degree of chemical change in the gel is related to dose. The dose-dependent changes are determined by imaging techniques, including MRI, CT, and optical CT. Hence, gel dosimetry has the potential to provide full 3D dosimetry throughout the volume of the irradiated gel dosimeter.

For example, one form of this method exploits the radiation-induced free-radical chain polymerization of acrylic monomers dispersed in an aqueous gel. When irradiated, discrete, microscopic regions of cross-linked polymer are formed, the concentration of which is proportional to radiation dose. The water proton nuclear MR relaxation rates in the gel are strongly affected by local

changes in the polymer molecular structure and dynamics; thus, the distribution of radiation dose may be visualized and quantified with high resolution using MRI. Because the polymer microparticles scatter light, the dose distribution also can also be visualized in the transparent gel as a dose-dependent 3D optical turbidity and read by optical CT.

Unfortunately, gel dosimetry, while having the potential for tissue-equivalent 3D dosimetry for a almost three decades, has not come into common clinical use, as it has proven too difficult to use in the clinic setting.[83] Research continues in gel dosimetry, as there is clearly a need for a robust 3D high-resolution dosimetry system.[83,84] Recent publications indicate that these research efforts may result in viable clinical and commercial solutions.[85]

DOSIMETRY PARAMETERS

Percentage Depth Dose

Percentage depth dose (*PDD*) can be understood by reference to Figure 6.32. It is the ratio, expressed as a percentage, of the absorbed dose on the central axis at depth d to the absorbed dose at the reference point d_0. PDD is given by

$$\mathrm{PDD}(d, d_0, S, f, E) = \frac{D_d}{D_{d0}} \times 100$$

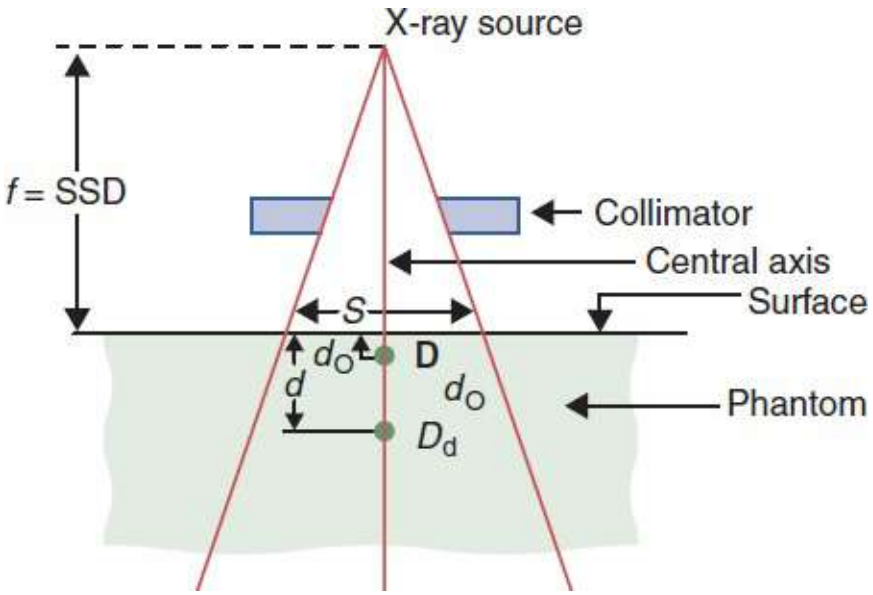

FIGURE 6.32. Schematic drawing illustrating definition of percentage depth dose, where d is any depth and d_0 is the reference depth, usually d_{max}.

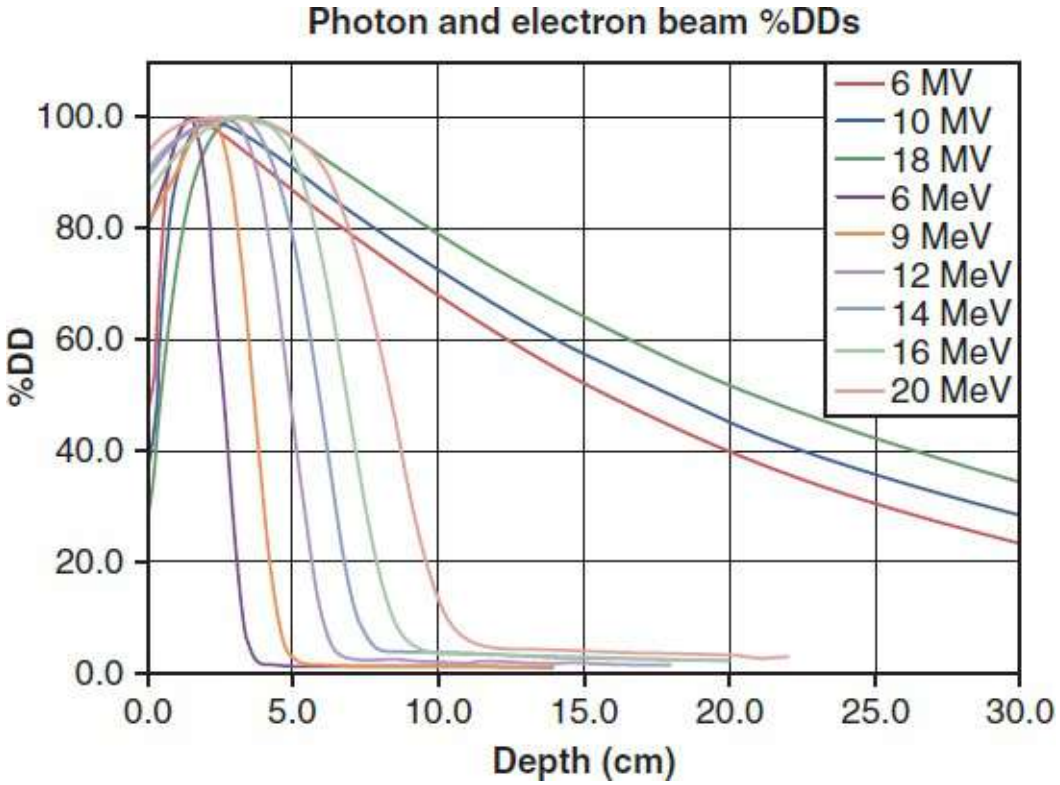

FIGURE 6.33. Examples of central axis percentage depth dose (DD) for megavoltage x-ray beams ranging from ^{60}Co to 18-MV x-rays and 6- to 20-MeV electron beams.

The functional symbols have been inserted in the expression to make it clear that the PDD is affected by a number of parameters, including d, d_0, field dimension S, source-to-surface distance f, and radiation beam energy (or quality) E. S refers to the side length of a square beam at a specified reference depth. Nonsquare beams may be designated by their equivalent square. Field shape and added beam collimation also can affect the central axis depth–dose distribution. Photon-beam PDD increases with increasing energy, SSD, and field size. Figure 6.33 shows that the depth of the 50th percentile increases from approximately 14 cm for 4-MV x-rays to nearly 23 cm for 25-MV x-rays. The depth of maximum dose varies from about 1 cm for 4-MV x-rays to >3.5 cm for 25-MV x-rays.

The PDD for one SSD is related to the PDD at a second SSD by the following equation:

$$\mathrm{PDD}(d, S, f_2) = \mathrm{PDD}(d, S, f_1)\left(\frac{f_1 + d}{f_2 d} \cdot \frac{f_2 + d_{\max}}{f_1 + d_{\max}}\right)^2$$

The term in the brackets is called the *Mayneord F-factor*.[86]

Tissue–Air Ratio

The tissue–air ratio (TAR) is defined as the ratio of the absorbed dose D_d at a given point in the phantom by the absorbed dose in free space, D_{fs}, that would be measured at the same point but in the absence of the phantom, if all other conditions of the irradiation (e.g., collimator, distance from the source) are equal (Fig. 6.34). The TAR is expressed as follows:

$$\mathrm{TAR}(d, S_d, E) = \frac{D_d}{D_{fs}}$$

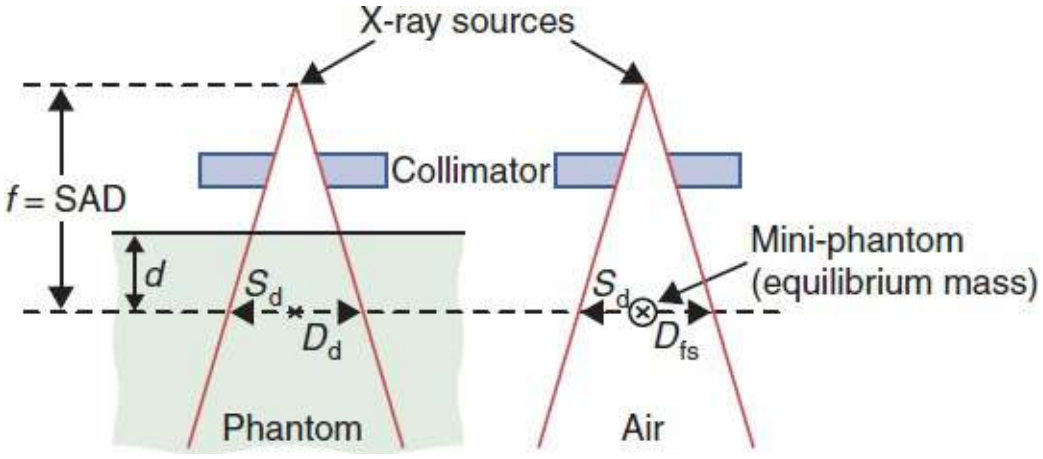

FIGURE 6.34. Schematic drawing illustrating the definition of tissue-air ratio, where *d* is the thickness of overlying material.

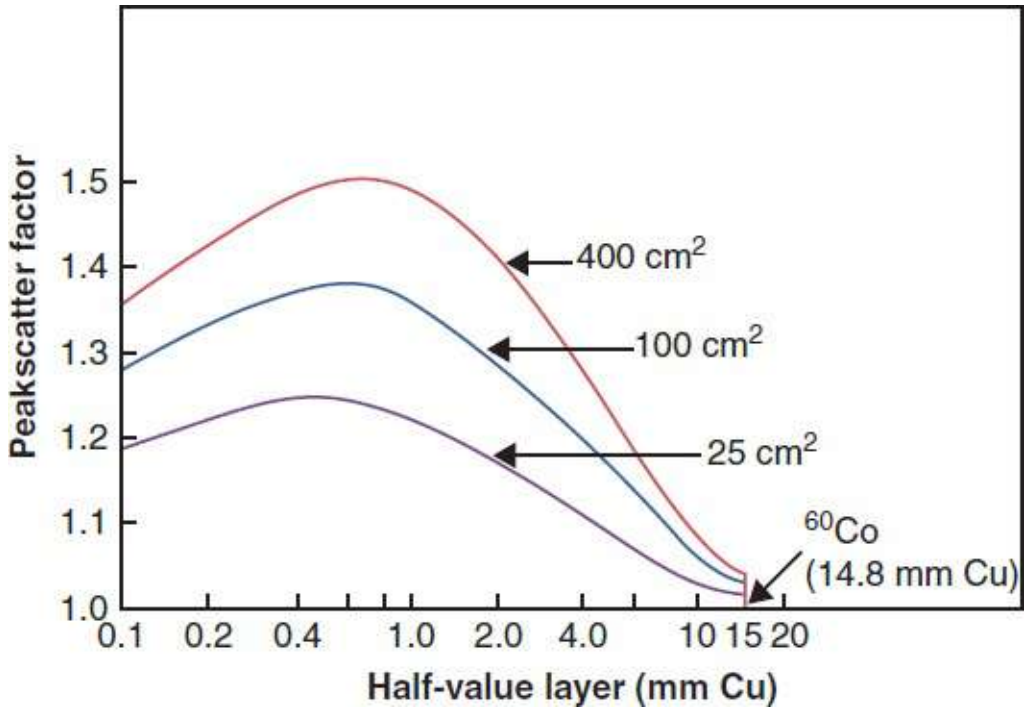

FIGURE 6.35. Variation of peakscatter factor with beam quality (half-value layer). (From Johns HE, Cunningham JR. *The physics of radiology*. 4th ed. Springfield, IL: Charles C Thomas, 1983:248. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, Illinois.)

where d is depth, E is radiation beam energy, and S_d is the beam dimension measured at depth d. TAR depends on depth, field size, and beam quality, but for all practical purposes, it is independent of the distance from the source.

The TAR at the depth of maximum dose is called the *peakscatter factor*. It is perhaps better known as the backscatter factor, but because of the finite depth d_0, this tends to be misleading. Figure 6.35 shows the peakscatter factors for various field sizes and beam qualities.

Tissue–Phantom Ratio and Tissue–Maximum Ratio

The concepts of tissue–phantom ratio (TPR) and tissue–maximum ratio (TMR) were proposed for high-energy radiation as alternatives to TAR in response to arguments raised against the use of in-air measurement for a photon beam with a maximum energy >3 MeV.[87,88] As originally defined, TPR is given by the ratio of two doses:

$$\mathrm{TPR}(d, d_r, S_d, E) = \frac{D_d}{D_{d_r}}$$

where D_{d_r} is the dose at a specified point on the central axis in a phantom with a fixed reference depth, d_r, of tissue-equivalent material overlying the point; D_d is the dose in the phantom at the same spatial point as before but with an arbitrary depth, d, of overlying material; and S_d is the beam width at the level of measurement (Fig. 6.36). In each instance, underlying material is sufficient to provide for full backscatter. There is no general agreement about the magnitude of the reference depth to be used for this quantity, particularly for high energies. The TPR is intended to be analogous to the TAR but has an advantage because the reference dose, D_{d_r}, is directly measurable over the entire range of x-rays and γ-rays in use, eliminating problems in obtaining a value for the dose in free space when the depth for electronic buildup is great.

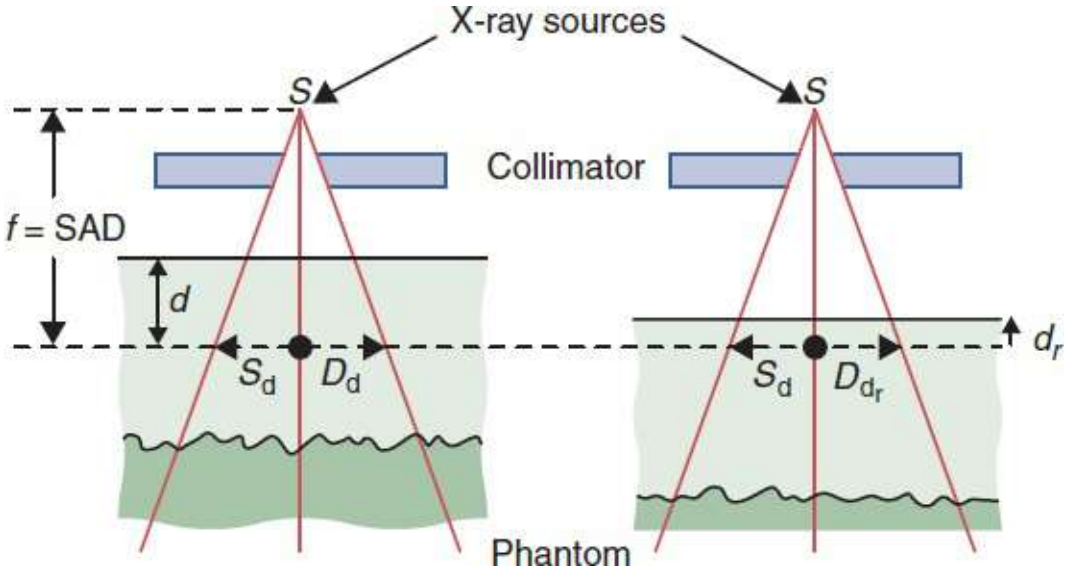

FIGURE 6.36. Schematic drawing illustrating the definition of tissue–phantom ratio and tissue–maximum ratio, where d is the thickness of overlying material and d_r is the reference thickness.

The original TMR definition is similar to the definition of TPR, except that the reference depth, d_r, is the depth of maximum dose. However, the depth of maximum dose for megavoltage x-ray beams varies significantly with field size and also is a function of SSD. Thus, the definition of TMR creates a measurement problem because a variable d_r is required and the TMR depends on SSD. A modification by Khan et al.[89] proposed that the reference depth, d_r, must be equal to or greater than the largest depth of maximum dose.

Purdy[90] reported on the relationships between the central axis PDD and the TPR, TMR, and TAR. This work suggested that the degree to which the TPR and TMR are independent of distance from the radiation source depends largely on the linac's collimator/flattening filter scatter component of the beam.

Scatter–Air Ratio and Scatter–Maximum Ratio

The scatter–air ratio (SAR) can be thought of as the scatter component of the TAR.[91] It is defined as follows:

$$\mathrm{SAR}(d, S_d, E) = \mathrm{TAR}(d, S_d, E) = \mathrm{TAR}(d, 0, E)$$

SAR is the difference between the TAR for a field of finite area and the TAR for a zero-area field size. The zero-area TAR is a mathematical abstraction obtained by extrapolation of the TAR values measured for finite field sizes.

Similarly, the scatter–maximum ratio (SMR), the scatter component of the

TMR, is defined as follows:

$$\mathrm{SMR}(d, S_d, E) = \mathrm{TMR}(d, S_d, E) \cdot \frac{S_p(S_d, E)}{S_p(S_0, E)} - \mathrm{TMR}(d, 0, E)$$

where S_p is a phantom scatter correction factor, which takes into account changes in scatter radiation originating in the phantom at the reference depth as the field size is changed.[89]

Output Factor

The output factor for a given field size is defined as the ratio of the dose rate at the depth of maximum dose for a given field size to that for the reference field size (usually 10 × 10 cm) at its d_{max}. The output factor varies with field size (Fig. 6.37) as a result of two distinct phenomena. As the collimator jaws are opened, the primary dose, D_p, at d_{max} on the central ray per monitor unit increases as a result of a larger number of primary x-ray photons scattered out of the flattening filter. In addition, the scatter dose, $D_s(d_{max}, r)$, at the measurement point per unit D_p increases as the scattering volume irradiated by primary photons increases with increasing collimated field size. These two components can vary independently of one another if nonstandard treatment distances or extensive secondary blocking is used.

Khan et al.[89] described a method for separating the overall output factor, $S_{c,p}$, into two components. One is the collimator scatter factor, $S_c(r_c)$, which is a function only of the collimator opening, r_c, projected to isocenter. The other is the phantom scatter factor, $S_p(r)$, which is a function only of the cross-sectional area or effective field size, r, irradiated at the treatment distance. They demonstrate that

$$S_{c,p}(r) = S_c(r_c) \cdot S_p(r)$$

In practice, the total and collimator scatter factors both are measured and the phantom scatter factor is calculated using the relationship listed previously. $S_c(r_c)$ is measured in air using an ion chamber fitted with an equilibrium-thickness buildup cap and given by the ratio of the reading for the given collimator opening to the reading for a reference field (typically 10 × 10 cm) collimator opening. The overall output factor is measured in-phantom using the standard treatment distance and is given by the reading relative to that for a 10 ×

10 cm field size. By carefully extrapolating this measured ratio to zero-field size, one obtains the zero-field-size phantom scatter factor, $S_p(0)$. If a small-ion chamber is positioned axially in the beam, it is possible to measure $S_{c,p}$ for field sizes as small as 1 × 1 cm. Because of the loss of lateral secondary electron equilibrium encountered near the edges of high-energy photon beams, S_p deviates significantly from unity. Consistent separation of primary and scatter dose components significantly improves the accuracy of dose predictions for irregular field calculations, especially near block edges and the resultant dose falloff resulting from lateral electron disequilibrium, and under blocks, overcoming many of the dose-modeling problems presented by use of extensive customized blocking.

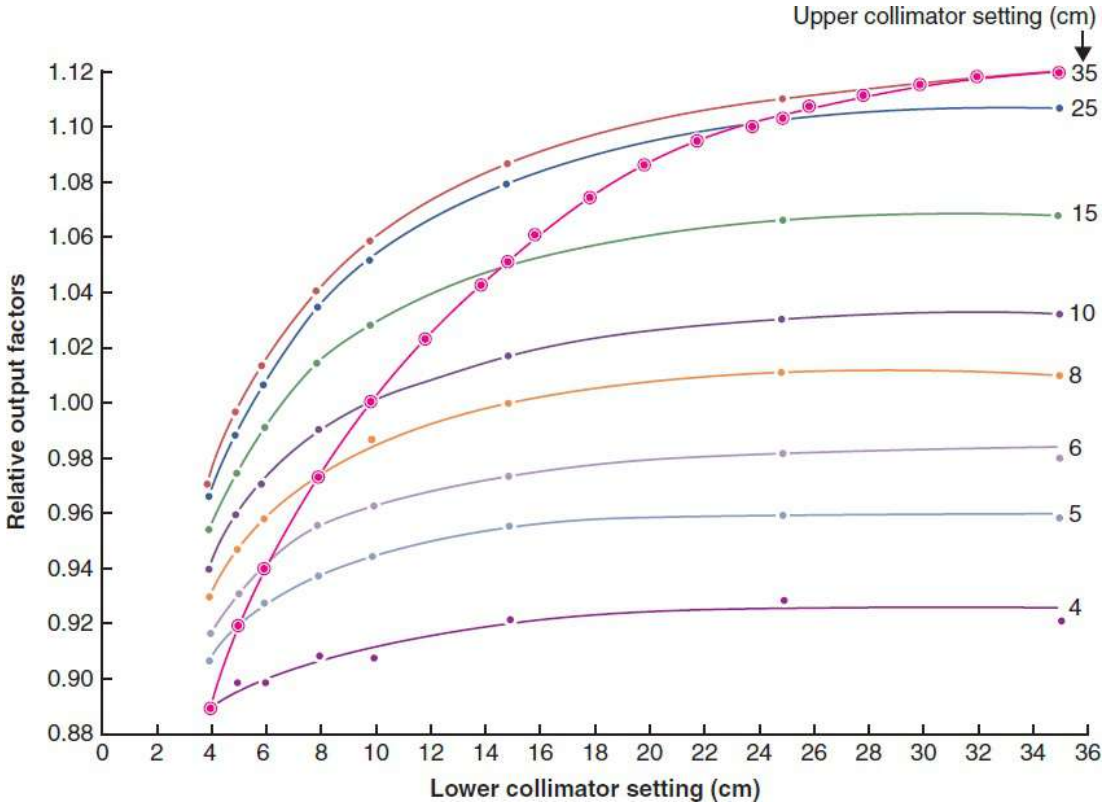

FIGURE 6.37. Example of output factor as a function of lower and upper collimator settings for a medical linear accelerator 18-MV x-ray beam.

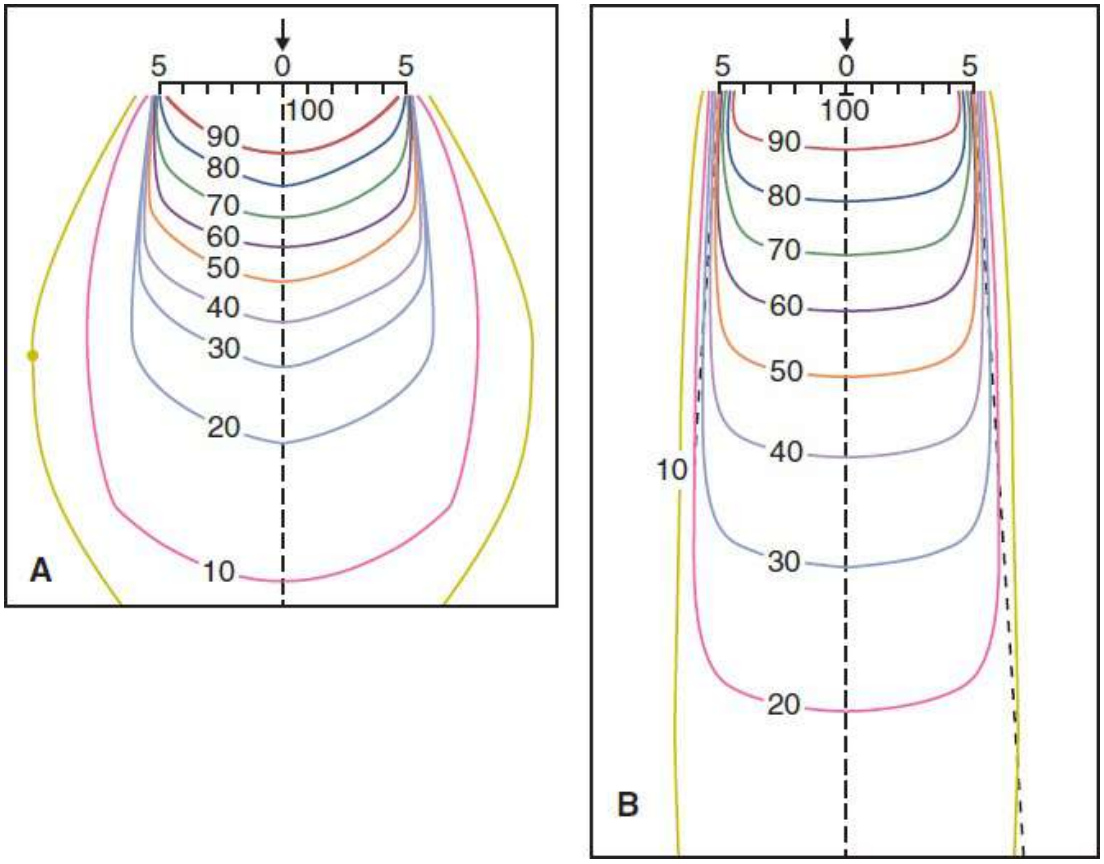
Isodose Curves

An isodose curve represents points of equal dose. A set of these curves, normally given in 10% increments normalized to the dose at the reference depth, can be plotted on a chart (i.e., isodose chart) to give a visual representation of the dose distribution in a single plane (Fig. 6.38). Beam parameters, such as source size,

flattening filter, field size, and SSD, play important roles in the shape of the isodose curve.

Dose Profiles

A dose profile is a representation of the dose in an irradiated volume as a function of spatial position along a single line. Dose profiles are particularly well suited to the description of field flatness and penumbra. The data most often are given as ratios of doses normalized to the dose on the central axis (Fig. 6.39). The profiles, called *off-axis factor*s or *off-center ratio*s, may be measured in air (i.e., with only a buildup cap) or in a phantom at selected depths. The in-air off-axis factor gives only the variation in primary beam intensity; the in-phantom off-center ratio shows the added effect of phantom scatter.



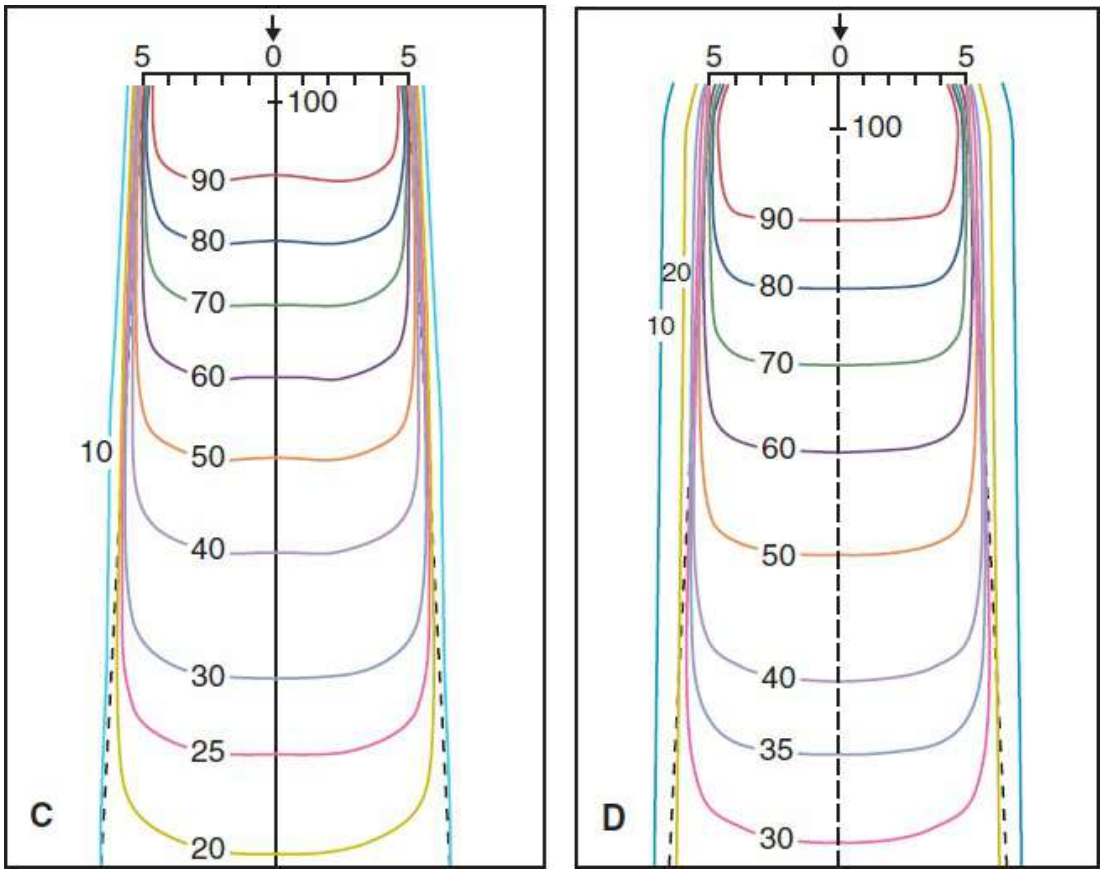


FIGURE 6.38. Isodose distributions for different quality radiations. **A:** 200 kVp, source–skin distance (SSD) = 50 cm, half-value layer (HVL) = 1 mm Cu, field size = 10 × 10 cm. **B:** ^{60}Co, SSD = 80 cm, field size = 10 × 10 cm. **C:** 4-MV x-rays, SSD = 100 cm, field size = 10 × 10 cm. **D:** 10-MV x-rays, SSD = 100 cm, field size = 10 × 10 cm. FIGURE 6.39. Example of dose profiles for an 18-MV linear accelerator x-ray beam measured at depths of 3 and 10 cm.

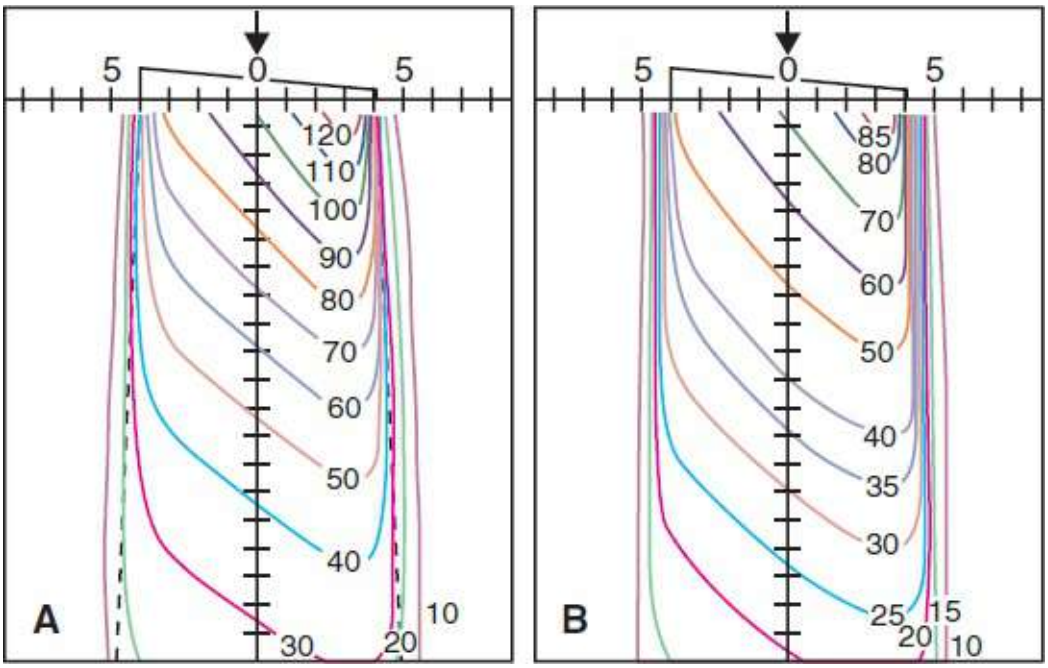

FIGURE 6.40. Isodose curves for a wedge filter. **A:** Normalized to D_{max}. **B:** Normalized to D_{max} without the wedge. ^{60}Co, wedge angle = 45 deg, field size = 8 × 10 cm, source–skin distance = 80 cm. (From Khan FM. *The physics of radiation therapy*. 2nd ed. Baltimore: Williams & Wilkins, 1994. With permission.)

Wedge Filter

Wedge filters, first introduced by Ellis and Miller,[92] generally are constructed of brass, steel, or lead. When placed in the beam they progressively decrease intensity across the field, causing the isodose distribution to have a planned asymmetry.

The wedge angle is defined as the angle the isodose curve subtends with a line perpendicular to the central axis at a specific depth and for a specified field size. Current practice is to use a depth of 10 cm. Past definitions were based on the 50th-percentile isodose curve and, more recently, the 80th-percentile isodose curve. The wedge angle is a function of field size and depth. The wedge factor is defined as the ratio of the dose measured in a tissue-equivalent phantom at the depth of maximum buildup on the central axis with the wedge in place to the dose at the same point with the wedge removed.

Wedge isodose curves can be normalized in different ways, as shown in Figure 6.40. The wedged isodose distribution on the left side of the figure has been normalized to 100% at d_{max} on the central axis with the wedge in place; on the right, the normalization is done without the wedge in place. Thus, it is imperative that the normalization and the use of the wedge factor should be

clearly understood before wedges are used clinically.

Beam hardening occurs when a wedge is inserted into the radiation beam. The PDD, therefore, can be considerably increased at depth. Differences in PDD of nearly 7% have been reported for a 4-MV x-ray, 60-deg wedge field, compared with the open field at a depth of 12 cm, and there have been reports of as much as a 3% difference between the 60-degree wedge field and the open field for a 25-MV x-ray beam.[93,94]

CHAPTER 7

Photon External-Beam Dosimetry and Treatment Planning

James A. Purdy and Sasa Mutic

INTRODUCTION

When planning the treatment of a patient with cancer, the radiation oncologist is faced with the problem of prescribing a treatment regimen with a radiation dose that is large enough to potentially cure or control the disease but does not cause serious normal tissue complications. This task is a difficult one because tumor control and normal tissue effect responses for most disease sites are typically steep functions of radiation dose; that is, a small change in the dose delivered (±5%) can result in a dramatic change in the local response of the tissue (±20%).[1–3] Moreover, the prescribed curative doses are often, by necessity, very close to the doses tolerated by the normal tissues. Thus, for optimum treatment, the radiation dose must be planned and delivered with a high degree of precision.

One can readily compute the dose distribution resulting from photons, electrons, protons, or a mixture of these radiation beams impinging on a regularly shaped, flat-surface, homogeneous unit-density phantom. However, the patient presents a much more complicated situation because of irregularly shaped topography and having tissues of varying densities and atomic composition (called *heterogeneities*). In addition, beam modifiers, such as wedges, compensating filters, or bolus, are sometimes inserted into the radiation beam, further complicating the calculation of the absorbed dose.

In this chapter, several aspects of photon external-beam treatment planning and dosimetry are reviewed, including methods used for dose/monitor unit (MU) calculations, correction for the effects of the patient's irregular surface and internal heterogeneities on the calculated photon dose distribution, isodose distributions for combined fields, field junctions, field shaping and design of treatment aids, and related clinical dosimetry issues.

DOSE CALCULATION METHODS

For purposes of discussion, it is convenient to characterize photon beam dose calculation methods as either *correction based* or *model based*.[4] In the former method, the dose at a given point is calculated using measured central-axis data, for example, percent depth dose (PDD), tissue–air ratios (TARs), tissue-maximum ratios (TMRs), tissue–phantom ratios (TPRs), and off-axis ratios (OARs). These quantities are measured under reference conditions (i.e., in a homogeneous water phantom with a flat surface normal to the incident radiation beam at a standard distance from the x-ray source). Hence, specific correction factors (CFs) are used in planning the treatment of real patients to account for varying patient surfaces, tissue heterogeneities, irregular field shapes, and any beam modifiers used.

In the model-based algorithms, the dose distribution is computed in a phantom or patient from more of a first-principles approach accounting for lateral transport of radiation, beam energy, geometry, beam modifiers, patient surface topography, and electron density distribution rather than correcting parameterized dose distributions measured in a water phantom. These models utilize convolution energy deposition kernels that describe the distribution of dose about a single primary photon interaction site and provide much more accurate results even for complex heterogeneous geometries. Both methods are discussed in the following sections, and more details on model-based photon dose calculation algorithms can be found in the references listed.[4,5] It should be noted that with the evolution of advanced computing methods, modern treatment planning systems generally do not rely on correction methods and are included here for historic reference rather than for practical treatment planning purposes. The correction-based models remain relevant for purposes of manual dose calculations and secondary/independent dose verification applications. However, many of the modern-day independent dose calculation programs include more sophisticated dose calculation algorithms.

Correction-Based Dose Calculation Methods

Using the notation of Khan et al.,[6] the dose at a point (D_P) at a depth d of overlying tissue on the central ray for an irregularly shaped field is given by:

$$D_P = D_{\text{ref}} \cdot S_c(r_c) \cdot S_p(r_d) \cdot \text{TF} \cdot \text{WF} \left(\frac{\text{SCD}}{\text{SAD}}\right)^2 \cdot \text{TMR}(d, r_d)$$

where S_c denotes the *collimator scatter factor;* S_p the *phantom scatter factor;* and TMR the tissue-maximum ratio. TF and WF denote the tray and wedge factors, respectively, and are defined as the ratio of the central ray dose with the tray or wedge filter in place relative to the dose in the open-beam geometry. The collimated field size is denoted by r_c and is usually described as the square field size equivalent to the rectangular collimator opening projected to isocenter. The effective field size is denoted by r_d and is specified to the isocenter distance (SAD). The inverse-square law factor accounts for the difference in distances from the source to point of dose calculation relative to the source to calibration point distance (SCD). Note that when isocentric calibration is used, this factor is unity. Also, note that collimator-defined field size is used for lookup of the collimator scatter factor, S_c, whereas effective field size projected to isocenter is used for lookup of the TMR value and the phantom scatter factor, S_p. By separately accounting for the effect of collimator opening on the primary dose component and the influence of cross-sectional area of tissue irradiated, most of the difficulties in accurately calculating a dose in the presence of extensive blocking are overcome. Details on determining the effective field size for an irregularly shaped field, taking into account both the primary and scatter dose components, will be discussed in a later section.

Correction for Varying Patient Topography (Air Gaps)

In the previous equation, it is assumed that the beam is normally incident on a unit-density uniform phantom. The following CF methods can be applied to the equation to account for the nonnormal beam incidence caused by the patient's varying surface.[7]

Air Gap CF: Ratio of Tissue–Air Ratio Method

In the ratio of TAR or TPR method, the surface (along a ray line) directly above point A (source-to-skin distance [SSD] = S′) is unaltered, so the primary component to the dose distribution at this point is unchanged (and the scatter component is also assumed to be unaltered) (see Fig. 7.1). Thus, the dose at point A can be considered as unaltered by patient shape. However, for point B, where there are considerable variations in the patient's topography, both the primary and scatter components of the radiation beam are altered. The CF may be determined using two TARs or TPRs as follows:

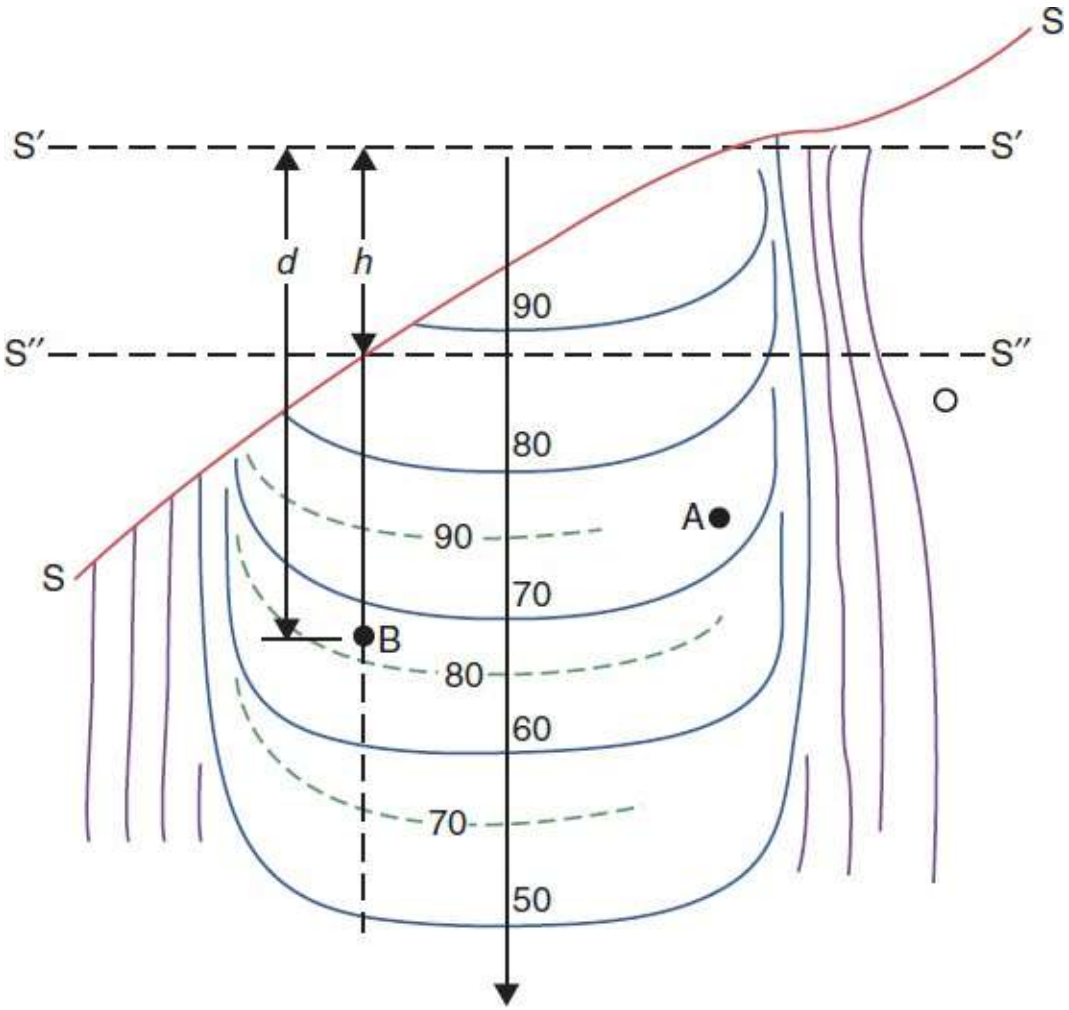

FIGURE 7.1. Schematic drawing illustrating tissue–air ratio and effective source-to-skin distance (SSD) methods for the correction of isodose curves under a sloping surface (*solid lines* for SSD = S'; *dashed lines* for SSD = S″). (From International Commission of Radiation Units and Measurements. Report 24: Determination of absorbed dose in a patient irradiated by beams of × or gamma rays in radiotherapy procedures. Washington, DC: International Commission of Radiation Units and Measurements, 1976. Reproduced by permission of International Commission on Radiation Units and Measurements.)

$$\mathrm{CF} = \frac{T(d-h, s_d)}{T(d, s_d)}$$

where h = air gap.

Air Gap CF: Effective Source–Skin Ratio Method

In the effective SSD method, the isodose chart to be used is placed on the patient's contour representation, positioning the central axis at the distance for which the curve was measured (Fig. 7.1). It then is shifted down along the ray

line for the length of the air gap, h, resulting in SSD = S″. The PDD value at point B is read and modified by an inverse-square calculation to account for the effective change in the peak dose. The CF can be expressed as follows:

$$\mathrm{CF} = \frac{P(d-h, d_0, S, f, E)}{P(d, d_0, S, f, E)} \cdot \left(\frac{f + d_0}{f + h + d_0} \right)^2$$

Correction for Tissue Heterogeneities

The following CF methods can be used to account for the tissue heterogeneities found within the patient.

Tissue Heterogeneities CF: Ratio of Tissue–Air Ratio Method

The ratio of TAR (RTAR) method of correction for inhomogeneities is given by

$$\mathrm{CF} = \frac{T(d_{\mathrm{eff}}, S_d)}{T(d, S_d)}$$

where the numerator is the TAR for the equivalent water thickness, d_{eff}, and the denominator is the TAR for the actual thickness, d, of tissue between the point of calculation and the surface along a ray passing through the point. S_d is the dimension of the beam cross section at the depth of calculation. The RTAR method accounts for the field size and depth of calculation. It does not account for the position of the point of calculation with respect to the heterogeneity. It also does not take into account the shape of the inhomogeneity; instead, it assumes that it extends the full width of the beam and has a constant thickness (i.e., referred to as *slab geometry*).

Tissue Heterogeneities CF: Power Law TAR Method

The *power law TAR method* was proposed by Batho[8] and generalized by Young and Gaylord.[9] This method, sometimes called the *Batho method*, attempts to account for the nature of the inhomogeneity and its position relative to the point of calculation. However, it does not account for the extent or shape of the inhomogeneity. The CF for the point P is given by

$$\mathrm{CF} = \left(\frac{T(d_2, S_d)}{T(d_1, S_d)} \right)^{\rho_2 - 1}$$

where d_1 and d_2 refer to the distances from point P to the near and far side of the

non–water-equivalent material, respectively; S_d is the beam dimension at the depth of P; and ρ_2 is the relative electron density of the inhomogeneity with respect to water.

Sontag and Cunningham[10] derived a more general form of this CF, which can be applied to a case in which the effective atomic number of the inhomogeneity is different from that of water and the point of interest lies within the inhomogeneity. The CF in this situation is given by

$$\mathrm{CF} = \frac{T(d_2, S_d)^{(\rho_b - 1)}}{T(d_1, S_d)^{(\rho_b - \rho_a)}} \times \frac{(\mu_{en}/\rho)_a}{(\mu_{en}/\rho)_b}$$

where *ra* is the density of the material in which point P lies at a depth *d* below the surface and r_b is the density of an overlying material of thickness $(d_2 - d_1)$; $(\mu_{en}/r)_a$ and $(\mu_{en}/r)_b$ are the mass energy absorption coefficients for the medium *a* and *b*.

Model-Based Dose Calculation Methods

Advanced three-dimensional dose calculation algorithms, such as the convolution/superposition algorithm and Monte Carlo, have for many years now been the standard of practice.[4,5,11–13] These models provide accurate results even for complex heterogeneous geometries.

Convolution/Superposition Dose Calculation Algorithm

The convolution/superposition dose calculation algorithm is based on the following equation[4]:

$$D(\vec{r}) = \iiint T_E(\vec{s}) h(E, \vec{r} - \vec{s})\, d^3 s\, \mathrm{dE}$$

where *D* represents the dose at some point, $T_E(\vec{s})$ represents the total energy released by primary photon interactions per unit mass (or TERMA), and $h(E, \vec{r} - \vec{s})$ is the *point spread function* (also called *dose spread array*, *differential pencil beam*, and *energy deposition kernel*). The point spread function represents the fraction of the energy deposited (per unit volume) at a point that is subsequently transported to the calculation point. Hence, the dose at a point is computed by integrating over all space the dose contributions from photons and electrons that are produced at all other points in the phantom or patient.

Ahnesjö et al.[14] showed that the point spread function, $h(E, \vec{r} - \vec{s})$, changes only slightly as a function of energy and, thus, can be replaced by $h(\vec{r} - \vec{s})$

(defined as the average point spread function weighted by the spectral components of the beam), reducing the basic convolution four-dimensional integral to a three-dimensional integral overall space. Point spread functions for monoenergetic photons are generally precomputed using Monte Carlo methods.[14] The energy dependence of the TERMA, $T_E(\vec{s})$, can be expressed by applying the inverse-square law and exponential attenuation to the photon fluence at the surface of the phantom or patient.

The three-dimensional integral is typically evaluated in a two-step process. The first step takes into account the properties of the accelerator (including the finite source size, primary collimator, flattening filter, collimator jaws, multileaf collimators, and any beam-modifying devices used for the treatment, such as wedges, alloy blocks, and compensating filters) to compute the energy fluence at the phantom or patient surface. The second step of the calculation takes into account the inverse-square law and exponential attenuation to this incident fluence to determine the TERMA, T_E $(\vec{s})$, at each point within the phantom or patient and convolve the result with the point spread function, $h(\vec{r} - \vec{s})$.

The convolution equation is strictly valid only for homogeneous media (i.e., $h(\vec{s})$ must be spatially invariant). To account for the effects of tissue heterogeneities, all physical distances in the convolution integral are replaced with radiologic distances, that is, the physical distance multiplied by the average density along the line in question.[11,14] Hence, the convolution/superposition algorithm accounts for the effects of heterogeneities anywhere in the vicinity of the calculation point in three dimensions. In contrast, most CF-based dose calculation techniques require only a simple one-dimensional evaluation of radiologic path length and can thus account for the effects of only those tissue heterogeneities that lie along a ray connecting the radiation source to the calculation point.

Several investigators have tested the convolution/superposition algorithm against measurements and Monte Carlo–generated data for complex phantom geometries including both homogeneous and heterogeneous phantoms and found that the convolution/superposition model gave accurate results, even in parts of the buildup region and penumbra.[15,16]

Monte Carlo Method

Monte Carlo is, in principle, the only method capable of computing the dose distribution accurately for all situations encountered in radiation therapy, including being able to accurately predict the dose near interfaces of materials

with very dissimilar atomic numbers, such as near metal prostheses, or different densities such as tumors in lung tissue.[17] The Monte Carlo method uses the known cross sections for electron and photon interactions in matter and follows individual photons and the associated electrons set in motion through the entire heterogeneous phantom or patient. By calculating the trajectories and interactions of a very large number of photons and electrons, one can accurately model the dose distribution. Recently, several Monte Carlo codes have been developed for radiotherapy treatment planning,[13,18] many of which have been implemented commercially. The reader is referred to the American Association of Physicists in Medicine (AAPM) Task Group (TG) 105 Report, which summarizes commercial use of Monte Carlo for radiation therapy treatment planning.[12] The reader is also referred to the review article by Siebers et al. for even more details on Monte Carlo calculation for external-beam radiation therapy.[17] More recently, Monte Carlo dose calculations have been extended to account for magnetic field effects on deposition of radiation dose for MR-guided treatment machines.[19–21]

Dose Calculation Algorithms and Tissue Heterogeneities

In 2004, the AAPM published Report 85 (Task Group 65) on tissue inhomogeneity corrections for megavoltage photon beams.[22] The task group recommended an accuracy goal for tissue heterogeneity corrections of 2% in order to achieve an overall 3% accuracy in dose delivery. The AAPM report recommended heterogeneity corrections be applied to plans and prescriptions, with the condition that the algorithm used for calculations be reviewed and rigorously tested by the medical physicist. A brief summary of the site-specific recommendations follows. For the head and neck region, a one-dimensional path correction algorithm for point-dose estimations beyond mandible and ear cavities was thought to be reasonable. However, for soft tissue regions and volumes that are adjacent to these heterogeneities, superposition/convolution or Monte Carlo algorithms should be used. For the larynx, specifically, if the target volume is adjacent to the air cavity or if there is a severe case of disease in the anterior commissure, then either the superposition/convolution or Monte Carlo algorithms should be used. For treatment of lung cancer, for interest points well beyond the lung interface, one-dimensional path corrections were thought to be reasonable. However, accounting for doses at tumor–lung interfaces, the superposition/convolution or Monte Carlo algorithms should be used. Also, the report recommended that photon energies of 12 MV or less should be used for

treatment of lung cancer in order to minimize nonequilibrium conditions that exist with higher energies. For breast cancer treatment (particularly if the dose of interest of the target volume is considered to be chest wall), it is recommended that calculations be performed with superposition/convolution or Monte Carlo. However, for simple intact breast planning, one-dimensional algorithms were adequate. For the upper gastrointestinal tract, one-dimensional corrections were adequate. However, one should be leery if barium contrast is used as it can erroneously impact the dose calculation because of its high Z. In terms of the pelvis and prostate, one-dimensional corrections were quite reasonable except in the presence of high-Z implanted hip prostheses. (Note that the dosimetric considerations for patients with hip prostheses undergoing pelvic irradiation are discussed in a later section). The study by Frank et al.[23] provides a clear method for safely transitioning clinical use from one based on planning that assumes a homogeneous unit-density patient to one using a heterogeneous patient model.

The Radiological Physics Center published the results of a study comparing measured results of irradiated lung phantoms having various geometries with dose calculations for similar conditions using commercial treatment planning systems. They found significant differences if algorithms less sophisticated than the superposition-/convolution-type algorithms were used.[24]

MONITOR UNIT CALCULATION METHODS

MU calculations refer to determining the linac MU setting per field to deliver the prescribed dose taking into account the tumor depth, treatment distance, multileaf collimator setting or secondary blocking configuration, and primary collimator opening. This is accomplished by using the various dosimetric quantities described in the preceding chapter to relate the dose corresponding to an arbitrary set of treatment parameters to the reference calibration geometry where the output of the machine is specified in terms of cGy/MU. The reference source to calibration point distance, field size, and depth of output specification are denoted by the symbols SCD, r_{cal}, and d_{cal}, respectively. For a fixed SSD calibration geometry:

$$\mathrm{SCD} = \mathrm{SAD}\,(\text{source} - \text{axis distance}) + d_{max}$$
$$r_{cal} = 10\ \mathrm{cm} \times 10\ \mathrm{cm}$$
$$d_{cal} = d_{max}$$

Normal incidence and open-beam geometry (i.e., absence of trays or any beam-modifying filters) are specified.

For treatment machines calibrated isocentrically, the point of MU specification is located at distance SAD rather than at distance SAD + d_{max} as stated previously. For isocentric calibration, SCD = SAD.

The linac is calibrated by adjusting the sensitivity of its internal monitor transmission ion chamber so that 1 MU equals 1 cGy for the reference calibration geometry condition. Several reports providing more details on MU calculations and their verification are listed in the references.[25–27]

MU Calculation for Fixed Fields

When the patient is to be treated isocentrically, the point of dose prescription is located at the isocenter regardless of the target depth. Using the notation of Khan et al.,[6] the MU needed to deliver a prescribed tumor dose to isocenter (TD_{iso}) for a depth d of overlying tissue on the central ray is given by

$$MU = \frac{TD_{iso}}{TMR(d, r_d) \cdot S_c(r_c) \cdot S_p(r_d) \cdot TF \cdot WF \left(\frac{SCD}{SAD}\right)^2}$$

where TF and WF denote the tray and wedge factors, respectively. They are defined as the ratio of the central ray dose with the tray or wedge filter in place relative to the dose in the open-beam geometry. The collimated field size is denoted by r_c and is usually described as the square field size equivalent to the rectangular collimator opening projected to isocenter. The effective field size is denoted by r_d and is always specified to the isocenter distance (SAD). The inverse-square law factor accounts for the difference in distances from the source to point of dose prescription relative to the point of MU specification. When isocentric calibration is used, this factor is unity. Note that collimator-defined field size is used for lookup of the collimator scatter factor, S_c, whereas effective field size projected to isocenter is used for lookup of TMR and the phantom scatter factor, S_p. By separately accounting for the effect of collimator opening on the primary dose component and the influence of cross-sectional area of tissue irradiated, most of the difficulties in accurately delivering a dose in the presence of extensive blocking are overcome.

When a fixed distance between the target and entry skin surface (SSD) is used to treat the patient, a dose calculation formalism based on PDD is used rather

than one based on isocentric dose ratios. When a dose TD is to be delivered to depth *d*, MUs are given by:

$$\mathrm{MU} = \frac{\mathrm{TD} \cdot 100}{\mathrm{PDD}(\mathrm{SSD}, d, r) \cdot S_c(r_c) \cdot S_p(r) \cdot \mathrm{TF} \cdot \mathrm{WF} \left(\frac{\mathrm{SCD}}{\mathrm{SSD} + d_{\max}} \right)^2}$$

The field size (or its equivalent square) on the skin surface at central axis is denoted by r and is used for lookup of both PDD and S_p. The collimated field size r_c at the isocenter must be used for lookup of S_c. When an extended treatment distance is used, the collimated field size at isocenter differs significantly from that at the skin surface of the patient. Note that PDD is a function of SSD, depth, and effective field size. Collimator scatter factors measured at SAD are valid over a wide range of extended treatment distances.[6]

When this dose calculation formalism for highly extended treatment distances such as encountered in administering total-body irradiation is used, care must be taken to verify the validity of inverse-square law at these distances. It is recommended that such setups always be verified by ion chamber measurement at the extended distance. Because of the large scatter contribution to effective primary dose originating from the flattening filter and other components in the treatment head, the virtual source of radiation may be as much as 2 cm proximal to the target of the accelerator.

The TAR system of dose calculation is a widely used alternative to the Khan formalism. It is simply an extension of the familiar TAR and backscatter factor concepts, as used in ^{60}Co and orthovoltage dosimetry, to the megavoltage photon energy range. The needed dosimetry parameters are determined from ion chamber measurements (both in-phantom and in-air) like those performed for ^{60}Co, but now using a much larger buildup cap (radius thickness = $d_{\max}$). Thus, the megavoltage peak scatter factor, PSF(r), for an effective field size r is simply the ratio of the two ion chamber readings as shown here.

$$\mathrm{PSF}(r) = \frac{\text{ionization at depth } d_{\max} \text{ in phantom}}{\text{ionization with buildup cap in air at same point in space}}$$

And the megavoltage beam dose rate (Gy/MU) in free space, $\dot{D}_{fs}$, is given by

$$\dot{D}_{fs}(\mathrm{SAD}+d_{\max},r_c)=\frac{\dot{D}(\mathrm{SSD},r_c,d_{\max})}{\mathrm{PSF}(r_c)}$$

where the numerator is the measured d_{max} dose at distance SSD = SAD + d_{max} and collimator setting r_c. Implementation of this system requires a table of $\dot{D}_{fs}$ (SAD + d_{max}, r_c) values for each collimator opening and a table of PSF versus effective field size. Then, dose at d_{max} per MU for any distance, effective field size, and collimator opening can be calculated easily.

When the patient is to be treated isocentrically, the MU needed to deliver a prescribed isocenter dose (ID) to a depth *d* on the central axis is given by:

$$\mathrm{MU}=\frac{\mathrm{ID}}{\mathrm{TAR}(d,r_d)\cdot\dot{D}_{fs}(\mathrm{SAD}+d_{\max},r_c)\cdot\mathrm{TF}\cdot\mathrm{WF}\cdot\left(\frac{\mathrm{SCD}}{\mathrm{SAD}}\right)^2}$$

If the treatment is fixed SSD, the MU needed to deliver a prescribed dose (TD) to a depth d on the central ray is given by:

$$\mathrm{MU}=\frac{\mathrm{TD}\times 100}{\mathrm{PDD}(d,r)\cdot\dot{D}_{fs}(\mathrm{SAD}+d_{\max},r_c)\cdot\mathrm{PSF}(r)\cdot\mathrm{TF}\cdot\mathrm{WF}\cdot\left(\frac{\mathrm{SCD}}{\mathrm{SSD}+d_{\max}}\right)^2}$$

All MU calculation formalisms require some means of estimating the square field size, *r*, that is equivalent, in terms of scattering characteristics, to an arbitrary rectangular field of width *a* and length *b*. Perhaps the most widely used rectangular equivalency principle is the “A/P” rule. It states that a square and a rectangle are equivalent if they have the same area/perimeter ratio; that is:

$$r=\frac{2(a\times b)}{(a+b)}$$

Another widely used approach to reducing rectangular estimates of effective field size to square field sizes is the equivalent square table published in the *British Journal of Radiology*.[28] Estimating the effective field size equivalent to an irregular field is best handled via irregular-field calculations as discussed later in this chapter.[29,30]

MU Calculations for Asymmetric X-Ray Collimators

Asymmetric x-ray collimators (also referred to as independent jaws) allow

independent movement of an individual jaw and may be available for one jaw pair or both pairs. Because MU calculations and treatment planning methods generally rely on symmetric jaw data, the dosimetric effects for asymmetric jaws must be fully documented before being implemented in the clinic. Several investigators have examined the effects of asymmetric jaws on PDD, collimator scatter, and isodose distributions.[31,32] MU calculations for asymmetric jaws are only slightly more complex than for symmetric jaws.[25] Typically, one simply applies an *off-axis ratio (OAR)* or *off-center ratio (OCR)* CF that depends only on the distance from the machine's central axis to the center of the independently collimated open field.[33,34] PDD is only minimally affected, but isodose curve shape can be altered and must be investigated for the particular treatment unit. Calculations for asymmetric wedge fields follow similar procedures by simply incorporating a wedge OAR or OCR.[32,35]

MU Calculations for Multileaf Collimator

Multileaf collimators (MLCs) have nearly completely replaced conventional alloy field shaping for photon beams in most clinics around the world. Several investigators have examined the effects of the Varian MLC design (tertiary system) on PDD, collimator scatter, and isodose distributions.[36] The effects due to field area shaped by this type of MLC on PDD and beam output parameters are similar to those resulting from Cerrobend field shaping. Thus, the dose/MU calculation methods discussed previously apply by simply using the equivalent area defined by the MLC. The collimator scatter factor and the dose in free space are determined using the x-ray collimator jaw settings, with an off-axis factor applied for any asymmetric jaw settings.

It should be noted, however, that for MLC systems that replace one of the collimating jaws, the MLC field shape can be a determining factor in selecting the appropriate output factor.[37] For example, in the case of the Elekta linacs (Elekta AB, Crawley, United Kingdom), in which the lower jaws are replaced by the MLC system, the calculation takes into consideration the collective blocked area that is created by both the MLC leaves and the lower backup diaphragms.[38] For an MLC system that replaces the upper jaw (e.g., Siemens linac, Siemens Medical Solutions USA, Inc., Malvern, PA), Das et al.[39] describe a method that relies on the blocked area for determining all the calculation parameters (mainly output, PDD, and scatter factor).

Hence, because of MLC design differences and the fact that vendors are continuing to modify/improve MLC designs, the authors caution that when a

new linac is installed, the impact of the MLC on the institution's MU calculation procedure should be fully documented before clinical use. The reader is also encouraged to review the AAPM Task Group 50 Report, which provides more detail on various MLC types and discusses quality assurance (QA) and MU calculations.[40]

MU Calculations for Irregular Fields

For large, irregularly shaped fields and at points off the central axis, it is necessary to take account of the off-axis change in intensity (relative to the central axis) of the beam, the variation of the SSD within the field of treatment, the influence of the primary collimator on the output factor, and the scatter contribution to the dose. Changes in the beam quality as a function of position in the radiation field also should be considered.[41,42]

The general method used for irregular-field calculations consists of summation at each point of interest of the primary and scatter irradiation, with allowance for the off-axis change in intensity (off-axis factor) and SSD.[29,30] The MUs required to deliver a specified tumor dose at an arbitrary point in an irregular field (Fig. 7.2) can be calculated as follows:

$$\mathrm{MU} = \frac{\mathrm{TD}}{[\mathrm{TAR}(d,0) + \overline{\mathrm{SAR}}(d)] \cdot \dot{D}_{fs}(\mathrm{SSD} + d_{\max}, r_c) \cdot \mathrm{TF} \cdot \mathrm{OAF}\left(\frac{\mathrm{SSD} + d_{\max}}{\mathrm{SSD} + g + d}\right)^2}$$

where the parameters used are

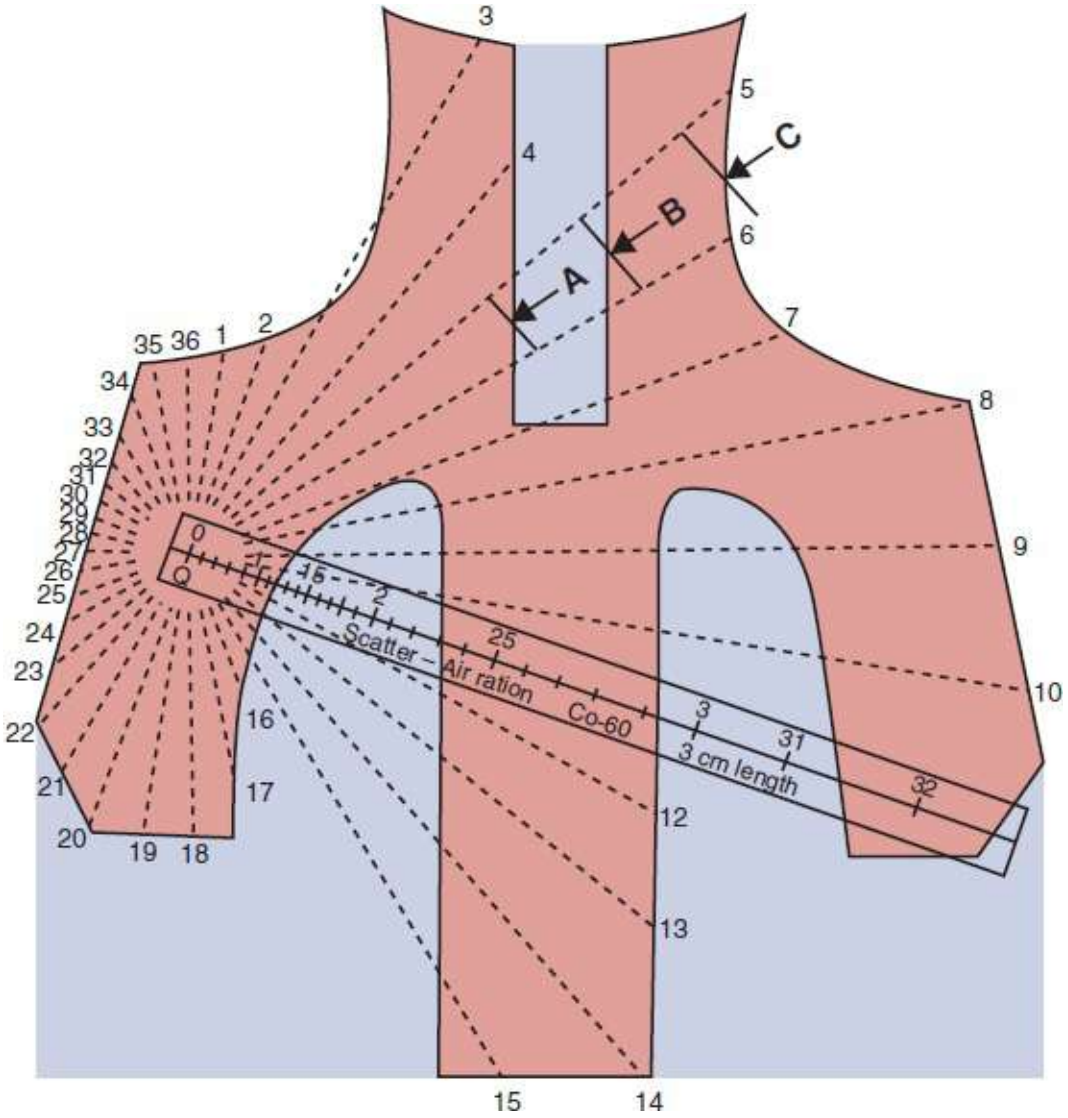

FIGURE 7.2. Outline of mantle field illustrating method of determining scatter-to-air ratio, used for irregular-field dose calculations. (From Cundiff JH, Cunningham JR, Golden R, et al. A method for the calculation of dose in the radiation treatment of Hodgkin's disease. *Am J Roentgenol* 1973;117:30–34. Reprinted with permission from the American Journal of Roentgenology.)

TAR (d,0) = zero-field size TAR at depth d

SAR (d) = average SAR for point in question at depth d determined using the Clarkson technique

D_{fs} = Gy/MU in a small mass of tissue, in-air, on the central axis at normal SSD + d_{max} for the collimated field size

SSD = nominal SSD for treatment constraints

d_{max} = depth of dose maximum

TF = blocking tray attenuation factor

g = vertical distance between skin surface over point in question and nominal SSD = (bean vertical)
d = vertical depth, skin surface to point in question
OAF = in-air off-axis factor

Computer implementations vary but typically include using the expanded field size at a depth for the SAR calculation, determining the off-axis factor using the distance from the central axis to the slant projection of the point of calculation to the SSD plane along a ray from the source and determining the zero-area TAR using the slant depth along a ray going from the source to the point of calculation. It is generally accepted that the off-axis factor should be multiplied by the sum of the zero-area TAR and the SAR as originally proposed.

Beam quality is a function of position in the field for beams generated by linear accelerators.[41,42] The TAR_0 may be expressed as a function of position in the beam so that changes in beam quality can be incorporated into calculations, and it can be related to the half-value layer (HVL) of water by the following equation:

$$\mathrm{TAR}(d,0,r) = e\left[\frac{-0.693(d-d_{\max})}{\mathrm{HVL}(r)}\right]$$

where d is the depth of the point of reference, $d_{\max}$ is the depth of maximum dose, r is the radial distance from the central axis of the beam to the point of calculation, e is the base of the natural logarithm, and HVL(r) is the beam quality expressed as the HVL measured in water.

MU Calculations for Rotation Therapy

The classic method for MU calculations for rotation therapy is given by the following equation:

$$\mathrm{MU} = \frac{\mathrm{ID}}{\mathrm{TAR}_{\mathrm{avg}} \cdot \dot{D}_{fs} \left(\frac{\mathrm{SCD}}{\mathrm{SAD}}\right)^2}$$

and the MU per degree setting is given by

$$\mathrm{MU/deg} = \frac{\text{monitor unit setting}}{\text{degrees of rotation}}$$

where the symbols have the previous meaning and TAR_{avg} is an average TAR

(averaged over radii [depth in the patient] at selected angular intervals, such as 10 or 20 degrees).

Most recently, manufacturers of linacs and their associated planning systems have introduced features that provide rotational intensity-modulated radiation therapy (IMRT) capability[43,44] (e.g., Elekta VMAT[45] and Varian RapidArc[46]). The linac-based rotational IMRT concept was first proposed by Yu[47,48] and called *intensity-modulated arc therapy (IMAT)*, but planning software was not commercially available at that time. Rotational IMRT approaches on conventional linacs may provide even more conformal dose distributions delivered in a shorter treatment time, compared with *SMLC-IMRT (step and shoot)* or *DMLC-IMRT (dynamic)* approaches that use only a limited number of gantry directions. In addition, plan optimization is simpler because it eliminates the planner's iterative choices of beam number and direction. MU calculations for this more complex form of rotational therapy are generated via advanced treatment planning systems having this capability. All are techniques in which the MLC shape changes during a rotation therapy, and depending on the specific linac, other parameters, such as dose rate, may also change. This advanced type of treatment delivery is currently predominantly checked via phantom measurements rather than manual calculations prior to the patient's treatment. Secondary computer programs can also be used to perform independent dose calculations and MU as well as 3D dose calculations.

It is apparent that the simple MU manual calculation methods described here are no longer adequate for the complex technologies in use today. Modern computer plans utilize dose weight points of interest, which classical MU calculation methods may not address; in addition, geometries that include the presence of heterogeneities, added tertiary devices such as MLCs and asymmetric jaws, and beam intensity modulation can all be problematic for manual check calculations. For example, when the dose weight point is within a small volume of mass surrounded by low-density tissue (e.g., a coin lesion in lung) or one that is at the border of a chest wall and lung (as in a postmastectomy patient), MU calculations cannot easily be confirmed by simple hand-calculated MU methods, and one must rely on the planning system for calculations such as these, emphasizing the importance of fully testing such system prior to clinical use. Dedicated commercial software for MU verification is widely available; for example, RadCalc (LifeLine Software Inc, Austin, TX)[49,50] offers a variety of independent MU beam on time calculations, including that for the Gamma Knife (software developed at Washington

University and licensed to RadCal).[51] Obviously, such systems must be validated by the physics user prior to clinical use.

CLINICAL PHOTON BEAM DOSIMETRY

Percent Depth Dose and Single-Field Isodose Charts

The central-axis PDD expresses the penetrability of a radiation beam. Table 7.1 summarizes beam characteristics for x-ray and γ-ray beams typically used in radiation therapy and lists the depth at which the dose is maximum (100%) and the 10-cm depth PDD value. Representative PDD curves are shown in Figure 7.3 for conventional SSDs. As a rule of thumb, an 18-MV, 6-MV, and ^{60}Co photon beam loses approximately 2%, 3.5%, and 4.5% per centimeter, respectively, beyond the depth of maximum dose, d_{max} (values are for a 10- × 10-cm field, 100-cm SSD). There is no agreement as to what is the single optimal x-ray beam energy; instead, institutional bias or radiation oncologist training typically influences its selection, and it is usually treatment site specific. As pointed out in Chapter 6, most modern linacs are multimodality and provide a range of photon and electron beam energies ranging from 4 to 25 MV, with 6-, 10-, and 15-MV x-ray beams becoming the most common. It should be noted that in the case of IMRT, the impact of energy on the quality of the delivered radiation dose distribution is less compared to 2D and 3DCRT treatments and that all recent developments in radiotherapy use lower-energy beams exclusively (e.g., CyberKnife, TomoTherapy, ViewRay, Halcyon).[52] The choice of high-energy beams in the era of predominantly IMRT delivery likely has much larger effect on operational efficiency and facility design than on the quality of delivered radiation. Selection of treatment machines with the highest energy of 10 MV or less results in simplification of radiotherapy treatment rooms, typically allowing elimination of the maze and use of thinner and faster room entry doors. These shielding gains come from the elimination of shielding requirements for secondary neutron radiation.

TABLE 7.1 BEAM CHARACTERISTICS FOR PHOTON BEAM ENERGIES OF INTEREST IN RADIATION THERAPY

200 kVp, 2-mm Cu HVL, SSD = 50 cm

- Depth of maximum dose = surface
- Rapid falloff with depth due to (a) low energy and (b) short SSD
- Sharp beam edge due to small focal spot

- Significant dose outside beam boundaries due to Compton scattered radiation at low energies

^{60}CO, SSD = 80 cm

- Depth of maximum dose = 0.5 cm
- Increased penetration (10 cm PDD = 55%)
- Beam edge not as well defined—penumbra due to source size
- Dose outside beam low because most scattering is in forward direction
- Isodose curvature increases as the field size increases

4-MV x-ray, SSD = 80 cm

- Depth of maximum dose = 1–1.2 cm
- Penetration slightly greater than cobalt (10 cm PDD = 61%)
- Penumbra smaller
- “Horns” (beam intensity off-axis) due to flattening filter design ≈14%

6-MV x-ray, SSD = 100 cm

- Depth of maximum dose = 1.5 cm
- Slightly more penetration than ^{60}Co and 4 MV (10 cm PDD = 67%)
- Small penumbra
- Horns (beam intensity off-axis) due to flattening filter design ≈9%

15- to 18-MV x-ray, SSD = 100 cm

- Depth of maximum dose = 3–3.5 cm
- Much greater penetration (10 cm PDD = 80%)
- Small penumbra
- Horns (beam intensity off-axis) due to flattening filter design ≈5%
- Exit dose often higher than entrance dose

HVL, half-value layer; PDD, percentage depth dose; SSD, source-to-skin distance.

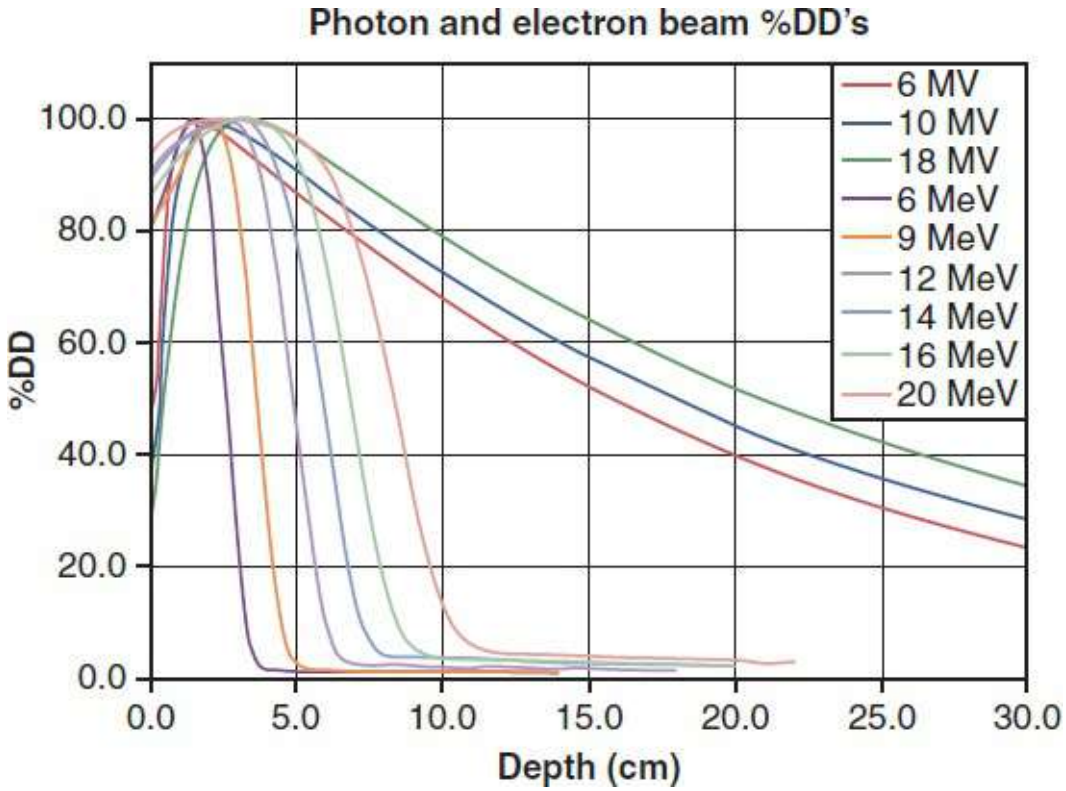

FIGURE 7.3. Typical photon and electron beam central-axis percentage depth-dose (DD) curves for a 10- × 10-cm beam for megavoltage beams ranging from ^{60}Co to 18-MV x-rays and 6- to 20-MeV electron beams.

Isodose charts provide much more information about the radiation beam characteristics than do central-axis PDD data alone. However, even isodose charts are limited in that they represent the dose distribution in only one plane (typically the one containing the beam's central axis) and are usually available only for square or rectangular fields. Isodose charts are usually measured in a water phantom with the radiation beam directed perpendicular to the phantom's flat surface. Isodose curves show the relative uniformity of the beams across the field at various depths and also provide a graphical depiction of the width of the beam's penumbra region. ^{60}Co teletherapy units exhibit a relatively large penumbra, and their isodose distributions are more rounded than those from linac x-ray beams. This is due to the relatively large source size (typically 1 to 2 cm in diameter vs. only a few millimeters for linacs). Linac beam penumbra width does increase slightly as a function of energy and if unfocused MLC leaves are used but is still much less than that for ^{60}Co units. The beam penumbra can be improved if focused MLCs are used. For example, the ViewRay's ^{60}Co could produce treatment plans equivalent in quality to that of modern linacs. This equivalence between ^{60}Co and linac plans was achieved

through combining ^{60}Co with doubly focused MLCs on ViewRay.[53] This ability to improve the IMRT plan quality through MLC design will undoubtedly lead to further refinements in approaches to MLC design. ViewRay's double-layer doubly focused and Varian Halcyon's dual-layer MLCs are early indication of this possibility. In addition to the smaller penumbra, linac x-ray isodose distributions have relatively flat isodose curves at depth. However, at shallow depths, particularly at d_{max}, linac x-ray beams typically exhibit an increase in beam intensity away from the central axis; this beam characteristic is referred to as the dose profile *horns* and depends on flattening filter design. In general, each treatment unit has unique radiation beam characteristics, and thus, isodose distributions must be measured, or at least verified, for each specific treatment unit. Excellent dosimetric reproducibility between modern treatment machines has been observed, and there is now a trend toward verification of the expected beam dosimetry rather than attempting to fully characterize dosimetry for each machine.[54]

Another important point to understand is how the radiation field size is defined. The radiation field size dimensions refer to the distance perpendicular to the beam's direction of incidence that corresponds to the 50% isodose at the beam's edge. It is defined at the skin surface for SSD treatments, and at the SAD for isocentric treatments.

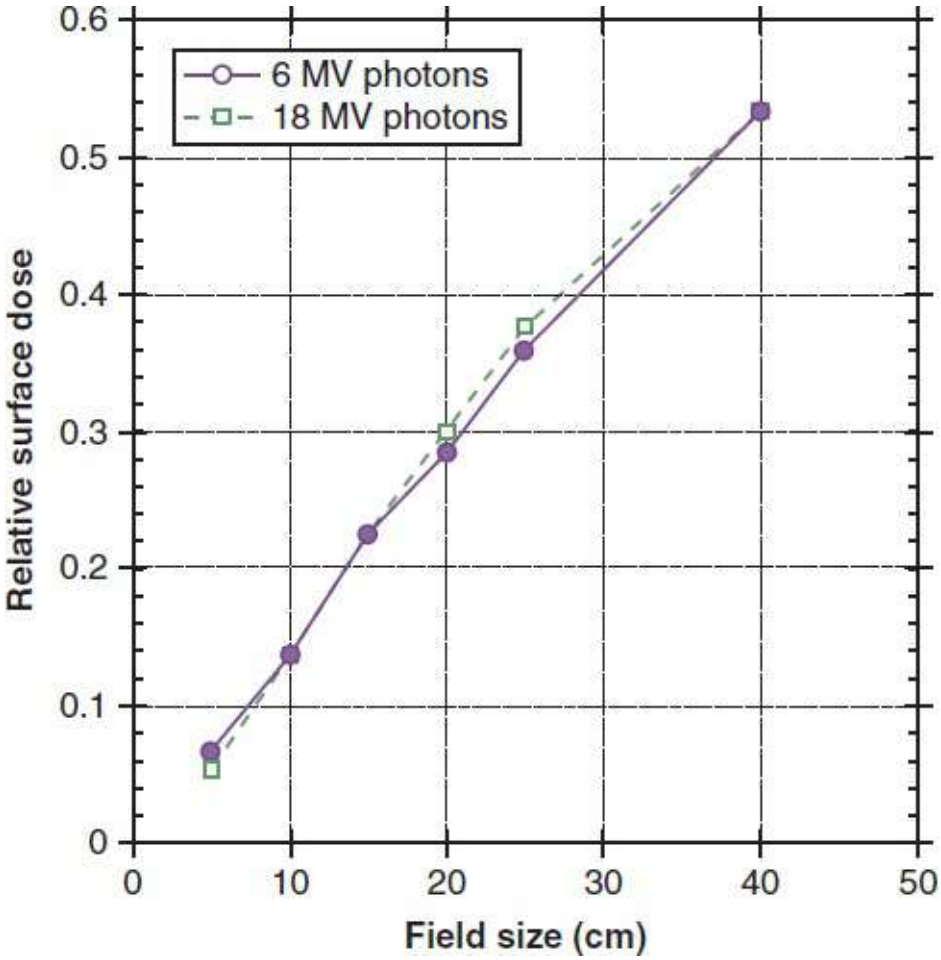

FIGURE 7.4. Relative surface dose versus field size with blocking tray in place for 6- and 18-MV photons. (Reprinted from Klein EE, Purdy JA. Entrance and exit dose regions for Clinac-2100 C. *Int J Radiat Oncol Biol Phys* 1993;27[2]:429–435. Copyright © 1993 Elsevier. With permission.)

Depth-Dose Buildup Region

When a photon beam strikes the tissue surface, electrons are set in motion, causing the dose to increase with depth until the maximum dose is achieved at depth d_{max}. As the energy of the photon beam increases, the thickness of the buildup region is increased. The subcutaneous tissue-sparing effects of higher-energy x-rays, combined with their great penetrability, make them well suited for treating deep lesions. In general, the dose to the surface and in the buildup region for megavoltage photon beams generally increases with increasing field size and with the insertion of blocking trays made of plastic or other type of material in the beam (Fig. 7.4). The blocking trays should be at least 20 cm above the skin surface because skin doses are significantly increased for lesser distances. Copper, lead, or lead glass filters beneath the blocking tray can be used to

remove the undesired lower-energy electrons that contribute to skin dose, but this is nowadays rarely done routinely in the clinic.[55,56]

As the angle of the incident radiation beam becomes more oblique, the surface dose increases, and d_{max} moves toward the surface (Fig. 7.5). This is primarily due to more secondary electrons' contribution from the media below the surface along the oblique path of the beam.[57]

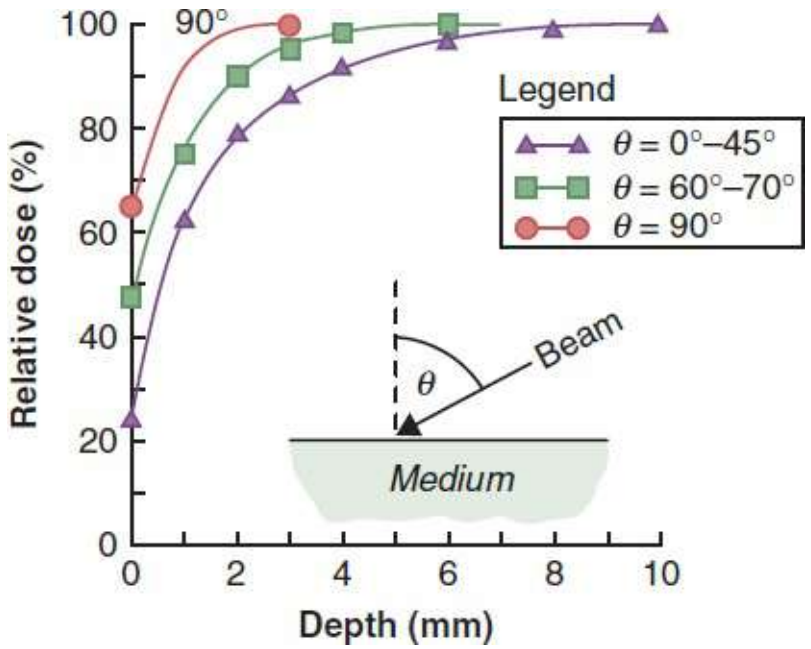

FIGURE 7.5. The variation of surface dose and depth of maximum dose as a function of the angle of incidence of the x-ray beam with the surface (4 MV, 10 × 10 cm).

Depth-Dose/Exit Dose Region

The skin and superficial tissue on the side of the patient from which the beam exits receive a reduced dose if there is insufficient backscatter material present. The amount of dose reduction is a function of x-ray beam energy, field size, and the thickness of tissue that the beam has penetrated reaching the exit surface. For a 6-MV beam, a 15% reduction in dose with little dependency on field size has been reported,[55] and for 18-MV beams, an 11% reduction in exit dose was measured.[58] In general, the addition of a thickness of tissue-equivalent material on the exit side equivalent in thickness to approximately two-thirds of the d_{max} depth is sufficient to provide full dose to the build-down region on the exit side. Figure 7.6 shows the effects of various backscattering media when placed directly behind the exit surface.

Tissue Heterogeneities and Tissue Interface Dosimetry

The presence of tissue heterogeneities, such as air cavities, lungs, bony structures, and prostheses, can greatly impact the calculated dose distribution. The change in dose is due to the perturbation of the transport of primary and scattered photons and that of the secondary electrons set in motion from photon interactions. Depending on the energy of the photon beam and the shape, size, and constituents of the inhomogeneities, the resultant change in dose can be large.

Perturbation of photon transport is more noticeable for lower-energy beams. There is usually an increase in transmission, and therefore dose, when the beam traverses a low-density inhomogeneity. The reverse applies when the inhomogeneity has a density higher than that of water. However, the change in dose is complicated by the concomitant decrease or increase in the scatter dose. For a modest lung thickness of 10 cm, there will be about a 15% increase in the dose to the lung for a ^{60}Co or 6-MV x-ray beam, but only about 5% for an 18-MV x-ray beam.[59]

When there is a net imbalance of electrons leaving and entering the region near an inhomogeneity (interfaces of different media), the condition of electron equilibrium is disrupted. The dose distribution in the patient in such transition zones depends on radiation field size (scatter influence), distance between interfaces (e.g., air cavities), differences between physical densities and atomic number of the interfacing media, and the size and shape of the different media. Because electrons have finite travel, the resultant change in dose is usually local to the vicinity of the inhomogeneity but may be quite large. The effects are more noticeable for the higher photon energy beams because of the increased energy and range of the scattered electrons. Near the edge of the lungs and air cavities, the reduction in dose can be larger than 15%.[60]

For inhomogeneities with density larger than water, there will be an increase in dose locally due to the generation of more electrons. However, most dense inhomogeneities have atomic numbers higher than that of water so that the resultant dose perturbation is further compounded by the perturbation of the multiple Coulomb scattering of the electrons. Near the interface between a bony

structure and water-like tissue, large hot and cold dose spots can be present. Several benchmark measurements have been reported for various geometries simulating clinical situations and are discussed briefly in the following sections.

Air Cavities

Air cavities that appear in various locations of the body, most particularly in the head and neck region, pose a problem because of loss of equilibrium at the air–tissue boundaries internal to the patient. Epp et al.[61] reported that for cobalt beams, a reduction in dose of approximately 12% was found for a typical larynx air cavity, which recovered within 5 mm in the new buildup region. The loss was due to a lack of forward scattered electrons. Epp et al.[62] reported that for a 10-MV x-ray beam, a 14.5% loss was measured at the distal interface of the air cavity with a buildup curve that plateaued within 20 mm of the interface. Klein et al.[63] measured distributions about air cavities for 4-MV and 15-MV x-ray beams in both the distal and proximal regions. The combined dose distribution in a parallel-opposed fashion showed a 10% loss at the interfaces for both beam energies.

Lung Tissue

Although the problem of reestablishing equilibrium for lung interfaces is not as severe as with air cavities, a transition zone region at the lung–tissue interface still exists over the range of typical clinical photon beam energies. Rice et al. measured responses within various simulated lung media for 4- and 15-MV x-rays using a parallel-plate ion chamber and a phantom constructed of solid water and simulated lung material (average lung material density, $\rho = 0.31$ g/cm^3; some additional measurements made with materials having densities of 0.015 and 0.18 g/cm^3).[64] Figure 7.7 shows the results in terms of measured CFs for the 15-MV beam. A considerable buildup curve was observed (10% change in CF) for small fields (5×5 cm^2) for the 15-MV beam, which began in the distal region of the lung and plateaued about 5 cm beyond the simulated lung interface.

Bone–Soft Tissue Interfaces

Das et al.[65] measured dose perturbation factors (DPFs) proximal and distal for simulated bone–tissue interface regions using a parallel-plate chamber for both 6- and 24-MV x-ray beams. They reported DPFs of 1.1 for the 6-MV beam and 1.07 for the 24-MV beam at the proximal interface. At the distal interface, a DPF of 1.07 was measured for the 24-MV beam, whereas the 6-MV beam exhibited a DPF of 0.95, resulting in a new buildup region in soft tissue. Note that both

buildup and build-down regions dissipate within a few millimeters from the interfaces and the perturbations are independent of thickness and lateral extent of the bone or radiation field size.

Metal Prostheses

Das and associates measured DPFs following a 10.5-mm-thick stainless steel layer simulating a hip prosthesis geometry.[65] They reported a DPF of 1.19 for 24-MV photons, but only 1.03 for 6-MV photons; on the proximal side, they reported a DPF of 1.30 due to the backscattered electrons that was independent of energy, field size, or lateral extent of the steel. These interface effects dissipated within a few millimeters in polystyrene. Other reports dealing with dosimetry perturbations due to metal objects are included in the references.[66,67]

Niroomand-Rad et al. reported on dose perturbation effects at the tissue–titanium alloy implant interfaces in patients with head and neck cancer treated with 6- and 10-MV photon beams.[68] They found at the upper surface (toward the source) of the tissue–dental implant interface DPFs of 1.22 and 1.20 for the 6- and 10-MV photon beams, respectively. At the lower interface, dose reduction was approximately −13.5% and −9.5% for the 6- and 10-MV beams, respectively.

The most complete information currently available on hip prosthesis dosimetry is found in AAPM Report 81 (TG 63).[69] The report provides the current state of scientific understanding and clinical dosimetry in use for patients with high-Z hip prostheses undergoing radiation therapy. Beam arrangements that avoid the prosthesis should always be a first consideration. If this cannot be done, valuable information is available in Report 81, including values for different prostheses' electron density, approximate attenuation of the beam passing through the prosthesis, and possible dose increase to the hip bone. It should also be noted that some of the data provided and recommendations are also applicable to patients having other implanted high-Z prosthetic devices such as pins and humeral head replacements.

Silicone–Soft Tissue Interfaces

Klein and Kuske reported on interface perturbations with silicone breast prostheses.[70] Such prostheses have a density similar to breast tissue but have a different atomic number. They observed a 6% enhancement at the proximal interface and a 9% loss at the distal interface.

Wedge Filter Dosimetry

When a wedge filter is inserted into the beam, the dose distribution is angled at some specified depth to some desired angle relative to the incident beam direction over the entire transverse dimension of the radiation beam (Fig. 7.8). For cobalt units, the depth of the 50% isodose usually is selected for specification of the wedge angle, whereas for high-energy linacs, higher-percentile isodose curves, such as the 80% curve, or the isodose curves at a specific depth (10 cm) are used to define the wedge angle.

Linacs are typically equipped with multiple wedges that may be used with an allowed range of field sizes. Although linac wedges can be designed for any

desired *wedge angle*, 15-, 30-, 45-, and 60-degree wedges are the most common.

Some linacs (Elekta AB, Sweden) feature a single wedge, referred to as a *universal wedge*, located in the treatment head, and the desired wedged dose distribution is obtained by the proper combination of wedged and unwedged treatment. A simple approximate model for combining open and wedged fields was first proposed by Tatcher,[71] in which the effective wedge angle q_E, resulting by the addition of a wedged and unwedged beam, is equal to the nominal wedge angle q_W for the wedged beam, weighted by the fraction of wedged field B:

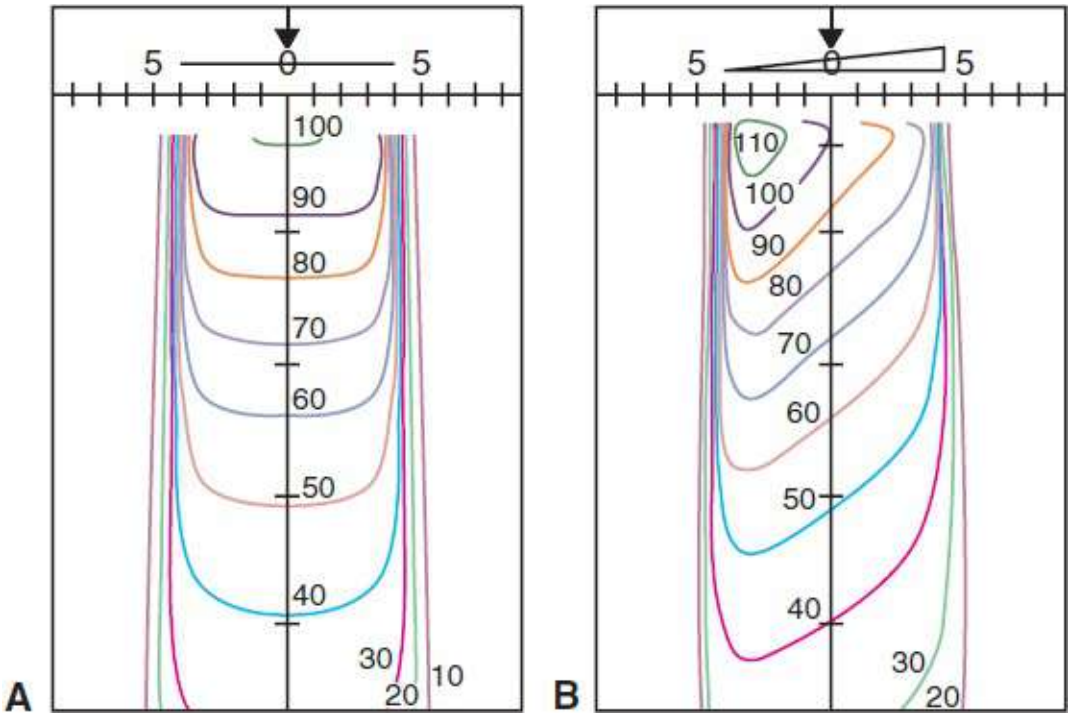

FIGURE 7.8. Isodose distributions for a 6-MV x-ray beam with an 8- × 8-cm field size. **A:** Open field. **B:** Field with a 45-degree wedge. (From Khan FM. *The physics of radiation therapy*. 2nd ed. Baltimore: Williams & Wilkins; 1994. With permission.)

$$B = \theta_E / \theta_W$$

The Philips Medical Systems Division[72] proposed a slightly different method as follows:

$$B = \tan(\theta_E)/\tan(\theta_W)$$

Petti and Siddon[73] investigated both methods and showed that these are approximations to an exact theoretical solution, which is given by

$$B = f/([\tan(\theta_W)/\tan(\theta_E)] + f - 1)$$

Most importantly, their investigations showed that Tatcher's approximation is good only for values of $q_W < 45$ degrees and thus is inadequate for accelerators such as Elekta, which use a 60-degree motorized universal wedge. They did show that for the field sizes studied (up to 20 × 20 cm), the Philips relationship was valid to within 3 degrees.

The wedged isodose curves can be normalized in two different ways. In some older systems, the wedge dose distributions have the wedge factor (i.e., the ratio of the measured central-axis dose rate with and without the wedge in place) incorporated into the wedged isodose distribution. More commonly, the wedge isodose curves are normalized to 100% at d_{max}, and a separate *wedge factor* is used to calculate the actual treatment MUs or time. McCullough et al.[74] noted that wedge factors measured at d_{max} usually are accurate to within 2% for depths up to 10 cm but, at greater depths, can be inaccurate to 5% or more. The inclusion (or noninclusion) of the wedge factor is an extremely important point to understand because serious error in dose delivered to the patient can occur if used improperly.

Sewchand et al.[75] and Abrath and Purdy[76] pointed out that beam hardening results when a wedge is inserted into the radiation beam. The PDD, therefore, can be considerably increased at depth. Differences reported were nearly 7% for a 4-MV 60-degree wedge field PDD from the open field PDDs at 12-cm depth, and a 3% difference in depth-dose values between the wedge field and the open field for a 60-degree wedge using 25-MV x-rays was reported.

Modern computer-controlled medical linacs now have software features that allow the user to create a wedge-shaped dose distribution by moving one collimator jaw across the field in conjunction with adjustment of the dose rate over the course of the daily single-field treatment.[77] This technology provides superior dose distributions and eliminates the previously mentioned beam-hardening problem seen in physical wedges. This feature can deliver a greater number of wedge angles, and over larger field sizes, including asymmetric field sizes (30 cm in the wedge direction, with 20 cm toward the wedge "heel" and 10 cm toward the wedge "toe"). The increased number of angles enhances planning options but also complicates commissioning and QA.[78]

When the patient's treatment is planned, wedged fields are commonly arranged such that the angle between the beams, the *hinge angle (q)*, is related to the wedge angle (φ) by the following relationship (Fig. 7.9):

$$\theta = 90 \text{ degrees} - \phi / 2$$

For example, as shown in Figure 7.10, 45-degree wedge fields orthogonal to one another yield a uniform dose distribution.

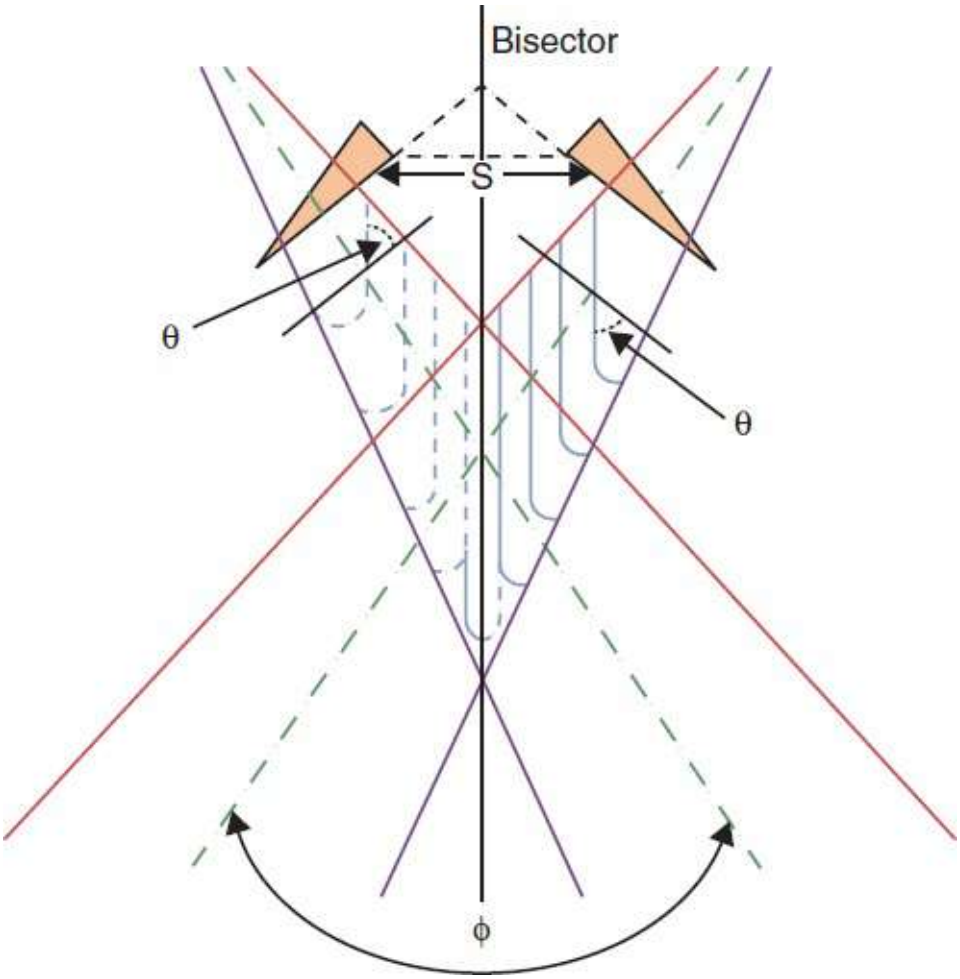

FIGURE 7.9. Parameters of the wedge beams: *f* is the wedge angle, *q* is the hinge angle, and *S* is separation. Isodose curves for each wedge field are parallel to the bisector. (From Khan FM. *The physics of radiation therapy*. 2nd ed. Baltimore: Williams & Wilkins; 1994. With permission.)

TREATMENT PLANNING: COMBINATION OF TREATMENT FIELDS

Parallel-Opposed Fields

When only two unmodified x-ray beams are used in radiation therapy, they usually are parallel-opposed beams (i.e., directed toward each other from opposite sides of the anatomic site with the central axes coinciding). Figure 7.11 presents the normalized relative axis dose profiles from parallel-opposed photon beams for a 10- × 10-cm field at an SSD of 100 cm and for patient diameters of

15 to 30 cm in 5-cm increments. The weight of a beam denotes a numeric value assigned to the beam at some normalization point. For SSD beams, the weight specifies the relative dose assigned to the beam at d_{max}, and for isocentric beams, at isocenter. The beams shown are weighted 1 to 1 (i.e., assigned equal value 100% at d_{max}), and the dose profiles have been normalized to the cumulative midline PDD.

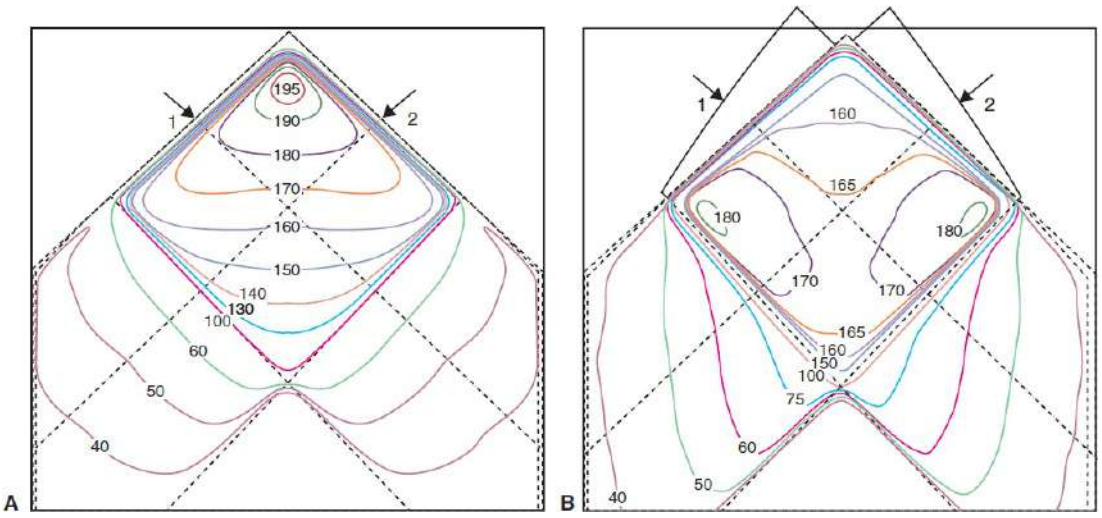

FIGURE 7.10. Isodose distribution for two angled beams. **A:** Without wedges. **B:** With wedges. Both: 4 MV; field size, 10 × 10 cm; source-to-skin distance, 100 cm; wedge angle, 45 degrees. (From Khan FM. *The physics of radiation therapy*. 2nd ed. Baltimore: Williams & Wilkins; 1994. With permission.)

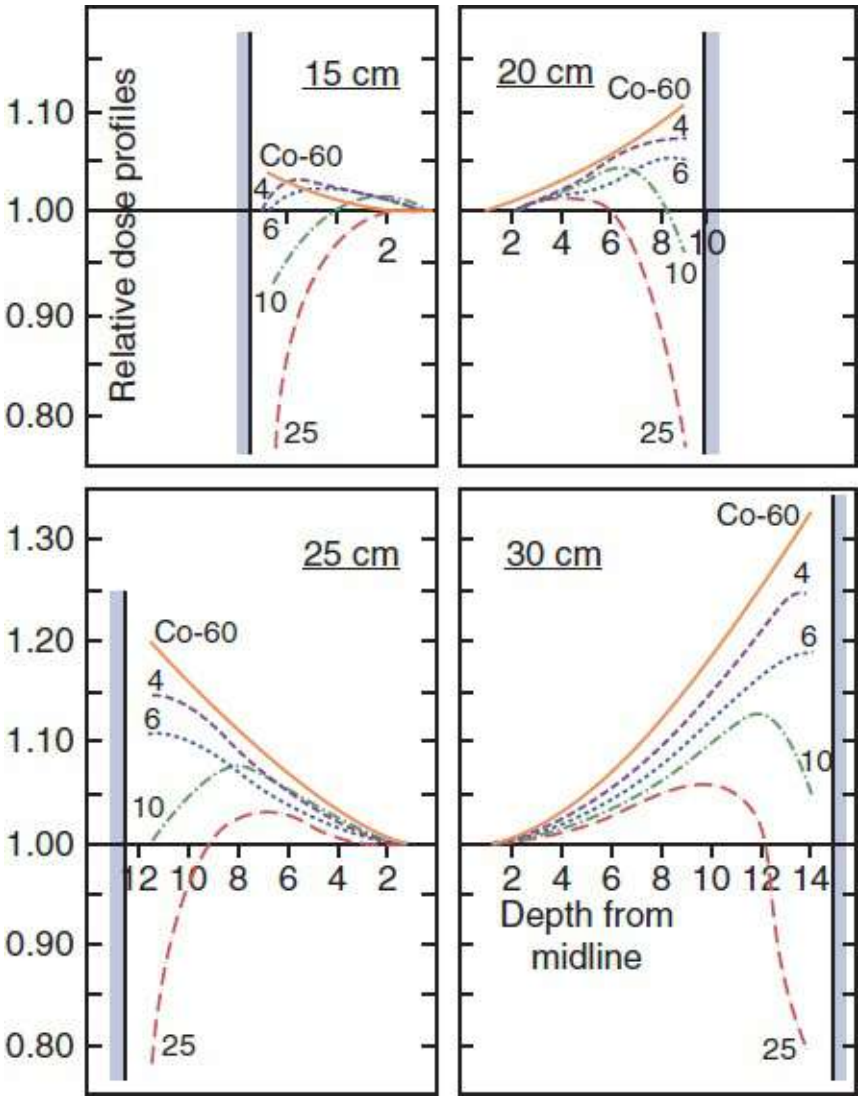

FIGURE 7.11. Relative central-axis dose profiles as a function of x-ray energy (^{60}Co or 4, 6, 10, and 25 MV) and patient thickness (15, 20, 25, and 30 cm). The parallel-opposed beams are equally weighted, and the profiles are normalized to unity at midline. Because of symmetry, only half of each profile is shown.

The maximum patient diameter easily treated with parallel-opposed beams for a midplane tumor requiring 50 Gy or less with low-energy megavoltage beams is approximately 18 cm. For “thicker” patients, higher x-ray energies produce improved dose profiles with less dose variation along the central axis without resorting to more complex multibeam arrangements.

For some treatment sites, the underdosing achieved near the skin surface with very–high-energy, parallel-opposed x-ray beams is a highly advantageous feature; but in others, it may be desirable to achieve a higher dose nearer to the skin. With very–high-energy x-ray beams traversing small anatomic thicknesses,

the exit dose can exceed the entry dose, and the exact dose distribution in the regions beneath the entry and exit surfaces from parallel-opposed high-energy x-ray beams must be carefully evaluated to consider properly the contribution from both entrance and exit components.

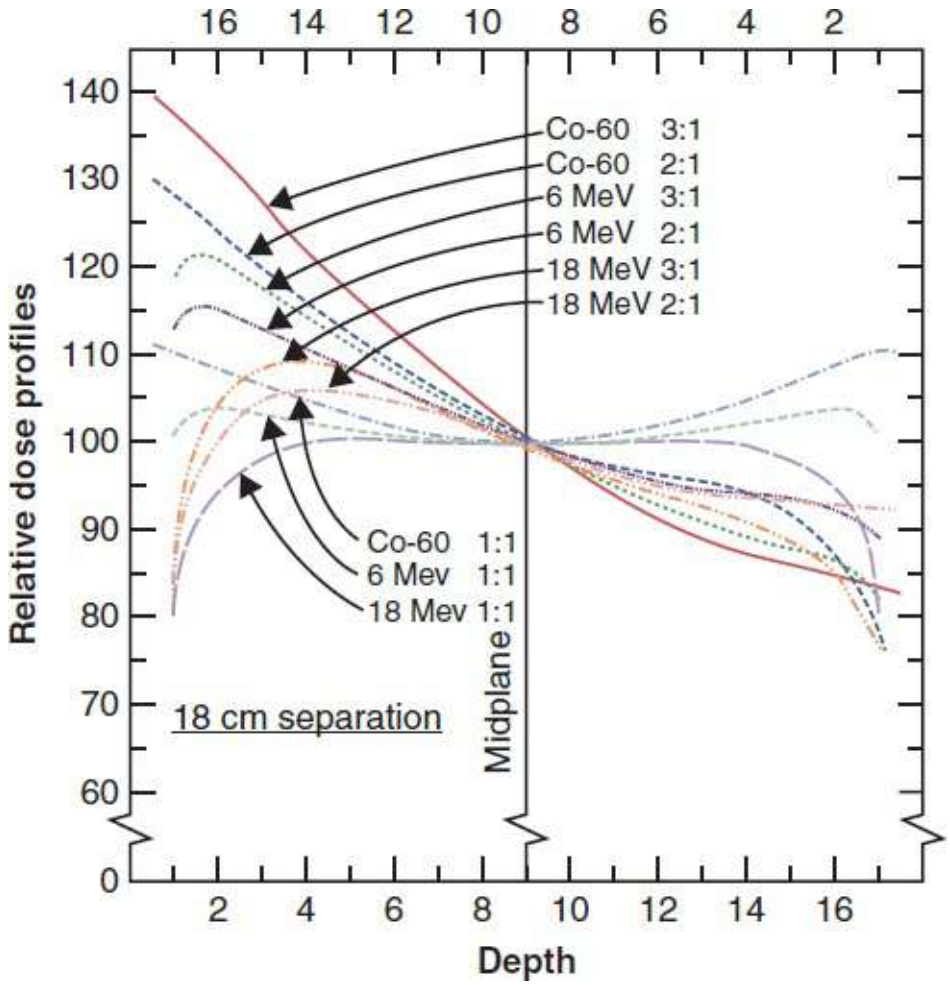

FIGURE 7.12. Dose profiles achieved with unequal weightings of parallel-opposed photon beams; profiles are normalized to unity at midline.

Unequal beam weightings are advantageous if the target volume is not midline. Figure 7.12 shows normalized central-axis dose profiles for other weightings, such as 2 to 1 and 3 to 1. The greater the unequal weighting, the greater will be the shift of the higher-dose region toward one surface and away from midline. Although in some anatomic sites unequal weighting may be advantageous, special attention must be directed to the anatomic structures in the high-dose volume.

Multiple-Beam Arrangements

Figure 7.13 shows three commonly used coaxial three-field beam arrangements. A direct anterior field with two anterior oblique fields can be used to generate a high-dose region where the three fields overlap, whereas a low-dose region exists beyond this intersection point. For example, if this arrangement is used for treating the mediastinum, the spinal cord might be included in the anterior beam but spared by the anterior oblique beams. Moving the anterior oblique fields laterally to form a parallel-opposed pair yields a rectangular isodose region with a more uniform dose gradient; however, the magnitude of the dose gradient is determined by the relative weighting of the beams and the thickness of tissue traversed. An anterior field with two symmetrically placed posterior oblique beams yields elongated isodose curves. The degree of elongation is determined by the relative thickness of tissue each beam traverses to the point of intersection and by the relative weights of the beams. Three-field arrangements are often useful for treating tumors lateral to the midline of a patient.

Three-field nonaxial (noncoplanar) arrangements are readily achieved with linacs by rotating the table and gantry. A common technique for treating pituitary tumors uses two lateral fields and a vertex field with the beam entering through the top of the head. Astrocytomas often are treated with parallel-opposed lateral fields and a frontal field entering through the forehead. A 90-degree couch rotation is used with the gantry rotated laterally for the vertex or frontal fields. The lateral fields are also rotated by collimator to ensure the “heels” of the wedges are in the plane of the vertex/frontal field trajectory.

Four-field techniques typically are used in such sites as the abdomen or the pelvis. In most instances, the arrangements consist of pairs of parallel-opposed fields, with a common intersecting point, which yield a “boxlike” isodose distribution. Figure 7.14 compares the dose distributions achieved with a four-field “box technique” for 6- and 18-MV x-ray beams. The central dose distribution is similar for all beam energies, but the greater penetrability of the higher-energy beams yields a lower dose to the region outside the box. Variations in the dose gradient are achieved by differential weighting of each pair of beams. Figure 7.15 shows other possible four-beam arrangements. Angulation of the beams yields a diamond-shaped dose distribution. A butterfly-shaped distribution is achieved if each pair of beams has a point of intersection lying on a common line but separated by a few centimeters.

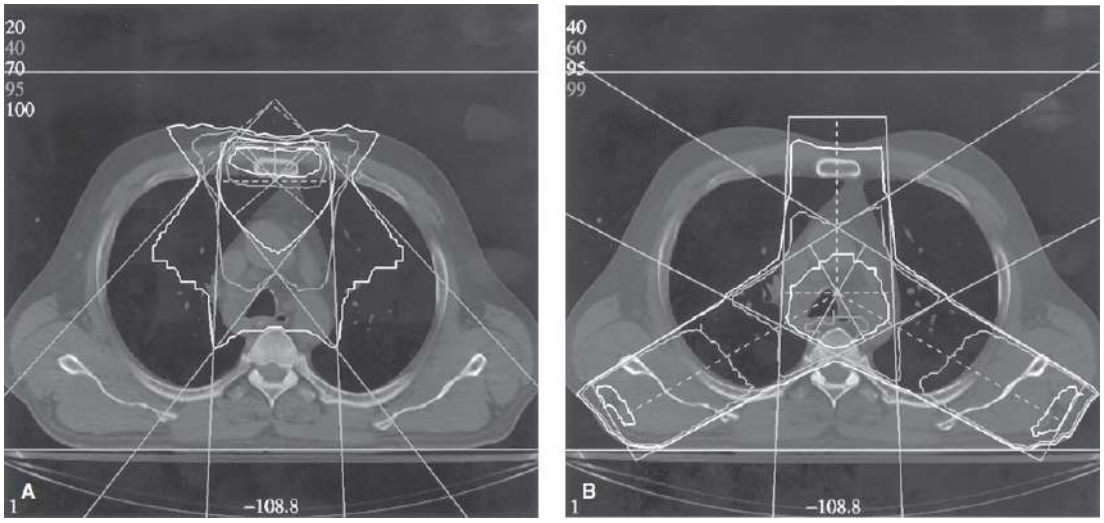

FIGURE 7.13. Three-field coaxial beam arrangements: dose distribution for two different beam arrangements using 6-MV x-ray beams, 8- × 10-cm field size, 100-cm source-to-skin distance. Isodose curves have been renormalized to show the 100% line almost encompassing the target volume. **A:** Anterior field with two anterior oblique fields at 40 degrees off the midline, all equally weighted. **B:** Anterior field with a weight of 0.8 with two equally weighted (1) posterior oblique fields separated by 120 degrees.

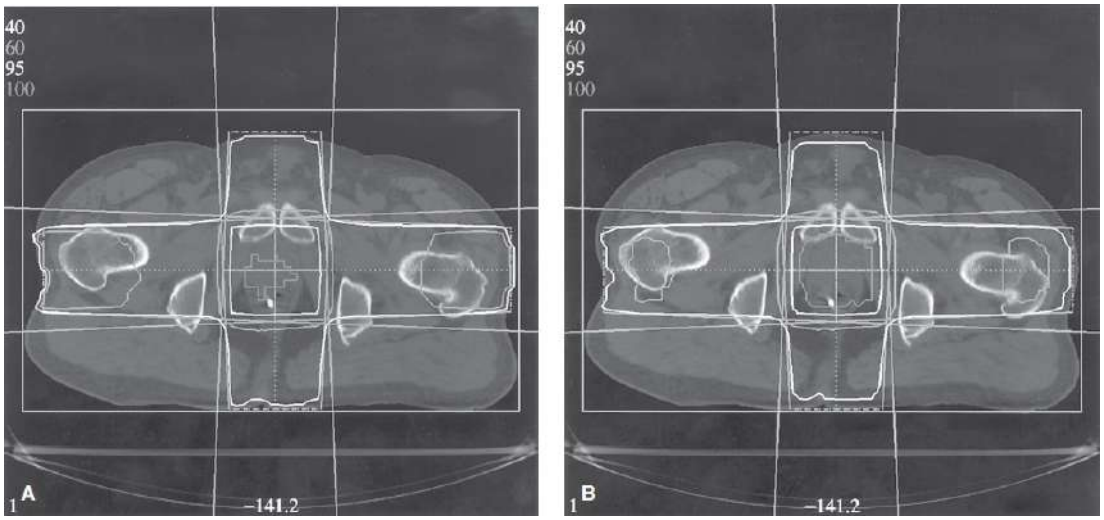

FIGURE 7.14. Four-field “box technique” coaxial beam arrangements (equal beam weightings). **A:** 6-MV x-ray beams. **B:** 18-MV x-ray beams. Note the improved dose distribution with the higher-energy beam technique (more uniform dose in the target region and lower doses near the femoral head region of the lateral fields) as a result of the increased percentage depth for 18-MV x-rays.

Treatments involving more than four gantry angles, historically required with orthovoltage x-ray units to treat deep, midline lesions, were originally rarely used with high-energy megavoltage therapy units. However, with the broad introduction of *three-dimensional conformal radiation therapy (3DCRT)* and

IMRT, there has been an increase in multibeam treatments such as the 3DCRT six-field technique commonly used for the treatment of prostate carcinoma[79] and the nine-field technique commonly used for head and neck cancer IMRT treatments.[80] More recently, these multibeam arrangements are further refined by adding segments of field with the same beam angle either to improve dose homogeneity or to intentionally generate an inhomogeneous dose distribution (e.g., the simultaneous integrated boost technique).[81]

Rotation Therapy

Rotational (or *arc*) *therapy* techniques, in which the treatment is delivered while the gantry (and thus the radiation beam) rotates around the patient, can be thought of as an infinite extension of the multiple-field techniques already described. This technique is most useful when applied to small, symmetric, deep-seated tumors and usually is limited to field sizes less than approximately 10 cm in width for the treatment of centrally located lesions (i.e., there is approximately an equal amount of tissue in all directions around the lesion).

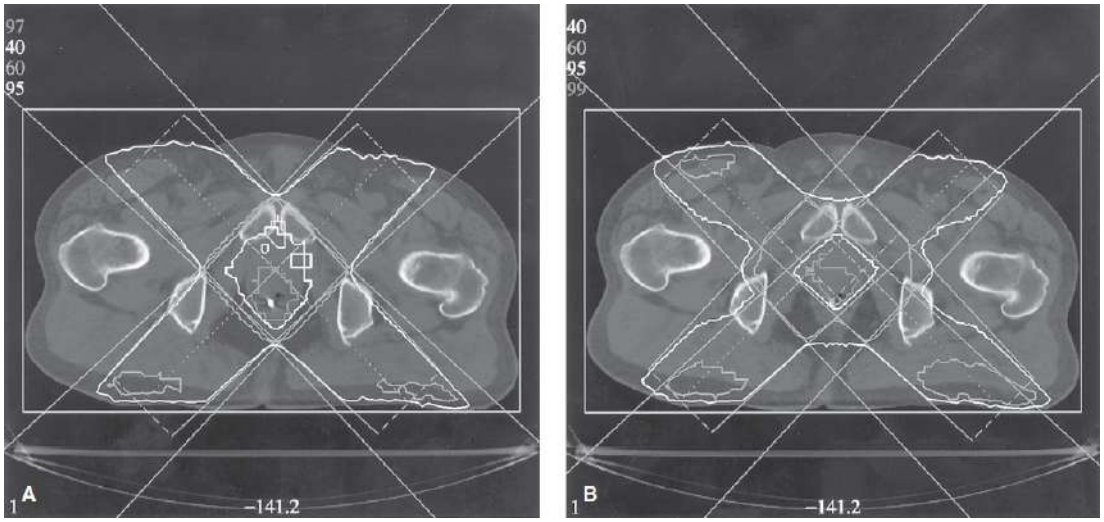

FIGURE 7.15. Four-field “oblique technique” coaxial beam arrangements (6-MV x-rays, equal beam weightings). **A:** With common isocenter resulting in a diamond-shaped dose distribution. **B:** Each beam pair intersecting at two different points on a common line resulting in a butterfly-shaped isodose distribution.

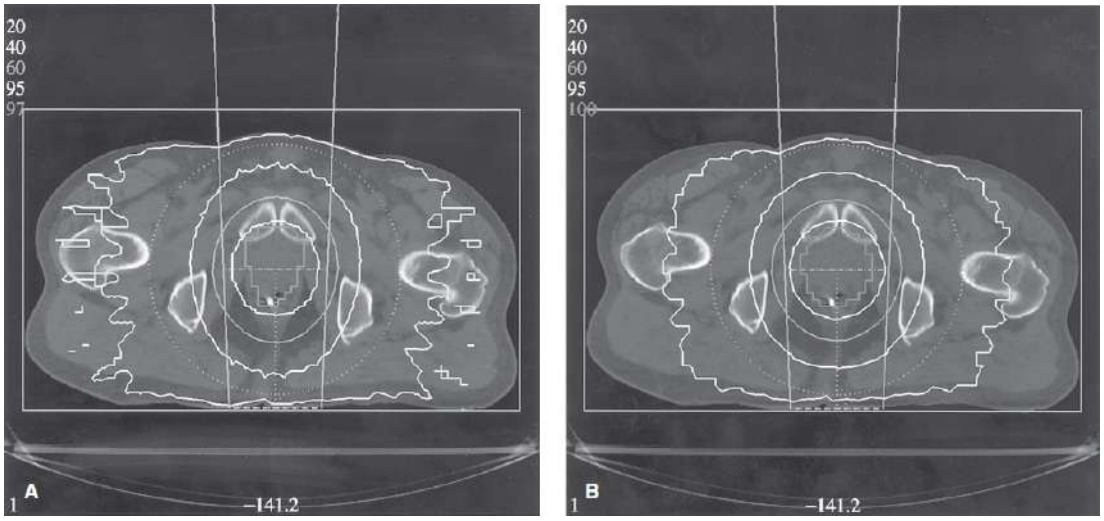

FIGURE 7.16. A 360-degree rotational therapy technique. **A:** 6-MV x-ray beams. **B:** 18-MV x-ray beams. Note that there is little difference in the dose distribution when using a higher-energy beam as a result of the offsetting effects of increased percentage depth versus higher exit dose.

Dose distributions generated by rotational techniques are not very sensitive to the energy of the photon beam. Figure 7.16 illustrates this fact, showing the dose distribution achieved using a 6-MV x-ray beam and also the distribution using an 18-MV x-ray beam. There is a little less elongation in the direction of the shorter dimension of the patient's anatomy for the 18-MV beam, and the dose distribution in the periphery is slightly lower.

In arc therapy techniques, one or more sectors of a 360-degree rotation are skipped to reduce the dose to critical normal structures. When a sector is skipped, the high-dose region is shifted away from the skipped region. Therefore, the isocenter must be moved toward the skipped sector; this technique is referred to as *past-pointing*, as illustrated in Figure 7.17.

The prostate, bladder, cervix, and pituitary are clinical sites that have been treated, either initially or for boost doses, with rotational or arc therapy techniques. Although the dose distributions achieved by rotation or arc therapy yield high target-volume doses, these techniques normally result in a greater volume of normal tissue being irradiated (albeit at low doses) than fixed, multiple-field techniques.

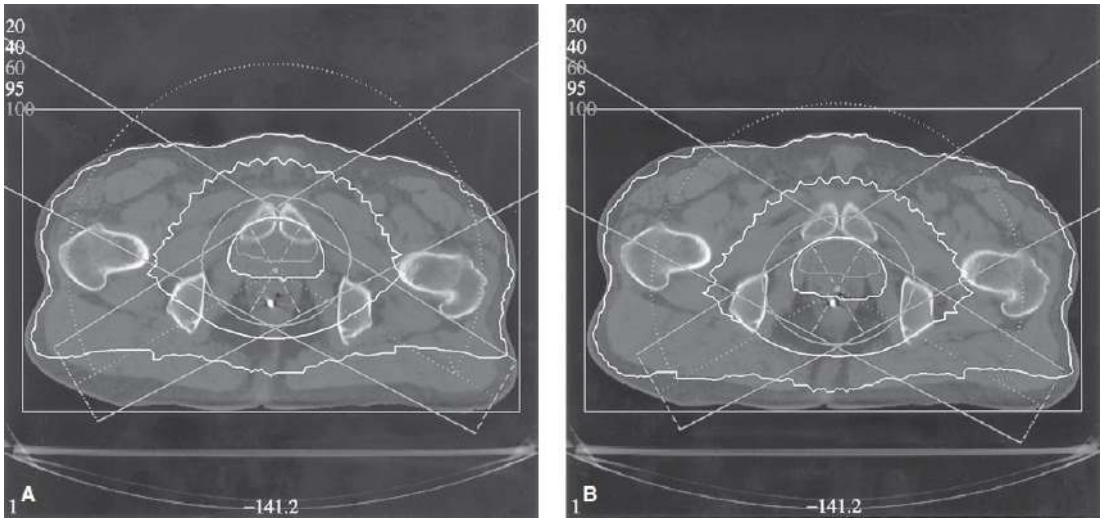

FIGURE 7.17. Arc therapy technique for 6-MV x-rays. **A:** 240-degree arc. Note that when a sector of the full 360-degree rotation is skipped, the high-dose isodose curves are shifted away from the skipped sector. **B:** 240-degree arc, but patient positioned so that isocenter is 2 cm lower toward the skipped sector (this technique is called *past-pointing*). Note high-dose isodose curves now encompass the target volume.

As previously indicated, modern-day rotational therapy is now delivered by a variety of techniques (e.g., TomoTherapy, RapidArc, VMAT). Recent developments also include rotational therapy with *flattening filter free (FFF)* beams.[82] The FFF feature allows dose rates up to 2,400 MUs per minute, thus greatly improving efficiency in dose delivery, which is particularly important for patients receiving treatments where very high daily doses are delivered, such as stereotactic body radiation therapy (SBRT).[83]

FIELD SHAPING

A major constraint in the treatment of cancer using radiation is the limitation in the dose that can be delivered to the tumor because of the dose tolerance of the tissue (critical organs) surrounding or near the target volume. Shielding normal tissue and critical organs has allowed the radiation oncologist to increase the dose to the tumor volume while maintaining the dose to critical organs below some tolerance level. The frequently used tolerance doses for these organs are not absolute and depend on a number of clinical and treatment factors. Depending on the predominantly serial or parallel organization of the organ at risk, a large dose can sometimes be given to fractional volumes of organs with a parallel structure (liver, kidneys, lungs).[84,85] Shielding is usually accomplished using collimator jaws (with the asymmetric feature) and multileaf collimators, in

which the beam aperture (field shape) is customized for individual patients. Use of low–melting-point alloy blocks is rapidly being replaced with the MLC technology.

MLC and Associated Dosimetry

Asymmetric Collimator Jaws

Field shaping and abutted field radiation therapy techniques have been made even more versatile with the asymmetric jaw feature found on modern-day linacs. This feature allows each set of jaws to open and close independently of each other (Fig. 7.18). The collimator jaw provides greater attenuation than the MLC leaf or alloy block, thus providing an advantage (which is readily apparent on portal films) in reducing the dose to blocked regions.

Depth-dose characteristics for asymmetric fields are similar to those of symmetric fields as long as the degree of asymmetry is not too extreme. Clinical sites where asymmetric jaws are typically used include breast (Fig. 7.19), head and neck, craniospinal, and prostate. In addition, the use of asymmetric jaws as beam splitters, for field reductions, and with MLCs is helpful for most sites. Several authors have reported on the use of asymmetric jaws to match supraclavicular and tangential fields for breast irradiation.[86–88] Such technology allows a single setup point for all of the treatment fields, including the posterior axillary field. The Y-jaws can beam split the caudal and cephalic regions for the supraclavicular and tangential beams, respectively, and the X-jaws are used to shield the ipsilateral lung and contralateral breast. Hence, a common match plane with one common isocenter can be used for all portals, eliminating the need to move the patient between portals, thus reducing overall patient setup time by almost a factor of two. In addition, the increased attenuation by the jaws reduces the dose to the contralateral breast and lung.[89] A technique for matching lateral head and neck fields and the supraclavicular field using asymmetric jaws was described by Sohn et al.[90]

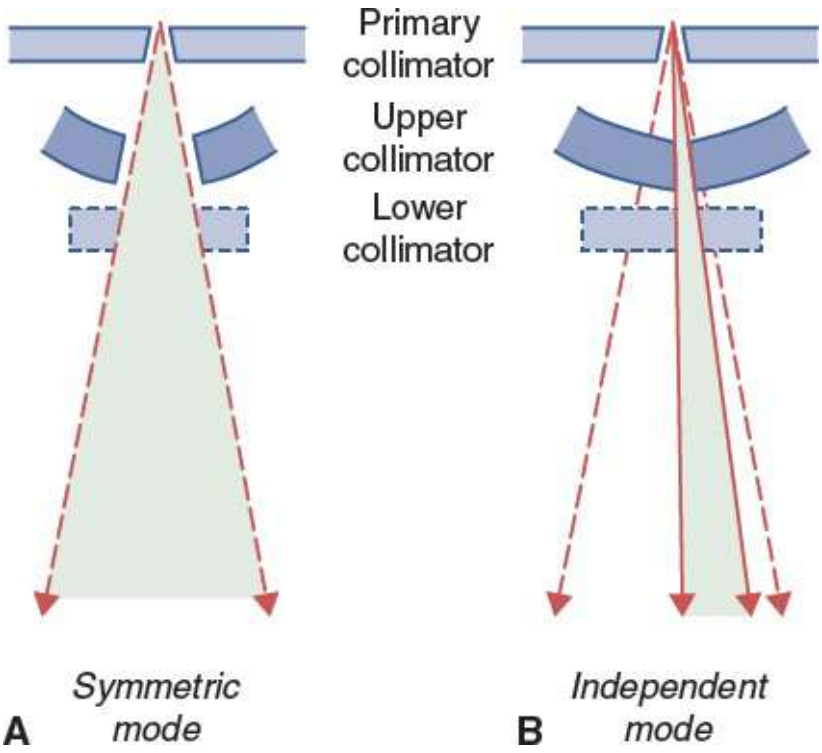

FIGURE 7.18. Independent or asymmetric collimators. **A:** Conventional symmetric pairs of collimators. **B:** Asymmetric collimators in which collimator jaws are allowed to move independently of each other.

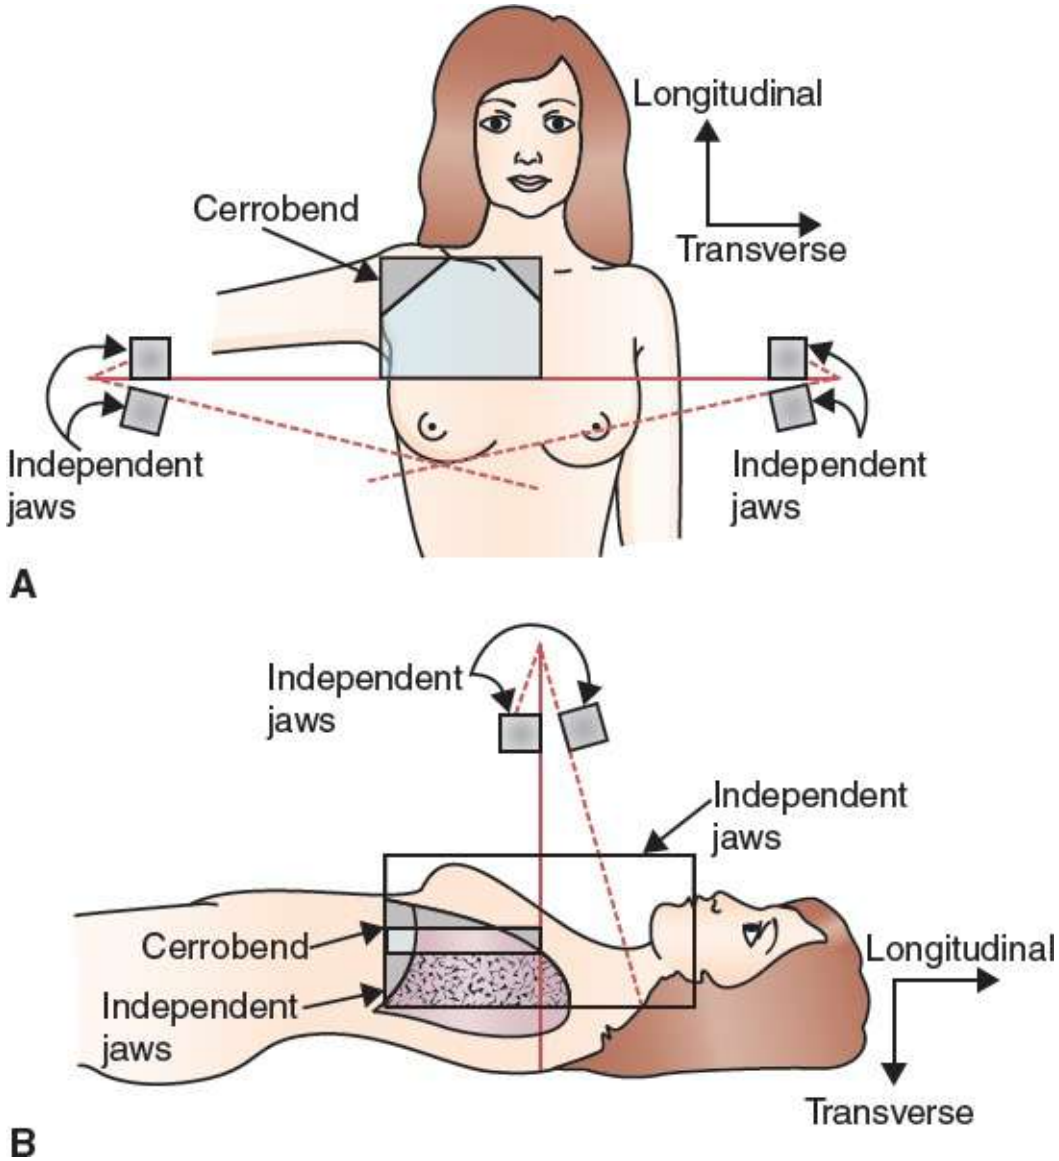

FIGURE 7.19. **A** and **B:** Treatment technique for breast cancer using independent collimators. (Reprinted from Klein EE, Taylor M, Michaletz-Lorenz M, et al. A mono isocentric technique for breast and regional nodal therapy using dual asymmetric jaws. *Int J Radiat Oncol Biol Phys* 1994;28[3]:753–760. Copyright © 1994 Elsevier. With permission.)

Multileaf Collimation

Multileaf collimation, first introduced in Japan in the 1960s,[91] has now gained widespread acceptance and has replaced alloy blocking as the standard of practice for field shaping in modern radiation therapy clinics. The different manufacturers' MLC systems vary with respect to MLC location, leaf design, and field size coverage. The leaves are typically carried on two opposed carriages that transport the leaves in unison. The leaves have individual controls

that are computer assigned and positioned. Initially, most commercial MLC systems were designed to serve as a block replacement but now provide for dynamic IMRT delivery as well.

Elekta first introduced its MLC system in the late 1980s.[92] Their current MLC system replaces the upper photon collimator jaws, and therefore, the maximum field size can open to a full 40 × 40 cm. The MLC system is augmented by parallel diaphragms, which increase the leaf's attenuation by an additional two HVLs.

The Varian MLC system is considered a tertiary system placed below the photon collimator jaws. The latest Varian MLC (non-SRS) is a 120-leaf (60 on each side) system, in which the middle 20 cm consists of 0.5-cm-wide leaves, whereas the outer 20-cm leaves still project to 1.0-cm widths. This set of leaves projects to 16.0 cm in length at isocenter, and the leaf span range (maximum–minimum positions on the same carriage) is limited to 14.5 cm. The leaves move perpendicular to the beam's central axis. The distance from the x-ray target to the bottom of the leaves (on the central axis) is 54.0 cm. The leaves fan away from the central axis so that their sides are divergent with the beam's fan lines. The leaves are interdigitated by a tongue-and-groove design. In May of 2017, Varian introduced the Halcyon machine, which does not have movable jaws and only has a double-layer MLCs with the two layers being offset by half of a leaf width and with each leaf being 1 cm wide. This "stacked and staggered" MLC design aims to provide optimized modulation and reduce interleaf leakage. The Halcyon also support 4 gantry rotations per minute (as opposed to 1 rotation per minute for conventional C shape linear accelerators), and the MLC have 5 cm/s speed to support this faster gantry rotation. The MLCs are also designed to have full overtravel and cover the full span of the field.

For the single-layer Varian MLC system, leaf transmission values of 1.5% to 2.0% for a 6-MV beam and 1.5% to 5% for an 18-MV beam have been reported.[36,93] These values are lower than those found for alloy blocks (3.5%) but higher than those for collimator jaw transmission (that being <1.0%). Transmission through abutted (closed) leaf pairs was as high as 28% for 18-MV photons on the central axis. The abutment transmission decreased as a function of off-axis distance to as low as 12%. The data for the double-layer MLC are not available as of this writing, but the MLC is specifically designed to reduce leaf transmission, and it is expected that this will translate into clinical benefits.

Figure 7.20 shows a comparison of MLCs and alloy blocks regarding penumbra. The discrete steps of the MLC systems introduce undulations in the

isodose lines. This effect causes an apparent increase in penumbra with wave patterns after the undulations. Single, focused MLC systems have a slightly larger penumbra than do alloy shields and have an even larger difference in comparison with collimator jaws. Boyer et al. found the penumbra (80% to 20% isodose lines) generated by leaf ends to be wider than those generated by upper collimator jaws by 1.0 to 1.5 mm, and 1.0 to 2.5 mm compared with the lower jaws, depending on energy and field size.[94] Powlis and associates compared multileaf collimation and alloy field shaping and found few differences.[95] LoSasso and Kutcher found similar results and concluded that geometric accuracy is even improved with MLCs.[96] ViewRay recently introduced a double-layer, doubly focused MLC and the design was reviewed by Li et al.[97] However, as of the writing of this chapter, there are no publications characterizing the performance of this MLC. The recently introduced Varian's MLC is also double layered with specially designed leaf tips to improve some of the above described shortcomings of the conventional MLCs.

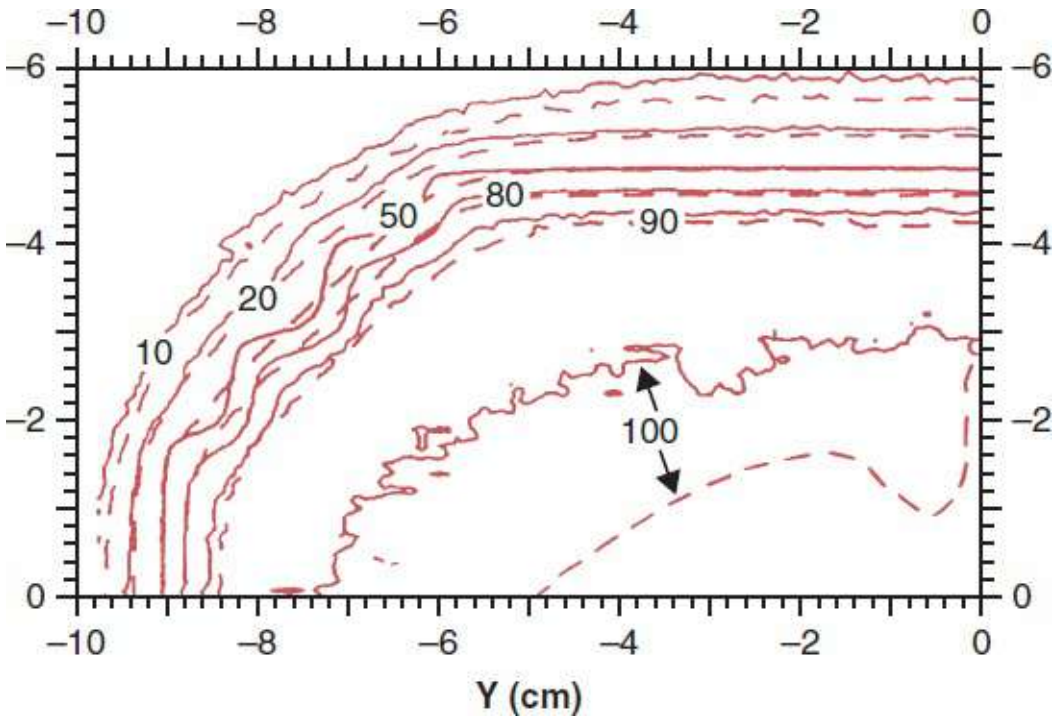

FIGURE 7.20. Comparison of beam's-eye view isodose curves at 10-cm depth for multileaf collimator (*solid line*) and Cerrobend-shaped (*dashed line*) beam apertures for 18-MV photons. (Reprinted from Klein EE, Harms WB, Low DA, et al. Clinical implementation of a commercial multileaf collimator: dosimetry, networking, simulation, and quality assurance. *Int J Radiat Oncol Biol Phys* 1995;33[5]:1195–1208. Copyright © 1995 Elsevier. With permission.)

The penumbras measured for the leaf sides are comparable with those found for upper jaws because of their divergent nature. The penumbra increase and stair-stepping effect are most prominent at d_{max}. The effects diminish at depth because of the influence of scattered electrons and photons as the scatter-to-primary ratio increases with depth. Adding an opposed beam leads to further smoothing of the undulations and penumbra differences become less significant. For multibeam arrangements, the differences in dose distribution between MLC and alloy shields are negligible.

The main limitation in optimizing the MLC leaf settings to conform to the shaped field is the discrete leaf steps. Most field shapes require only minor adjustment of collimator angle to achieve minimal discrepancy between the desired and resultant field shape. The criteria for optimizing the MLC leaf settings are governed by placing the most leaf ends tangent to the field and also maintaining the same internal area as originally prescribed. MLC shaping systems typically provide an option to place the leaf ends entirely outside the field (exterior), entirely within the field (interior), or crossing the field at midleaf (leaf-center insertion). The last is the most widely used criterion because the desired field area is more closely maintained. However, this choice leads to regions in which some treatment areas are shielded and some normal tissues are irradiated. Zhu et al. reported on a variable insertion technique in which leaves are placed only far enough into the field to cause the 50% isodose contour to undulate outside and up to the desired contour.[98] LoSasso et al. reported on a method in which each leaf is inserted such that the treatment area covered by the leaf equals the normal tissue area that is not spared.[99] Brahme also demonstrated optimal choices for choosing a collimator angle to optimize leaf direction, depending on whether the field shape is convex or concave.[100] Du et al. reported on a method that defines optimal leaf positioning in combination with optimal collimator angulation.[101] Typically, the optimal direction for the leaf motion is along the narrower axis. For a simple ellipse, the optimal leaf direction is parallel to the short axis. Reports on the effects of tissue heterogeneities on penumbra and resultant field definition indicate that the penumbra in lung increases (especially for 18-MV photons), whereas in bone, it decreases for both alloy blocks and MLCs.[36]

As indicated previously, because MLC systems are still evolving, a careful evaluation of the effect of MLCs on MU calculations must be performed before clinical use. Extensive testing over the clinical range of field sizes and shapes should be undertaken before the MLC system is used clinically.

Low-Melting Alloy Blocks

Although alloy blocks are rapidly disappearing from clinical use, a short section is included in this chapter for completeness. The Lipowitz metal (Cerrobend) shielding block system was introduced by Powers et al.[102] Lipowitz metal consists of 13.3% tin, 50% bismuth, 26.7% lead, and 10% cadmium. The physical density at 20°C is 9.4 g/cm^3, compared with 11.3 g/cm^3 for lead. The block fabrication procedure is illustrated in Figure 7.21, and more details on using this form of field shaping can be found in the review article by Leavitt and Gibbs.[103]

Specific doses to critical organs may be limited by using either a full-thickness block, usually five HVLs (3.125% transmission) or six HVLs (1.562% transmission), or a partial transmission shield, such as a single HVL (50% transmission) of shielding material. The actual dose delivered under the shielded area is usually greater than these stated transmission levels because of scatter radiation beneath the blocks from adjacent unshielded portions of the field. The scatter component of the dose increases with depth as more radiation scatters into the shielded volume beneath the block. Thus, the dose to the blocked area is a function of block material, thickness (and width), field size, and energy. Figure 7.22 shows the attenuation of Lipowitz metal of x-rays produced at 2, 4, 10, and 18 MeV and ^{60}Co γ-rays.[104] Alloy blocks made from the standard thickness (7.6 cm) of foam molds reduce the primary beam intensity to 5% of its unattenuated value. Increasing the block thickness usually is not worthwhile because it makes the block heavier, whereas the scatter radiation contributes an equal or greater share of the dose under the blocks.

Because of the advent of multileaf collimation, metal blocks for photon beams are rarely used, as multileaf collimation afforded there to be no room for entry between treatment fields. In addition, the construction of blocks was time consuming and expensive. Also, the materials themselves, as they were heated, gave off potentially toxic air, particularly because of the lead and cadmium. The one advantage of blocks is that they provide smooth boundaries by having a continuous shape around the field and incur no field size limitation. However, the weight of the blocks can be excessive, sometimes up to 15 pounds, leading to

the potential for injury to therapists and patients should they be mishandled.

COMPENSATING FILTERS

The compensating filter, introduced by Ellis et al.,[105] counteracts the effects caused by variations in patient surface curvature while still preserving the desirable skin-sparing feature of megavoltage photon beams. This is accomplished by placing the custom-designed compensating filter in the beam, sufficiently "upstream" from the patient's surface, as illustrated in Figure 7.23. Several different compensator systems have been used in the clinic.[106] However, the use of physical compensators to account for patient surface curvature is almost nonexistent in clinics today because of the advent of IMRT. But one particular IMRT delivery method does use a physical compensator, which is designed from the planning system and often constructed from a third-party vendor to deliver a modulated field.[107]

One exception where the use of compensating filters or really custom bolus has increased is in electron beam applications.[108] The decimal company (Sanford, FL) offers a product BolusECT, which enables creation of custom three-dimensional bolus to improve conformality of electron beams at depth. These devices offer a simple and relatively inexpensive method to significantly improve electron beam dosimetry. The main shortcoming is the delay involved in ordering and shipping the devices, but overall, this approach appears to be clinically manageable.

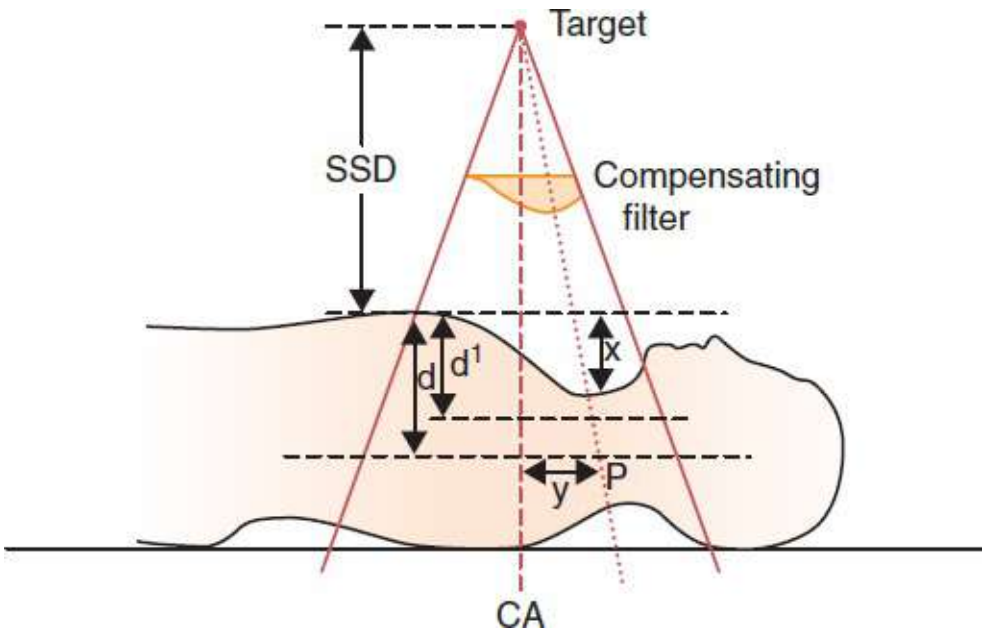

FIGURE 7.23. Schematic illustrating typical geometry used in the design of a compensator filter to account for patient's irregularly shaped surface. SSD, source-to-skin distance; CA, central axis.

BOLUS

Tissue-equivalent material placed directly on the patient's skin surface to reduce the skin sparing of megavoltage photon beams is referred to as *bolus*. A tissue-equivalent bolus should have electron density, physical density, and atomic number similar to those of tissue or water and be pliable so that it conforms to the skin surface contour. Inexpensive, nearly tissue-equivalent materials used as a bolus in radiation therapy include slabs of paraffin wax, rice bags filled with soda, gauze coated with petrolatum, and synthetic-based substances, such as Superflab or Super Stuff.[109]

Thin slabs of bolus that follow the surface contour increase the dose to the skin beneath the bolus with a maximum reduction when the bolus thickness is approximately equal to the d_{max} depth for the photon beam. In addition, adding bolus to fill a tissue deficit may smooth an irregular surface. A bolus also can be shaped to alter the dose distribution as well, but normally, wedges are used to alter the dose distribution for megavoltage photon beams to retain skin sparing.

PATIENT POSITIONING, REGISTRATION, AND IMMOBILIZATION

Ensuring accurate daily positioning of the patient in the treatment position and reduction of patient movement during treatment is essential to deliver the prescribed dose and achieve the planned dose distribution. The reproducibility achievable in the daily positioning of a patient for treatment depends on several factors other than the anatomic site under treatment, including the patient's age, general health, and weight. In general, obese patients and small children are the most difficult to position.

The fields to be treated typically are delineated in the computed tomography (CT) simulation process using either visible skin markings or skin markings visible only under an ultraviolet light. In some instances, external tattoos are applied. These markings are used in positioning a patient on the treatment machine using the machine's field localization light and distance indicator and the laser alignment lights mounted in the treatment room that project transverse, coronal, and sagittal light lines (or dots) on the patient's skin surface.

It is vital that the rigidity of the mask maintain consistency over the course of treatment. In the last 10 years, the normal method of aligning the patient for treatment relied on the marks on a patient before placing a mask on. Therefore, the systems that interface with the immobilization systems and the treatment couch need to also be rigid and registered. As of now, patients are set up to treatment coordinates once they are fit onto the mobilization systems.

Numerous patient restraint and repositioning devices have been designed and used in treating specific anatomic sites. For example, the disposable foam plastic head holder provides stability for the head when the patient is in the supine position. If the patient is treated in the prone position, a face-down stabilizer can be used. This device has a foam rubber lining covered by disposable paper with an opening provided for the patient's eyes, nose, and mouth. It allows comfort and stability as well as air access for the patient during treatment in the prone position.

A vacuum-form body immobilization system is commercially available. This system consists of a vacuum pump and an outer rubber bag filled with plastic minispheres. The rubber bag containing the minispheres is positioned to support the patient's treatment position. A vacuum is then applied, causing the minispheres to come together to form a firm, solid support molded to the patient's shape. The bite block (Fig. 7.24) is another device used as an aid in patient repositioning in the treatment of head and neck cancer. With this device, the patient, in the treatment position, bites into a specially prepared dental impression material layered on a fork that is attached to a supporting device. When the material hardens, the impression of the teeth is recorded. The bite-block fork is connected to a support arm, which is attached to the treatment couch, and may be used either with or without scales for registration.

FIGURE 7.24. Example of a bite-block registration and immobilization system used in treatment of head and neck cancer. (Courtesy of Radiation Products Design, Inc.)

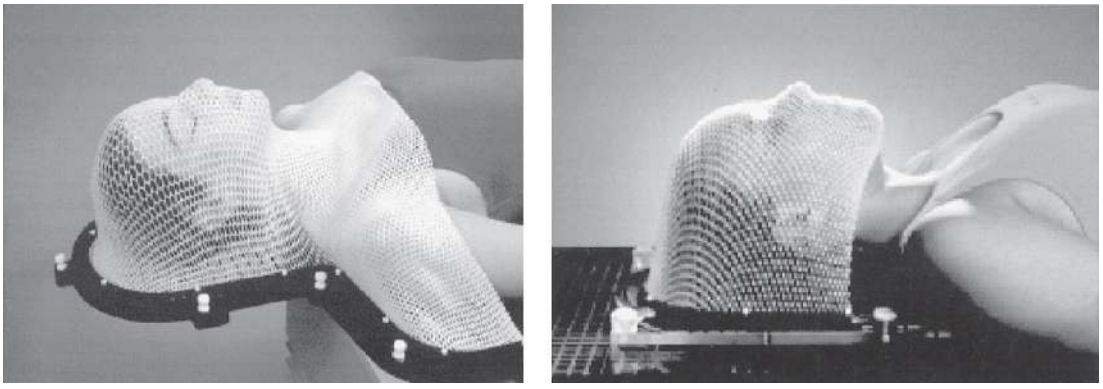

FIGURE 7.25. Example of a registration and immobilization system (thermal plastic mask) used in treatment of head and neck cancer.

Thermal plastic masks are widely used in the United States (Fig. 7.25). A plastic sheet is placed in warm water or an oven and, once soft, draped over the site. As the plastic sheet cools, it hardens and forms a permanent mask.[110] The use of thermal plastic masks allows treatments with few skin marks made on the patient because most of the reference lines can be placed on the mask. Treatments can be given through the mask; however, there is some minimal loss of skin sparing. When skin sparing is critical, the mask may be cut out to match

the treatment portal, although some of the structural rigidity is lost. One of the concerns with use of plastic masks is that they sometimes shrink a bit. This shrinkage can cause changes in patient positioning or can introduce discomfort. A problem with discomfort is that patients often overcorrect their position to avoid pain caused because of poorly fitting immobilization. As a general rule, comfortable patients are easier to reproduce the daily setup and they tend to be less movable during an individual fraction. Therefore, it is important to monitor masks for shrinkage and to follow manufacturer instructions for making masks. These instructions often have procedures designed to minimize shrinkage.

Custom molds constructed from polyurethane formed to patient contours have gained widespread use as aids in immobilization and repositioning (Fig. 7.26). The constituent chemicals for the polyurethane foam are mixed in liquid form and allowed to expand and harden around the patient while the patient is in the treatment position. These molds are used for treatment of Hodgkin disease with the mantle irradiation technique, in patients with cancer of the thorax or prostate, and for extremity repositioning/immobilization. Johnson et al.[111] reported on the effect on surface dose caused by the mold for ^{60}Co, 6- and 18-MV photon beams. Also, when concerned about surface dose effects caused by immobilization devices, one should not neglect understanding the effects also caused by carbon fiber couch inserts.[112]

A bite-block system or a thermal plastic face mask system is commonly used to immobilize patients with head and neck tumors. Patients immobilized with the bite-block system typically require a larger number of adjustments than when more effective systems like the thermal face mask are used. Also, patients may prefer the face mask because most of the reference marks are on the mask rather than on the skin. However, the final assessment of accuracy and reproducibility of the daily treatment is obtained by radiographic imaging of the area treated because there is the possibility of patient movement within the mask, especially if significant tumor shrinkage or weight loss has taken place.

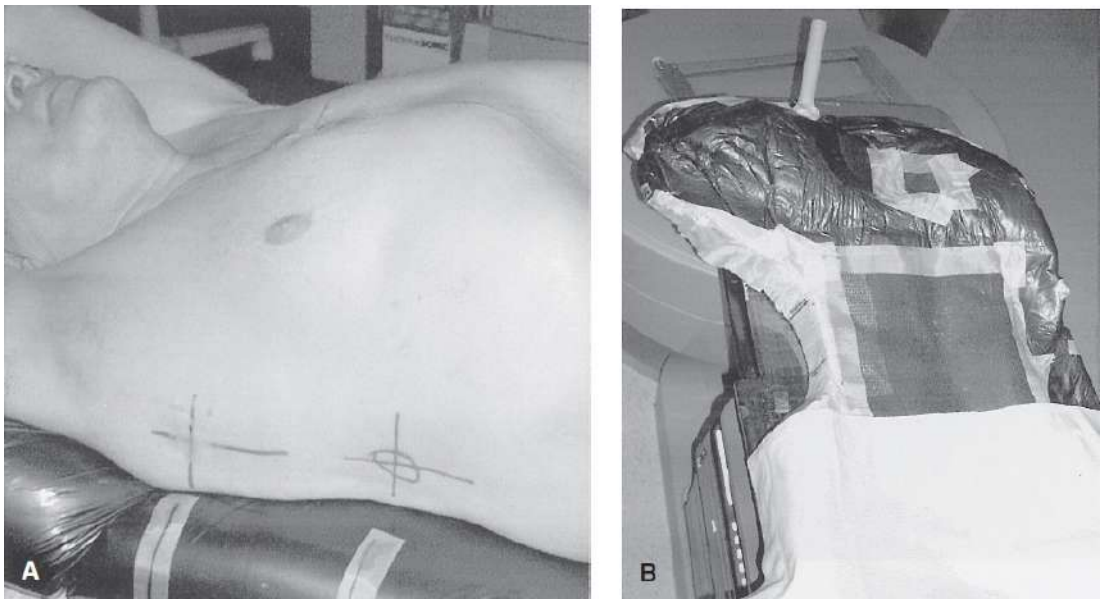

FIGURE 7.26. Examples of registration and immobilization systems (foam mold) used in treatment of the thorax. **A:** Mold is registered to table and the patient is registered to the mold by fiducial markings. **B:** Mold with cutout area to allow clear access to the treatment area and built-in handgrip.

SEPARATION OF ADJACENT X-RAY FIELDS

Field Junctions

Different techniques for matching adjacent fields are illustrated in Figure 7.27. A commonly used gap calculation method for adjacent radiation fields is illustrated in Figure 7.28A. The separation between adjacent field edges necessary to produce junction doses similar to central-axis doses follows from the similar triangles formed by the half-field length and SSD in each field. The field edge is defined by the dose at the edge that is 50% of the dose at d_{max}. For two contiguous fields of lengths L_1 and L_2, the separation, S, of these two fields at the skin surface can be calculated using the following expression:

$$S = \tfrac{1}{2} L_1 \left(\frac{d}{\text{SSD}} \right) + \tfrac{1}{2} L_2 \left(\frac{d}{\text{SSD}} \right)$$

A slight modification of this formula is needed when sloping surfaces are involved, as shown in Figure 7.28B.[113] Typically, the skin gap location is moved a number of times to reduce the hot and cold spots that arise with this technique. Figure 7.29 illustrates the dose distribution for three different field separations.[114]

Beam divergence may be eliminated by using a “beam splitter,” created using

a five- or six-HVL block over one-half of the treatment field. The central axes of the adjacent fields, where there is no divergence, are then matched. As previously discussed, this is a useful method on linacs with the asymmetric jaws feature. Match-line wedges or penumbra generators that generate a broad penumbra for linac beams have been reported but have not found widespread use.[115] Here, the intent is to broaden the narrow penumbra of the linacs so that it is not so difficult to match the 50% isodose levels. The resulting dose distributions are similar to those obtained with a moving gap technique. Finally, there are several reports of edge-matching techniques based on the mathematical relationships between adjacent beams and the allowed angles of the gantry, collimators, and couch.[116]

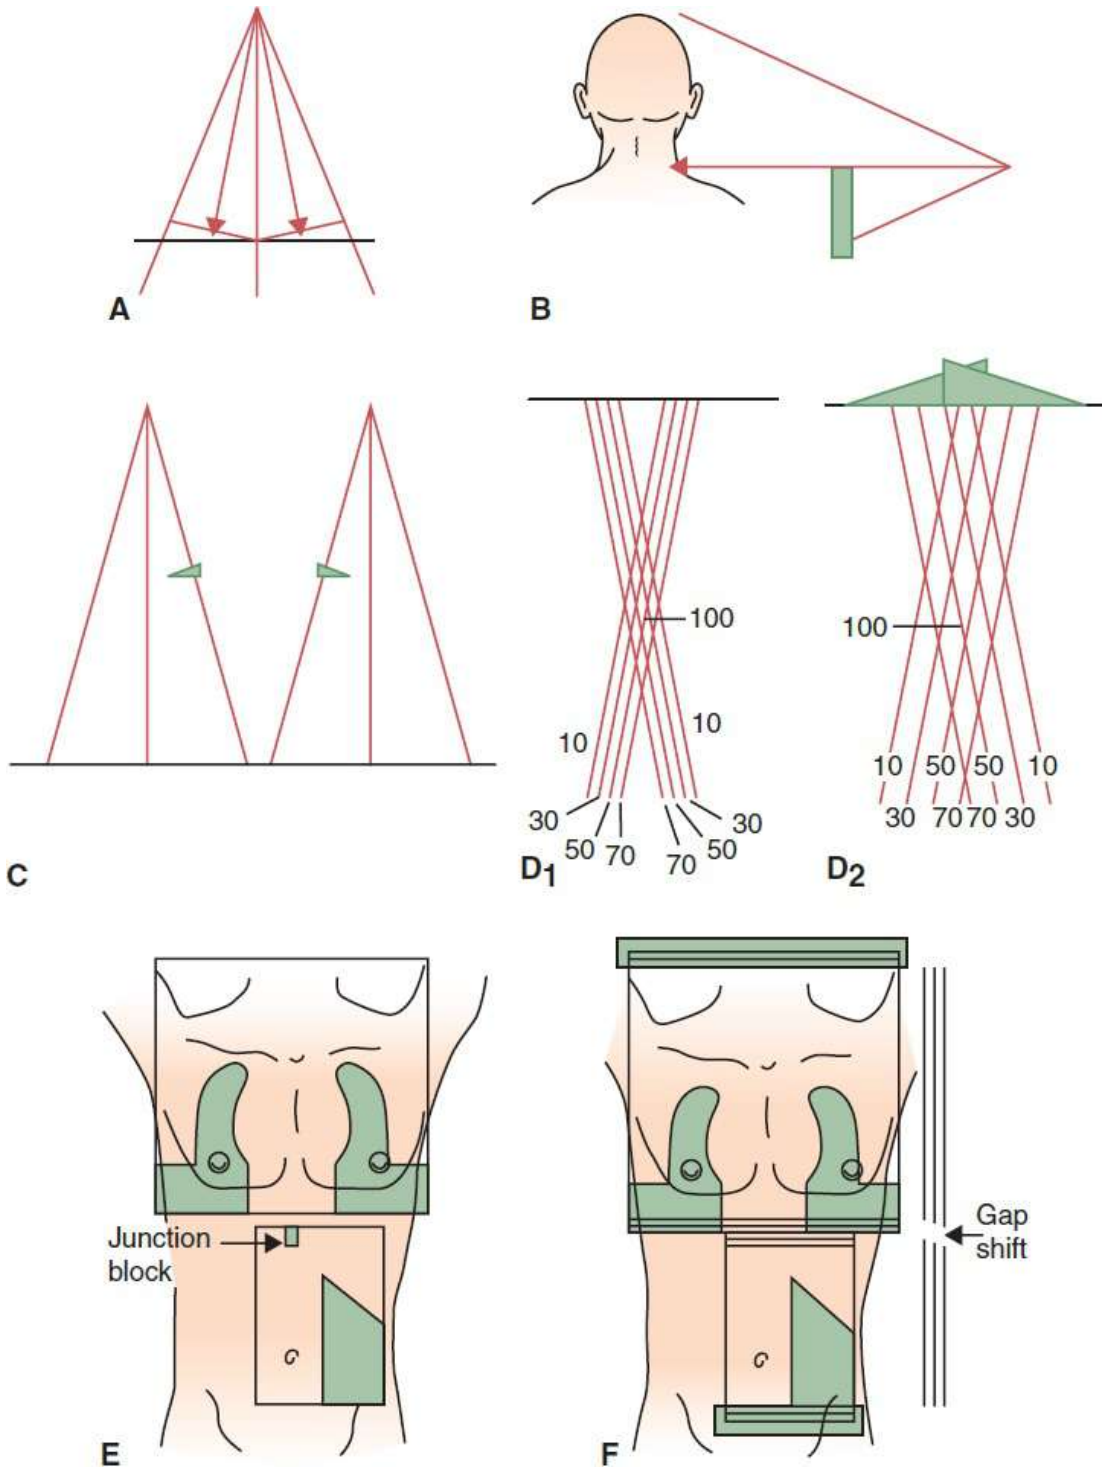

FIGURE 7.27. Different techniques for matching adjacent fields. **A:** Beam's central rays are angled slightly away from one another so that the diverging beams are parallel. **B:** Half-beam block to eliminate divergence. **C:** Penumbra generators (small wedges) to increase width of penumbra, as illustrated in $\mathbf{D_1}$ and **D2**. **E:** Junction block over spinal cord. **F:** Moving gap technique. Orthogonal Field Junctions

Figure 7.30 illustrates the geometry of matching abutting orthogonal photon beams. Such techniques are necessary, particularly in the head and neck region where the spinal cord can be in an area of beam overlap, in the treatment of medulloblastoma with multiple spinal portals and lateral brain portals. A common method of avoiding overlap is to use a half-block, as previously discussed, so that abutting anterior and lateral field edges are perpendicular to the gantry axis. In head and neck cancer, a notch in the posterior corner of the lateral oral cavity portal is commonly used to ensure overlap avoidance of the spinal cord when midline cord blocks cannot be used on anteroposterior portals irradiating the lower neck and matched to the oral cavity portals. Other techniques rotate the couch about a vertical axis to compensate for the divergence of the lateral field.[117] The angle of rotation is given by

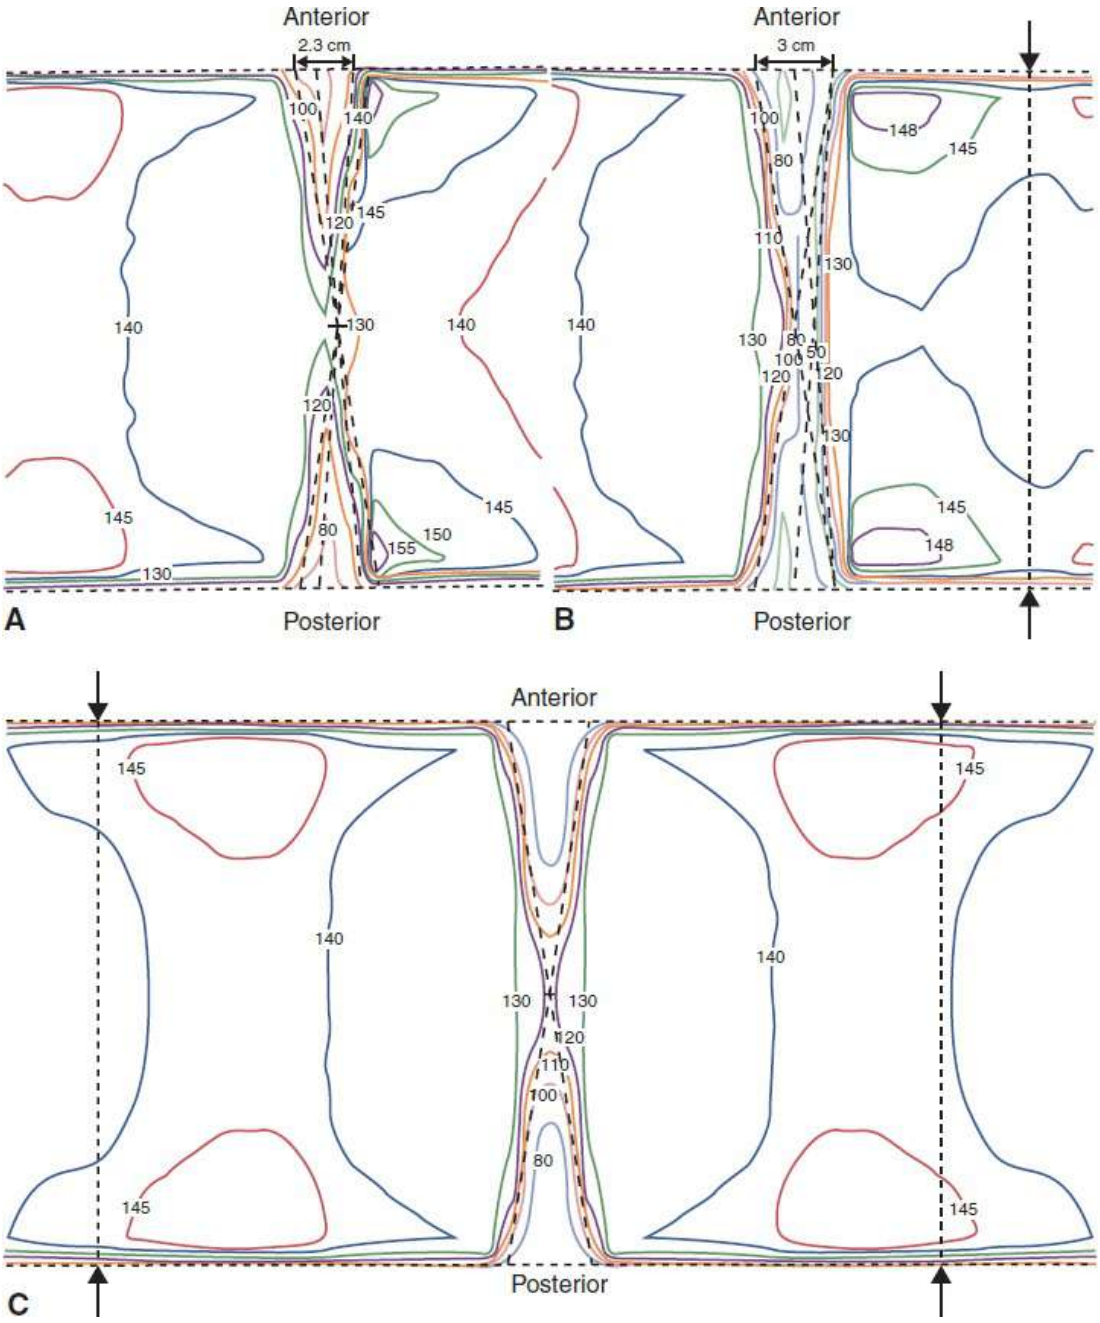

FIGURE 7.29. Dose distribution for geometric separation of fields with all four beams intersecting at midpoint. Adjacent field sizes: 30 × 30 cm and 15 × 15 cm; source-to-skin distance (SSD), 100 cm; anteroposterior thickness, 20 cm; 4-MV x-ray beams. **A:** Field separation at surface is 2.3 cm. A three-field overlap exists in this case because the fields have different sizes but the same SSD. **B:** The adjacent field separation increased to eliminate three-field overlap on the surface. **C:** Field separation adjusted to 2.7 cm to eliminate three-field overlap at the cord at 15 cm depth from anterior. (From Khan FM. *The physics of radiation therapy*. 2nd ed. Baltimore: Williams & Wilkins; 1994. With permission.)

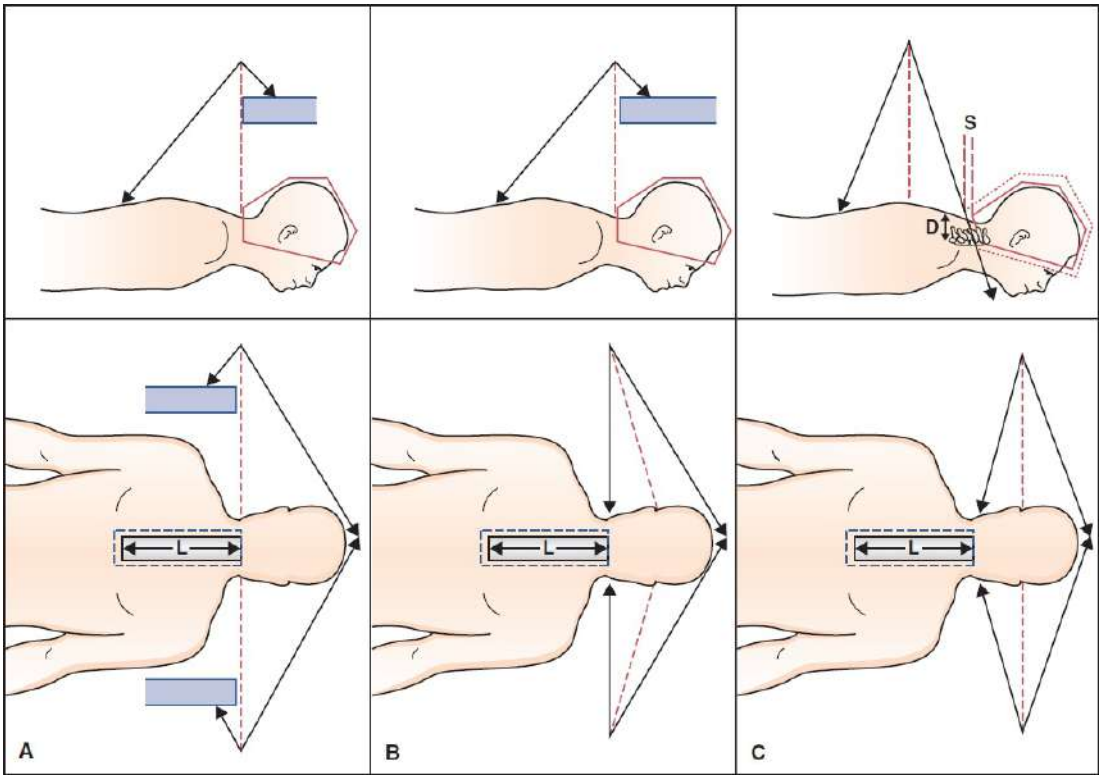

FIGURE 7.30. Some solutions for the problem of overlap for orthogonal fields. **A:** A beam splitter, a shield that blocks half of the field, is used on the lateral and posterior fields and on the spinal cord portal to match the nondivergent edges of the beams. **B:** The divergence in the lateral beams may also be removed by angling the lateral beams so that their caudal edges match. Because most therapy units cannot be angled like this, the couch is rotated through small angles in opposite directions to achieve the same effect. **C:** A gap technique allows the posterior and lateral field to be matched at depth using a gap *S* on the skin surface. The *dashed lines* indicate projected field edges at depth *D*, where the orthogonal fields meet. (Reprinted from Williamson TJ. A technique for matching orthogonal megavoltage fields. *Int J Radiat Oncol Biol Phys* 1979;5[1]:111–116. Copyright © 1979 Elsevier. With permission.)

$$\tan \theta^{-1} = \left(\frac{\frac{1}{2}\text{field width}}{\text{SAD}} \right)$$

Another technique is to leave a gap, *S*, on the anterior neck surface between the posterior field of length *L* and lateral field edges.[118] *S* can be calculated using the following formula where d is the depth of the spine beneath the posterior field:

$$S = \frac{1}{2}(L)\left(\frac{d}{\text{SAD}}\right)$$

The potential for the occurrence of radiation myelopathy resulting from a potentially excessive dose from misaligned overlapping fields is always a concern when central nervous system tumors are treated. Craniospinal irradiation is well established as a standard method of treating suprasellar dysgerminoma, pineal tumors, medulloblastomas, and other tumors involving the central nervous system. Uniform treatment of the entire craniospinal target volume is possible using separate parallel-opposed lateral cranial portals rotated so that their inferior borders match with the superior border of the spinal portal, which is treated with either one or two fields, depending on the length of the spine to be treated.[119] Two junctional moves are typically made at one-third and two-thirds of the total dose. The spinal field central axis is shifted away from the brain by 0.5 cm and the field size length reduced by 0.5 cm with corresponding increases in the length of the cranial field, so that a match exists between the inferior border of the brain portal and the superior border of the spine portal. To achieve the match, a collimator rotation for the whole-brain portals must be done for an angle given by the following relationship:

$$\tan \theta^{-1} = \left(\frac{\frac{1}{2}\text{spinal field length}}{\text{SAD}} \right)$$

In addition, in order to eliminate the divergence between the cranial portal and spinal portal, the table is rotated through a floor angle given by the following relationship:

$$\tan \alpha^{-1} = \left(\frac{\frac{1}{2}\text{cranial field length}}{\text{SAD}} \right)$$

RADIATION THERAPY PATIENTS WITH CARDIAC PACEMAKERS

As the population ages, the likelihood of encountering patients with either a pacemaker or an implantable cardioverter–defibrillator (ICD) who require radiation therapy for chest and lower neck neoplasms has become commonplace. Pacemakers are electrical devices that may stimulate the atria, ventricles, or both (single-chamber and dual-chamber models, respectively) in order to regulate the

heart's natural rhythm.[120] ICDs are generally larger than pacemakers and also actively shock the heart to help control life-threatening, irregular heartbeats, especially those that could cause sudden cardiac arrest; most new ICDs can act as both pacemakers and defibrillators.[121] Modern pacemakers and ICDs incorporate complementary metal oxide semiconductor (CMOS) circuitry into their generator units (encompassing a sealed lithium battery pack and circuitry only). Several groups have shown that these modern devices are much more sensitive to radiation than the older models that utilized bipolar transistor circuitry.[122–124]

To safely and adequately treat such patients, it is important to understand the potential effects of radiation therapy on these devices' operation and to take steps to minimize any actions that could jeopardize the cardiac health of the patient. The AAPM TG 34 Report provides a list of widely accepted clinical management guidelines.[125] Potential interactions between a functioning pacemaker and the radiation therapy environment fall into two categories: (a) electromagnetic noise interference (EMI) created by the treatment machine in the course of producing high-energy photon and electron beams and (b) damage due to radiation. Most experts now believe category 1 is no longer a source of concern. However, dose and dose rate are very much a concern.[122,124] Modern pacemakers are radiosensitive and have a significant probability of failing catastrophically at radiation doses well below normal tissue tolerance and, therefore, should never be irradiated by the direct beam. Also, several authors have shown that recommended maximum doses obtained from manufacturers have not proven to be reliable and vary greatly among manufacturers.[126] A recent review by Hudson et al. provides the latest information and points out that radiation-induced device malfunctions are rare, and death associated with that malfunction is even more uncommon.[126] However, they conclude that the adequacy of published guidelines is not supported by hard data. They recommend that it is important to consider all aspects of radiation therapy treatment, not just accumulated dose. These include the effect of backscatter, dose rate, fractionation, and potential EMI with new technologies such as IMRT and respiratory gating. They recommend that each radiation oncology department employ their own policy for the management of patients with pacemakers and ICDs, potentially based on an updated standard national or international guideline similar to that released by the AAPM in 1994 (Table 7.2).

FETAL DOSE

Radiation therapy is standard treatment for several malignancies (e.g., Hodgkin lymphoma, breast cancer) in which the population of women is often of child-bearing age. The issues are complex, and the patient along with the radiation oncologist must evaluate treatment risk to the fetus in such cases. Radiation effects to the fetus are not fully understood and cannot be comfortably predicted for each individual case. If the decision is to irradiate, the dose levels outside the treatment fields should be quantified, and every effort should be made to lower the dose to the fetus. This may require changes in irradiation technique (i.e., modified mantle fields), elimination of double-exposure portal images, and the addition of special patient shields. The AAPM TG 36 Report provides data and techniques to estimate and reduce radiation dose to the fetus for beam energies ranging from ^{60}Co to 18 MV.[127] Before the pregnant patient is treated, the pregnancy stage should be known to estimate the size and location of the fetus throughout the treatment. Dose-estimation points should be selected that allow estimation of dose throughout the fetus (e.g., fundus, symphysis pubis, and umbilicus).

TABLE 7.2 MANAGEMENT GUIDELINES FOR RADIATION THERAPY PATIENTS WITH CARDIAC PACEMAKERS

1. Pacemaker-implanted patients should never be treated with a betatron.
2. Have the patient's coronary and pacemaker status evaluated by a cardiologist before and soon after completion of therapy.
3. Always keep the pacemaker outside the machine-collimated radiation beam, both during treatment and when taking portal films.
4. Carefully observe the patient during the first therapy session to verify that no transient malfunctions are occurring and during subsequent treatments if magnetron or klystron misfiring (sparking) occurs.
5. Before treatment, estimate and record the dose (from scatter) to be received by the pacemaker. The total accumulated dose should not exceed ~2 Gy.
6. If treatment within these guidelines is not possible, the physician should consider having the pacemaker either temporarily or permanently moved before irradiation.
7. If a patient has an automatic implantable cardioverter–defibrillator (AICD), the physicist should follow the same steps as one would for pacemakers in contacting the manufacturer and simultaneously ascertaining the dose expected to the AICD. If there is no manufacturer information concerning radiation effects to the AICD, a conservative threshold of 100 cGy should be considered.

Modified from Marbach JR, Sontag MR, Van Dyk J, et al. Management of radiation oncology patients with implanted cardiac pacemakers: report of AAPM Task Group No. 34. *Med Phys* 1994;21(1):85–90.

Two methods can be used to reduce the dose to the fetus, namely,

modification of treatment techniques and the use of special shields. Modifications include changing field angle (avoiding placement of the gantry close to the fetus, i.e., treatment of a posterior field with the patient lying prone on a false tabletop), reducing field size, choosing a different radiation energy (avoiding ^{60}Co because of high leakage or energies of >10 MV because of neutrons), and using tertiary collimation to define the field edge nearest to the fetus. When shields are designed, the shielding device must allow for treatment fields above the diaphragm and on the lower extremities. Safety to the patient and personnel is a primary consideration in shield design. As part of the management of a pregnant patient, the treatment planning tasks listed in Table 7.3 should be performed to ensure that the dose to the fetus is kept to a minimum.[127]

It should be noted that the aforementioned AAPM TG Report was based on treatment machines that predated modern MLCs. One study showed that the use of tertiary MLC systems such as those found on Varian linacs actually reduced fetal dose during irradiation of a pregnant patient.[128] The leaf and carriage system provided some absorption, and if the MLC leaves were oriented in direction along the plane of concern, such as typically when a patient with Hodgkin disease is treated (i.e., leaves oriented along the length of the table), the reduction difference when compared to having no MLCs was on the order of 2.5 to 3.

TABLE 7.3 TREATMENT PLANNING TASKS TO ENSURE THAT DOSE TO THE FETUS IS KEPT TO A MINIMUM

1. Complete all planning as though the patient were not pregnant.
2. Consider modifications of the plan that would minimize the fetal dose (e.g., changing field size and angle, using a different energy).
3. Estimate dose to fetus without shielding using a phantom or data from the AAPM report.[120]
4. Design and construct special shielding if necessary; four or five HVLs of lead usually suffice.
5. Measure dose to fetus in a phantom during simulated treatment with shielding in place.
6. Document the treatment plan and discuss the treatment with all personnel involved with the treatment.
7. Check all aspects of safety, including the load-bearing limits of the couch and support and movement of the shields, to ensure that there will be no injury to the patient or to personnel. The setup of each field should be photographed for documentation.
8. Monitor fetal size and location throughout the course of therapy and update estimates of fetal dose if necessary.
9. Document the completion of treatment by estimating the total dose to the fetus because of the radiation therapy.

Modified from Stovall M, Blackwell CR, Cundiff J, et al. Fetal dose from radiotherapy with photon beams: report of AAPM Radiation Therapy Committee Task Group No. 36. *Med Phys*

1995;22(1):63–82.

GONADAL DOSE

Many of the reports used to estimate peripheral dose and fetal dose apply to dose estimations to both testes and ovaries.[129,130] Simultaneously, there have been studies to determine the genetically significant dose (GSD) as it applies to peripheral radiotherapy dosage to ovaries and testes. Niroomand-Rad and Cumberlin[131] combined measured data and GSD data to determine the GSD for particular treatment techniques that deliver peripheral dose to ovaries and testes. They summarized that GSDs from conventional therapies are minimal. However, there are circumstances, such as treatment of seminoma, when it is necessary to use a testicular shield to surround the testes to reduce head scatter and leakage, and some internal scatter.[132]

CHAPTER 8

Electron Beam Therapy Dosimetry, Treatment Planning, and Techniques

Angelica Perez-Andujar and Eric E. Klein

INTRODUCTION

Megavoltage-photon–based radiation therapy treatment of shallow tumor volumes is complicated by the buildup and radiation transport properties of photon beams. These beams are capable of treating both shallow and deep tumors; however, when treating shallow tumors, the radiation beams transit through the entire patient, exposing distal normal tissues. Megavoltage electron beams have the property of a finite range and therefore do not deliver significant radiation doses to distal depths. Electron beam therapy is therefore suitable for shallow tumors (<5 cm deep), such as head and neck cancers, skin cancers, chest wall irradiation for breast cancer, and boost dose to nodes. Electrons typically provide dose uniformity in these target volumes, with minimal dose to distal organs. In fact, G.H. Fletcher[1] had gone as far as saying, “There is no alternative treatment to electron-beam therapy.” Even the strongest proponents of photon or proton therapy acknowledge that electron therapy is necessary to complete any radiotherapy program.

In 1976, Tapley[2] published one of the earlier comprehensive treatises on electron radiation therapy, in which she states, “There is no practical way for every radiation therapy department, in either hospitals or private offices, to be equipped with all modalities of irradiation beams. Ideally, electron beams should be available for those clinical situations where electrons are indispensable or very clearly superior.” Electrons are now used at most radiation therapy centers. It still might be advantageous to refer patients to regional centers for special treatment techniques utilizing electrons.

Since the late 1970s, there have been three developments in electron beam radiation therapy technology that have improved significantly our ability to

deliver electron therapy. First, the advent of computed tomography (CT)-based treatment planning allowed for coverage of the planning target volume (PTV) by the therapeutic dose and the dose to normal tissues and structures to be more accurately assessed. Use of CT provides a physical description of the anatomy, which is required for accurate dose calculations.[3,4] Second, the development of the electron pencil beam algorithms (PBAs) and their implementation into treatment planning systems in the early 1980s provided a mechanism for accurately calculating dose.[5,6] More recently, the use of Monte Carlo calculations has moved development to commercial platforms.[7] They have demonstrated high degrees of accuracy, especially with the presence of inhomogeneities. Third, manufacturers have refined the quality of their electron beams (i.e., depth dose, off-axis uniformity, and penumbral width) by providing dual-scattering foil systems and electron applicators. Klein et al.[8] describe dosimetric improvement with the most recent Varian electron beam delivery system. Presently, the differences in the electron beam dose characteristics of various radiation therapy machines from different vendors are minimal. Kashani et al.[9] described electron beam characteristics of a new configured beam line for the Varian TrueBeam machine.

Electron beam therapy is advantageous because it delivers a reasonably uniform dose from the surface to a specific depth, after which dose falls off rapidly, eventually to a near-zero value. The depth of treatment is controlled by selecting the appropriate energy and, when necessary, the bolus thickness. Using electron beams with energies up to 20 MeV allows disease within approximately 6 cm of the surface to be treated effectively, sparing distal normal tissues.

Electron beam therapy is useful in treating cancer of the skin and lips, upper respiratory and digestive tract, head and neck,[10,11] breast, and a variety of other sites.[2,12,13] Treatment sites of the skin include the eyelids, nose, ear,[14] scalp,[2,15] and more widely spread diseases of the limbs (e.g., melanoma and lymphoma)[16] or total skin (e.g., mycosis fungoides).[17,18] Treatment sites of the upper respiratory and digestive tract include the floor of mouth, soft palate, retromolar trigone, and salivary glands.[10,19] Treatments of the breast include chest wall irradiation following mastectomy[2,20,21]; nodal irradiation, often internal mammary chain (IMC) and occasionally axillary; and boost to the surgical bed following mastectomy or lumpectomy.[22] Current techniques of using tangential photon adjunct fields abutting supraclavicular and posterior axillary fields are difficult enough without the addition of treating a separate medial breast internal mammary field with a mixture of photon and electrons. Other sites of electron

beam therapy include the retina,[23] orbit,[24] paraspinal muscles,[3,25] pancreas and other abdominal structures (intraoperative therapy),[26] vulva,[27] and cervix (intracavitary irradiation).[28]

The purpose of this chapter is to discuss the treatment and treatment planning techniques necessary to deliver the most effective electron beam therapy. This requires a basic knowledge of dose distribution in water, dose in the heterogeneous patient, treatment planning tools and principles, and special techniques using electron beams.

DOSE DISTRIBUTION IN WATER

To appreciate the clinical use of electron beams, their dose distributions in water must be understood. Understanding the properties of depth dose, off-axis ratios (OARs), and two-dimensional (2-D) isodose contour plots will clarify the concept of dose distribution in water. As well, an understanding of the dependence of the dose distribution on incident energy, field size, and source-to-surface distance (SSD) is required. It is assumed that the dose distribution for a specified energy, field size, and SSD is machine dependent. Applicator design may have a minor influence on dose distributions.

Depth Dose

This section discusses percentage of dose (values are normalized to 100% at the depth of dose maximum, R_{100}) versus depth in water. Central-axis depth dose implies that the electron field is symmetric about the central axis, and the focus initially will be on square fields. Electron depth dose varies with field size; however, once the field reaches a certain size, side-scatter equilibrium is achieved, and further increasing the size has an insignificant effect on depth dose.[29,30] In the energy range of up to 20 MeV, a 10 by 10 cm^2 field size typically will achieve side-scatter equilibrium on central axis. The energy dependence of depth dose is illustrated in Figure 8.1, where central-axis depth dose is plotted for a 10 by 10 cm^2 field for energies in the range of 7 to 18 MeV. The family of curves illustrates how the dosimetric characteristics vary with the incident electron energy:

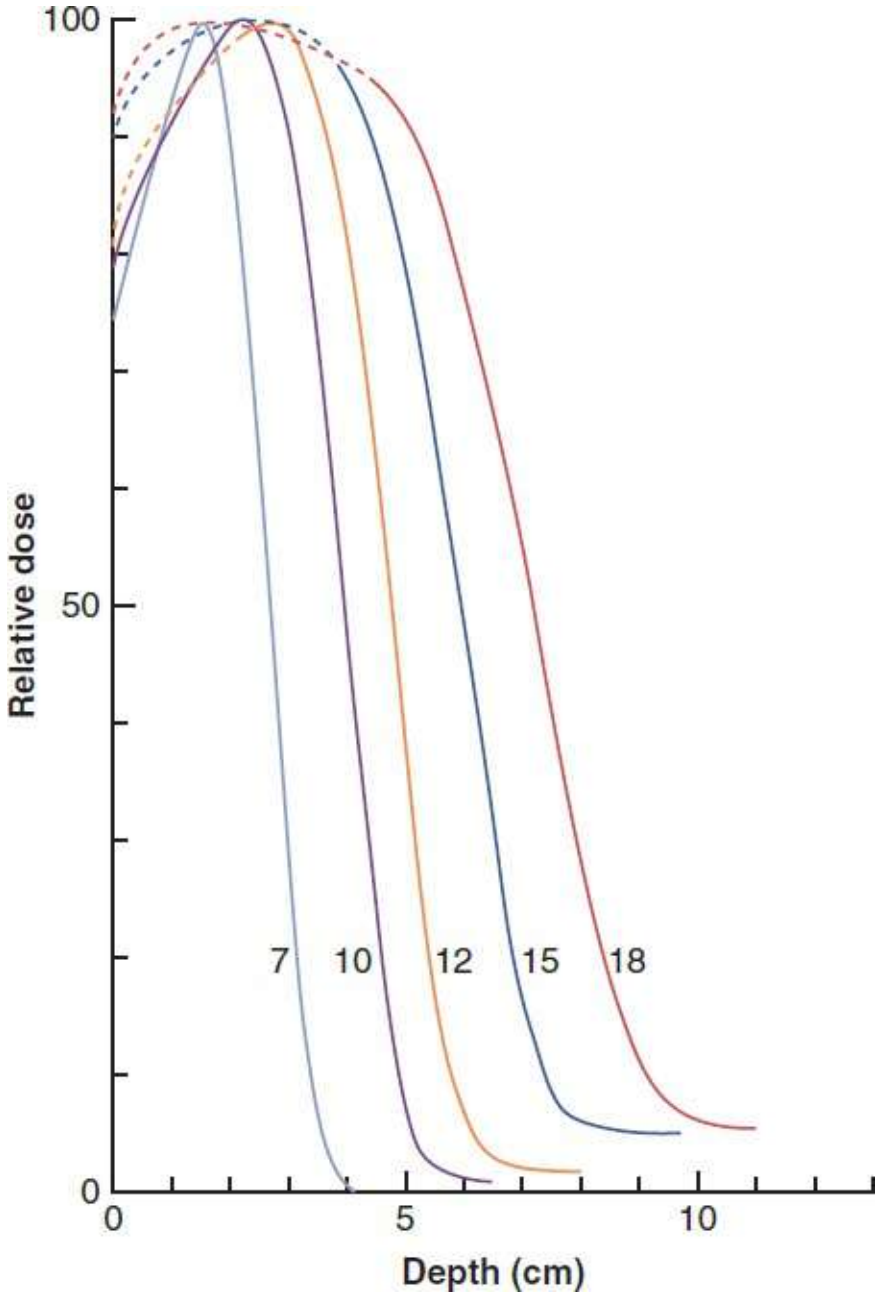

FIGURE 8.1. Energy dependence of depth dose. Plot of relative dose (%) versus depth for a 10 by 10 cm^2 field size for 7- to 18-MeV beams on a Siemens Mevatron 77 radiation therapy unit (source-to-surface distance, or SSD = 100 cm). (From Meyer JA, Palta JR, Hogstrom KR. Demonstration of relatively new electron dosimetry measurement techniques on the Mevatron 80. *Med Phys* 1984;11[5]:670–677. Copyright © 1984 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.)

. Surface dose (D_s) increases from approximately 75% to 95% as energy increases. The slow increase in dose from the surface to the depth of maximum dose (R_{100}) occurs as a result of electrons undergoing multiple Coulomb

scattering in water.[29]

- Depth of distal 90% (R_{90}), often the therapeutic prescription depth, increases as energy increases. A physician may also prescribe to the 80% or 100% depth.
- The practical range (R_p) (maximum penetration) of the electrons increases as energy increases.
- X-ray dose attributable to bremsstrahlung that lies beyond the electron dose component is characterized by its value (D_x) and is taken from the PDD curve 10 cm beyond the practical range (R_p). D_x increases as energy increases. Machines are designed to provide Rx values to be <5%.
- The R_{100} depth (d_{max}) can vary irregularly with depth and model of electron treatment machine; its dependence is insignificant for treatment planning, although it is significant to the medical physicist for constructing percent depth-dose data and in beam calibration.

Table 8.1 gives dosimetric parameters for a modern (Trilogy, Varian) linear accelerator.

Depth dose has a significant dependence on field size, which varies with incident electron energy. The primary reason for the field-size dependence is loss of side-scatter equilibrium, which has been discussed in detail by Hogstrom[29] and Khan et al.[30] Figure 8.2, which shows the field-size dependence of percentage depth dose at 9 and 20 MeV, clearly illustrates that it is a greater issue at higher energies. Loss of side-scatter equilibrium, which begins first at the deeper depths, results in R_{90} shifting toward the surface as field size decreases. As the field size gets even smaller, the maximum dose decreases; and when it is normalized to 100%, the relative dose at the surface, D_s, increases. In addition, the effects on the distal portion of the depth-dose curve are greater. The most clinically significant effect is the decrease in R_{90} with decreasing field size, which can require a greater energy than initially proposed for treatment using very small fields (<5 cm).

Depth-dose variations with SSD are usually minimal. Differences in the depth dose resulting from inverse square effect are small because electrons do not penetrate that deep (≤6 cm in the therapeutic region) and because the significant growth of penumbra width with SSD restricts the SSD in clinical practice to typically 115 cm or less. The primary effect of inverse square is that R_{90} penetrates a few millimeters deeper at extended SSD at the higher energies, as illustrated in Figure 8.3. In relatively few cases (e.g., when the electron beam has a large component of collimator-scattered electrons), the variation in depth dose

with SSD can become more significant. In such cases, the collimator-scattered electrons are scattered out of the beam, resulting in a depth dose with a lower D_s and greater R_{90}.[31]

For rectangular fields, Hogstrom[32] derived and others have confirmed[31,33] that percentage of depth dose can be calculated by taking the geometric mean of the percentage of depth doses for a square field of length dimension (L) and one of width dimension (W). That is:

$$\%D(d; LxW) = \sqrt{\%D(d; LxL) \cdot \%D(d; WxW)} \qquad (1)$$

If the square field percentage of depth-dose curves do not have a common R_{100}, then the result of Eq. (1) must be normalized such that its maximum equals 100%. This method is referred to as the square-root method.

In some instances (e.g., intraoperative, intraoral, or intravaginal cones), circular fields are used. In such cases, it is necessary to measure dose distributions independent of those determined for square or rectangular fields.

Usually, a collimating insert is placed inside an electron applicator to form an irregular-shaped field, occasionally blocking the central axis. In this instance, central-axis depth dose makes little sense, and the term *central-field depth dose* should be used, provided that the field has an axis of symmetry. In cases where the insert is irregular, the depth dose can be approximated using a rectangular-shaped field that approximates the irregular-shaped field.[34] In highly irregular-shaped fields, the dose distribution should be calculated using an appropriate dose algorithm in a three-dimensional (3-D) treatment planning system. For very small fields, irregular or otherwise, it is highly recommended that PPD measurements be performed to properly determine prescriptive choices (i.e., R_{90}).

TABLE 8.1 Varian Trilogy Measured Electron Depths (R_p, R_{50}) and Calculated Energies (E_p, E_0)

Nominal Energy	Measured E_o (MeV)	Measured E_p (MeV)	R90: Depth of 90% (cm)	R50: Depth of 50% (cm)	R_p (cm)	Dx (%)
6	5.55	6.08	1.53	2.38	2.95	0.1
9	8.41	8.84	2.69	3.61	4.33	0.3
12	11.77	12.23	3.85	5.05	6.02	0.9
16	15.63	16.02	5.10	6.71	7.900	1.6

20	19.62	20.78	6.14	8.42	10.25	2.1

E_o: Average energy at the surface, where $E_0 = 2.33 \times R_{50}$.

E_p: Most probable electron energy at the surface, where $E_p = C_1 + C_2 R_p = C_3 R_p^2$ and where C1, C2, and C3 are constants, with C1 = 0.22 MeV, C2 = 1.98 MeV cm^1, and C3 = 0.01025 MeV cm^2.

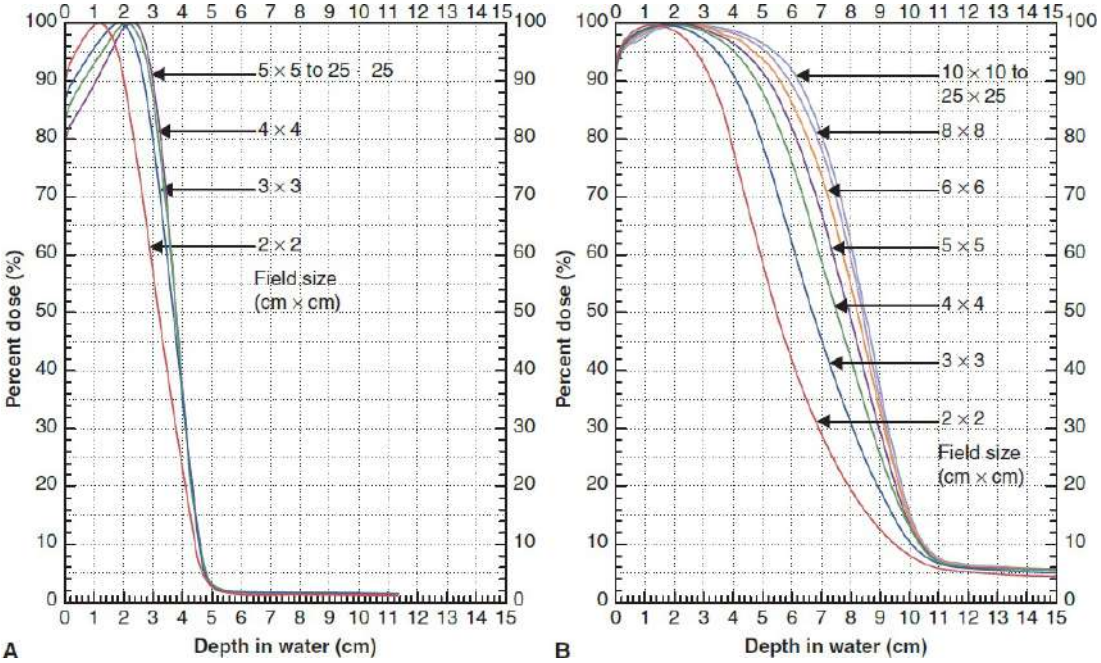

FIGURE 8.2. Field-size dependence of depth dose. Plot of percent dose versus depth for field sizes from 2 by 2 to 25 by 25 cm^2 for 9-MeV **(A)** and 20-MeV **(B)** beams on a Varian Clinac 2100C radiation therapy unit (source-to-surface distance, or SSD = 100 cm). (Courtesy of Varian, Palo Alto, CA.)

Off-Axis Dose

Dose profiles in the dimensions perpendicular to the central axis can be described by OARs. The OAR is defined as the ratio of dose at an off-axis position to that on the central axis at the same depth. The OARs measured in water are used to assess off-axis beam quality, which is characterized by flatness and symmetry in the uniform portion of the beam and by its falloff in the region of the penumbra (e.g., 90% to 10%, or 80% to 20%).

Manufacturers should be able to provide electron beams with a symmetry specification of 2% for opposing points in the beam and a flatness specification of ±3% of the *central-axis value* along the major axes (±4% along diagonals). The American Association of Physicists in Medicine (AAPM) Task Group 25 recommended that flatness and symmetry should be evaluated along major axes (lines containing central axis and perpendicular to the collimator edges) and along diagonal axes.[30] Task Group 25 also recommended that flatness and

symmetry be evaluated at depths near the surface and therapeutic depth. Practically, this is performed at R_{100}.

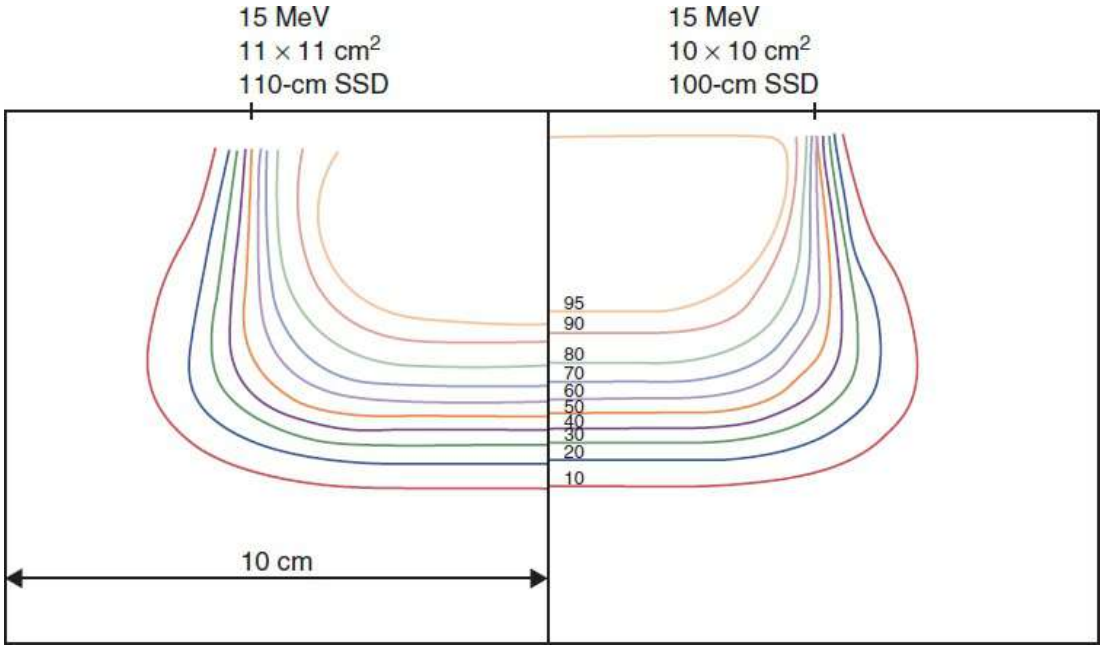

FIGURE 8.3. Source-to-surface distance (SSD) dependence of depth dose. Comparison of isodose plots for 15-MeV beam, 10 by 10 cm^2 at 100-cm SSD with 11 by 11 cm^2 field at 110-cm SSD. (From Hogstrom KR. Clinical electron-beam dosimetry: basic dosimetry data. In: Purdy JA, ed. *Advances in radiation oncology physics: dosimetry, treatment planning, and brachytherapy. Woodbury*: American Institute of Physics, 1992:390–429. Copyright © 1992 by American Association of Physicists in Medicine. Reprinted by permission.)

Flatness and symmetry are evaluated inside the penumbra, which usually is ensured by setting the boundaries of evaluation 2 cm inside the collimating edge ($2\sqrt{2}$cm along diagonals). When physicist perform acceptance-tests for a treatment machine, and during subsequent annual reviews, they use the AAPM Task Group 142 recommendations of 2% symmetry and 5% flatness.[35] This is usually performed for each energy with an average-size applicator but should be tested for each applicator during acceptance. Subsequently, the profiles acquired during acceptance should be reviewed monthly and be consistent to within 1% of the acceptance values.[35,36]

Penumbra of electron beams is predetermined by the design of the beam flattening system, the air gap between the final collimator, and the scatter of electrons in water. The penumbra is a function of depth and is the root mean square addition of two penumbral components: one the result of the air gap and one the result of scatter in the water.[6] This dependence is complex but can be

appreciated qualitatively by the illustration in Figure 8.4, which compares isodose plots for normal (100 cm) and extended (110 cm) SSD at 6 and 16 MeV, respectively. These data show that penumbra grows in a nonlinear fashion with depth, that air gap is more significant at the lower energies, and that scatter in water dominates at the higher energies. Fortunately, the complex dependence of penumbra can be modeled accurately in treatment planning systems using the pencil beam or more sophisticated dose algorithms.[29,32,34,37]

Isodose Plots

Combining depth dose with OARs results in the 3-D dose distribution, and the properties of the 3-D dose distribution can be appreciated by viewing 2-D isodose contour plots in a plane containing the central axis and a major axis. Examples of these plots for a 15 by 15 cm^2 field are illustrated in Figure 8.5. As field width decreases or increases, the penumbra shape changes insignificantly because it is most significantly influenced by air gaps and by collimation type. Collimating on the skin, for example, reduces penumbra significantly.

Data required for isodose contours are acquired for an inclusive spread of field sizes at each energy. Two-dimensional isodose contour plots and data are useful for manual treatment planning, input data required by dose algorithms, verification of dose calculated by a treatment planning system, and quality assurance standards.[29,30,38]

DOSE IN THE HETEROGENEOUS PATIENT

For most clinical circumstances, the ideal irradiation condition is for the electron beam to be incidentally normal to a flat surface with underlying homogeneous soft tissues. The dose distribution for this condition, similar to that for a water phantom described previously, contains a reasonably uniform dose inside the penumbra from the surface to R_{90}, and it has the sharpest possible falloff laterally and with depth. As the angle of incidence deviates from normal, as the surface becomes irregular, and as internal heterogeneous tissues (e.g., air, lung, and bone) become present, the qualities of the dose distribution degrade.[39] Internal heterogeneities can change the depth of beam penetration as a result of differences in the rate of energy loss, which can result in PTV underdose and critical structure overdose. Both irregular surfaces and internal heterogeneities create changes in side-scatter equilibrium, producing volumes of increased dose (hot spots) and decreased dose (cold spots), potentially leading to an increased dose to critical structures and decreased dose to the PTV.[3,39] These perturbations can be reduced or eliminated by modifying the treatment technique.

Irregular Surfaces

Two geometries that illustrate the effects on the dose distribution caused by an irregular patient surface are the sloped skin surface and the stepped skin surface. Figure 8.5 illustrates changes in the depth-dose curve as a result of nonnormal incidence of an electron beam onto a flat surface. Compared with normal incidence, the nonnormal incident electron beam, central-axis, depth-dose curve shows the following: (a) an increased surface dose, (b) an increased maximum dose, (c) a decreased penetration of the therapeutic dose (R_{90}), and (d) an increased range of penetration.[30,40] These changes can be clinically significant, particularly at angles of incidence >30 degrees from the normal. Such conditions can occur when irradiating curved patient surfaces with large fields (e.g., chest

wall, limbs, neck, and scalp). In addition, it should be appreciated that the depth of R_{90} is specified along the central axis of the beam; and if the depth is taken perpendicular to the surface, then the depth is further reduced (approximately) by a factor cos (φ), where φ is the deviation of the incident angle from the normal.

Any time a sharp gradient (stepped surface) occurs on the patient's surface, side-scatter equilibrium will be lost, resulting in a cold spot beneath the proximal surface and a hot spot beneath the distal surface.[32,39,41,42] This can occur as a result of a sharp bolus edge, surgical defects, or within normal anatomy. For example, in the use of a uniform-thickness bolus that partially covers a field, a 90-degree step can result in hot or cold spots as great as 20%, as illustrated in Figure 8.6. In such a case, the bolus should be tapered as much as possible. The results of a 45-degree tapered bolus in Figure 8.6 show a reduction in the hot spot but more significantly an increased coverage of the 90% isodose contour. The nose is a protrusion that creates a cold spot, often the location of the tumor.[5,33,39] The ear canal (Fig. 8.7) and surgical voids, which are characterized by a depression in the patient's surface, can result in hot spots in excess of 50%, depending on void dimension and beam energy.[43,44] Such depressions normally should be filled with some type of bolus material. Normal anatomy contains many irregular surface depressions and protrusions (e.g., the ear canal and the nose, respectively) and should be accounted for by accurate treatment planning.

Air Cavities

The influence of an internal air cavity is illustrated in Figure 8.8, which compares isodose contours beneath an air cavity to those without the air cavity. Results show that (a) the isodose contours in the shadow of air are shifted distally, (b) the dose beneath the air cavity increases as a result of loss of side-scatter equilibrium, and (c) the influence of the air increases laterally with depth. Internal air cavities of clinical interest primarily occur in treatment of the head and neck (e.g., nasal passages, ethmoid sinuses, maxillary sinuses, larynx, and mastoids).[32,39]

Another significant effect is the reduction in dose in unit density tissue lateral to an air cavity. Electrons scattering from the unit density tissue into the air are not replaced because air is unable to scatter an equal amount back into the unit density tissue. Frequently, nose tumors can spread into the septum, in which case bolus should be used to eliminate or reduce underdosing.

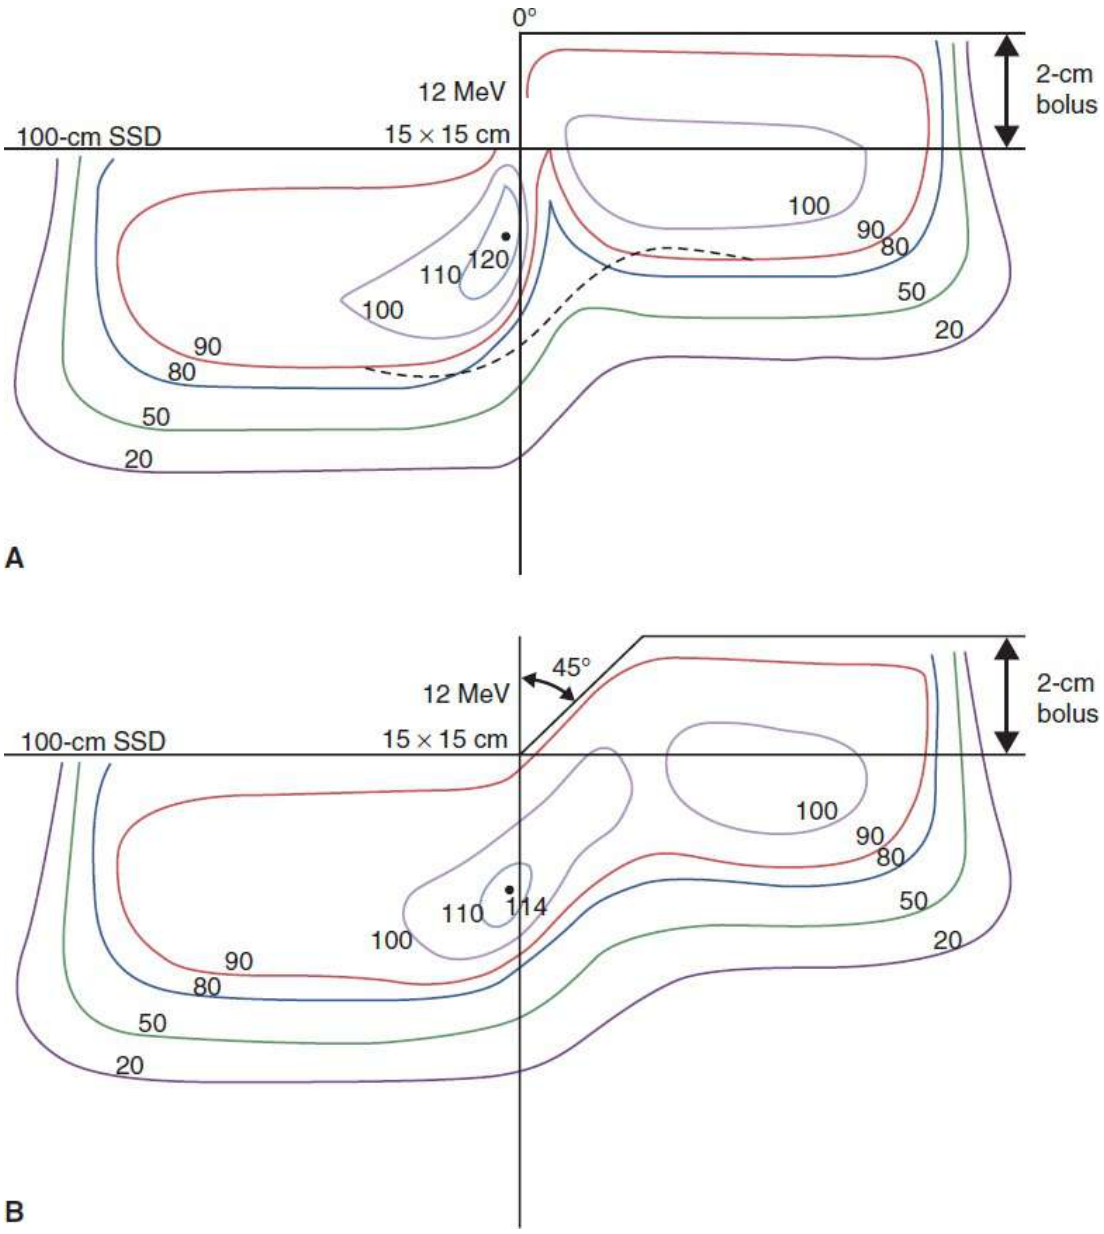

FIGURE 8.6. Effect of irregular patient surface on dose distribution. Plot of isodose contours for a 12-MeV, 15 by 15 cm^2 beam incident on water at 100-cm source-to-surface distance (SSD) having a stepped surface resulting from a 2-cm slab of bolus **(A)** and a beveled edge (45 degree) on the stepped surface **(B)**. The *dashed line* in the top figure shows the location of the 90% isodose contour in the bottom one. (From Hogstrom KR. Treatment planning in electron-beam therapy. Lung

In lung, electrons can penetrate three to four times farther than in unit density tissue. This is demonstrated in Figure 8.9, where isodose contours from a typical electron chest wall treatment are compared with those in which the lung is assumed unit density. Assuming a given dose of 50 Gy, the 40% isodose contour corresponds to 20 Gy, approximately the threshold for pneumonitis, if significant lung volume is irradiated. Ignoring the low density of lung would grossly underestimate the volume of lung receiving more than 20 Gy.[32]

This effect increases with energy. For example, increasing the beam energy from 9 to 12 MeV results in an additional 1.5 cm of penetration in water-like

tissue (electrons lose energy at a rate of ~2 MeV per centimeter in water), and this corresponds to as much as 6.0 cm in lung (assuming a lung physical density of 25%). Consider the patient whose chest wall thickness requires an energy of 10 MeV for treatment and that 12 MeV must be selected. This results in as much as 4 cm in depth of needless irradiation in lung, unless 1 cm of bolus is used to effectively lower the energy incident on the patient to 10 MeV.

Care must be taken when irradiating targets where the lung is immediately distal, such as with entire chest wall postmastectomy irradiation.

Bone

Interactions of electrons with bone are complex and interesting. The influence of bone is illustrated in Figure 8.10, which compares isodose contours beneath the hard bone to those without the bone. The results show that:

- The isodose contours in the shadow of the bone are shifted proximally,
- Dose outside (inside) the bone–water interface increases (decreases) by approximately 5% as a result of loss of side-scatter equilibrium, and
- The lateral dimension of the region having its dose perturbed by the bone increases with depth.

Living bones are not uniformly dense throughout their cross-section, and in most cases, their edges are not parallel to the incident beam. Both differences decrease the influence of bone in generating inhomogeneity in the patient's dose distribution. Dense bones that significantly affect the dose distribution include the mandible, bones of the skull (e.g., frontal bone and zygoma in orbit treatment or temporal bone in treatment of parotid), clavicles, and vertebral processes (e.g., craniospinal irradiation).

One might ask, "What is the clinical significance of the increase in dose in or around bone because of increased scatter?" The maximum dose increase expected as a result of backscattered electrons is 5%, and the maximum dose increase expected inside bone and in adjacent exit tissues is approximately 7%.[45] These increases represent maximum dose estimates because actual bones are not as dense through and through as are the bone substitute in which these data were taken. These estimates of the increased dose are not expected to be clinically significant. In fact, untoward effects in or around bone that can be attributed to dosimetry have not been observed in patients treated with electron beam therapy.

DOSE PRESCRIPTION AND CALCULATION OF MONITOR

UNITS

Dose Prescription

It is recommended that dose be prescribed to given dose or 90% of given dose. Intermediate or lower prescription (95%, 85%, 80%) can be prescribed if the energy (typically stepped in 3- to 4-MeV increments) choices are too coarse to maintain a single baseline prescription recipe. Given dose is defined as the maximum central-axis dose in a water phantom at the SSD of the patient for the energy, applicator, and field size identical to that used for patient treatment. If the field shape is irregular, then the field size is taken to be a rectangular field representative of the irregular field shape. The most representative rectangular field is not well defined; however, Hogstrom et al.[37] have provided one methodology for determining its estimate.

It is recommended that the dose is prescribed to given dose or a percentage of it and not to a point in the patient. It is quite possible that a dose prescription point in the patient could be in a region of increased or decreased dose because of tissue heterogeneity or irregular surface, which could result in PTV underdose or overdose, respectively.

Calculation of Monitor Units

Monitor units can be determined by

$$MU = \frac{D_{\text{prescribed}} / \%D}{O(E, C, LxW, SSD)}, \qquad (2)$$

where $D_{\text{prescribed}}$ is the prescribed dose, $\%D$ is the percentage of given dose to which dose is prescribed (e.g., 90%), and $O(E, C, LxW, SSD)$ is the output (dose per monitor unit) for a beam of energy E, applicator C, field size LxW, and SSD. To use this methodology, the medical physicist must measure dose output as a function of square field size and SSD for each energy–applicator combination at the time of commissioning the accelerator. Output for rectangular fields can be determined using the square-root method of Mills et al.[14,46] and Shiu et al.[31]:

$$O(E, C, LxW, SSD) = [O(E, C, LxL, SSD) \cdot O(E, C, WxW, SSD)]^{1/2}. \qquad (3)$$

Output for rectangular fields also can be determined using an equivalent square method[30,33,47,48]; however, Biggs et al.[47] recommend limiting this method to an aspect ratio ($L:W$) of 2:1. The square-root method is not limited to the

aspect ratio, and Shiu et al.[31] have shown it to be more accurate. Figure 8.11 illustrates beam output data at 9 MeV for four common applicators used on the Varian Clinac 2100C (Varian Medical Systems, Palo Alto, CA) at 100 cm SSD.

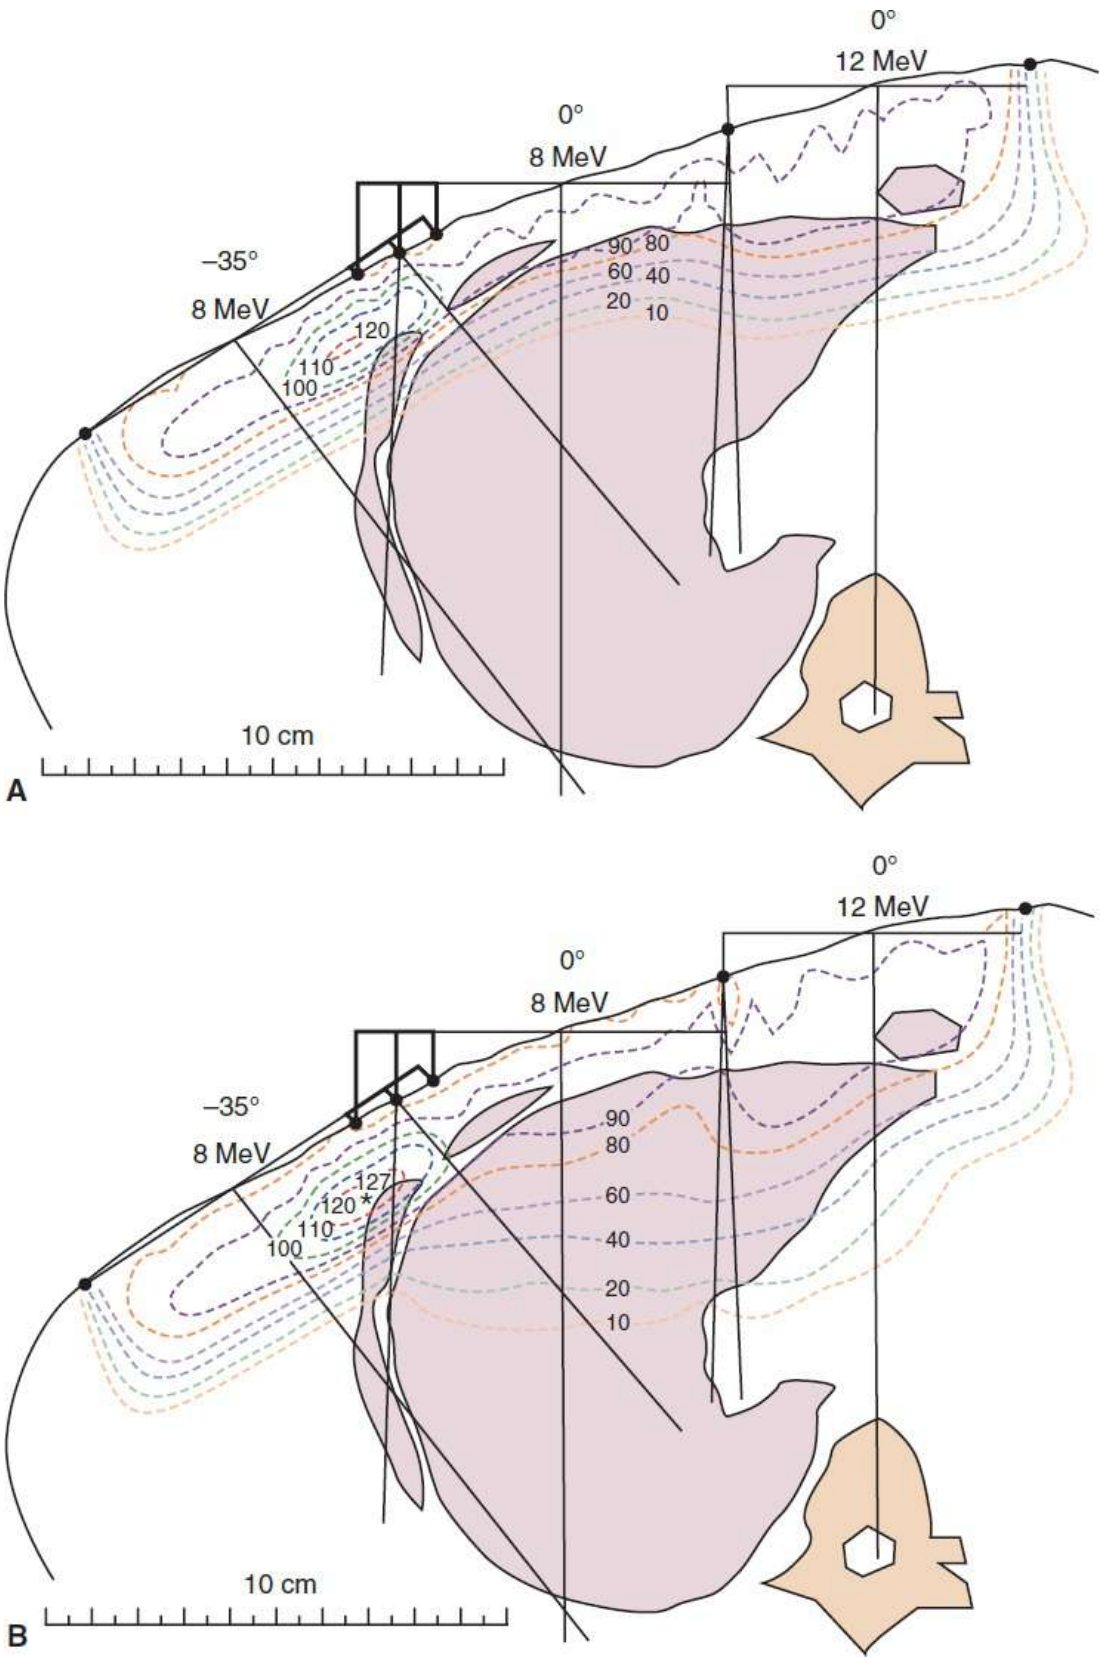

FIGURE 8.9. Effect of lung on dose distribution underlying chest wall. Comparison of dose calculated by the pencil beam algorithm (PBA) for 8-MeV chest wall irradiation,

assuming patient's water **(A)** and heterogeneous anatomy **(B)** based on computed tomography data.

Output at extended SSD can be determined by either the air-gap method or the effective-source method.[30] The effective-source method is covered in detail by Khan.[48] The air-gap method has a sounder physical basis. Although both methods give similar answers, only the air-gap method will be covered here.[33] Output at extended SSD is given by the product of output at the nominal SSD (SSD_0), the air-gap factor (fair), and an inverse square term,

$$O(E, C, LxW, SSD) = O(E, C, LxW, SSD_0)\, f_{air}\,(E, LxW, SSD) \times \left(\frac{SSD_o + R_{100}}{SSD + R_{100}}\right) \quad (4)$$

f_{air} is determined by measuring dose output for square fields at the extended SSD and then solving equation 4. For rectangular fields, the air-gap factor is determined using the square-root method[31]:

$$f_{air}(E, LxW, SSD) = \sqrt{f_{air}(E, LxL, SSD) \cdot f_{air}(E, WxW, SSD)} \quad (5)$$

As f_{air} is assumed independent of applicator, the dose output needs to be measured only for the smallest applicator that contains the square field size. Figure 8.12 plots the square field air-gap factors for the 9-MeV beam of the Varian Clinac 2100C for SSD from 100 to 120 cm. For a more detailed explanation of dose output and sample calculations of monitor units for electron beams, refer to Hogstrom et al.[34] Another practical option is to fix incremented SSDs to be used clinically (i.e., 100, 105, 110, 115 cm) and establish tabular outputs for each energy–applicator SSD combination.

CALCULATION OF DOSE IN PATIENT

Standards for Patient Dose Calculations

Sound treatment planning decisions require accurate dose calculation in the patient. Therefore, the following recommendations are made for electron beam treatment planning. First, dose should be calculated in the full three dimensions to allow for evaluation of dose homogeneity in the PTV, coverage of the PTV by the 90% isodose contour, and dose to critical structures. Second, the dose algorithm should account for patient heterogeneity. Failure to properly account for patient heterogeneity can result in failure to appreciate dose heterogeneity, PTV underdose, or normal-tissue overdose.[5,39,49] Third, the dose algorithm should be accurate; and for those conditions for which this is not the case,

physicians and physicists should discuss the proper interpretation of the dose calculations.

To expand on the final recommendation, a dose algorithm must meet certain criteria to be most effective in the clinic.[50] First, it should be accurate to within 4% in regions of low dose gradients or within 2 mm in regions of high dose gradient (e.g., penumbra or depth-dose falloff region).[38,51] Second, the dose algorithm should be commissioned easily by a qualified medical physicist. Third, the accuracy of the dose algorithm should be well documented. Since 1981, the PBA has best this requirement. Presently, several new, more accurate algorithms, both analytical- and Monte Carlo–based, are being implemented into commercial treatment planning systems and will replace or supplement the PBA in due time.[52] Regardless of the algorithm, it is the medical physicist's responsibility to commission the algorithm, to understand its accuracy, and to train medical dosimetrists and radiation oncologists in its use and limitations.

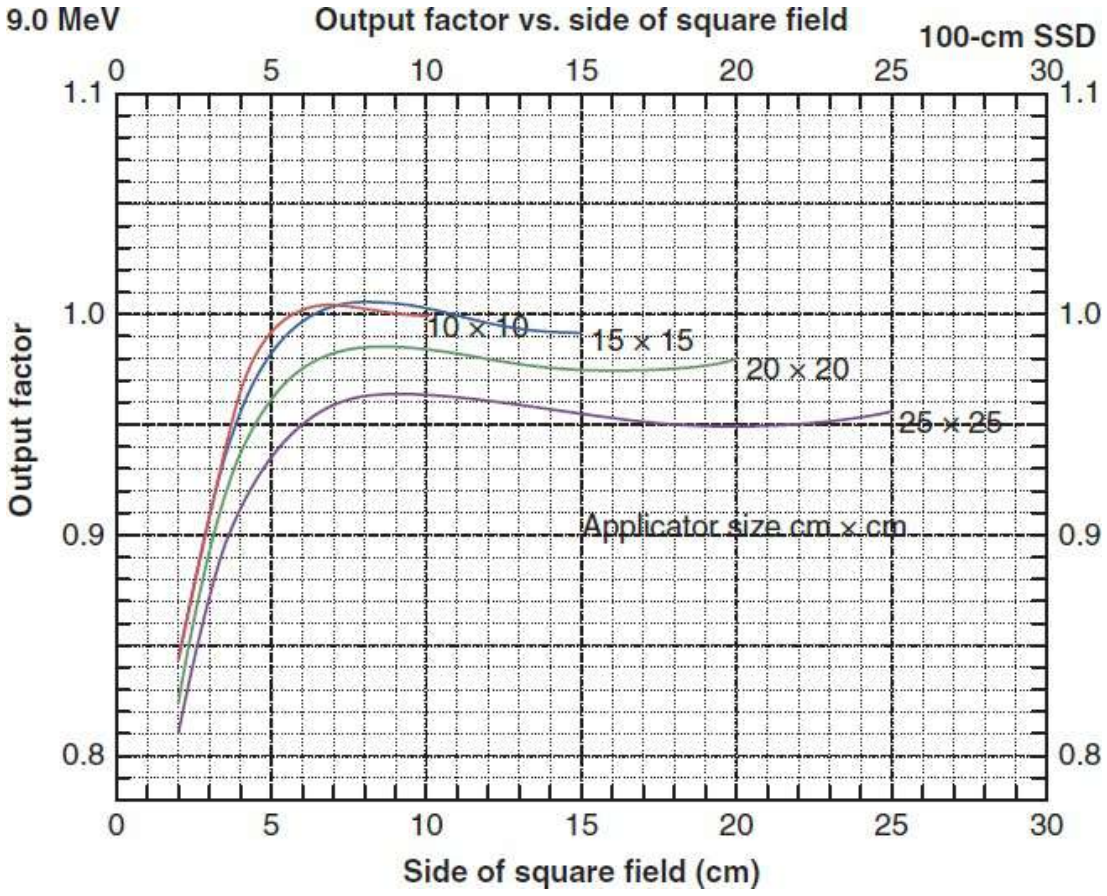

FIGURE 8.11. Field-size dependence of output (dose/monitor unit). Plot of output factor (cGy/MU) versus side of square field from 2 by 2 cm^2 to the open applicator for four applicators and for the 9-MeV beam of a Varian Clinac 2100C. (Courtesy of Varian, Palo Alto, CA.)

Dose Algorithms

As stated, the standard methodology for dose calculation in the patient has been the PBA. As computing power increased, it was possible to implement the algorithms into 3-D format.[53] Detailed instructions for commissioning the dose

algorithm and documentation of its accuracy have been published.[5,6,50] The PBA has been shown to be quite accurate in water at standard and extended SSD, correctly predicting the changes in penumbra.[29,32,34] It is also quite accurate in predicting changes in dose resulting from oblique incidence and irregular surfaces.[5,50] Regarding internal heterogeneities, the PBA correctly predicts the penetration in lung and the growth of the penumbra width in lung[50]; however, it tends to underestimate the dose in lung near the mediastinum as a result of its central-axis approximation.[50] In bone, it correctly predicts the shortening of the dose penetration behind the bone, and it slightly underestimates (<5%) the magnitude of the *hot* and *cold* spots under the edge of a thick hard bone such as the mandible.[5] The PBA does not predict the increased dose (<5%) resulting from backscatter at the proximal tissue–bone interface, nor does it predict the increased dose (>7%) in bone resulting from increased scatter. The PBA underestimates the hot and cold spots under the air–tissue interfaces.[5,50]

New dose algorithms that are accurate to 4% or better are becoming available in commercial treatment planning systems. Many of these algorithms have been reviewed by Hogstrom and Steadham.[50] One of these is the pencil beam redefinition algorithm (PBRA), whose commissioning is similar to that of the conventional PBA, although its accuracy is significantly improved.[54–56] Figure 8.13 illustrates the improvement of the PBRA.

Many of the newer algorithms are based on Monte Carlo methods, which allow them to be quite accurate.[57–61] Cygler et al.[52] published a report on the first commercial system using Monte Carlo–based electron calculations, demonstrating excellent results. Ding et al.[62] demonstrated outstanding results for a macro–Monte Carlo algorithm, along with a companion report showing superior results for Monte Carlo compared with PBA.[63]

TREATMENT PLANNING PRINCIPLES, TOOLS, AND METHODS

Electron therapy is usually restricted to a PTV that is within 6 cm distal from the patient's surface. Electrons may be used alone or in conjunction with photon beams. In the case of the former, the objective of the treatment planner is usually to select the appropriate beam direction, energy, and field size to provide as uniform a dose as possible to the PTV while delivering minimal dose to normal tissue and structures. To optimize dose homogeneity, the beam direction should be as close to normal incidence to the patient surface as practical. Once beam

direction is specified, the selection of energy and field-size specification follows. Figure 8.14 compares the isodose contours in water with the beam edges and R_{90}. Electrons are unique in that the uniform region of dose lies inside the 90% isodose contour. Dose outside the 90% isodose contour falls off rapidly. However, the patient anatomy can differ significantly from water so that effects resulting from patient heterogeneity make the resulting treatment plan unacceptable, according to the original prescription. In addition, the PTV can be at a variable depth beneath the surface so that a single beam energy is inadequate. The treatment plan can be improved by utilization of special treatment aids such as skin or internal collimation, bolus, field abutment, or other special techniques.

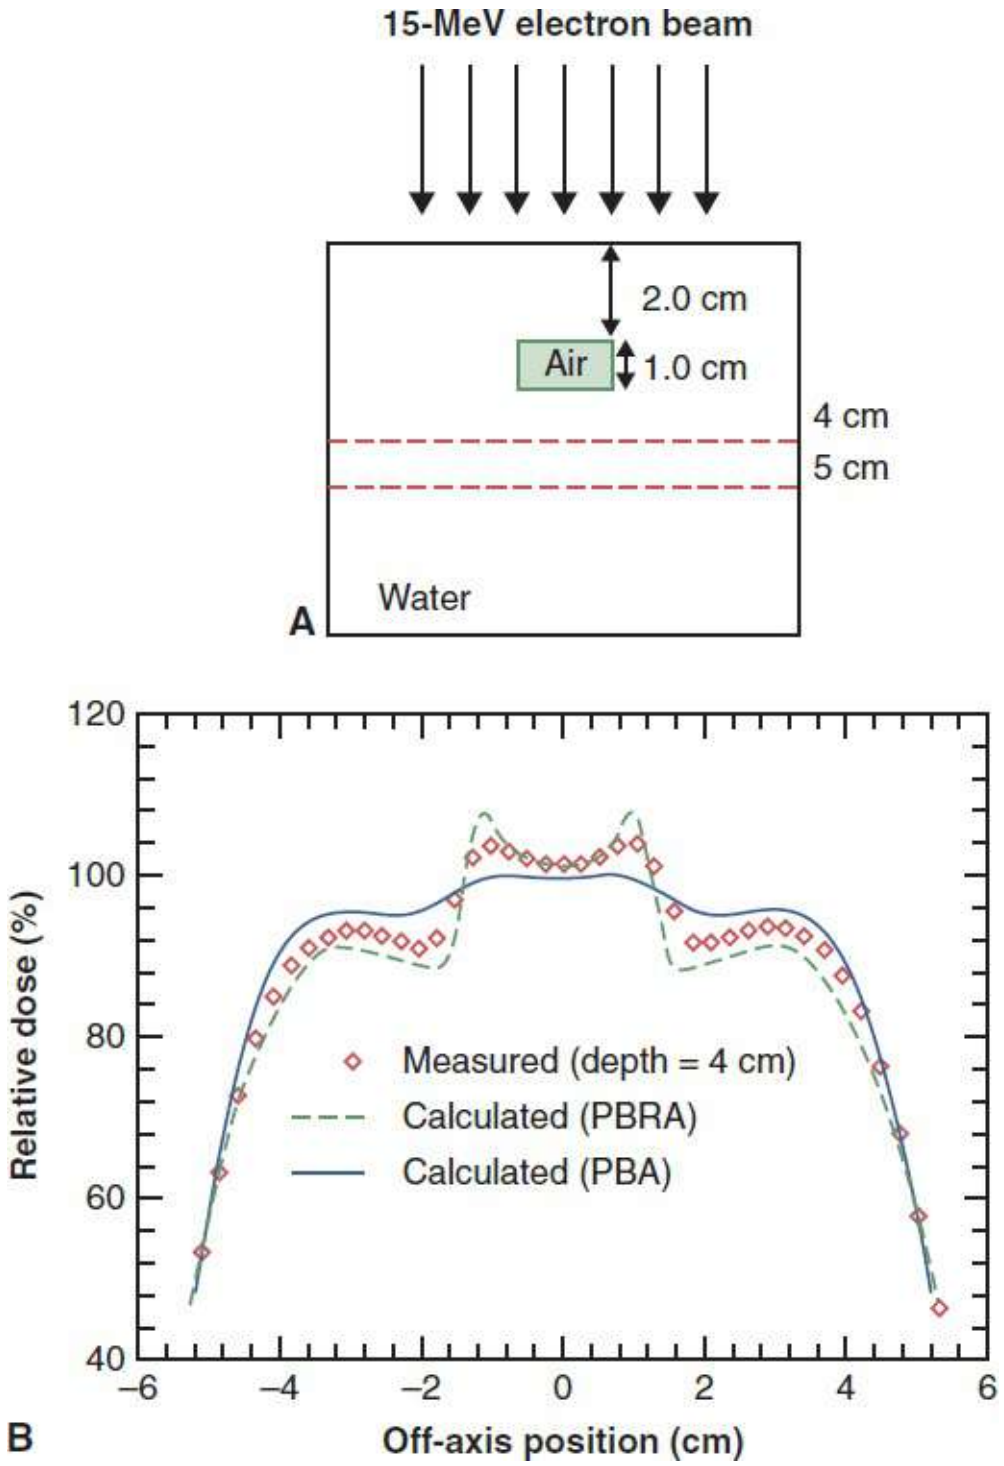

FIGURE 8.13. Evaluation of accuracy of dose algorithms below air cavity. **A:** Dose is measured distal to an internal air cavity. **B:** Measured dose profile at a depth of 4 cm is compared to that calculated by the pencil beam algorithm and the pencil beam redefinition algorithm. PBA, pencil beam algorithm; PRBA, pencil beam redefinition algorithm. (From Shiu AS, Hogstrom KR. Pencil-beam redefinition algorithm for electron dose distributions. *Med Phys* 1991;18[1]:7–18, with permission. Copyright © 1991 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.)

Selection of Energy

The energy of the incident electron beam should be selected so that the distal surface of the 90% (of given dose) dose surface encompasses the PTV and that critical structures lie beyond the maximum penetration of the electrons or at an acceptable dose level. For planning purposes, a general rule is the following:

$$E_{p,0}(MeV) \sim 3.3 \cdot R_{90}(cm), \qquad (6)$$

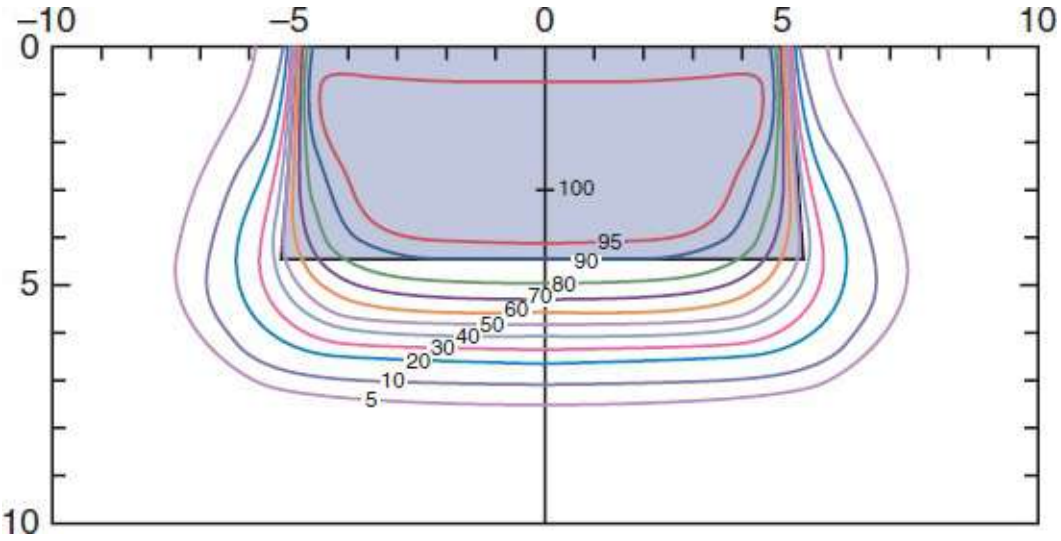

FIGURE 8.14. Plot of isodose curves for a 15-MeV, 10 by 10 cm^2 electron beam in water (source-to-surface distance, or SSD = 100 cm). Note the shape of the 90% isodose contour with respect to the shaded area, which is framed by the diverging field edges and the R_{90} depth.

where $E_{p,0}$ is the most probable incident electron energy in MeV. The energy should be selected such that R_{90} just exceeds the maximum depth of the PTV. This approximation is true in water for field sizes large enough to have side-scatter equilibrium on the central axis. For small field sizes that do not have side-scatter equilibrium, R_{90} will be less; thus, a higher energy might be required. As well, heterogeneous tissue (e.g., bone or air) can affect the penetration, requiring greater or lesser energy, respectively.

Similarly, for planning purposes, a general rule is the following:

$$E_{p,0}(MeV) = 2 \cdot R_p(cm), \qquad (7)$$

where R_p is the practical range in centimeters of the electron beam.[32] The treatment planner can select an energy such that R_p is less than the minimal depth of a critical structure. This approximation has no field-size limitation;

however, as before, heterogeneous tissue (e.g., bone, lung, or air) can affect the penetration, allowing greater or lesser energy.

As an example of how to use these general rules, consider treating the posterior cervical nodes of the neck with electrons to spare the spinal cord because its dose is already near tolerance. If the maximum depth of the nodes is 3 cm and the minimum depth of the spinal cord is 6 cm, then Eqs. (6) and (7) indicate that the minimum energy to cover the PTV is 9.9 MeV, and the maximum energy that protects the spinal cord is 12 MeV, respectively. Hence, beam energies in the range of 10 to 12 MeV are acceptable. In all cases, the energy of the beam should be confirmed by performing a 3-D dose calculation for the planned treatment using a CT representation of the patient. Bolus may be strategically used to tune the beam penetration either globally or in discrete areas and ideally should be placed at the time of the CT.

Design of Electron Collimation

Electron collimation consists of multiple collimating components; however, the electron field shape usually is defined by an applicator's collimating insert and/or skin collimation. Custom electron collimators are constructed from lead or low–melting-point lead alloy (Lipowitz metal). The lead thickness in millimeters required to stop the primary electrons equals one-half the incident of most probable energy of the electron beam in MeV.[29,30] To account for small variations in thickness resulting from the lead-sheet manufacturing process, a 1-mm surplus can be added. That is:

$$t_{pb}(mm) = 0.5 \cdot E_{p.0}(MeV) + 1 \qquad (8)$$

For example, an 18-MeV beam requires 10 mm of lead. Lipowitz metal is comprised mostly of lead along with bismuth that has a density of 20% less lead; therefore, its thickness should be increased by 20%. For example, an 18-MeV beam requires 12 mm of Lipowitz metal. Lipowitz metal collimating inserts usually are fabricated at a constant thickness—namely, that sufficient for the greatest energy on the treatment machine. For a machine whose maximum energy is 20 MeV, the Lipowitz metal thickness should be at least 13 mm.

Skin Collimation

The closer the field-defining collimator is to the patient, the sharper the beam's penumbra; hence, skin collimation provides the sharpest possible penumbra. Because of the significant effort often required to fabricate skin collimation, its

use is restricted to applications for which it has the greatest benefit, for example, (a) small-field (<4 cm) treatments providing maximal protection to adjacent critical structures, (b) sharpening penumbra (c) reducing penumbra when treating at an extended air gap, (d) reducing penumbra in electron arc therapy, and (e) where patient motion may be an issue. Proper use of skin collimation requires that it be in contact with the skin surface and that it extend sufficiently inwardly and outwardly to intercept the penumbra from upstream collimation.

Skin collimation absorption can be accomplished using lead sheets and normally is taken to be the minimum thickness necessary to shield the maximum. The maximum possible dose beneath the skin collimation occurs at the skin surface with no air gap between the two.[30,33] The transmitted dose, which is the result of bremsstrahlung photons from the incident beam and those generated by electrons stopping in the lead, is slightly greater than that with no lead present. It is recommended that a table of measured dose under the lead, as a function of lead thickness, is available for each beam energy.[29] As the air gap between the lead and the patient increases, the transmitted dose to the patient decreases. These values can be measured at the time of beam commissioning. If not, and for cases where precise determination of dose beneath a block is critical, *in vivo* dosimetry (e.g., thermoluminescent dosimetry) should be used.

In designing the shape of the aperture of a collimating insert, due consideration is made for the penumbra. Typically, there is approximately a 1-cm margin between the projected edge of the collimator and outer boundary of target volume when both are projected to the isocenter. This margin varies with energy, depth, and air gap; and it only can be appreciated by utilization of isodose curves (Figs. 8.4 and 8.14). Again, the adequacy of the margin between the aperture and PTV should be confirmed by performing 3-D dose calculations using CT images.

The utility of skin collimation for small-field treatments is illustrated in Figure 8.15. A 6-MeV, 3 by 3 cm^2 field with a 10-cm air gap (collimator to surface) is essentially all penumbra, resulting in an unsatisfactory dose distribution. However, by opening the collimator to 6 by 6 cm^2 and then forming the 3 by 3 cm^2 field using skin collimation, the dose distribution becomes clinically satisfactory. This application is used for treatment of the eyelid, nose, and other small target volumes.

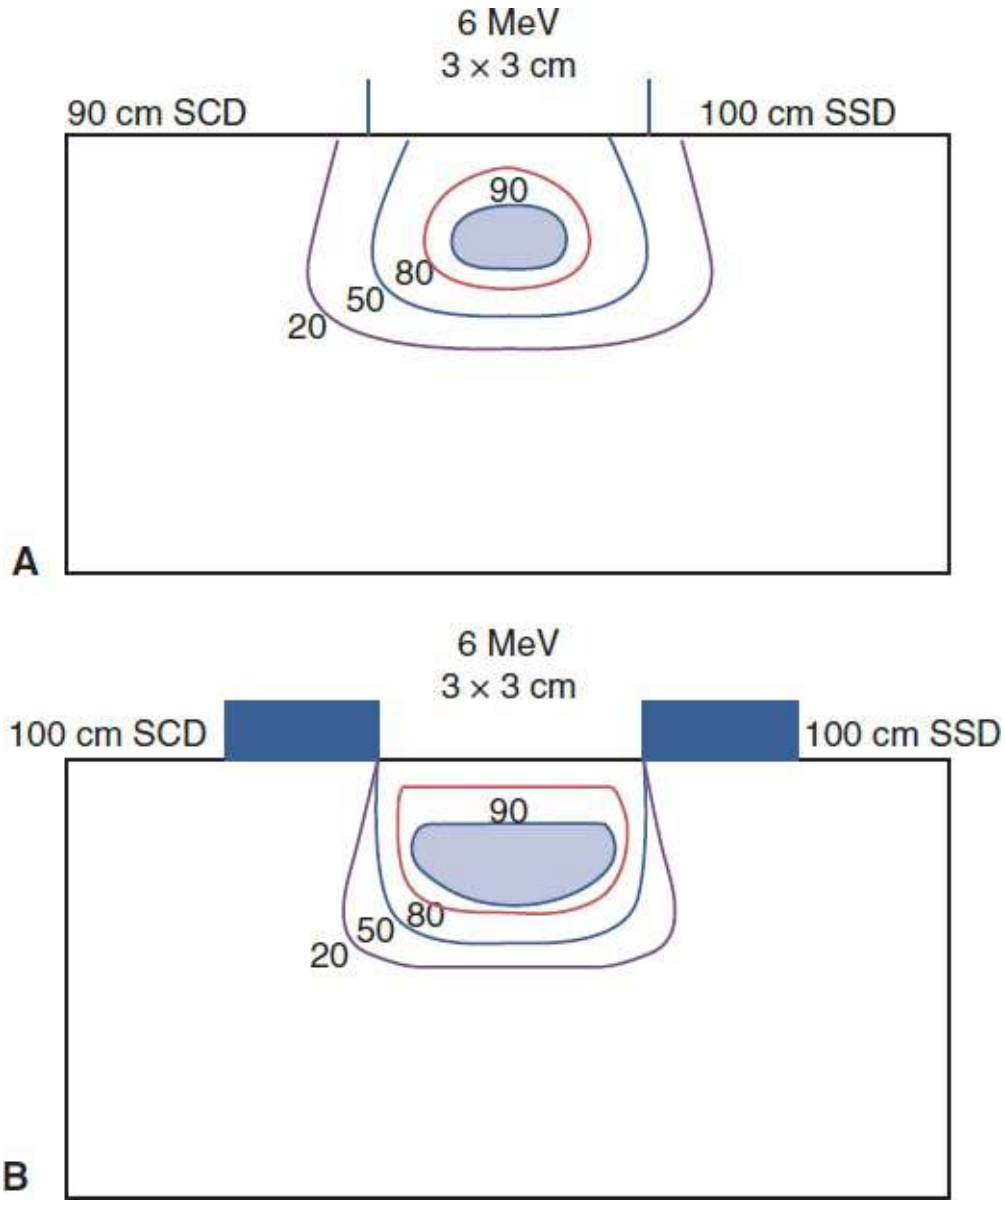

FIGURE 8.15. Impact of skin collimation for small electron fields. Isodose plots are compared for results of a computer simulation of a 6-MeV electron beam in water for a 3 by 3 cm^2 field formed by an applicator insert 10 cm above the patient **(A)** and a 3 by 3 cm^2 field formed by collimation at the surface with a 6 by 6 cm^2 applicator insert 10 cm above the patient **(B)**. (From Hogstrom KR. Clinical electron-beam dosimetry: basic dosimetry data. In: Purdy JA, ed. Advances in radiation oncology physics: dosimetry, treatment planning, and brachytherapy. Woodbury: American Institute of Physics, 1992:390–429. Copyright © 1992 by American Association of Physicists in Medicine. Reprinted by permission.)

In the presence of skin collimation, the depth dose is approximated by that for the field size on the skin surface (i.e., that defined by the skin collimator). In contrast, the dose output is approximated by that for the field-size incident on the skin collimation (i.e., that defined by the applicator cutout). For the example in

Figure 8.15, the depth dose is taken to be that of the 3 by 3 cm^2 field; the dose output is taken to be that of the 6 by 6 cm^2 field. This simple approximation slightly overestimates dose output, if the depths of maximum dose for the two field sizes differ. In such a case, the output of the larger field is multiplied by the depth-dose factor of the larger field at the depth of maximum dose of the smaller field.[34]

Multileaf Collimation

The use of existing photon multileaf collimators (MLCs) to modulate electron beams has been shown to be somewhat feasible, although a report by Klein et al.[64] showed that an SSD of 70 cm was necessary to provide clinical acceptable fields using the photon MLC. This is because of the dispersion of the electrons in air. They performed a feasibility study of using existing photon MLC to modulate electron beams, which was shown to be somewhat feasible. An important aspect from that work demonstrated that when using existing photon MLC to produce narrow electron beam segments, the large generated penumbra could be an advantage in terms of beam matching.

The other possibility is not to use the existing photon MLC but rather to have a tertiary electron MLC system that is closer to the patient, thereby narrowing the penumbra that is produced when the MLC is far from the patient. Lee et al.[65] found that replacing air with helium in the treatment head made a significant impact in predicted dose distributions. Karlsson et al.[66] demonstrated that penumbra, effective-source position, field shape, and matching could be optimized by replacing air with helium in the treatment head below the MLC leaves and by shifting the position of the scattering foils, monitor chamber, and MLC position.

Bolus

Bolus is an essential tool for the delivery of optimal electron radiation therapy. Electron bolus is defined as water- or near water-equivalent material that normally is placed in direct contact with the patient's skin surface, close to the patient's skin surface, or inside a body cavity. This material is designed to provide extra scattering or energy degradation of the electron beam. Its purpose usually is to shape the dose distribution to conform to the target volume or to provide a more uniform dose inside the target volume.[29,32] More specifically, electron bolus has three primary applications:

. To shape the coverage of the treatment volume in the depth direction to

conform as closely as possible to the target volume while avoiding critical structures,
- To increase dose to the patient's external surface, and
- To serve as a missing tissue compensator for surface irregularities and internal air cavities.

In the second application, bolus is being used to either eliminate or decrease the adverse effects of patient heterogeneities on the dose distribution, which can result in a geographic miss at depth, dose nonuniformity within the target volume, and excessive dose-to-distal critical structures.[29,32]

Because dose typically is prescribed to 90% of the given dose, it is often desirable to increase surface dose to 90% or higher when treating with low-energy electrons. To accomplish this, a higher energy beam is selected and a uniformly thick bolus is placed on or near the skin surface. The surface dose of the higher energy electron beam is greater, and the bolus places the skin at a deeper depth, further increasing the surface dose. The energy–bolus thickness combination is selected to place R_{90} at the prescription depth while increasing the surface dose (D_s) to near 90%. To assist in usage of this technique, a table that allows selection of the optimal energy–bolus thickness combination is recommended. Table 8.2 illustrates a sample for the five electron beam energies of a typical radiation therapy machine.

TABLE 8.2 VALUES OF SURFACE DOSE AND THERAPEUTIC DEPTH FOR VARIOUS ENERGY–BOLUS COMBINATIONS

Superflab Thickness (cm)	0.0	0.3	0.5	1.0	1.5	2.0
Energy: 6 MeV						
D_s (%)	72	79	83	93	100	—
R_{90} (cm)	2.0	1.7	1.5	1.0	0.5	—
Energy: 9 MeV						
D_s (%)	78	83	85	89	95	99
R_{90} (cm)	3.0	2.7	2.5	2.0	1.5	1.0
Energy: 12 MeV						
D_s (%)	83	88	89	91	94	96
R_{90} (cm)	4.0	3.7	3.5	3.0	2.5	2.0
Energy: 16 MeV						
D_s (%)	87	92	93	96	97	98

R_{90} (cm)	5.0	4.7	4.5	4.0	3.5	3.0
Energy: 20 MeV						
D_s (%)	91	96	97	98	99	100
R_{90} (cm)	6.1	5.8	5.6	5.1	4.6	4.1

Two bolus methods are used for this function. One places flexible sheet material (e.g., Superflab) directly on the skin surface. Materials are approximately water equivalent and come in thickness increments of 0.3 to 4 cm. It is particularly useful for chest wall irradiation, for both fixed beam and arced-beam therapies. In some treatments, the bolus is used for only a portion of the field, in which case care must be taken to ensure the edge of the bolus is tapered to reduce the magnitude of the hot or cold spot created by the surface irregularity (such as is seen in Fig. 8.6).[29,32]

For highly irregular or sensitive skin surfaces, which often are encountered in head and neck or postsurgical irradiations, it is advantageous to have a rigid bolus sheet (often referred to as a scatter plate because it not only degrades the energy of the electron beam but also scatters the beam) close to but not necessarily in direct contact with the patient.[32] For such cases, standard thicknesses of polymethylmethacrylate (PMMA) (0.125 to 0.25 inches) are placed perpendicular to the beam. To restore a sharp penumbra, skin collimation usually is recommended with use of the scatter-plate bolus method. Rules for using skin collimation with the bolus have been discussed by Hogstrom.[32] It is important that the bolus be in contact or close to the patient because too large of an air gap can create an exceedingly large penumbra.

Bolus is considered part of the beam; however, it also can be considered part of the patient, effectively shortening the SSD. For uniform bolus thickness (t), it is recommended to adjust the dose output for inverse square.[34] That is:

$$O_{bolus} = O \cdot \left[\frac{SSD + t + R_{100}}{SSD + R_{100}} \right]^2 \qquad (9)$$

A more sophisticated use of bolus is to design custom bolus for the purpose of electron conformal therapy. In this application, the bolus usually is designed to conform the 90% isodose line to the PTV while minimizing dose to nearby critical structures and maintaining dose uniformity as much as possible within the 90% dose contour. Proper design of custom bolus requires use of a 3-D treatment planning system[67] that utilizes bolus design operators[68] and a 3-D PBA.[53] The methodology of bolus design to optimize target coverage and critical

structure searing is seen in Figure 8.16. Perkins et al.[20] showed the use of custom bolus for chest wall irradiation in the cases of highly distorted anatomy and of a chest wall recurrence (Fig. 8.17), and Kudchadker et al.[69] have demonstrated its use in head and neck treatment. And Low et al.[25] have shown its utilization for sparing spinal cord, lung, and kidney in treatment of the paraspinal muscles.

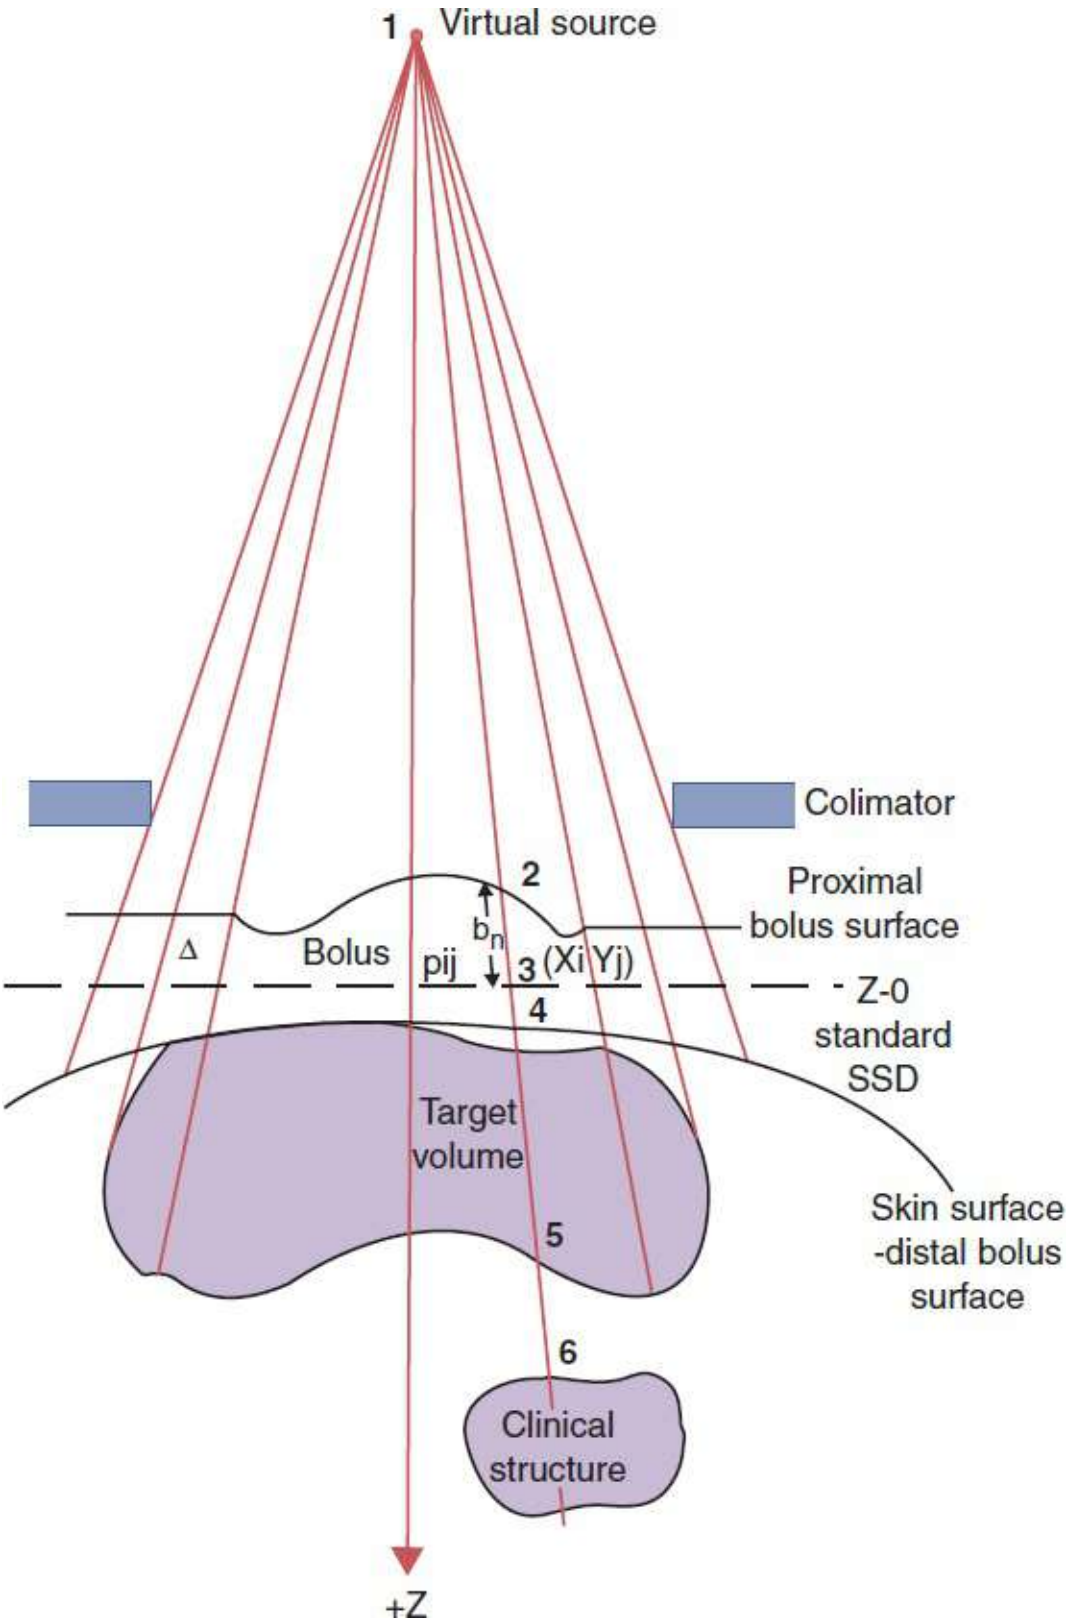

FIGURE 8.16. Schematic representation of the patient contour, target volume, and compensating bolus designed to optimize the coverage of the target while minimizing the dose to the underlying critical structure. (From Low DA, Starkschall G, Bujnowski

SW, et al. Electron bolus design for radiation therapy treatment planning: bolus design algorithms. *Med Phys* 1992;19[1]:115–124. Copyright © 1992 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.)

It is recommended that the intent of bolus be verified by measurement or calculation. Bolus used to increase skin dose can be verified by performing *in vivo* dosimetry measurements (e.g., using thermoluminescent dosimetry). Complex bolus shapes, as used to remove surface irregularities or for electron conformal therapy, can be verified by CT scanning the patient with the bolus in place.[20,25] The dose distribution then can be recalculated using the electron dose algorithm in a treatment planning system.

This method of electron conformal therapy may be facilitated by a commercial vendor that can create the custom bolus from treatment plan machinist coordinates.[70]

Along these lines, customization could also be achieved with the use of a 3-D printer.[71–73] In this process, a customized bolus is made using the patient's CT with a commercial treatment planning system. Figure 8.18 shows an example of such process. The bolus' structure is sent to a 3-D modeling software that will convert the file to the appropriate language (standard tessellation language), which will be used by the 3-D printer to manufacture the bolus.[71]

The dimensions of the bolus are dependent on the type of 3-D printer available, which will also determine the composition of bolus material. There are printers that could print using only one material, whereas there are others that can print multiple materials at once [71]. Mainly, the materials used are some type of variation of acrylonitrile butadiene styrene (ABS) and polylactic acid (PLA). It is important to clearly characterize the material's electron density in order to calculate the correct dose that will be delivered to the patient. In addition, the 3-D printed bolus might have air bubbles, which will affect the dose distribution. It is recommended, as for any type of bolus, to perform the necessary measurement to characterize the 3-D printed bolus as well as to develop the necessary quality assurance procedures before using the bolus for any patient.

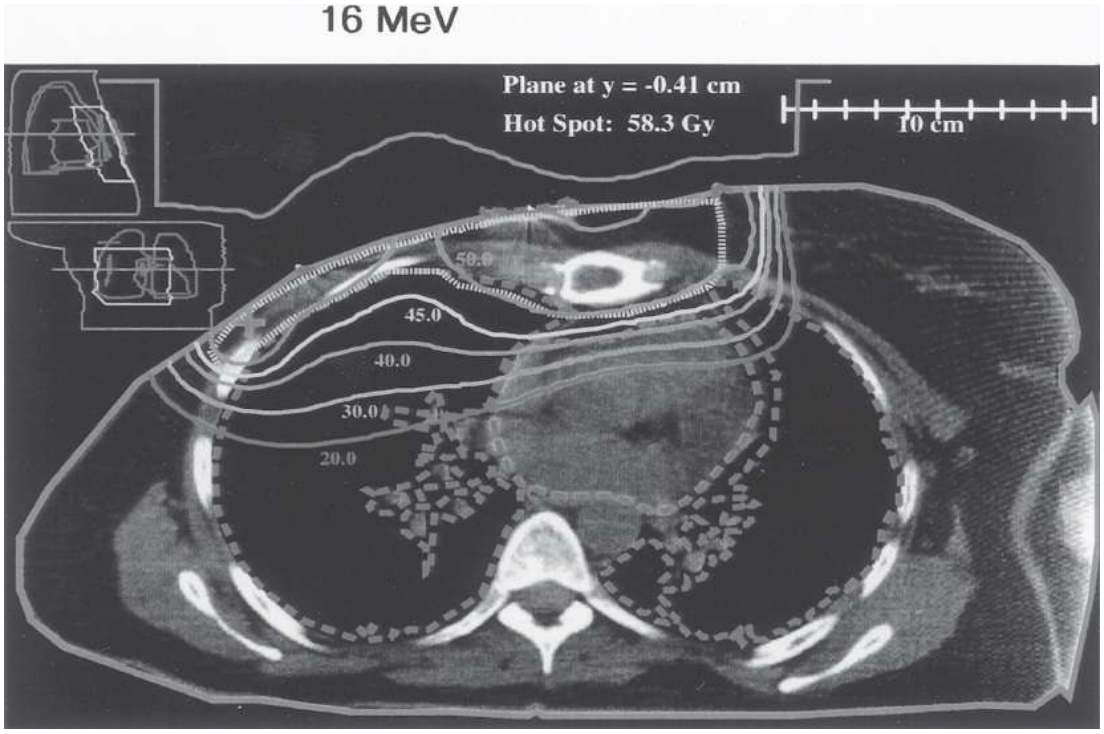

FIGURE 8.17. Conformal electron therapy using variable thickness bolus. Bolus is used to shape the 90% isodose surface (45 Gy) to the distal surface of the chest wall in treating a chest wall occurrence, optimally sparing lung. (Reprinted from Perkins GH, McNeese MD, Antolak JA, et al. A custom three-dimensional electron bolus technique for optimization of postmastectomy irradiation. *Int J Radiat Oncol Biol Phys* 2001;51[4]:1142–1151. Copyright © 2001 Elsevier. With permission.)

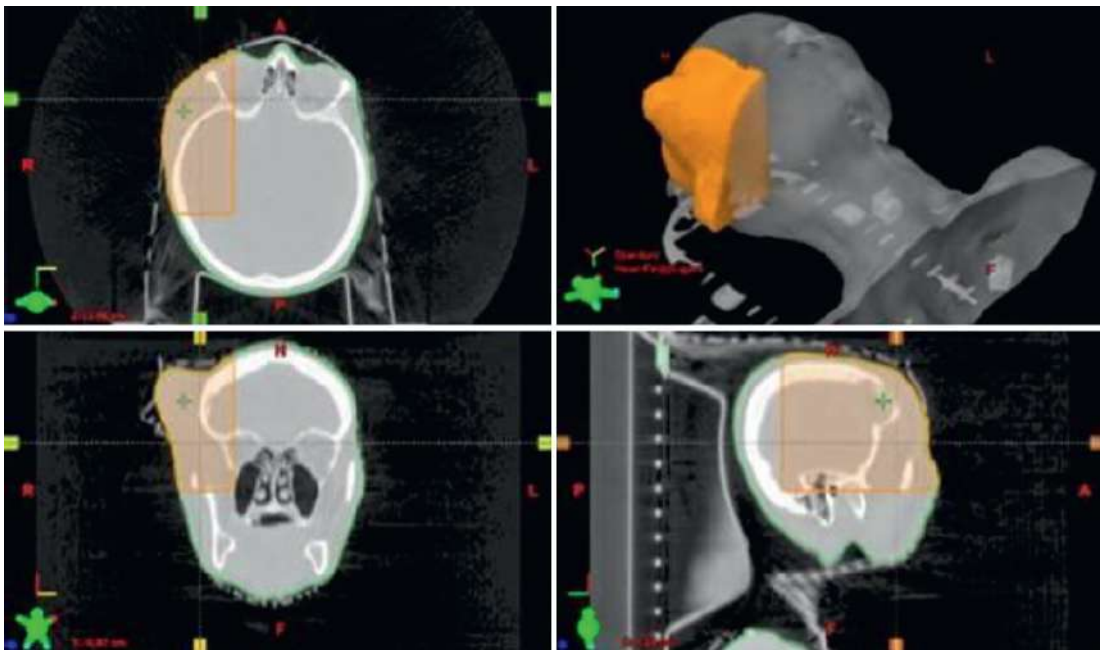

FIGURE 8.18. Example of a bolus structure (shown in orange) defined on the treatment planning system that was subsequently made by a 3-D printer. (From Burleson S, Baker J, Hsia AT, et al. Use of 3D printers to create a patient-specific 3D

bolus for external beam therapy. *J Appl Clin Med Phys* 2015;16[3]:166–178.)

Two of the main limitation of using 3-D printed bolus routinely for radiotherapy is the availability of a 3-D printer and the time that it takes to print a complete bolus. Although 3-D printers should become more affordable as these are gaining popularity in radiotherapy. The printing time could also vary widely among printers. The time that it takes to print a bolus is highly dependent on the type of printer's filament and, of course, on the dimensions and complexity of the bolus. Printing could take from 4 to 24 hours.[71,72] This time could be doubled if by any chance there is any failure in the printing process.

Internal Shielding

Internal shields stops electrons that enter the body before they reach critical structures and deposit any significant dose. Examples of clinical utilization of internal shielding are intraoral blocks protecting salivary glands during head and neck treatments[2]; eye blocks protecting the lens in irradiation of the eyelid,[74] orbit, or retina; and sheets of lead used to protect internal structures during intraoperative therapy.

There are two important concepts to remember in the use of internal shielding. First, the collimator must be sufficiently thick to stop the energy of the electrons in the beam at depth. Electron beam energy is reduced by 2 MeV per centimeter in unit density tissue; hence, the energy of a 12-MeV beam at a depth of 2 cm is 8 MeV. The thickness of lead required to stop 8-MeV electrons is 4 mm (8 MeV to 0.5 mm/MeV).

One application where ensuring that collimation is sufficiently thick that has been sometimes overlooked is the use of internal eye shields. Shiu et al.[74] showed that x-ray eye shields constructed of plastic-coated lead and designed to shield the eyes from kilovoltage x-rays did not stop 6-MeV electrons, resulting in penetration of approximately 50% of the given dose. However, electron eye shields constructed of enamel-coated tungsten can stop electrons with energies as great as 9 MeV (Fig. 8.19). By using higher-density tungsten (ρ = 19.3 g/cm^3) instead of lead (ρ = 11.5 g/cm^3), the eye shields remain sufficiently thin to fit under the eyelid. If only x-ray eye shields are available, bolus should be placed on top of the eye and eye shield to ensure that the electron energy is reduced sufficiently so that electrons do not penetrate the eye shield.

Second, electrons backscattered from lead at a lead–tissue interface increase dose, the increase ranging from approximately 20% at 20 MeV to 60% at 4 MeV,

where the energy is the average energy of electrons incident on the lead.[30,75] Das and Bushe[76] published a comprehensive dataset demonstrating the range for backscatter electrons as a function of energy, on the order of a few millimeters, and increases as a function of energy. Inserting two half-value layers of bolus between the lead and the tissue usually reduces the dose to upstream tissue to a clinically acceptable value. The thickness of one half-value layer ranges from approximately 1 cm at 10 MeV to 0.5 cm at 3 MeV.[30,77] Intraoral lead stents are routinely coated with acrylic,[28] and a material such as dental wax can be applied easily to lead sheets placed between the mucosa and gums. Eye shields, however, only have clearance for 1 to 2 mm of coating; hence, backscatter dose to the eyelids is an important consideration in treatment management.[77] When determining lead thickness for an internal shielding at a particular depth, one must first determine the energy of the electron beam at that location. The energy of the electron beam on the surface is $E_{o,p}$ typically close to the nominal stated energy. As electrons lose energy by 2 MeV per centimeter, one can determine the remaining energy of any depth. For example, 12 MeV beams at surface would be approximately 6 MeV after 3 cm.

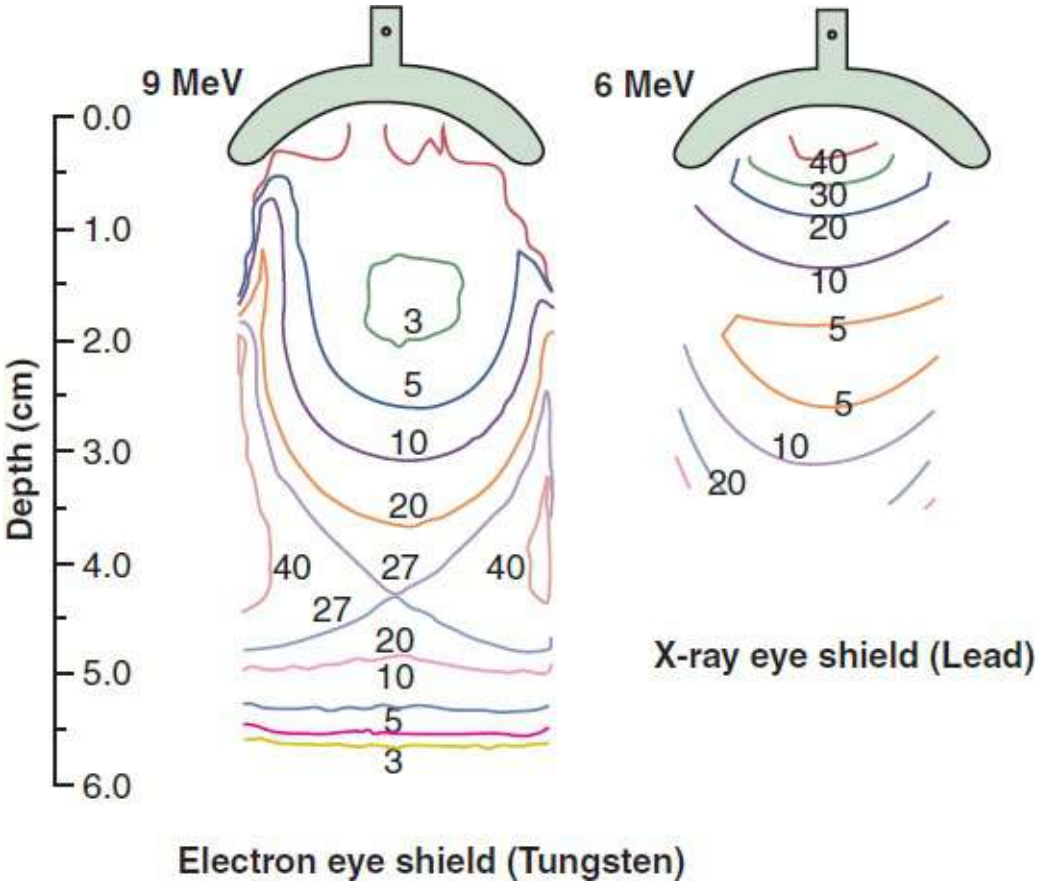

FIGURE 8.19. Electron eye shields. The dose distribution under tungsten electron eye shields demonstrates its ability to stop 9-MeV electrons. The dose distribution under a lead x-ray eye shield shows its inability to stop 6-MeV electrons. (Reprinted from Shiu AS, Tung SS, Gastorf RJ, et al. Dosimetric evaluation of lead and tungsten eye shields in electron-beam treatment. *Int J Radiat Oncol Biol Phys* 1996;35[3]:599–604. Copyright © 1996 Elsevier. With permission.)

Field Abutment

The purpose of field abutment is to enlarge the radiation area by using parallel matched beams or to change the beam energy or modality. In either case, beam uniformity requires that three criteria be met. First, the beams must abut along the entire border.[29,30,32,78] If the edges of the two beams coincide exactly (Fig. 8.20A), then the two beams will be equivalent to a single beam and optimal uniformity will be achieved. If the central axes of the two beams are parallel (Fig. 8.20B), then the diverging beam edges will overlap, creating a cold spot upstream and a hot spot downstream of the region of intersection. This is least significant for narrow fields, as encountered in irradiation of the cervical nodes of the neck or abutting the internal mammary and medial chest wall fields. If the central axes are converging (Fig. 8.20C), then there is an even greater amount of overlap. This is the case for abutting lateral and medial chest wall fields. In such cases, feathering the beam edge ±1 cm can reduce the dose heterogeneity. This is illustrated in Figure 8.21 for a standard postmastectomy chest wall irradiation using electrons.

The second criterion is that the beam penumbra must be matched. This is the case for the two spinal fields referred to earlier; however, it is not the case in general, particularly in abutting electron to photon fields. In such cases, either one or both of the field edges must be feathered. Third, it is best that the penumbra be somewhat broad. This reduces the impact of misalignment on the uniformity of dose in the abutted region. Harms and Purdy[49] demonstrated the influence of SSD energy and match bolus on match-line dosimetry. Figure 8.22 displays dose homogeneity for abutted 12-MeV fields depending on gap. In addition, the matching of electron and photo fields is a planning challenge, as two differing penumbra are abutted. Johnson and Khan[79] performed a study of matched electron–photon fields as a function of energy and SSD. Figure 8.23 demonstrates match-line profiles for a typical head and neck field match.

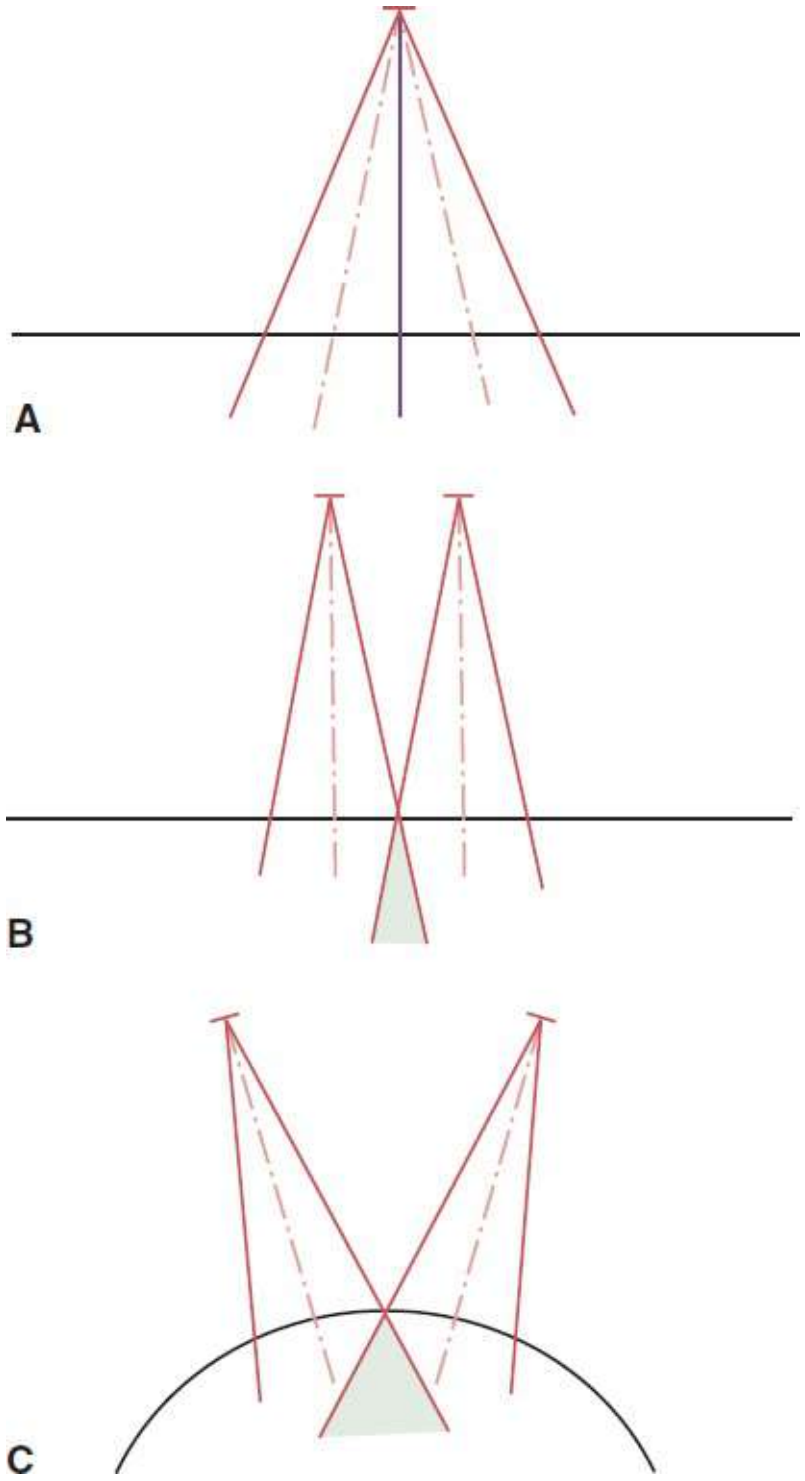

FIGURE 8.20. Comparison of abutment geometries. **A:** Common edge is created by having diverging central axes. **B:** Parallel central axes result in overlapping edges. **C:** Converging central axes result in the greatest overlap. (From Svensson H, Almond P, Brahme A, et al. ICRU Report 35. *Radiation dosimetry: electron beams with energies between 1 and 50 MeV*. Bethesda, MD: International Commission on Radiation Units and Measurement, 1984. Reproduced by permission of International Commission on Radiation Units and Measurements.)

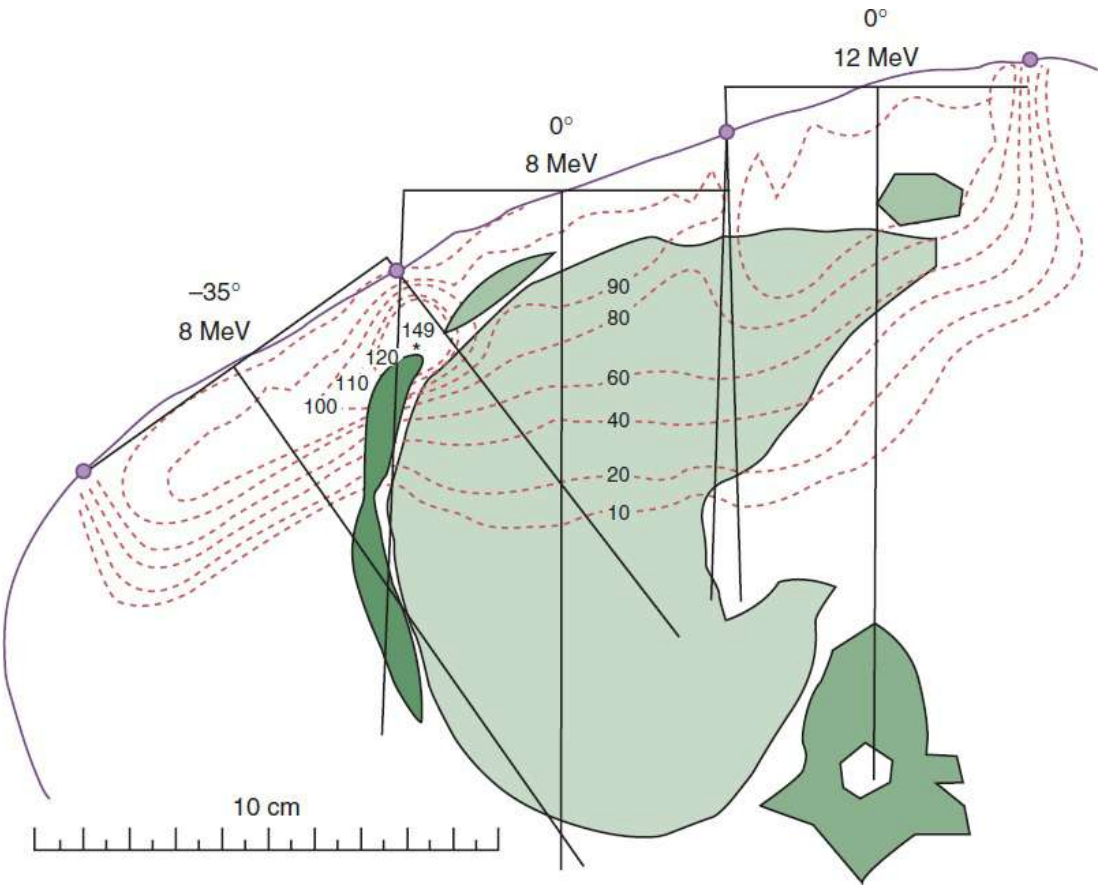

FIGURE 8.21. Clinical example of abutting electron fields in chest wall treatment. Dose homogeneity is acceptable at the border of internal mammary chain (IMC) and medial chest wall fields because central axes are parallel and field widths are small. Dose homogeneity is unacceptable at the border of medial and lateral chest wall fields because central axes are converging (Fig. 8.10B). Dose homogeneity is improved at border of medial and lateral chest wall fields by delivering equal doses with the match line being moved 1 cm twice during treatment.

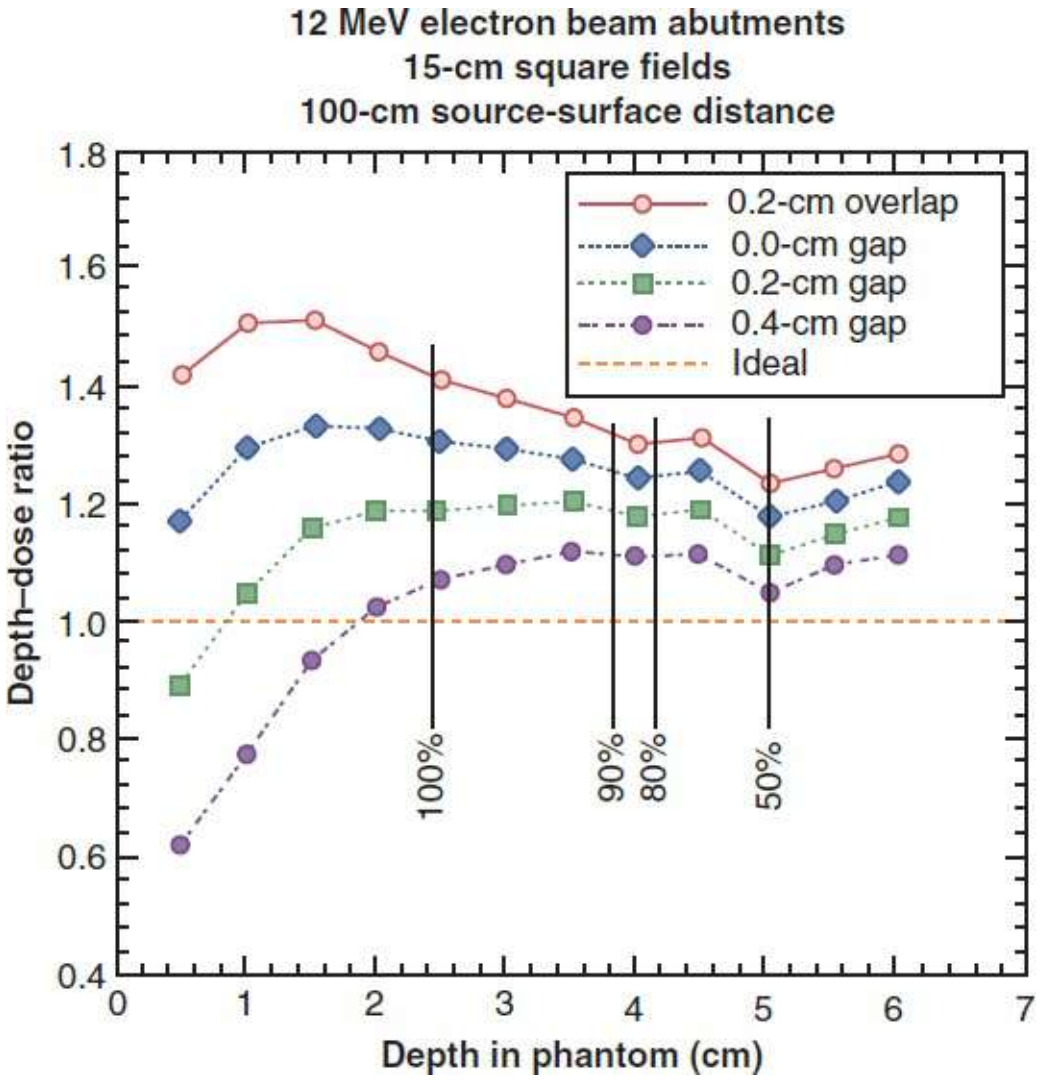

FIGURE 8.22. Graph depicting dose homogeneity for abutted 12-MeV electron fields for a series of gaps. (Reprinted from Harms WB, Purdy JA. Abutment of high energy electron fields. *Int J Radiat Oncol Biol Phys* 1991;20[4]:853–858. Copyright © 1991 Elsevier. With permission.)

Mixed Beam Therapy

Electron beams frequently are mixed with photon beams to create an appropriate treatment. The mixed beams can irradiate a common volume of tissue, or they can be abutted. In the former case, an electron field may be added to a primarily photon beam treatment, or a photon field may be added to a primarily electron beam treatment. For example, electron boosts are used to deliver localized dose to the surgical site following photon breast irradiation, to treat the postcervical nodes once spinal cord tolerance is reached, and to reduce spinal cord dose (e.g., in lymphoma treatment).[80] In some head and neck treatments, the photon beam is a surrogate to the electron beam, being used to reduce skin dose and to

increase dose penetration while still sparing the contralateral salivary gland.[2,10] With the future availability of intensity-modulated photon and modulated electron therapy, the effectiveness of mixed beam therapy can be expected to increase in breast and head and neck radiation therapy.

Abutted mixed beams are used when separate portions of the anatomy can benefit from two individual beams. The most common application of this process is the utilization of electron fields for irradiation of the IMC, supraclavicular, or axillary lymph nodes as part of breast or chest wall irradiation.[2] Matching of tangential photon fields and IMC electron fields is complex because of surface irregularities and heterogeneities. Careful treatment planning must be performed, especially if prescriptive decisions for electron energy and dosage are predicated on the resultant dose distribution. Figure 8.24 displays a tangential photon IMC electron field initial plan with a plan performed with partially wide tangent, a technique suggested to remove the field abutment dilemma.[81] This technique is also used for irradiating the total scalp or for craniospinal irradiation, which are described later. The use of combined modulated photon and electron fields has been reported. This has the potential to be an ideal therapy for particular treatment sites. Thus far, this combined therapy has been demonstrated with microtron (helium head) machines. Early publications demonstrated conventional (nonmodulated) use of photons and electrons as collimated by MLC. Zackrisson and Karlsson[82] described a technique for matching of electron and photon beams for conformal therapy of target volumes at moderate depths. Mu et al.[83] showed that mixed photon and electron was superior in obtaining planning goals versus intensity-modulated radiotherapy (IMRT) alone. One essential aspect was the reduction of integral dose. The same computer-controlled MLC of microtron model is used for photons and electrons. Das et al.[84] developed an algorithm using automated beam orientation and modality selection for optimal beam arrangement selection in IMRT of mixed photon and electron beams. Finally, Ma et al.[85] performed a comparative study on tangential photon beams, IMRT, and modulated electron radiotherapy (MERT) for breast cancer treatment.

FIGURE 8.23. SPECIALIZED ELECTRON TECHNIQUES

Although electron beam therapy is used less frequently than is photon beam therapy, it remains an essential modality. To fully use electron beam therapy, there must be access to comprehensive electron treatment and treatment planning techniques. This includes specialized electron techniques, which, in the present context, are defined as those that are seldom required and that use a complex treatment geometry, special treatment delivery hardware, or special treatment planning software. It is not recommended that all radiation therapy facilities offer all techniques. However, radiation oncologists should be aware of these techniques and should be able to refer patients to a regional center for those that are impractical in smaller settings. This recommendation is based on the significant time, resources, and costs of implementing, maintaining, and providing some of the more complex special electron procedures. The American College of Medical Physics (absorbed into the AAPM) has reviewed the manpower effort and cost associated with several special procedures, which include electron arc therapy, intraoperative electron therapy, and total skin electron irradiation.[86]

Four types of special techniques are discussed here. First, the treatment of internal tissues is exemplified by intraoperative radiation therapy and intracavitary radiation therapy. Second, the utilization of abutted electron and

photon fields is exemplified by craniospinal and total-scalp treatment techniques. Third, the treatment of superficial tissues for a cylindric geometry is exemplified by the total-limb and total skin treatment techniques. Fourth, an alternative to fixed beam therapy of the chest wall is exemplified by arc therapy.

Intracavitary Irradiation

Applicators of appropriate design can be used for intracavitary electron irradiation, which delivers an improved dose distribution over that traditionally delivered using orthovoltage x-rays. Intracavitary irradiation most frequently is used to boost the primary site while sparing nearby normal tissues. Intracavitary irradiation has been a choice for intraoral, transvaginal, and intraoperative treatments. Wang[19] showed the benefit of intraoral cones for boosting the oral lesions of the floor of the mouth, soft palate, tongue, and retromolar trigone while sparing mandible, teeth, gum, and salivary glands. McGinnis et al.[28] reported using a transvaginal applicator to boost carcinoma of the cervix with electrons, reducing bulk tumor to subsequently allow intracavitary brachytherapy. Intraoperative radiation therapy can be used in many sites[13]; however, it is used primarily for abdominal sites. Merrick et al.[26] reviewed the experience in the United States of using intraoperative radiotherapy for treatment of pancreatic, biliary, and gastric carcinomas.

The criteria for intracavitary electron irradiation are similar regardless of site. A treatment applicator is necessary so that healthy tissue can be restrained from intercepting electrons irradiating the tumor. The applicator wall must be sufficiently thick to stop electrons from escaping to outside tissue while being thin enough not to interfere with tumor access. Guidelines for accomplishing this for intraoperative applicators have been discussed by Hogstrom et al.[87] Another issue is how to ensure accurate alignment while maintaining patient safety with an applicator. Appropriate cone positioning requires having a method for looking down the cone to view the tumor. Proper alignment of the applicator after inserting it into the patient requires methods for docking it to the machine. For soft docking, the applicator is not physically attached to the machine[87,88] (Fig. 8.25). For hard docking, the applicator is physically attached to the machine, and there are methods for its breaking away under stress.[28,89]

Treatment planning for intracavitary cones typically is done manually because it is not possible to CT scan the patient in the treatment position or under operating room conditions. The electron energy and cone size are selected to match measured isodose distributions to the dimensions of the clinical target

volume. Examples of dose distributions for intraoperative applicators are shown in Figure 8.26.[90] These examples show two characteristics of such applicators. First, for the larger diameter applicators, scattering off the wall of the applicator can lead to hot spots near the applicator's periphery. Second, ends of the applicator often are beveled to make it easy to establish contact when the anatomic plane is not perpendicular to the direction of approach (i.e., the central axis of the beam). Note how the depth of the 90% isodose contour beneath the surface decreases from 3.6 cm at 0 degree incidence to 3.0 cm at 30 degrees incidence, as a result of the effects described earlier.

Total-Scalp Irradiation

Total-scalp irradiation is sometimes necessary in the management of malignancies (e.g., cutaneous lymphoma, melanoma, and angiosarcoma) that present with widespread involvement of the scalp and forehead.[2,15] Electron beam therapy is a practical means of achieving the therapeutic goal of delivering a uniform dose to the scalp with minimal dose to underlying brain. For many years, total-scalp irradiation was achieved by patching multiple electron fields.[2,91] Although effective, the treatment was tedious as a result of the large number of fields, their requirement for skin collimation, and the need to move the abutment border to improve dose homogeneity.[91] Akazawa[92] from the University of California–San Francisco reported a simpler technique that abuts lateral electron fields to parallel-opposed photon fields, the latter of which treats the rind of the scalp while avoiding brain tissue. Tung et al.[15] modified the abutment scheme to account for beam divergence and demonstrated improved dose uniformity by comparing 3-D dose calculations with *in vivo* dose measurements. Figure 8.27 illustrates the abutment scheme. The outer edge of the electron field overlaps the inner edge of the 6-MV x-ray field by 3 mm to account for the divergence of the contralateral 6-MV x-ray field. Because the electron and x-ray penumbras are not matched, their common border is moved 1 cm toward beam center halfway through treatment to improve dose homogeneity. Figure 8.28 shows the dose distribution in a transverse CT plane, which illustrates the dose homogeneity achieved in the region of abutment and the sparing of brain tissue. Initially, the common border is set at approximately 0.5 cm inside the inner table of the skull. Moving the common border farther toward the inner table of the skull reduces brain irradiation at the expense of the x-ray beam being replaced by an electron beam that would begin to graze the skull. As discussed earlier, grazing radiation penetrates less deeply, possibly underdosing the scalp in this region. Also noticeable in Figure 8.28 is a 6-mm thick wax bolus, which increases surface dose for both the electron and x-ray fields. Although this technique is straightforward to plan and implement, concern of hot spots along to the midline superior brain tissue along the plane is a concern.

Walker et al.[93] described a six-field electron beam technique for treatment of mycosis fungoides of the scalp. This technique of overlapping beams was verified with thermoluminescent dosimetry measurements. The dose prescriptions were 20 and 30 Gy for the two patients in this study. Yaparpalvi et al.[94] developed a technique for scalp irradiation that used a single posterior-superior field with concentric circles that varied in electron energy. This interesting technique was not confirmed with anthropomorphic phantom dosimetry studies. Peters[95] described use of an electron reflector to improve dose uniformity to the scalp during total skin electron therapy.

Total-Limb Irradiation

It may be advantageous to irradiate the superficial anatomy of a limb for management of cancer (e.g., melanoma, lymphoma, Kaposi sarcoma). If the depth beneath the surface is 2 cm or less, electrons offer a uniform dose while sparing deep tissues and structures. This technique has been described by Wooden et al.[16] for the treatment of the lower calf of a patient with Kaposi sarcoma. Illustrated in Figure 8.29, six equally spaced 5-MeV electron beams are used to irradiate a 9-cm diameter cylinder. Each beam is sufficiently wide so that the entire circle falls within the uniform portion of each beam. Tangential radiation to the surface of the cylinder delivers a greater dose as a result of oblique incidence, which is partially offset by the inverse square effect. Additionally, the tangential radiation penetrates less deeply. The utilization of six or more beams begins to simulate 360-degree arc therapy (which is not feasible because of collisions). The resulting dose distribution illustrates three interesting characteristics. First, the average maximum dose along each radius is approximately 2.5 times the given dose of each of the six fields. Second, 90% of the average maximum dose penetrates 8 to 10 mm, reduced from the value of 15 mm for a single beam incident normally on a flat surface (Fig. 8.30). Third, the surface dose has increased to 90% or greater of average maximum dose compared with approximately 70% of the given dose for a single beam incident normally on a flat surface. This is the result of the self-bolusing effect of tangential electron radiation.

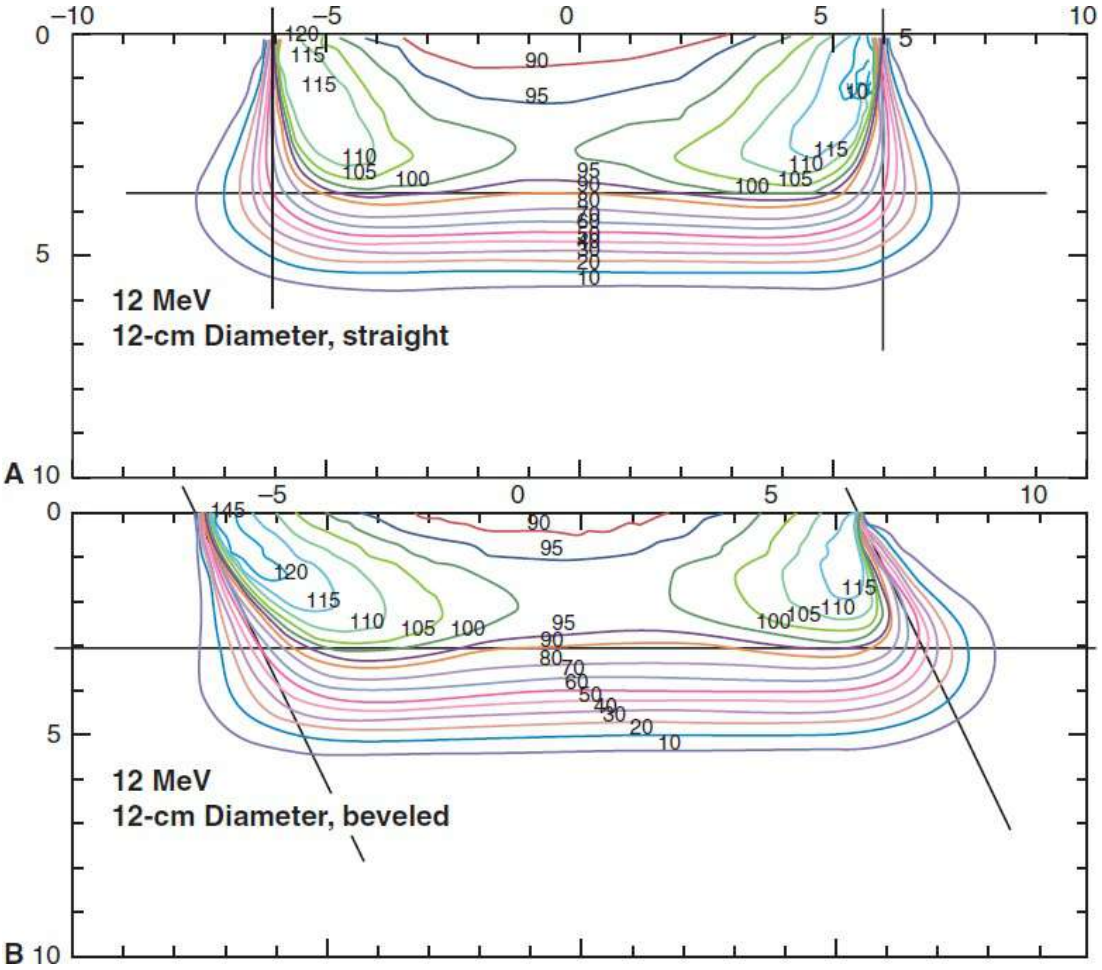

FIGURE 8.26. Isodose plots illustrating typical intraoperative dose distributions at 12 MeV. **A:** 12-cm diameter cone, normal incidence. **B:** 30-degree beveled, 12-cm diameter cone. Note the decreased depth of the 90% dose beneath the surface for the beam 30 degrees from normal incidence relative to that for normal incidence. (Reprinted from Nyerick CE, Ochran TG, Boyer AL, et al. Dosimetry characteristics of metallic cones for intraoperative radiation therapy. *Int J Radiat Oncol Biol Phys* 1991;21[2]:501–510. Copyright © 1991 Elsevier. With permission.)

The dosimetric characteristics should be carefully evaluated using one's treatment planning system.

Total-Skin Irradiation

Total-skin electron irradiation is a modality designed for management of diseases that require irradiation of the entire skin surface or a significant portion of it. The technique is used most frequently for treatment of mycosis fungoides, whose management is reviewed by Hoppe,[17] and Kaposi sarcoma.

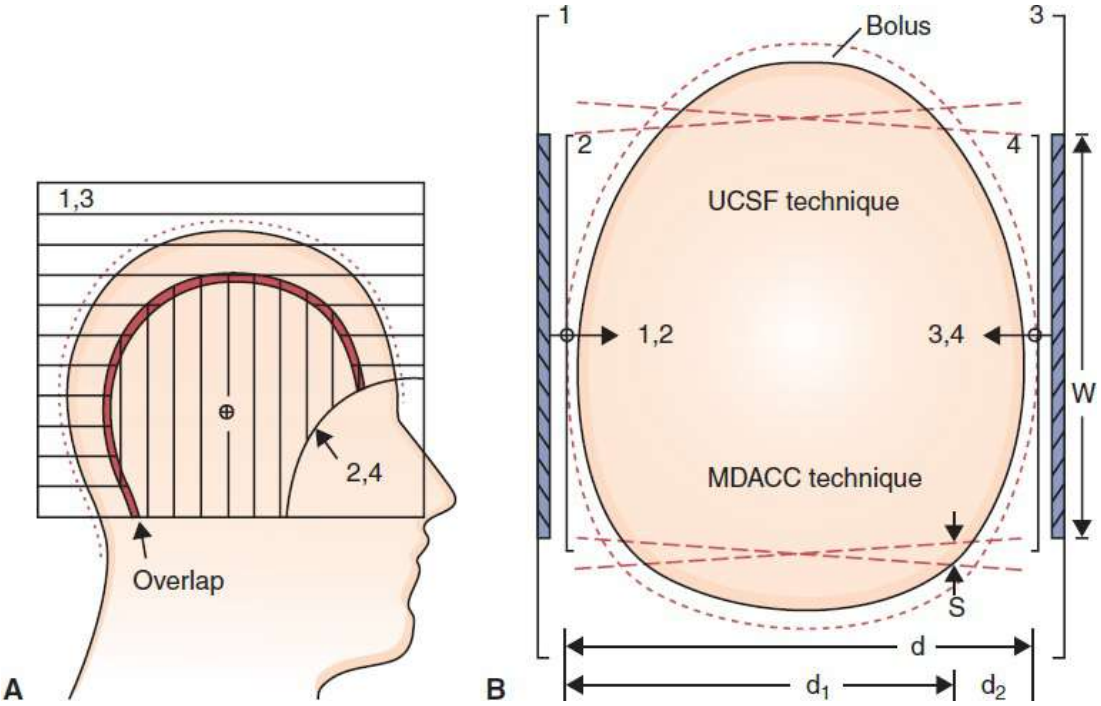

FIGURE 8.27. Abutment scheme for total-scalp irradiation (x-ray fields, 1, 3; electron fields, 2, 4). **A:** The electron field edge, placed just inside the skull, overlaps the edge of the ipsilateral x-ray field by approximately 3 mm to account for divergence of the edge of the contralateral x-ray field. Halfway through treatment, the field edges are moved 1 cm to improve dose homogeneity in the region of abutment. **B:** The need for the 3-mm overlap (MD Anderson Cancer Center [MDACC] technique) is better appreciated viewing the divergent edges of all fields in a transverse plane. (Reprinted from Tung SS, Shiu AS, Starkschall G, et al. Dosimetric evaluation of total scalp irradiation using a lateral electron-photon technique. *Int J Radiat Oncol Biol Phys* 1993;27[1]:153–160. Copyright © 1993 Elsevier. With permission.)

Isodose values in *gray*. (Reprinted from Tung SS, Shiu AS, Starkschall G, et al. Dosimetric evaluation of total scalp irradiation using a lateral electron-photon technique. *Int J Radiat Oncol Biol Phys* 1993;27[1]:153–160. Copyright © 1993 Elsevier. With permission.)

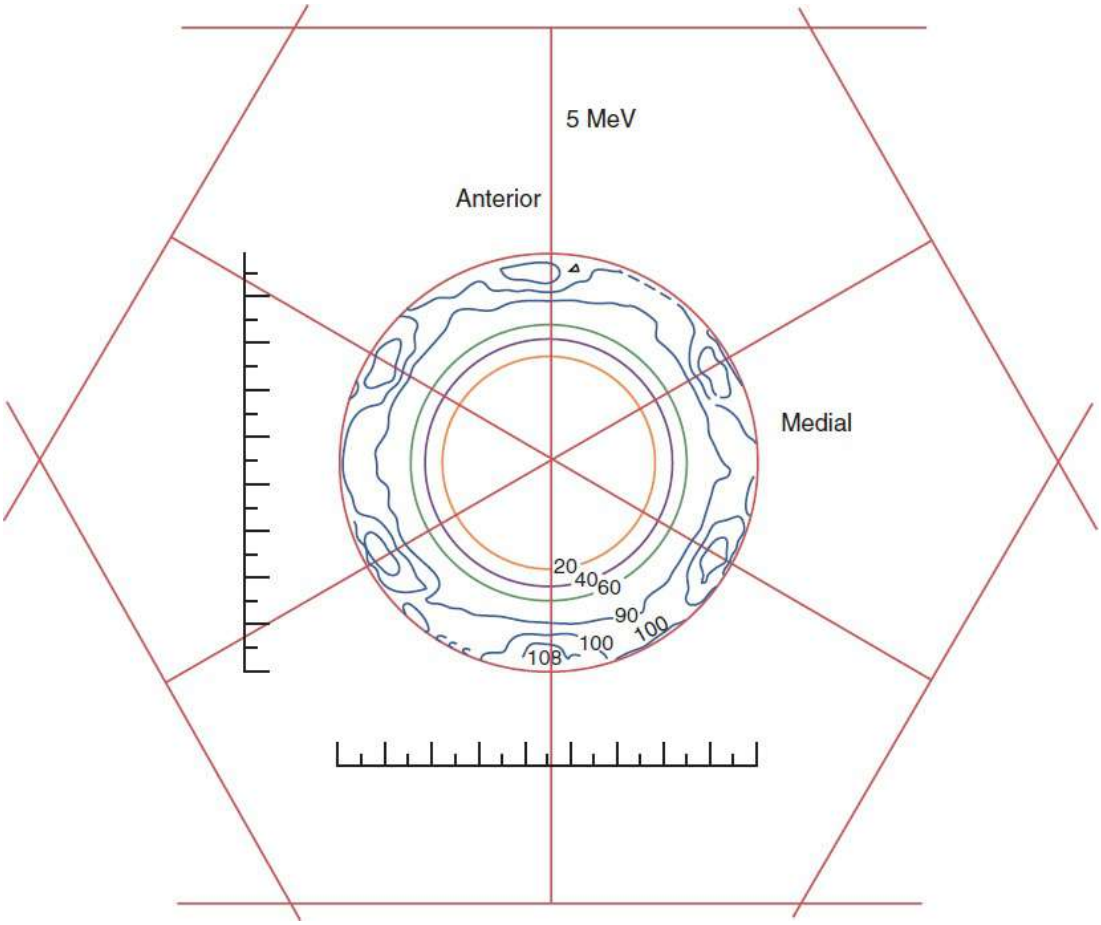

FIGURE 8.29. Dose distribution for total-limb irradiation. Six equally spaced 17-cm wide, 5-MeV electron beams are used to irradiate a 9-cm diameter cylinder. 100% equals 2.55 times the given dose from a single field. (Reprinted from Wooden KK, Hogstrom KR, Blum P, et al. Whole-limb irradiation of the lower calf using a six-field electron technique. *Med Dosim* 1996;21[4]:211–218. Copyright © 1996 Elsevier. With permission.)

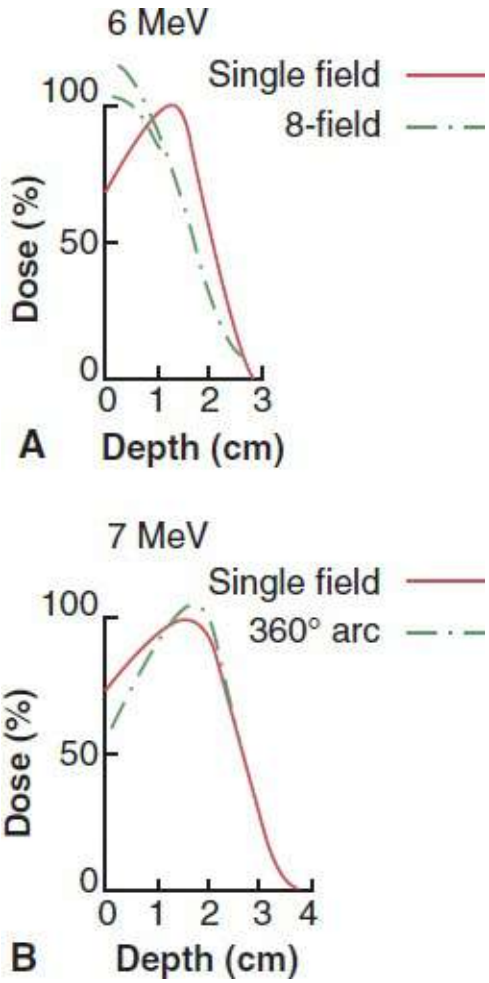

FIGURE 8.30. Treating circular anatomy with multiple beams spaced over 360 degrees. Depth dose along a radial axis depends on the field width. **A:** Depth dose for a broad, 6-MeV beam, resulting from an 8-field technique around a 20-cm diameter water cylinder, is governed by grazing radiation, typical of total skin and total-limb irradiation. **B:** Depth dose for a narrow, 7-MeV beam, resulting from rotating around a 20-cm diameter water cylinder, is governed by focusing of the radiation toward isocenter, typical of arc electron therapy.

Multiple techniques for total skin electron therapy have been reviewed in AAPM Report No. 23.[18] The underlying principles of the various techniques are similar, which are exemplified by the modified Stanford technique, illustrated in Figure 8.31. First, the treatment requires a broad beam from right to left, which can be achieved by a combination of treating the patient at an extended SSD (300 to 400 cm). The beam is made uniform from head to foot by abutting two fields at the 50% OAR (Fig. 8.31A). (Note that the 50% OAR lies outside the edge of the light field; thus, when properly abutted, there is a gap between the edges of the respective light fields.) By aiming the beams up and down, the largest bremsstrahlung contribution (central axis) misses the patient. The dose is

made uniform around the circumference of the patient by irradiating from six different directions (Fig. 8.31B). Similar to total-limb irradiation, tangential radiation results in a higher surface dose and a less penetrating dose. Placed upstream of the patient is a plastic screen that serves as both an energy degrader and a scatterer. Dose homogeneity depends on patient position, and reproducing the positions of the Stanford technique (Fig. 8.31C) is important. Despite efforts to create a homogeneous dose, there always will be areas that are underdosed (e.g., top of scalp, sole of feet, perineum, and under the breast or under the panniculus of obese individuals). These areas and sometimes tumorous lesions require separate treatment and boosting, respectively. In contrast, fingers, feet, and toes typically receive excess dose and are shielded for a portion of the treatment. *In vivo* measurement of patient dose on an individual basis is important when making decisions on prescriptions for supplemental treatments.

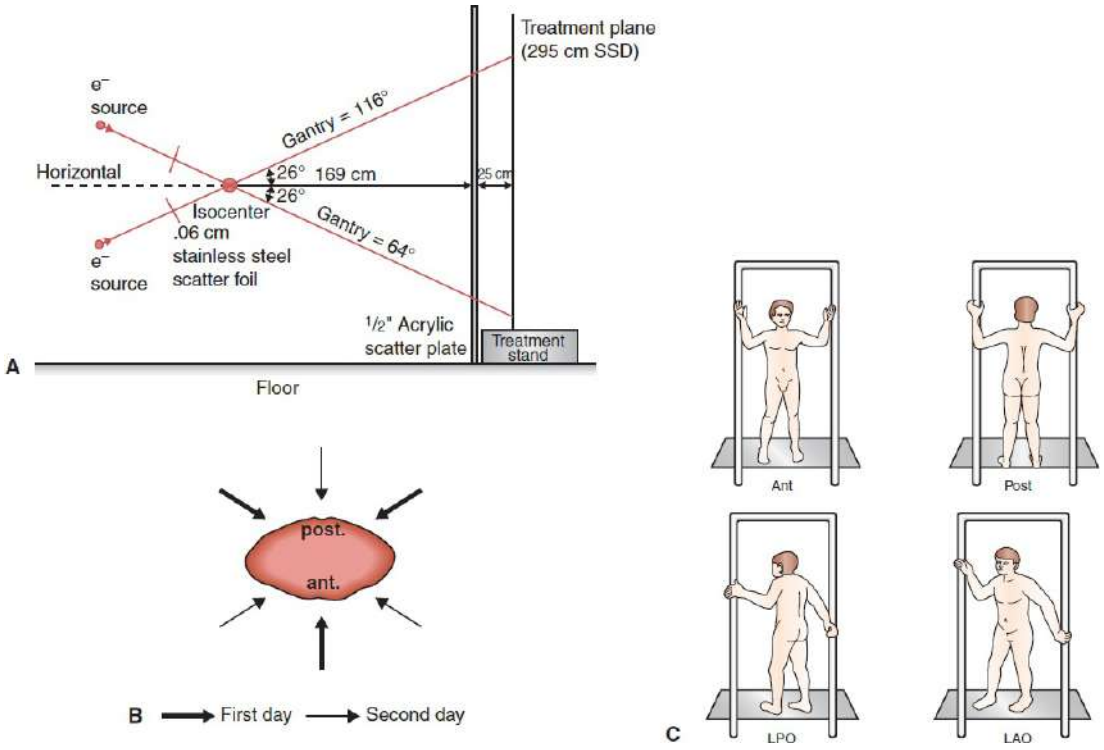

FIGURE 8.31. Schematic of modified Stanford technique for total skin irradiation. Side view of setup shows the relative position of patient plane, scatter plate, isocenter, and gantry angles **(A)**. Six beam directions **(B)** are achieved by placing the patient in six patient positions **(C)**. (From Almond PR. Total skin electron irradiation technique and dosimetry. In: Kereiakes JG, Elson HR, Born CG, eds. *Radiation oncology physics 1986*. New York: American Institute of Physics, 1987:296–332; and Karzmark CJ, Anderson J, Fessenden P, et al. *AAPM Report No. 23, total skin electron therapy: technique and dosimetry*. New York: American Institute of Physics, 1987. Reprinted by permission of American Association of Physicists in Medicine.)

Implementation of this technique is complex. It requires an external patient stand with a plastic diffuser, special dosimetry equipment for quality assurance and calibration, special shields for selected parts of the patient, and access to *in vivo* dosimetry.[96] It is also necessary for the radiation therapy accelerator to have a high dose rate mode and interlocks for electron energy, gantry angle, and x-ray jaws. Implementation of this technique has been estimated at 105 hours.[86] An institution must have a warranted patient population requiring this technique.

Electron Arc Therapy

Electron arc therapy is a useful technique for treating postmastectomy chest wall(s).[21] It is used in lieu of parallel-opposed tangential photon irradiation. It is more useful in "barrel-chested" women, where tangential beams can irradiate too much lung. It is also difficult to achieve homogeneous dose in the region where the medial tangential beam used for the chest wall abuts the anterior beam used for the IMC. In such cases, treating both areas with only opposed tangent photon beams irradiates too much lung. In such cases, electron arc therapy is a viable option. This can be particularly important in patients with bilateral disease.

The treatment geometry and dosimetry for arc therapy are unique. There are three levels of collimation in electron arc therapy: the primary x-ray collimators, a shaped secondary Cerrobend insert, and skin collimation (Fig. 8.32). The secondary collimator typically projects a 5- to 6-cm beam width at isocenter. There is typically a large air gap between the secondary collimating insert and the patient, resulting in a large penumbra; also in addition, the finite width of the field results in a broad edge at the end of the arc. The sharpness of the penumbra is restored utilizing skin collimation. This requires that the edge of the field of the secondary collimator extends well beyond the edge of the field defined by skin collimation. In the plane of rotation, this is achieved by rotating approximately 15 degrees beyond the treatment field edge (Fig. 8.33).

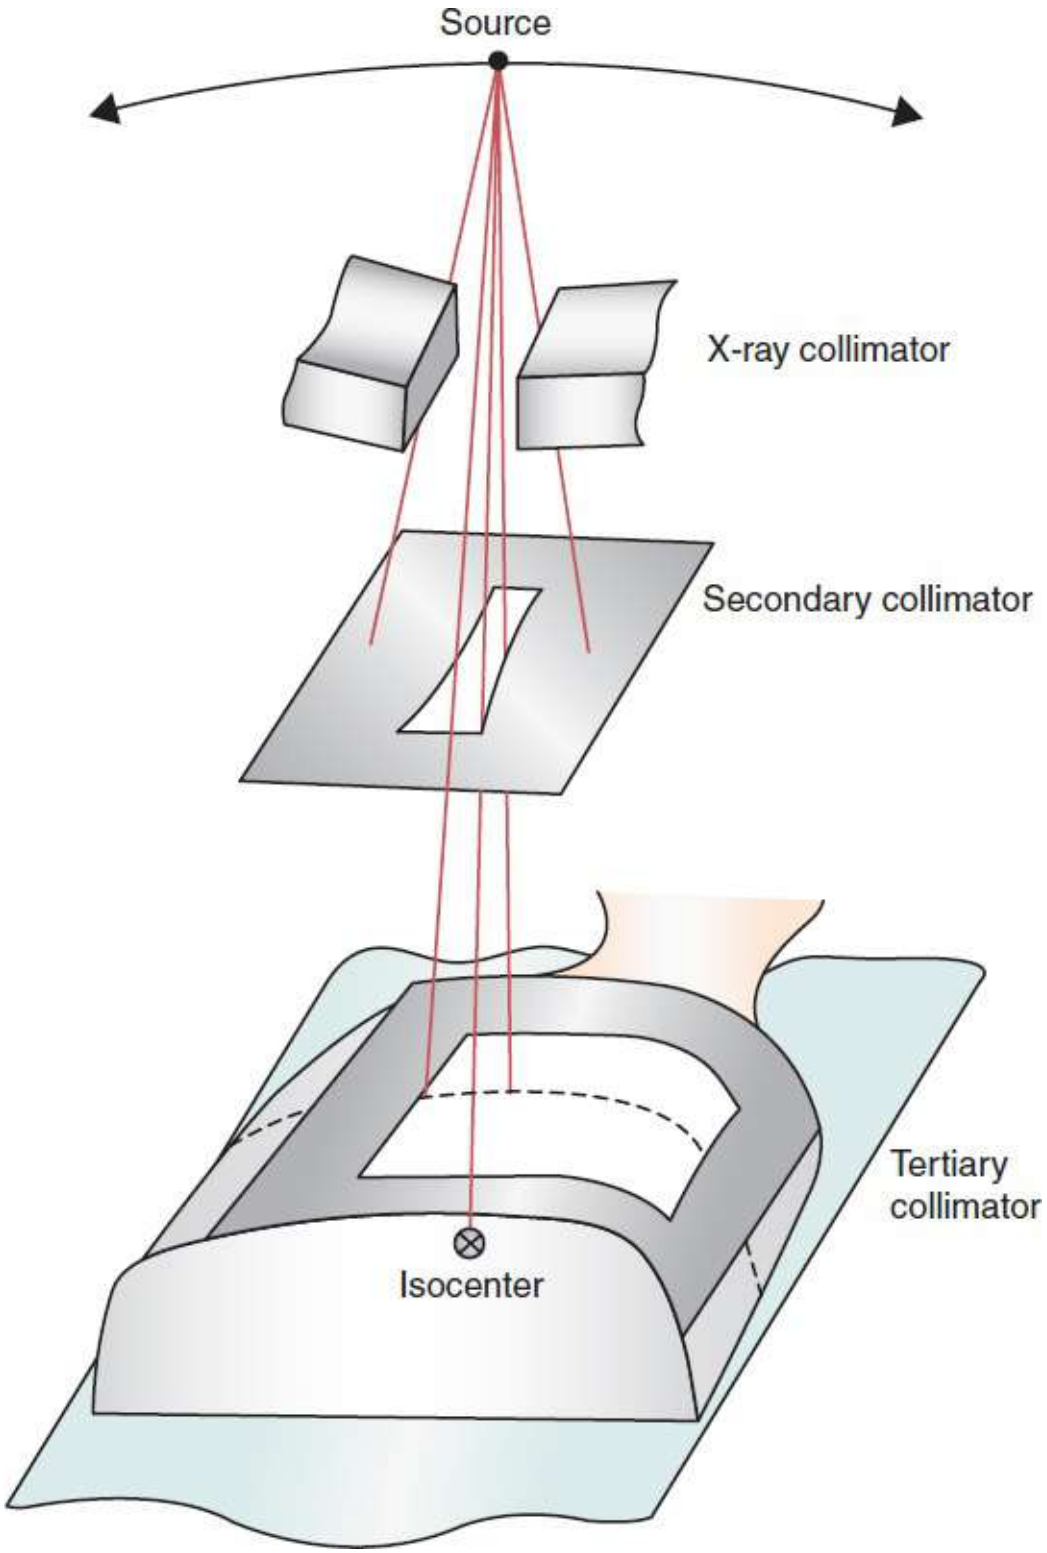

FIGURE 8.32. Schematic of treatment geometry for electron arc therapy. Skin collimation is required because of the large air gap between secondary collimator and patient, which is needed to allow rotation of the gantry around the patient.

As discussed previously, depth dose for an arced beam differs from that for a fixed beam (Fig. 8.24B); the surface dose is significantly less, and the dose falloff becomes slightly sharper. Consequently, bolus may be required to deliver adequate dose superficially. Another consequence of beam arcing is that a constant width of the secondary collimator results in dose inhomogeneity in the cephalocaudal direction. The radius of curvature of the patient with respect to the accelerator isocentric axis is typically less superiorly, as the neck is approached. If the radius of curvature is less, then the skin is farther from the electron source (i.e., a greater SSD). Contrary to fixed beam therapy, the dose to that region increases rather than decreases as a result of focusing of the electron fluence toward isocenter. However, by reducing the collimator width, the dose can be made more uniform.

The treatment planning process for arc therapy requires patient CT scanning, delineation of PTV, selection of isocenter location, specification of electron arc boundaries, energy and slab bolus selection, design of secondary collimator, and calculation of dose and monitor units. Figure 8.34 shows a typical dose distribution that can be achieved using arc therapy for irradiation MERT of the IMC and chest wall. Physics commissioning to initiate this procedure is on the order of 4 to 6 weeks.

Electron radiotherapy has not advanced beyond conventional therapy because of the labor-intensive (cutouts and bolus) tasks to shape and modulate beams, limited conformity in the depth direction, limited lateral conformity, no inverse planning, and no dynamic beam delivery. If these were overcome via an automated method, the conformation of dose distributions to shallow tumors might greatly improve—hence the advent of MERT. There is a definitive niche for MERT to complement a photon IMRT program. MERT will be able to achieve lateral dose conformity by intensity modulation (such as photon IMRT) and dose conformity along the depth direction using energy modulation (unique to electron beams). In addition, MERT may increase dose uniformity in the target both laterally and along the depth direction, reduce high or moderate concomitant dose to distal organs (e.g., lung, heart, and contralateral breast for breast treatments), and improve skin coverage or sparing when combined with photon IMRT.[88,97]

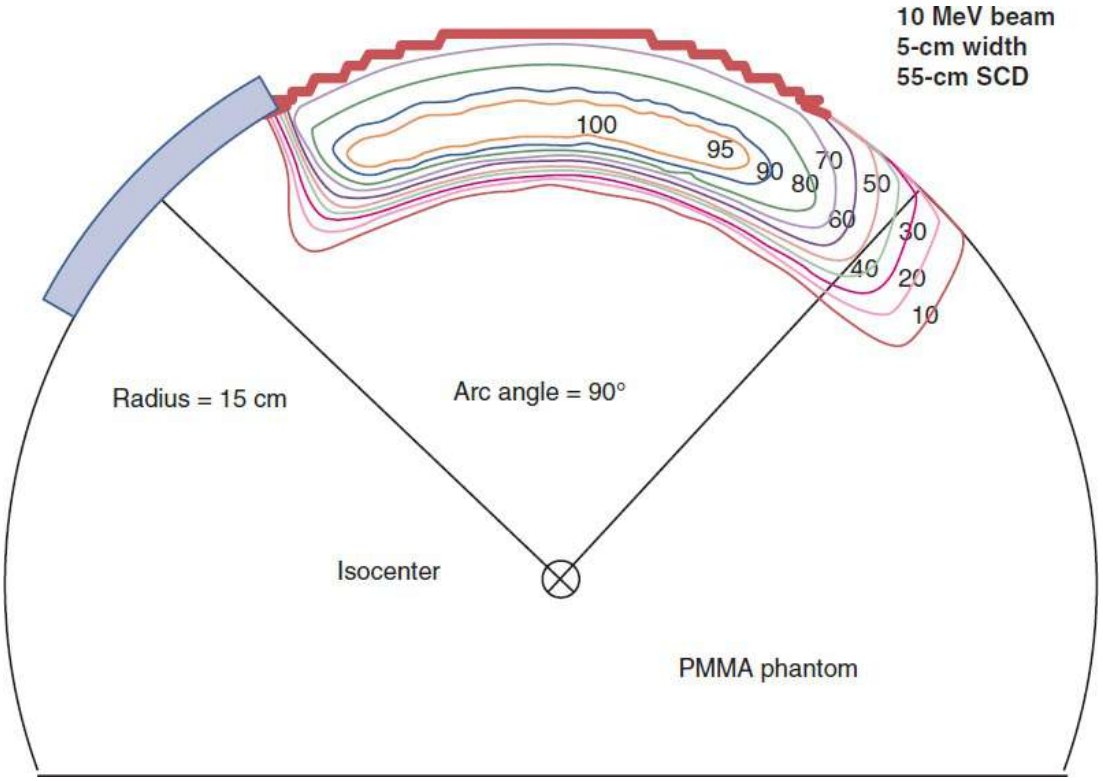

FIGURE 8.33. Comparison of dose distribution with and without skin collimation. The uncollimated edge has a slow dose falloff that is useful for abutting to other arced fields. The skin collimation restores the beam edge but requires rotating the beam 15 degrees beyond the edge of the skin collimator.

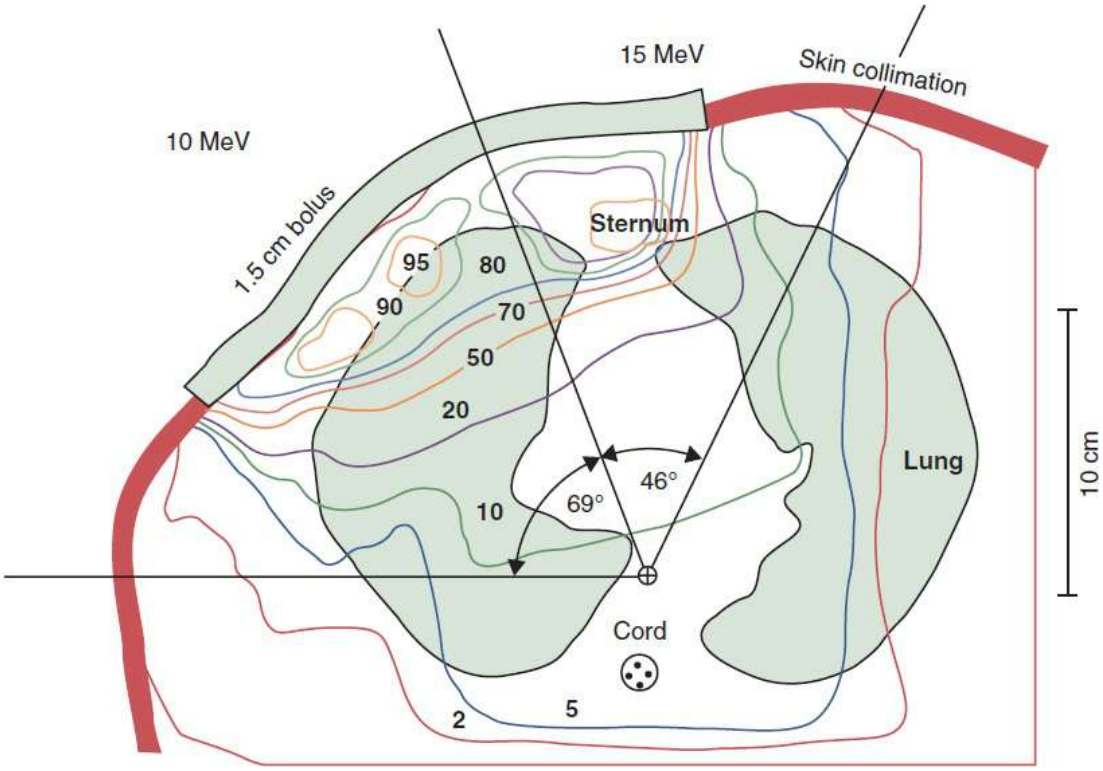

FIGURE 8.34. Typical dose distribution achieved by arc electron therapy. Note the different energies used for the internal mammary chain (IMC) and chest wall fields, the exact abutment of the IMC and chest wall fields, the rotation 15 degrees beyond the skin edges of the skin collimator, and the use of bolus to increase the surface dose. (From Hogstrom KR, Kurup RG, Shiu AS, et al. A two-dimensional pencil-beam algorithm for calculation of arc electron dose distributions. *Phys Med Biol* 1989;34[3]:315–341. doi:10.1088/0031-9155/34/3/005. © Institute of Physics and Engineering in Medicine. Reproduced by permission of IOP Publishing. All rights reserved.)

Disease sites such as postmastectomy chest wall, and mycosis fungoides or any cutaneous manifestation of lymphoma of the scalp, and so forth are likely best suited for modulated electrons, either with or without photons, or perhaps a combination of both. However, the inherent collimation systems in modern accelerators were optimized for megavoltage photons and are not conducive to electron beam delivery (in lieu of extended applicators), nor do commercial treatment planning systems model electrons collimated without applicators.

As an example of targeted sites that would be improved with MERT, treatment to the chest wall stands out. Current techniques of using tangential photon adjunct fields abutting supraclavicular and posterior axillary fields are difficult enough without the addition of treating a separate medial breast internal mammary field with a mixture of photon and electrons. Although there has been extensive work to optimize these techniques,[98] there are shortcomings because of match-line problems and delivery of unacceptable doses to volumes of heart, lung, and contralateral breast. Clinical side effects include edema, fibrosis, heart disease, and pneumonitis. Delivery by tangential photon beams to the chest wall is also not ideal because of the heterogeneous dose delivered in the secondary electron buildup region of the breast. Bolus may be used; however, this unfortunately reduces skin sparing. Electron arc therapy was developed in the 1980s to address the limitations of tangential photon beam treatments,[99] although it was extremely time consuming to implement. Use of MERT will phase out electrons arcs.

Many centers have used photon IMRT to improve dose conformity; however, the fundamental limitations because of megavoltage photon beams, such as excess distal dose and the buildup dose, are still challenges. MERT has been proposed as an alternative, particularly for postmastectomy patients.[8,62] The principal advantage is the rapid distal dose falloff. In principle, electron beams are well suited for these shallow targets, as they will spare distal regions, such as lung and heart.

Optimization is another important aspect for a MERT program. Many people

have come up with inverse planning techniques for photons and even more recently for electrons. Al-Yahya et al.[100] came up with a method of optimizing electron beam planning for a few leaf-electron collimator (FLEC). Planning was performed via Monte Carlo calculations and optimization using simulated annealing—a powerful mathematical tool that is the basis for inverse planning. The FLEC system consists of four motor-driven trimmer bars at the end of an applicator that creates rectangular shapes. The report claims potential treatment times of 15 minutes or less. Very comprehensive work by Lee et al.[65] described a Monte Carlo optimization scheme for modulated electron beam radiotherapy based on a stop-and-shoot technique. One of the most challenging things in both calculating and optimizing is the leaf scatter, where distributions could vary up to 20% depending on leaf positions. Lee et al.[65] performed MLC planning accomplished by calculating composite distributions for electron beamlets as collimated by tertiary electron MLC. Scatter and leakage contributions were included in the final dose calculation. An inverse planning dose optimization engine designed weights for each beamlet. The particle generation and absorption within the MLC leaves created demanding calculations but were necessary for accurate organ-at-risk calculations. Therefore, modeling of leaf scatter and transmissions is vital for accurate dose calculations. It is key that a multiple source model be developed. Publications describing the use of photon MLCs to modulate electrons have promoted an effective method to reform conformal electron therapy.[101–103]

Summary

Electron beam therapy remains an important modality to the practice of radiation therapy. As discussed earlier, its effective use requires knowledge of the unique properties of electron beam dose distributions, the impact of the patient on the dose distribution, and the basic principles for good practice. It requires access to and the proper use of comprehensive treatment planning and delivery tools. It also requires access to special techniques that offer unique treatment solutions for a limited number but broad range of patient conditions.

Electron therapy can be expected to become more sophisticated in the future as the enthusiasm for MERT grows. Advances in electron dose calculations, methods for electron beam optimization, and availability of MLCs for electrons will enable the practice of combined intensity-modulated photon and energy-modulated electron therapy. This will advance both electron conformal and mixed beam therapy.

CHAPTER 9

Conformal Radiation Therapy Physics, Treatment Planning, and Clinical Aspects

James A. Purdy and Sasa Mutic

INTRODUCTION

Modern anatomic imaging technologies, such as x-ray computed tomography (CT) and magnetic resonance imaging (MRI), provide a fully three-dimensional model of the cancer patient's anatomy, which is often complemented with functional imaging, such as positron emission tomography (PET) or magnetic resonance spectroscopy (MRS). Such advanced imaging allows the radiation oncologist to more accurately identify tumor volumes and their relationship with other critical normal organs. Powerful x-ray CT simulation and three-dimensional treatment planning systems (3DTPS) have been commercially available since the early 1990s, and three-dimensional conformal radiation therapy (3DCRT) has been the standard of practice for many years.[1–3] In addition, advances in radiation treatment delivery technology continue to evolve, as evident by developments in MRI-LINAC technology by Elekta (Stockholm, Sweden) and ViewRay (Oakwood Village, OH) as well as developments in proton beam delivery. Although these machines have different goals and features and it is beyond the scope of this text to provide an in-depth analysis of these technologies, some of the topics that are relevant in the designs of these technologies include improving imaging localization and intrafractional patient monitoring, increasing delivery efficiency, improving quality of delivered dose distributions, reducing cost of the equipment and of operation, improving clinical outcomes, simplifying use, and improving global access to modern day radiotherapy.

3DCRT treatment plans generally use an increased number of radiation beams that are shaped to conform to the target volume. To improve the conformality of

the dose distribution, conventional beam modifiers (e.g., wedges, partial transmission blocks, and/or compensating filters) are sometimes used. This *forward planning* approach used for 3DCRT (Fig. 9.1) is rapidly giving way to an *inverse planning* approach used for *intensity-modulated radiation therapy* (IMRT) (Fig. 9.2), which can achieve even greater conformity by optimally modulating the individual beamlets that make up the radiation beams.[4,5] IMRT dose distributions can be created to conform much more closely to the target volume, particularly for those volumes having complex/concave shapes, and also shaped to avoid critical normal tissues in the irradiated volume. This increased conformality results in IMRT treatments being much more sensitive to geometric uncertainties than the two-dimensional or forward-planned 3DCRT approaches and has spurred the development of treatment machines integrated with advanced volumetric imaging capabilities.[2,3,6,7,8] This has pushed the frontiers in conformal radiation therapy (CRT) practice from IMRT to what is now referred to *image-guided radiation therapy* (IGRT).[2,3,9] Of course, the concept of image guidance is not revolutionary and really should be viewed as an evolutionary component in the development of CRT. In the past, many systems and/or processes have been developed to help better localize the patient for treatment (and hence conform the dose), including dedicated x-ray simulators, megavoltage radiographic port films, electronic portal imaging devices (EPIDs), implanted radiopaque markers, ultrasound imaging systems, optical surface tracking systems, etc.[10,11] Even the early isocentric cobalt-60 teletherapy machines in the 1960s came equipped with a kilovolt x-ray tube attached to the beam stop.

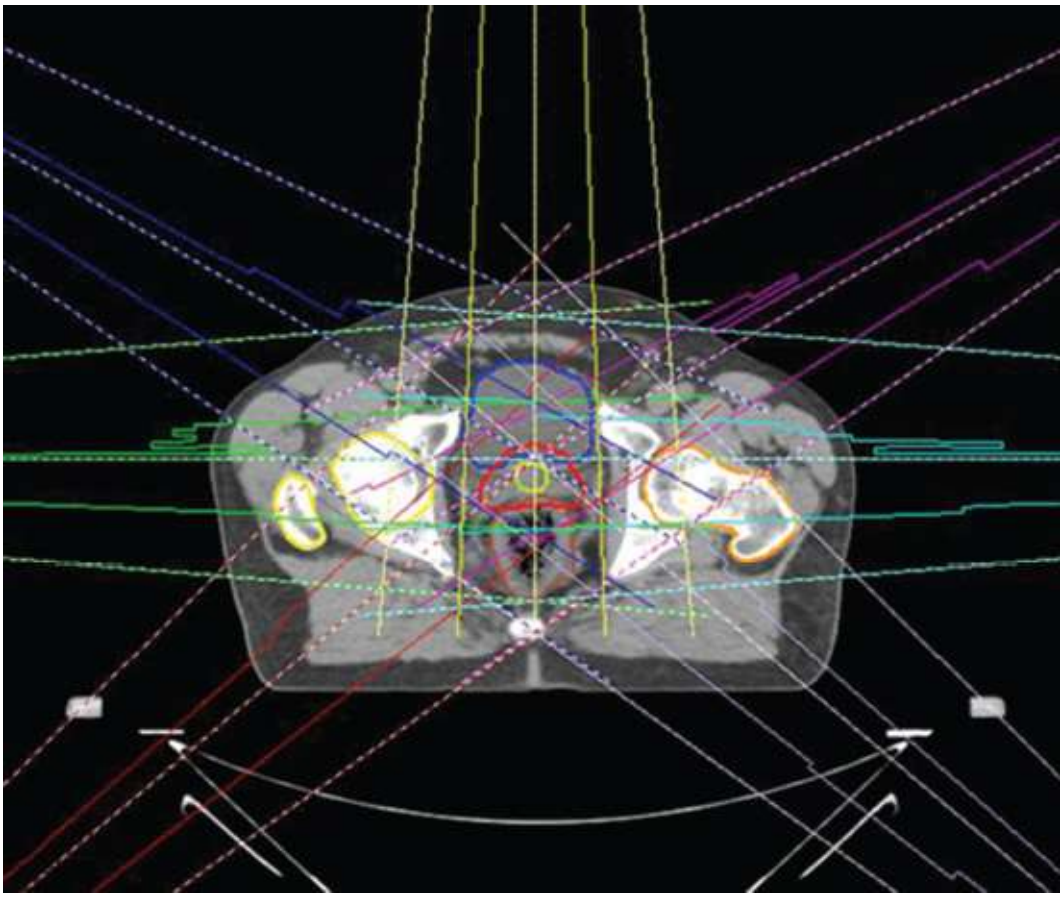

FIGURE 9.1. Three-dimensional conformal radiation therapy (3DCRT), considered a "forward planning" CRT approach that uses an increased number of radiation beams that are shaped to conform to the target volume. To improve the conformality of the dose distribution, beam modifiers (e.g., wedges, partial transmission blocks, and/or compensating filters) are sometimes used. Shown is a prostate seven-field coplanar beam arrangement.

This chapter will review the critical components that make up the CRT planning and delivery process, focusing mainly on the forward-planned 3DCRT process. However, it should be understood that most of the concepts and tasks discussed apply equally well to IMRT and IGRT, particularly with regard to target volume definition, plan evaluation, and many aspects of clinical quality assurance (QA). The reader should also understand that the use of the terms two-dimensional (*2-D*), three-dimensional (*3-D*), and even four-dimensional (*4-D*)[12] as descriptors for the CRT planning and delivery process refers to a process and the various tools used and not merely to beam arrangements. For example, 3-D treatment planning certainly does not require the use of "noncoplanar" beams—a common misconception—but does require the ability to plan and visualize volumetric dose distributions for such beam arrangements. Even today, newer

tools are being developed that allow 4-D, image-based CRT planning, that is, target-volume segmentation and dose calculation in the presence of moving organs and target volumes. Hence, the reader will be able to appreciate the CRT approach much more fully if it is viewed as a constantly evolving planning and treatment delivery workflow process using ever-advancing computer software and technology.

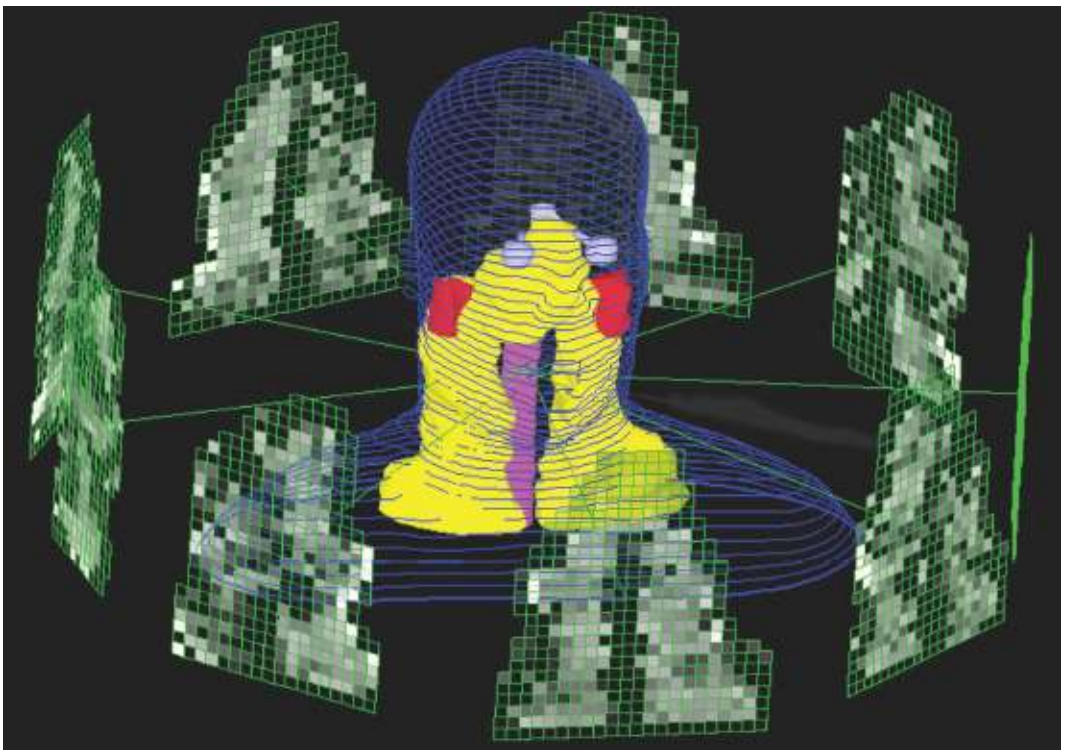

FIGURE 9.2. Intensity-modulated radiation therapy (IMRT) is considered an "inverse planning" conformal radiation therapy approach that can achieve even greater conformity than three-dimensional conformal radiation therapy by optimally modulating the individual beamlets that make up the radiation beams. IMRT dose distributions can be created to conform much more closely to the target volume, particularly for those volumes having complex/concave shapes, and also shaped to avoid critical normal tissues in the irradiated volume.

HISTORICAL DEVELOPMENT OF CONFORMAL RADIATION THERAPY AND 3-D TREATMENT PLANNING SYSTEMS

Conformational treatment methods were pioneered in the 1950s and 1960s by several groups, including Takahashi[13] in Japan; Proimos,[14] Trump, and Wright et al.[15] in the United States; and Green et al.[16] in Great Britain. Work continued into the 1970s, when several groups actually implemented computer-controlled radiation therapy, including a project of the Joint Center for Radiation Therapy

in Boston led by Bjarngard and Kijewski[17] and the Tracking Cobalt Project led by Davy et al.[18] at the Royal Free Hospital in London.

Sterling et al.[19,20] are credited with the first 3-D approach to treatment planning (dose calculation and display). They demonstrated a technique by which a computer-generated film loop gave the illusion of a 3-D view of the patient's relevant anatomic features and the calculated isodose distribution (2-D color washes) throughout a treatment volume. However, this effort did not result in a practical 3DTPS and was viewed as simply a demonstration project. The Rhode Island Hospital/Brown University group made the first real step in implementing a clinically usable 3DTPS based on a new type of display, called beam's-eye view (BEV), which simulated the treatment planner's viewing point from the perspective of the radiation source looking out along the axis of the radiation beam, similar to that obtained when viewing a simulation radiograph.[21,22]

The advent of CT spurred further development of 3-D planning systems. In 1983, Goitein and coworkers[23,24] reported on their system, which took advantage of CT and increased minicomputer capabilities. The system produced high-quality color BEV displays and could display radiographic images computed from the digital CT data; such computed radiographs are now called digitally reconstructed radiographs (DRRs). By the latter half of the 1980s, several other academic groups had developed 3-D planning systems having powerful new features.[25–28]

In the 1990s, the commercial availability of 3DTPS led to widespread adoption of 3-D planning and CRT as the standard of practice. One of the keys to this development was a series of research contracts funded by the National Cancer Institute (NCI) in the 1980s and 1990s to evaluate the potential of 3-D planning and to make recommendations to the NCI for future research in this area.[29] Each of the research contracts funded a collaborative working group (CWG). The participating institutions in each CWG are shown in Table 9.1. Their charge was to evaluate various aspects of this new planning process and develop new software tools needed. The CWGs were composed of physicists, clinicians, and computer scientists. Many important developments and/or refinements in 3-D planning came from these NCI research CWGs, particularly planning evaluation software tools such as *dose–volume histograms* (DVHs),[30,31] *electronic view box*,[32] and biologic effect models such as *tumor control probability* (TCP) and *normal tissue complication probability* (NTCP) models.[33] Even IMRT has benefited from the CWG approach, as a consensus

statement was developed in 2001 that helped clarify many issues and pointed to important research areas regarding that form of CRT.[34]

VOLUME SPECIFICATION FOR CONFORMAL RADIATION THERAPY

The International Commission on Radiation Units and Measurements (ICRU) first addressed the issue of consistent volume and dose specification in radiation therapy with the publication of ICRU Report 29 in 1978.[35] That report defined the *target volume* as *the volume containing those tissues that are to be irradiated to a specified absorbed dose according to a specified time–dose pattern* (Fig. 9.3A). It is interesting to note that this report (even though published in the 2-D era) attempted to address spatial uncertainties by pointing out that the size and shape of a target volume may change during the course of a treatment and that one should take into account the following parameters when describing the target volume:

- Expected movements (e.g., caused by breathing) of those tissues that contain the target volume relative to anatomic reference points (e.g., skin markings, suprasternal notch)
- Expected variation in shape and size of the target volume during a course of treatment (e.g., urinary bladder, stomach)
- Inaccuracies or variations in treatment setup during the course of treatment

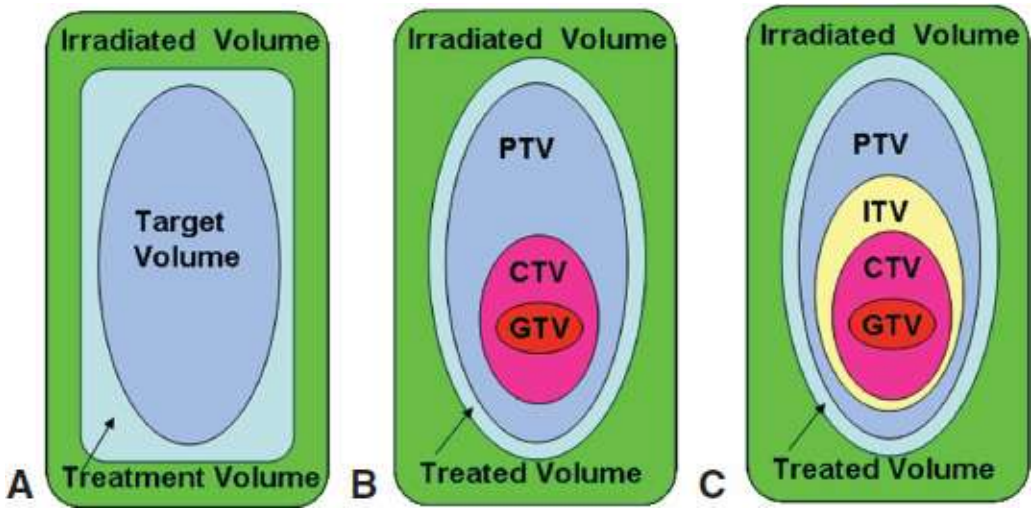

FIGURE 9.3. **A:** Schematic illustration of the boundaries of the volumes defined by International Commission on Radiation Units and Measures (ICRU) Report 29: target volume, treatment volume, and irradiated volume. **B:** Boundaries of the volumes defined by ICRU Report 50: gross tumor volume (GTV), clinical target volume (CTV), planning target volume (PTV), treated volume, and irradiated volume. **C:** Boundaries of the volumes defined by ICRU Report 62: GTV, CTV, internal target volume (ITV), PTV, treated volume, and irradiated volume.

However, the report did not address the issues of coordinate systems (e.g., patient vs. treatment machine), and no attempt was made to define and explicitly separate the margins for the different types of uncertainties.

In addition to the target volume, ICRU Report 29 defined two other volumes: (a) the *treatment volume* and (b) the *irradiated volume*. These volumes were not based on anatomy, but instead were based on the dose distribution. The treatment volume was defined as *the volume enclosed by the isodose surface representing the minimal target dose*, and the irradiated volume was defined as *the volume that receives a dose considered significant in relation to normal tissue tolerance* (e.g., 50% isodose surface).

Report 29 defined *organs at risk* (OARs) as *especially radiosensitive organs in or near the target volume whose presence influences treatment planning and/or prescribed dose*. The report also recognized the importance of tissues

outside the target area that received a dose higher than 100% of the specified target dose. This was defined as a *hot spot* and was considered clinically meaningful only if the corresponding isodose curve enclosed an area of at least 2 cm^2 in a section.

In retrospect, ICRU Report 29 recommendations were well suited for the technology of the 1970s and 1980s, that is, using a conventional simulator to generate a planning radiograph for designing beam portals based on bony and soft tissue landmarks for standardized beam arrangement techniques applied to whole classes of comparable patients. Several generations of radiation oncologists were trained using this nomenclature and method, and the ICRU recommendation for reporting dose and volumes helped advance radiation oncology.

In 1993, the ICRU updated its recommendations for specifying dose/volume in Report 50, which were well suited for conformal therapy.[36] The target volume definition was separated into three distinct volumes: (a) visible tumor, that is, *gross tumor volume* (GTV); (b) a volume to account for uncertainties in microscopic tumor spread, that is, *clinical target volume* (CTV); and (c) a volume to account for geometric and other uncertainties, that is, *planning target volume* (PTV), as illustrated in Figure 9.3B.

The GTV and CTV are anatomic–clinical concepts that should be defined before a choice of treatment modality and technique is made. Labels or subscripts with the GTV nomenclature can be used to distinguish between primary disease and other areas of macroscopic tumor involvement such as involved lymph nodes that are visible on imaging studies (e.g., $GTV_{primary}$ and GTV_{nodal}, or GTV-T and GTV-N). Similarly, the GTV together with this surrounding volume of local subclinical involvement that defines the CTV can be denoted as CTV-T. Note that even if the GTV has been removed by radical surgery, the volume can be designated as CTV-T. In specifying the CTV, the physician must consider not only microextensions of the disease near the GTV but also the natural avenues of spread for the particular disease and site, including lymph node, perivascular, and perineural extensions. These may be designated CTV-N (and, if necessary, CTV-N1, CTV-N2, etc.).

The *PTV* is defined by specifying the margins that must be added around the CTV to manage the effects of organ, tumor and patient movements, inaccuracies in beam and patient setup, and any other uncertainties. The PTV is a static, geometric concept used for treatment planning and for specification of dose. Its size and shape depend primarily on that of the GTV/CTV and the effects caused

by internal motions of organs and the tumor and technical aspects of treatment technique (e.g., patient fixation). The PTV can be considered a 3-D envelope in which the tumor and any microscopic extensions reside and move. Once the PTV is defined, appropriate beam sizes to account for penumbra and beam arrangements must be selected to ensure the desired dose coverage of the PTV. Note that multiple PTVs may be defined for a patient's radiation therapy treatment. For example, it is common practice to plan a higher dose to the PTV enclosing the GTV and a lower dose to the PTV containing the CTV. Such planning volumes are typically subscripted using the dose level prescribed; for example, PTVs for 66 Gy and 54 Gy can be represented as PTV_6 and PTV_{54}, respectively.

ICRU Report 50 essentially retained the definition of the two dose volumes defined in ICRU Report 29, changing the treatment volume name to *treated volume* and refining the definition as *the volume enclosed by an isodose surface, selected and specified by the radiation oncologist as being appropriate to achieve the purpose of treatment* (e.g., tumor eradication, palliation), and the irradiated volume as that *tissue volume that receives a dose that is considered significant in relation to normal tissue tolerance.*

Report 50 refined the definition of organs at risk as *normal tissues whose radiation sensitivity may significantly influence treatment planning and/or prescribed dose.* The report did state that any possible movement of the organ at risk during treatment, as well as uncertainties in the setup during the whole treatment course, must be considered, but did not provide a method to do so.

The hot spot definition was modified to be *a volume outside the PTV that received a dose larger than 100% of the specified PTV dose.* This was considered clinically meaningful only if the minimum diameter exceeded 15 mm (note: previously, it had been 2 cm^2). However, if the hot spot occurs in a small organ, such as the optic nerve, a dimension smaller than the recommended 15 mm should be considered.

As previously stated, Report 50 was well suited to conformal therapy, and it stimulated broad interest in the radiation oncology community. However, irradiation techniques continued to evolve (e.g., IMRT, IGRT), and advances in imaging procedures (e.g., PET, MRI) provided even more information on functionality, the location; shape, and limits of tumor/target volumes; and organs at risk. In response to these developments, the ICRU in 1999 published Report 62,[37] which expanded on some of the definitions and concepts of Report 50 and took into account the consequences of the technical and clinical progress

referred to previously. However, it should be clearly understood that Report 62 is intended to complement the recommendations contained in Report 50 and not to replace it.

ICRU Report 62 refined the definition of PTV by introducing the concept of an *internal margin* to take into account variations in size, shape, and position of the CTV in reference to the patient's coordinate system using anatomic reference points, as well as the concept of a *set-up margin* to take into account all uncertainties in patient beam positioning in reference to the treatment machine coordinate system. Identification of these two types of margins is needed, as they compensate for different types of uncertainties and refer to different coordinate systems. Internal margin uncertainties are due to physiologic variations (e.g., filling of the rectum, movements because of respiration) and are difficult or almost impossible to control from a practical viewpoint. Set-up margin uncertainties are related largely to technical factors that can be dealt with by more accurate setup and immobilization of the patient and improved mechanical stability of the machine. However, exactly how these margins should be combined is still not clear. This point will be discussed further in a later section, but for now, it is necessary to understand that the selection of an overall margin and delineation of the border of the PTV typically involve a compromise that requires the experience and the judgment of the radiation oncologist and the treatment planning team.

ICRU Report 62 defines the volume formed by the CTV and the internal margin as the *internal target volume* (ITV) (Fig. 9.3C). The ITV represents the movements of the CTV referenced to the patient coordinate system and is specified in relation to internal and external reference points, which preferably should be rigidly related to each other through bony structures. In cases not involving significant internal organ motion, the radiation oncologist can simply ignore having to explicitly define the ITV and use only the GTV, CTV, and PTV concepts. However, in cases involving significant motion, such as often is the case with lung cancer, the ITV concept has proven useful and should be used.[38]

TABLE 9.2 SUMMARY OF THE INTERNATIONAL COMMISSION ON RADIATION UNITS AND MEASUREMENTS (ICRU) NOMENCLATURE FOR VOLUMES (1970S TO PRESENT)

ICRU Report 29: 1970s–	ICRU Report 50: 1993–	ICRU Report 62: 1999–	ICRU Report 83: 2010–

1993	Present	Present	Present
Target volume	GTV	GTV	GTV
	CTV	CTV	CTV
	PTV	ITV	ITV
		PTV	PTV
Treatment volume	Treated volume	Treated volume	Treated volume
Irradiated volume	Irradiated volume	Irradiated volume	Irradiated volume
Organ at risk	Organ at risk	Organ at risk	Organ at risk
		PRV	PRV
			RVR
Hot spot (area outside target that receives dose >100% of specified target dose; at least 2 cm^2 in a section)	Hot spot (volume outside PTV that receives dose >100% of specified PTV dose; >15 mm diameter)	Hot spot (volume outside PTV that receives dose >100% of specified PTV dose; 15 mm diameter)	High dose to RVR
Dose heterogeneity (no value given)	Dose heterogeneity (+7% to −5% of prescribed dose)	Dose heterogeneity (+7% to −5% of prescribed dose)	Not specified

CTV, clinical target volume; GTV, gross tumor volume; ITV, internal target volume; PRV, planning risk volume; PTV, planning target volume; RVR, remaining volume at risk.

ICRU Report 62 refined the definition of the two dose volumes defined ICRU Report 50 as follows:

> The treated volume is the tissue volume that (according to the approved treatment plan) is planned to receive at least a dose selected and specified by radiation oncology team as being appropriate to achieve the purpose of the treatment, e.g., tumor eradication or palliation, within the bounds of acceptable complications.

The irradiated volume is the *tissue volume that receives a dose that is considered significant in relation to normal tissue tolerance.*

Report 62 refined the definition of organs at risk as *normal tissues* (*e.g., spinal cord) whose radiation sensitivity may significantly influence treatment planning and/or prescribed dose.* The report also included a discussion regarding a system of classifying organs at risk as “serial,” “parallel,” or “serial–parallel.” Report 62 also addressed what was perhaps the most criticized limitation of Report 50, which was that it did not provide a method to account for organ-at-risk movements and changes in shape and/or size, as well as set-up uncertainties.

To account for such spatial uncertainties, Report 62 introduced the concept of the *planning organ at risk volume* (PRV), in which a margin is added around the organ at risk to compensate for that organ's geometric uncertainties. The PRV margin around the organ at risk is analogous to the PTV margin around the CTV. The introduction of the PRV concept is timely, as its use is even more important for those conformal therapy cases involving IMRT because of the increased sensitivity of this type treatment to geometric uncertainties. For example, it is common practice to add a 0.5-cm rind around the spinal cord contour. Note that the PTV and the PRV may overlap, and often do so, which implies searching for a compromise in weighting the importance of each in the planning process. A summary of the ICRU volume nomenclature recommendations per report is presented in Table 9.2.

CONFORMAL RADIATION THERAPY PLANNING PROCESS

As previously stated, CRT treatment planning and delivery is best considered as a process and the tools used. This process is summarized in Table 9.3 and includes (a) establishing the patient's treatment position, constructing a patient repositioning immobilization device when needed, and obtaining a volumetric image data set of the patient in treatment position; (b) contouring target volume(s) and organs at risk using the volumetric planning image data set; (c) specifying a prescription dose for the PTV and dose–volume constraints for any OARs; (d1) for 3DCRT forward planning, determining beam orientation and designing beam apertures and computing a 3-D dose distribution according to the dose prescription; (d2) for IMRT inverse planning, setting up initial beam orientations and entering optimization parameters (i.e., dose–volume constraints for PTV[s] and all regions of interest) and initiating the TPS optimization process, which generates beam fluences, resulting dose distribution, monitor units (MUs), and leaf motion files; (e) evaluating the treatment plan and, if needed, modifying the plan (e.g., beam orientations, apertures, beam weights, etc.) until an acceptable plan is approved by the radiation oncologist; and (f) implementing the approved plan on the treatment machine and verifying the patient's treatment using appropriate QA procedures throughout the treatment. All of these tasks make up the CRT process and are discussed in the ensuing sections.

TABLE 9.3 CONFORMAL RADIATION THERAPY PROCESS

1. Patient treatment position, immobilization, and planning imaging
   a. Position patient in proposed treatment position.
   b. Fabricate immobilization devices.
   c. Place radiopaque markers, and mark repositioning lines on patient and immobilization devices.
   d. Obtain topograms to check patient alignment.
   e. Perform volumetric computed tomography (CT) scan of patient in treatment position.
   f. Make illustrative photographs to assist in repositioning the patient at the treatment couch.
   g. Transfer CT images to three-dimensional treatment planning system (3DTPS).
   h. Perform imaging studies (e.g., MRI, PET/CT, etc.) as requested by treating physician, and transfer image data to 3DTPS.
2. Delineation of tumor/target volumes and organs at risk
   a. Physician contours target volume(s).
   b. Physician or dosimetrist contours organs at risk.
3. Dose prescription
   a. Physician provides prescription dose for planning target volume (PTV) and dose–volume constraints for organs at risk.
   b. Forward planning (three-dimensional conformal radiation therapy)
      i. Set up initial beam configuration and design field shapes; wedges/bolus/no beam modifiers; beam weights.
      ii. Compute 3-D dose matrix.
      iii. Compute treatment machine monitor units.
   c. Inverse planning (intensity-modulated radiation therapy [IMRT])
      i. Set up initial beam configuration.
      ii. Enter desired dose–volume constraints for PTV(s) and all regions of interest.
      iii. Initiate treatment planning system optimization process, which generates beam fluences, resulting dose distribution, monitor units, and leaf motion files.
4. Plan evaluation and improvement
   a. Evaluate plan (dose–volume histograms, planar isodose display, 3-D isodose display) and modify until plan is found to be acceptable by treating physician.
   b. Transfer patient's plan to patient's chart (electronic medical record) and treatment machine verify and record (V&R) system.
5. Plan implementation and treatment verification
   a. Physicist performs second check of treatment plan and transfer of data to V&R system.
   b. For IMRT plans, perform phantom dosimetric verification.
   c. Verify patient position and isocenter placement on treatment machine using orthogonal portal electronic portal imaging devices (EPIDs) vs. digitally reconstructed radiograph (DRRs) or using onboard CT vs. planning CT.
   d. For 3DCRT, check field shapes by comparing treatment field DRRs with treatment beam EPIDs.
   e. Capture treatment machine settings in V&R system.
   f. Check first-day treatment with diode measurements.
   g. Perform periodic imaging verification checks during treatment (e.g., orthogonal EPIDs/DRRs or beam EPIDs/DRRs, cone-beam CT/planning CT).

Patient Treatment Position and Immobilization and Planning of Imaging

In the initial part of the CRT process (preplanning), the proposed treatment position of the patient is determined, and the immobilization device to be used during simulation/treatment is selected. It should be clearly understood that

repositioning patients and accounting for internal organ movement for fractionated radiation therapy in order to accurately reproduce the planned dose distribution remain difficult technical aspects of the CRT process. Errors may occur if patients are inadequately immobilized, with resultant treatment fields inaccurately aligned from treatment to treatment (interfraction). In addition, patients and/or their tumor volume may also move during treatment (intrafraction) because of either inadequate immobilization or physiologic activity. Accounting for all of the uncertainties in the CRT planning and delivery process remains a challenge for radiation oncology, and research and development is ongoing.

Determining the treatment position of the patient and constructing the immobilization device are typically done in a dedicated radiation therapy CT simulator facility. A radiation therapy CT simulator consists of a diagnostic-quality CT scanner, laser patient positioning/marking system, virtual simulation 3-D treatment planning software, as well as various digital display systems for viewing the DRRs.[39,40] The CT scanner is used to acquire a volumetric planning CT scan of a patient in treatment position. The use of intravenous or other contrast to help delineate target volumes needs to be considered during simulation in some cases. CT topograms should be generated first and reviewed prior to acquiring the planning scan to ensure that patient alignment is correct, with adjustments to be made if needed. Radiopaque markers can be placed on the patient's skin and the immobilization device to serve as fiducial marks to assist in any coordinate transformation needed as a result of 3-D planning and eventual plan implementation. An example of a typical immobilization repositioning system used for patients undergoing radiation therapy for head and neck (H&N) cancer is shown in Figure 9.4. PET-CT simulators[41] are also used in a number of departments. Trend for replacement of CT simulators with PET-CT simulators was especially active in the 2000s. More recently, there is a trend for use of MR simulators in RT- and MR-only–based simulation, and treatment planning has been an active topic of research and development.[42,43]

Planning CT scan protocols are tumor site dependent and typically range from 2 to 5 mm in slice thickness and 50 to 200 slices. In general, a 3-mm slice thickness provides adequate-quality DRR. In some sites, such as those of H&N cancer, slice thicknesses of 1 mm are often needed for delineation of very small volumes, such as the optic chiasm and the optic nerves. The same holds true for optimal reconstruction of the position of any implanted markers used, such as in prostate cancer radiation therapy.

FIGURE 9.4. Example of immobilization repositioning system used for patients undergoing radiation therapy for head and neck cancer. It should be clearly understood that being able to accurately reposition the patient and account for internal organ movement in order to accurately deliver the planned dose distribution is one of the most important steps in the conformal therapy process. (Courtesy of CIVCO Radiotherapy.)

The planning CT data set is typically transferred to a 3DTPS via a computer network. The planning CT data set provides an accurate geometric model of the patient, as well as the electron density information needed for the calculation of the 3-D dose distribution that takes into account tissue heterogeneities.

Delineation of Tumor/Target Volumes and Organs at Risk

Delineation of tumor/target volume and organs at risk contours using the volumetric CT data set is typically performed by the radiation oncologist and the medical dosimetrist working as a team. The CT data are displayed at the 3DTPS workstation (Fig. 9.5), and contours are drawn manually by the radiation oncologist/dosimetrist, most often using a computer mouse or stylus on a slice-by-slice basis. Some OARs with distinct boundaries (e.g., skin, lung) can be contoured automatically, with only minor editing required; others (e.g., brachial plexus) require the hands-on effort of the radiation oncologist.[44] With modern 3DTPS image segmentation software, contouring generally takes 0.5 to 1 hour, depending on the disease site. However, for some complex sites, such as H&N cancer, where many OARs and complex tumor/target volumes are the norm, this

task can take several hours.

CT is still the principal source of imaging data used for defining the GTV for most sites, but this imaging modality presents several potential pitfalls. First, when contouring the GTV, it is essential that the appropriate CT window and level settings be used in order to determine the maximum dimension of what is considered potential gross disease (Fig. 9.6). Second, for those treatment sites in which there is considerable organ motion, such as for tumors in the thorax, CT images do not correctly represent either the time-averaged position of the tumor or its shape, and hence newer 4-D CT technology must be used.[45–47] This can be understood by appreciating the fact that CT simulators rely almost exclusively on the use of fast spiral CT technology and thus acquire data essentially in limited width slices and combine them to construct a 3-D matrix. This has the effect of capturing the tumor cross-sectional images at particular positions in the breathing cycle. If the tumor motion is significant, different, and possibly noncontiguous, transverse sections of the tumor could be imaged at different points of the breathing cycle, leading to volume uncertainties. The interpolation process in spiral CT technology adds further to the uncertainty. As a result, the 3-D reconstruction of the GTV from temporally variant 2-D images often results in a poor representation of the tumor and its motion. Currently, 4-D CT technology has become the standard for CT simulators, making it possible to capture images in each phase of the respiratory cycle.[48,49] In addition, other technologies and methodologies to explicitly help manage the movements induced by the respiratory motion (to the order of <5 mm during treatment preparation and delivery) continue to be developed, including respiratory-gated techniques, respiration-synchronized techniques, breath hold techniques, and forced shallow-breathing methods.[50]

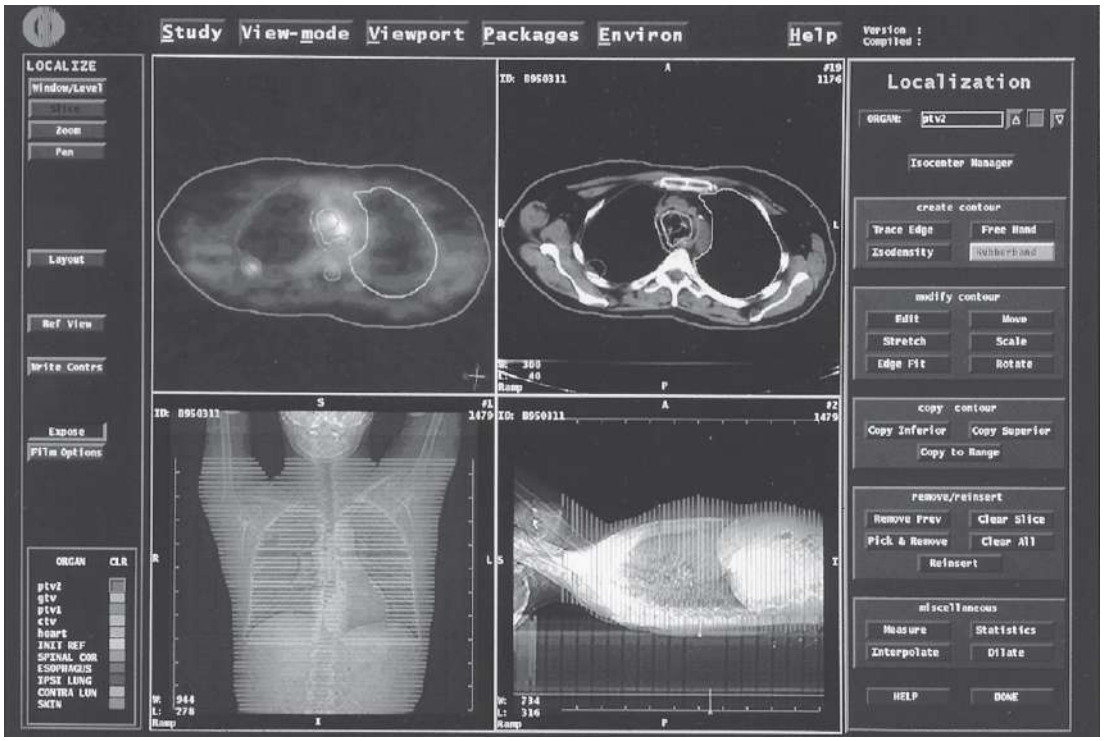

FIGURE 9.5. Advanced image segmentation software provides tools for radiation oncologists and treatment planners to determine critical structures and tumor and target volumes for three-dimensional planning. Computed tomography (CT) data are displayed, and contours are drawn by the treatment planner/radiation oncologist around the tumor, target, and normal tissues on a slice-by-slice basis, as seen in **upper right panel**. At the same time, planar images from both anterior–posterior and lateral projections are displayed in **bottom right** and **left panels**. **Upper left panel** shows positron emission tomography scan data with overlying contours after image registration with the CT data.

FIGURE 9.6. Computed tomography (CT) slice for patient with lung cancer showing that the appropriate CT window and level settings **(right frame)** must be used to determine the maximum dimensions of the gross tumor volume (GTV). Note that a

much smaller GTV would have been contoured with the settings used in the left frame. (Reprinted from Purdy JA. Advances in three-dimensional treatment planning and conformal dose delivery. *Semin Oncol* 1997;24[6]:655–671. Copyright © 1997 Elsevier. With permission.)

Delineating the CTV is even more difficult and must be done by the radiation oncologist based on clinical experience (and/or the use of published CTV atlases for certain clinical sites) because current imaging techniques cannot be used to directly detect subclinical tumor involvement. This field has seen a virtual explosion in the use of multimodality imaging over the last decade, and radiation oncologists have developed considerable imaging expertise in order to accurately define GTVs and be able to define nonimaged CTVs. However, the need for a higher level of image-based cross-sectional anatomy training in this field is well recognized.[51] The AAPM Task Group 132 addresses integration of multimodality imaging in the treatment planning and treatment processes.[52]

The PTV margin is specified by the radiation oncologist, often in consultation with the radiation oncology physicist and/or dosimetrist. In most occasions, it is based on published clinical experience that is not calculated based on measurements performed by the department for a particular treatment machine/technique and team. Van Herk and colleagues reported extensively on the influence of systematic and random errors/variations on the required margins to account for set-up error and organ motion and developed margin recipes for calculating individualized (for a department, machine, and team) margins as given by the following equation[53,54]:

$$\text{PTV margin} = 2.5\Sigma + 0.7\sigma$$

where Σ is the standard deviation of the systematic errors and σ is the standard deviation of the random errors.

When defining the PTV, the radiation oncologist should account for the asymmetric nature of positional uncertainties (Fig. 9.7). For example, it is recognized that prostate organ motion and daily set-up errors may be anisotropic (side-to-side or rotational shifts of the position of the patients are likely to have a different result compared to movement in the anterior–posterior direction). Thus, the PTV margin around a CTV generally should not be uniform.

Typically, when the beam portal is defined, additional margin beyond the PTV is required to obtain dose coverage because of beam penumbra and treatment technique. This emphasizes that treatment portal margins in relation to the PTV must be set according to the dosimetric characteristics of the beams

being used. Often, a 5-mm margin (portal edge to PTV) is a good starting point, which can be increased if needed, but one must be knowledgeable about the characteristics of the actual beams used to make this starting-point determination. An additional point to understand is that in the case of coplanar treatment techniques, the margins required across the plane of treatment and the margins orthogonal (say superior–inferior) to this plane will be different. To clarify this point, consider a pelvic four-field axial technique as an example. Portions of the lateral aspects of the PTV that are in the low dose regions (near the penumbra) of the anterior–posterior and posterior–anterior fields will be in the high dose regions (well away from the beam penumbra) of the lateral fields. However, the superior and inferior aspects of the PTV will always be in the same low dose regions of all four fields, so there will be no dose filling from any of the fields. Thus, a larger portal margin in the inferior–superior dimension is needed to ensure that the prescription isodose resulting from all beams contains the PTV, whereas the lateral and anterior–posterior portal margins for each field may be reduced due to the other beams filling in the dose. The same holds true for the portals of the boost fields used in the so-called integrated boost technique, in which the beams used for treating the large volume fill up the dose in the buildup region of the boost volume. Last, the size of the margins will also be affected by the relative beam weighting. Hence, making hard rules about margin sizes is impossible and requires some planning iteration to find the right mix of beam margins.

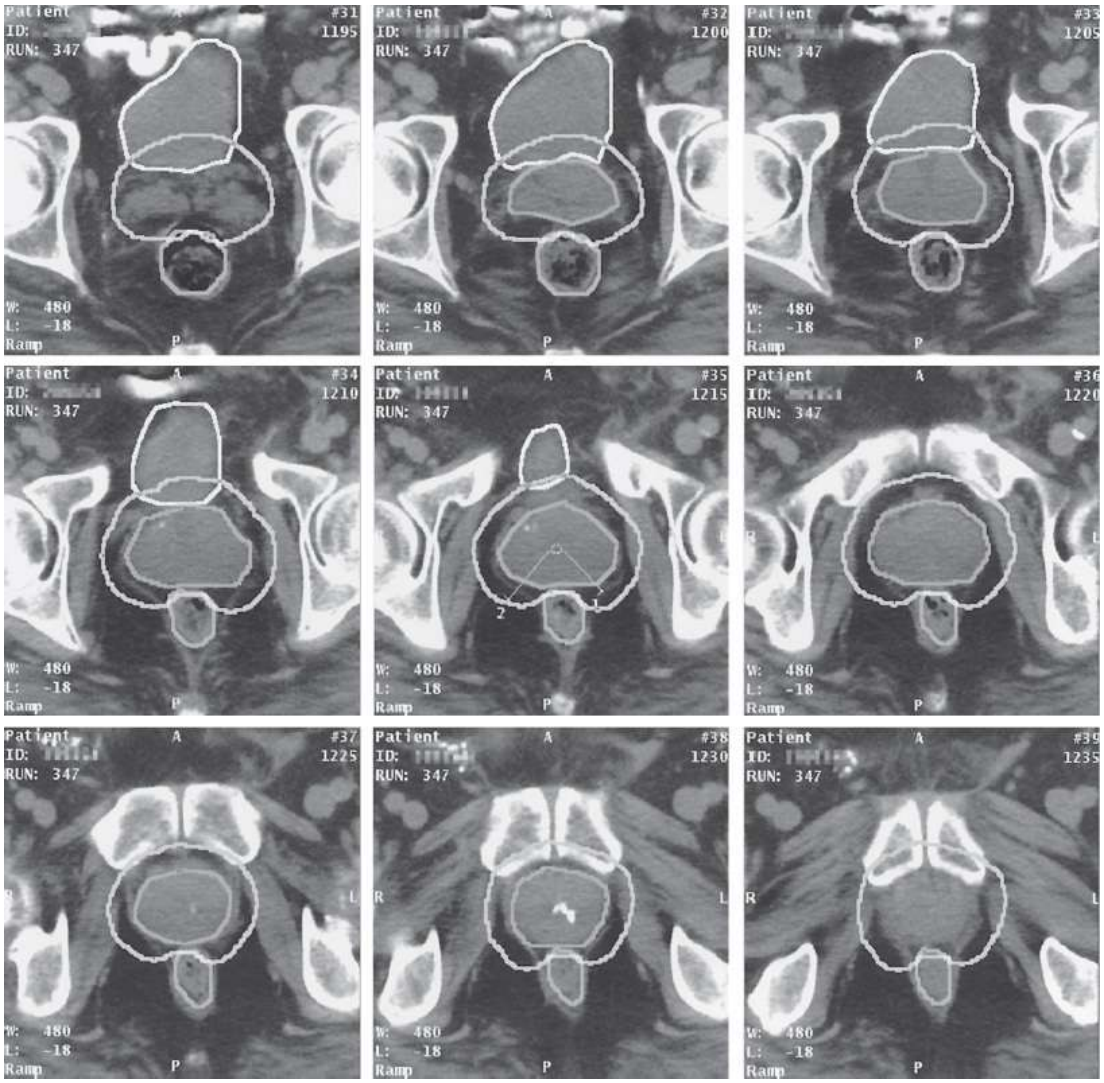

FIGURE 9.7. Computed tomography images of patient with prostate cancer showing the contour outlines for the gross tumor volume (GTV), planning target volume (PTV), bladder, and rectum. The physician made the decision that no additional margin around the prostate for the clinical target volume (CTV) was required (i.e., CTV = GTV). Note that a nonuniform margin around the GTV/CTV was used to define the PTV in the region of the rectum **(middle frame)**. Also, note the additional PTV contours needed to cap the GTV/CTV **(upper left** and **lower right frames)**. (Reprinted by permission from Springer: Purdy JA. Three-dimensional treatment planning and conformal dose delivery: a physicist's perspective. In: Mittal BB, Purdy JA, Ang KK, eds. *Advances in radiation therapy*. Boston: Kluwer Academic Publishers, 1998:1–33. Copyright © 1998 Springer Science+Business Media New York.)

When a PTV overlaps with a contoured normal structure, it is important to be explicit as to which volume the overlapping voxels are assigned for optimization purposes and for DVH calculations. Planning systems should allow the overlapping voxels to be included in both volumes for plan evaluation and

reporting purposes. This ensures that the clinician is aware of the potential for the high dose region to include part of the normal structure as well as the PTV when reviewing the DVHs.

In addition, most 3DTPS cannot accurately account for a PTV contour that extends outside the skin surface, resulting in a DVH that does not reflect clinical reality because of the lack of dose generated in air and in the buildup region just below the skin. In those cases, the best solution is to delineate the PTV 3 to 5 mm below the skin surface. This will also help reduce acute skin reactions by preventing the optimization process from increasing the skin dose to excessive levels. In all cases, however, the treating physician should be aware of this approximation when setting or approving actual field margins.

All of the issues discussed in this section point out the fact that the PTV/PRV concept is a useful tool that simplifies accounting for geometric uncertainties. However, its use does give rise to several dilemmas. Particularly important is the loss of actual tumor and normal organ volume information reported for researchers developing TCP and NTCP models. Although it does not appear possible to totally eliminate the PTV concept at this time, it does appear possible to use smaller margins for some sites if more frequent imaging or other technical innovation is used to reduce geometric uncertainties. For example, for prostate cancer, the use of daily imaging and other technologies to relocate the target volume in reference to the machine isocenter does allow for a smaller margin for the PTV.[11,55] However, one must still be prudent in the amount of margin reduction for the prostate PTV when using these technologies. The different methods include various trade-offs ranging from treatment machine control, which is not dependent on the patient, to systems that are completely dependent on the patient. Again, regardless of which technique is used to reduce the overall PTV margin, one must be prudent in deciding the amount of margin reduction. Data do exist for support of margin reduction, but one must be systematical in approaching such reductions and ensure that there are no adverse effects on expected patient outcomes.[56]

Dose Prescription

Dose prescription is the responsibility of the radiation oncologist, generally using institutional protocols based on evidence published in the literature combined with institutional experience. Typically, the CRT prescription is specified as a dose at or near the center of the PTV or (particularly for IMRT) as a dose covering a certain percentage of the PTV—for example, $D_{95\%}$, a dose that

covers 95% of the PTV. Because the resulting dose distribution can be quite different depending on the dose prescription methodology, it is imperative that publications provide a clear and unambiguous description of the dose specification for the radiation treatment results being reported. The ICRU recently updated their recommendations for dose specification, and these will be discussed in a later section.[57]

Conformal Planning

For 3DCRT planning, beams can be arranged and beam apertures shaped with MLC leaves or shielding blocks to help conform the prescribed dose to the PTV and avoid OARs using BEV displays. This "forward planning" approach to CRT has now been supplemented—but not replaced—by an "inverse planning" approach as used for IMRT, which can achieve even greater conformity and OAR dose avoidance.

Forward Planning: 3DCRT

Design of the beam arrangement is the next step in the planning process for 3DCRT. The ability to orient beams in 3-D allows one to develop treatment plans that use noncoplanar beams. However, when noncoplanar beam arrangements are used, care must be taken to avoid the selection of gantry and couch angles that results in table/gantry collisions or a conflict with other treatment room restrictions. The *BEV* and the *DRR display*,[24,58] as shown in Figure 9.8, allows the planner to easily view the target volume and the organs at risk so that shielding blocks or MLC apertures can be drawn using a computer mouse or, as available with most current 3DTPS software versions, automatically generated with a chosen margin around the selected volume. DRRs also provide planar reference images that can be used in facilitating the plan implementation and treatment verification phases of CRT.

Inverse Planning: IMRT

The major differences between 3DCRT forward planning and IMRT inverse planning are the use of a computer optimization program that requires a formal description of the requirements using a mathematical *objective function* and constraints that are used by the program to find the solution. For example, after the design of the initial beam geometry, the physician/treatment planner puts into the TPS the desired dose–volume constraints for the PTVs and all OARs. The TPS optimization algorithm then divides each beam into many small *beamlets* (i.e., pencil beams that together make up the IMRT beam) and then iteratively

alters the beamlet intensities until the 3-D dose distribution best conforms to the *a priori* specified dose–volume objectives. After the optimal beam intensities and resulting dose distribution have been determined, the TPS then calculates the MLC leaf sequence motions that will achieve this dose distribution and the dose recalculated. Typically, there may be some differences in the optimized dose distribution and the final dose distribution that is delivered with the computer-controlled MLC system, but this difference is usually acceptable.

Noncoplanar Multibeam Delivery

Sheng and colleagues recently investigated benefits of increasing the number of beams in noncoplanar delivery and showed that significant normal tissue sparing and dose conformality gains can be achieved when 14 to 22 beams are used for delivery.[59] In this approach, an optimization algorithm, in addition to conventional fluence optimization, also optimizes noncoplanar beam orientations considering a patient-specific deliverable beam geometry solution space, parameterized with patient and linear accelerator gantry orientations. This delivery technique, dubbed 4π, has been extended to other disease sites and has shown that research can lead to additional improvements in radiotherapy photon dose distributions.[60,61]

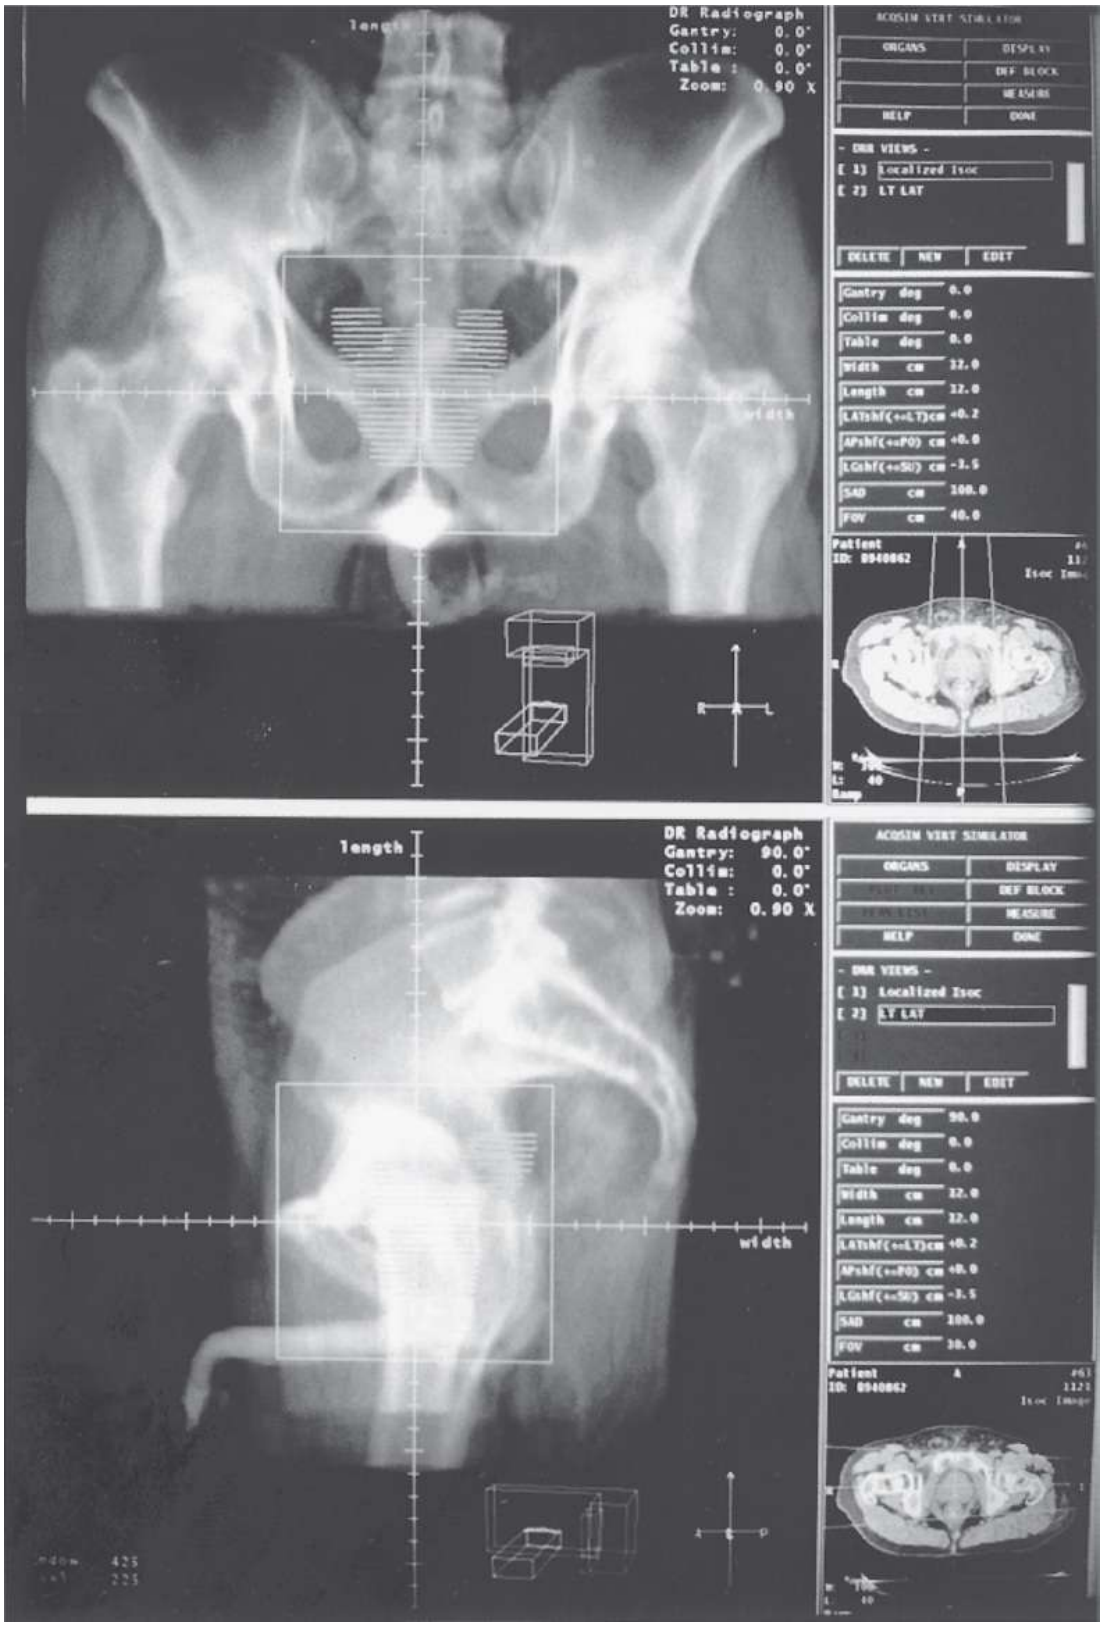

FIGURE 9.8. Beam's-eye–view (BEV) and digitally reconstructed radiograph (DRR) display of three-dimensional radiation therapy treatment planning for a prostate cancer patient. BEV display is useful in identifying best gantry, collimator, and couch

angles at which to irradiate the target and avoid irradiating adjacent normal structures by interactively moving patient and treatment beam. Critical structures and target volumes are outlined on the patient's serial computed tomography sections. Contours are seen in perspective, as though the observer's eye is at the radiation source looking out along the axis of the radiation beam. The beam shape is defined by multileaf collimator (MLC). (Reprinted from Purdy JA. Advances in three-dimensional treatment planning and conformal dose delivery. *Semin Oncol* 1997;24[6]:655–671. Copyright © 1997 Elsevier. With permission.)

Dose Distribution Calculation

A rectilinear coordinate system affixed to the patient 3-D CT image set is typically used for calculating the dose distribution. This "patient or CT system" coordinate system typically has its *x*-axis along the horizontal axis of the transverse CT images, the *y*-axis along the vertical axis, and the *z*-axis along the couch motion. Contour points are specified as a sequence of points having *x*-, *y*-, and *z*-coordinates in this system. The center of each voxel in the 3-D CT image matrix is computed relative to the same coordinate system and is used to look up the relative electron density values that are related to the CT numbers (see later discussion). The selection of grid spacing for the 3-D dose matrix is an important consideration regarding dose computational accuracy, calculation speed, and computer hardware requirements. Drzymala et al.[31] pointed out that a 2% dose accuracy or 2-mm isodose positional accuracy can generally be achieved with a grid spacing of 5 mm. However, in regions of high dose gradients, a finer grid is typically needed, which creates larger computer files and increases the 3DTPS memory and mass storage requirements. With modern computing capabilities, these issues are not a practical limitation, and high-resolution dose computations are achievable that can lead to dosimetric benefits.[62]

The reader should also understand that CT numbers are not used directly in photon dose calculations. Instead, the CT numbers are correlated with the electron density of the corresponding tissues at each voxel relative to the electron density of water.[63] This is because Compton scattering is the dominant mode of interaction for the type of photon beam used in radiation therapy (cobalt 60 through 25-MV x-rays), and the absorption and scattering of photons in tissue depend primarily on the electron density of the tissue. Errors in CT numbers can result in inaccurate dose calculations. Generally, however, errors of 10% or less in electron density (CT numbers) will not result in significant errors in the dose distribution.[63] A recent development has been direct electron density imaging[64]; full clinical impact of this technology remains to be investigated.

Details on specific dose calculation algorithms are discussed in a separate

chapter, and so only issues pertinent to the CRT planning process are discussed in this section. In the past, dose calculation algorithms were traditionally based on parameterizing dose distributions measured in water phantoms under standard conditions and applying correction factors to the beam representations for the nonuniform surface contour of the patient or the obliquity of the beam, tissue heterogeneities, and beam modifiers such as blocks, wedges, and compensator. However, more advanced models, such as the superposition/convolution method, have been developed for CRT planning[63] and are now the standard of practice today for CRT planning. The study by Frank et al.[65] provides a clear method for safely transitioning from a clinical experience based on planning assuming a homogeneous unit density patient to a heterogeneous patient model.

Plan Evaluation and Improvement

The 3DCRT plan evaluation/improvement process involves an iterative, interactive approach. Typically, the initial beam arrangement has been selected based primarily on clinical experience using BEV displays. The generated dose distribution is reviewed by the planner/physician, and the beam arrangement is then modified based on the review of DVHs (Fig. 9.9) and multilevel 2-D displays showing isodose lines superimposed on CT images (Fig. 9.10); sometimes, the display is in the form of a *color wash*, that is, a spectrum of colors superimposed on the anatomic information. Historically, the planned dose distribution approved by the radiation oncologist is most often one in which a uniform dose is delivered to the target volume (e.g., +7% and –5% of the prescribed dose) with doses to critical structures held below tolerance levels,[66–69] as well as within the constraints for the absolute maximum dose, median dose, or a volume (e.g., V_{20Gy}) that has been specified by the radiation oncologist. With IMRT and SBRT approaches, there is an increased acceptance of larger-dose heterogeneities, whereas the approach to other evaluation parameters remains unchanged.

Over the recent years, the plan creation and evaluation process has significantly evolved adding several new options and tools to the process. The calculation of Pareto surfaces in multicriteria optimization (MCO) based IMRT treatment planning involves creation of several treatment plan options where each plan offers a combination of different dose volume trade-offs.[70] Pareto optimal plans offer a plan bundle where each plan favors an organ at risk or a combination of organs at risk at an expense of some other organ or organs. In other words, radiotherapy treatment planning is all about trade-offs between

doses delivered to target volumes and various organs at risk. These trade-offs involve physicians making decisions on dose sacrifices and sparing, which critical organs to give less dose at expense of some other organs getting more dose or they involve compromises in the balance of dose delivery between targets and organs at risk. In MCO, a set of plans optimized for unique combinations of dose trade-offs is combined with tools to offer a physician an efficient way to navigate through these trade-offs or plan options and to select a plan offering the trade-offs favored by that physician. This approach has been shown to have quantifiable dosimetric advantages.[71] Both RaySearch (Garden City, NY) and Varian (Palo Alto, CA) offer MCO approaches. The advantages of this technique include the flexibility offered to physicians in guiding the treatment delivery; however, there can be inconsistencies in physician selection process, which can increase the variability of clinical practices.

In knowledge-based planning (KBP), treatment plans of previously treated patients are used to create models of achievable dose distributions for future plans.[72,73] The historical plans constitute a training data set, and machine learning–like approaches are used to create DVH range predictions unique to a patient's specific organ geometry (Fig. 9.11). In the KBP approach, a DVH or 3-D dose prediction can be created as soon as there are contours of the patient geometry and the prescription.[74] The proposed solution is driven by the prior treatment planning practices and results in a single-treatment plan rather than multiple plan options as in the MCO. In this approach, treatment models can be created at one institution or globally and transferred to other, presumably less experienced, institutions[72,73] as well as used to standardize treatment planning quality in multi-institutional trials.[75,76] The ability to standardize plan quality in multi-institutional trials minimizes a significant source of historical variability and shortcoming in these trials, which should translate in increased confidence in the trial outcomes. Another potential benefit is the minimization of variability of transfer of planning protocols from multi-institutional trials to individual clinics if the KBP models used in a trial are available to individual clinics. The KBP approach is commercially available through Varian's RapidPlan software.

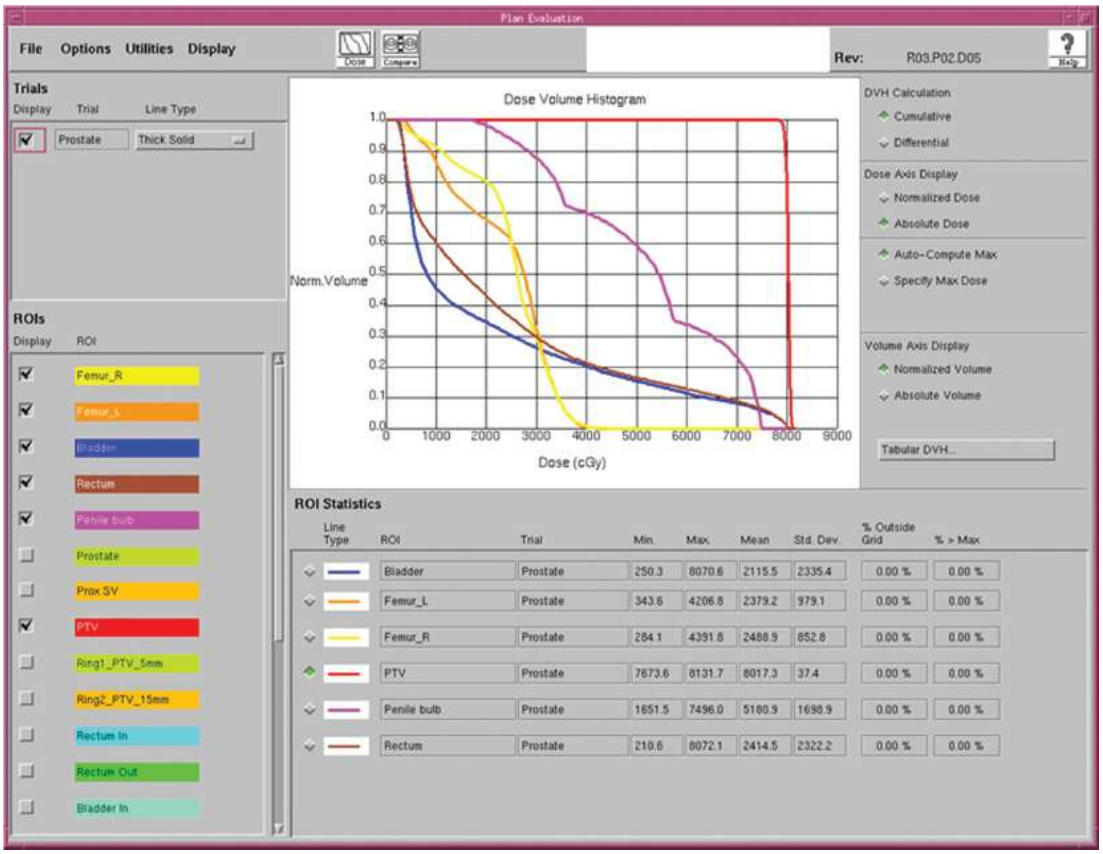

FIGURE 9.9. Example of a treatment planning system display (Pinnacle; Philips Medical Systems, Highland Heights, OH), showing the cumulative dose–volume histograms for a typical prostate cancer patient's plan: the prostate PTV (*red*) and multiple OARs (penile bulb, *magenta*; right femur, *yellow*; left femur, *orange*; rectum, *brown*; bladder, *blue*); also shown are associated dose statistics for the various defined volumes.

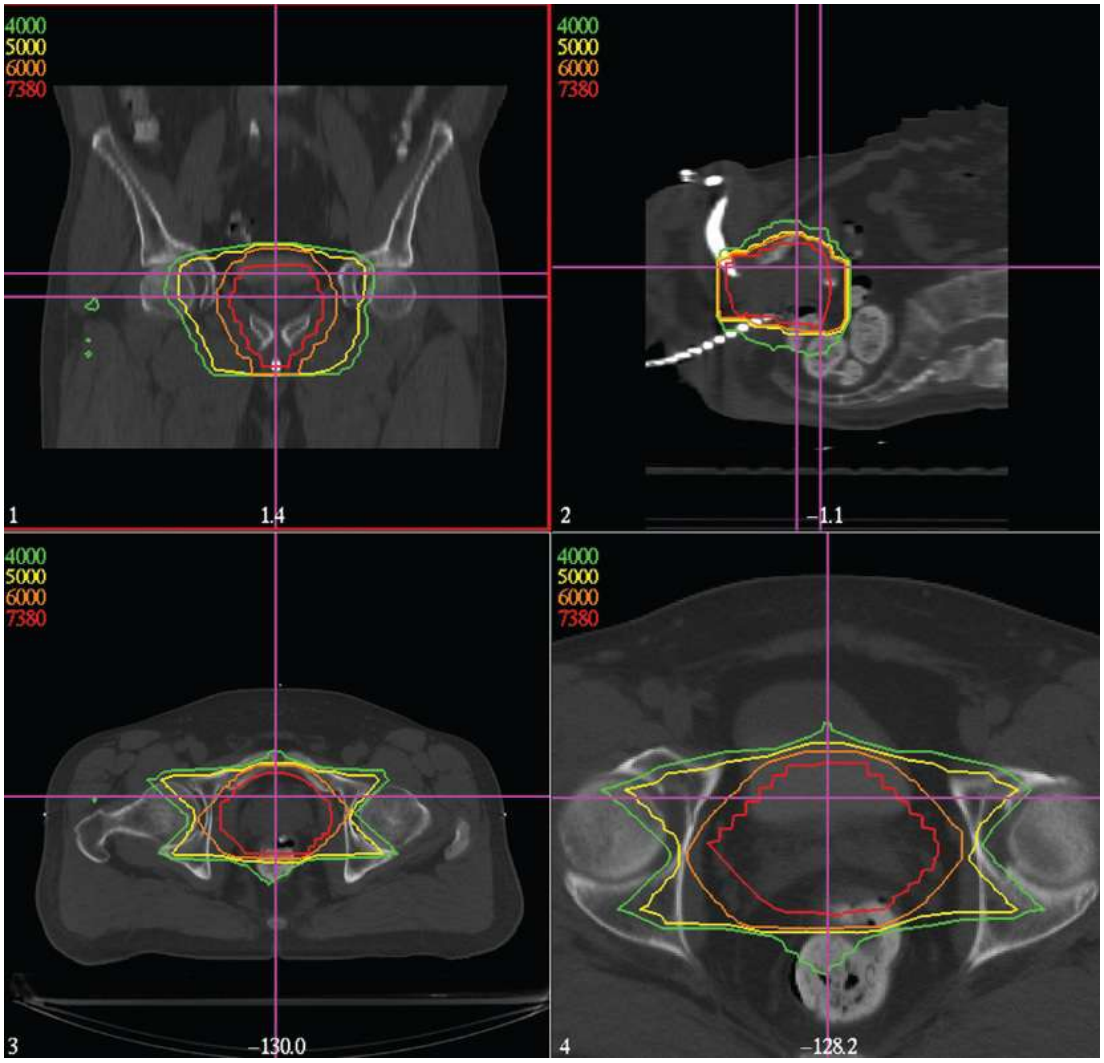

FIGURE 9.10. Dose distribution displays for a patient with prostate cancer showing coronal, sagittal, and two axial computed tomography (CT) sections with superimposed color-coded isodose lines (73.8, 60, 50, and 40 Gy). *Vertical* and *horizontal lines* displayed on each CT section indicate the positions of each section. Evaluating volumetric three-dimensional dose distributions using only this type of two-dimensional display is difficult and time-consuming.

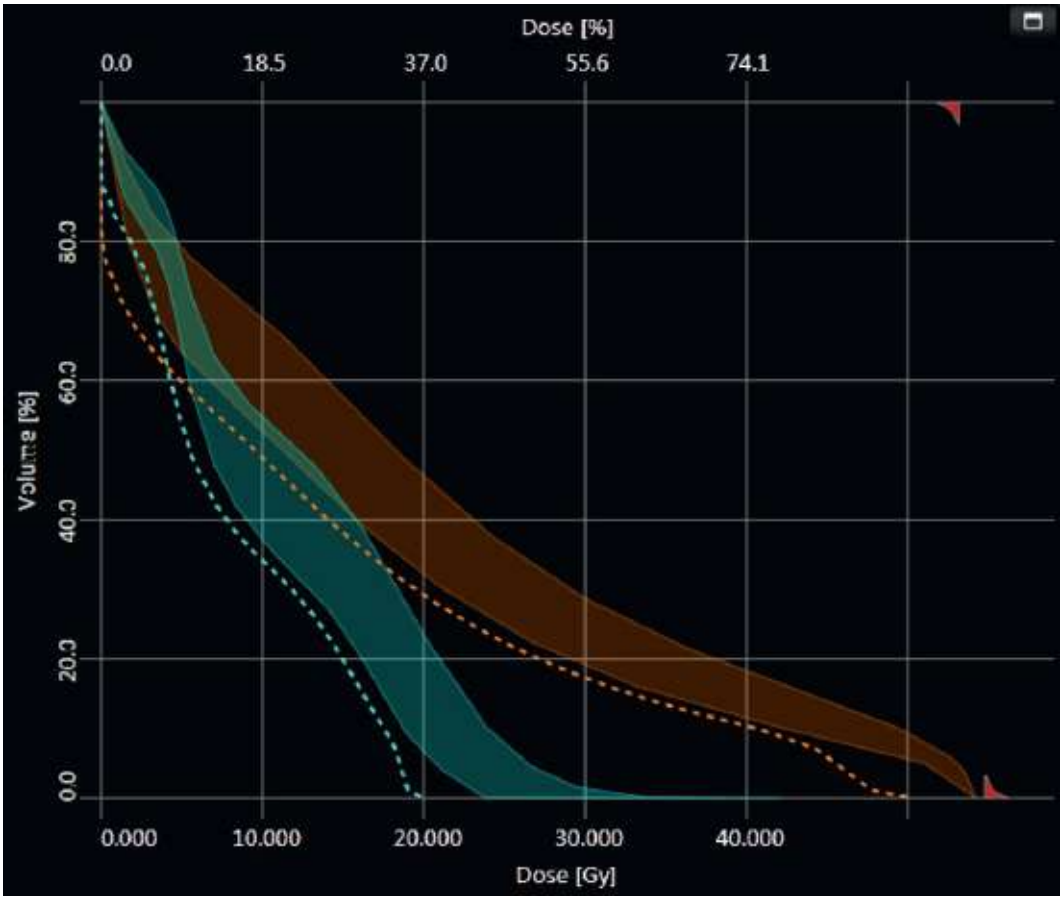

FIGURE 9.11. Colored range is the DVH prediction range for two OARS, and the *dotted lines* are treatment planning objectives, which are set at the lower bound of these predictions and are automatically passed to the optimization engine for treatment planning purposes. The use of lower bound setting in the optimization ensures that the system is driven in the direction of optimal dose distributions.

Another powerful display feature in a 3DTPS is the "*room-view*" or *room's-eye–view* (*REV*) (also referred to as 3-D view), in which the planner can simulate any arbitrary viewing location within the treatment room.[27,77] The REV display is used to display "*dose clouds*" along with rendered PTVs and OARs. Hot or cold spots that occur in the volumes of interest are clearly seen, as shown in Figure 9.12. Another valuable REV display is the so-called Skin View, in which the beam aperture projection can be clearly seen on the skin of the (virtual) patient (Fig. 9.13).

Plan Implementation and Treatment Verification

Once the treatment plan has been designed, evaluated, and approved, documentation for plan implementation must be generated. Documentation includes beam parameter settings transferred to the treatment machine verify and

record (V&R) system, including multileaf collimator parameters communicated over a network to the treatment machine's computer system that controls the MLC system, and transfer of setup or reference images (DRRs, CTs, etc.) and the machine's image database.

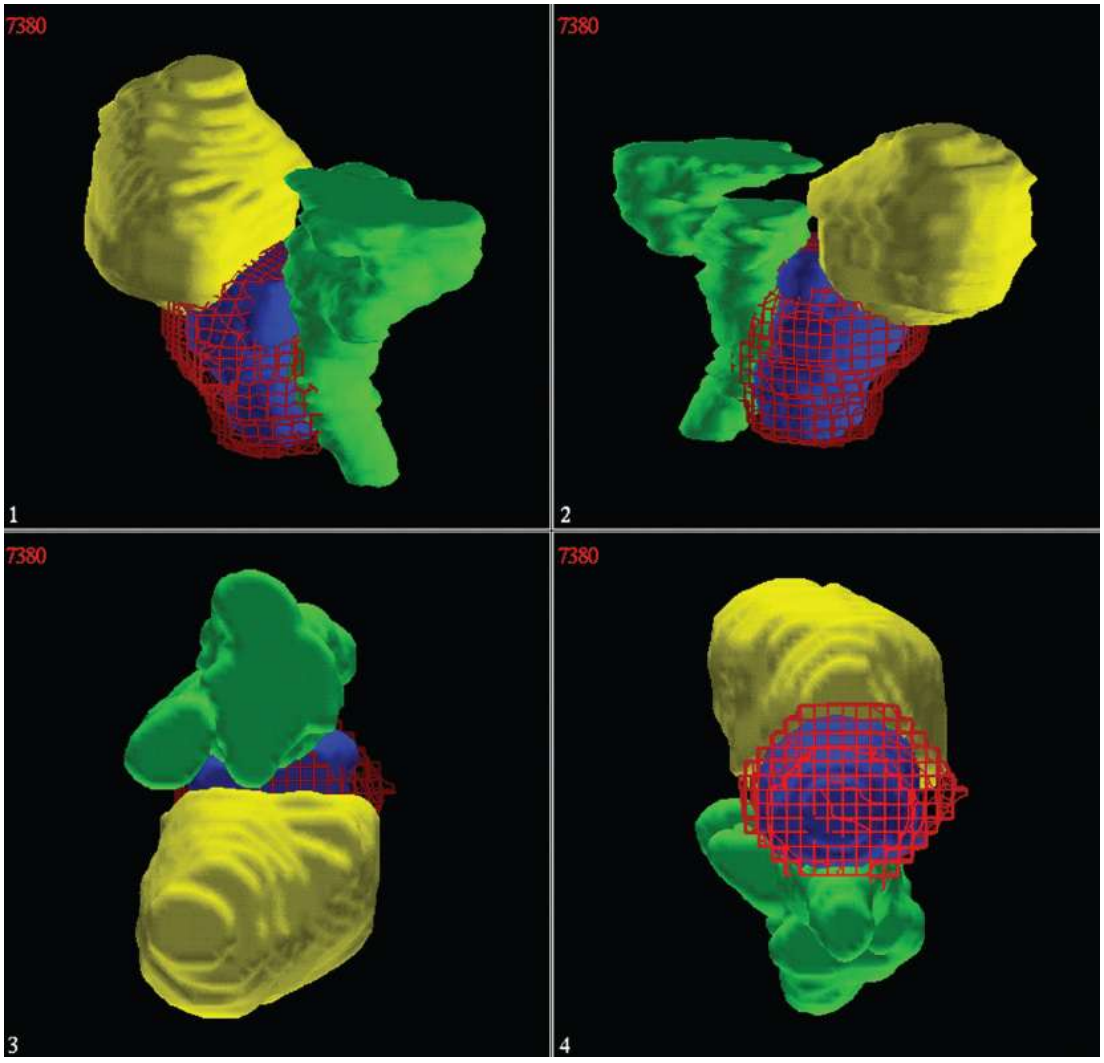

FIGURE 9.12. Room's-eye–view (REV) three-dimensional (3-D) isodose surface display with real-time interactivity is a valuable tool for evaluation of 3-D dose distributions in terms of adequate coverage of target volumes and sparing of critical structures. The REV display enables radiation oncologists to view target volume or normal tissue volume with superimposed isodose surfaces or "dose clouds" from any arbitrary viewing angle. Shown is a four-panel REV display of the 73.8-Gy isodose volume, the prostate planning target volume (PTV), bladder, and rectum of a patient with prostate cancer treated with a six-field technique. The location of the PTV region not covered by the specified dose level is easily discernible using the REV display.

Validation of patient position and treatment setup may involve acquiring images of all individual treatment beams. However, with IMRT, SBRT,

TomoTherapy, ViewRay, etc., these processes are not practical and are generally not done. Instead, orthogonal radiographs, CBCTs, and other images of the patient (rather than of treatment beams) are now the preferred method to ensure correct isocenter positioning. When available, the optical distance indicator is also useful in assessing the correctness of the setup of a particular beam. Documentation provides the depth of isocenter below the skin surface on the central ray of the beam, which can then be compared with the isocenter depth measured on the simulator or treatment machine after the beam is set up using the couch and gantry positions specified by the treatment plan.

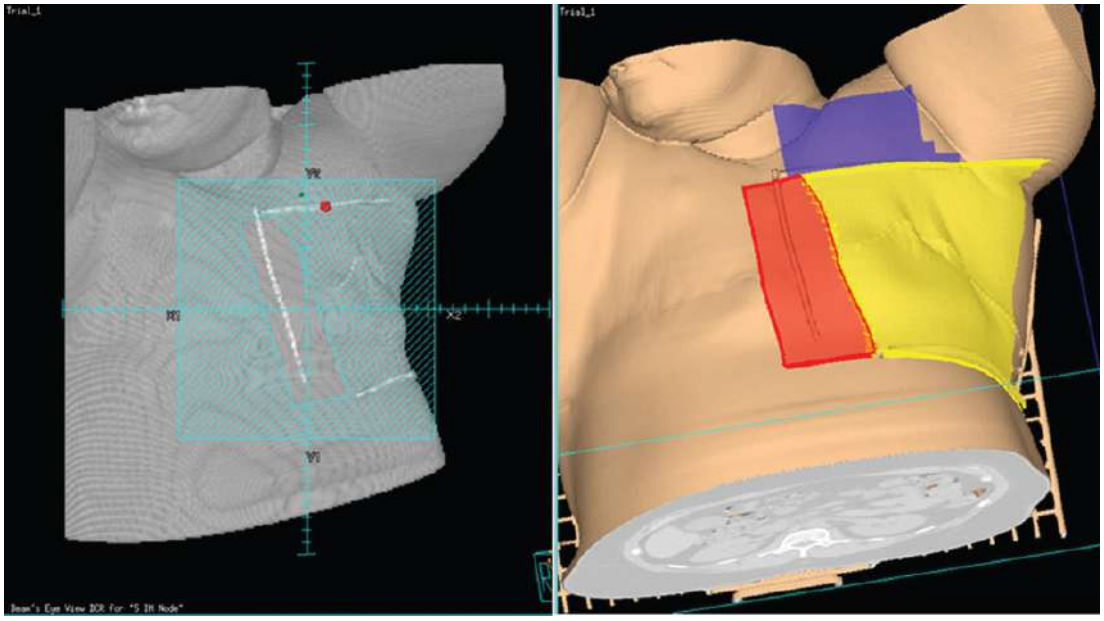

FIGURE 9.13. Room's-eye–view (REV) display showing simulated skin surface for a breast cancer patient undergoing radiation therapy using tangential, supraclavicular, and internal mammary fields. Beam aperture projection can be clearly seen on the skin of the (virtual) patient.

QA checks used to confirm the validity and accuracy of the CRT plan typically include an independent check of the plan and MU calculation by a physicist; radiation therapists also evaluate the integrity of the plan information that is passed to them for treatment (i.e., therapist new start check). Most importantly, careful scrutiny must be given to the input of data into the V&R system to assure that it is correct. These checks are discussed in more detail in a separate section. Additional information on standards for CRT plan verification can be obtained from the most current AAPM Task Group reports, ACR, and ASTRO practice accreditation guidelines.

Dose Reporting and Dose Prescription

ICRU Reports 50 and 62 define a series of doses, including the minimum, maximum, mean dose, and *ICRU reference dose* (defined at the *ICRU reference point*), for reporting dose relevant to CRT. The *ICRU reference point* for a particular treatment plan should be chosen based on the following criteria: It should be (a) clinically relevant and defined in an unambiguous way, (b) located where the dose can be accurately determined, and (c) located in a region where there are no steep dose gradients. In general, this point should be in the central part of the PTV. In cases in which the treatment beams intersect at a given point, it is recommended that the intersection point be chosen as the ICRU reference point.

ICRU Report 83[57] updates the previous ICRU recommendation on CRT dose reporting and recommends moving from single spatial point reporting (i.e., the ICRU reference point dose, minimum and maximum dose) to dose–volume reporting. This is justified based on the availability of more accurate dose calculation algorithms and the advances and ubiquity of modern-day anatomic/functional imaging.

It also should be understood that in the past, *minimum dose* and *maximum dose* referred to point doses in the dose calculation grid assigned to a single voxel. It is now acknowledged that the minimum dose may not be accurately determined because it is often located in a high-gradient region at the edge of the PTV, making it highly sensitive to the resolution of the calculation and the accuracy of delineating the CTV and determining the PTV. Moreover, treatment planning today represents only one single representation of the calculated dose distribution, whereas over the full course of a radiation treatment, the minimum and maximum dose points are likely to shift slightly from one day to another. For all those reasons, ICRU Report 83[57] recommends discontinuing the use of maximum dose and minimum dose and instead recommends for dose reporting the use of the *near-maximum* (corresponding to $D_{2\%}$) and the *near-minimum* ($D_{98\%}$). In addition, the *median dose*, specified by $D_{50\%}$, should be reported, as it is considered to best correspond the previously defined dose at the ICRU reference point.

The maximum dose as specified by a single calculation point ($D_{\max}$ or $D_{0\%}$) has often been reported for serial-like organs or structures. Previously, such a reported maximum dose was considered relevant only if the involved organ had a minimum diameter of at least 15 mm, whereas an even smaller dimension was considered appropriate for some organs, such as the eye, optical nerve, or

larynx.[36] The ICRU acknowledged that the minimum diameter for the maximum dose region in a structure is not always easy to establish and hence recommend that $D_{2\%}$ be reported. However, the ICRU pointed out that care should be taken in a change from maximum dose to the near-maximum dose, $D_{2\%}$.

As stated previously, with regard to dose homogeneity, ICRU Report 50 recommends that the dose coverage of the PTV be kept within specific limits, namely, +7% and −5% of the prescribed dose.[36] However, this level of dose homogeneity might not be achieved in all cases (particularly for current IMRT techniques), and ICRU Report 50 explicitly states that if this degree of homogeneity cannot be achieved, it is the responsibility of the radiation oncologist to decide whether the dose heterogeneity is acceptable. Similarly, a slight underdose to the PTV might be required (particularly if in close proximity to an OAR) or result for lung tumors surrounded by low-density lung tissue as a result of electronic disequilibrium.

Note that ICRU Reports 50 and 62 do not make strict recommendations regarding dose prescription; instead, the ICRU states “the radiation oncologist should have the freedom to prescribe the parameters in his/her own way, mainly using what is current practice to produce an expected clinical outcome of the treatment.”[36] For dose reporting, however, it is recommended to also state the prescribed dose if the actual prescription was not done accordingly.

It is now recognized that there is a large variability among institutional results in IMRT planning and reporting.[78,79] Studies strongly support the ICRU Report 83 recommendation to move away from single-spatial-point prescription/reporting to dose–volume prescription/reporting. In addition, ASTRO has gone even further and recommends that specific details of the inverse treatment planning and image-guided treatment processes be recorded using (a) an *IMRT treatment planning directive*, (b) a *treatment goal summary*, (c) an *image guidance summary*, and (d) a *motion management summary*.[80] Das et al.[81] recently evaluated compliance with ICRU-83 prescribing guidelines and found that the overwhelming majority of patient treatments in the surveyed institutions do not comply with these guidelines. The KBP planning approach and automatic DVH analysis are both aimed in reducing these variabilities. More extensive and standardized methods and supporting software for treatment prescribing currently do not exist. Just as the tools have emerged for more consistent plan creation and evaluation, it is critical that a process be developed, which will improve the standardization and quantification of radiation therapy prescribing. It would be very beneficial if the prescription parameters (treatment

planning goals) and the evaluation metrics overlap.

Dose–Volume Histograms

The large amount of dosimetric data that must be analyzed when a CRT plan is evaluated has prompted the development of methods of condensing and presenting the data in more easily understandable formats. One such data reduction tool is the *dose–volume histogram*.[30,31] Two types of DVHs, *differential* and *cumulative*, are available in CRT planning, with the latter now universally used in plan evaluation for assessing PTV(s) coverage and dose to OARs, as displayed in Figure 9.14. However, it must be clearly understood that the DVH does not provide any spatial information and thus can only complement and not replace spatial dose distribution display tools such as isodose displays.

The *differential DVH* (*dDVH*), as shown in Figure 9.14A, is essentially a plot of the frequency distribution of the individual dose distribution elements (called dose voxels) obtained from the dose grid. Typically, the grid size is small enough so that the dose can be assumed to be constant within each voxel. The volume's dose distribution is then divided into *dose bins*, and the voxels are grouped according to their dose bin value without regard to their spatial location. A plot of the number of voxels in each bin (*y*-axis) versus the bin dose range (*x*-axis) is by definition a differential DVH. The size of the dose bin used determines the height of each bin of the dDVH. For example, if the bin widths were increased, the heights of the histogram bins would increase because more voxels would fall into any given bin. Thus, it should be clearly understood that the detailed shape of a differential DVH depends on the dose bin size used, even though the underlying dose–volume data are the same.

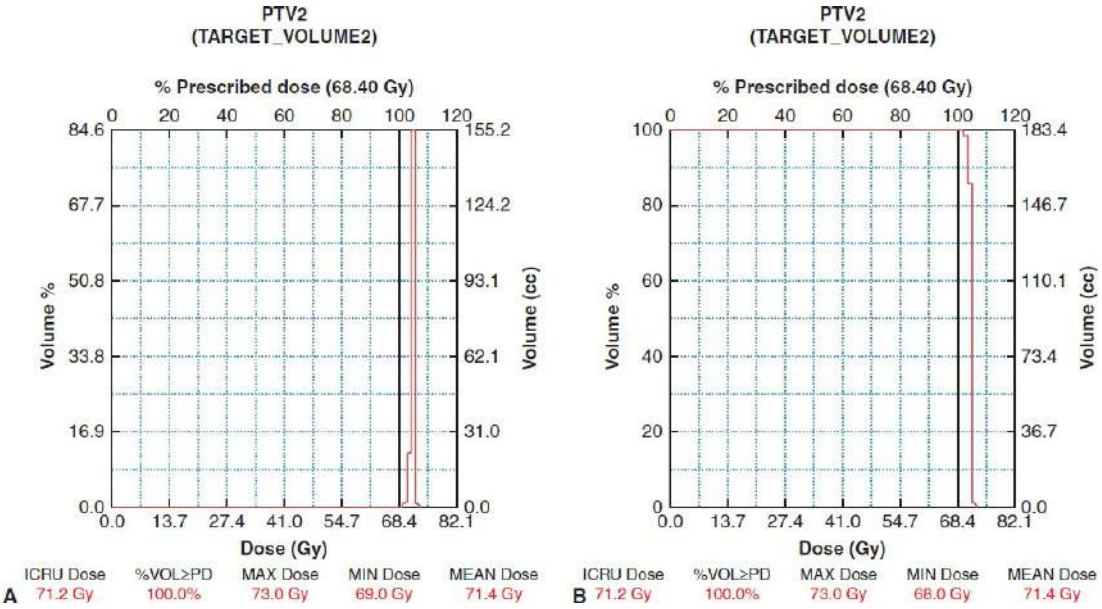

FIGURE 9.14. A: The differential dose–volume histogram (dDVH) for a specified target volume (PTV2)—the volume is subdivided into individual elements (called voxels) and tagged according to dose received as determined from the three-dimensional dose grid. Voxels are then grouped according to each specified dose bin value without regard to their spatial location. A plot of the number of voxels in each bin (*y*-axis) versus the bin dose range (*x*-axis) is by definition a dDVH. **B:** The corresponding cumulative DVH (cDVH) is generated by summing for each dose bin all of the voxels of the PTV2 dDVH to the right of each dose bin; the *y*-axis gives the volume, or percentage of volume, that receives a dose equal to or greater than the indicated dose on the *x*-axis.

A *cumulative DVH* (*cDVH*), as shown in Figure 9.14B, is a plot in which each bin represents the volume, or percentage of volume (*y*-axis), that receives a dose equal to or greater than the indicated dose on the *x*-axis. The cDVH is generated by summing all of the voxels of the corresponding dDVH to the right of each dose. The volume value for the first bin (dose origin) is the full volume of the structure because the total volume receives at least zero dose and the volume for the last bin is that which receives the maximum dose. Note that in the literature, the "c" in the cDVH is generally dropped, leaving just DVH.

Explicit values of dose–volume parameters can be extracted from the DVH data and are called dose–volume statistics or simply *dose statistics*. Examples for target volumes include maximum dose, minimum dose, mean dose, and percentage volume receiving greater than or equal to the prescription dose; for OARs, they typically include maximum point dose, mean dose, and percentage volume receiving greater than or equal to an established tolerance dose. As previously stated, ICRU Report 83[57] recommends replacing the *minimum dose* and *maximum dose* point doses with *near-maximum* (corresponding to $D_{2\%}$) and

near-minimum ($D_{98\%}$).[57]

There is an ever-increasing reliance on DVH-based evaluation of treatment plans. Because the majority of planning objectives in clinical trials and QUANTEC recommendations are based on dose–volume tolerances of individual organs, it is natural to extend plan evaluation with a primary focus on DVH or derived metric (e.g., R_{50}) evaluation. There are now also several commercial and homegrown software packages for automatic extraction and evaluation of these parameters with easy to assess indicators for which parameters meet the planning goals and which ones fail. Although the automatic evaluation is fundamentally more efficient, its main advantage is reduced likelihood for error and greater efficiency in the evaluation process. Also, the transfer and implementation of multi-institutional plan evaluation parameters are easier and more systematic to implement with automated dose–volume metric evaluation. It should be reemphasized that DVH review is not a substitute for reviewing the actual isodose distributions and plans are best evaluated in combination of all these review parameters.

Biologic Models for Dose–Volume Response

Evaluation of the quality of a treatment plan (i.e., is plan A better than plan B?) is difficult and at best a qualitative procedure. For example, it is not clear what degree of dose uniformity within the PTV is optimum, as dose levels can now be significantly escalated using CRT techniques, nor is it always clear which plan is best if the two DVHs for a specific OAR cross each other (i.e., difficulty in weighting importance of dose vs. volume).

Researchers have developed biophysical models that attempt to translate the dose–volume information into estimates of biologic response—*tumor control probability* (*TCP*) and *normal tissue complication probability* (*NTCP*) models.[68,69,82] Most authors agree that the TCP and NTCP models developed thus far are not accurate enough such that the absolute values can be used to predict clinical outcome; however, they are used to compare rival plans and as such help to rank plan quality. In any case, such biologic indices should be used clinically only when their utility has been firmly established for well-defined clinical conditions. ICRU Report 83 is clear in stating that if biologically based metrics are to be reported, the assumptions used in the models, their parameters, and the model itself must be unambiguously specified.[57]

Tumor Control Probability

TCP plotted as a function of dose has a classic sigmoid shape, having zero control at some low dose to control at some high dose. Rather than attempt to review in detail the various models, here I discuss some relevant issues. Readers are referred to the article by Moiseenko et al. for more details.[83] Simple phenomenologic TCP models can be represented by the logistic function as follows:

$$\mathrm{TCP} = \frac{1}{1 + \left(\frac{\mathrm{D}_{50\%}}{D}\right)^{4\gamma_{50\%}}}$$

where $\mathrm{D}_{50\%}$ is the dose at which the TCP is 50%, $\gamma_{50\%}$ is the slope of the dose–response curve at 50% tumor control, and D is the dose administered.[84] Note that the use of the logistic function assumes an approximate uniform cell response and a uniform dose distribution.

For a nonuniform dose distribution, the total tumor volume is reduced to smaller volumes having "uniform" doses within each subvolume element v_i. The TCP value for each volume element, TCP(v, D), can be inferred from the TCP for uniform irradiation of the entire tumor volume, TCP(1, D), using the following equation:

$$\mathrm{TCP}(v, D) = \mathrm{TCP}(1, D)^{v}$$

Thus, the TCP for the tumor receiving an inhomogeneous dose is given by the product of the individual volume element TCPs as follows:

$$\mathrm{TCP} = \prod_{i=1}^{N} \mathrm{TCP}(v_i, D_i)$$

Here, TCP(vi, D_i) is the TCP for the ith volume element receiving dose D_i, and N is the total number of tumor volume elements. Recall that the validity of this equation is highly dependent on the validity of the assumptions that the individual tumor volume elements are uniformly distributed throughout the tumor volume and are equally radiosensitive.

Normal Tissue Complication Probability

There are mainly two different approaches used in radiation therapy in modeling NTCP: the *empiric model* introduced by Lyman and Wolbarst[85,86] and *functional models* that introduced concepts of *serial* and *parallel* tissue organization and

functional subunits (FSUs).[84,87–89]

The *Lyman NTCP model* can be expressed in terms of an error function of dose (D) and volume (v) as follows:

$$\mathrm{NTCP}(D,v)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{t}\exp\left(-t^2/2\right)dt,$$

where

$$t=\left[D-\mathrm{D}_{50}(v)\right]/\left[m\cdot\mathrm{D}_{50}(v)\right],$$

with v equal to the partial volume (V/V_{ref}) and the tolerance dose volume dependence given by the following power–law relationship:

$$\mathrm{D}_{50}(v)=\mathrm{D}_{50}(1)\cdot v^{-n}$$

$\mathrm{D}_{50}(1)$ is the tolerance dose for 50% complications for uniform whole-organ irradiation, and $\mathrm{D}_{50}(v)$ is the 50% tolerance dose for uniform partial-organ irradiation to the fractional volume v. The arbitrary variables m and n are found by fitting tolerance doses for uniform whole- and uniform partial-organ irradiation, where m characterizes the gradient (slope) of the dose–response function at D_{50} and n characterizes the effect of volume. When n is near unity, the volume effect is large; conversely, when n is near zero, the volume effect is small. When NTCP is plotted against dose, the NTCP equation demonstrates a sigmoid shape.

Two methods are used to extend this model to nonuniform organ irradiation. The *interpolation method*, proposed by Lyman and Wolbarst,[86] modifies the DVH to one in which the whole organ receives an effective uniform dose, D_{eff}, that is less than or equal to the maximum organ dose. The second method, called the effective volume method, proposed by Kutcher and Burman,[90] modifies the DVH to one in which a fraction of the organ, v_{eff}, receives the maximum organ dose. The Lyman model coupled with the Kutcher-Burman DVH reduction scheme (now called the Lyman-Kutcher-Burman model) is the most widely used NTCP model.[82]

Other NTCP models include two developed by Niemierko and Goitein—the *critical element model*, used for serial-like organs,[91] and the *critical volume model*, for parallel-like organs.[92] These are similar in form to that of Lyman and Wolbarst[85] but include additional terms to better account for the radiosensitivity

of the FSUs.

Equivalent Uniform Dose

Equivalent uniform dose (EUD) is a concept first introduced by Niemierko[93] for use in evaluating and reporting inhomogeneous dose distributions and later redefined by the following equation[94]:

$$\mathrm{EUD} = \left(\sum_i v_i \, D_i^{\alpha} \right)^{1/\alpha}$$

where v_i is the volume of the dose–volume bin with a dose D_i and the exponent α is a complication-specific parameter.

The EUD concept assumes that any two dose distributions are equivalent if they cause the same radiobiologic effect and appears well suited for use in evaluating competing conformal plans. However, McGary et al. pointed out that there are conditions in which EUD is not adequate as a single parameter to report or analyze inhomogeneous dose distributions—for example, when the minimum dose is significantly lower than the mean dose.[95–97]

MANAGEMENT OF CONFORMAL RADIATION THERAPY DATA

To accurately perform the steps involved in CRT, several forms of patient imaging and other data must be acquired, displayed, manipulated, and stored. Typically, patient image data acquired from several imaging subsystems must be communicated to a TPS to permit these images to be used for treatment planning. Several software components also must be integrated so that the output of one processing step can be made available for use as input to the next step. Daily IGRT imaging is also putting large demands on data storage, and the need for more robust image processing tools is evident. These issues in data management in CRT are complex and continue to be somewhat problematic, although some progress is being made through the Integrating the Healthcare Enterprise in Radiation Oncology effort initiated by ASTRO.[98]

This issue is just part of larger informatics issues facing radiation oncology. There is an explosion in the types and volume of data that must be made available for scientific query. Difficulty in accessing the data in practical ways has become a critical limitation to investigators in the field and to its

advancement. Unfortunately, the commercially available radiation oncology information systems are not yet adequate to meet this challenge. The great volume and diversity of the data have rendered their storage, management, and processing extremely problematic, resulting in situations in which important data and information are inefficiently disseminated and sometimes lost. In the busy clinic, failure to manage critical information may compromise patient safety. Here, a major issue is the lack of integration of the radiation oncology electronic medical record (EMR), based on systems such as Elekta-Impac MOSAIQ (Sunnyvale, CA) or Varian ARIA, with the electronic hospital record (EHR), based on systems such as those provided by Epic (Verona, WI). In most cases, we must resort to hybrid charting systems (ad hoc combinations of EMR, EHR, and paper charting), which entails risks and gives rise to a dangerous situation. Immediate and focused efforts in achieving these integrations and improving the radiation oncology informatics infrastructure are urgently needed.

QUALITY ASSURANCE FOR CONFORMAL RADIATION THERAPY

It is most important to realize that a QA program for CRT is an interdisciplinary effort involving radiation oncologists, radiation physicists, dosimetrists, radiation therapists, clinical engineers, and information technology specialists and that the efforts of each group often overlap substantially. To be effective, it is also essential to have the full support of the department chair and hospital administration.

Although in general, radiation therapy has a long, successful history of QA, most authors have come to realize that the current approach (which relies heavily on prescriptive QA tests, tolerances, and frequencies as provided by consensus expert groups from national/international professional/scientific organizations) is likely inadequate by itself for more advanced modalities such as CRT.[99–101]

For example, today's imaged-guided CRT planning and delivery processes have become much more complex and much less intuitive. These complexities, coupled with the inadequate informatics infrastructure and outdated national QA guidelines, have created enormous QA challenges. Communication among members of the planning team, including physician, resident, simulation therapist, dosimetrist, physicist, and treating therapist, is often rushed, cryptic, and complicated by the lack of integration of the radiation oncology EMR (e.g., Elekta-Impac MOSAIQ) with the hospital's EHR (e.g., Epic software). In fact, in

most cases, one must resort to a hybrid charting system (ad hoc combinations of EMR, EHR, and paper charts), which is a dangerous situation. In addition, multiple imaging modalities are often used to define target volumes, all complicating the processing of the information. CRT plan data, transferred over a network to the V&R system and computer-controlled LINAC systems, carry complex specifications for treatment, including positioning of MLC leaves, sometimes variable dose rates, collimator rotation, gantry angles, and, in some instances, a moving treatment table or gantry or both. In some cases, different vendor software systems are used, and interoperability is not always robust. This continuing increasing complexity of devices and systems is clearly problematic for a totally prescriptive QA approach, and it results in increased time demands on staff and groups where there are already shortages. A series of *New York Times* articles[100] brought needed attention to this issue and spurred national organizations to work to improve the current QA situation.[102,103]

Although it is believed that the prescriptive QA approach is valid and valuable for much of the CRT technology and procedures currently in place, new and different approaches need to be developed in parallel.[104,105] These must be risk/evidence based and process oriented rather than device and procedure oriented; they likely need to be multidisciplinary in nature, resource and risk optimized, and flexible enough to cope with current and anticipated changes in technology.[106] Such process-oriented QA includes risk-based analysis, process mapping, application of failure modes and effects analysis (FMEA), and fault tree analysis (FTA), including analyses of human actions and responses.[107]

In support of this direction, the AAPM recently published recommendations of Task Group 100 on the application of risk analysis methods to radiation therapy quality management.[108] This report provides a mechanism for individual facilities to create custom QA protocols based on their individual situation and risk profile. This task group also calls on the future AAPM task groups to embrace the same methodology. The significance of the TG-100 is the departure of more or less purely prescriptive QA guidelines to the provision of a tool set for individual clinics to establish their own QA methods. Advantages of this approach, as described above, include the ability to create custom QA protocols considering the unique needs and circumstances of the particular institution. Shortcomings include the time required to create these QA protocols and potential absence of local expertise that can objectively assess individual facility needs. However, both of these are likely transient limitations as efficiency and proficiency in this process will be developed over time. Another great advantage

of this approach is the evaluation of new processes and establishment of QA methods and QA tool development based on that analysis. For example, Noel et al.[109] analyzed QA processes and tools needed for implementation of online adaptive radiotherapy, and Acharya et al.[110] subsequently relied on that analysis for clinical implementation of an actual online adaptive radiotherapy program. The TG-100 report is poised to make a major impact on QA practices in radiotherapy and our future practices should proceed with that in mind.

That said, radiation oncology departments must do all that they can now to ensure that processes for safe planning and delivery of CRT are in place and appropriately resourced. Table 9.4 provides a list of guiding principles to help a department prioritize QA efforts for improving patient safety and quality for CRT. This list is a compilation of pertinent key recommendations made by several national and international groups.[99,102,111–115]

Quality Assurance: Treatment Planning System

The complexity of 3DTPS continues to increase to better facilitate the accurate delivery of CRT. In a number of instances, the TPS is an integral component of the treatment machine. Hence, this results in having more than one planning system in the department, thus increasing QA complexity. Rigorous acceptance and commissioning of the TPS are essential to ensure it is functioning accurately before it is used clinically; in this respect, it is no different than other medical devices. AAPM recently published Medical Physics Practice Guideline 5.a on commissioning and QA of treatment planning systems.[116] There has also been activity in automating QA of treatment planning systems, and the automation in this area should offer improvements in consistency and efficiency as well as reduction in errors.[117] More details on acceptance, commissioning, and periodic QA tests are available elsewhere.[118–125]

The accuracy of dose calculations must be examined thoroughly during the 3DTPS commissioning process. Periodic checks of calculations versus measured dose are also essential because of possible data corruptions in the TPS itself and to how well treatment machine parameters such as flatness and symmetry are maintained. It should be appreciated that the 3DTPS can never be fully tested, nor can the manufacturer assure the user that the system is “bug-free.” Rather, the system should be tested over a range of parameters that are typical of those used in the clinic. For example, tests should include (a) consistency of input/output data; (b) monitor unit calculations, (c) relative dose distributions, (d) graphical data, including BEV and field aperture display, and (e) plan

evaluation tools such as DVHs and DRRs. The test procedures and results should be fully documented, as they will provide the baseline data to which the periodic QA tests can be compared.

TABLE 9.4 GUIDING PRINCIPLES FOR CONFORMAL RADIATION THERAPY QUALITY ASSURANCE PROGRAM

1. Establish a safety-conscious culture within the department and ensure that the processes for safe delivery of conformal radiation therapy (CRT) are in place and appropriately resourced. To that end, perform the following:
   a. Establish a formal covenant and commitment to safety. The radiation therapy team should work under a radiation safety covenant, and each member of the team should pledge a commitment to protect the safety of each and every patient.
   b. Make sure it is clear that each member of the treatment team has the right and the responsibility to declare a “time-out” if he or she has concerns or questions about the plan or course of treatment for a patient.
   c. Make sure that the quality assurance (QA) program is properly resourced.
2. Seek practice accreditation by the appropriate national body, for example, the American College of Radiology (ACR)/American Society for Radiation Oncology (ASTRO).
3. Participate in external dosimetric audits such as provided by the Radiological Physics Center (RPC) annual External Reference Dosimetry Audit.
4. Expand the use of checklists in CRT treatment planning and treatment delivery.
5. Implement a formal policy that ensures that CRT policy and procedures (P&Ps), including checklists, are in place and are regularly updated and reviewed on an annual basis (require documentation that this is actually done).
6. Conduct periodic reviews of staffing levels to ensure that the staffing and skills mix are appropriate for the numbers of patients treated and the complexity of treatments delivered.
7. Implement a Clinical Operations Committee (COC), with supervisor representatives from each group, to address any problematic issues in the clinic and to help ensure that good communication exists among all groups involved in the CRT treatment process.
8. Conduct town hall meetings (with QA program being a major focus) with department faculty/staff at least quarterly to help ensure good communication exists among all groups involved in the treatment process.
9. Maintain training records for all staff involved in radiation therapy. They should be detailed and specific to particular procedures, that is, an internal form of CRT credentialing.
10. Maintain funding to support training and continuing education, particularly when new CRT techniques are introduced.
11. Introduction of new CRT techniques always needs to be carefully planned with a thorough risk assessment, review of staffing levels and skills required, and development of pertinent P&Ps. All staff involved in the process should undergo specific training in the new treatment technique or process prior to clinical use.
12. Working environment, particularly in two areas—treatment machine console and treatment planning—needs to be conducive to safety and designed such that it ensures that staff can work without inappropriate interruptions.
13. Prescriptive QA program should be in place but continually evaluated to ensure that each specific test adds value and that those that do not add the required value are eliminated.
14. Perform systematic risk analysis and improvement using industrial engineering–based tools such as process mapping, failure modes and effects analysis (FMEA), and fault tree analysis (FTA) for all advanced treatment modalities.
15. Implement a treatment table registration system (CT simulator and treatment machines) so

that all patient/immobilization device positions on the table can be registered.
16. Use treatment planning/delivery systems tolerance tables for specific procedures, and monitor set-up variability (i.e., any therapist overrides of treatment couch, gantry, collimator position, etc., settings in order to treat patient).
17. Perform on-treatment verification imaging as needed, but be mindful of imaging dose, and look for ways to become more efficient.
18. Perform *in vivo* dosimetry (e.g., diode checks) at the beginning of treatment for all 3DCRT patients when physically possible.
19. Conduct weekly peer review chart rounds (review prescription, verification images, dose distribution, and other pertinent documentation, e.g., signed consent, pathology, etc.).
20. Conduct weekly peer review planning conference to review CRT plans. Review of GTV, CTV, and PTV contours, DRRs, and dose distributions helps to develop a consistent approach in implementing ICRU 50/62/83 methodology.
21. Implement a treatment planning workflow monitoring software system.
22. Implement a software system for reporting and analyzing errors and near misses, with feedback to the staff at town hall meetings.
23. Strive to have the right balance between accountability and openness in the department's incident reporting culture.
24. Department should strongly endorse a national/international incident reporting system for radiotherapy incidents.

It has been a practice to validate IMRT treatments with patient-specific dose measurements. However, for online adaptive radiotherapy, it is not practical to perform a phantom-based measurement, and an alternative approach to validation of dose calculation accuracy is needed.[110] The prevailing method for assurance of online adaptive treatment is to perform a secondary independent dose calculation combined with a rules engine to verify integrity of the treatment plan. As online adaptive radiotherapy becomes more mainstream practice, it is expected that the patient-specific measurement-based QA will diminish in prevalence.

Quality Assurance: Patient Positioning and Immobilization and Imaging Data Acquisition

CT, MRI, PET, and ultrasound imaging are used, depending on disease site, for acquiring imaging data to determine patient external contours and target and organs-at-risk volumes. Hence, there are a number of additional QA demands placed on imaging units that are specific to CRT treatment planning.[40] Because the patient needs to be repositioned reproducibly on the treatment machine, special patient positioning immobilization devices are needed. Such devices should be constructed so that they can be attached in a similar manner to the treatment machine couch and the CT, MR, or PET imaging system couches used in obtaining the planning imaging data. These devices should not only attach and lock to all couches, but they also should do so in a configurable manner to allow

indexing of the devices to the treatment couch for daily reproducibility.

In some instances, the composition of these devices is also important; for example, low–atomic number materials are necessary for CT scanners, whereas carbon fiber devices are not compatible with MRI. In addition, patient motion can distort MRI and CT images, which can lead to inaccuracies in organ delineation and plan calculation. Large-bore CT simulators often offer extended or extrapolated field of view option.[126] With this option, the native image field of view can be extended by reconstructing the image in the portion of the CT scanner bore opening where partial data collection occurred. Depending on the scanner model and image reconstruction software age, there can be spatial and quantitative CT distortions in those areas of images, which ultimately can translate to treatment planning errors.

Geometric accuracy of all imaging modalities used for planning must be checked. This can be accomplished by imaging suitably designed phantoms on the various machines and comparing the results with the known values. Special care should be given to MRI units, which may suffer from appreciable spatial distortions. If a PET-CT is used, special attention should be paid to the physical alignment of the table couch and both imaging rings. If images from CT, MR, and/or PET are registered and fused, a QA program must be implemented to ensure that the inherent algorithm used and departmental procedures are able to produce accurate composite images for planning.[127,128] Finally, for CT, it is necessary to obtain or confirm the relationship between CT number and electron density.

The transfer of image data routinely occurs directly via a computer network but should be checked on a regular basis. Vigilance is also necessary to eliminate any systematic errors; for example, an error in the specification of a scan diameter can lead to geometric distortions of the image.

Quality Assurance: Volume(s) Delineation

Target volume delineation is viewed by many experts in the field as being the weakest link in the entire CRT workflow chain. A high variation continues to be seen in all studies evaluating consistency of delineation of target volumes and organs at risk among physicians.[129–134] This can be explained by a lack of generally accepted guidelines for volume delineation and also, most likely, insufficient training of radiation oncology residents in modern cross-sectional imaging. It is clear that errors/inconsistencies in volume delineation can seriously undermine the goals of CRT. One approach toward solving this

difficult issue is to adopt guidelines and consensus volumes based on the delineation performed by a number of experts in the field.[133,135] Both the Radiation Therapy Oncology Group and the European Society of Therapeutic Radiation Oncology have placed high priority on this approach and now offer more online guidelines for several sites. Standardization in naming convention of targets and organs at risk[136] should be a component of the effort to improve organ delineation process. To this end, the AAPM has formed the TG 263 on standardizing nomenclature in radiation therapy, and it is expected that the results of this work will lead to significant improvements in standardization in this area.

It is also possible to improperly define an OAR because of faulty or incomplete CT procedures. For example, the base of the brain may be better defined on the CT slice if sagittal reconstructions are also available while contouring. In addition, if contrast is used, density overrides may be needed before treatment planning is performed to avoid the erroneous effects of the high-Z media. Related to this is the situation that occurs when high-Z materials like hip prostheses are found within the patient and density overrides are required to account for artifacts. Because of likelihood and significance of contouring errors in radiotherapy, there is an ever-increasing emphasis on peer review of contoured volumes. In certain situations (e.g., solo practices, online adaptive radiotherapy), it may not be practical to perform peer review or independent review of contoured organs. It is expected that automatic contour checking will play a role in the future of radiotherapy.[137–139]

Quality Assurance: Designing Beams

MLC leaf settings or block apertures and beam orientation displays must be confirmed prior to clinical use and checked after any software modification. In addition, it is possible to define beam orientations that are physically impossible to set up, and this process requires use of clinical judgment by the dosimetrist generating the treatment plan. Thus, the ability to physically set up a particular beam orientation must be reviewed and verified, particularly for beam orientations involving couch rotation. In such cases, tests might have to be performed to verify clearance between the treatment machine gantry and the patient or the gantry and the treatment couch before finalizing the treatment plan. This is especially true for SBRT treatments and will likely be the case for 4 π treatments.

Quality Assurance: Treatment Plan Review

All CRT treatment plans should be reviewed, signed, and dated by the treatment planner. The treating physician should of course also review, approve, and sign the treatment plan. Because most of the clinics are paperless today, various combinations of treatment planning systems, V&R systems, and EMR pose unique challenges as to where to approve plans and how to document plan reviews by treatment planner, medical physicist, and radiation oncologist. Each clinic should develop a process where there is a traceability of these approvals and it is transparent as to who was involved in the planning and plan review processes. In addition, all plans should be independently checked prior to initiation of radiation therapy by a physicist who was not involved directly in the production of the plan. The independent plan check should assure that set-up instructions have been properly recorded—for example, field size, gantry angle, and so on. In addition, beam normalization points (normally at isocenter) can be problematic if near nontissue medium or under or near an MLC leaf edge and hence should be moved to a more suitable location. The number of MUs to realize the dose prescription is typically obtained directly from the 3DTPS. These values must be independently checked either by hand calculations or, more typically, independent computer calculations. An action level should be established based upon the accuracy of the computer algorithm and independent dose calculation procedure. Obviously, any MU check system must be tested prior to clinical use and following any change or software upgrade. The American Association of Physicists in Medicine Task Group 114 report provides valuable information on the verification of MU calculations for non-IMRT radiotherapy treatments.[140]

Note that IMRT plans require additional checks, including review of optimization parameters, minimum gap size, minimum MU/segment, and maximum doses in and outside of the target. In addition, in the United States, the patient's plan must undergo phantom measurement checks on the intended treatment machine to verify both point dose and spatial dose distribution agreement.

AAPM plan checks are becoming largely automated through homegrown[141,142] and commercial solutions. These software packages range from basic secondary dose calculation to more sophisticated rules engine and industrial methods-driven software. The AAPM's Task Group 275 on Strategies for Effective Physics Plan and Chart Review in Radiation Therapy is in part charged with developing recommendations for software vendors for

development of patient plan checking software. Although, in the past, most could afford the time needed to perform plan checks manually, the online adaptive radiotherapy process does not afford that time. In the age of adaptive radiotherapy, automated plan checks are becoming the necessity, and that will undoubtedly change the field's overall approach to plan checks moving systematically away from manual work and toward computer-assisted checks.

Quality Assurance: Planning Conference

One of the most important components of a CRT QA program is the establishment of a weekly planning QA conference that is attended by radiation oncologists, medical physicists, radiation therapists, and dosimetrists. This is in addition to the normal new-patient chart rounds conference, at which the patient's pertinent medical history, physical, pathology, and diagnostic imaging findings along with the tumor staging and proposed plan of treatment, including the prescription, are presented by the attending radiation oncologists or residents. In a planning QA conference, the group can review the CRT plans using a high-resolution, large-screen video projector connected to the 3DTP network. GTV, CTV, and PTV contours, DRRs, and dose distributions can all be reviewed very efficiently. This type of planning conference helps the staff to develop a very consistent approach in implementing ICRU 50/62/83 methodology for specifying volumes and provides a very effective peer review mechanism for a CRT clinical program.

Quality Assurance: Plan Implementation and Treatment Verification

If a clinic is in the initial phases of implementing CRT techniques or if experienced users implement new CRT modalities using nonconventional beam orientations, a verification simulation procedure is recommended to confirm the correctness of the beam orientations. It is important to check that all treatment plan parameters are properly implemented. This can be best accomplished by having the treatment planning team available (or on call) during this procedure so that any detected ambiguities or problems can be addressed immediately. When a beam orientation cannot be simulated, EPIDs can be used to obtain orthogonal images for comparison with similar DRRs to ensure correct isocenter positioning. Today, even more advanced onboard imaging and other data localization systems (i.e., ultrasound, video surfacing, static kilovolt imaging, kilovolt cone-beam CT, megavolt helical CT, megavolt cone-beam CT, and MRI) are available.[11,55] Clearly written policy and procedures (P&Ps) should be

in place with regard to (a) localization procedures, (b) therapist instructions and tolerance criteria to move (or not move) a patient, (c) whether post imaging is required when a move is made, (d) subsequent reviews by physicians, and (e) the process for peer review of verification images. Special care should be taken to ensure that all beam-modifying devices are correctly positioned. Although errors in MLC settings or block fabrication/mounting should be observed when reviewing the portal images, wedge or compensator misalignment is much more problematic and may only be revealed by careful observation during patient setup.

When available, the optical distance indicator is also useful in assessing the correctness of the setup of a particular beam. Documentation provides a depth of isocenter below the skin surface on the central ray of the beam, which can then be compared with the isocenter depth measured on the simulator or treatment machine after the beam is set up using the couch and gantry positions specified by the treatment plan.

A V&R system should be used to assure that the same parameters (within tolerance limits) are used each day. Such systems are valuable for the verification and recording of at least the following parameters: (a) monitor units, (b) energy, (c) mode, (d) collimator settings (including independent jaws and multileaf collimator), (e) collimator angle, (f) gantry angle, (g) table position, and (h) wedge number and orientation. However, V&R systems must be used with care because they can give the user a false sense of security. For example, if a set-up error is made on the first day and the machine geometry parameters are captured, the system will faithfully verify this erroneous setting from day to day. To reduce the chance of this occurring, the patient should be carefully set up according to the treatment plan (best if there is a direct electronic transfer of plan parameters to the V&R system), and a robust P&P for approval of patient treatment position should be in place; upon approval, the parameters are captured with the V&R system. As vendor implementation of Digital Imaging and Communications in Medicine data exchange has matured significantly, the direct transfer of data from the TPS to the V&R system has undoubtedly reduced such errors; however, a careful check of patient position is still recommended.

Thermoluminescent dosimeters (TLDs), diodes, optically stimulated luminescence dosimeters (OSLs), and MOSFET detectors are often used for *in vivo* dosimetry. Diodes or MOSFETS are most used for dose checks at the beginning of treatment for non-IMRT patients. TLDs or OSLs are typically used for checking multiple dose locations for unusual treatment conditions or for

critical structures in or near the treatment volume. Recently, exit portal dosimetry using EPIDs has been used to provide full-field information, even for IMRT fields.[143,144] Transmission detectors are also playing an increasing role in patient treatment verification. In transmission dosimetry, a large-area detector is mounted on the exit surface of the gantry head, and it compares radiation (fluence and shape) exiting the LINAC with the expectations from the treatment planning system.[145] There has also been a push to use machine log files for daily analysis of patient treatments.[146–148] It is difficult to determine which one of these methods is most effective as they all have some unique benefits and a combination of techniques may be needed for in-depth defense. To the extent that some of these processes (e.g., log file analysis) are passive and run in background, they are easy and inexpensive to perform and almost offer free information for prevention of patient treatment errors.

Summary

We strongly believe that the use of 3-D treatment planning and CRT has had (and will continue to have) a major impact on the practice of radiation therapy. Phase I/II and III CRT dose escalation studies in several disease sites have been conducted (or are underway) by the Radiation Therapy Oncology Group under cooperative agreement with the NCI.[149] In addition, there are many other individual institutional studies that have shown the benefits of 3-D planning and conformal therapy, particularly for prostate cancer, head and neck cancer, and lung cancer, as documented in the literature.[150] Patients identified to benefit most from 3-D planning and CRT are those with tumors in sites with complex anatomy, irregularly shaped tumor volumes, tumors adjacent to radiation-sensitive normal structures, and undergoing small-volume or high dose treatments. However, as with any major technical advance in radiation oncology, CRT use must be supported with enhanced quality assurance from all members of the treatment team.

CHAPTER 10

Physics and Dosimetry of Proton Therapy

Brian Winey

PHYSICS OF PROTON

As protons travel through media, protons interact with the media through electromagnetic interactions, nuclear interactions, and Coulomb scattering.[1,2] The electromagnetic interactions between the proton and the media can be described according to the stopping power equation, known as the Bethe equation:

$$\frac{S_{el}}{\rho} = -\frac{1}{\rho}\frac{dE}{dx} = \frac{4\pi r_e^2 m_e c^2}{\beta^2}\frac{1}{u}\frac{Z}{A}z^2 L(\beta)$$

where r_e is the electron radius, $m_e c^2$ is the electron rest energy, u is the atomic mass unit, β is the particle velocity, Z is the atomic number of the medium, A is the relative atomic mass of the medium, and z is the charge number of the particle ($p = 1$, $C = 6$).

The term $L(\beta)$ can be expanded as:

$$L(\beta) = L_0(\beta) + zL_1(\beta) + z^2 L_2(\beta)$$

where the individual terms are as follows:

$$L_0(\beta) = \frac{1}{2}\ln\left(\frac{2m_e c^2 \beta^2 W_m}{1-\beta^2}\right) - \beta^2 - \ln(I) - \frac{C}{Z} - \frac{\delta}{2}$$

$$L_1(\beta) = g_1 \beta^{-2g2}$$

$$z^2 L_2(\beta) = -\left(\frac{za}{\beta}\right)^2 \sum_{n=1}^{\infty} \frac{1}{\left[n\left(n^2 + \left(\frac{za}{\beta}\right)^2\right)\right]}$$

where *Wm* is the largest possible energy loss in a single collision with a free electron, *C*/*Z* is the shell correction to account for the bound state of K and L shell electrons, and *δ*/2 is the Fermi density effect correction. The second factor, L_1, is known as the Barkas correction factor and is an empirical fit with variable *g* dependent upon the medium. The final term can be approximated in the limit of the particle traveling faster than the atomic electron as the Bloch approximation:

$$z^2 L_2(\beta) = -\left(\frac{za}{\beta}\right)^2 \left[1.20 - \left(\frac{za}{\beta}\right)^2 \left(1.04 - 0.85\left(\frac{za}{\beta}\right)^2 + 0.343\left(\frac{za}{\beta}\right)^4\right)\right]$$

which now gives the Bethe-Bloch equation that describes the proton stopping power in a medium:

$$\frac{S_{el}}{\rho} = -\frac{1}{\rho}\frac{dE}{dx} = \frac{4\pi r_e^2 m_e c^2}{\beta^2}\frac{1}{u}\frac{Z}{A}z^2 \left[\frac{1}{2}\ln\left(\frac{2m_e c^2 \beta^2 W_m}{1-\beta^2}\right) - \beta^2 - \ln(I) - \frac{C}{Z} - \frac{\delta}{2} + L_1(\beta) + z^2 L_2(\beta)\right]$$

In general, the electromagnetic interactions increase as the proton velocity (energy) decreases (Fig. 10.1).

In addition to the electromagnetic interactions, the nuclear interactions are comprised of both elastic and nonelastic interactions with the majority of dose deposited by the nonelastic interactions that result in secondary nuclear particles, primarily protons along with gamma radiation. The nonelastic nuclear interactions are mostly independent of particle velocity until the particle slows to a resonance velocity, which results in an increase in the nuclear interaction cross section, similarly to the electromagnetic interactions. Combined, the nuclear and

electromagnetic interactions give rise to the famous Bragg curve of particle therapy (Fig. 10.2). The relationship between proton energy and proton range[3] is detailed in Figure 10.3. Typical clinical proton therapy centers provide proton energies from about 70 MeV to 235 or 250 MeV.

Because particles traveling through media is a stochastic process, the particles can lose energy at different rates. The energy straggling of the protons broadens the Bragg peak as the particles travel deeper into the media and the spectrum of energies in the beam increases in width. The clinical result is the broadening of the distal penumbra of the particle beam particularly evident when treating deep targets (Fig. 10.2).

As the particles travel through the medium, the particles undergo Coulomb scattering events with the nuclei. Because of the elastic nature, little energy is lost in the Coulomb scattering events, but the effect is most pronounced in the shape of the beam as it progresses through the medium. Multiple Coulomb scattering (MCS) affects the beam output for small fields, dose coverage of targets, dose homogeneity, range straggling, and increased lateral penumbra (Fig. 10.4). In fact, for small proton beams (diameter < 1 cm for ranges > 10 cm), the MCS events can result in a loss of the Bragg peak along the central axis and inside the treatment target (Fig. 10.4).

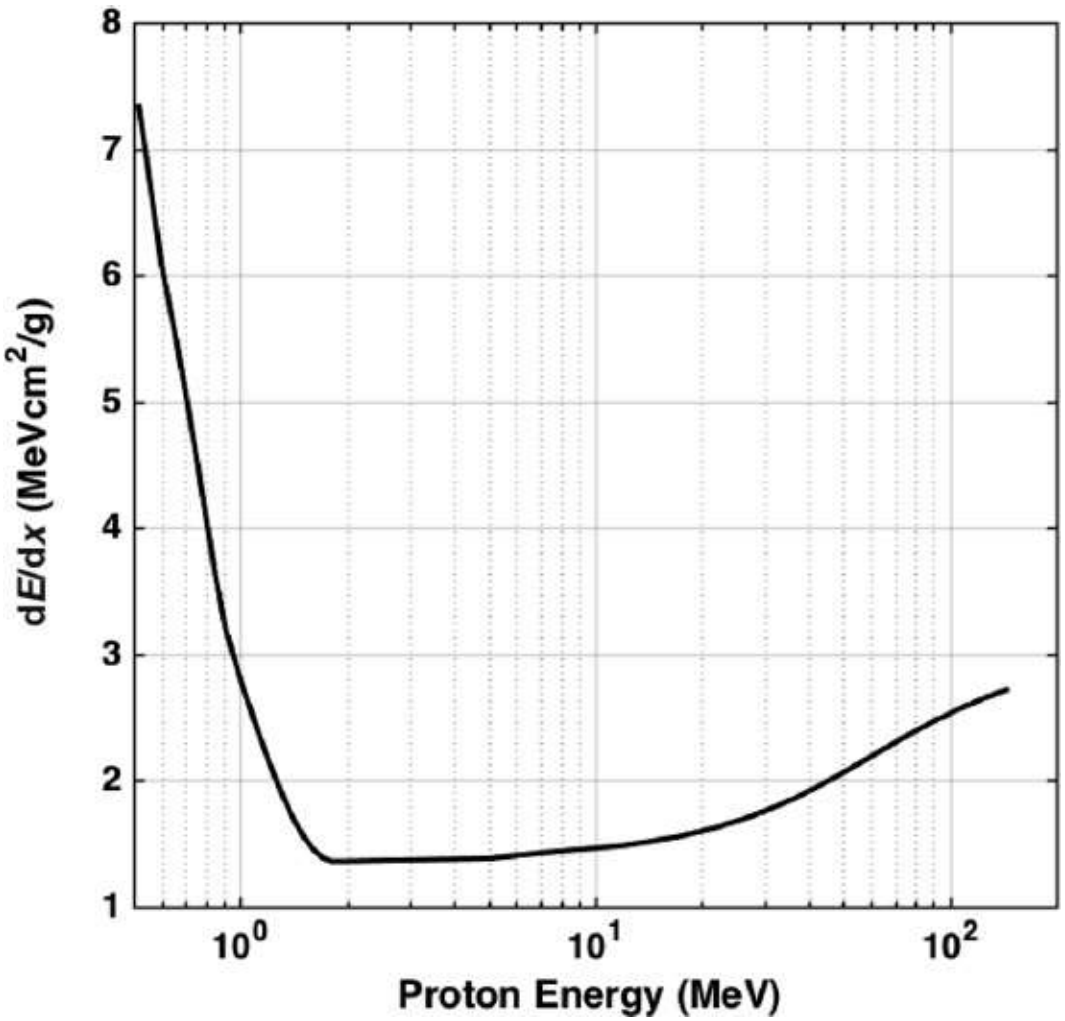

FIGURE 10.1. The energy loss (*dE*/*dx*) as a function of proton kinetic energy for protons traveling through water. Most importantly, the energy loss increases rapidly as the proton slows in the medium. This rapid energy loss gives rise to the Bragg peak.

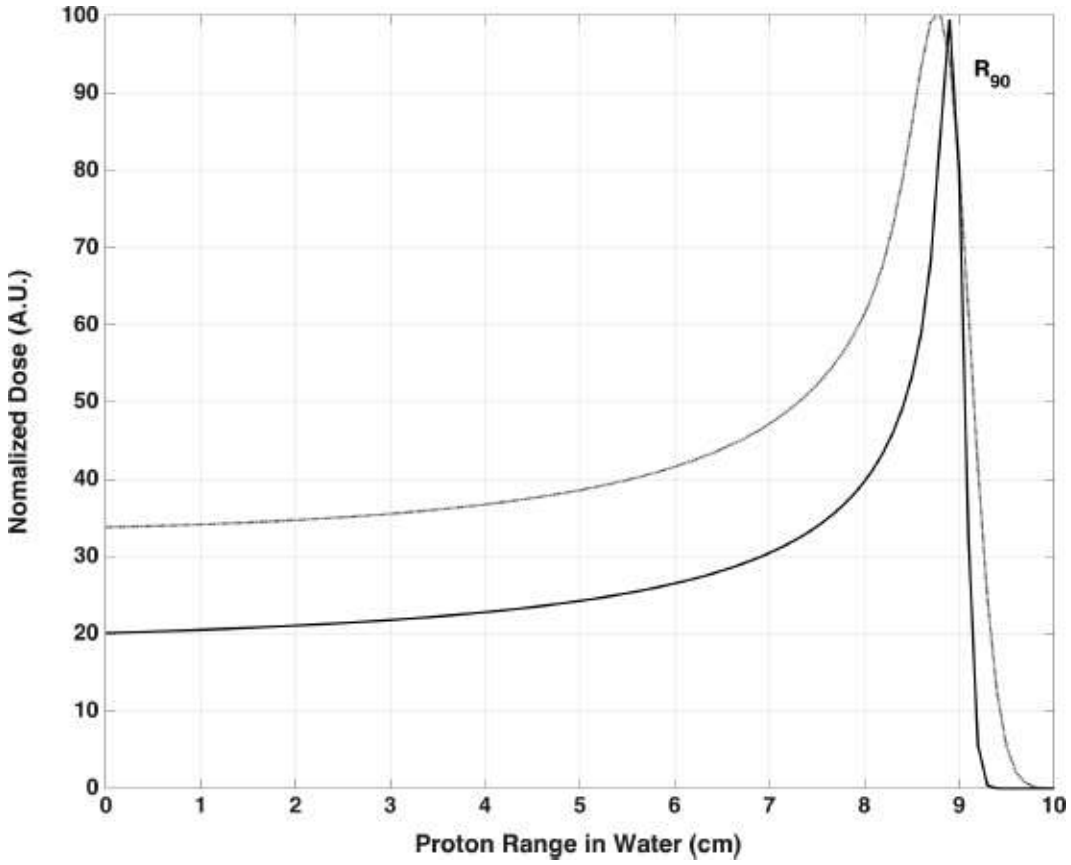

FIGURE 10.2. The proton energy deposited into the medium (water) as a function of proton range. The *dotted line* represents the effects of proton energy straggling as the protons stochastically interact with the medium. The R_{90} range is labeled.

DOSIMETRY

Absolute dosimetry in proton therapy is typically performed using Faraday cups or calorimetry, with Faradays cups being more common[2]. Aside from absolute dosimetry, most clinical proton therapy centers rely upon ionization chambers to perform beam calibrations. In many ways, proton beam dosimetry is similar to photon therapy. Dosimetry must be traceable to a primary standard radiation source (e.g., NIST in the United States), where radiation dose is typically defined in a free air ionization chamber with a cobalt source. Institutions can rely on Accredited Dosimetry Calibration Laboratories to supply an absolute calibration factor for ionization chambers. Current protocols utilize dose to water calculations and correct for the proton beam quality relative to Cobalt.

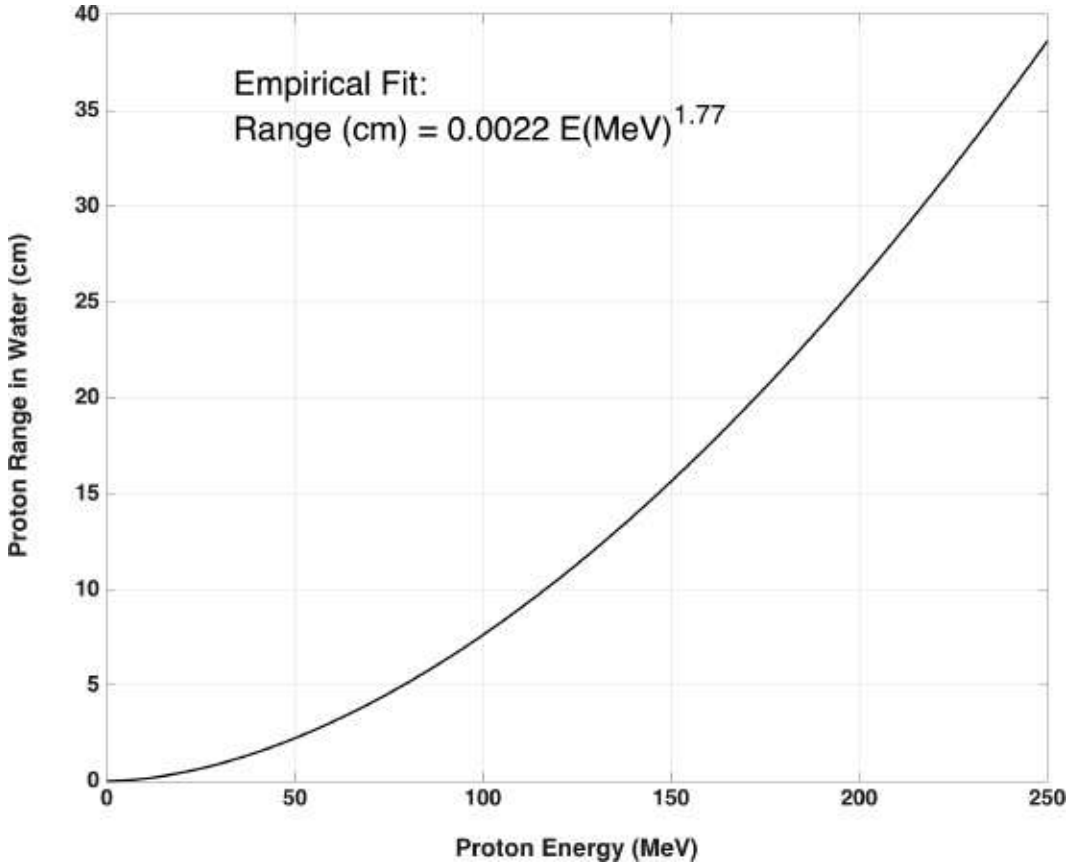

FIGURE 10.3. The relationship of proton energy and range (R_{90}) in water. The graph is a commonly cited fit[3] to empirical data that are not displayed. Typical clinical proton therapy accelerators provide proton energies from about 70 MeV (R_{90} = 4 cm) to 235 MeV (R_{90} = 35 cm). (From Bortfeld, T. An analytical approximation of the Bragg curve for therapeutic proton beams. *Med Phys* 1997;24[12]:2024–2033. Copyright © 1997 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.)

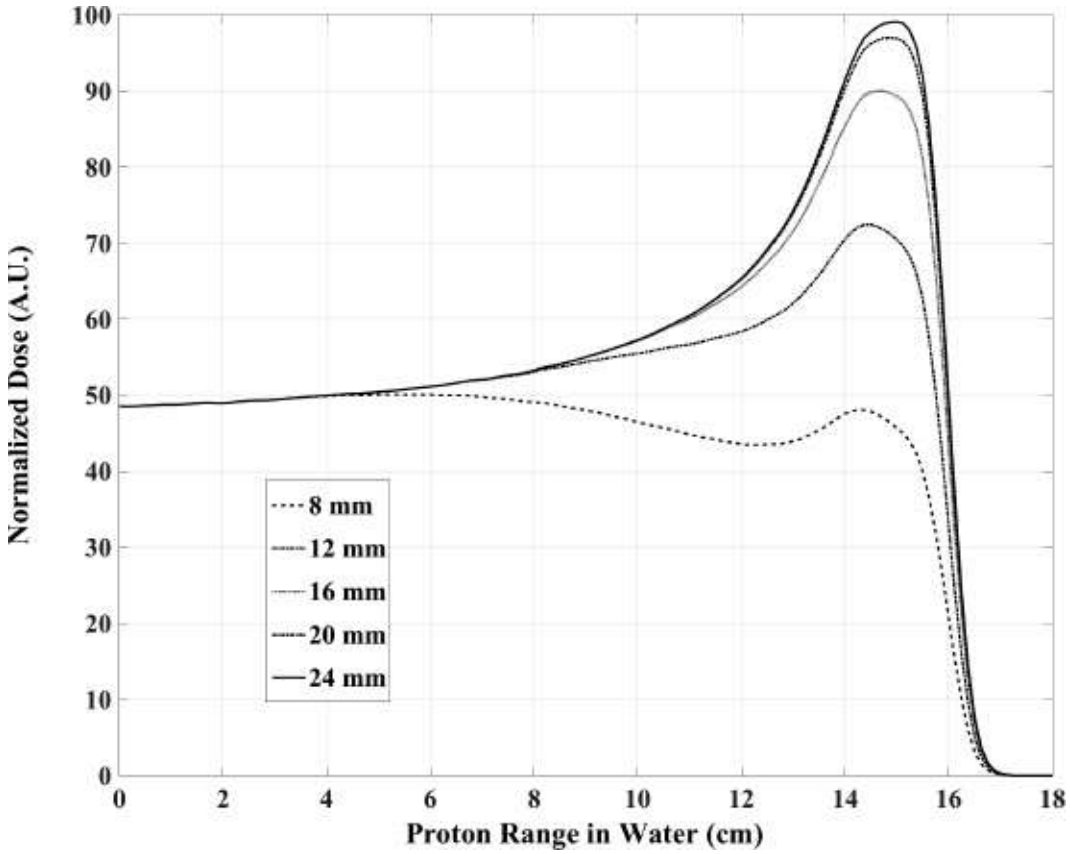

FIGURE 10.4. A central axis depth dose curve for a Bragg peak with a range of 15.5 versus field size. All fields are given for a range of 15.5 cm, and the field size decreases from 24 to 8 mm. Similar effects can be observed with single pencil beams. As the field size increases, the lateral scatter of neighboring pencil beams provides lateral equilibrium along the central axis and restores the Bragg peak.

According to TRS-398 and ICRU Report 78,[1] a calibrated ionization chamber can be used to perform calibration of a proton beam according to the following equation:

$$D_{w,Q_p} = M_{Q_p} N_{D,w,Q_{p0}} k_{Q_p,Q_{p0}}$$

where the measurement, M, is corrected for pressure, temperature, polarization, and recombination. The k_q factor is a function of residual range (R_{res}) of the proton beam, which is correlated with the spectrum of proton energies at the point of measurements.

Of particular note in scanned beam proton therapy, instantaneous dose rates in the volume of the ionization chamber can be significantly higher than most proton beams and recombination can become a problem. Some proton therapy accelerators can deliver lower beam currents, or an institution can purchase

ionization chambers designed for scanned proton beams. A proton beam calibration measurement will be performed in an irradiated volume large enough to reduce the effects of scattering and volume averaging in the volume of the ionization chamber. Typically, an ionization chamber will be placed in the center of a field size of 10 cm × 10 cm and a modulation width of at least 10 cm (R_{res} = 5 cm).

Although the physical dose of protons is measured and recorded similarly to photon therapy beams, the biologic dosimetry is different. The historical and still common practice is to apply a relative biologic effectiveness (RBE) correction factor of 1.1 to the physical dose in order to correct for the increased clinical effectiveness of the proton physical dose delivered to the patient relative to a photon treatment of the same physical dose.[4] Proton beam radiation therapy is typically quoted in Gy RBE such that the physical dose is multiplied by the RBE correction factor:

$$D_{\mathrm{Gy,RBE}} = 1.1 \times D_{\mathrm{Gy}}$$

The RBE factor of 1.1 is not constant for all cell types, clinical end points, or locations along the proton dose curve. There are more recent studies analyzing the effects of variable RBE or measuring cell- and end point–specific RBE values. There remains uncertainty regarding the most accurate RBE factor for proton beam therapy, but there is little clinical evidence that the current practice requires immediate remedy.

UNCERTAINTIES

Physical dose and particle interactions have long been described in the literature, and the fundamental physics is generally well understood. There remains some uncertainty in the cross-section interactions between protons and nuclei (I) in the above equations, but commissioning measurements of clinical systems can greatly reduce the uncertainties of the underlying physics.

Uncertainties in proton therapy delivery remain and affect the accuracy of the proton beam delivery to the intended target. Because of the sharpness of the Bragg peak, uncertainties that affect the proton range can result in large underdosing in the target when the Bragg peak stops prematurely or overdosing of the surrounding tissues when the Bragg peak travels farther than intended into the patient.

There are generally two classes of uncertainties that affect the range of the

proton Bragg peak in the patient: systematic and random. Uncertainties in both categories can be mitigated with various methods during pretreatment imaging, treatment planning, and treatment room imaging. A summary of both categories of uncertainties can be found in Table 10.1. The important note is the larger dosimetric effect of systematic versus random uncertainties in the proton beam delivery. It is also important to note that many of the uncertainties are present in photon or electron beam therapy, but the Bragg peak in proton therapy can create unique dosimetric uncertainties.

Many of the uncertainties have both systematic and random contributions because of the differences of calibration and delivery or treatment planning system calculation versus delivery. For example, anatomy might not be accurately captured in the computed tomography (CT) in the case of a filled sinus cavity, which can become a systematic range error for the treatment of a nasopharyngeal lesion if the sinus were to drain prior to the first treatment. Other anatomic changes such as motion can be random.

To mitigate the dosimetric effects of the listed uncertainties, or increase the robustness of the treatment plan, there are multiple methods that can be employed. One of the simplest and most robust methods is to utilize more than one treatment beam. The use of multiple beams can spread the uncertainty of a single beam direction and reduce the magnitude of a dose uncertainty to a single location. Depending upon the time scale of the random uncertainties, multiple beams can also reduce the magnitude of the random uncertainty simply by the increased time of delivery.

TABLE 10.1 A BRIEF AND NONEXHAUSTIVE LIST OF UNCERTAINTIES THAT AFFECT THE DOSIMETRIC DELIVERY OF PROTONS. THE MAGNITUDE OF THE UNCERTAINTIES IS NOT LISTED.

Systematic	Random
CT stopping power calibration	CT noise
Beam energy/range calibration	Beam energy tuning
Ion chamber calibration	Spot position and weight
Immobilization densities	Patient positioning
Implanted device densities/artifacts	Anatomic motion
Anatomic changes	Anatomic changes
Heterogeneities *in silico*	Heterogeneities *in vivo*

Although the Bragg peak reduces both the entrance and exit dose compared to

photon beams to greatly reduce the integral dose to organs outside of the target, the use of multiple beams can increase the integral dose. It is a clinical decision whether the increase of robustness using multiple beams is worth the increased integral dose. In some treatment sites, the increased integral dose can be deposited in the surrounding tissues that have a low risk of toxicities. In other sites, the risk of toxicities is greater and the clinical decision leads to the use of a single treatment beam.

A second method to increase robustness of the treatment delivery is to use margins, similar to photon therapy. Specific to proton therapy is the distal edge of the target, and distal margins are often determined separately from the lateral margins in a beam angle geometry. In addition to margins, the distal edge of a treatment beam can be "smeared," which decreases the distal conformality in the lateral direction of the beam such that tissue motion or patient setup uncertainties have a reduced effect on the target dose.

A third method that can be used in more recent treatment planning systems is a "robust optimization" technique. The basic premise of a robust optimizer is to include random and systematic uncertainties in the dose optimization in addition to the more common dose objectives and constraints for the targets and organs. Generally, more robust plans result in less sharp dose gradients in close proximity to avoidance regions such that the effect of range or dose uncertainties will be reduced.

TREATMENT PLANNING

Although the Bragg peak is commonly known, it is less known how the Bragg peak is optimized for the treatment of a target volume. There are essential two methods for proton therapy delivery: scattered and scanned. Scattered therapy was the dominant solution for more than 50 years of treatment but is fading as most proton therapy centers purchase scanning systems.

Scattered Beams

Briefly, scattered systems use scatters composed of various plastic and metals to increase the diameter of the proton beam within a specified flatness and symmetry. A proton beam exits the accelerator with a sigma on the scale of millimeters or 1 to 2 cm, depending upon the system and energy selection method. A typical ocular line requires very little scattering, but targets larger than an ocular target require larger beam diameters. Common double-scattering

systems that use multiple scattering elements can achieve flat proton beams up to a clinically flat 25 cm diameter. Once the beam is scattered to the appropriately specified diameter, apertures are used to laterally shape the proton beam to the shape of the target volume.

In addition to the lateral shape of the proton beam, the size of the beam along the beam axis is variable and specified by the modulation of the Bragg peak. There are multiple methods of modulation, which essentially modulate the energy of the proton beam to change the range of the protons in the patient. The summation of the multiple energy proton beams results in a spread out Bragg peak (SOBP) that provides a flat dose distribution inside the target volume (Fig. 10.5). The modulation of the proton beam energy can occur at the accelerator, in the energy selection system, with a modulation wheel, or generally with any technique that adds material in the beam path. One of the more common modulation methods uses a modulation wheel that is composed of a wheel with increasing steps of material thickness. The wheel rotates through the beam path and essentially sweeps the proton Bragg peak through the treatment volume multiple (hundreds) times each second.

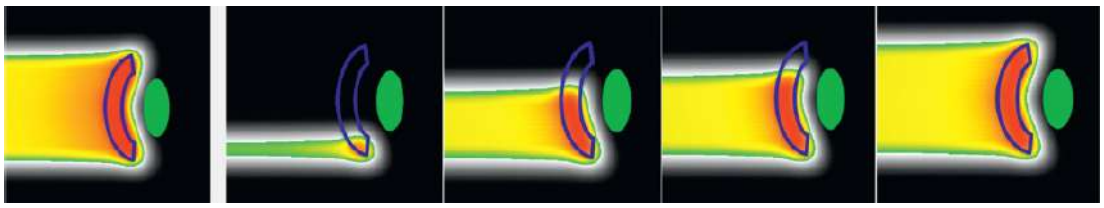

FIGURE 10.5. A comparison of the dose delivered by a scattered beam (*left*) and a scanned beam at different times in the field delivery beginning with the first pencil beam and scanned across the blue target volume.

Scanned Beams

Although scattered beams spread the beam laterally, shaped by an aperture, to deliver a uniform dose to the specific target volume, scanned beams sweep a single proton pencil beam (Fig. 10.5) laterally to deposit dose to a volume of tissue, either continuously or spot scanning. In most scattered beam deliveries, the entire target receives a uniform dose, and the beam continues to deliver a uniform dose to the entire target until the time that the prescription dose is delivered. In a scanning system, a small portion of the target is irradiated with a single Bragg peak pencil beam until the prescribed dose of that pencil beam is delivered and then the pencil beam is scanned to the next location. The pencil beam is scanned over the entire volume, using energy changes when necessary to

modulate the depth of the pencil beam, until the prescribed dose pattern is delivered (Fig. 10.5).

Although a scanned beam delivery does not require apertures to provide lateral conformality to the target volume, apertures can provide additional conformality for shallow targets and larger spot sizes. The target depth when the apertures no longer provide a clinical advantage depends upon the spot size of the delivery system.

In addition to reducing the need for physical hardware, scanning systems can provide multiple dosimetric benefits over scattered beams. The primary benefits include the following:

- Reduced proximal dose in the entrance region
- Greater proximal conformality because of nonuniform modulation
- Ability to deliver nonuniform doses to the target (intensity modulation)
- Greater conformality and organ sparing for complex-shaped targets
- Gradient match lines for large targets, particularly craniospinal irradiation (CSI) treatments

Scanned beam dosimetry can be less robust to motion and other uncertainties listed above, but the robustness of the scanned beam delivery can be improved using robust optimization, margins, rescanning, rapid scanning, and variable spot sizes.

With greater effort toward the deployment of scanned beam systems, the challenges of robustness are being overcome and the utility of scattered beams is diminishing.

Site-Specific Proton Treatment Planning

The earliest proton therapy treatments were delivered to cranial (pituitary) and ocular targets. Currently, ocular proton therapy is the most common proton therapy site by patient numbers worldwide.[5] The primary reasons for the popularity of ocular treatment popularity are the target location, low proton energy, and small treatment fields. When proton therapy began in the physics accelerator laboratories, there were many accelerators capable of reaching 70 MeV and the beam delivery required little scattering to achieve the lateral field sizes needed for the ocular targets.

Brain

Cranial targets were the first recorded treatments with proton and ion beams.[6–11] The treatments were straightforward with opposed lateral beams targeting the

sella for pituitary therapies. With the advent of 3D imaging, more diagnoses in the brain are currently treated, including both conventional and stereotactic radiosurgery fractionation techniques.

When considering a treatment plan for a cranial target, protons can reduce the normal brain integral dose and dose to sensitive structures such as the optic apparatus and the brainstem. The clinical significance of the dose reduction to normal brain is not discussed here. Cranial targets present an excellent proton therapy site because of the ability to use multiple beam entrance angles to increase the dose conformality, reduce the uncertainties from any single beam, and increase the overall robustness of the proton delivery. Typical treatment plans are displayed in Figures 10.6.

Base of Skull

From a treatment planning perspective, base of skull targets such as chordomas can be treated with protons to reduce integral dose to the brain and spare many organs in close proximity to the target volume, particularly the brainstem. Prior to the clinical deployment of scanned beams, the treatment of concave base of skull targets with scattered beams required the use of matched beams inside the target volume. Scanned beam treatment plans can now provide more robust treatments with gradient match lines and increase the dose sparing of organs in close proximity to the targets. Similar to cranial targets, the base of skull lesions can be treated with multiple beam entrance angles, including superior oblique beams to increase the dose conformality, treatment robustness, and normal tissue sparing (Fig. 10.7).

Head and Neck

The treatment of head and neck lesions can provide some challenges to treatment planning and delivery, irrespective of the method of proton delivery. Large anatomic variations because of sinus filling, tumor shrinkage, and patient weigh loss can greatly affect the accuracy of the proton treatment. The treatment planning advantages for head and neck targets are typically the sparing of normal tissues to reduce acute and chronic toxicities.

Typical treatment plans for targets in the nasal region employ two or more treatment fields, but the possible beam angles are often reduced because of the location of the target with respect to the eyes and optic nerves. Beam angles for lesions around the oral cavity and inferior have greater flexibility than nasal targets. Additionally, simultaneous boost volumes can also be treated easily with

scanned proton beams. Tumor shrinkage or sinus filling/draining can also increase the uncertainty of proton treatment. Adaptive proton therapy will greatly benefit targets in the nasal and oral cavities and neck locations.

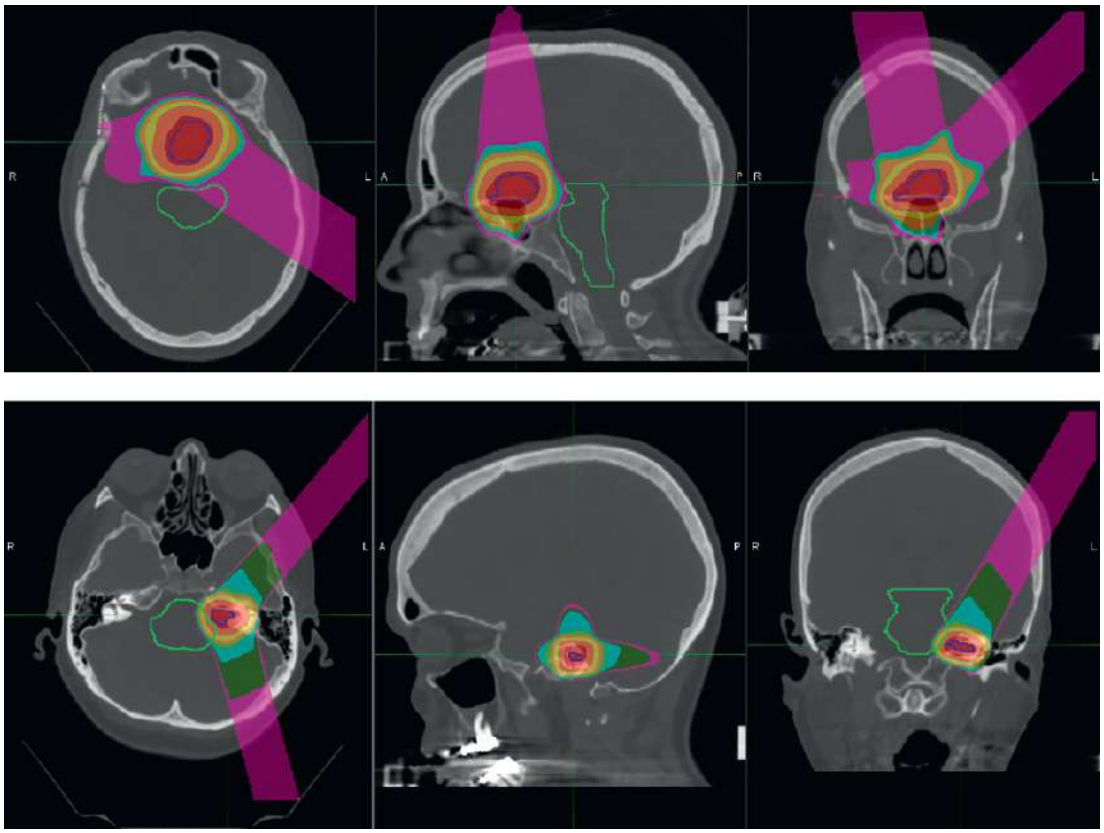

FIGURE 10.6. An example of cranial target treatment plans for a meningioma **(top)** and an acoustic schwannoma **(bottom)**. The beam angles can be visualized by the low dose.

Breast

Recently, breast proton therapy has become an option for breast radiation therapy.[12,13] The typical treatment employs a single *en face* proton beam. Breathing motion is mostly oriented along the beam angle such that the motion has little effect on the treatment delivery. With the use of proton therapy, nodal target volumes can be included in a single scanned beam so long as the total target volume fits in the maximum field size of the treatment delivery system. Additionally, simultaneous boost volumes can also be treated easily with scanned proton beams (Fig. 10.8).

Compared to photon therapy, protons do not have a buildup region because protons are directly ionizing radiation. The increased surface dose can be reduced in the optimization process of a scanned beam plan. Additionally, range

uncertainties at the distal edge of the treatment volume in the region of the chest wall and lung interface should be accounted in the plan optimization.

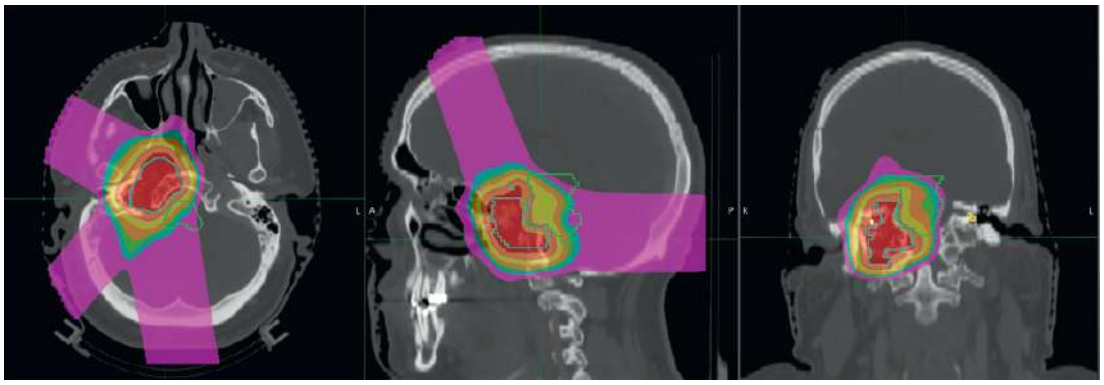

FIGURE 10.7. A representative treatment plan for a base of skull lesion utilizing beam angles in the axial plane as well as superior oblique beams.

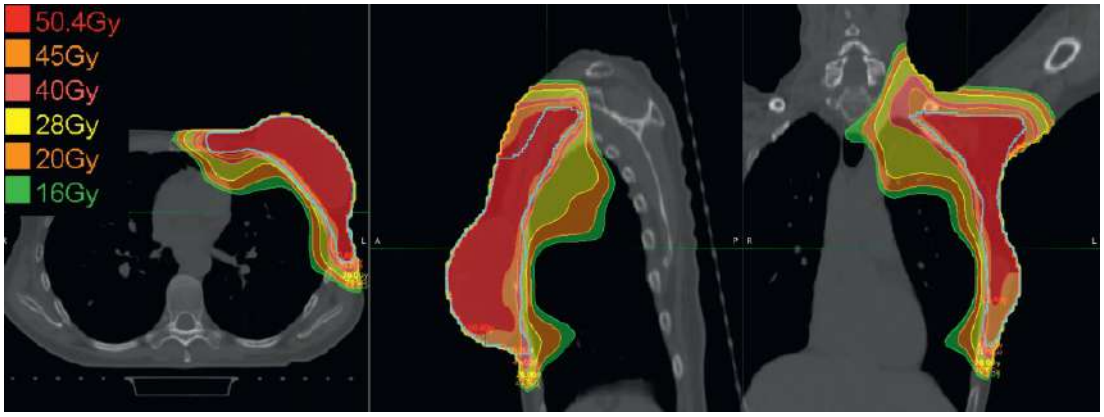

FIGURE 10.8. An example of a scanned beam breast treatment plan with nodal volumes. The treatment uses a single *en face* proton beam from the anterior oblique direction.

Thoracic and Abdominal

All thoracic lesions require extensive quality assurance (QA) to determine the optimal method of addressing the tissue heterogeneities in the region of the target volume. Range uncertainties in lung tissue can greatly increase the amount of healthy lung irradiated. Additionally, shrinkage of thoracic lesions must be assessed during the course of treatment to reduce the risk of errantly irradiating healthy tissues.

The motion of thoracic and abdominal lesions has long been studied in the context of proton therapy.[2,14–22] Methods to provide robust treatment plans include density overrides inside the ITV, use of 4D CT for optimization, gating, layer rescanning, volumetric rescanning, and tracking.[2,14–22] Although there is

not yet a consensus regarding the optimal method for treating lesions with large amplitudes of motion (>1 to 2 cm), it is necessary for any institution to perform a complete analysis of their treatment protocols because the dosimetry is dependent on spot size, scanning speed, dose rate, time for energy (layer) changes, and fractionation scheme.

Generally, as the spot size becomes smaller and the fraction number decreases, the effects of the interplay between the breathing motion and the treatment delivery increase the risk of dosimetric errors. Combinations of the previously mentioned motion management techniques can be deployed to reduce the magnitude of the interplay effects. Briefly, rescanning can effectively increase the number of “fractions” by scanning the same target volume or layer multiple times similar to repeating the same field over multiple fractions.

Sarcomas

Sarcomas can be located in various regions of the body. Some locations, such as the sacral, pelvic, and vertebral locations, can be treated with protons to avoid dose delivery to radiosensitive organs. Typical beam arrangements for sarcomas located along the vertebral column use a single or a couple posterior or posterior oblique beams to provide maximal sparing of organs located anterior to the treated volume.

Pediatric

Pediatric treatments can cover many of the aforementioned treatment sites in the brain and other body sites. More specific and common in the pediatric population is CSI. Proton therapy is commonly used for CSI treatment delivery because of the zero dose exposure in the organs anterior to the vertebral column and whole brain. The long-term secondary cancer risk is much lower for protons, especially for soft tissues of the abdomen and thoracic region. Because the in-field doses are similar for both photon and proton pediatric treatments, the secondary risk is assumed to be similar, that is, secondary meningiomas following brain irradiation.

In the past, proton CSI treatments with scattered fields required three levels to reduce the risk of dosimetric hot and cold spots at the match lines. Each level required 4 to 5 treatment fields, each with custom apertures and range compensators. The total of 12 to 15 fields and custom hardware can be challenging for treatment planning and delivery workflows. Scanned beams greatly simplified the CSI treatment because of the ability to easily delivery

gradient match lines instead of feathering with three levels (Fig. 10.9).[23,24]

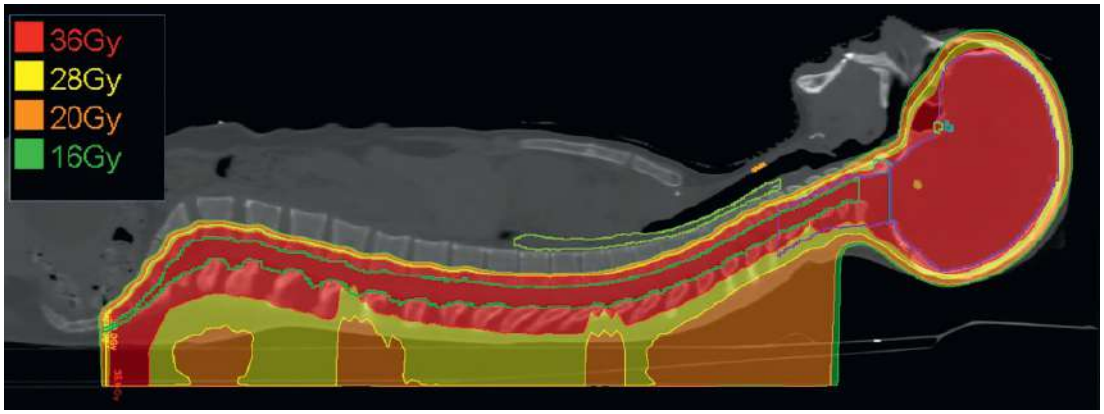

FIGURE 10.9. An example of a scanned beam CSI treatment. The plan uses gradient match lines.

QUALITY ASSURANCE

There are several distinct challenges for quality assurance in a proton therapy clinic.[25] First, there are very few national or international protocols specific for proton therapy quality assurance. The ICRU Report 78[1] specifies the calibration procedure and recommends other QA measurements. The AAPM is currently developing several proton-specific protocols, but photon protocols are typically referenced until the proton-specific documents are published. Although the imaging and mechanical systems should operate with similar specifications, the dose delivery systems and dose measurements are lacking in photon protocols. To supplement the photon documents, previously published single-institution studies are often used.[2,26–39]

Second, there are three common treatment planning system (TPS) dose verification methods. Photon TPS dose verification is typically performed with a secondary dose calculation in an independent software application that is independently commissioned. Monte Carlo dose calculations might be the most similar independent check in proton therapy, and several institutions have deployed such software for dose checks.[37,40–44] Other institutions measure every field prior to delivery.[26,32] The third option is an analytic model based on empirical data.[34]

Third, the proton therapy user base is much more diverse than the photon radiotherapy clinic. There are currently multiple proton therapy vendors with multiple beam delivery and verification systems. Each system can have different beam parameters, hardware, and software, in addition to the aforementioned

scattered and scanning delivery techniques. Such diversity of systems can make consensus protocols difficult to design and requires extensive expertise at each center or appropriate credentialing processes.

DEVELOPMENTS

Image guidance in proton therapy is beginning to incorporate volumetric imaging solutions. The Paul Scherrer Institute in Switzerland was one of the first centers to install an in-room CT device. Other centers in Trento (Italy), Dresden (Germany), and the Mayo Clinic (Rochester, MN) have also installed in-room CT devices. The advantage is high-quality imaging and the option for 4D imaging. A diagnostic CT cannot, however, perform imaging at isocenter and always requires transferring the patient from an imaging position, up to several meters from isocenter, to the treatment position.

Other institutions have deployed cone beam computed tomography (CBCT) as a volumetric imaging solution. Recent advances in CBCT image quality improvement have allowed for better soft tissue visualization and HU accuracy for dose calculations.[45–53] Some proton vendors have deployed CBCT using the proton gantry as the mechanical rotation mount, and others have deployed C-arm or couch-mounted 0-ring systems (Fig. 10.10).

Simultaneously with the deployment of in-room volumetric imaging, there are multiple institutions attempting to integrate the 3D imaging into adaptive workflows.[45–48,50–52] Previously, adaptive proton therapy required separate imaging sessions with external imaging systems such as a CT or MR. In-room options can provide more streamlined workflows for adaptations based upon CT information. At this time, there are no in-room MR deployments at proton therapy centers, but there are multiple feasibility studies.[54,55]

FIGURE 10.10. Example of a novel CBCT design such that the imaging ring is attached to the patient positioner.

More than photon therapy, proton therapy greatly benefits from adaptive workflows when the patient has anatomic variations or the target has motion because of breathing or bowel movements. Even in other target locations, online adaptive proton therapy might reduce the need for some margin expansions.

In addition to adaptive methods, robust planning methods can reduce the need for some margins and increase the certainty of the dosimetry calculated in the treatment planning system being delivered to the patient. The basic premise of robust optimization in the treatment planning system is to incorporate any random range uncertainties as variables in the cost function that controls the optimizer.[24,56–58] In other words, the optimizer not only considers the dose to the target or organs at risk (OAR) but also considers the risk of overdosing the OAR or underdosing the target in the presence of range uncertainties. The cost function penalizes plans that have higher risk of dose uncertainty and essentially reduces the presence of high-dose gradients in the optimized plan. More robust plans may have higher OAR doses, but the certainty of the delivery is much higher if the model accurately captures the uncertainties of the treatment workflow.

Although patient setup, anatomic, and dosimetric uncertainties have been addressed by the previous developments, range uncertainties remain in the delivery of proton therapy. There are multiple methods being explored to measure the *in vivo* range of the proton beam during or post treatment. A simultaneous measurement of the range can be accomplished using implanted devices for lesions located in close proximity to the rectal or vaginal cavity.[59–61] Other methods measure the nuclear products of the directly ionizing radiation by the prompt gammas[62–65] or positrons[66–72] (Fig. 10.11). With the *in vivo* range information, margins might be reduced.

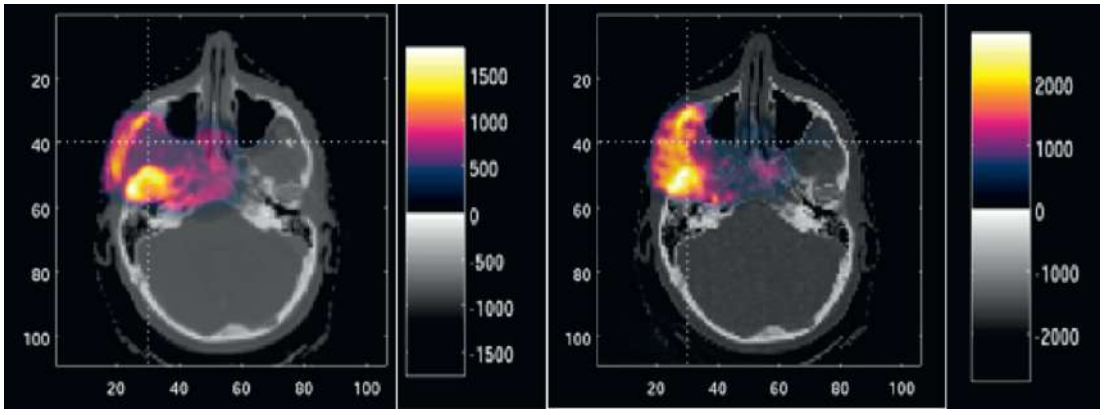

FIGURE 10.11. A sample of a PET signal following a proton beam irradiation as simulated in Monte Carlo **(left)** and measured **(right)**.

Finally, the biologic dose of proton therapy remains a research topic. Although most clinical dose calculations rely upon a static RBE value of 1.1, it is well known that the RBE value is not constant within a treated volume. The

RBE can depend upon cell type, the position of the cells in the cell cycle, linear energy transfer (LET) of the protons, and the local tissue environment. Recent studies continue to evaluate the RBE[73–79] and the local (micro) dosimetry through biologic Monte Carlo simulations.[80–82]

CONCLUSIONS

The physics of proton therapy are generally well understood, and the physical dose distributions greatly reduce the integral dose to healthy tissues as well as organs in close proximity to the targeted volume. There are many topics for further discovery including the integration of 3D imaging, adaptive workflows, range measurements, and biologic modeling, and more discoveries will increase the therapeutic ratio of proton therapy.

CHAPTER 11

Intensity-Modulated Radiation Treatment Techniques and Clinical Applications

Tony J. C. Wang, Cheng-Shie Wuu, and K. S. Clifford Chao

INTRODUCTION

The previous edition of this chapter included literature reports through 2013. For the past 10 years, intensity-modulated radiation therapy (IMRT) has become the *de facto* standard practice for many tumors. IMRT's coming of age is described in thorough terms in the 2010 International Commission on Radiation Units (ICRU) report (hereafter ICRU 83), which spans 106 pages with over 350 references.[1] Readers new to the field will find this report an excellent synthetic introduction to IMRT and other techniques; experienced physicians should also note that it contains new reporting guidelines for clinical treatments.

The use of ionizing radiation for treatment of cancer has more than a century of history; for a wonderfully concise review, see Bernier et al.[2] An enduring clinical problem has been to achieve high doses of irradiation at the tumor site without causing extremely toxic or even fatal consequences in normal tissues in the path of the treatment beam. Developments in technology allowed true three-dimensional (3D) tailoring of radiation fluence with equipment and a planning time scale feasible for clinical application. Since its introduction into clinical use,[3–5] IMRT has generated widespread utilization. IMRT optimally assigns nonuniform intensities (i.e., weights) to tiny subdivisions of beams, which have been called rays or "beamlets." The ability to optimally manipulate the intensities of individual rays within each beam permits greatly increased control over the radiation fluence, enabling custom design of optimum dose distributions. These improved dose distributions potentially may lead to improved tumor control and reduced normal tissue toxicity. For example, tumors of the head and neck often require concave-shaped treatment volumes to spare

closely adjacent sensitive critical structures (e.g., brainstem, spinal cord). Such fluence distributions are easily done with IMRT but may be difficult or impossible by other techniques, including three-dimensional conformal radiation therapy (3DCRT). This is illustrated in Figure 11.1, which is taken from ICRU 83.

IMRT requires designing the intensities of tens of thousands of rays (beamlets) that make up an intensity-modulated treatment plan. This task requires the use of specialized computer-aided optimization methods. Optimal beamlet intensities are determined using a systematic iterative process, which a computer sequentially generates intensity-modulated plans one by one, evaluates each of them according to user-selected criteria ("desired objectives"), and makes changes in the ray intensities based on the desired objectives. The quality of an intensity-modulated treatment plan produced in this manner depends on a variety of factors. These include the parameters used by the optimization process to evaluate and compare competing treatment plans; the mathematics and algorithms of optimization; the number, orientation, and energy of radiation beams; margins assigned to the planning target volume (PTV) and to normal structures; dose calculation algorithms; and so on.

Both ICRU 83 report and the ASTRO report[6] have some important conceptual changes in plan evaluation and dose reporting. The previous ICRU reports for photon therapy (No. 50 in 1993 and its supplement, No. 62 in 1999) defined a reference point within the treatment volume, one that was easily located with anatomic landmarks and where dosage could be accurately measured. The prescription dose was something of an ideal to be sought. With IMRT, treatment *volumes* are more relevant, and doses are given and bounds set within those volumes. The prescription dose itself is taken to be the final result of treatment planning by the physicists and radiation oncologists. With literally thousands of degrees of freedom available to the planner, the dosage to a single point is not adequate to describe or evaluate a plan.

ICRU 83 report and the ASTRO report cite the increase in the clinical impact and use of IMRT in the recent past: "In a survey performed in 2003 in the USA, among 168 radiation oncologists randomly selected, one-third was using IMRT. In 2005, a similar survey showed that more than two-thirds of radiation oncologists were using some form of IMRT, mainly for increased normal-tissue sparing or target-dose escalation."[1,7,8] Another noteworthy metric is the number of research reports in the peer-reviewed literature concerning IMRT. A scan of the Web of Science database showed full papers with IMRT in the title as

numbering <50 per year through 2001. It reached 100 in 2005, and it plateaued at about 140 for the years 2009 to 2011 and continues to increase incrementally.

IMRT RATIONALE

IMRT is a form of 3DCRT in which a *computer-aided iterative optimization process is used to determine customized nonuniform fluence distributions to attain certain specified dosimetric and clinical objectives*. IMRT is intimately tied to 3D imaging. As ICRU 83 states: “Three-dimensional CRT, in general, and IMRT, in particular, increase the need for accurate anatomic delineation. This requires an adequate specification of the tumor location and a thorough knowledge of the processes of likely infiltration and spread.”[1]

IMRT has many advantages. It can be used to produce dose distributions that are far more conformal than those possible with standard 3DCRT. Dose distributions within the PTV can be more homogeneous and a sharper falloff dose at the PTV boundary can be achieved. With respect to dose homogeneity, the IMRT plan always should produce more homogeneous dose distribution (dose conformality) than a plan made with uniform beams. A sharper falloff dose at the PTV boundary, in turn, means that the volume of normal tissues exposed to high doses may be reduced significantly. These factors may allow escalation of tumor dose, reduction of normal tissue dose, or both, leading to improved outcomes, including reducing morbidity. IMRT has the potential to be more efficient with treatment planning and delivery than standard 3DCRT. The treatment design process is relatively insensitive to the choice of planning parameters, such as beam direction.[9–11] There are no secondary field-shaping devices other than the computer-controlled multileaf collimator (MLC). Furthermore, large fields and boosts can be integrated into a single treatment plan, and electrons can be dispensed with, permitting the use of the same integrated boost plan for the entire course of treatment.[12,13] An integrated boost treatment may offer an additional radiobiologic advantage[14] in terms of lower dose per fraction to normal tissues while delivering higher dose per fraction to the target volume. Higher dose per fraction also reduces the number of fractions and hence lowers the cost and burden to the patient for a treatment course. IMRT also offers the potential of adaptive therapy—revision of the treatment plan according to imaging of tumor reduction and organ movement during the course of radiation therapy. Mechalakos et al. presented a case study where weekly cone beam computed tomography (CBCT) was used to track treatment of a recurrent

neck mass from a nasopharyngeal cancer.[15]

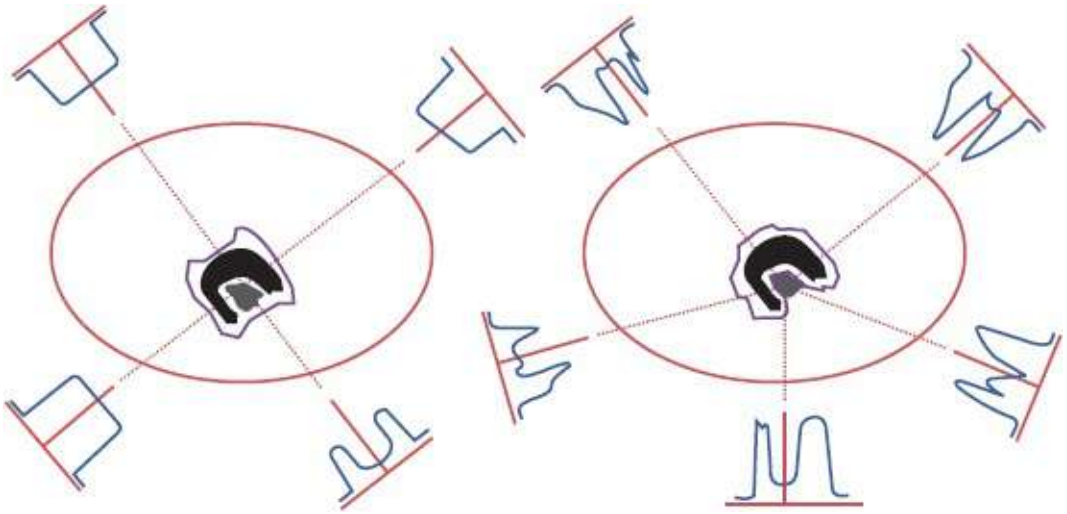

FIGURE 11.1. Comparison of conformal radiation therapy (CRT) (*left*) and intensity-modulated radiation therapy (IMRT) (*right*). The ability for CRT to alter isodose lines was limited to shaping of field boundaries with multileaf collimators (MLCs) or blocks, the use of wedges or compensators for missing tissues, and the use of central blocks for shielding critical structures. The IMRT beams can have highly nonuniform beam intensities (fluences) and are capable of producing a more concave-shaped absorbed dose distribution. With neither conformal therapy nor IMRT can the planning organ at risk volume (PRV) always be completely avoided, but with IMRT the concave isodose curve that includes the planning target volume (PTV) better avoids the PRV. The black region indicates the PTV, the gray region indicates a PRV, and the line surrounding the PTV is a typical isodose contour. (From International Commission of Radiation Units and Measurements. IMRT Limitations and Risks

We should recognize that IMRT has limitations. There are many dose distributions (or dose–volume combinations) that are simply not physically or technically achievable. Furthermore, our knowledge about what is clinically optimal and achievable and how best to define clinical and dosimetric objectives of IMRT is often limited. Moreover, the best solution may elude us because of the limitations of the mathematical formalism used or because of the practical limits of computer speed and the time required for finding it.

Uncertainties of various types (e.g., those related to daily or interfraction patient positioning; displacement and distortions of internal anatomy; intrafraction motion; and changes in physical and radiobiologic characteristics of tumors and normal tissues during the course of treatment) may limit the

applicability and efficacy of IMRT. Dosimetry characteristics of a delivery device, such as radiation scattering and transmission through the MLC leaves, introduce limitations in the accuracy and deliverability of IMRT fluence distributions. In addition, the limited spatial and temporal coverage and overall accuracy of current IMRT dosimetric verification systems diminish the confidence in the delivered dose. Furthermore, dose calculation models are limited in their accuracy, especially for the small, complex fields. It is quite conceivable that inaccuracies in dose calculations may yield a solution different from the one derived if dose calculations were accurate. However, an important factor that may limit IMRT is the inadequacy of imaging technology to define the true extent of the tumor, its extensions, and radiobiologic characteristics as well as geometric, dose–response, and functional characteristics of normal tissues.

We should be aware of the potential risks of IMRT. The effect of large fraction doses used in integral boost IMRT on tissues embedded within the gross tumor volume (GTV) is uncertain and may present an increased risk of injury.[16] There also may be an increased risk that improper use of spatial margins, coupled with the high degree of conformality with IMRT, may lead to geographic misses of the disease and recurrences, especially for disease sites where positioning and motion uncertainties play a large role or where there are significant changes in anatomy and radiobiology during the course of radiotherapy. This uncertainty has been decreased with newer image guidance technology. Similarly, high doses in close proximity to normal critical structures may pose a greater risk of normal tissue injury. In addition, although IMRT can spare specific tissues compared to conventional radiation therapy, the use of many more beams and irradiation angles resulting in a higher integral dose exposure.

IMRT: An Unconventional Paradigm

The application, process, and dose distributions of IMRT are different from those of conventional two-dimensional (2D) CRT or 3DCRT. This means the conventional methods of specification and fractionation of treatments, evaluation of treatment plans, and reporting of results are limited and new methods are required.

The traditional 3DCRT process involves “forward planning,” in which beam parameters (directions, apertures and their margins, beam weights, beam modifiers) are specified and dose distributions are computed. The treatment plan

is evaluated by a human being, and if necessary, beam parameters are modified to achieve an acceptable dose distribution. In IMRT, an inverse process ("inverse planning") is used in which the desired dosimetric and clinical objectives are stated mathematically (in the form of an "objective function").[10,17–19] The term *inverse planning* should not be confused with the mathematical operation of matrix inversion. In the present context, the word *inverse* is used to distinguish it from forward planning for conventional 3DCRT. As ICRU 83 concisely notes:

> *The word "inverse" is used in reference to the established body of mathematical inverse problem-solving techniques, which start at the final or desired result and works backwards to establish the best way to achieve it. So-called inverse treatment planning starts by describing a goal, i.e., a series of descriptors characterizing the desired absorbed dose distribution within the tumor, with additional descriptors designed to spare normal tissues*.

The inverse planning process works iteratively to determine beam shapes and fluence patterns to achieve an optimal or acceptable absorbed dose distribution. The IMRT optimization software iteratively adjusts beam parameters with the aim of obtaining the best possible approximation of the desired dose distribution. In each optimization iteration, the optimization software computes the value of the objective function (i.e., the IMRT plan score) to judge the overall quality of each of a large number of plans to choose the optimum one. However, it must be kept in mind that limitations of planning time may preclude full exploration of all the degrees of freedom (there can be many thousands), so whether the optimization is done by a variant of gradient or stochastic methods, the computed solution may not be the true global one. Importantly, the final review by the radiation oncologist of any plan is required.

IMRT is the most conformal and efficient technique when all target volumes (gross disease, subclinical extensions, and electively treated nodes) are treated simultaneously using different fraction sizes. Such a treatment strategy has been called the simultaneous integrated boost (SIB).[16,20] This is in contrast to conventional radiation therapy in which the same fraction size (typically 1.8 or 2 Gy) is used for all target volumes with successive reductions in field sizes to protect critical normal structures and to limit the dose to electively treated and subclinical disease regions.

Alternative IMRT Approaches

During the past 20 years, a variety of techniques have been explored for designing and delivering optimized IMRT.[3–5,9,16,18,21–43] Many of these are implemented in commercial IMRT systems. The most significant differences among the various approaches are in terms of the mechanisms they use for the delivery of nonuniform fluences. Although the merits of each often are speculated, the superiority of any of the approaches is difficult to assess because there have been no systematic comparisons of clinical treatment plans.

Of the various approaches proposed, two dominant but significantly different techniques have emerged. Mackie et al.[30] proposed an approach called *tomotherapy* in which intensity-modulated photon therapy is delivered using a rotating slit beam. A temporally modulated slit MLC is used to rapidly move leaves in or out of the slit. Like a computed tomography (CT) unit, the radiation source and the collimator continuously revolve around the patient. The patient is translated either stepwise between successive rotations (serial tomotherapy) or continuously during rotation (helical tomotherapy). For helical tomotherapy, the system looks like a conventional CT scanner and includes a megavoltage portal detector to provide for the tomographic reconstruction of the delivered dose distribution.

A commercial slit collimator (called *MIMiC*) of the type proposed by Mackie et al.[30] was designed and built by the NOMOS Corporation (North American Scientific, Chatsworth, CA), and it was incorporated into the company's serial tomotherapy system, known as Peacock, for planning and rotational delivery of intensity-modulated treatments.[3,25] Figure 11.2 shows an original "binary" collimator built by NOMOS and as mounted on a LINAC. The figure also shows a modern tomotherapy machine.

In the second approach, implemented first into clinical use at Memorial Sloan-Kettering Cancer Center,[4,5,18,32,33,40,44] a standard MLC is used to deliver the optimized fluence distribution in either dynamic mode (defined as the leaves moving while the radiation is on) or static mode (i.e., "step-and-shoot" mode, defined as sequential delivery of radiation subportals that combine to deliver the desired fluence distribution), to deliver a set of intensity-modulated fields incident from fixed-gantry angles (see Fig. 11.3). These techniques are gaining wide acceptance rapidly. Every major commercial treatment planning system manufacturer has implemented one or both of these.

A third approach, called *intensity-modulated arc therapy* or IMAT, developed by Yu,[43] uses a combination of dynamic multileaf collimation and arc therapy. The method is similar to the step and shoot in that each field is subdivided into

subfields of uniform intensity, which are superimposed to produce the desired intensity modulation. However, the MLC moves dynamically to shape each subfield while the gantry is rotating and the beam is on all the time. Multiple superimposing arcs are delivered with the leaves moving to new positions at a regular angular interval, for example, 5 degrees. Each arc is programmed to deliver one subfield at each gantry angle. A new arc is started to deliver the next subfield and so on until all the arcs and their associated subfields have been all delivered. A typical treatment takes three to five arcs, and the operational complexity is comparable to conventional arc therapy.[45] It has the theoretical advantage of increased flexibility in delivering highly conformal plans by using a large number of beam directions. The IMAT delivery technique was never widely utilized partly because of the necessity of treating several arcs to deliver a single IMAT treatment field. In the late 2000s, both Varian and Elekta introduced variable dose rate rotational delivery options into their linear accelerators. The delivery of a rotational cone beam with variable shape and intensity is commonly called volumetric-modulated arc therapy (VMAT). In a VMAT treatment, in order to create a satisfactory dose plan with a single arc, it is necessary to optimize the field shapes and beam intensities from a large number of gantry angles. However, the field shapes are restricted by the constraints placed on MLC leave motions. The MLC leaves must be able to move to their new positions within the time required for the gantry to rotate between consecutive gantry positions. Unfortunately, the larger the sampled gantry angles, the more difficult it is for the TPS to optimize the MLC leave motion constraints. A novel plan optimization for a VMAT delivery was first proposed by Otto.[46] Other optimization algorithms have since been developed.[47,48] The biggest advantage of a VMAT delivery is in its delivery efficiency. Several investigators have reported significant reductions in treatment times and possible MUs over conventional IMRT.[49–51] One major benefit of VMAT compared with tomotherapy is the possibility of delivering this treatment on conventional linear accelerators, which are configured to have this capability. Currently, there are several VMAT systems available under various names (RapidArc, Varian; SmartArc, Phillips; and Elekta VMAT, Elekta). Arc therapy is discussed in a recent review of various intensity-modulated techniques.[52]

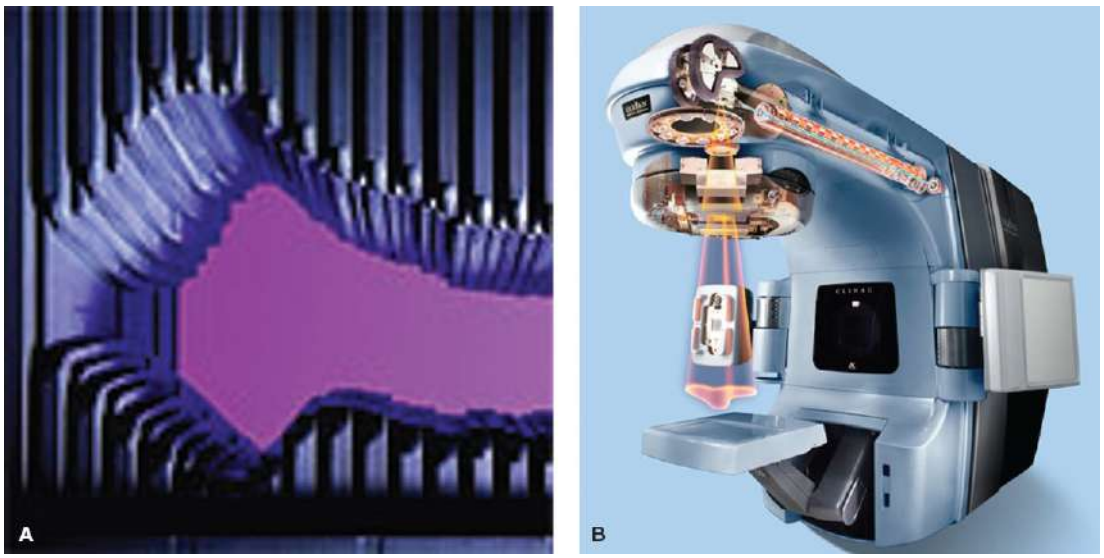

FIGURE 11.3. **A:** A typical multileaf collimator used for delivery of intensity-modulated radiation therapy looking toward the radiation source. In the dynamic mode, the leaves move back and forth or sweep across the field continuously to form the sequence of required field shapes while the beam is on. In the static or step-and-shoot mode, the beam is turned off when the leaves move to form the required field

shapes. **B:** Cutaway diagram of LINAC head, Varian Clinac. (Courtesy of Varian, Palo Alto, CA.)

IMRT techniques have led to improved conformal dose delivery methods. However, IMRT tends to have higher monitor units (MU) compared to 3DCRT technique. This contributes to higher leakage from the gantry head and consequently increased dose to normal tissues and whole body in general.[53] This undesirable dose is likely to result in higher second tumor induction rate.[54] It is, therefore, desirable to reduce the unnecessary scatter from the gantry head and shorten the treatment time for IMRT delivery. The removal of the flattening filter has been a logical choice to reduce the scatter.[55] The development of IMRT eliminates the need for a flattening filter in modern linear accelerator (LINAC) systems. In recent years, the application of the flattening filter-free (FFF) photon beam has been studied extensively.[56–61] Forward peaked dose profile is the major characteristic of the FFF beam.[62–65] Compared with the flattened beam, the FFF beam also has increased dose rate,[57,58] reduced dose to organ at risk (OAR),[66,67] reduced neutron contamination for high-energy beams (>15 MV),[68] and reduced uncertainty in dose calculation.[57] Thus, clinical application of the FFF beam would lead to reduced treatment time and secondary cancer risk induced by radiation.[58,59]

In addition to these approaches, the University of Michigan has used the so-called multisegment approach in which each of a number of beams is divided into multiple segments.[69] One segment for each beam frames the entire target, whereas the others spare one or more normal structures. Each segment is uniform in intensity. The weights of segments of all beams are optimized to produce the desired treatment plan. The treatments are delivered as a sequence of multiple uniform field segments. A similar approach previously was proposed by Mohan et al.[70] In almost all of these significantly different treatment delivery approaches, the underlying principles of optimization are similar, although the specifics may be quite different.

THE IMRT PROCESS OVERVIEW

As mentioned previously, there are significant differences in 3DCRT and IMRT concepts and processes. Yet, there are also many similarities. In particular, IMRT relies on many of the same imaging, dose calculations, plan evaluation, quality assurance (QA), and delivery tools as 3DCRT.

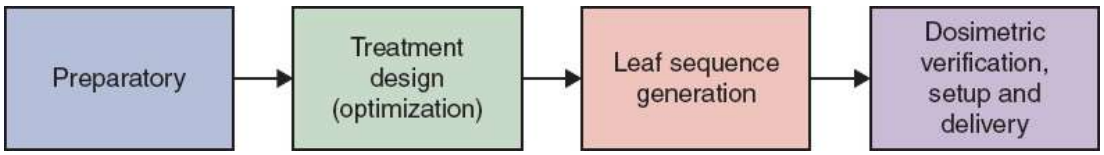

FIGURE 11.4. Overview of a typical intensity-modulated radiation therapy planning and delivery process.

The IMRT planning, QA, and delivery phases of the dynamic or static MLC process are summarized in Figure 11.4. Figure 11.5 shows the steps in each phase of the IMRT optimization process. The tomotherapy process is similar, except that the fixed beam angle selection is replaced by selection of the slice thickness and, for serial tomotherapy, the gantry rotation angles.

In the preparatory phase of the IMRT process, volumes of interest (such as tumors and normal organs) are delineated on 3D CT images,[71] often with assistance from other coregistered imaging modalities. The second imaging technique most often used is magnetic resonance imaging (MRI); the latter has an advantage over CT in that it can provide both structural and physiologic information.[72] Other imaging modalities such as positron emission tomography (PET) use intrinsic or externally added molecular markers to visualize specific metabolic processes or cellular phenotypes.[73–77] Also, the desired objectives in the form of an objective function, its parameter values, and the IMRT fractionation strategy are specified, and beam configuration is defined. Typically, the objective function[78] assigns a weighted "cost" to the square of the difference between the desired 3D fluence distribution and that calculated at a given iteration. The software attempts to minimize the costs—maximizing dosage to the tumor volume and minimizing exposure of normal tissues.

In the treatment plan optimization phase, an iterative process is used to adjust and set the intensities of rays of each beam (or portion of the arc) so that the resulting intensity distributions yield the best approximation of the desired objectives. The IMRT plan then is evaluated to ensure that the trade-offs made by the optimization system are acceptable. If further improvement is deemed necessary and possible, the objective function parameters are modified, and the optimization process is repeated until a satisfactory treatment plan is achieved.

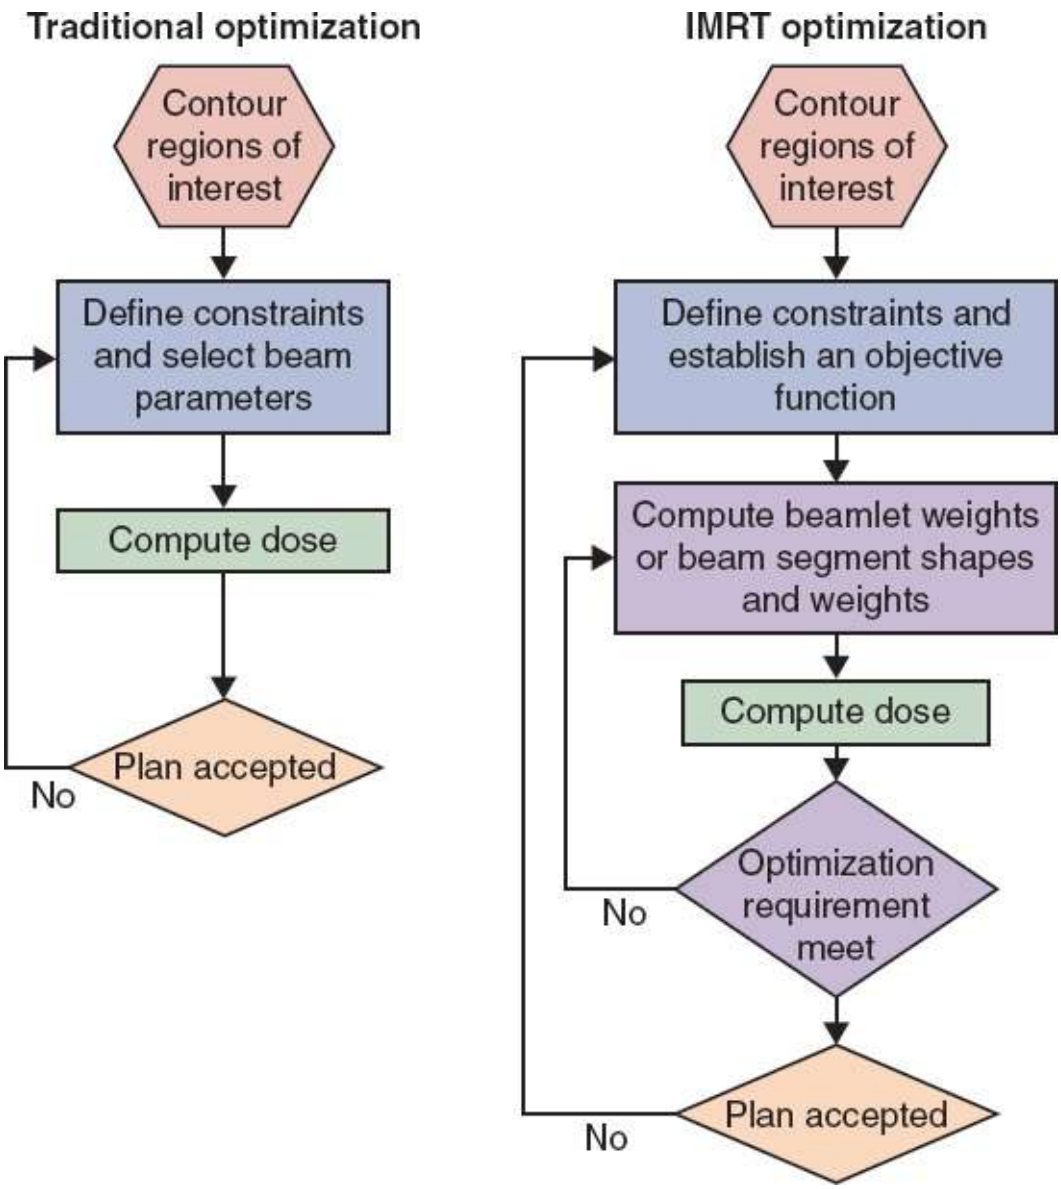

FIGURE 11.5. Comparison between traditional (*left*) and intensity-modulated radiation therapy (IMRT) (*right*) optimization processes. (From International Commission of Radiation Units and Measurements. ICRU Report 83: prescribing, recording, and reporting photon-beam intensity-modulated radiation therapy [IMRT]. *J ICRU* 2010;10[1]:1–106. Reproduced by permission of International Commission on Radiation Units and Measurements.)

In the leaf sequence generation phase, the intensity distributions are converted into sequences of leaf positions. It is conceivable that certain dose distributions cannot be delivered as a result of the leakage characteristics of the delivery devices. Therefore, in most treatment planning systems, the leaf sequences are used in a reverse process to calculate the dose distributions they are expected to deliver. These dose distributions, called the *deliverable dose distributions*, are

evaluated for clinical adequacy. If necessary, objective function parameters are further adjusted to produce an intensity distribution that leads to a deliverable dose distribution that meets the desired objectives. This is the practice in most systems. However, in some systems, the leaf sequence generation process is incorporated into the IMRT plan optimization loop so that the optimized and deliverable dose distributions are identical. More details on this are given later in this chapter.

The leaf sequences then are transmitted to the treatment machine and used to verify that the dose distribution that will be delivered to the patient is correct and accurate. The patient then is set up in the usual fashion and treated. In general, the entire treatment is delivered remotely without the need to re-enter the treatment room in between fields.

PREPARATORY AND IMRT PLANNING PHASES

This section discusses each of the steps of the preparatory and IMRT plan design phases. For reasons of clarity, the order in which these steps are discussed is not the same as the order in which they occur as shown in Figure 11.5. Figure 11.6 sketches the QA process.

Imaging and Volumes of Interest

ICRU 83 presents updated definitions for the assorted volumes that will form the skeleton of the treatment plan.[1] Conceptually, the volumes contain three types of tissue: (a) malignant/benign lesion, (b) otherwise normal tissue near the tumor that is already or likely to be infiltrated by microscopic disease, and (c) more distant normal tissue and organs. The quoted definitions that follow are from ICRU 83.

- *Gross tumor volume (GTV)*: "The GTV is the gross demonstrable extent and location of the tumor. The GTV may consist of a primary tumor (primary tumor GTV or GTV-T), metastatic regional node(s) (nodal GTV or GTV-N), or distant metastasis (metastatic GTV or GTV-M)."[1] They note that in some cases, it may not be possible to differentiate expanding primary lesions from nearby metastatic disease. The GTV for IMRT is always defined from anatomic images, usually CT with or without MRI, and increasingly supplemented by PET.
- *Clinical target volume (CTV)*: "The CTV is a volume of tissue that contains a demonstrable GTV and/or subclinical malignant disease with a certain

probability of occurrence considered relevant for therapy. There is no general consensus on what probability is considered relevant for therapy, but typically, a probability of occult disease higher than from 5% to 10% is assumed to require treatment."[1] The volumes outside the GTV encompassed by the CTV will depend a great deal on the particular tumor (e.g., with high or low propensity for lymph node extension). In the past, the CTV was effectively the GTV (including affected nodes) plus a 1- to 2-cm margin. The current definition stresses more the physiologic criteria based on the specifics of disease spread for each tumor. Gregoire et al.[79] have compiled studies on CTV margins into a book. In postoperative situations, following an R0 or R1 resection, there is no gross tumor, so only the CTV need be defined. Readers are strongly encouraged to consult ICRU 83 for details.

- *Planning target volume (PTV)*: "The PTV is a geometrical concept introduced for treatment planning and evaluation. It is the recommended tool to shape absorbed dose distributions to ensure that the prescribed absorbed dose will actually be delivered to all parts of the CTV with a clinically acceptable probability, despite geometrical uncertainties such as organ motion and setup variations."[1]
- *Organ at risk (OAR)*: "The OAR or critical normal structures are tissues that if irradiated could suffer significant morbidity and thus might influence the treatment planning and/or the absorbed dose prescription. In principle, all nontarget tissues could be OARs. However, normal tissues considered as OARs typically depend on the location of the CTV and/or the prescribed absorbed dose."[1] All normal tissue exposed to radiation during treatment is at risk, but the OAR is generally taken to be rather more specific—structures in the immediate vicinity of the PTV, sparing of which may demand specific recontouring of the CTV or PTV. Historically, OARs have been loosely grouped into "serial" or "parallel" organs or a combination of the two, following the work of Withers et al. using the concept of functional subunits in each organ.[80,81] Serial organs, such as the spinal cord, can suffer unacceptable damage if only a small portion is irradiated, whereas parallel organs, such as the liver, can suffer loss of a portion without total loss of function.
- *Planning organ at risk volume (PRV)*: "As is the case with the PTV, uncertainties and variations in the position of the OAR during treatment must be considered to avoid serious complications. For this reason, margins have to be added to the OARs to compensate for these uncertainties and variations, using similar principles as for the PTV. This leads, in analogy with the PTV, to the concept of PRV."[1] As with the OAR itself, margins in the PRV will be affected by the serial or parallel attributes of the adjacent tissues.

- *Remaining volume at risk (RVR)*: "The RVR is operationally defined by the difference between the volume enclosed by the external contour of the patient and that of the CTVs and OARs on the slices that have been imaged."[1] Definition of an RVR and its inclusion in the treatment plan (at least in the form of dose constraints) is essential in IMRT. Without such limits, the optimization software could craft excellent dose distributions for the CTV and OAR but cause toxic irradiation levels in otherwise uncontoured tissues.
- *Treated volume (TV)*: "The TV is the volume of tissue enclosed within a specific isodose envelope, with the absorbed dose specified by the radiation oncology team as appropriate to achieve tumor eradication or palliation, within the bounds of acceptable complications."[1] The TV is what is physically deliverable given limitations of beam collimation and homogeneity and, more importantly, the risks of treatment-associated morbidity acceptable to the oncologist and the patient. ICRU 83 proposes that, in conformity with its proposal for proton therapy, the TV be defined as the dosage received by 98% of the PTV. This serves as a measure of the minimum absorbed dose and is also referred to as $D_{\text{near minimum}}$. In an analogous manner, a $D_{\text{near maximum}}$ is defined as $D_{2\%}$, the dose received by 2% of the PTV receiving the highest fluence. Readers are referred to Section 3 of ICRU 83.

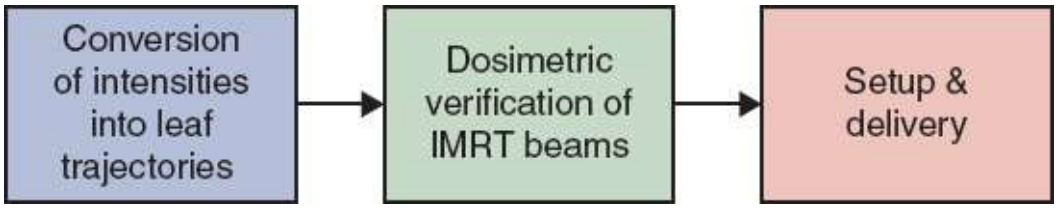

FIGURE 11.6. Intensity-modulated radiation therapy (IMRT) process: quality assurance (QA) and delivery phase.

It should be noted that the GTV, CTV, and OAR represent volumes based on anatomic and physiologic judgments on the location of malignant growths or normal tissues in danger from metastatic spread and/or treatment-induced toxicity. These are independent of the particular irradiation protocol employed (i.e., 3DCRT, IMRT, or particle beams). The PTV, PRV, and TV are intimately tied to the specific radiation therapy used.

Beam Configurations

Systems Using Fixed Intensity-Modulated Fields

The beam configuration can have a significant impact on the quality of an optimized IMRT plan. It may be argued that, because of the greater control over

dose distributions afforded by optimized intensity modulation, the fine-tuning of beam angles may not be as important for IMRT as it is for standard radiotherapy. However, optimization of beam angles may find paths least obstructed by critical normal tissues, thus facilitating the achievement of desired distribution with a minimum of compromise.

Beam angle optimization, however, is not a trivial problem. There have been some attempts to solve this problem,[82–84] and advances in mathematical operations research applied to the problem have been reviewed recently.[85] To appreciate the magnitude of the problem, consider the following example. If the angle range is divided into 5-degree steps, nearly 60,000 combinations would need to be tested for three beams, nearly 14 million combinations for five beams, nearly 1.5 billion combinations for seven beams, and so on. Considering the magnitude of the search space, none of the optimization methods is likely to be able to demonstrate a significant improvement in treatment plans, let alone find a truly optimum combination when the number of beams is five or more. Furthermore, the beam angle optimization problem is known to have multiple minima,[86] which means that fast gradient-based optimization techniques may fail. Stochastic methods,[87,88] in principle, should avoid the local minimum problem but may present excessive computing time demands. These should prove less of a problem in the near future, especially with the use of dedicated parallel processors, which can drastically reduce computation time. For a review, see Pratx and Xing.[89]

Another question that may be asked is how many beams are optimal. In principle, a larger number of beams would provide a larger number of parameters to adjust and therefore a greater opportunity to achieve desired dose distributions. (Thus, in theory, a rotational beam would be the ultimate.) However, for fixed beam IMRT, it may be desirable to minimize the number of beams to reduce the time and effort required for planning, QA, dosimetric verification, and delivery of treatments. Fewer intensity-modulated beams would be needed if beam angles were optimized than if the beams were placed at equiangular steps. Calculations by Webb[10] indicate that seven or nine fields give adequate conformal dose distributions for both serial tomography and fixed-gantry IMRT. Consideration of technical feasibility of the plan is very important.

Figure 11.7 compares prostate treatment plans employing different numbers of fields using 3DCRT, serial tomography, and step-and-shoot IMRT. Consistent with published experience, the plan quality improves, but the incremental improvement diminishes with increasing number of beams. Optimum

nonuniform placement of beams can further improve dose distribution. Figure 11.8A and B shows a head and neck IMRT case for two different beam angles. The patient, treated with the beam configuration shown in Figure 11.8A, developed significant mucositis at the early phase of treatment. This was consistent with the "horn" in dose distribution shown by the arrow. Revising the beam angle arrangement as shown in Figure 11.8C led to improved dose distribution, shown in Figure 11.8D.

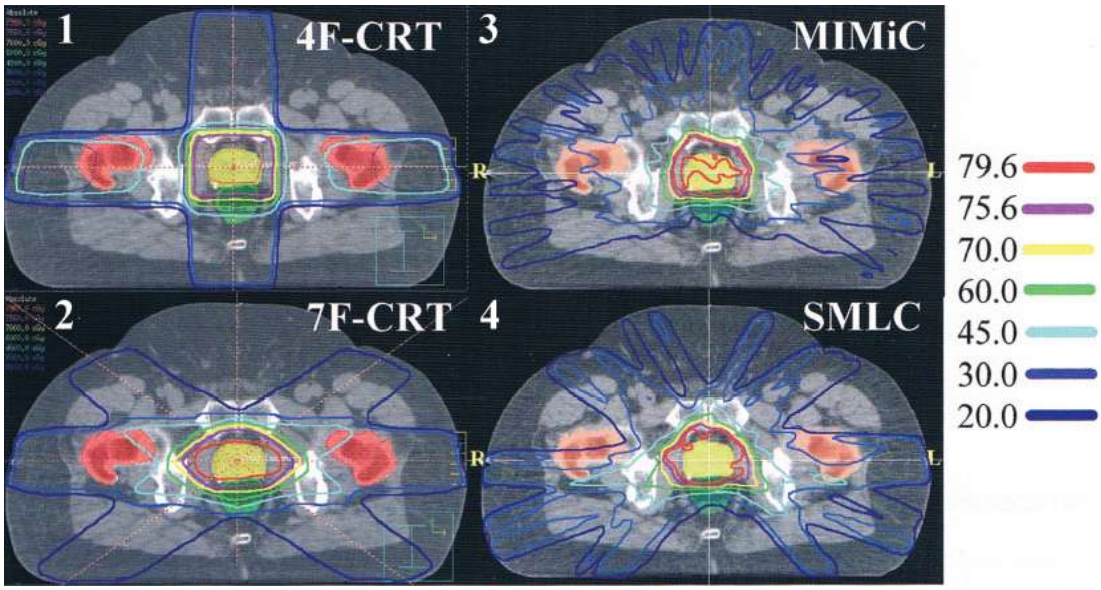

FIGURE 11.7. Typical isodose distributions for treating prostate cancer from (*1*) a four-field three-dimensional conformal radiation therapy (3DCRT) plan; (*2*) a seven-field 3DCRT plan; (*3*) an intensity-modulated radiation therapy (IMRT) plan delivered by serial tomotherapy using MIMiC (NOMOS Corp, Sewickley, PA); and (*4*) a 10-field step-and-shoot segmental multileaf collimator (SMLC) plan. (Reprinted from Clifford Chao KS, Apisarnthanarax S, Ozyigit G. *Practical essentials of IMRT.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005. With permission.)

In general, it is most advantageous to place beams so that they are maximally avoiding each other and the opposing beams with the stipulation that directions that overlap significant obstructions, such as heavily attenuating bars in the treatment couch, be avoided. For simplicity, beams often are constrained to lie in the same transverse plane. However, noncoplanar beams will provide an additional degree of freedom and potentially an additional gain in the quality of treatments but at the expense of setup variability. It should be noted that the beam configurations used for 3DCRT may not be optimal for IMRT.[90]

Although reducing the number of beams is a desirable goal for IMRT delivered with several fixed-gantry angles and dynamic MLC, it should not be

the overriding consideration. IMRT can be planned and delivered automatically in times not significantly different from the times for much simpler conventional treatments. Therefore, the delivery times for 6 to 20 beams may be quite acceptable.

Systems Using Rotating Arc Approach

Tomotherapy delivery has substantial differences from fixed-portal IMRT. Mackie[91] has published a historical review of tomotherapy, intertwined as it is with his career. The linear accelerator rotates during delivery, and the beams are modulated during rotation. Typically, the modulation is subdivided into small gantry angle ranges (e.g., 5 degrees), and the beam is independently modulated at each gantry angle. Each leaf is used to deliver a single rotating pencil. The pencil-beam modulation is conducted for each leaf by opening that leaf for a fraction of the gantry range consistent with the fractional fluence to be delivered from that gantry angle. For example, for a 5-degree-angle-range bin, if a leaf is to deliver 50% fluence, the leaf will be open for 2.5 degrees over the 5-degree range. Because of geometric constraints of modulating the radiation fan beams, only one or two thin planes can be treated with each rotation. The Peacock system,[3] for instance, uses two banks of opposing leaves projecting to 1.7 or 3.4 cm, depending on user-selected mechanical stops. This delivers modulated beams to two abutting, independently modulated planes. The helical tomotherapy unit uses a single leaf bank with a backup collimator that allows the radiation field width to be continuously adjusted. Narrower leaf widths provide higher spatial resolution for modulation but require more treatment arcs and consequently more delivery time. The current TomoHD MLC uses tungsten leaves 10 cm thick (in beam direction) and with a width of 0.625 cm. Leaves are driven pneumatically and switch in 20 msec.

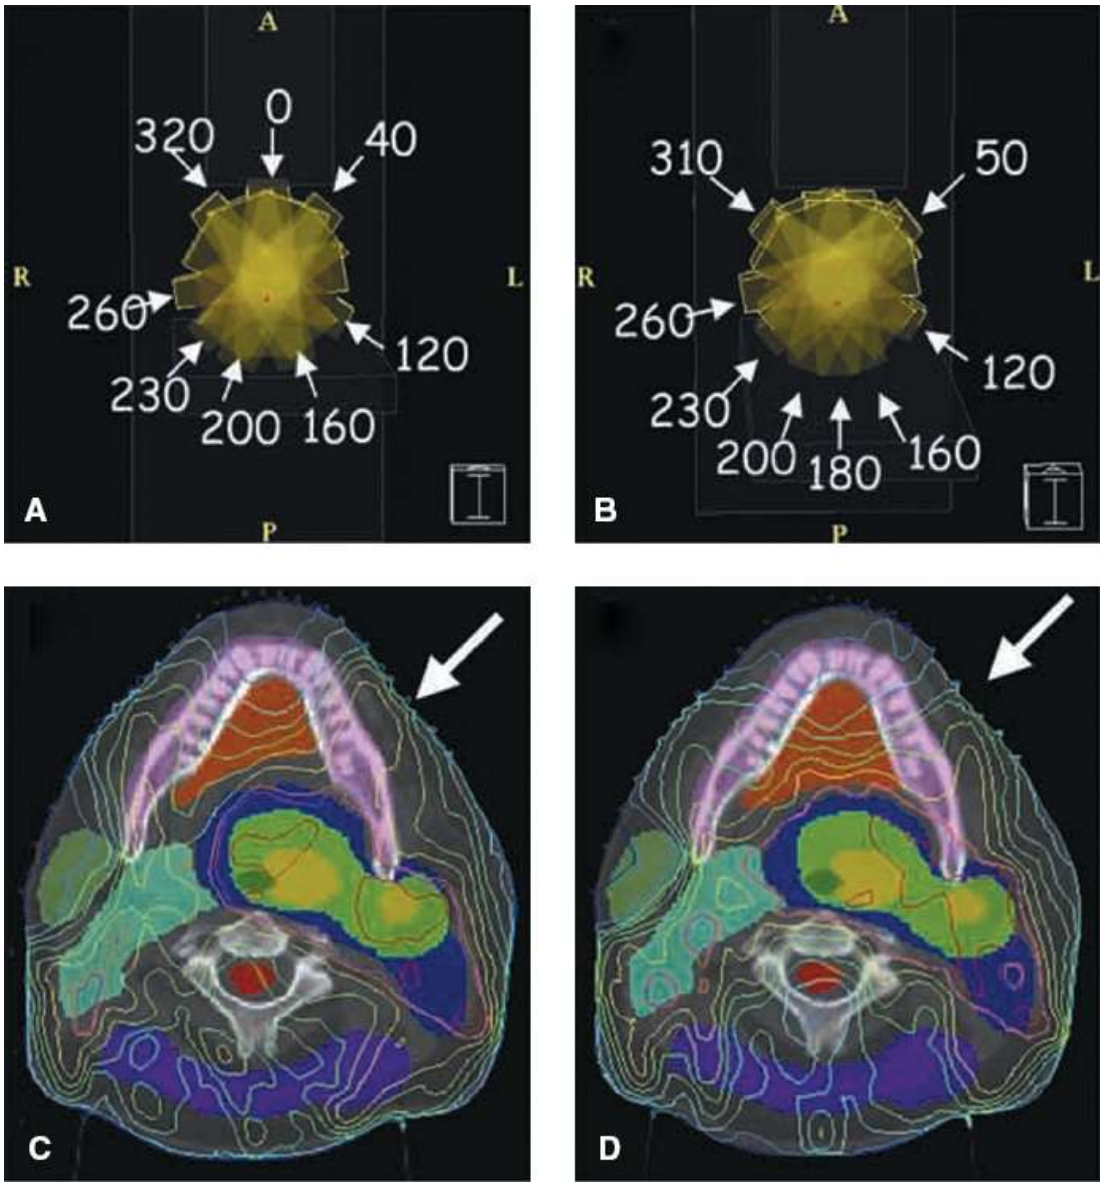

FIGURE 11.8. A patient with carcinoma of the base of the tongue was treated with intensity-modulated radiation therapy. **A** and **B** depict the beam angle arrangement and the resulting isodose distribution. *Arrow* on **(C)** indicated a "horn" of high dose to the left oral tongue and buccal mucosa. Rearrangement of anterior beam placement as shown in **(B)** led to improvement of dose distribution to the normal mucosa of the left anterior oral cavity **(D)**.

In a VMAT treatment, the gantry rotates continuously, with MLC leaves, gantry rotation speed, and dose rates varying throughout the arc. VMAT is similar to tomotherapy in that the LINAC source rotates through a 360-degree arc around the patient. The most important difference between the two methods arise from the slice-by-slice delivery of tomotherapy versus the single arc volumetric delivery of VMAT. The difficulty with the optimization of VMAT

field shaping throughout the arc is that the MLC leaf position changes between consecutive gantry positions must be restricted. The novel optimization for VMAT proposed by Otto employed a technique called progressive sampling to alleviate this problem.[46] In this approach, the arc is subdivided into a small number of gantry angle samples (e.g., 6), whose beam shapes and/or intensities are varied during the first iteration of the optimization. There are little if any restrictions on MLC leaf position for these fields, because the initial samples are spaced far apart. After several iterations, a new arc sample is added with a field shape interpolated between the first two samples, and optimization continues. After more iterations, another new arc sample is added in the fashion midway between samples 2 and 3. This process continues until desired gantry sampling is met. By starting with a small number of samples and gradually introducing new samples, a high-quality plan can be achieved in a short period of time. Also, a sufficient number of samples ensure the preservation of dose modeling accuracy.

Aperture Margins

IMRT has the inherent capacity to reduce margins attributable to the beam penumbra. When a photon beam traverses the body, it is scattered, depositing dose not only along the path of each ray of the beam but also at points away from it. The electrons knocked out by the incident photons travel laterally to points in the neighborhood of each ray, depositing dose along the way. Near the middle of a uniform beam, outgoing electrons are offset by incoming electrons and equilibrium exists. However, at and just inside the boundaries of the beam, there are no incoming electrons to balance electrons flowing out of the beam. Therefore, a “lateral electronic disequilibrium” exists that leads to a dose deficit inside the boundaries of beams. For lower-energy beams and at large depths, scattered photons significantly contribute to this effect also. The conventional approach to overcome this deficiency is to add a margin for the “beam penumbra” to the PTV so that the tumor dose is maintained at the required level.

For IMRT plans, there is another method to counterbalance the dose deficit. The intensity of rays just inside the beam boundary may be increased. Because some of the increased energy must also flow out, a very large increase would be required if the margin for the penumbra were set to zero or to a very small value. Therefore, an increase in boundary fluence alone is not enough. A combination of an increased fluence and the addition of a margin, albeit a much smaller one, is a better solution. This reduction in margin can be exploited quite usefully to reduce the volume of normal tissues exposed to high doses of radiation with a

corresponding reduction in toxicity and a further potential for dose escalation.

The beam boundary–sharpening and margin reduction feature of IMRT can be taken advantage of only if the dose computation method is able to adequately take into account the lateral transport of radiation[92] and if the intensity matrix grid size is sufficiently small. Initially, dose distribution for a given configuration of beams is computed by taking lateral transport into consideration. In each optimization iteration, the intensity distribution first is designed ignoring lateral transport. At the end of the iteration, the dose distribution is recalculated, thereby incorporating the effects of field-shaping devices on lateral transport and revealing the resulting deviations from the anticipated dose distribution. In the next iteration, ray intensities are adjusted further to rectify the deviations, and so on.[44] Carrasco et al.[92] compared several dose computation algorithms in lung phantoms.

A schematic example shown in Figure 11.9 illustrates the issues involved. Figure 11.9A shows a normal organ overlapping the target volume. The target volume is being irradiated by two parallel-opposed beams. It is desired that the dose to the region of overlap be 60% of the target dose. If more dose is delivered, damage to the normal organ may result; but lower than the desired dose may cause local failure. If the role of lateral transport in optimization is ignored, the intensity resulting from the optimization process is essentially a step function, as shown in Figure 11.9B (solid curve). The corresponding dose distribution (the dotted curve) shows a dose deficit inside the high-dose target volume as well as the outside edge of the region of overlap and an excess of dose in the region of overlap adjacent to the high-dose volume. If lateral transport is incorporated by adjusting fluence, the fluence and dose patterns shown in Figure 11.9C result. Fluence is increased at both boundaries. It also is increased in the high-dose side of the interface with the overlap region and decreased on the lower-dose side. The dose is now much closer to the desired dose. Comparing Figure 11.9B and C, it also appears that a modest increase in fluence just inside the boundary does not lead to a perceptible increase in dose outside the beam boundary. This is presumably the result of the fact that the excess dose flowing out of the target periphery is deposited in a much larger volume of tissue. A reduction of margins attributable to penumbra by as much as 8 mm has been found to be feasible for prostate treatments.[44]

IMRT Fractionation

In principle, conventional fractionation strategies can be used to design IMRT

plans as well. For example, in a strategy similar to the conventional 1.8-Gy to 2-Gy/fx schedule, a major portion of the dose could be delivered in the initial phase using uniform fields designed with standard 3D conformal methods followed by an IMRT boost. Alternatively, separate IMRT plans could be designed for both the initial large-field treatment and the boost treatment. It may be intuitively obvious that, if a large portion of the dose already has been delivered using large fields, it may be very difficult, if not impossible, to achieve a high level of dose conformation with the remaining fractions in the IMRT boost phase.[16] As indicated earlier in this chapter, IMRT may be most conformal if all target volumes (gross disease, subclinical extensions, and electively treated nodes) are treated simultaneously using different fraction sizes.[15] Such a treatment strategy has been called the SIB.[12,13,16,20] Mackie et al.[30] had also indicated the possibilities for irradiation boost in their first paper on serial tomography. The SIB IMRT strategy not only produces superior dose distributions but also is an easier, more efficient, and perhaps less error-prone way of planning and delivering IMRT because it involves the use of the same plan for the entire course of treatment. Furthermore, in many cases, there is no need for electron fields, and the nodal volumes can be included in the IMRT fields; thus, the perennial problem of field matching[93] encountered in the treatment of many sites is thereby avoided.

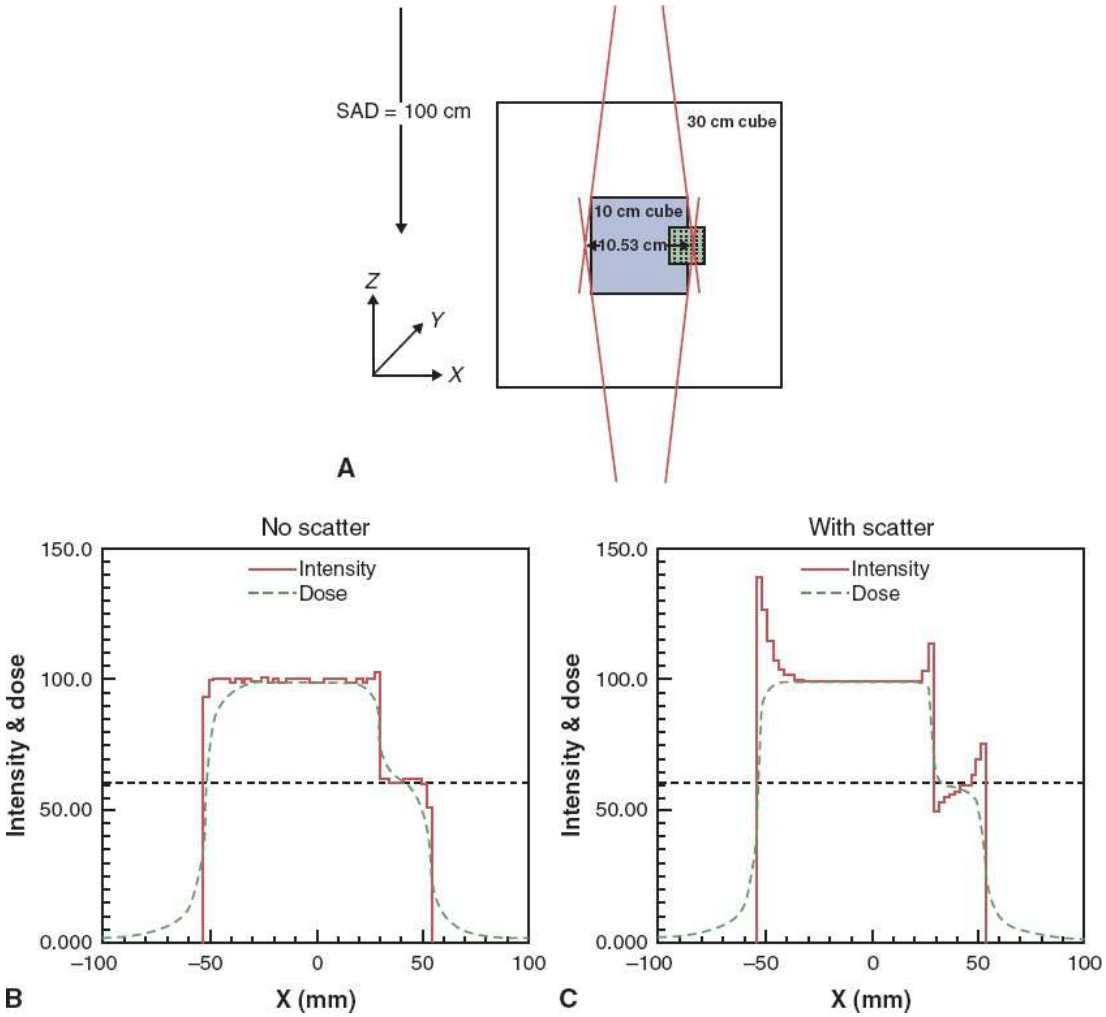

FIGURE 11.9. A–C: A schematic example illustrating the sharpening of penumbra with intensity-modulated radiation therapy.

Because each of the target regions receives different doses per fraction in the SIB IMRT strategy, prescribed nominal (physical) dose and dose per fraction must be adjusted appropriately. The adjusted nominal dose and fraction size for each target region depend on the number of IMRT fractions. The fraction sizes may be estimated using an isoeffect relationship based on the linear-quadratic model and the values of its parameters (such as α/β ratios, tumor doubling time).

The effect of the modified fractionation on acute and late toxicity of normal tissues both outside and within the volumes to be treated also should be considered. Because of the improved conformality of IMRT plans, dose to normal tissues outside the target volume is typically lower than for conventional treatment plans. In addition, if the number of fractions is greater than the number of fractions used to deliver large fields in conventional therapy, the dose per fraction to normal tissues is lower. Therefore, the biologically effective dose

would be lower still. However, normal tissues embedded within or adjacent to the target volumes would receive high doses per fraction and may be at higher risk. Isoeffect formulae for normal tissues also may be derived to estimate the effect of a particular fractionation strategy (see ICRU 83, pp. 36–38). These formalisms would need to incorporate regeneration and change in sensitivity over the treatment course.

The values of parameters for the computation of altered fractionation may, in theory, be obtained from published studies. Studies by Maciejewski et al.[94] and Withers et al.[95–97] for example, have yielded important information for estimating tumor parameters for head and neck carcinoma. In general, the data available are limited. Furthermore, there is considerable uncertainty in the data, and there are concerns about the validity of numerous assumptions in the linear-quadratic model and the isoeffect formalism, especially with regard to normal tissues. (For an early review of the linear-quadratic model, see Fowler.)[98] Much of the accumulated data on normal tissue complications comes from clinical experience in the era of wide-field radiation therapy, so the dosage limits reported from such studies may not be immediately applicable to IMRT. Nevertheless, various investigators have carried out the necessary calculations and adopted SIB IMRT fractionation strategies. Continued investigations and clinical trials are needed to develop more reliable time–dose fractionation models, to produce better estimates of their parameters, and to evaluate alternate SIB IMRT fractionation strategies for all sites.[14] The following are some examples of IMRT fractionation strategies that have been used for IMRT of head and neck cancers.

In the Radiation Therapy Oncology Group H-0022 protocol for early-stage oropharyngeal cancer, 30 daily fractions (5 per week × 6 weeks) are used to simultaneously deliver 66 Gy (2.2. Gy per fraction) to the PTV, 60 Gy (2 Gy per fraction) to the high-risk subclinical disease (“levels II to IV bilaterally, Ib ipsilaterally, and level V and retropharyngeal nodes if the jugular nodes were involved”), and 54 Gy (1.8 Gy per fraction) to subclinical disease. These are biologically equivalent to 70, 60, and 50 Gy, respectively, if given in 2 Gy per fraction. For normal structures, brainstem, spinal cord, and mandible are maintained below 54, 45, and 70 Gy, respectively. The mean dose to the parotid glands is maintained below 26 Gy, and/or 50% of one of the parotids is maintained below 30 Gy and/or at least 20 mL of the combined volume of both parotids is constrained to receive no more than 20 Gy. Sixty-nine patients were accrued at 14 institutions. Treatment-associated xerostomia improved following

therapy, in contrast to regular radiation therapy. High locoregional control was achieved with stringent adherence to protocol guidelines.[99]

The SIB strategy at Virginia Commonwealth University involves a dose escalation protocol in which primary nominal dose levels of 68.1, 70.8, and 73.8 Gy, given in 30 fractions (biologically equivalent to 74, 79, and 85 Gy, respectively, if given in 2 Gy per fraction), are used.[100] Simultaneously, the subclinical disease and electively treated nodes were prescribed 60 and 54 Gy, respectively (biologically equivalent to 60 and 50 Gy, respectively, if given in 2 Gy fractions). Spinal cord and brainstem are maintained below 45 and 55 Gy, respectively, and an attempt is made to allow no more than 50% of at least one parotid to receive higher than 26 Gy.

At the Mallinckrodt Institute of Radiology, the SIB strategy for definitive IMRT prescribes 70 Gy in 35 fractions in 2 Gy per fraction to the volume of gross disease with margins. The adjacent soft tissue and nodal volumes at high risk were treated to 63 Gy in 1.8 Gy per fraction and simultaneously 56 Gy in 1.6 Gy per fraction to the elective nodal regions. This regimen has been shown to be well tolerated when combined with concurrent chemotherapy.[101]

The normal tissue constraints for head and neck sites based on the most recent NRG and RTOG protocols (0912, HN001, HN002, HN003) are optic nerve and chiasm <54 Gy; eyes <45 Gy; brainstem <50 to 54 Gy to any 0.03 cc volume; brain <60 Gy to any 0.03 cc volume; spinal cord <45 to 50 Gy to any 0.03 cc volume; ipsilateral cochlea <50 Gy; parotid glands mean dose <26 Gy and at least 20 cc volume <20 Gy; submandibular glands mean <39 Gy; mandible <60 Gy; cervical esophagus mean <34 Gy; and pharynx mean <40 to 45 Gy (for details, see www.nrgoncology.org). Other workers[102–104] have determined dose levels to the pharyngeal constrictors above which severe dysphagia will occur: V (65 Gy) >30%, V (55 Gy) >80%, and a mean dose >60 Gy were predictive of feeding tube dependence.

Optimization of Intensity Maps

The optimization of ray intensities may be carried out using one of several mathematical formalisms and algorithms, also termed *optimization engines*.[85] Each method has its strengths and weaknesses. The choice depends in part on the nature of the objective function and in part on individual preference. Although the details are complex, the basic principles are not difficult to comprehend. Each ray of each beam is traced from the source of radiation through the patient. Only the rays that pass through the target volume need to be traced (plus through

a small margin assigned to ensure that the lateral loss of scattered radiation does not compromise the treatment). Others are set to a weight of zero.

The patient's 3D image is divided into voxels. The dose at every voxel in the patient is calculated for an initial set of ray weights. The resulting dose distribution is used to compute the "score" of the treatment plan (i.e., the value of the objective function that mathematically states the clinical objectives of the intended treatment).

The ray-tracing process identifies the tumor and normal tissue voxels that lie along the path of the ray. The effect of a small change in a ray weight on the score then is calculated. If the increase in ray weight would result in favorable consequences for the patient, the weight is increased, and vice versa. Mathematically speaking, the ray weight is changed by an amount proportional to the gradient of the score with respect to the ray weight. Realizing that the improvement in the plan at each point comes from rays from many beams and that each ray affects many points, only a small change in ray weight may be permitted at a time. This process is repeated for each ray. At the end of each complete cycle (an iteration), a small improvement in the treatment plan results. The new pattern of ray intensities then is used to calculate a new dose distribution and the new score of the plan, which then is used as the basis of further improvement in the next iteration. The iterative process continues until no further improvement takes place, the optimization process is assumed to have converged, and the optimum plan is assumed to have been achieved.

Many current optimization systems use variations of gradient techniques to optimize IMRT plans. These calculations are prodigious given the thousands of free parameters in variation—it was only with the advent of powerful and affordable computers that such calculations could become clinically realistic. Direct aperture optimization has been proposed as an alternative that reduces the parameter space and eliminates nonphysical dose distributions at the start; for a review, see Broderick.[105] The use of gradient techniques assumes that there is a single extremum (a minimum or a maximum, depending on the form of the objective function). This is indeed the case for objective functions based on variance of dose and when only ray weights are optimized. For other cases, it would be necessary to determine whether multiple extrema exist and whether such multiple extrema have an impact on the quality of the solution found. Multiple extrema have been found to exist when beam directions are optimized or when dose–response-based objective functions are used to optimize weights of uniform beams.[70,86,87] One can expect that multiple minima also exist when

dose–response-based objective functions are used to optimize IMRT plans. Using simple schematic examples, it also has been shown that multiple minima exist when dose–volume-based objectives are used.[106] Although this may be the case in theory, the existence of multiple minima has not been found to be a serious impediment in dose–volume-based or dose–response-based optimization using gradient techniques. In fact, in a study of dose–volume-based IMRT optimization, Wu and Mohan[107] found that, starting from vastly different initial intensities, the solutions converged to nearly the same plans. The reasons for this have been speculated but not conclusively proven and need to be investigated further.

If multiple minima are discovered to be a factor, then some form of stochastic optimization technique may need to be considered. At the simplest, one may use a random search technique in conjunction with one of the gradient techniques. A more sophisticated stochastic technique is "simulated annealing" or its variation, the "fast simulated annealing."[9,41,70,87] These techniques allow the optimization process to escape from the local minima traps. Other forms of stochastic approaches, such as "genetic algorithms," also have been proposed.[108] In principle, the simulated annealing technique and other stochastic approaches can find the global minimum, but, practically, there is no guarantee that the absolute optimum has been found, only that the best among the solutions examined has been found. (This, of course, is true for gradient techniques as well.) Stochastic techniques tend to be extremely slow and should be used in routine work only if it is established that they are necessary. Nevertheless, some commercial systems have implemented the simulated annealing approach for IMRT optimization.[3] Also, as noted earlier, rapid advances in parallel processing using off-the-shelf components can dramatically reduce computation times.[89] In 2005, Xu and Mueller[109] reported an order of magnitude decrease in the time to process a CT image on a PC when equipped with a dedicated graphics board.

OBJECTIVE FUNCTIONS

Dose-Based Objective Functions

A simple example of an objective function is the criteria stated in terms of the sum of the squares of the differences of desired dose and computed dose at each point within each of the volumes of interest. That is,

$$S = \sum_i (D_{T,0} - D_{T,i})^2 + \sum_n \sum_j p_n \times H(D_{n,0} - D_{n,j}) \times (D_{n,0} - D_{n,j})^2 \quad (1)$$

This type of objective function is called the *quadratic* or *variance* objective function. The optimization process attempts to minimize the treatment plan score *S*. $D_{T,0}$ in expression Eq. (1) is the desired dose to the target volume, and $D_{n,0}$ is the tolerance dose of the *n*th normal structure. $D_{T,i}$ is the computed dose at the *i*th voxel of the target, and $D_{n,j}$ is the computed dose at the *j*th voxel of the *n*th normal structure. For normal organs, the function $H(D_{n,j} - D_{n,0})$ is a Heaviside step function defined as follows:

$$H(D_{n,j} - D_{n,0}) = 0 \quad \text{for} \quad D_{n,j} \le D_{n,0} \quad \text{and} \qquad = 1 \quad \text{for} \quad D_{n,j} > D_{n,0} \tag{2}$$

In other words, so long as the dose in a normal tissue voxel does not exceed the tolerance limit, the voxel does not contribute to the score function. The quantity p_n is the "relative penalty" for exceeding the tolerance dose.

Dose–Volume-Based Objective Functions

Purely dose-based criteria, such as the one previously described, are not sufficient. In general, the response of the tumor and normal tissues is a function of not only radiation dose but also (to varying degrees depending on the tissue type) the volume subjected to each level of dose. Currently, dose–volume-based objective functions are the most widely used clinically. Dose–volume-based objective functions are expressed in terms of the limits on the volumes of each structure that may be allowed to receive a certain dose or higher. ICRU 83 sets its IMRT reporting guidelines in terms of dose–volume criteria, and dose–volume histograms (DVHs) are a mandatory part of treatment planning.

A practical scheme to incorporate dose–volume-based objectives has been suggested by Bortfeld et al.[110] It is explained in Figure 11.10 using a simple schematic example of one organ at risk. The dose–volume constraint is specified as $V(>D_1) < V_1$. In other words, the volume receiving dose greater than D_1 should be less than V_1. To implement such a constraint into the objective function, we seek another dose value D_2 so that in the current DVHs $V(D_2) = V_1$. The objective function component for this OAR then may be written as:

$$p_n \cdot \sum_i H(D_2 - D_j) \cdot H(D_j - D_1) \cdot (D_j - D_1)^2 \tag{3}$$

That is, only the points with dose values between D_1 and D_2 contribute to the score. Therefore, they are the only ones penalized.

For the target volumes, two types of dose–volume criteria may be specified to limit both the hot and cold spots. For instance, for the desired target dose of 80 Gy, we may specify V (>85 Gy) ≤ 5% and V (>79 Gy) ≥ 95%. In other words, the volume of the target receiving dose >85 Gy should be no more than 5%, and the volume of target receiving 79 Gy or higher should be at least 95%. Dose-based criteria can be considered as a subset of the dose–volume criteria in which the volume is set to an extreme value (0% or 100%, as appropriate). Dose–volume criteria provide more flexibility for the optimization process and greater control over dose distributions. The reason is that dose-based optimization penalizes all the points above the dose limit, whereas the dose–volume-based optimization penalizes only the subset of points within the lower end of range of dose values above the dose limit. For the example of Figure 11.10A, the dose–volume-based optimization process attempts to bring only the points between D_1 and D_2 into compliance with the constraint. In contrast, the dose-based optimization process attempts to constrain all of the points above D_1. Furthermore, dose–volume criteria are highly "degenerate" functions of dose distributions (i.e., there is a very large number of dose distributions that correspond to the same dose–volume constraint). Therefore, the optimization system has a large solution space to choose from, making it easier to find a better solution.

Limitations of Dose–Volume-Based Objective Functions

Dose–volume-based criteria have been demonstrated to have limitations. To illustrate one such limitation, consider the example in Figure 11.10B of a normal structure for which a constraint has been specified that no more than 25% of the volume is to receive 50 Gy or higher. All three DVHs shown meet this criteria. However, the DVH represented by the solid curve clearly causes the least damage. One can argue that we can overcome this limitation by specifying multiple dose–volume constraints or even the entire DVH. However, as illustrated in Figure 11.10C, this would be too limiting. Multiple DVHs could lead to an equivalent injury to a particular organ, but each DVH may produce a different effect on other organs and the tumor. When this happens, DVHs usually cross each other, as shown in Figure 11.10C. Only one of them is optimum so far as the tumor and other organs are concerned.

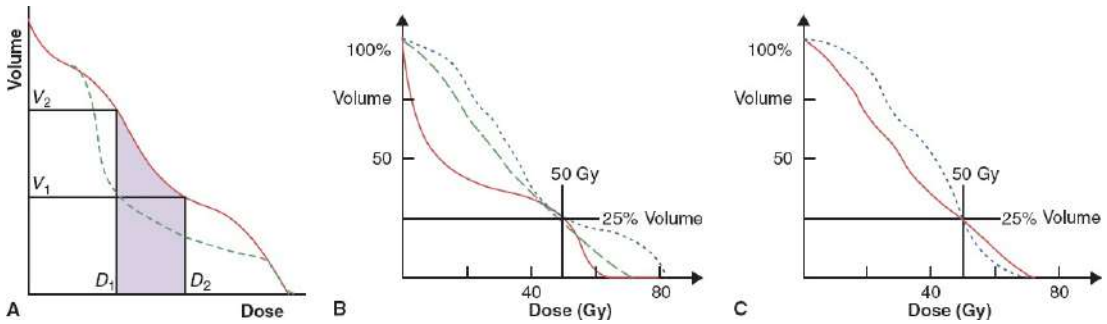

FIGURE 11.10. A: Incorporation of dose–volume constraints in intensity-modulated radiation therapy optimization. (Adapted from Wu Q, Mohan R. Multiple local minima in IMRT optimization based on dose-volume criteria. *Med Phys* 2002;29[7]:1514–1527. Copyright © 2002 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.) **B** and **C:** Limitations of dose–volume-based criteria (see text).

To overcome the limitations of dose–volume-based criteria, they may be supplemented with biologic (or dose–response-based) criteria, for instance, in terms of such indices as tumor control probability (TCP), normal tissue complication probabilities (NTCPs), and equivalent uniform dose (EUD).[92] Dose–response-based objective functions are the subject of ongoing investigations.[44,111] The ICRU currently includes NTCP and EUD projections in its level 3 reporting (i.e., still investigative). The report (see p. 51) notes that most of the tissue tolerance data go back to the period before 3D imaging, but they do cite newer prospective studies involving 3DCRT or IMRT.[112,113]

Objective Function Parameters

The desired IMRT dose distributions are specified in terms of parameters of the objective function. In Eq. (1), for instance, the parameters of the objective function are the desired dose limits $D_{T,0}$ and $Dn_{,0}$ for target and normal structures, respectively, and the relative importance (or penalty) factors p_n for deviating from desired dose limits. Most often, the objective functions are specified in terms of one or more "soft" dose–volume constraints for each volume of interest, one for each constraint. That is, if the computed dose deviates from the desired value, the plan is not rejected, but it is assessed a penalty. The optimization software computes a "subscore" corresponding to each constraint. The subscore value depends on the deviation of dose distribution from the desired dose distributions and the penalty factor. The overall score of an IMRT plan is an accumulation of subscores of individual volumes of interest. The IMRT optimization system uses the IMRT plan score to arrive at the optimum plan according to the specified objective function. The optimized

solution involves trade-offs that balance specified normal tissue objectives against each other and against tumor objectives. An IMRT treatment planning system should provide parameters that allow the treatment planner to adjust the trade-off for each critical structure in a straightforward manner. An example of this is shown in Figure 11.11, where a head and neck target volume nearly abuts the parotid gland.[114] Two of six plans are shown—plans C and F use parameters that emphasize parotid gland sparing and tumor coverage, respectively. This is an excellent example of the flexibility of moving the steep dose gradient in and out of the target volume.

The plan considered to be the best by the computer may not be judged the best (or even good enough) by the treatment planner. Parameters are adjusted by trial and error to obtain a satisfactory plan. A confounding factor is that a change in a parameter of one volume of interest affects not only its own subscore and DVH but also the subscores and DVHs of other structures in a complicated manner. For a complex IMRT problem, in which there may be several dozen parameters, their adjustment is an extremely difficult task. The trial-and-error approach used currently is time consuming and leads to suboptimal results. Future research based on artificial intelligence techniques may provide a systematic means of determining optimum parameter values.

Treatment Plan Evaluation

IMRT dose distributions tend to be highly conformal but complex and unconventional. Traditional methods of evaluation and reporting may be too limited for such dose distributions. In principle, the target dose distributions for IMRT should be more homogeneous than for 3DCRT. In practice, the opposite is the case, due in part to the competing demands of sparing of normal tissues and in part to the inadequacy of objective functions. Dose distributions in normal structures as well are, in general, more nonuniform than for 3DCRT.

In the current practice of radiation therapy, treatment plans are evaluated using dose and dose–volume parameters including such quantities as dose to a point in the volume of interest, minimum dose, maximum dose, minimum dose to a specified fractional volume, or the volume of the structure receiving a specified dose or higher. MUs are set to deliver the prescribed dose to a specified point or to an isodose line (or surface) just enclosing the target volume. For some sites and techniques (e.g., stereotactic radiosurgery of brain tumors), an index of conformality (the ratio of volume occupied by the prescription isodose surface and the volume of the target) is used for plan evaluation. Cumulative dose and

dose–volume data are reported as a part of the patient's chart and used for correlation with outcome.

Because of the unconventional nature of IMRT dose distributions, especially the high degree of dose heterogeneity and fluctuations in dose as a function of position in volumes of interest, indices such as dose to a point, minimum dose, or maximum dose may not correlate well with dose response. Instead, dose to a specified fractional volume is more appropriate, and this is the approach taken by ICRU 83. ICRU reporting now specifies a $D_{98\%}$ or $D_{\text{near minimum}}$ (dose to at least 98% of the PTV) and a corresponding $D_{2\%}$ (dose received by the most heavily irradiated 2% of the PTV).[1]

Limitations of dose and dose–volume plan evaluation parameters have been articulated in the literature.[115] These limitations become more significant for the complex dose distributions of IMRT. It has been argued that biophysical dose–response indices, which summarize complex dose distributions using a single clinically relevant index in each volume of interest, may be more appropriate. Currently, indices such as TCP, NTCPs, and biologically EUD often are computed and recorded but rarely are used for routine plan evaluation. This is because of the unreliability of published dose–response data and weaknesses of models to compute these indices. This is, in turn, the result of the various sources of uncertainty both in the quantification of response and in doses delivered to the structures. Levegrun et al.[116] analyzed data from patients with prostate cancer treated at Memorial Sloan-Kettering Cancer Center and concluded that the biopsy-based response did not correlate with minimum tumor dose, EUD, or TCP. Instead, they found the mean dose to be a very good predictor of response. They attributed this observation to large treatment margins for PTV, substantial target motion, and relatively homogeneous dose distributions. As functional imaging (e.g., PET and nanoparticle optical probes) becomes more widespread, treatment will become more adaptive, with planning readjusted to reflect tumor regression or persistence. Recently, Moeller et al.[77] reported a prospective study using 18-fluorodeoxyglucose (FDG)-PET to assess tumor response in head and neck cancers. PET was seen to be superior to CT in the subset of patients with high-risk disease.

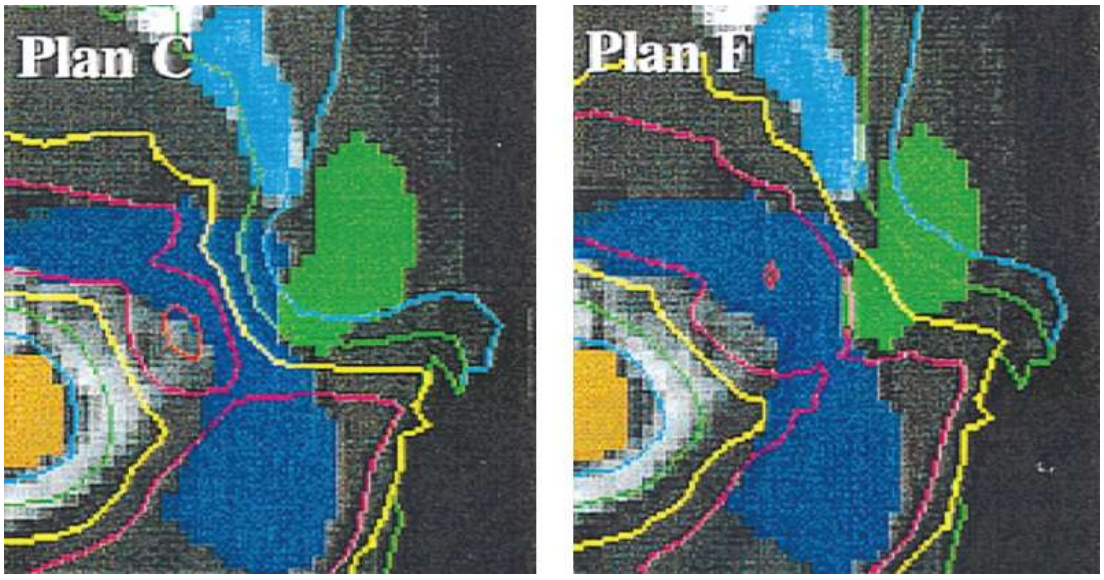

FIGURE 11.11. Effect of adjusting dose prescription parameters on the resulting treatment plan. The parotid gland and target are shown in *green* and *blue*, respectively. *Plan C* emphasizes parotid sparing, and *plan F* emphasizes tumor coverage. (Interested readers should view the full set of six plans as presented in the original paper. From Chao KS, Low DA, Perez CA, et al. Intensity-modulated radiation therapy in head and neck cancers: the Mallinckrodt experience. *Int J Cancer* 2000;90[2]:92–103.)

GENERATION OF LEAF SEQUENCES

Fixed Intensity-Modulated Fields

For the IMRT mode using multiple fixed fields, the plan optimization process produces nonuniform intensity distributions (see Fig. 11.12) for each set of fields. In principle, such intensity distributions can be delivered using custom-fabricated compensators made of lead alloys to attenuate the appropriate amount of radiation along each ray of the beam. Such devices would have to be produced using computerized milling machines. In addition, to use them it would be necessary for the operator (radiation therapist) to enter the treatment room to insert the device for each field. This process would be highly labor intensive and impractical considering that a large number of beams often may be needed for optimum intensity-modulated treatments.

The most efficient means of delivering fixed-field IMRT is the standard MLC in dynamic mode using such methods as the “sliding-window” technique or the step-and-shoot technique. In either case, leaf position sequences as a function of MUs need to be generated. The MLC leaves are made of approximately 5- or 6-cm-thick tungsten and are typically 0.5 or 1 cm wide (projected to isocenter). MLCs with leaves of a width as small as 1 mm have been introduced. Smaller

leaf width may be of greater value for IMRT than for standard 3DCRT. For the former, the leaf width affects the dose delivered to the entire slice, whereas for the latter, it affects only the shape of the boundary. A smaller leaf width undoubtedly would produce more conformal dose distributions, but the electromechanical complexity and cost of the device would increase. Because of the smearing caused by finite-sized radiation sources, lateral secondary electron transport, and the use of multiple fields, and because of motion and positioning uncertainties, an acceptable leaf width may not need to be very small. The minimum desirable leaf width would depend on numerous factors including shapes and locations of volumes of interest, dose gradients desired, and number and orientations of beams. Although the issue of leaf width has been debated for quite some time, there are no definitive studies to guide the choice of the most suitable width.

MLCs transmit only 0.5% to 2% of incident radiation (except through small interleaf gaps and the rounded ends of some MLCs). However, as discussed later in this chapter, because intensity-modulated treatments require a substantially larger number of MUs than do the conventional uniform field treatments, the cumulative effective transmission may be considerably larger.

Leaf Sequence Generation: Sliding-Window Technique

In the sliding-window method, the gap formed by each pair of opposing leaves is swept across the target volume under computer control while the radiation is on. The gap opening and its speed are optimally adjusted. Because the dose rate of the treatment machine might fluctuate slightly, the motion is indexed to MUs rather than time. The basic principle is that as the gap slides across a point, the radiation received by the point is proportional to the number of MUs delivered during the time the tip of the leading leaf goes past the point and exposes it until the tip of the trailing leaf moves in to block it again. (The point also receives additional radiation transmitted through or scattered from the leaves, which must be accounted for. See later discussion in this chapter.) The setting of the gap opening and its speed for each pair at any instant are determined by a technique first introduced by Convery and Rosenbloom[117] and refined and studied further by Bortfeld et al.,[24] Spirou and Chui,[36,37] Stein et al.,[38] Svensson et al.,[118] and others.[40,119] Knowledge of the maximum leaf speed is taken advantage of to maximize the gap between the opposing pair of leaves and, therefore, to minimize the treatment time. The number of leaves participating in the delivery of a beam depends on the projected size of the target volume. The data

describing leaf trajectories, produced by the leaf sequence generation process, are in the form of a table of positions of leaves versus the corresponding MUs (depicted graphically in Fig. 11.13).

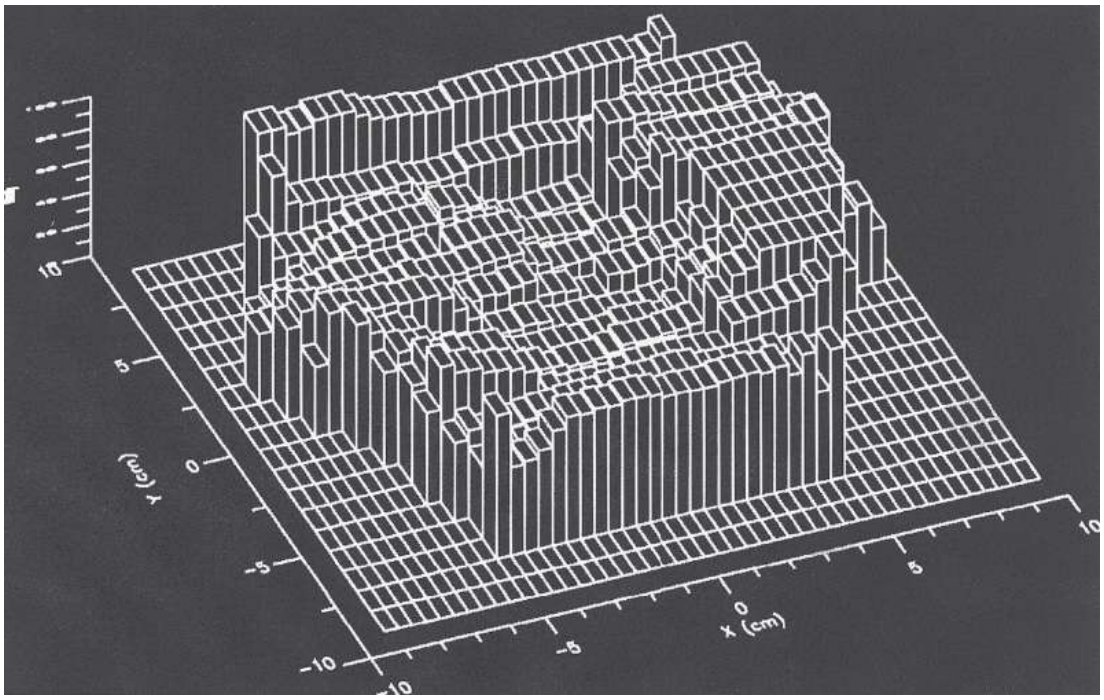

FIGURE 11.12. Intensity profile of the left lateral beam of an intensity-modulated radiation therapy plan designed for the treatment of the cervix. Intensity distribution in a plane through the isocenter and normal to the direction of the beam is plotted. The grid size along the *y*-axis is 1 cm, corresponding to the width of multileaf collimator leaves. Each intensity curve along the *x*-axis corresponds to one pair of opposing leaves.

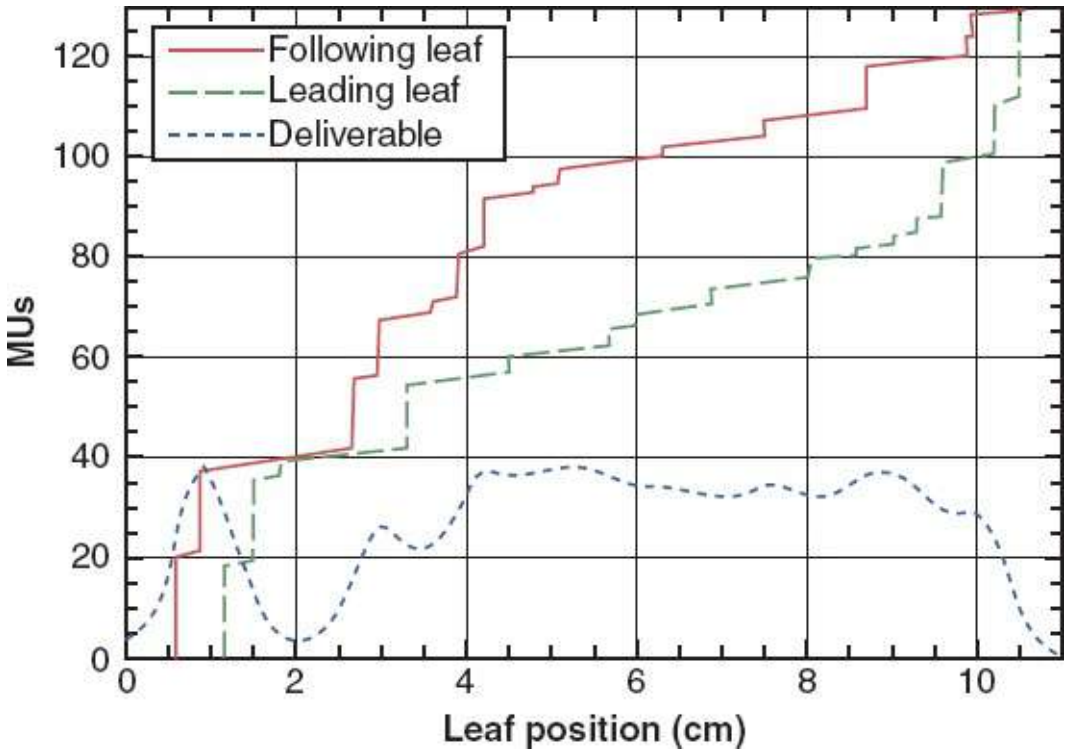

FIGURE 11.13. A typical trajectory of one of the pairs of leaves used to deliver intensity-modulated beam profiles of the type shown in Figure 11.12. Intensity-modulated radiation therapy optimization based on deliverable dose distributions using the sliding-window technique. Positions of the leading and following leaves are plotted as a function of monitor units (MUs). The gap formed by the pair of leaves moves from left to right. Its width and speed are adjusted by the computer to allow a predetermined amount of radiation to reach each point within the field. Note that the fluence is the differences in MUs for the left leaf and the right leaf.

Leaf Sequence Generation: Step-and-Shoot and Multisegment Techniques

With the step-and-shoot technique (as well as for multisegment technique), the fixed-gantry radiation beam is composed of multiple static MLC segments, with each segment having its own aperture shape and weight or monitor (MU) settings. The leaf sequence generation algorithms take the optimized intensity pattern as the input and decompose it into multiple segments, each to be shaped as an aperture formed by the MLC. Fluence intensity throughout each MLC segment is relatively uniform. The summation of all static segments yields the required intensity-modulated dose distributions. Ideally, the segments are sorted to minimize the MLC leaf travel time between the segments. Note that such sorting is neither necessary nor possible for the sliding-window technique.

The first step of the leaf sequence generation process is the discretization of the continuous intensity distribution into a limited number of intensity levels.

These intensity levels then are converted into leaf sequences using one of several methods described in the literature. Bortfeld et al.,[24] for example, have proposed a method in which each row of intensity is handled separately, similar to the sliding-window algorithm. The advantage is that the total number of MUs is small but at the cost of possibly large numbers of segments. Xia and Verhey[120] proposed the so-called areal algorithm. Instead of dividing the intensities into levels of equal steps, they divided them into levels in powers of 2 to reduce the number of steps and to gain efficiency. Wu et al.[111] proposed a technique called the *K-means clustering* in which the intensity levels are grouped together based on their values and the user-specified error tolerance levels. The intensity levels are not equally spaced and can be arbitrary.

Unlike the sliding-window algorithm, the maximum leaf speed is not important for the step-and-shoot and multisegment techniques. Similarly, although the number of segments is not an issue for the sliding-window techniques, it could affect the step-and-shoot delivery efficiency significantly. For the former, the only penalty of the large number of segments is the size of computer storage, whereas for the latter, it leads to inefficiency because the beam is off during the transition between the segments. Furthermore, for some linear accelerators, there is an overhead time associated with each segment.

Que[121] compared several step-and-shoot algorithms and found that the algorithm used by Xia and Verhey[120] frequently, but not always, produces the least number of segments. Other investigators have reported methods to minimize the number of segments as well. The algorithm of Dai and Zhu[122] checks numerous candidates for each segment, and the candidate that would result in a residual intensity matrix with the least complexity is selected. If more than one candidate exists with the same complexity, the one with the largest size is chosen. Langer et al.[123] reported a technique based on the integer programming that can minimize the number of segments under the constraints that the MUs do not exceed a certain limit. It was found that the technique produces considerably fewer segments than the algorithms of Bortfeld et al.[9,110] and Xia and Verhey[120] for the same or fewer MUs.

Monitor Units of IMRT Beams

Based on methods similar to those previously described, software systems have been developed to convert intensity distributions to leaf trajectories. The input to this software is the intensity distribution for each field in terms of MUs or, to be more precise, “effective” MUs. Effective MUs are fractions of MUs transmitted

through the intensity modulation or compensation device. The intensity distribution-to-leaf trajectory conversion software not only produces trajectories but also computes actual MU settings for each beam as a natural by-product of the conversion process. Trajectories of leaves and the MUs for each beam are transmitted to the computer-controlled radiation treatment machine for dosimetric verification and the delivery of treatment.

It is important to note that the relationship between the prescribed dose and MUs required for delivering each of the intensity-modulated beams is highly complex and not obvious. There is no practical way to calculate MUs by hand as is done for traditional treatments as an independent check of the predicted MU values. To ensure patient safety and to satisfy the requirements of the independent check, some systems have implemented independent software for a second MU calculation. Others have adopted the policy to measure the dose or dose distribution for each of the beams before the first treatment.

Impact of MLC Characteristics

ICRU 83 notes that the tolerances for MLC operation must be more stringent than even those required for beam blockage in 3DCRT. This stems from the steep dose gradients made possible by and employed with IMRT. Slippage of leaf position would cause a cumulative degradation of the dose distribution actually delivered. Leakage through closed leaves may also pose a problem for which consideration in planning must be taken.[124] Adjustments to leaf trajectories are required to account for the various effects associated with MLC characteristics, including the rounded leaf tips, tongue-and-groove leaf design, interleaf and intraleaf transmission, leaf scatter, and collimator scatter upstream from the MLC. The accuracy of dose delivered and the agreement between calculated and measured dose distributions depend on the adequate accounting of these effects. Approximate empirical corrections are applied for these effects by algorithms and software that convert optimized intensity distributions into leaf trajectories.

MLCs have an interlocking tongue-and-groove leaf design to minimize interleaf leakage. However, there is a difference in interleaf leakage and leakage through the leaves. This difference can become significant for beams that require a large number of MUs and in portions of the beams that receive large fractions of their dose through leakage. Currently, this effect is ignored, although the use of Monte Carlo techniques to account for it is being investigated.[125,126]

In addition, there are circumstances during creation of intensity profiles when

a thin strip of the irradiated medium is shielded by the tongue of one leaf pair or the groove of the adjacent leaf pair rather than being completely exposed or completely blocked. Van Santvoort and Heijmen[39] have demonstrated that this leads to an underdosage in the thin strip. They, and subsequently Webb et al.,[42] also showed that this effect could be removed by the use of leaf motion-synchronizing techniques. However, such techniques result in an increase in the number of MUs. Furthermore, this effect is not considered to be of significant clinical consequence because of the smearing caused by multiple fields and the positioning and motion uncertainties. Using different collimator angles for each field can reduce this effect further.

Depending on the complexity (the frequency and amplitudes of peaks and valleys) of the intensity pattern, points within the field aperture may receive a substantial portion of the dose as a result of radiation transmitted through or scattered from the leaves when the points are in the shadow of the leaves. Points outside the leaf aperture receive their entire dose through these “indirect” sources. The complexity of intensity distributions produced by the IMRT optimization process depends on a combination of several clinical factors including the shapes, sizes, and relative locations of tumor and normal tissues; required tumor dose; dose homogeneity; and dose–volume limits of normal tissues. Intensity distributions for head and neck cases, for example, tend to be considerably more complex than for prostate cases. For beams with highly complex intensity patterns, the average window width to deliver the treatment tends to be small, and for the same dose received by the tumor, the treatment time (i.e., the number of MUs) is long. Consequently, the contribution of radiation transmitted through and scattered from the leaves may form a significant fraction of the total dose delivered. Because these contributions are accounted for approximately, the uncertainty in dose delivered is increased. In addition, the differences between interleaf and intraleaf transmissions may no longer be negligible. Another consequence of complex intensity patterns is that the lower limit of the deliverable intensity is high.

The deliverable dose distributions may be significantly different from the original optimized ones. There are different ways to overcome the difficulties resulting from the differences in desired and deliverable dose distributions. For example, if the deliverable dose to a particular normal structure is higher than the original optimized dose, the planner could modify the objective function to demand an appropriately lower dose. Alternatively, the optimization loop could include a pass-through leaf sequence generation and calculation of deliverable

dose distributions. The optimizer then adjusts ray weights based on deliverable dose distributions rather than the idealized ones. This scheme has been investigated by Siebers et al.[127]

QA FOR INTENSITY-MODULATED TREATMENTS

A number of QA steps unique to IMRT are needed to ensure the accuracy and safety of treatments. These include QA of the MLC in dynamic mode, dosimetric verification for each dynamic beam as well as for the composite treatment plans, portal imaging, treatment verification, *in vivo* dosimetry, and reduction in uncertainty associated with daily positioning and internal organ motion during irradiation. In recognition of the special demands of IMRT, the American Association of Physicists in Medicine (AAPM) commissioned Task Force 142[128] to replace the earlier Task Group 40[129] and recommend new QA guidelines. When using conventional 3DCRT, MLC leaf position calibration errors influence the accuracy of the radiation distribution at the portal boundary. Because of PTV and beam penumbra margins, small errors in leaf calibration will have a minimal effect on the target volume dose. The accepted leaf calibration accuracy is 2 mm, but this is too large[1] because in IMRT the MLCs are used to generate inhomogeneous fluence distributions. In the sliding-window technique, for instance, this is done by adjusting the velocity and width of leaf gaps during radiation delivery. If the MLC calibration is inaccurate, the delivered dose distribution will be in error. The error is a function of the ratio of leaf calibration error to the sliding-window width. For example, a 1-mm imprecision in the gap would result in a 10% error in dose if a uniform field were to be delivered using a sliding window of 1 cm. For step-and-shoot delivery, magnitudes of dose errors are greater (owing to the steep dose gradients near the MLC leaf edges), but they are confined to the subfield edges. Thus, it is essential to verify the IMRT absorbed dose calculation algorithm against measurements for the IMRT accelerator in question using a suitable small-field detector.[130] In addition, it is absolutely essential for leaf-positioning accuracy to be verified. The AAPM TG-142 protocol recommends that a leaf should be positioned with an accuracy of 1.0 mm and the physicists must ensure through routine QA procedures that such precise positioning is achieved and maintained. It is interesting that integral dose error is similar for both the step-and-shoot and sliding-window techniques, but the distribution of the error is different.

Because MLC leaf calibration and the accuracy of MLC operations influence

the delivered dose distribution, new, more rigorous MLC QA procedures have been developed. Chui et al.,[131] LoSasso and Chui,[132] and Ling et al.,[5] among others, have developed QA procedures specifically for MLCs used in dynamic mode. Periodic QA checks must ensure that the leaves of the MLC do indeed move to their designated positions at the specified values of MUs. Moreover, to ensure safe and accurate delivery of treatments with an MLC, the manufacturers must include redundant and independent sensors for the leaves of the MLC. Furthermore, in the event of treatment field interruption and resumption, there should be no perceptible change in dose delivered.

Another aspect of QA important for IMRT is the daily positioning uncertainty and motion during irradiation. IMRT is a highly conformal and highly precise form of radiotherapy frequently used to escalate dose. Dose distributions may have steep dose gradients between the target and the neighboring normal structures. Furthermore, margins may be much smaller than in conventional treatments. Patient positioning and immobilization requirements are more stringent than ever to ensure that the target volumes are covered adequately and the normal tissues are spared adequately. In fact, special immobilization devices and techniques are being developed to reproducibly and accurately position the target volume and normal anatomy. Many of these devices already are available commercially (e.g., rectal inserts to improve positioning for prostate IMRT).

Similarly, motion during treatment, mainly as a consequence of respiration, also can be a serious problem for IMRT of sites in the thorax and abdomen. Because IMRT is delivered dynamically, the moving target volume may move in and out of the instantaneous field of radiation. Some portions of the target volume may get more than the planned dose, whereas others may get less. A way to minimize effects of respiratory motion would be to use “gated treatments” in which radiation and leaf motion are turned on only during a specific, reproducible portion of the respiratory cycle or in an interval during which the patient’s breath is voluntarily, or involuntarily, held.[133] New methodologies, typically employing CT imaging, are being used to synchronize patient breathing motion with the irradiation beam.[134–136]

DOSIMETRIC VERIFICATION OF INTENSITY-MODULATED TREATMENTS

To implement a new treatment technology into routine clinical use, there are usually three distinct but closely related phases. *Acceptance tests*: This is the

initial set of tests that ensures the hardware and software meet the factory- or customer-provided specifications. Usually, but not always, the written specifications contain the necessary instructions or guidelines for these tests (in order to avoid legal ambiguity in the measurements). It is also a good opportunity for the users to establish some performance baselines, especially for the hardware purchased. *Commissioning tests*: The IMRT commissioning is a process to implement IMRT treatments using the customer's hardware and beam data. Various groups have studied the general guidelines for commissioning a treatment planning system, and the AAPM issued a new report on IMRT commissioning in 2009.[137] The process usually starts with collection of essential beam data for beam modeling. The parameters of the dose calculation algorithm are then tuned to provide the best performance for the user's beam. Additional tests should be performed to evaluate the limitations of the treatment planning system and a solution or a work-around should be found if the problem is clearly identified. Then IMRT phantom measurements should be performed to test the accuracy of the delivery system and data connectivity. If the accuracy is judged to be acceptable, the system can be released to the clinic after the necessary user training and procedural implementations. It is recommended that a small (interdisciplinary) focus group should be assigned to lead the IMRT implementation in the clinic. The "train-the-trainer" approach has proven to be effective in translating new technology into routine clinical practice. *Ongoing QA*: After the system is released to the clinic, it is important to establish a routine QA program. The performance of various steps involved in performing IMRT treatments needs to be tracked so that the quality of the treatments can be maintained. The ongoing QA program can be separated into patient-specific QA and equipment QA, which will be described in more detail in the following section.

Patient- and Equipment-Specific QA

Because of the complexity of irregular field shapes, small-field dosimetry, and time-dependent deliverable leaf sequences, it is recommended by the AAPM and ASTRO that patient-specific QA should be performed as a part of the IMRT management process and a requirement for billing for IMRT services. Figure 11.14 shows the general categories of patient- and equipment-specific QA, which are detailed in the following.

Patient setup, although not specific to IMRT dosimetry, is considered a key step in ensuring accurate IMRT treatments. A variety of image-guided

localization techniques have been proposed for use with IMRT treatments, from simple orthogonal portal films to the beam's eye view portal film with IMRT intensity pattern overlays,[138] imaging of implanted fiducials,[139,140] daily ultrasound-guided localization,[141–143] conventional CT, megavoltage CT, cone beam CT, orthogonal kV images, and to the most integrated tomotherapy solutions.[144] Emerging technologies also allow the acquisition of MR images. These images, when approved by the radiation oncologist, assure that the subsequent treatment is properly administered to the designated clinical volumes. The detailed discussion of these specific image-guided procedures is out of the scope of this chapter, but QA in patient positioning remains an important issue for IMRT. A somewhat related problem of organ motion because of breathing has been discussed earlier. Several recent studies have examined the use of cone beam CT for patient setup or respiratory gating.[145–148] The implementation of patient-specific QA depends highly on each institution. For example, dosimetric measurements of MU settings can be verified for each beam individually (usually in a flat [slab] phantom geometry) or for the composite treatment plan (usually in a specially designed phantom, but it is also possible to use the simple slab phantom setup). Unlike single-beam verification in which the single-beam dose distribution can be significantly different from the original patient plan, the advantage of measuring the composite treatment plan in a phantom (regardless of the shape of the phantom) is that the composite dose distribution or the dose "pattern" generated in a phantom is usually similar to those in the original patient plan. This can be useful in selecting the measurement points or in visualizing potential dose errors. Absolute dosimetry is usually referred to as "MU verification" for IMRT. The traditional manual process for MU verification is virtually impossible to perform because of the large number of fields involved and the irregular shape and size of the treatment segments. Attempts have been made to verify MU settings in an IMRT plan using alternative calculation methods.[149] However, these alternative calculation methods cannot predict the uncertainties during the actual delivery at the treatment machines and are also subject to limitations and approximations in their dose calculation models. The most reliable and practical technique currently for IMRT MU verification is still the ion chamber-based point dose measurement in a phantom. Absolute dose measurement in a phantom is usually performed through a process called the *hybrid phantom plan*. In this plan, all beam angles and deliverable intensity patterns for a patient plan are transferred to the phantom, and doses in the phantom are computed for QA. The basic

assumption in this process is that if the dose calculated in the phantom agrees with the measurement in the phantom, then the dose delivered to the patient agrees with the dose calculated in the patient. Originally, IMRT QA involved the use of an ion chamber to verify absolute dose and film to verify the relative 2D dose distribution. Subsequently, detector arrays and the necessary software became widely adopted tool for this verification.[149–151] For film dosimetry, it is important to convert film density into relative dose using a film calibration process. Because of the additional dimensionality, it becomes difficult to define good numerical criteria for evaluating relative 2D/3D measurements. Various numerical indicators (such as the distance to agreement, and gamma, or normalized agreement test) were proposed. In particular, the most common evaluation method is the gamma index originally described by Low and Dempsey.[152] This method uses both dose difference and distance to agreement criteria to evaluate the difference between planned and measured doses on a point-by-point basis. This is to allow for different criteria to be used in different areas of the dose distribution based on the gradient in that area. Dose difference is used for the low-dose gradient areas, and the distance to agreement is used in high-dose gradient areas. Results are generally reported as the percentage of points passing a combination of the two criteria (i.e., 98% of points passing 3%/3 mm criterion). There is some controversy regarding how the beams should be measured (fixed-gantry vs. clinical gantry angles, field by field vs. composite) and what criteria to use.[153,154] If clinical gantry angles or arcs are being measured, the measurement device angular dependence must be carefully characterized.[155–158] It has been shown that the gamma index method may not detect significant errors. With the absence of a standard for gamma index criteria, each institution must determine its own criteria based on the known weaknesses in the institution's system. AAPM TG-119[137] suggests that IMRT QA limits should be set based on a determination of statistical variability in clinical practice. Special attention should be paid to the low-dose regions near critical structures in the original patient plan. Attention should also be paid to the systematic shifts of isodose lines, which may reveal if the isocenter or any reference setup point may be off. It would be useful if the relative dose distribution can be normalized to the absolute dose measurement point, which converts the relative dose measurement into absolute dose distributions.

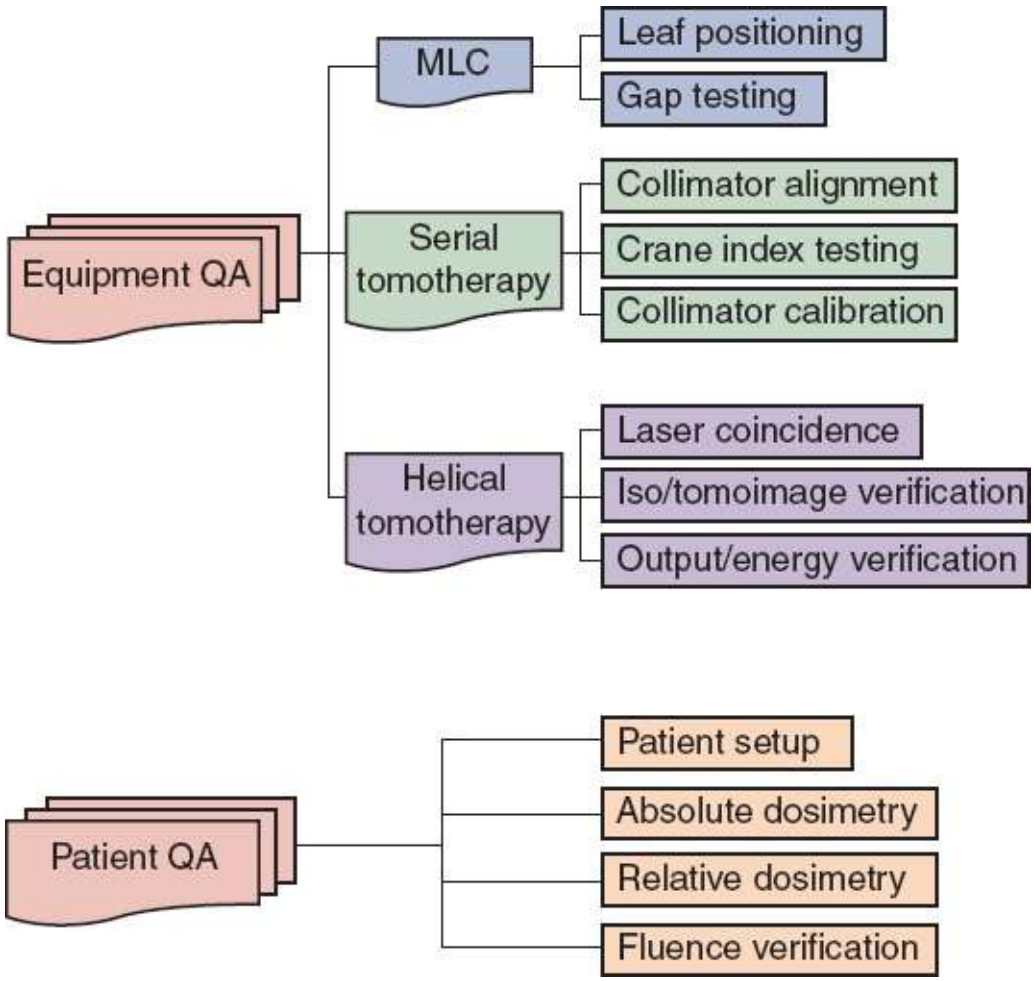

FIGURE 11.14. Overview of intensity-modulated radiation therapy quality assurance (QA) includes patient-specific and equipment-specific procedures. MLC, multileaf collimator.

Figure 11.14 also illustrates equipment-specific QA procedures. In general, IMRT QA is a subset of general equipment QA processes. The technology of IMRT and techniques for QA are also evolving. It is strongly suggested that users of IMRT should attempt to attend national meetings and technology conferences or training courses so that their knowledge about the use of IMRT can be updated regularly.

IMRT has been variously termed as *opaque*, *unintuitive*, and *nontransparent*, partly because it is delivered using dynamic techniques. Many are skeptical about whether the dose distribution displayed on an IMRT plan is, in fact, delivered. Furthermore, because of the complexity of computations involved, there is no practical way to verify the MU settings by hand calculations, as is done for conventional treatments. Moreover, because of the inherent nonuniformity of IMRT fields, it is important to know the dose accurately at

every point within the beam. One way to check if the intended dose would be delivered to the patient at the time of the treatment is to conduct dosimetric verification measurements.

Two broad categories of IMRT treatment plan verification approaches have been developed for MLC-based IMRT. First, the dose distribution from radiation fields is independently measured and evaluated. This often is accomplished by using a flat homogeneous water-equivalent phantom and irradiating each field independently. The dose distributions measured with a film or 2D detector array are compared against calculations conducted by the treatment planning system under the same geometric conditions. The process is explained in Figure 11.15. For calculation of dose distributions, each field is transferred to a treatment plan with a flat homogeneous phantom. A typical example for a sliding-window intensity-modulated beam dosimetric verification is shown in Figure 11.16. This technique has the advantage that discrepancies between the planned and delivered dose can be attributed to individual radiation portals. However, the total integrated dose distribution is not checked.

The second method uses a phantom irradiated by all beam portals, allowing the evaluation of the total dose distribution delivered.[159,160] Typically, ionization chambers and radiographic film are the dosimeters used for these measurements. Although ionization chambers can be benchmark-quality dosimeters, they suffer from volume averaging and are inefficient for measuring multiple points. Because of the complexity of the dose distributions being measured, a 2D dosimeter is required for thorough evaluations of nonuniform dose distribution. Quantitative radiographic film measurements require careful dose calibrations using independently measured sensitometric curves. The film optical densities are measured and converted to absolute dose using film calibration data and compared with the predictions of the treatment planning system.[40]

In vivo dosimetry commonly is used to verify the dose delivered by conformal therapy radiation fields. The complex fluence distribution of IMRT fields makes quantitative use of *in vivo* dosimetry, specifically the use of skin surface–mounted dosimeters, difficult.

Film, thermoluminescent dosimeters, and diodes may not be sufficiently accurate; are laborious to use; and, in the case of thermoluminescent dosimeters and diodes, are incapable of providing detailed information. In the long run, the most efficient way to verify fixed intensity-modulated fields is expected to be with real-time 2D or 3D dosimetry systems using appropriately calibrated electronic portal imaging devices (EPIDs). A general review of EPIDs was

published in 2008.[161] Such devices could be used for dosimetric verification of IMRT beams before treatment delivery and for exit dosimetry using transmitted portal dose images (PDIs). For EPIDs to be used for pretreatment dosimetric verification and exit dosimetry, they must operate in the integration mode to capture the transmitted radiation over the entire exposure of each beam. The result is a PDI that can be compared with an intensity-modulated digitally reconstructed PDI. For pretreatment dosimetric verification of a given beam, a PDI may be created using a 3D treatment planning system to compute dose deposited in the EPID detector.[162–165] For exit dosimetry, the PDI may be calculated using the 3D CT image of the patient.[166,167] In either case, for accurate dosimetric verification, the effect of scattered radiation and the variation in response of the detector with energy must be included. The former effect can be taken into account with dose-spread kernel superposition methods, but both can be accounted for using Monte Carlo techniques. 3D *in vivo* dose verification for IMRT and VMAT using a-Si EPIDs has also been developed recently. The EPID-based 3D dose distribution can be reconstructed using either a back-projection algorithm[168,169] or a model-based forward-calculation algorithm.[170,171]

TREATMENT SETUP AND DELIVERY

Fixed-Gantry Intensity-Modulated Fields

Similar to conventional radiotherapy, for IMRT techniques using fixed intensity-modulated fields, it is necessary to verify the patient alignment using portal images with beams used for actual treatment or other image guidance technology before the delivery of the first treatment and then periodically thereafter. However, no beam apertures are required for IMRT. Therefore, special fields for portal imaging with apertures are created in which the shape of each aperture is defined by the terminal positions of the leading leaf tips and the starting positions of the trailing leaf tips.

Intensity-modulated treatments may be delivered remotely or automatically under computer control. The treatment machine computer may automatically set up the various components of the machine and switch on the radiation beam. For the sliding-window technique, the leaves move during radiation in the sequence specified in the leaf motion dataset. In the step-and-shoot mode, the radiation pauses while the leaves move. At the completion of the first field, the computer sets the machine for the next field and again goes through its leaf motion sequence and irradiation. This process is repeated until all fields have delivered. The treatment times may vary somewhat and depend on the number of fields involved and the complexity of the fluence distribution. Current time estimates range from 5 to 20 minutes, excluding patient setup.[4,5,40]

SETUP AND IMRT DELIVERY WITH SERIAL TOMOTHERAPY

Current delivery of serial tomotherapy is concisely described in a review.[172] A new-generation serial treatment machine with multiple photon heads as well as an electron source has been described by Achterberg and Müller.[173] Because there are no specific beam directions or portals associated with serial tomotherapy beam delivery, the treatment QA concentrates on patient positioning and immobilization. The add-on multileaf collimator (MIMiC) is relatively heavy and its removal is time consuming, so portal films often are acquired with the MIMiC in place. This limits the portal fields to a roughly 3.4- × 20-cm^2 field size. Therefore, the imaging of useful, immobile, bony anatomic landmarks is critical for each port film, meaning that the selection of the portal film locations is critical to the accurate determination of patient-treated indices, but the digitally reconstructed radiograph that is used to compare against the portal film must be simulated at the same relative couch position as the portal film is acquired. Typically, anterior–posterior and lateral films are acquired, and if the target is longer than 10 cm and is in a location where patient structures are flexible (e.g., in the neck), portal films may be required at multiple couch positions to ensure the patient is in the correct orientation throughout the length of treatment.

Treatments are conducted by placing the patient on the couch and aligning the patient to the linear accelerator in the standard fashion. Once the patient is aligned (to a point analogous to isocenter for conventional treatments), the couch translation device (called *CRANE*) coordinates are set to zero, and the couch is moved to the location of the first index. This position is determined by the treatment planning system. The gantry is rotated to the starting arc position, and the patient treatment plan is loaded onto the MIMiC control computer. The linear accelerator is operated in normal arc mode, and the MIMiC control computer determines if the treatment can proceed. If the gantry speed is within acceptable limits, the MLC leaves are opened in their programmed sequence. The MIMiC communicates with the linear accelerator using the conventional door interlock. If the MIMiC control computer determines the treatment should not continue, the door interlock circuit is interrupted, and the linear accelerator ceases operation just as if the door had been opened (the door interlock fault is tripped on the accelerator). Once the arc is delivered, the therapist enters the room to move the CRANE to the next couch position and reprograms the MIMiC control

computer by following the screen prompts.

TOMOTHERAPY VERSUS FIXED-GANTRY IMRT

The physical and operational differences between tomotherapy and fixed-gantry IMRT lead to trade-offs when considering each system. The rotational beams used in tomotherapy could be a significant advantage until robust beam configuration optimization tools are developed, particularly those involving noncoplanar beams.

For serial tomotherapy delivery, one of the difficulties is the requirement of precisely moving the patient between successive arc deliveries (couch indexes). The dose delivery error made for an incorrect junction move is similar to the errors in abutting conventional fields. Studies have shown that the maximum dose error is 25% mm^{-1} in the abutment region for errors in couch index movement or intrajunction patient motion.[174] When conventional fields are abutted, feathering often is used to reduce the risk of systematic dose errors. A similar technique has been suggested for distributing the abutment regions for serial tomotherapy[175] by creating multiple treatment plans with modified target volumes to force a redistribution of indexes.

Even when perfectly abutted, there are dose heterogeneities within the abutment region caused by the divergent radiation fields, especially when arcs of <360 degrees are used. Low et al.[174] studied the abutment region dose distributions for arcs ranging from 180 to 340 degrees and determined that the tumor doses can have significant cold spots when short arcs are used. These become more severe when the longer leaf setting (1.7 cm) is used. The accuracy of the treatment planning system in predicting these heterogeneities was not evaluated, but the system tends to underestimate the severity of the heterogeneities. Although the divergence in the radiation beams is still present in helical tomotherapy, the helical path of the field edge distributes the diverging distribution such that dose errors caused by inaccuracies in couch motion, or by patient movement, are significantly smaller than with serial tomotherapy.

One of the advantages of fixed-gantry IMRT is the availability of noncoplanar directions. The commercial hardware device used to precisely move the couch between successive indexes also is produced in a model that attaches directly to the couch, allowing for couch rotations. Although limited noncoplanar dose delivery is possible when using serial tomotherapy, especially when treating the brain, this has not been widely adopted.

Gating for serial tomotherapy is impractical because of the use of conventional linear accelerators and the lack of shared information between the MLC and the linear accelerator control computers. Breath hold techniques are also impractical because of the relatively long time to rotate the linear accelerator gantry. Because of the potentially large abutment region dosimetry errors, it is important to consider the immobilization accuracy of targets and critical structures when selecting targets for serial tomotherapy. Gating for helical tomotherapy is possible by pausing the radiation beam and the couch motion when the gating circuitry dictates that no treatment should be delivered. However, there will be a delay in restarting the treatment after the gating signal has been restarted while waiting for the gantry to return to its position when the gating signal was interrupted.

Because the dose is delivered over many indexes or gantry rotations, there are many more MUs used when treating with tomotherapy than for conventional 3DCRT or MLC-based IMRT. The ratio of MUs can be as high as 10:1 even when compared with MLC-based IMRT.[176] This increase in MUs leads to increases in whole-body dose that may yield a significant increase in secondary radiation-induced malignancies. The solution to this is to improve the linear accelerator head shielding, the source of most of the whole-body dose in tomotherapy.

Another limitation of tomotherapy is the lack of electron beams. Electron beams (including energy and intensity-modulated electron beams), by themselves or in combination with intensity-modulated photon beams, currently are employed in the treatment of both breast and skin cancers.

A major advantage of helical tomotherapy is that it is a dedicated IMRT device. However, MLC-based IMRT is likely to compete as a delivery mode resulting in part from the limitations of tomotherapy discussed earlier. Furthermore, the large base of MLC-mounted linear accelerators will mean that the adoption of tomotherapy for significant numbers of IMRT patient treatments will take years.

SPECIAL REQUIREMENTS OF FACILITY DESIGN FOR IMRT

The room-shielding design characteristics for IMRT delivery are different than those for conventional radiotherapy. Shielding requirements are determined separately for primary and scattered radiation barriers and for tomotherapy and MLC-based IMRT. For MLC-based IMRT, the total integrated radiation fluence

remains similar to that used in conformal therapy, so no change in primary barrier thicknesses is expected. However, the increase in MUs of about a factor of 3 is expected to increase the required secondary shielding barrier attenuation, at least until the linear accelerator manufacturers improve the head leakage characteristics. For serial tomotherapy without a beam stopper, the same primary barrier is struck for each couch index, indicating that an increase in primary barrier thickness may be required. However, the use of a rotating beam, and the relatively small angle subtended by the MIMiC, reduces effective use factor to the point that it almost exactly cancels the number of times the beam strikes the primary barrier. Increases in secondary shielding, however, may be greater than for IMRT because the total number of MUs is significantly greater.

CLINICAL EXPERIENCE WITH IMRT

IMRT of Head and Neck Cancer

The first report of the application of IMRT to head and neck neoplasms was from Baylor College. Kuppersmith et al.[177] reported a decrease in dose to the parotid glands to <30 Gy in 28 patients treated with IMRT using serial tomotherapy. They also found the incidence of acute toxicity to be drastically lower than with conventional radiation therapy. Later, Butler et al.[178] implemented the “simultaneous modulated accelerated radiation therapy”[179] technique, an equivalent of the SIB technique, and found that 19 out of 20 patients treated had complete response with acceptable toxicity. Low et al.[180] described the application of the serial tomotherapy technique and QA practices for head and neck treatments at Washington University in St. Louis. Preliminary results of the use of these techniques for 17 patients were reported by Chao et al.[101] and showed that the tumor control is promising with no severe adverse acute side effects. A subsequent prospective clinical study conducted by Chao et al.[181] also showed that the sparing of parotid glands translated into objective and subjective improvement of both xerostomia and quality of life scores in patients with head and neck cancers treated with IMRT.

In another study, Chao et al.[182] also reported the dosimetric advantage of IMRT treatment in patients with oropharyngeal carcinoma (260 with primary tumors in the tonsil and 170 with primary tumors at the base of the tongue). No adverse impact on local tumor control or disease-free survival (DFS) was seen, but there was a significant reduction of late salivary toxicity. Fixed-field IMRT and serial tomography gave superior GTV coverage and lower parotid doses

compared to conventional RT in nasopharyngeal cancer.[183] Groups at Memorial Sloan-Kettering[184] and UCSF[185] found similar results for nasopharyngeal patients. IMRT likewise showed promise for oral and oropharyngeal cancer[186] and in dose escalation studies of head and neck squamous cell carcinoma.[13,100] Examples of target delineation for nasopharyngeal and hypopharyngeal cancer are shown in Figures 11.17 and 11.18, respectively.

Since the early part of the past decade, IMRT usage in head and neck cancers has become the standard of care. The Web of Science database records 2,087 papers with "head and neck" and "IMRT" in the title from 2002 through 2016. Of these, 1,044 appeared in or after 2012. Review articles pertaining to head and neck cancers include the following: Lee and Terezakis[187] in 2008 and Maingon et al.[188] in 2010. Lu and Yao[189] found improved quality of life and survival benefit in IMRT treatment of nasopharyngeal cancer. Reviews focused on quality of life issues include Scott-Brown et al.[190] and Tribius and Bergelt[191]; swallowing issues are reviewed by Roe et al.[192] Early work by Chao et al.[181,182] showed significant reduction in salivary gland toxicity in the IMRT-treated patients. Nutting et al.[193] reported the results from a head-to-head phase III trial of IMRT versus conventional radiation therapy in patients with pharyngeal squamous cell carcinoma (T1–T4, N0–N3, M0). The IMRT arm showed significantly less grade 2 (or worse) xerostomia compared to radiation therapy: at 12 months, 74% for radiation therapy versus 38% for IMRT, and at 24 months, 83% for radiation therapy versus 29% for IMRT. At 24 months, no significant differences were seen in other toxicities or in local tumor control or overall survival.

This raises a question—given the increased complexity and cost in equipment and physician/physicist/staff time for IMRT compared to conventional radiation therapy, is the improvement in quality of life alone worth the cost? This was the *raison d'être* for the study by Tribus and Bergelt.[191] and the answer is obviously yes for the patient. More to the point, what possibilities are there for improvement of outcome in survival and locoregional control? IMRT by itself is still radiation therapy—the photon sources do not have the coherence of an optical laser, so there are beam-edge effects and also beam scattering from the MLC leaves and within the patient's body as the depth increases. This puts limits on the dose gradients that can actually be achieved, and if OAR sparing is to occur, it will mean less homogeneous doses to the GTV. There are several ways to approach this problem:

. Better imaging during a course of treatment. Changes in tumor size and/or

location during treatment will require imaging to adjust the IMRT plan and possibly adaptive radiation therapy. Various promising imaging modalities useful for radiation oncology were reviewed by Apisarnthanarax and Chao[74]; more recently Moeller et al.[77] reported on a prospective trial using FDG-PET and CT imaging in head and neck cancer. Cone beam CT has also been reviewed recently.[194]

- Accelerated fractionation. One makes use of the radiobiologic advantages of IMRT to perform dose escalation to tumor while constraining the dose to critical normal tissue.[14] Ling et al.[195] have discussed the effects of dose rate in terms of the widely used linear-quadratic model. Chakraborty et al.[196,197] observed 95% DFS in 20 patients with squamous cell carcinomas at various head and neck sites, but the SIB group treated at a higher dose did have more acute toxicities.
- Combined modality treatment. Combined chemotherapy and radiation treatment is the current approach for locally advanced head and neck squamous cell carcinoma.[198] Chemoradiation for locally advanced head and neck disease has also been reviewed by Seiwert et al.[199] Similar themes were expressed in the 2008 Southwest Oncology Group report.[200] Riesterer et al. discuss the last decade of work on chemosensitization with molecular signaling agents followed by radiation.[201]

New technologies, in particular beams of charged heavy ions (protons or carbon), show promise because of their highly depth-dependent energy deposition profile (the spread-out Bragg peak). Thariat et al. recently published a concise review of these and other techniques as applied to head and neck cancers.[202] Heavy ion beam therapy is very costly and available only at a few centers, so in the immediate future, it will likely be limited to those cases such as malignancies close to the eyes or optic chiasm where photon beams cause

unacceptable vision loss.

IMRT of Prostate Cancer

The prostate was one of the first targets of IMRT in the work of Ling et al. at Memorial Sloan-Kettering.[4,5]Studies involving hundreds of patients followed: in 2000, Zelefsky et al.[203] demonstrated superior target coverage with IMRT compared to conventional RT and 3DCRT; in 2002, they reported a larger study showing the feasibility of high-dose IMRT with reduced acute toxicities.[204]

A total of 772 patients were treated: 698 to 81.0 Gy and 74 to 86.4 Gy. Acute grade 2 rectal toxicity was seen in 35 (4.5%), but none at grade 3 or above. Acute grade 2 urinary symptoms developed in 217 patients (28%), but only 1 patient with grade 3 problems. Late rectal bleeding (grade 2) was experienced by 11 patients (1.5%). PSA relapse-free survival rates (3-year actuarial) were 92%, 86%, and 81% for the favorable, intermediate, and high-risk groups, respectively.

This early work was extended by other workers,[205,206] and the field has been extensively reviewed.[207–209]

Combined radiation and hormonal therapy is used for patients at higher risk. For a review, see Sanfilippo et al.,[210] who reported on a phase I/II trial in 22 patients with locally advanced hormone-ablated disease (T1–T3). Paclitaxel was given biweekly, with four-field 3DCRT starting at 63 Gy and escalating to 66.6, 70.2, and 73.8 Gy. Acute toxicities included diarrhea (mostly grade 1 and 2, but with grade 3 in four patients); at 38 months, 21 (95%) were alive. But 6 of 22 (27%) had developed relapsed disease. Tucker et al.[211,212] analyzed Radiation Therapy Oncology Group (RTOG) 9406 data to obtain Lyman NTCP parameters and the linear-quadratic α/β ratio for late rectal toxicity in prostate-irradiated patients.

The treatment of prostate cancer has been greatly impacted by advances in magnetic resonance, both standard MRI and magnetic resonance spectroscopic imaging (MRSI). This growing field has been extensively reviewed; for two recent articles, see Sciarra et al.[213] and Mazaheri et al.[174,214] Magnetic resonance can often “see” details of the prostate tumor that are not observable on a CT scan. MRI can be used for much more precise tumor target delineation for IMRT than would otherwise be possible, and this has had significant clinical impact.

IMRT of Intracranial Malignancies

With FDG-PET and/or MRI, tumors within the brain can be visualized more

clearly than on CT. Given the desire to avoid extensive neurologic damage, IMRT is expected to offer some advantages in sparing normal tissues and possibly improving the often bleak prognosis of central nervous system cancer patients. For example, Gutierrez et al.[215] reported a planning study with tomotherapy to provide an integrated boost to whole-brain irradiation in an effort to spare the hippocampus. This has also been replicated in RTOG and ongoing NRG Oncology trials.

Iuchi et al.[216] from Japan published a retrospective report on 25 patients with malignant astrocytomas (World Health Organization grade III and IV) treated with IMRT using a hypofractionated regimen of 48 to 68 Gy in eight fractions. Thirteen patients were treated to 68 Gy and 12 patients received doses of 48 to 65 Gy. The IMRT group was compared to 60 patients treated with conventional techniques to doses of 40 to 60 Gy using 2 Gy daily fractions. The 2-year overall survival was significantly improved (P = .043) in patients treated with hypofractionated IMRT (55.6%) compared to those patients treated with conventional techniques (19.4%).

Huang et al.[217] reported on 15 patients with pediatric medulloblastoma treated with conventional craniospinal radiotherapy followed by a boost to the posterior fossa using IMRT. IMRT delivered lower doses of radiation to the auditory apparatus while maintaining full doses to the desired target volume. Their findings suggested that, despite receiving higher doses of cisplatin and despite receiving radiotherapy before cisplatin therapy, IMRT can significantly decrease the rate of hearing loss in children treated for medulloblastoma.

Glioblastoma multiforme (GBM) has a very poor outcome, with a median survival of 12 to 16 months following resection.[218] Floyd et al.[219] used hypofractionated IMRT tomotherapy to treat 20 patients with primary disease. Fifty Gy in 10 daily fractions was given with 30 Gy (10 fx) to surrounding edema. Time to disease progression was 7 months, so no gain in survival was seen, but the treatment time was reduced from 6 to 2 weeks. Stupp et al.[220] studied outcomes in GBM patients after resection who were treated with RT with or without adjuvant temozolomide: the chemoradiation group had a median survival of 14.6 months compared to 12.1 months with RT alone. A review of temozolomide therapy for brain tumors was recently done by Koukourakis et al.[221] Amelio et al.[222] recently reviewed the use of IMRT, including hypofractionation, in the treatment of glioblastoma and in particular for elderly patients. They concluded that there is clinical advantage with IMRT because higher doses can be given in shorter times without increasing toxicity.

IMRT of Breast Cancer

Radiation therapy for breast cancer poses challenges, in particular large differences in tissue thickness in the radiation field and the close proximity of the lung apex and the heart, coupled with target motion during the breathing cycle. Taylor et al.[223] reviewed excess mortality because of cardiac damage in patients treated from 1950 through 1990, when cardiac doses of up to 14 to 17 Gy were given. In addition, part of the radiation field contains the skin boundary between tissue and air. Because air scatters much less of the x-ray fluence, there can be significant dose inhomogeneities and overdosing of the skin ("skin flash"). Commercial systems are available that can autocontour the volume of breast tissue within conventionally designed tangential photon portals and then use an inverse planning algorithm to optimize dose homogeneity within these tangential portals. However, most commercial inverse planning systems could not handle the "skin flash" appropriately. The traditional IMRT technique to overcome target motion uncertainty (such as breathing) is to expand the PTV and optimize the dose coverage to the entire PTV. However, this strategy may not work because a portion of the PTV will be expanded into the air, which does not have the necessary mass to absorb the dose. Some treatment planning systems ignore the regions outside the skin contour entirely. Therefore, it may be necessary to add "virtual" tissues in the PTV for the inverse planning system. Sometimes, it may require users to manually open certain IMRT segments to take care of the skin flash effect.

Nevertheless, there has been interest in using IMRT for left-sided breast cancers in order to spare myocardium from the high-dose region of the radiotherapy fields. The Guerrero Urbano and Nutting IMRT review includes a concise summary of early work through about 2002.[224] No robust data regarding clinical outcomes after IMRT for breast cancer exist; however, a variety of dosimetric studies[225–231] have suggested reductions in lung and myocardium doses when IMRT is compared to conventional radiotherapeutic techniques. Hurkmans et al.[232] used an NTCP model to estimate the NTCP for cardiac and lung complications because of radiotherapy and found that IMRT did decrease the NTCP for late cardiac toxicity compared to more conventional radiotherapy techniques but had a minimal effect on the NTCP for radiation pneumonitis. A potential drawback is a larger volume of normal tissue in the thorax receiving lower radiation dose levels.

Hong et al.[227] reported a dosimetric study of IMRT in 10 cases of intact breast cancer showing significant reduction of dose to the coronary arteries, ipsilateral

lung, and surrounding soft tissues. It simultaneously improved dose homogeneity throughout the target volume. Li et al.[228] described a combined electron and IMRT technique for breast cancer treatment, which led to improvement over the conventional treatment technique using tangential fields with reduced dose to the ipsilateral lung and the heart. Other studies[226,231] also confirmed that IMRT reduces the high-dose volume in tangential breast irradiation significantly and enables more complete cardiac sparing without compromising PTV coverage in some patients. Furthermore, IMRT creates a possibility to improve field matching in case of multiple field irradiations of the breast and lymph nodes.[231,233,234] In addition, IMRT for tangential breast radiation therapy was found to be an effective and efficient method to achieve uniform dose throughout the breast. Preliminary findings showed minimal or no acute skin reactions with different breast sizes in 32 patients with early-stage breast cancer.[233] Taylor et al.[235] reviewed results of RT of breast cancer patients in 2006 and found that use of more modern planning had significantly reduced mean heart doses to 2.3 Gy but that a small part of the heart still received more than 20 Gy in left-sided irradiation.

IMRT of Gynecologic Cancer

In regard to the targeting of pelvic lymphatics with IMRT, Taylor et al.[236] mapped the pelvic lymphatics of 20 patients using MRI with the administration of iron oxide particles and found that a modified CTV margin of 7 mm around the iliac vessels resulted in adequate coverage of the pelvic lymphatics.

Ahamad et al.[237] analyzed the normal tissue-sparing effects of IMRT in the treatment of the pelvis after hysterectomy in patients with gynecologic cancers and found that although more small bowel, bladder, and rectum could be spared with IMRT compared to conventional radiotherapeutic techniques, these benefits rapidly diminished with even small expansions of the target volumes. D'Souza et al.[238] used the same dataset of patients as Ahamad et al.[237] and found that IMRT may allow higher doses of radiation (54 Gy) to be delivered safely to the node-bearing regions of the pelvis and the vaginal apex compared to conventional techniques that administer 50.4 Gy. Gielda et al.[179] reported on a small study of gynecologic cancer patients ineligible for brachytherapy who were treated with tomotherapy in an attempt to reduce toxicity to bowel and femoral heads.

Salama et al.[239] reported on 13 patients treated with extended field pelvic and para-aortic radiotherapy using IMRT and found that two patients experienced grade 3 or higher toxicity. Both of these patients received concurrent cisplatin-

based chemotherapy.

Portelance et al.[240] described dosimetric comparison between 3DCRT and IMRT for 10 patients with cervical cancer. They demonstrated that, with similar target coverage, normal tissue sparing was superior with IMRT. Mundt et al.[241] reported the clinical experience of 40 patients with gynecologic malignancy who underwent IMRT to the pelvis. Compared with 35 historic control patients who were treated with conventional techniques, patients treated with IMRT experienced fewer acute gastrointestinal (GI) symptoms than those treated with conventional whole-pelvic radiotherapy. The ability of IMRT to deliver local control while reducing grade ≥2 bowel toxicity was shown in a recent report by Portelance et al.[242] from the multi-institutional RTOG 0418 cervical cancer trial. Ring et al.[243] did a study on 36 patients with FIGO (International Federation of Gynecology and Obstetrics) stage IB2 to IIIB cervical cancer. They were treated with extended field radiation therapy with concurrent cisplatin to target suspicious pelvic or para-aortic lymph nodes or excessive local pelvic tumor burden. At 32 months, 24 patients were disease-free and an additional 8 were still alive but with disease.

IMRT of Gastrointestinal Cancer

Pancreatic cancer remains a disease with a poor prognosis. In 1995, Lillemoe[244] reviewed then-current disease management. By this time, mortality from surgical resection had been reduced to 2% or 3%, but the weighted average 5-year overall survival was still only about 22%. In 2011, Showalter et al.[245] reanalyzed the data from RTOG 9704 on the results of surgical resection and adjuvant chemoradiation. Interpolating their Figure 11.2, one can estimate 5-year overall survival as about 28% for node negative and 19% for one to three positive nodes —not significantly different in 15 years.

Crane et al.[246] attempted a dose escalation study with RT and gemcitabine in unresectable pancreatic cancer patients but had to discontinue due to dose-limiting toxicity.

Ben-Josef et al.[247] reported on 15 patients with pancreatic cancer treated with concurrent capecitabine and IMRT (45 to 55 Gy) and reported that only one patient had grade 3 GI toxicity, specifically GI ulceration, which responded to medical management.

Brown et al.[248] performed a dosimetric analysis of 15 patients with pancreatic cancer and compared 3DCRT, IMRT with sequential boost, and IMRT with integrated boost and found that IMRT with integrated boost allowed dose

escalation up to 64.8 Gy to the primary tumor. More recently, Yovino et al.[249] reported that IMRT produced a statistically significant reduction in upper and lower GI toxicity compared to 3DCRT in chemoradiation treatment following RTOG 9704 guidelines.

IMRT for GI cancers (including pancreas) was recently reviewed by Bockbrader and Kim[250] from the radiobiologic and dosimetric as well as clinical outcomes viewpoint. Meyer et al.[251] gave the rationale for IMRT with PET/CT in anorectal cancers as to reduce radiation-associated morbidity. They also present some clinical data.

Guerrero Urbano et al.[252] performed a dosimetric evaluation in five patients with locally advanced rectal cancer and found that IMRT with SIB theoretically reduced the radiation dose to the small bowel compared to 3D conformal techniques. Milano et al.[253] reported on 17 patients with squamous cell carcinomas of the anal canal treated with IMRT with whole-pelvic radiation doses of 45 Gy followed by boost to the anal canal. Thirteen patients received concurrent 5-fluorouracil and mitomycin C chemotherapy. Treatment was well tolerated with no grade 3 or higher nonhematologic toxicity and no required treatment breaks from skin or GI toxicity. However, one patient receiving mitomycin C chemotherapy did experience grade 4 hematologic toxicity. Three patients who did not achieve a complete response required abdominoperineal resection and colostomy. With a mean follow-up of 20.3 months, there were no other local failures.

Milano et al.[254] also reported on seven patients with gastric cancer treated with IMRT to a dose of 50.4 Gy. No patient experienced grade 3 toxicity. The treated IMRT plans were compared to conventional anterior–posterior/posterior–anterior and three-field plans, and the IMRT plans were found to provide better coverage of the target volumes compared to conventional techniques, with better sparing of the liver and kidneys.

RTOG0529 reported in their dose-painted IMRT technique that dose–volume normal tissue design is somewhat predictive for acute and late GI toxicity for anal carcinoma chemoradiotherapy.[255]

IMRT of Lung Cancer

Because of concerns regarding respiratory motion in radiation therapy of lung cancer, the use of IMRT requires some method to account for tumor and organ motion during treatment planning and delivery; these techniques include both respiratory gating[134] and four-dimensional CT planning.[256] Starkschall et al.[257]

recently reported direct 4D CT measurements of interfraction GTV movement during free breathing and concluded that breath hold gating provides reproducible tumor localization. With cone beam CT or orthovoltage x-ray, the appropriate margins are 0.3 cm for implanted fiducials and 0.8 cm for bony landmarks.

The poor local tumor control rates of conventional radiation therapy doses in the treatment of lung cancer[258] have led to much interest in using IMRT to allow for dose escalation to improve local control. Holloway et al.[259] reported the initial results of five patients with unresectable stage II and III non–small cell carcinoma treated on a phase I dose escalation trial using induction chemotherapy followed by IMRT to a dose of 84 Gy (2.4 Gy daily fractions). PET/CT was used to define target volumes. One patient developed lethal radiation pneumonitis and the trial was halted. Murshed et al.[260] performed a dosimetric analysis of 41 patients initially treated with 3DCRT to a dose of 63 Gy. IMRT plans were generated using these patients' initial planning CT scans, and IMRT was found to decrease the volume of lung irradiated to both 10 and 20 Gy. Target coverage was improved with IMRT, and the volumes of heart and esophagus irradiation were also reduced. Figures 11.19 and 11.20 illustrate MLC portals and IMRT treatment plans for lung cancer.

Grills et al.[261] performed a dosimetric comparison of four radiotherapy techniques in 18 patients with stages I to IIB lung cancer comparing IMRT, optimized multiple-beam 3DCRT, two- to three-beam 3DCRT, and traditional wide-field radiotherapy with elective nodal irradiation. This study found that IMRT and optimized 3DCRT resulted in similar doses of radiotherapy to normal tissues in node-negative patients; however, in node-positive patients, IMRT resulted in a 15% decrease in the volume of lung treated to 20 Gy (V_{20} GY) and a 30% decrease in the NTCP for radiation pneumonitis. In 2010, Liao et al.[262] reported the outcomes of 409 non–small cell lung carcinoma patients treated at MD Anderson. Three hundred and eighteen patients received CT/3DCRT and 91 received 4D CT/IMRT to a median dose of 63 Gy. The mean lung dose was slightly higher for the IMRT group (24.9 Gy compared to 22.1), but the mean and 95% confidence interval range was lower for IMRT (34.4% ± 1.2% vs. 37.0% ± 1.1%). When corrected for factors such as smoking status, histology, and nodal status, the hazard ratio for IMRT to 3DCRT was significantly less than one, as was that for toxicity (grade 3 pneumonitis), whereas distant metastases were similar. Therefore, IMRT gave similar or better results in terms of survival and local control while reducing treatment toxicity. Vogelius et al.[263,264] pose a

cautionary warning—their dosimetric modeling showed that when RT is used in combination with chemotherapy, the larger volume exposed to lower radiation doses in IMRT could pose problems with pneumonitis as compared to 3DCRT or proton therapy.

IMRT Experience with Other Cancer Sites

Complementing strong evidence supporting the use of IMRT in head and neck and prostate cancer, a number of studies report the feasibility and outcomes of IMRT in other cancers; many of these reports are theoretical dosimetric studies. Theoretically, improved dosimetry alone probably does not serve as sufficient justification for the routine use of IMRT in these cases, and in the absence of robust clinical data regarding actual treatment outcomes, IMRT in these settings should be considered investigational.

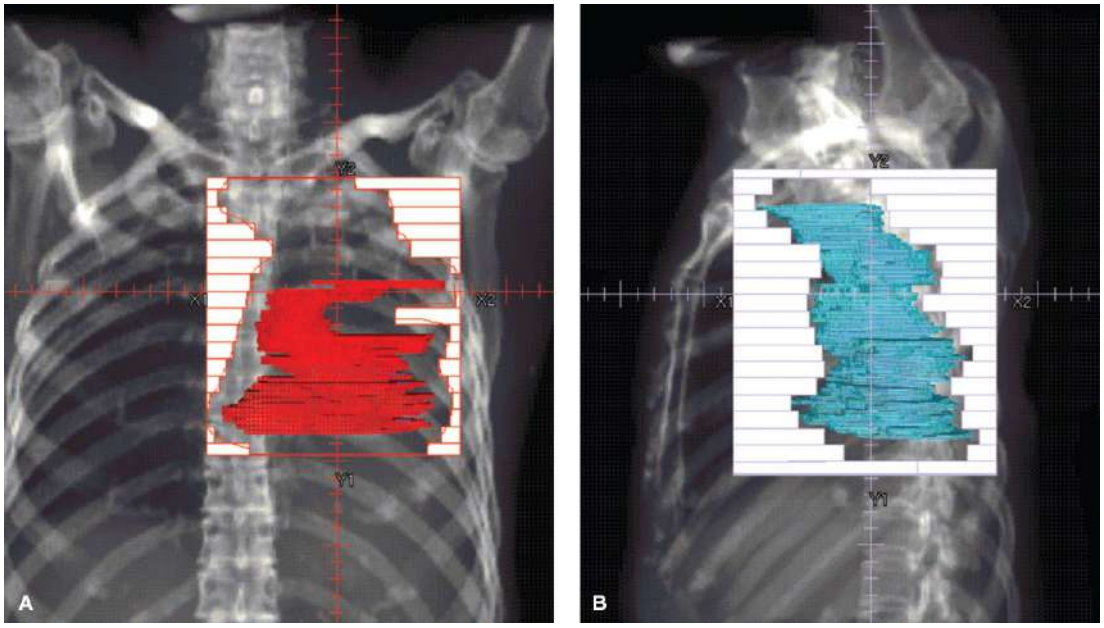

FIGURE 11.19. Illustration of anterior–posterior **(A)** and oblique **(B)** multileaf collimator configuration.

In closing, IMRT results in improved radiation dose distributions in a variety of cancers. In some cases, the superior dosimetry of IMRT has resulted in improved clinical outcomes for patients; however, the scientific evidence documenting these clinical improvements lags far behind the data documenting improved dosimetry. Many patients present with disease for which the likelihood of cure is remote, but for whom reduction of tumor burden with fewer debilitating toxicities will be an attractive option. Reduction in treatment

morbidity is an immediately realizable benefit of IMRT. Improvement of survival will require better ability to image the biologic activity of malignancies, and this is an area of very active research. It is incumbent on radiation oncologists to continue to document improved clinical outcomes with IMRT in the peer-reviewed literature if we wish to justify the use of this expensive technology to our communities in an era of skyrocketing medical costs.

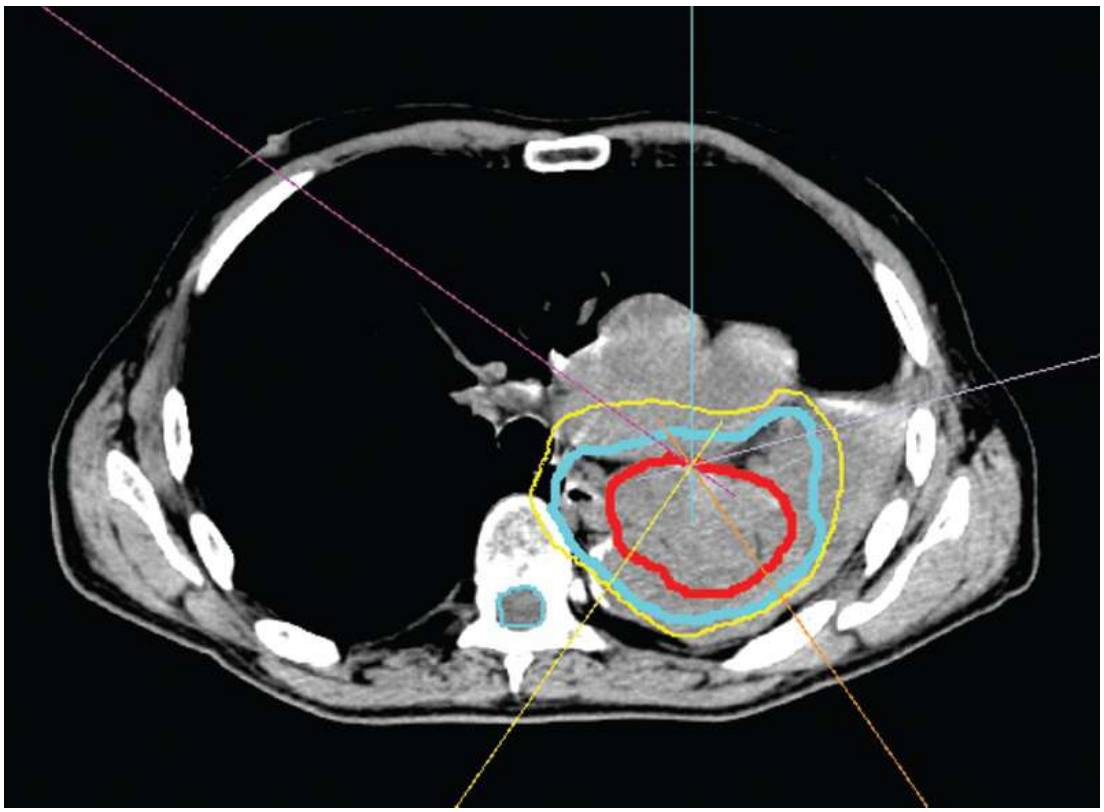

FIGURE 11.20. Intensity-modulated radiation therapy (IMRT) plan for locally advanced non–small cell lung cancer. Inner red line is the gross tumor volume (GTV); clinical tumor volume (CTV) is shown as a light blue aqua contour, which includes nodal regions to left of the GTV. The outermost yellow contour is the 60-Gy isodose line.

CHAPTER 12

Image-Guided Radiation Therapy

Daniel Robert Simpson, Loren K. Mell, Arno J. Mundt, and Todd F. Atwood

INTRODUCTION

Over the past few decades, the field of radiation oncology has seen rapid and extensive technologic advancements that have completely transformed radiation therapy planning and delivery. Undoubtedly, this transformation would not have been possible without the introduction of image-guided radiotherapy (IGRT). Although there are various definitions of IGRT, for the discussion herein, the term broadly refers to applications that incorporate imaging into radiation therapy planning and delivery with the overarching goal of improving treatment accuracy. Thus, this chapter will discuss a wide range of imaging modalities, old and new, and their applications in radiation therapy.

Why is IGRT Necessary?

As clinical radiation therapy devices continue to evolve with improving capabilities for precision treatment delivery, so increases the need for improved treatment accuracy. Modern treatment techniques such as intensity-modulated radiation therapy (IMRT), stereotactic radiosurgery (SRS), and stereotactic body radiation therapy (SBRT) are able to conform radiation dose to a much greater degree than conventional techniques. These technologies create highly conformal dose gradients that allow for potential dose reduction to surrounding normal organs at risk (OAR), but in turn, there is increased risk of missing the target. Although this presents opportunity for mitigation of radiation-related toxicity, this also increases the likelihood of subtherapeutic tumor dose delivery, which can have catastrophic clinical consequences. In addition, practitioners of radiation oncology still face the common challenges inherent to radiation therapy caused by tumor heterogeneity, anatomic variation, physiologic motion, and patient positioning error. IGRT applications designed to address these issues can

be classified into two categories: image-guided *tissue delineation* and *in-room imaging*.

Tissue delineation refers to identification and definition of tumor or normal tissue during the treatment planning process. In modern radiation therapy practices, 3-D planning is standard and tissue volumes are delineated using computed tomography (CT) images. Although CT imaging provides adequate information for treatment planning in many cases, there are limitations in soft tissue definition and identification of physiologic subregions within tumors and normal tissues. The first part of this chapter will focus on applications of IGRT designed to improve tissue delineation through integration of advanced functional and biologic imaging modalities. In-room setup before and during radiation delivery introduces further potential uncertainty in target positioning. This uncertainty stems from various factors including human error, weight loss, tumor regression, and physiologic changes. These factors can cause drastic changes in target and normal tissue positioning over seconds to weeks and are often difficult to identify at the outset of treatment planning. The second part of this chapter will discuss various in-room IGRT modalities used to address these hurdles.

IMAGE-GUIDED TARGET/TISSUE DELINEATION

Positron Emission Tomography

Positron emission tomography (PET) has dramatically changed the way oncologists stage and treat cancer. PET scanning involves the systemic administration of a tracer labeled with a radioactive isotope, which emits positrons as it decays. PET scanners are able to detect the interaction of positrons in tissues and thus detect regions of increased radiotracer accumulation. Radiation therapy planning systems are equipped with rigid image registration software that can readily fuse PET images to planning CT images for purposes of target delineation. In addition, commercial software systems that incorporate deformable image registration can aid delineation by accommodating changes in patient anatomy and positioning between scans and segmenting target volumes based on quantitative methods (Fig. 12.1).[1,2]

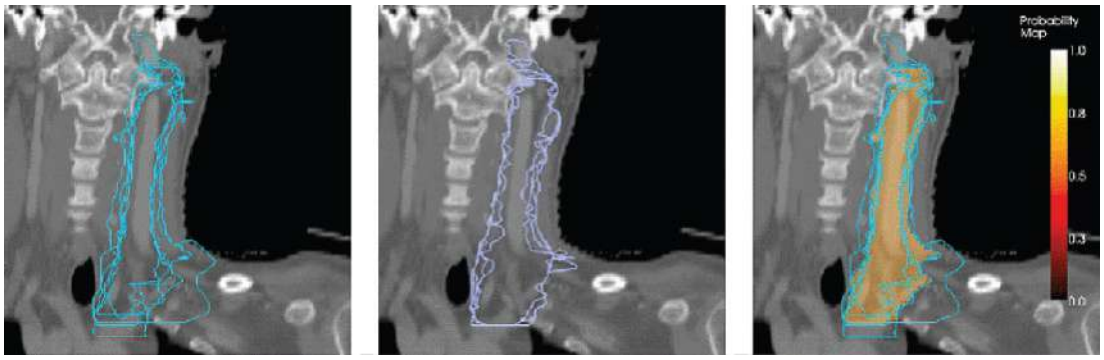

FIGURE 12.1. Reductions in contour variability are observed with automatic contouring. Physician manual contours shown in *blue*, automatic contours modified by physicians shown in *purple*, and manual contours using Simultaneous Truth and Performance Level Estimation (STAPLE) algorithm shown in *brown*. ^{18}F-Fluorodeoxyglucose-Positron Emission Tomography

The most widely used tracer is F18-fluorodeoxyglucose (^{18}F-FDG), which is taken into cells and trapped intracellularly. ^{18}F decays to ^{18}O, and the molecule enters the glycolytic pathway, but the metabolism of ^{18}F-FDG is slow relative to normal glucose, accounting for the high relative accumulation in metabolically active cells, including inflammatory tissue, neurons, brown fat, bone marrow, gastrointestinal (GI) epithelium, and tumors.[3] Studies in many different types of cancer have found that ^{18}F-FDG-PET improves staging,[4–8] thus improving risk-adapted management. In addition, multiple studies have shown correlation with ^{18}F-FDG uptake values and cancer prognosis,[9–11] making PET a desirable potential imaging biomarker for use in patient-directed treatment paradigms.

Multiple studies have evaluated the utility of ^{18}F-FDG-PET in radiotherapy planning for lung cancer.[12–17] Many of these studies have shown that incorporation of ^{18}F-FDG-PET imaging leads to significant alterations in treatment volumes in non–small cell lung cancer (NSCLC)[15–18] and mesothelioma.[19] PET aids in detection of occult nodal involvement and improves distinction of tumor from atelectasis compared to CT alone (Fig. 12.2).[16,20] Vanuytsel et al.[15] found that ^{18}F-FDG-PET-CT altered treatment volumes in over 60% of lymph node–positive patients staged by mediastinoscopy. The results of the Radiation Therapy Oncology Group's (RTOG) study RTOG-0515, a phase II trial with 52 NSCLC patients, demonstrated that ^{18}F-FDG-PET–guided treatment planning led to altered nodal volumes in 51% of patients and in general led to smaller tumor gross tumor

volumes (GTV) and mean lung dose. Although there is controversy regarding the optimal method of PET-guided target volume delineation, the use of PET does appear to reduce interobserver variation in target definitions.[12] Although early studies[18] reported on the use of standardized uptake values (SUV) for tumor demarcation, recent studies in both phantoms and patients indicate that gradient-based methods may be a more accurate and consistent technique for target volume contouring.[2,21]

Several studies have shown that ^{18}F-FDG-PET has similar utility for target definition in head and neck cancer (HNC).[17,22–26,26a,26b] Paulino et al.[27] compared CT and ^{18}F-FDG-PET–guided IMRT planning in HNC patients and found that CT-based plans were suboptimal in covering the PET-delineated GTV in 25% of patients. In a prospective analysis of 20 patients, Schwartz et al.[23] found that IMRT plans could be optimized with ^{18}F-FDG-PET-CT to improve parotid and laryngeal sparing and allow dose escalation up to 81 Gy. A study from Memorial Sloan Kettering Cancer Center found significant differences in magnetic resonance imaging (MRI) and PET-delineated target volumes drawn, thus indicating that various modalities provide important and complementary information for accurate target delineation.[24] GTVs delineated by using ^{18}F-FDG-PET appear to be significantly smaller than those delineated on CT alone.[24–26] Some concerns exist regarding the technical aspects of PET-guided radiation therapy in HNC, including difficulties in establishing optimal image registration[28] and large variability in target definition.[29] Recent studies indicate that automated techniques to guide delineation in HNC can improve consistency.[1,30,31] Leclerc et al.[32] tested a gradient-based ^{18}F-FDG-PET segmentation method in HNC patients in a prospective multicentric study. They found that this method consistently decreased the size of target volumes with resultant reduction in dose to the parotid glands and oral cavity. Importantly, they saw comparable clinical outcomes in terms of survival and no marginal tumor recurrences with a minimum follow-up of 2 years. Nonetheless, target delineation is still highly dependent on both segmentation and reconstruction methods, emphasizing the importance of clarifying and standardizing methodologies across institutions.[33,34]

^{18}F-FDG-PET–guided target delineation has also been evaluated in GI malignancies including both esophageal[8,35–40] and rectal[41–45] cancer. Hong et al.[37] studied 25 esophageal cancer patients undergoing ^{18}F-FDG-PET-CT for radiotherapy planning; PET influenced target delineation in 21 patients (84%), with changes classified as major in 9 (34%). However, Muijs et al.[8] reviewed 30

studies spanning 1,222 patients and found no conclusive evidence supporting the necessity of PET for radiation therapy planning. It is clear that PET is helpful in determining lymph node status and detecting occult metastases, but whether it is superior to other modalities for GTV delineation remains unclear. If used to delineate GTV, a threshold of 2.5 for either absolute SUV or SUV relative to liver uptake has been proposed.[40] As for rectal cancer, Braendengen et al.[41] compared GTV delineation with MRI versus ^{18}F-FDG-PET-CT in 77 patients. The results of this study indicate that PET-guided volumes tend to be smaller than MRI volumes, but PET guidance also often complements data from MRI. Dynamic ^{18}F-FDG-PET-CT may also play a role in the future.[43]

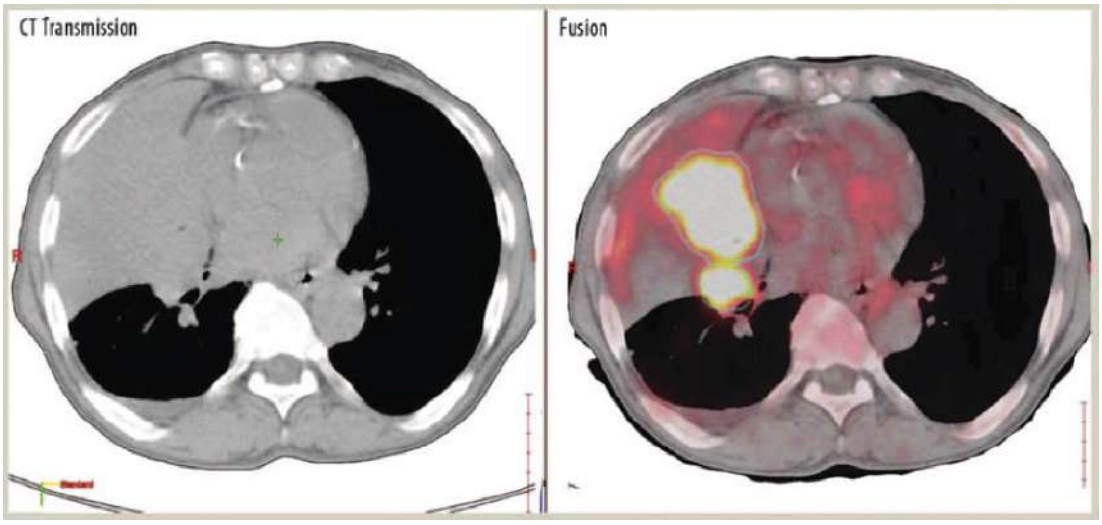

FIGURE 12.2. ^{18}F-FDG-positron emission tomography/computed tomography (PET-CT) scan in a patient with a right middle lobe lung carcinoma. On CT (*left*), the limits of the tumor are obscured by postobstructive pneumonia and atelectasis. On the fused scan (*right*), the tumor is intensely FDG-avid and more easily differentiated. (Reprinted from Spratt DE, Diaz R, McElmurray J, et al. Impact of FDG PE T/CT on delineation of the gross tumor volume for radiation planning in non-small-cell lung cancer. *Clin Nucl Med* 2010;35[4]:237–243. With permission.)

Investigators at Washington University have carried out extensive research in ^{18}F-FDG-PET for cervical cancer.[46–48] They have shown that PET-guided target delineation for cervical cancer patients with involved para-aortic lymph nodes can facilitate safe dose escalation to 60 Gy when used in conjunction with IMRT.[49] Serial changes in cervical tumor volume during brachytherapy[50] and external beam RT[51] have been documented, but the optimal treatment approach for metabolically unresponsive tumors is yet to be determined. Lin et al.[52] reported that ^{18}F-FDG-PET–based brachytherapy planning significantly optimized GTV coverage without increasing bladder or rectal dose. Liang et al.[53]

found that ^{18}F-FDG-PET–guided bone marrow–sparing IMRT for pelvic malignancies was feasible and reduced dose to active bone marrow. Related work by Rose et al.[46] has indicated that dose to metabolically active bone marrow subregions identified by ^{18}F-FDG-PET is a significant predictor of hematologic toxicity. Recently, Mell et al.[47] showed that reducing dose specifically to PET-identified active pelvic bone marrow mitigates hematologic toxicity in gynecologic cancer patients undergoing chemoradiotherapy, potentially permitting delivery of more intensive chemotherapy regimens.

The utility of ^{18}F-FDG-PET–guided radiation therapy in other disease sites is less clear. Although ^{18}F-FDG-PET can aid in contouring lumpectomy cavities in breast cancer[48] that involved nodal radiation therapy for lymphoma[54,55] and GTV delineation for pancreatic cancer,[56] the results from studies in sarcoma, central nervous system (CNS) tumors, and prostate cancer show ^{18}F-FDG-PET to be less helpful.[57,58] The data for ^{18}F-FDG-PET guidance in pediatrics are limited. Kornerup et al.[59] analyzed the utility of PET-CT simulation in pediatric patients with primary cancers in various sites. They compared target volumes contoured with and without ^{18}F-FDG-PET and used normal tissue complication probability (NTCP) modeling to estimate the effect of PET-guided treatment planning. Although their results indicated an impact for some individual patients, overall they found no consistent impact in target volume or NTCP across the cohort.

Non–^{18}F-FDG-Positron Emission Tomography

In addition to ^{18}F-FDG, many other radiotracers have been studied, including ^{18}F-thymidine (FLT), ^{18}F-misonidazole (^{18}F-MISO), ^{18}F-azomycin arabinoside (^{18}FAZA), ^{18}F-choline, ^{11}C-choline, ^{11}C-methionine (^{11}C-MET), ^{11}C-acetate, and ^{60}Cu(II)-diacetyl-bis(N^4-methylosemicarbazone) (^{60}Cu-ATSM). ^{15}O and ^{13}N—labeled H_2O, CO_2, O_2, or NH_3—molecules have also been used to measure blood flow, apoptosis, or hypoxia with PET.[60–62] New tracers are continually being developed and tested. For further discussion of novel molecular imaging applications, refer to several reviews.[60–64] Because of low physiologic uptake in brain tissue, ^{11}C-MET is a potentially useful radiotracer for image-guided planning of brain tumors. Grosu et al.[65] analyzed the use of ^{11}C-MET in patients with glioblastoma multiforme (GBM) and found that ^{11}C-MET uptake extended (up to 4.5 cm) beyond the tumor identified by MRI in nearly 75% of patients. ^{11}C-MET has also been shown to improve GTV delineation for skull base meningiomas.[66] A limitation of ^{11}C-MET PET, however, is the short half-life of

^{11}C (20 minutes). ^{18}F-ET leads to different GTV compared to MRI alone[67] but appears to be comparable to ^{11}C-MET (Fig. 12.3),[68] with the advantage of a longer isotope half-life. Milker-Zabel et al.[69] evaluated ^{68}Ga-(0)-D-Phe (1)-Tyr (221)-octreotide (^{68}Ga-DOTATOC) PET in meningioma patients and demonstrated that ^{68}Ga-DOTATOC PET significantly influenced target delineation in the majority of cases. Gehler et al.[70] found similar results, with ^{68}Ga-DOTATOC PET-CT changing target volumes in 17 of 26 patients.

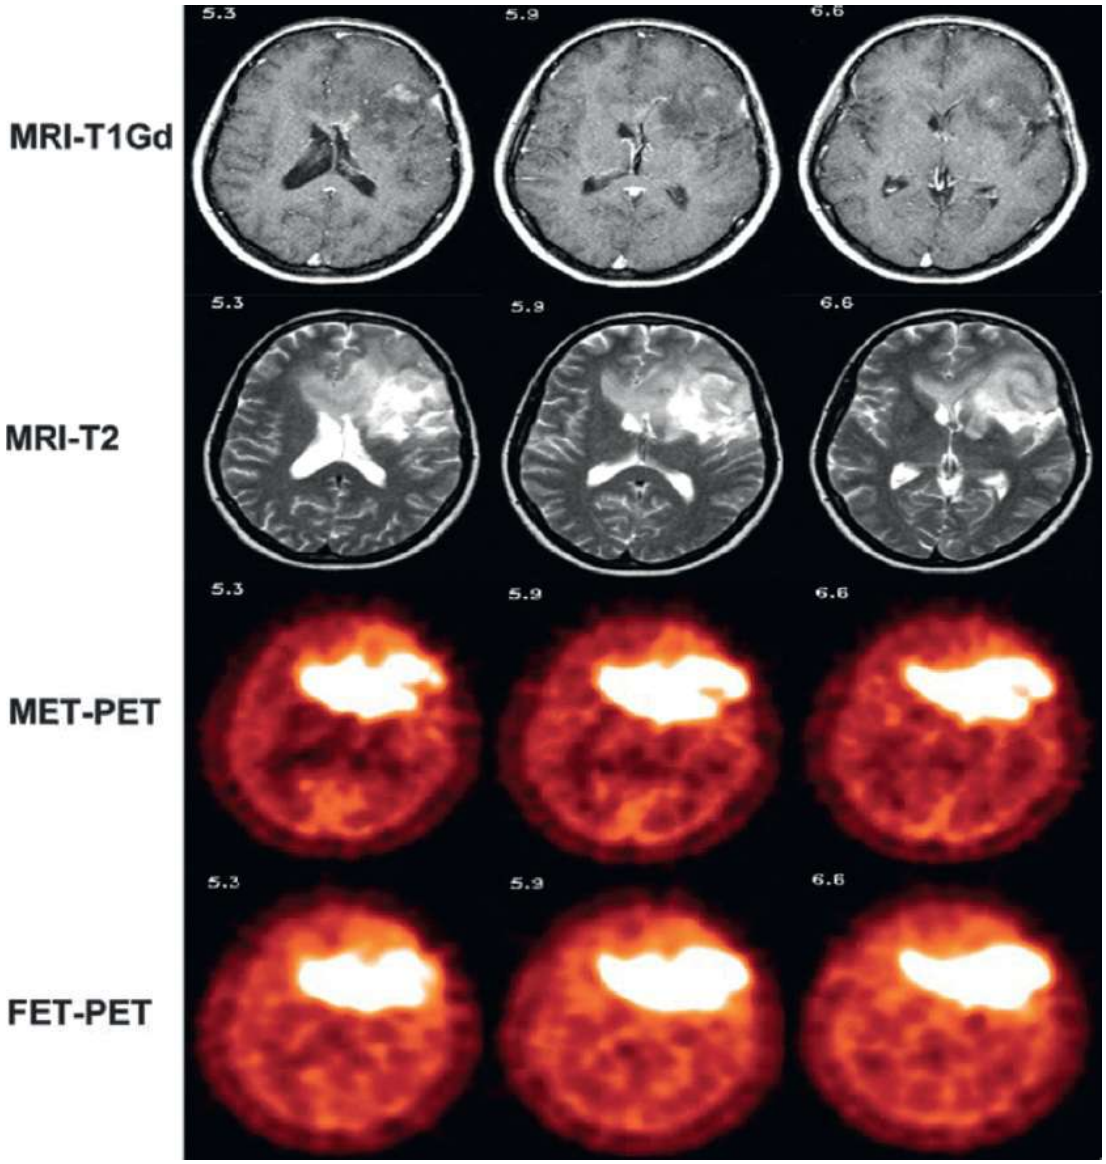

FIGURE 12.3. Comparison of magnetic resonance imaging, ^{11}C-methionine (^{11}C-MET) positron emission tomography (PET), and ^{18}F-fluoroethyl-L-tyrosine (^{18}F-ET) PET for a patient with grade III astrocytoma. (Reprinted from Grosu AL, Astner ST, Riedel E, et al. An interindividual comparison of O-(2-[^{18}F]fluoroethyl)-L-tyrosine (FET)- and L-[methyl-^{11}C]methionine (MET)-PET in patients with brain gliomas and

metastases. *Int J Radiat Oncol Biol Phys* 2011;81[4]:1049–1058. Copyright © 2011 Elsevier. With permission.)

Several investigators have explored PET-guided RT using ^{18}F-MISO[71,72] and ^{18}F-AZA.[73] The Trans-Tasman Radiation Oncology Group correlated hypoxia identified on ^{18}F-MISO PET with outcomes in 45 stage III or IV HNC patients undergoing chemoradiation therapy, with or without the hypoxic cytotoxin tirapazamine.[72] Baseline hypoxia and residual hypoxia (detected on ^{18}F-MISO PET scans at week 4 or 5 of treatment) were correlated with higher rates of locoregional failure. ^{60}Cu-ATSM has attracted attention for hypoxia imaging because of its potential biokinetic advantages and better resolution. ^{60}Cu-ATSM PET-guided hypoxia imaging has been investigated in HNC and cervical cancer.[74,75] In a pilot study in 14 cervical cancer patients, ^{60}Cu-ATSM appeared to provide good prognostic discrimination; 5 of 5 patients with hypoxic tumors developed recurrence versus 3 of 9 with normoxic tumors.[75]

^{11}C-choline and ^{18}F-choline have both been studied in prostate cancer,[76,77] but their utility for routine clinical care is unclear. SUV values from ^{11}C-choline PET appear to correlate well with histopathologic specimens as a threshold for contouring dominant intraprostatic lesions.[76] ^{18}F-FLT PET can be potentially useful in certain cancers, such as esophageal cancer, where its positive predictive value for involved nodes may be higher than for ^{18}F-FDG-PET.[39] In a study of five NSCLC patients undergoing serial baseline and on-treatment ^{18}F-FLT PET, reductions in ^{18}F-FLT uptake within both tumor and bone marrow were observed.[78] However, ^{18}F-FLT PET guidance appears to provide less benefit for tumor and nodal delineation in rectal cancer and HNC.[79,80] Arens et al.[81] tested the use of an ^{18}F-FLT PET–based adaptive segmentation method in HNC. They demonstrated robustness and reproducibility with this method as well as clinical prognostic value associated with serial ^{18}F-FLT PET parameters. Novel PET agents have also been used for normal tissue sparing. Investigators at the University of Melbourne[82] conducted a prospective clinical trial using 4-D ^{68}Ga-labeled macroaggregated albumin PET for functionally adapted lung sparing in 20 patients with NSCLC. Their results showed a significant reduction in functional mean lung dose with this method (Fig. 12.4).

MRI

MRI-guided RT planning has well-established utility, particularly for CNS, HNC, and pelvic malignancies.[83–91] Some radiation departments have even transitioned to using MR simulators, and MRI-only planning approaches are

becoming more widely available (Fig. 12.5).[92] In addition to standard MRI modalities, functional MRI (fMRI) techniques have been used to enhance radiation planning. For example, fMRI has been used to reduce radiation dose to a normal functioning brain during planning for CNS tumors.[93–97] Aoyama et al.[96] evaluated the use of magnetoencephalography and anisotropic diffusion-weighted MRI for CNS targets including arteriovenous malformation (AVM). In 15 patients, target volumes were modified with significant reduction in the volume of sensitive regions receiving more than 15 Gy. Fast imaging employing steady-state acquisition can facilitate visualization of the trigeminal nerve during radiosurgery planning.[98,99] The ^{1}H MR spectroscopy (MRS) has also been used to guide planning in gliomas.[100,101] Underdosing of volumes delineated using ^{1}H MRS metabolically active areas has been associated with worse outcomes in GBM.[101]

In patients with prostate cancer, van Lin et al.[102] have reported the feasibility of escalating doses to 90 Gy to dominant intraprostatic lesions identified by ^{1}H MRS. MR lymphography with intravenous ferumoxtran-10 has also been used to identify pathologic nodal involvement in prostate cancer (Fig. 12.6).[103,104] In a study of 47 patients treated with salvage RT for rising postprostatectomy prostate-specific antigen (PSA), 79% were found to have at least one aberrant positive lymph node, including 10 of 18 (61%) with a PSA <1.0 ng/mL. MR lymphography may therefore be useful in helping to define nodal boost volumes in prostate cancer. Dynamic contrast-enhanced (DCE) MRI has been investigated for RT planning in a variety of tumors including HNC, lung, rectal, and cervical cancers.[105–108] Mayr et al.[108] studied 102 cervical cancer patients treated with DCE MRI. Patients with a low total volume of tumor voxels with low DCE signal had significantly worse tumor control and disease-specific survival. Carmona et al.[109] used an MRI technique called iterative decomposition of water and fat with echo asymmetry and least squares estimation (IDEAL) to study fractional changes in fat content of pelvic bone marrow during pelvic chemoradiation therapy (Fig. 12.7). Conversion of the bone marrow from low fat, high cellularity to high fat, low cellularity during RT is readily observed, enabling noninvasive quantitative methods to analyze the impact of local changes in radiation dose.

Axial iterative decomposition of water and fat with echo asymmetry and least squares estimation (IDEAL) magnetic resonance imaging scans of the pelvis in a gynecologic cancer patient undergoing chemoradiotherapy. Scans were acquired at baseline (*left*), midtreatment (*middle*), and posttreatment (*right*) and show a steady increase in fraction of fat relative to water within the pelvic bones, indicated by conversion to progressively higher signal.

SPECT

Single-photon emission computed tomography (SPECT) is a well-established functional imaging technique, with a wide range of potential tracers. In addition to being relatively cost-effective compared to PET, SPECT has some dosimetric advantages. Although PET can provide more accurate quantitative information regarding *in vivo* radiation dose distribution,[63] SPECT tracers typically have longer half-lives and release less energy, leading to favorable dosimetry and utility for studying slower biologic processes.[63] Nonetheless, SPECT-guided treatment appears to be less widely adopted in radiation oncology.[110]

Several studies have demonstrated utility of ^{111}In-capromab pendetide radioimmunoscintigraphy (RIS) guidance for both external beam RT[111–113] and brachytherapy[114,115] for prostate cancer. Jani et al.[116] found that RIS guidance led to alteration of RT volumes and decision-making in a significant proportion of patients undergoing postprostatectomy salvage RT. Of 54 evaluable patients, 18.5% had treatment plans altered by RIS, including 4 patients who were not offered RT based on the RIS findings. In a multivariate analysis of 107 patients (53 planned with RIS), RIS was associated with an improved 3-year biochemical failure-free survival (bFFS).[112] A similar analysis of 82 patients undergoing RIS for salvage therapy, however, did not reveal a clear benefit of RIS.[116] Ellis et al.[114] treated 80 low–intermediate-risk prostate cancer patients with RIS-assisted brachytherapy. Regions of the prostate showing increased RIS uptake were prescribed 150% of the standard dose. The overall 4-year bFFS was 97.4%.

Other applications of SPECT-guided treatment planning have been studied, including ^{123}IMT (^{123}I-alpha-methyl-L-tyrosine) SPECT for gliomas[117–119] and meta-^{123}iodo-benzylguanidine scans for neuroblastoma.[120] Krengli et al.[119] studied 21 patients with high-grade gliomas using fused ^{99m}Tc-MIBI SPECT and MRI. Similar to findings of Grosu et al.,[118] target volumes were significantly augmented by SPECT, with an average increase of 33% over MRI alone, particularly in resected cases.

SPECT has also been used to guide normal tissue avoidance. In patients with NSCLC, Christian et al.[121] used ^{99m}Tc SPECT to identify functional lung to avoid using inverse RT planning and showed the V20 of functioning lung could

be reduced without compromising target coverage. Roeske et al.[122] used ^{99m}Tc SPECT to identify active bone marrow subregions to reduce hematologic toxicity in patients receiving pelvic chemoradiation therapy.

Four-Dimensional Imaging and Motion Management

Respiratory-induced organ motion is a significant problem in radiation therapy. Tumors located in the thorax and upper abdomen can move in large amounts during normal respiration. If ignored, respiratory motion can result in substantial imaging artifacts on the treatment planning images, which can lead to inaccurate target delineation and/or unnecessarily large target volumes.[123,124] Several motion management strategies currently exist: free breathing (target compensates for the full range of tumor motion), abdominal compression (device limits diaphragm expansion and tumor motion), respiratory gating (select portions of the respiratory cycle are utilized for treatment), and real-time tumor tracking (radiation beam follows the moving target).[125] Although all of these techniques have their advantages and disadvantages, choosing the optimal technique for an individual institution depends on the clinical needs and staff expertise.

Respiratory Gating

Respiratory gating refers to the process of limiting the radiation beam to select portions of the respiratory cycle, thus treating the tumor at a specific position. Respiratory gating has two main approaches: internal (utilizing internal surrogates for tumor motion) and external (utilizing an external device to monitor respiration as a surrogate for tumor motion).[126–128] The external approach is far more prevalent in radiation oncology today, where respiration information is determined from markers on the patient's abdomen, a compression belt, or spirometer signals.

The Real-time Position Management (RPM) system (Varian Medical Systems, Palo Alto, CA) is a popular example of an external respiratory gating system. This system consists of a lightweight plastic block containing multiple passive reflective markers, which is monitored by a charge-coupled device video camera mounted in the treatment room. When the block is placed on the patient's abdomen, the system can be used to generate a respiratory waveform surrogate for tumor motion during both simulation and treatment.
