patients with low-grade tumors. With longer follow-up of the high-grade tumors only, local control was 89% versus 66% (P = .0025) but no effect was seen on distant metastases or overall survival. Functional parameters were well maintained post brachytherapy. PDR brachytherapy has been used in adults and children, either as a boost (for large tumors where compartmental surgery proved difficult) or as radical treatment.[239–241] Studies report excellent local control with good cosmetic results and acceptable toxicity, comparable to results achieved with LDR. However, a retrospective study of adjuvant LDR brachytherapy to pre- or postoperative IMRT in primary extremity sarcoma showed 5-year local control with IMRT to be better than that with brachytherapy (92% vs. 81%, P = .04). This is despite the fact that the IMRT group had significantly higher rates of adverse features (e.g., tumors over 10 cm in size and close or positive surgical margins).

Surface Applicators

Brachytherapy surface applicators can be used to treat a variety of superficial targets using LDR or PDR. For curved or irregular surface or thicker lesions a customized mold can be constructed, often using an acrylic or thermoplastic cast (see Fig. 26.28). The brachytherapy catheters can be laid directly onto the mold or used with a spacer to ensure uniform catheter distribution. When used with computerized optimization, this surface applicator technique has been shown to give dose distributions that are more homogeneous than those for conventional

electron techniques.[242] A survey of members of ABS showed that many respondents preferred brachytherapy over EBRT because of shorter overall treatment times, conformality of treatment for irregular-shaped targets, and shallow dose deposition.[243] PDR carries the benefit of dose optimization, which allows the treatment depth to vary along different points of an individual catheter for lesions of varying thickness. Suitable superficial targets can also be treated with interstitial implants, which can give greater penetration of dose beneath the skin surface.

TABLE 26.4 GENERAL RECOMMENDATIONS FOR STS BRACHYTHERAPY (INCORPORATING ABS GUIDELINES)

Discuss patient preoperatively in a multidisciplinary setting
Determine CTV by radiographic, surgical, and pathologic findings
Place catheters to encompass CTV, demarcate CTV with surgical clips if possible
Identify and demarcate normal structures that are at risk for complications
Cover tenuous wounds with well-vascularized flaps
Place microvascular anastomoses away from radiation target area
Use drains over catheters to act as a spacer to increase the distance of the wound from the implant
Use spacers (e.g., Gelfoam) to increase the distance between catheters and critical normal structures
Ensure catheters enter skin at least 1 cm from surgical incision
Space catheters at 1–1.5 cm intervals in parallel arrays
Secure catheters carefully, immobilizing extremity if necessary
Use CT to determine the CTV and OAR
Do not load catheters until after the 5th day postoperatively

Surface applicator techniques have been used to treat primary tumors in both the radical and the palliative setting. A meta-analysis has shown that radiotherapy following surgery yields a lower keloid recurrence rate compared to radiotherapy alone and that brachytherapy had the lowest recurrence rate when comparing radiotherapy modalities (15% for brachytherapy compared to 23% for photons and 23% for electrons).[244] There does not appear to be a difference in recurrence rate between LDR or HDR.[245]

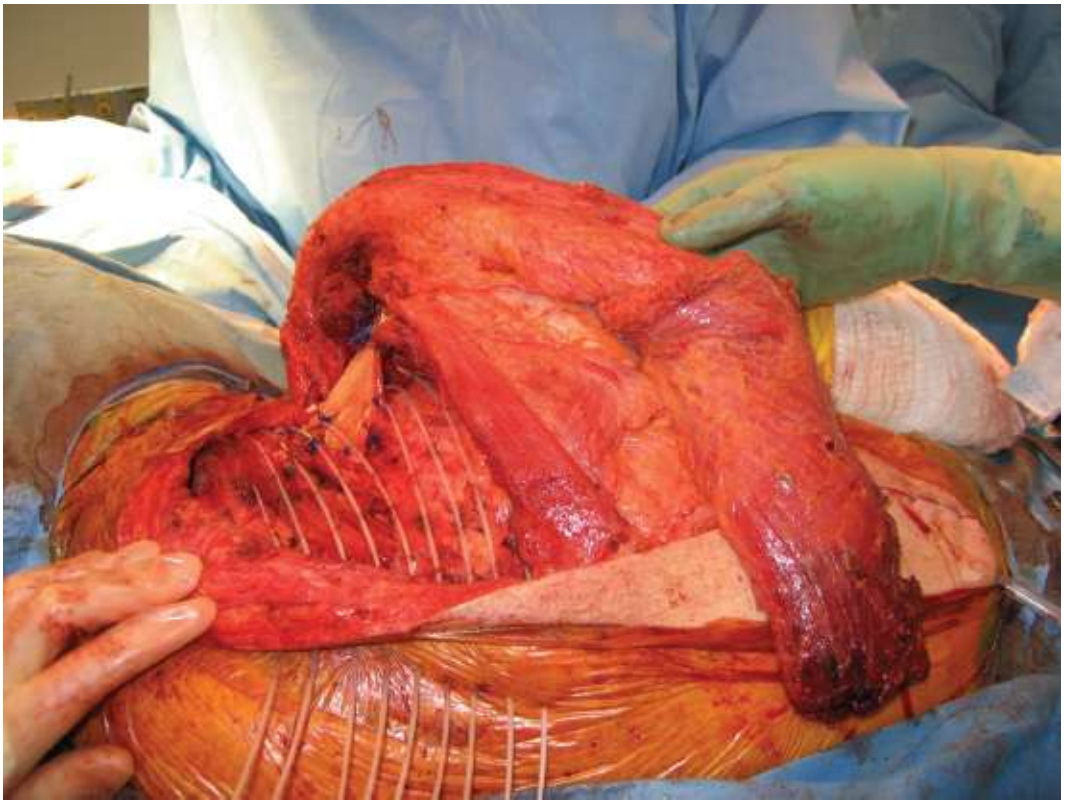

FIGURE 26.27. Intraoperative photograph of a multicatheter interstitial pulsed dose rate brachytherapy implant following excision of a sarcoma of the upper back.

FIGURE 26.28. Surface applicator mold used to administer brachytherapy to the dorsum of the foot following incomplete excision of an STS.

Surface applicator brachytherapy techniques have been used to treat locally recurrent breast cancer following previous chest wall irradiation. Using LDR ^{192}Ir implanted into flexible silicone sheets delivered in 2 to 3 fractions at monthly intervals to administer a total dose of 65 Gy 2 to 4 mm below the skin surface, Delanian et al.[246] showed a complete regression of tumor in 9 of 11 patients. The two patients who did not respond died from pulmonary lymphangitis 4 and 5 months after brachytherapy. One patient developed a necrotic ulcer in the skin, which healed after 8 weeks of symptomatic treatment. One patient died from respiratory failure that may have been related to cumulative pulmonary toxicity, which must be considered as a treatment complication. Some patients also received interstitial implants in the chest wall,

which would have increased the dose at depth to the previously irradiated tissue and to the underlying lung.

Harms et al. used PDR brachytherapy and flexible rubber surface applicator moulds in 58 patients with local recurrence of breast cancer who had received previous breast or chest wall EBRT. A median dose of 40 Gy to the skin surface in 2 fractions was administered at a median time interval of 31 days.[247] The local recurrence-free survival at 1 year was 96% for patients with microscopic disease at the time of brachytherapy and 89% for patients with macroscopic disease, and at 3 years, 75% and 71%, respectively. Seven percent of patients developed chronic ulcer, two of whom had undergone surgical treatment prior to reirradiation, and 50% of patients developed grade 3 telangiectasia in the treatment field. The skin toxicity was higher in this study, but this may have been a result of improved reporting of skin complications because the incidence of telangiectasia and fibrosis was not reported in the LDR study.

Ophthalmic Plaques

Ophthalmic brachytherapy applicators can be applied directly to the eye to deliver a highly localized dose with rapid falloff (see Fig. 26.29). These deliver dose to the conjunctiva of the eye, most commonly for malignant tumors of the conjunctiva such as squamous carcinoma, melanoma, and lymphoma or to prevent recurrence of pterygium following surgical excision. ^{125}I seeds are inserted into plaques formed of silicone, rubber inner seed holder with a gold exterior shield, and are then sutured to the sclera. ^{90}Sr and ^{106}Ru are manufactured as curved applicators, ^{90}Sr as a fixed diameter applicator (typically 12 mm) (see Fig. 26.30), and ^{106}Ru in a range of diameters. The eye is anesthetized with installation of local anesthetic eye drops. The applicator is soaked in an antiseptic solution, followed by double-rinsing in sterile saline. Sterile lubricant is then applied to the active surface of the applicator to lessen trauma to the cornea and sclera. The applicator is then gently applied over the area of bare sclera, adjacent limbus, and affected cornea and held in place by the operator for short applications or sutured to the sclera for longer applications. Undue pressure must be avoided, as this increases trauma and reduces the distance from the applicator to the lens, which is the dose-limiting normal tissue. If necessary, two treated fields can be overlapped if the area to be treated exceeds that of the active surface of the applicator though this, inevitably, carries a risk of increased acute and chronic sequelae. After treatment, the patient wears an eye patch for 2 hours until the local anesthetic wears off. Some degree of

conjunctivitis is common and if mild, can be treated with antibiotic eye drops. If moderate to severe, steroid-containing eye drops should be used. Long-term sequelae are unusual but more likely with higher fraction size and higher total dose. Scleral ulceration is the most common complication in doses up to 52 Gy, with a small percentage of eyes developing symblepharon—fusion of the eyelid to the globe. Surgical trauma also plays a part in these sequelae. A small percentage of eyes will develop radiation-induced cataracts, again at higher doses (>45 Gy).

FIGURE 26.30. Strontium ophthalmic applicator.

The Collaborative Ocular Melanoma Study (COMS) group conducted 2 randomized trials in North America, examining the use of ^{125}I for choroidal melanoma. The study, examining the use of ^{125}I brachytherapy versus enucleation for tumors of 3- to 8-mm depth, demonstrated no difference in survival and similar rates of toxicity[248,249] for the two techniques, thus supporting the use of ^{125}I. A SEER database analysis has shown similar survival outcomes for plaque brachytherapy compared to EBRT for choroidal melanoma.[250]

The use of Palladium-103 and Cesium-131 seeds has also been investigated with promising dosimetric results.[251,252] In fact, ^{103}Pd has similar efficacy to ^{125}I, but patients have an improved visual acuity following treatment with ^{103}Pd.[253] Modern dosimetry planning is being employed to investigate whether side effects may be lessened with optimal planning techniques.[252,254,255]

Strictly speaking, ^{90}Sr delivers high-dose-rate brachytherapy (a beta emitter with a typical dose rate of 100 Gy/hour compared to ^{125}I, a gamma emitter with a dose rate of 0.5 to 1 Gy/hour). Thus, ^{90}Sr delivers a single fraction treatment dose over 2 to 3 hours whereas ^{125}I delivers a treatment dose over 30 to 300 hours. The percentage depth dose in tissue falls from 100% at the surface to 4%

at 4 mm, 1% at 6.5 mm, and 0.9% at 8 mm (corresponding to the anterior surface of the lens, equator, and posterior surface of the lens, respectively). Van Ginderdeuren et al. demonstrated a 90% 15-year tumor control for sclera melanoma using a ^{90}Sr applicator with a proportion of the recurrences at the edges possibly due to the small applicator size, using doses of 450 to 800 Gy at the sclera.[256] There was a 45% preservation of good vision, which was generally dependent on tumor position rather than dose delivered. Ruthenium-106 eye plaques can also be used and may become the beta emitter of choice as ^{90}Sr eye plaques gradually decay beyond useful dose delivery. They deliver similar results to ^{90}Sr and have even been used with thermotherapy to deliver improved outcomes.[257,258]

Pterygium is a benign proliferation of the conjunctiva over the cornea, occurring most commonly in areas with high sun exposure. Surgery can be performed for irritative symptoms, effects on vision, or cosmesis but carries a high recurrence rate. Locally applied ^{90}Sr has been used to decrease the rate of recurrence to as low as 0.5%,[259] using doses varying from 20 to 60 Gy in 1 to 6 fractions. The incidence of sclera complications is lower with fractionated treatment (4.5% vs. 1%). However, alternative treatments such as topical chemotherapy and conjunctival autografting are replacing ophthalmic plaque brachytherapy.[260,261] Brachytherapy should not be combined with topical chemotherapy because of the risk of scleral melting.

^{90}Sr has been used in the treatment of neovascular age-related macular degeneration (AMD), visual impairment caused by neovascularization beneath the retinal pigment of the retina. However, a phase 3 trial comparing patients with active AMD who were already on a vascular endothelial growth factor (VEGF) inhibitor to either vitrectomy followed by 24-Gy brachytherapy (and continuing prn anti-VEGF treatment) to anti-VEGF treatment on an as-required basis alone showed that visual acuity and disease activity was actually better in the as-required anti-VEGF arm.[262]

Anus

Squamous cell carcinoma of the anus is a rare cancer that is usually treated with chemoradiotherapy with good rates of sphincter preservation. The most common site of relapse is locally, and thus methods of local dose escalation have been explored. EBRT, preferably with chemotherapy, is necessary to treat the tumor and wider nodal area, and then the tumor boost can be delivered using brachytherapy.[263] Interstitial brachytherapy implants typically consist of a

single-plane catheter implant using a plastic perineal template curved around the anus. Catheter placement may be optimized by the use of advanced imaging techniques such as three-dimensional endoluminal ultrasound.[264,265] Papillon described an LDR boost using ^{192}Ir to deliver 20 to 30 Gy in 221 patients 2 months after completing EBRT. Local control rates were comparable to surgical techniques, and 90% of patients with no evidence of relapse remained colostomy free.[266] It has been suggested that when using a split-course technique, if treatment time is extended over 80 days a brachytherapy boost may provide better local control than EBRT.[267] PDR techniques have been described with similar rates of disease control and toxicity to LDR.[268–270]

Esophagus

A phase 3 randomized trial of conventional stents versus stents loaded with ^{125}I seeds showed that median overall survival was increased in the irradiation stent arm compared to the conventional stent arm whereas side effects were similar.[271]

Biliary

Stent insertion with insertion of ^{125}I seeds for malignant obstructive jaundice has been shown to increase the mean stent patency time (191 days vs. 88 days) and the median survival (241 days vs. 142 days).[272]

Central Nervous System

Although initial treatment for glioblastoma has improved over the past decade, most glioblastomas recur, the majority of these within 2 cm of the original tumor cavity. Because the majority of patients will have received 60 Gy to the tumor at the time of initial diagnosis, retreatment techniques may be limited; ^{125}I seeds can be used to deliver a conformal dose of reirradiation. At the time of recurrence the surgeon will perform the maximal resection possible and implant ^{125}I seeds in the excision cavity at 0.5 to 1 cm intervals. This gives a highly localized boost, assuming the volume of disease residual is small because the dose falloff is rapid. The procedure appears to be well tolerated, and survival compares favorably to that of similar patients who did not receive brachytherapy.[253,273,274] The use of ^{125}I seeds at the time of initial radiotherapy has been investigated but no difference was seen in randomized trials.[275,276] Thus, if a boost is required, this technique has generally been supplanted by stereotactic radiosurgery, which does not require a second invasive surgical procedure. GliaSite balloon brachytherapy (GBST) is a technique in which a balloon is sited in the resection cavity and liquid ^{125}I is injected through a

subcutaneous port for either primary or recurrent glioblastoma.[277] Results appear favorable.

^{125}I seed placement has also been described in patients with paraspinal tumors with a low rate of toxicity and good local control rates.[190,196] The procedure was well tolerated, and no myelitis was seen despite cumulative cord doses of up to 167 Gy.

Customized yttrium-90 dural plaques have been used intraoperatively in patients with spinal or paraspinal sarcomas to deliver a high localized dose to the dura whilst minimizing the dose delivered to the underlying spinal cord (see Fig. 26.31). Local control rates are promising, and there were no acute or late complications from brachytherapy.[278]

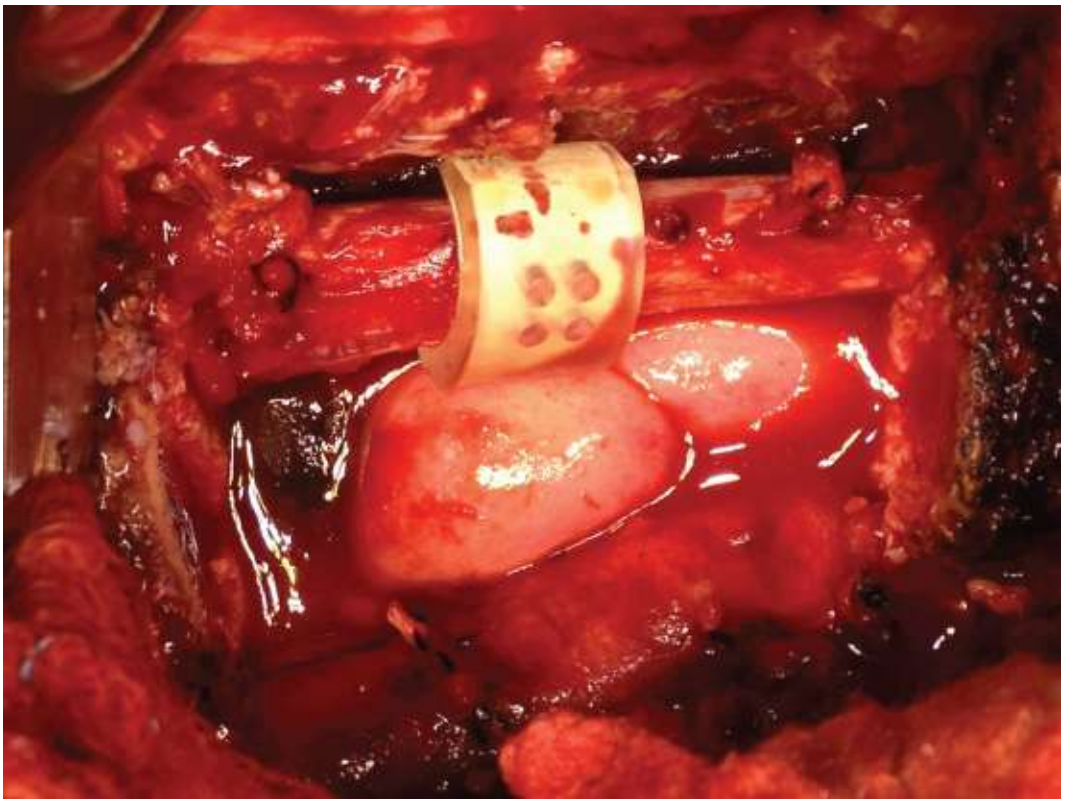

FIGURE 26.31. A dural plaque utilizes phosphorus-32 chemically bonded to a flexible polymeric film. The film is 0.5 mm thick and is backed by 4.5 mm of polycarbonate. Typical dose rates at time of treatment are in the 1.5 to 2.5 Gy/minute range.

CONCLUSIONS

The dosimetry of LDR brachytherapy treatment planning has evolved from estimation of dose delivered to accurate image-guided computer-optimized determinations of dose. Exact knowledge of the position of OAR and of the

conformation of target volumes combined with dose optimization achievable with PDR computerized afterloading source delivery allows the brachytherapist to tailor dose delivery to highly specific ideals and deliver with great fidelity. This has allowed improved prediction of late toxicity and the possibility for dose escalation in areas with a high tumor burden.

Brachytherapy is particularly suited to subvolume dose escalation because of the ability to deliver a highly localized dose with rapid dose falloff in the surrounding tissue. This could allow increased dose to subvolumes within a CTV without a corresponding increase in dose to surrounding normal tissues. It is important with the advent of these new techniques that the accepted methods of practice are constantly reexamined to ensure that the patient receives the optimum treatment with the lowest risk of complications in the future.

Dosimetry remains critically important within modern brachytherapy practice. Knowledge of the established dosimetry systems is critical to prevent late complications resulting from suboptimal catheter placement with reliance on computerized optimization to overcome this. Modern imaging techniques can provide three-dimensional information about a target volume and surrounding normal structures. It is important to generate methods of incorporating this new knowledge with existing practice.

LDR and PDR brachytherapy often require indwelling applicators or catheters that necessitate hospitalization for the duration of the brachytherapy course. Surgical procedures are often required to place the brachytherapy seeds and applicators. Special skill and training are required to perform brachytherapy, much of which is not generally a part of oncology training rotations. Fellowships in brachytherapy are valuable but unfortunately rare.

LDR brachytherapy may result in a radiation exposure to medical staff, though remote afterloaders and PDR techniques minimize this exposure. HDR techniques are more prevalent than PDR due in part to the ability to treat more patients each day with a single machine. However, PDR still appeals to many centers, especially those with a high throughput of interstitial brachytherapy cases. Such a highly localized treatment can result in little or no dose to adjacent areas at risk of tumor spread, risking marginal misses and tumor recurrence if case selection is not carefully considered.

Brachytherapy also requires a high initial capital outlay. The choice of brachytherapy as a radiotherapeutic modality must be made carefully with consideration of many factors: patient centered, tumor centered and resource centered.

CHAPTER 27

The Physics and Dosimetry of High Dose Rate Brachytherapy

Bruce Thomadsen and Rupak K. Das

NATURE OF HIGH DOSE RATE BRACHYTHERAPY

Conventional brachytherapy was developed very soon after the discovery of radium. The limited amount of radium that could be packed into the needles and tubes dictated the use of many sources to deliver a treatment dose through a target volume, and even with many sources, the delivery of the dose required durations from 1 day to 1 week. For the most part, when new radionuclides became available, they matched the strength of the radium sources to facilitate application of the clinical experience gained through the decades of radium treatments. This conventional treatment format describes low dose rate (LDR) brachytherapy, as discussed in detail in Chapter 25.

Beginning around 1962, a new approach to brachytherapy developed. Using very intense, small sources (usually of ^{60}Co in the early machines and often three in number) on the ends of cables, a treatment unit would move the source through the volume to be treated, delivering the radiation in a relatively short time (<1 hour). The rapid treatment delivery gave these treatments the name high dose rate (HDR) brachytherapy. The original units most often oscillated the source through a catheter's treatment length, a method in common use until the modern generation of units developed in the early 1980s, described later. The treatments took so little time that the therapy proceeded on an outpatient basis. However, for reasons discussed later in this chapter, the treatment regimen usually entailed several fractions delivered over days or weeks.

The modern HDR units move a single source through the treatment volume in a stepwise fashion, moving at intervals, determined by the machine construction and the operator, to positions where the source pauses (dwell positions) for durations (dwell times) determined through optimization procedures.

Advantages and Disadvantages

Advantages of HDR brachytherapy over LDR include the following:

- *Optimization*. The stepping-source design permits very fine control of the source position through the target volume. In most treatments, the determination of the dwell times comes from inverse planning, that is, specifying the doses desired at various locations and using some algorithm to calculate the dwell times that best fit the dose specifications. The map of how long the source dwells at each possible dwell position can be finely tailored to the geometry and needs of the particular patient because of the wide range of dwell times available. This process constitutes *optimization*. Although optimization is possible, and frequently used, with LDR applications, it forms a more natural part of the planning process with HDR brachytherapy.
- *Immobilization and stability*. The relatively short duration of the HDR treatments allows better stability of many intracavitary treatment applicators during the treatment and, thus, higher precision in conforming the dose to the target. In addition to simply not giving much time for applicator motion, the applicator and the patient can both be immobilized with respect to the treatment table over the duration of the treatment. Such fixation is not possible with LDR brachytherapy because the patient would not tolerate the immobility for long periods. Interstitial cases may or may not exhibit better stability. The needles often tend to slide outward over the time that prostate implants remain in the patient, even with a template sutured to the patient that fixes the needles. In such a patient, the needles' positions require adjustment before each fraction but move very little during the treatment delivery. Performing the same treatment using LDR brachytherapy would include needle movement during the long, slow delivery and require larger margins around the clinical target volume (CTV). On the other hand, head and neck implants, with buttons anchoring the catheters at both ends, may allow very little movement from the time of insertion through removal. Such cases would not find improvement in stability with HDR brachytherapy.
- *Dose reduction to normal tissue*. Again, the short duration of HDR intracavitary treatments often allows displacement of normal tissue structure to a greater extent than with LDR treatments. This holds true for gynecologic and oral intracavitary cases but not for intraluminal applications, such as endoesophageal or endobronchial treatments. Most interstitial cases cannot make use of this feature because the needles or catheters fix all the tissues in place. Exceptions are mostly in the head, where the tongue sometimes can be moved away from the treatment site.

- *Outpatient treatment*. Most HDR patients receive treatment as an outpatient. Exceptions include patients with indwelling needles such as prostate or gynecologic implants delivered in multiple fractions. Patients containing plastic catheters that enter the patient on one end and exit the patient on the other (i.e., not with sharp needle tips poking into flesh) almost always leave the hospital between fractions. All intracavitary treatments are on an outpatient basis, unless there are medical conditions that keep the patient in the hospital between fractions. Outpatient treatments present many advantages over the inpatient treatments characteristic of LDR brachytherapy:
  - *Patient comfort*. Patients confined to a room during LDR treatments often feel closed in. Compounding the claustrophobic effects, radiation safety considerations limit the time nursing staff can spend with the patient (sometime very severely), leading the patient to feel like a pariah.
  - *Patient health*. Many LDR brachytherapy applications require the patients to stay in bed, increasing the probability of thrombosis or bedsores. Although pneumatic socks greatly reduce the likelihood of thrombosis, aching muscles from immobility still create discomfort. In many cases, patients who could not tolerate protracted LDR treatments will be able to receive their treatments using HDR techniques.
  - *Economics*. The cost of staying in the hospital greatly exceeds that of outpatient treatment. Counterbalancing the cost of hospitalization, the costs of the HDR remote afterloading equipment far exceed those for LDR applications. However, the HDR equipment costs quickly become amortized with a modest patient load, whereas the hospitalization costs remain constant, or continually increasing, for each LDR brachytherapy patient.
- *Less discomfort due to small size*. Because the encapsulated HDR source is only 1 mm or less in diameter, the gynecologic intrauterine tandem need only be 3 mm in diameter, compared with 7 mm for the standard LDR tandem. Another way of looking at this comparison is to recognize that the diameter of the HDR tandem equals the smallest size dilator used to stretch the cervical os to accept the LDR tandem. Much of the pain and discomfort from a cervical cancer treatment come during the dilation. Eliminating that step eliminates much of that pain. Some facilities use only light sedation for the HDR tandem insertion rather than a general anesthetic, as is common with LDR procedures.
- *Elimination of delays*. When applications fail to follow a plan or when plans have to change because of a finding in the operating room during the procedure, HDR treatments can still proceed following localization with little, if any, delay. LDR treatments likely would require ordering new sources to

match the new situation and a delay in treatment to await delivery. The HDR model eliminates extra charges accruing from multiple-source orders.

- *Intraoperative procedures*. HDR brachytherapy allows treatment intraoperatively, with suitable shielding in the operating room. With the short duration for dose delivery, a surgeon can add placement of the applicator and treatment of the patient to surgery with little additional time.
- *Radiation safety*. HDR brachytherapy eliminates radiation exposure to personnel.

Unfortunately, HDR brachytherapy carries with it the following disadvantages:

- *Radiobiology*. Compared with LDR brachytherapy, HDR treatments have worse therapeutic ratios, that is, the amount of damage to tumor cells compared with damage to normal tissue cells for the same dose. The damage to both types of cells per unit dose increases with dose rate, but the increase is greater for normal cells. Just as with external beam radiotherapy, which also is HDR delivery, fractionating the treatment mitigates this effect. Although LDR therapy usually entails a single session or two, most curative HDR regimens use three or more fractions. The next section discusses the radiobiology in greater detail.
- *Error hazard*. The increased complexity of the procedures and the compressed time frame of delivery increase the probability of errors in the treatment compared with LDR therapy.
- *Potential for very high radiation doses to patients and unit operators following failure of the source to retract*. The HDR source can deliver 7.4 Gy/min at 1 cm in the patient. If the source stops moving or separates from the drive cable, serious injury occurs in a short time.
- *Resources*. HDR treatments demand more resources than do LDR treatments:
  - *Personnel*. Because many HDR treatments proceed quickly from placement of the treatment appliance to delivery of the treatment, all of the persons involved with the treatment must be available at the same time or in relatively quick secession. That means that the facility must have sufficient staffing to release these persons from other duties on demand of the HDR brachytherapy cases.
  - *Economics*. The HDR afterloading equipment comes with a large initial investment (at the time of writing ~$500,000 to $1,000,000), not including the significant costs of shielding the treatment room and the increased cost for all the treatment applicators and supplies.

Radiobiologic Dosimetry

Because of the radiobiologic disadvantage of HDR treatments, considerable care must be taken in planning the time course of the therapy regimen. The following discussion is intended as a supplement to that in Chapters 2, 3, 13, 14, 25, 26 and 28 of this book. One of the important tools for such planning is the linear-quadratic (LQ) model for biologic response.

The Linear-Quadratic Model

The basis for the model for biologic response to radiation stems from an approximation to the cell survival curves as shown in Figure 27.1.

Several models have been used over the years to describe the shape of the curve, each giving different insights into the interaction of the radiation and the organism irradiated. One of the more useful when investigating radiotherapy regimen is the LQ model.[1–3]

This model approximates the cell survival, *S*, a function of dose, *D*, as

$$S = e^{-\alpha D - \beta D^2} \qquad (1)$$

Like any model, this equation fits the curves well over a particular range—in this case, the ranges of doses and dose rates used in radiotherapy—which makes it useful. It can also shed some light on biologic underpinnings. However, the model should not be seen as a true and complete description and explanation of a complex biologic phenomenon.

The curves shown apply to a single exposure of the cells over a short period of time at given dose rate. As can be seen, the effect of dose rate markedly changes the survival of the cells. This discussion need only consider the two components of the exponent in Eq. (1). Conceptually, the first term, αD, corresponds to damage to the cells when a single charged-particle track breaks both sides of a DNA molecule rung (e.g., both a guanine and a cytosine), referred to as a double-strand break. This form of killing the cells requires a double-strand break. The surviving fraction depends only on the dose, and the effect does not depend on the dose rate. The second term, βD^2, represents damage done when one charged-particle path breaks the bonds on one side of the DNA rung, say the guanine, and a different track breaks the other side (the cytosine). After the break on the first side, called a single-strand break, the DNA attempts repair. Because of the remaining cytosine on the opposite side, only a guanine will fit into the hole left on the damaged side. The nucleus contains many free guanine molecules, and one will be attracted to the opening and heal

the wound. The repair takes place with a half-time of T_{bio}, which corresponds to a repair rate of

$$\mu = 0.693 / T_{bio}. \quad (2)$$

Because the repair takes some time, there is a window in which the second break must take place for the entire rung to be removed. If the second hit takes place after repair of the first, the damage still only forms a single-strand break, and the opposite side must be hit again to form a double-side break. Because forming a double-strand break in this way requires two independent hits, the probability follows D^2. Because the second hit must occur before the repair of the first, the incidence of double-strand breaks depends on the dose rate. Frequently, calculations use a value for T_{bio} of 1.5 hours, although most normal tissues probably have a more complicated repair pattern, with a fast component of about 20 minutes and a longer one of about 2 hours (see Chapters 3 and 14).

The surviving fraction also depends on the values of α and β. These parameters are characteristic of the tissue being irradiated and the type of tissue injury being caused. The actual values are often not well known, and large variations in most tissues have been reported. However, in general, the values of α tend to be very similar for most tissues (within the uncertainties), with most of the variations being in the β term. Although the variations in the values determined for the two parameters tend to be large, smaller variation characterizes the ratio of α/β, the quantity most often given in the literature. For the most part, this ratio tends to be on the order of 2 to 3 for late effects in normal tissues and 5 to 20 for early effects. In general, tissues exhibiting less mitotic activity show lower values. Most tumors behave similarly to normal-tissue early effects but with a much wider range of values. Prostate cancer forms a notable exception, with an α/β between 1.5 and 2.

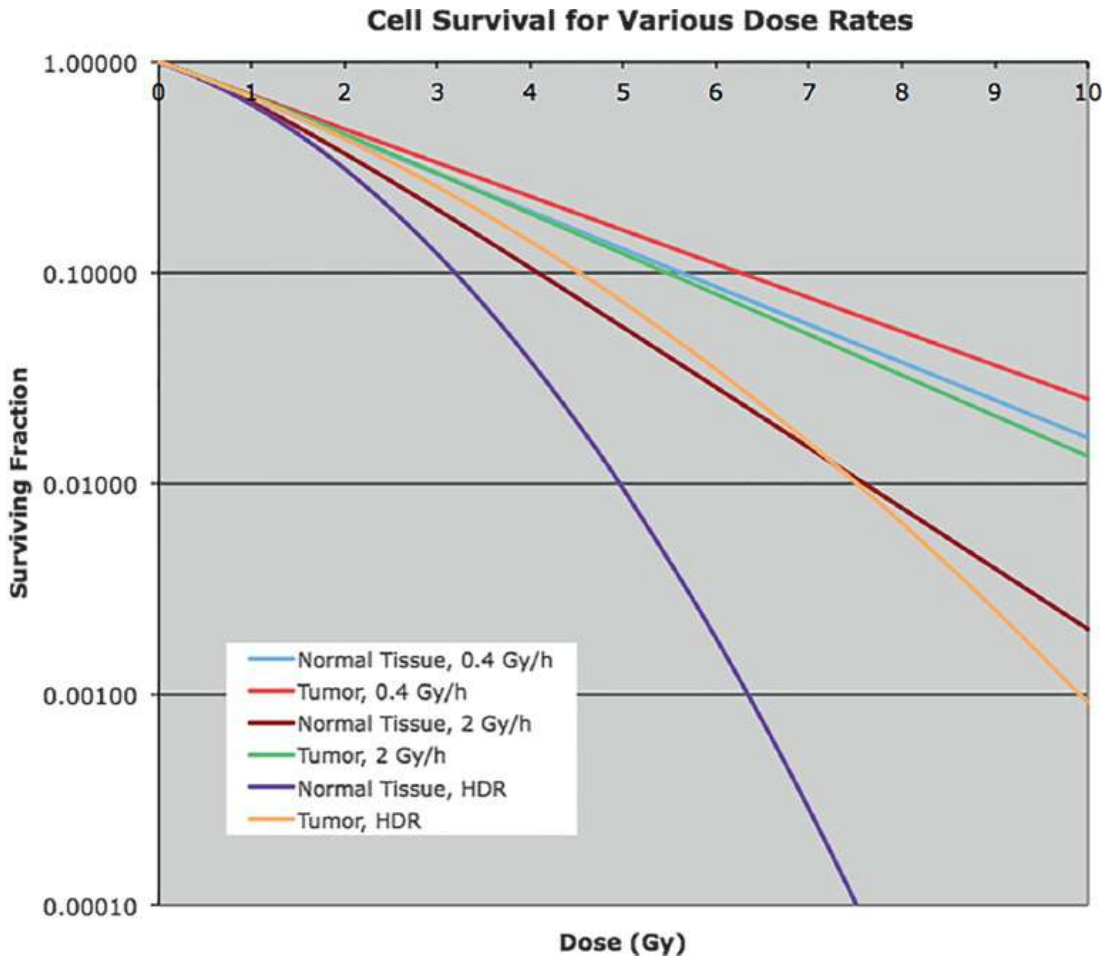

FIGURE 27.1. Typical cell survival curves with dose on the abscissa and surviving fraction on the ordinate, for three dose rates. The curves in the figure used α/β = 3 Gy for normal tissue, α/β = 10 Gy for the tumor, and α = 0.35 Gy^{-1} and μ = 1.5 h^{-1} for both types of tissue.

Figure 27.1 shows that as the dose rate increases, the fraction survival decreases for a given dose, and this effect is more marked for tissues with a low value for α/β. Thus, as stated earlier, compared with LDR brachytherapy, normal tissue has a comparative disadvantage for HDR brachytherapy. The usual approach to overcome the disadvantage fractionates the dose delivery. Figure 27.2 shows a survival curve with the dose delivered in several fractions. The pauses in the delivery allow repair of those single-strand breaks not converted into double-strand breaks by a second hit. Thus, at the beginning of each fraction, the curve exhibits a new shoulder as the first single-strand breaks begin accumulating. The fractionation has no affect on the α term. Fractionation has a long history in external beam radiotherapy, which, as noted, also is HDR delivery. Understanding the repair mechanism allows for a definition of what

dose rates qualify as “high”: a delivery duration that remains much less than T_{bio}, or about 30 minutes.

Surviving fraction does not depend directly on dose; instead, the whole exponent forms the independent variable. Because the α tends to be constant, it is often pulled out, leaving what is called the biologically effective dose (BED) or equivalently the effective radiation dose (ERD) as

$$\mathrm{BED} = D + \frac{D^2}{\left(\frac{\alpha}{\beta}\right)} = D\left[1 + \frac{D}{\left(\frac{\alpha}{\beta}\right)}\right]. \tag{3}$$

For the fractionated, HDR irradiations, each new fraction starts the shape of the curve over but at the surviving fraction level where it left off at the end of the previous fraction (in the absence of proliferation), and the equation becomes

$$\mathrm{BED}_{\mathrm{HDR}} = n\left[d\left(1 + \frac{d}{\left(\frac{\alpha}{\beta}\right)}\right)\right] = nd\left[1 + \frac{d}{\left(\frac{\alpha}{\beta}\right)}\right], \tag{4}$$

where n is the number of fractions and d is the dose per fraction.

The LDR situation becomes more complicated because repair takes place during the irradiation, reducing the effectiveness. In this case, BED becomes

$$\mathrm{BED}_{\mathrm{LDR}} = D\left(1 + \frac{2R}{\left(\frac{\alpha}{\beta}\right)\mu} \cdot \frac{1 - e^{-\mu T}}{\mu T}\right), \tag{5}$$

where T is the duration of the treatment and R is the dose rate. Because the BED depends on the α/β used, the convention when giving a value for BED requires that the units of gray carry a following subscript specifying the α/β. For example, the BED of 10 Gy for late-responding tissue with an α/β of 3 might be stated as BED = 10 Gy_3.

In fact, the equations for both modalities also contain a term, not shown in the equations,

$$\frac{0.693T}{\alpha T_{pot}} \qquad (6)$$

to account for cell repopulation over the total treatment duration. T_{pot} represents the potential cell doubling time. Most applications ignore this term because of the large uncertainties in the values for α and T_{pot}. In situations comparing the BED of LDR and HDR applications where the total duration of the therapy would be approximately the same, this omission probably causes no significant loss of information.

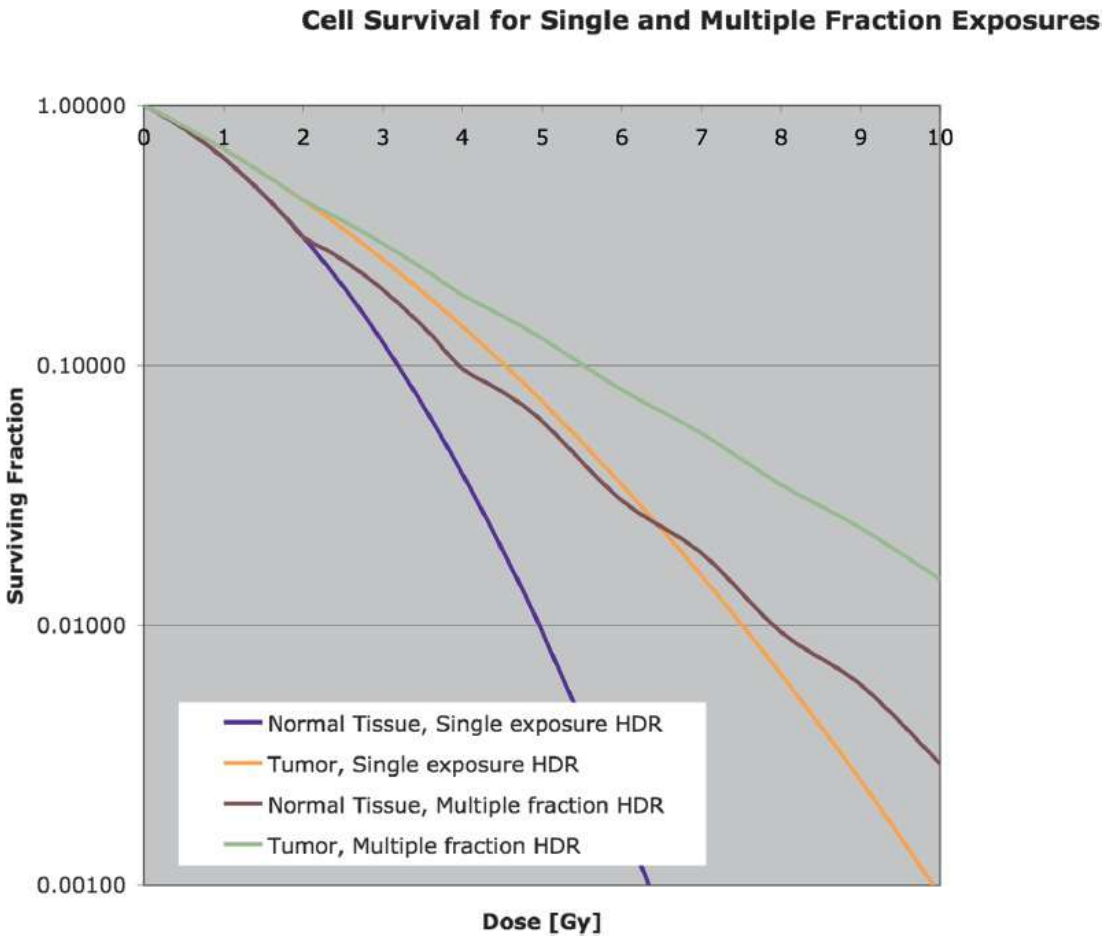

FIGURE 27.2. Survival curves illustrating the effects of fractionation. Again, the curves used α/β = 3 Gy for normal tissue, α/β = 10 Gy for the tumor, and α = 0.35 Gy^{-1} and μ = 1.5 h^{-1} for both types of tissue.

Conversion from Low to High Dose Rate Brachytherapy

Often, when beginning an HDR brachytherapy program, the biggest questions relating to treatments become how many fractions to use and what dose per fraction. The larger the number of fractions, the better is the therapeutic effect,

measured as the ratio of the damage to tumor cells to the damage to normal tissue cells. This ratio improves with each additional fraction, but the amount by which the ratio increases decreases with each added fraction. For example, with the parameters used for the figures, going from 4 to 5 fractions improves the therapeutic ratio by 4%. Adding a 6th fraction improves the therapeutic ratio but only by another 3.5%. Each additional fraction carries with it costs in departmental resources (particularly the time of those persons involved) and inconvenience (and possibly discomfort) to the patient. Thus, selecting the number of fractions becomes a compromise. Most curative regimens use 5 or 6 fractions if applicator insertion procedures are involved and 8 to 12 fractions if the applicator can be left in place and the patient simply treated. Small-volume applications, such as vaginal cuff or most endobronchial treatments, may require only 3 or 4 fractions. After establishing the number of fractions, determining the dose per fraction comes next. One method that uses the LDR experience sets the BED equal for the two modalities and then solves for the dose per fraction:

$$\mathrm{BED}_{\mathrm{HDR}} = \mathrm{BED}_{\mathrm{LDR}} \tag{7a}$$

$$nd\left[1+\frac{d}{\left(\frac{\alpha}{\beta}\right)}\right] = D_{\mathrm{LDR}}\left\{1+\left[\frac{2R}{\left(\frac{\alpha}{\beta}\right)\mu}\right]\bullet\left[\frac{1-e^{-\mu T}}{\mu T}\right]\right\} \tag{7b}$$

$$d = \frac{-\left(\frac{\alpha}{\beta}\right)+\sqrt{\left(\frac{\alpha}{\beta}\right)^2+\left(\frac{4D_{\mathrm{LDR}}}{n}\right)\left(\frac{\alpha}{\beta}\right)\left[1+\frac{2R}{\left(\frac{\alpha}{\beta}\right)}\left(\frac{1-e^{-\mu T}}{\mu^2 T}\right)\right]}}{2} \tag{7c}$$

The absolute value for the dose per fraction depends on the ratio α/β, thus requiring another decision. Projecting d from the LDR experience, the normal-tissue toxicities could be held constant and an α/β of 3 used, or tumor cure could be the endpoint, suggesting an α/β of 10 (or a value of the particular type of tumor under treatment). Holding the late complications constant will lead to a BED for the tumor considerably less than was used with the LDR treatments, whereas attempting to achieve the same tumor control produces normal-tissue BED values much higher than those for the LDR regimen. For intracavitary

treatments, the normal tissues sometimes can be held away from the applicator during the treatment delivery, for example, by keeping the rectal retractor in the vagina during a tandem and ovoid treatment. This would allow a dose based on equivalent tumor control. In interstitial applications, distance to the normal tissue in the implanted volume cannot be increased, but often with the improved optimization available with the HDR approach, high doses in the implant can be significantly reduced compared to conventional LDR implants, again allowing the dose based on tumor control. Seldom have HDR treatments produced more severe normal-tissue toxicities than those delivered at LDR. In general, the maximum significant dose, that is, the highest value of isodose surface that encompasses more than one catheter or needle track, should be kept to <150% of the prescription dose.[4]

High Dose Rate Devices

Remote Afterloaders

A remote afterloader (RAL) is a computer-driven system that transports the radioactive source from a shielded safe into the applicator placed in the patient. On termination or interruption of the treatment, the source is driven back to its safe. The device may move the source by one of several methods, most commonly pneumatic or cable drives. A stepping-source RAL is a particular design of the treatment unit that consists of a single source at the end of a cable that moves the source through applicators placed in the treated volume. The treatment unit can treat implants consisting of many needles or catheters in the patient. Multiple catheters are often required to cover the target with uniform radiation doses. Each catheter or part of an applicator is connected to the RAL through a channel. The computer drives the cable so that the source moves from the safe through a given channel to the programmed dwell position for a specific dwell time. In any applicator, there may be many dwell positions. After treating all the positions in a given catheter (channel), the source is retracted to its safe and then driven to the next channel. There can be several dwell positions per centimeter in each channel, and the dwell time can vary from 0 to almost 1,000 seconds in 0.1-second increments, thereby giving a high level of flexibility of dose delivery. All currently available HDR RALs use the stepping-source design. Five models of HDR RALs are common. Three are marketed in the United States: Flexitron (Elekta Company, Georgia, USA) and GammaMed and VariSource (both from Varian Medical Systems, Palo Alto, CA). The MicroSelectron (Elekta Company, Georgia, USA) is no longer sold but is one of

the most common units in service. In Europe, the BEBIG MultiSource (Eckert & Ziegler BEBIG, Seneffe, Belgium) is also available. Figure 27.3 shows two of the units. Even though they may vary in details, all available HDR RALs consist of the same general components: (a) shielded housing, (b) radioactive source, (c) source drive mechanism (cable, reel stepper motor), (d) indexer, (e) transfer tube, all shown in Figure 27.4, and not shown, (f) treatment control station, and (g) treatment control panel.

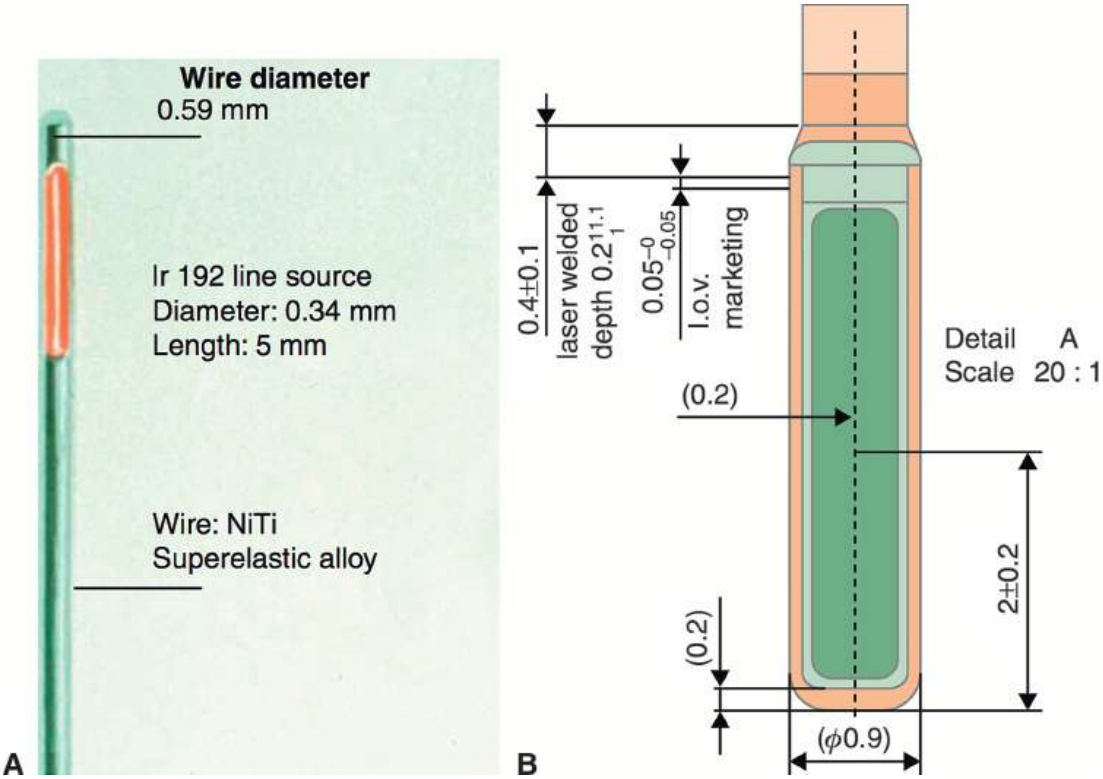

FIGURE 27.5. Diagrams of two HDR brachytherapy sources: for the **(A)** VariSource and **(B)** MicroSelectron. (**A**, courtesy of Varian, Palo Alto, CA; all rights reserved; **B**, courtesy of Nucletron, an Elekta Company, Veenendaal, Netherlands.)

Sources

Whereas delivering HDR brachytherapy requires an intense source, passing the source through needles placed through a tumor requires one of a small size. The radioactive source in an HDR RAL is usually 3 to 10 mm in length and approximately 1 mm or smaller in diameter, fixed at the end of a steel cable. The microSelectron source is placed in a stainless steel capsule and welded to the cable, whereas the Varian source is placed in a hole drilled into the cable and closed by welding. Figure 27.5 shows diagrams of the sources. Iridium-192 is now used for most HDR RALs; the BEBIG unit offers the choice of ^{192}Ir or ^{60}Co. Iridium-192 emits many photon energies, mostly between 110 and 704 keV, with an effective energy around 380 keV. A new source has an activity near 0.37 TBq (10 Ci, ~44 mGy m^2 h^{-1}). Because ^{192}Ir has a half-life of 74 days, the source should be replaced every 3 months to keep the treatment in the HDR radiobiologic regimen (see later discussion). The potential advantage of using ^{60}Co is the 5.3-year half-life, extending the time between source changes to approximately 5 years. The emissions of ^{60}Co, 1.12 and 1.33 MeV, require considerably more shielding than for devices using ^{192}Ir. A trained medical

physicist calibrates the source after each installation using a reentrant, well-type ionization chamber, as discussed later. The resulting source calibration is verified against the manufacturer's source calibration.

Applicators

An array of applicators for different treatment sites is marketed by each vendor. Each vendor designs its own applicators that can only be used with its transfer tubes and HDR RALs. Before an applicator is used clinically, tests should be performed to verify the functionality of the applicator. An applicator should also be radiographed with dummy sources (ribbons) to verify agreement with the vendor's specifications. The length of each applicator, location of the dwell positions with respect to the applicator, and integrity of the applicators should be a part of the routine quality assurance (QA) program to ensure safe and precise delivery of the radiation treatment plan. Figure 27.6 shows a comparison between an HDR and an LDR intrauterine cervical tandem. The smaller diameter of the HDR applicator leads to greater patient comfort during the procedure. Because the HDR iridium source is much smaller than the LDR cesium tubes, HDR applicators have a smaller radius.

Pulsed Brachytherapy

Pulsed brachytherapy (also known as pulsed HDR brachytherapy or, not quite correctly but most commonly, pulsed dose rate [PDR] brachytherapy) attempts to eliminate the unfavorable radiobiology of HDR brachytherapy while maintaining the ability to optimize finely the dose distributions and eliminate the personnel exposure to radiation. The pulsed brachytherapy unit is the same as an HDR unit except the source can be shorter and only about one-tenth as active. The treatment also follows the same pattern as an HDR treatment, except that the patient remains in the hospital, and instead of 5 to 10 fractions, the source runs through the treatment pattern once each hour. These hourly treatment pulses last only a few minutes, but the overall treatment duration usually covers 1 or 2 days. Thus, biologically, because each fraction comes before complete repair of sublethal cellular damage, the tissues experience the radiation as almost continuous, mimicking LDR brachytherapy.

Although this approach incorporates the biologic advantages of LDR treatments and the optimization advantage of HDR brachytherapy, it also has many of the disadvantages of both modalities, including (a) inpatient treatments, (b) lack of applicator stabilization, and (c) possibility of mechanical failures.

Because the source treats the patient 24 times per day, and each treatment includes three or more catheters, the number of source transits becomes quite large and many times more than for a normal HDR regimen. Such frequent source use increases the likelihood of source failure during a treatment. Should a source become caught during transit, the dose to the patient could become quite large. Unlike HDR procedures, the operator does not sit at the control panel always ready to retrieve a stuck source. Limiting the activity of the source to one-tenth of the normal HDR source allows 10 times the response time for a stuck source before significant injury to the patient. The other reason for the low activity is that, with the treatment divided into so many small fractions, the dwell times become too short for the treatment unit to control were the source very highly active. In summary, pulsed brachytherapy presents opportunities to potentially improve brachytherapy, but it also comes with detriments. PDR brachytherapy is discussed in more detail in Chapter 26.

OPERATION

Personnel Roles

The report of Task Group 59 (TG-59) of the American Association of Physicists in Medicine discusses the roles of the members of the treatment team for HDR brachytherapy.[5] For the most part, the roles follow standard procedures for any brachytherapy, with the physician inserting the treatment appliance and prescribing the treatment, the nurse monitoring the patient's condition and welfare, therapists or radiographers performing the imaging for localization, a dosimetrist or physicists performing optimization and dose calculation, a physicist checking the plan for correctness and assuring the correct calibration of the source, and the physician and physicist evaluating the plan. Who performs some of the functional roles discussed in what follows varies by institution but needs clarification so all persons involved understand the distribution of responsibilities.

Daily Quality Assurance

The tests of the treatment unit at the beginning of the treatment day often fall to the medical physicist. However, in some facilities, a therapist or dosimetrist performs the actual tests, and the medical physicist reviews the results of the tests before the first treatment.

Treatment Planning Calculation

The report of TG-59 discusses options for entering the patient data into the dose calculation computer and generating the treatment parameters (dwell positions and dwell times).[5] One model presented in that report had a dosimetrist running the program and a physicist monitoring the input to correct errors as they occur. Studies have shown that such supervision provides little protection against errors.[6] Either a physicist or a dosimetrist may perform the treatment plan generation.

Quality Assurance on the Treatment Plan

Regardless of who generates the treatment plan, a medical physicist should review the plan for appropriateness and correctness. The reviewing medical physicist should *not* be the same person who generated the plan, so in facilities with only one medical physicist, a dosimetrist should perform the planning.

Delivery of the Treatment

Several factors enter into considerations of who should staff the control panel during the treatment. In some states, regulations dictate that only therapists may deliver treatments and control treatment units. The regulations in most states and

from the U.S. Nuclear Regulatory Commission are silent on the issue. At the time of writing, regulations almost uniformly require the attendance of a medical physicist at the treatment (or within unamplified voice communication of the unit operator). As a result, many facilities have the medical physicist operate in the unit during treatments. One important consideration is that at least one person in the control area during treatments must be ready and willing to enter the room and take appropriate actions in case the source becomes stuck in the patient.

Normal Procedures

When the afterloader receives a command from the treatment control panel to initiate a treatment, the source cable advances from the shielded safe through the Y tube and then the S tube to the first channel in the indexer and then along a path constrained by transfer tubes to the first treated dwell position in the applicator (see Fig. 27.4). The source dwells at that position for a predetermined duration. After completing that dwell, it goes on to the subsequent dwell positions. Some units step as the source drives out (Flexitron, MicroSelectron, and GammaMed), stopping first at the dwell position most proximal to the afterloader, whereas in the other (VariSource), the source travels first to the most distal dwell (toward the tip of the applicator) and a bit farther and then steps as the source returns toward the safe. Stepping on the outward drive obviates any concern about the effect of slack in the drive mechanism affecting the accuracy of the source position. The units that steps on the way back into the unit include correction for slack in the calibration of the source location. Regardless of the direction of stepping, on completion of the treatment for the first channel, the source is retracted into the safe and redirected to travel to the second channel. The process is repeated for all the subsequent treatment channels. The programmed movement of the source is verified by means of an optical encoder or other device that compares the angular rotation of a stepper motor or cable length ejected or retracted with the number of pulses sent to the drive motor. This system is capable of detecting catheter obstruction or constriction as increased friction in the cable movement. Under certain fault conditions, such as if the stepper motor fails to retract the source, a high-torque, direct current emergency motor will retract the source.

The confirmation of the source exit from and return to the safe is carried out by an opto-pair, consisting of a light-sensitive detector and an infrared light source, which detects the cable when its tip obstructs the light path. All the

currently marketed afterloaders are also equipped with check cables, or “dummy sources.” The check cable is an exact duplicate of the radioactive source along with its cable, except that it is not radioactive. Before the ejection of the radioactive source, the check cable is first ejected to check the integrity of the catheter system. After a noneventful check by this dry run with the dummy source, the radioactive source is then sent for treatment.

Emergency Procedures

Because HDR RALs are complicated devices containing very-high-activity radioactive sources, serious accidents can happen very quickly, thereby demanding many safety features and operational interlocks to prevent erroneous source movement or facilitate rapid operator response in the event of a system failure.

Door Interlock

Interlock switches prevent initiation of a treatment with the treatment-room door open. Opening the door interrupts the treatment’s progress. This safety feature protects the medical personnel from radiation exposure in the event someone enters the treatment room without the knowledge of the operator. If a door is opened inadvertently during the treatment, the treatment is interrupted and the source returns to the safe. The treatment can be resumed at the same point where it was interrupted by closing the door and pressing the start or the resume button at the control panel.

Emergency Switches

Numerous emergency off switches are located at convenient places and are easily accessible in case a situation arises. One is located on the control panel for the HDR operator. Another is located on the top of the RAL treatment head. Vendors also install two or more switches in the walls of the treatment room. In the event a treatment is initiated with someone other than the patient in the treatment room, that person can stop the treatment and retract the source by pressing the emergency off button.

Emergency Crank

In the event of the failure of a source to retract normally, as well as the failure of the emergency motor, all HDR RALs have emergency cranks to retract the source cable. Using the crank requires the operator to enter the room with the source unshielded.

Emergency Service Instruments

If the radioactive source fails to retract after termination or interruption, pushing the emergency switch, or cranking the stepper motor manually, the immediate priority is to remove the source from the patient. Because the source is in contact with the patient, it can cause severe injury in a very short time. However, working at a greater distance, it is unlikely that the operator will receive a dose exceeding regulatory limits for 1 year, let alone one that would cause health problems. Once the source is removed from the patient and moved to the distance of even 1 m, the exposure rate drops drastically, and actions can then be taken to remove the patient from the room safely.

The safest approach to a source that will not retract by any of the methods is to remove the applicator from the patient as quickly as possible and place the applicator containing the source in a shielded container. If it is clear that the cable is caught in the transfer tube and not in the applicator *per se*, the applicator may be disconnected from the transfer tube and the patient removed from the treatment room. In some cases, this will be faster than removing the applicator. The reason to avoid disconnecting the applicator from the transfer tube is that a source may stay in the applicator if the source capsule shatters or come free from the cable. In that case, removing the applicator attached to the transfer tube keeps the system closed, whereas disconnecting the two opens a path for parts of a broken source to fall from the applicator into body cavities or crevices or roll onto the floor.

A situation might arise when the source needs to be detached manually from the treatment unit. Such a rare situation might occur if the unit with an unretractable source fell on a person and could not be moved by hand (perhaps by something else falling on the unit). The source could be close to the person but not inside. In this situation, the source cable should be cut from the unit and the source placed in the shielded container always present in the room. In cutting the source cable, it must be clear that the cut is *not* through the source capsule. For units with the capsule welded on the cable, the cut must be through the braided cable as opposed to the smooth steel capsule. For sources imbedded in the cable, a sufficient length of the cable must be seen to ensure that the cut occurs behind the source. Thus, emergency tools that must be present in the treatment room and always readily accessible include a wire cutter, a pair of forceps, and a shielded service container. The source should *never* be cut from the cable while the source is still in an applicator in the patient!

FACILITY DESIGN

Typically, the radioactive source in the HDR machine starts with an air kerma source strength of 44 mSv m/h, which is about at 10 Ci. According to the rules and regulations of the Nuclear Regulatory Commission (NRC), the annual limit for radiation exposure to the public is 1 mSv and the annual occupational limit is 5 mSv. (The actual limit for occupational exposure is 50 mSv/y, but following the principle of maintaining exposures as low as is reasonably achievable, the NRC usually holds licensees to exposure one-tenth of the actual limit.) In addition to the annual limit, NRC regulations requires that in an unrestricted area the dose equivalent rate should not be more than 0.02 mSv in any hour. Thus, the HDR machine needs to be housed in an adequately shielded room. To meet these requirements in an HDR suite, where the walls and the ceiling are at least 5 feet from the machine head, concrete walls of about 43 to 50 cm (or 4 to 5 cm of lead) are needed. For larger rooms, the concrete wall thickness will be lower because the exposure rate is inversely proportional to the square of the distance from the radioactive source. The tenth-value layer thicknesses for ^{192}Ir are 1.6 cm and 15 cm of lead and concrete, respectively. For details on the procedures for calculating the thickness of barriers for a particular facility, see a health physics text such as that by Cember and Johnson[7] or McGinley[8] or the report from the Nation Council on Radiation Units and Measurement.[9]

Imaging plays an important part in most brachytherapy, so consideration of required imaging modalities should enter into the room design. Having fluoroscopy and radiography in the treatment room can facilitate checking for applicator movement if moving the patient is required for CT or MRI imaging. It, of course, would be best to have the necessary imaging modalities in the procedure room. Having space and access for anesthesia in the room facilitates HDR brachytherapy for prostate cases.

All HDR brachytherapy rooms must have video and audio communication for monitoring the patient. Radiation detectors for monitoring the radiation levels in the room and indicating when the source is out of its shielding also are required.

QUALITY ASSURANCE OF THE REMOTE AFTERLOADING DEVICE

Several of the disadvantages of HDR brachytherapy concerned the probability of failure, either human or mechanical. Both aspects of the treatments require effective quality management. This section deals with quality assurance for the

treatment unit. A report from the American Association of Physicists in medicine discusses this topic.[5,10–16] Williamson et al.[17] summarized much of the important material into a chapter. For a fairly comprehensive discussion, the reader is directed to Thomadsen.[18] Although most of these references are fairly old, the QA appropriate for these units has not changed.[19]

As for any piece of radiotherapy equipment, the QA begins with acceptance testing and commissioning. Periodic QA includes tests performed with each new source (approximately quarterly for most units) and those at the beginning of each treatment day. Of all of these, the daily morning checks form the basic set of essential tests.

Morning Checks

Although the list of safety checks seems long, the evaluation need not consume a great deal of time. At our facility, the entire morning routine takes about 10 to 15 minutes. Most of the items could be tested in numerous manners, but only one set of techniques will be discussed here. Individual units may differ in the exact methods. The procedure in the list often assumes the successful completion of all of the items going before. Failure of *any* item requires evaluation by the physicist of the appropriateness of continuing with patient treatments in light of the particular failure. The morning checks focus on ensuring that the unit is operating safely and correctly.

Safety Checks

The following items should be considered in a safety check:

Communication equipment. See that the television and intercom systems function.

Catheter-attachment lock. Attach a transfer tube to one of the channels of the unit, but do not lock the transfer tube in place (often accomplished by the locking ring). Program the unit to send the source to a dwell position that would be in an applicator were one attached, and initiate a source run. A program time for a single dwell of about 20 seconds would allow execution of the tests to follow. The unit should detect that the transfer tube has not been locked in place and prevent the source run. Were a treatment to take place in this condition, the source cable could push the transfer tube out of the unit and never enter the applicator.

Applicator attachment. Keeping the same program, lock the transfer tube in place but still do *not* attach an applicator to the transfer tube. Again, attempt

to initiate a source run. The check cable run should detect the absence of an applicator and prevent sending out the source. Failure of the unit to detect this situation could lead to the source indicating that it treated a catheter when, in reality, the catheter was never attached. This test also checks that the unit will not send out a source if the pathway is blocked, because, for most transfer tubes, the applicators push aside a blockage of the tube when they lock in place.

Door interlock. Lock an applicator into the transfer tube. For future tests, it is convenient to use a needle in a well-type ionization chamber. Keeping the same program as in the previous tests and with the door to the room open, try to initiate a run. The unit should refuse to initiate the treatment and indicate that the door is open.

Source-out indicators. Close the door, and initiate the source run. Observe that the indication lamps operate. Most rooms have three beam-on indicator lamps: one connected to a treatment unit microswitch that triggers when the source leaves its shielded housing, one that lights when the signal on the radiation detector in the room exceeds its trip level, and one from the onboard Geiger counter. Let the exposure continue for the next test.

Room monitor audio operation. Listen through the intercom for the sound of the room radiation monitor. It should make a mild but clearly audible sound. It should not be too loud, for that would disturb the patient. There is no regulation in most states or with the NRC that the in-room monitor provides any audible signal. The presence of such a signal would alert anyone who is in the room unintentionally when the source is out. Some practitioners feel that any such signal causes concern on the part of the patient. We have tried both situations and have found that patients do not mind the signal if they have been informed that it would occur. Continue the exposure.

Room monitor visual operation. Open the door to the room and observe the visual indicators on the room monitor. The room design should provide protection to a person in the doorway until the source retracts. At the same time as this test is performed, so is the next.

Handheld monitor operation. Immediately on opening the door during the previous test, hold the handheld monitor in the doorway and see whether it indicates the presence of radiation. The handheld detector is to be carried upon entry to the treatment room any time after a source run. Alternatively, the detector could be tested with a dedicated check source at the beginning of each day. Performing the test along with the room monitor makes the treatment unit the dedicated check source.

Door interrupt. During the previous two tests, the unit should have been

retracting the source, beginning from the opening of the door. The retraction should take no longer than 4 to 6 seconds to return the source to its shielded location.

Emergency stop. Close the door and reinitiate the exposure. Once the source reaches the dwell position, press the emergency off button. The unit must immediately retract the source and likely require a reset.

Treatment interrupt. Reinitiate the exposure, and once the source again reaches the dwell position, press the treatment interrupt button. Again, the unit must immediately retract the source.

Timer termination. Reinitiate the exposure and let it continue until the elapsed duration equals the time set on the timer. At that time, the unit stops the exposure and retracts the source.

Dosimetry Checks

The thrust of the dosimetry checks focuses on the delivery of the correct dose to the proper location.

Source Positioning Accuracy

Proper treatment requires that the source occupy the position along the catheter corresponding to that used in the treatment plan. The uncertainty of the determination of the dwell positions on the treatment plan is discussed elsewhere in this chapter. Here, the issue becomes duplicating the dwell locations on the treatment plan during execution. A usual criterion for coincidence with the planned treatment dwells is 2 mm, although the HDR units are able to place the source in a given location within 1 mm. Precision <0.5 mm begins to be less reproducible. To direct the source to correct locations corresponding to each dwell position, the source controller requires the distance along the catheter corresponding to the first dwell position. The distance may refer to the length from some part of the unit (such as the front face, the point of catheter insertion, or a microswitch that tells the unit when the source enters the catheter), or it may be from some fictitious point (similar in concept to the effective source for electron beams). Verifying that the unit can place the center of the source at a specified distance becomes an important part of the morning QA.

The most expeditious method uses the ruler provided with the unit. Such a ruler provides a channel for the source to follow alongside a scale marked in the distance. Using any ruler requires a high-definition television system that will be able to distinguish the source capsule clearly and resolve the markers on the ruler. The lighting of the ruler becomes an important variable. For one vendor’s

unit, a televised check of the source positions on a ruler forms a routine part of any treatment. For another, the ruler is just part of the unit QA equipment and requires a separate television system, such as that used to monitor the patient. To perform the check, attach the ruler as appropriate for the unit and program the source to a distance that shows on the rule. Watch on the video screen as the source moves into position. The tip of the source will be seen at some distance that should be farther than that distance programmed. From the distance of the tip, subtract the distance from the tip to the center of the source as shown in Figure 27.7. This check is performed with the source cable itself; the check cable, for some units, does not go to the same distance as the source cable and would give an incorrect result.

FIGURE 27.7. A typical image made to test the accuracy of the HDR unit source positioning.

A simpler and more precise method of verifying the positioning of the source follows the technique determined by DeWerd et al.[20] This procedure uses a well-type ionization chamber with a special insert that includes lead attenuators and plastic transmission discs and is shown in Figure 27.8. The lead attenuators reduce the signal from the source to approximately one-third its unshielded

value, whereas the plastic discs have little effect. As the source passes through the needle centered in this insert, the measured signal appears as in Figure 27.9. The peaks occur when the source is centered on the plastic discs, and the greatest gradient occurs when half the source is shielded and half is on the plastic. At these points, the signal depends critically on the precise position of the source, with the signal changing approximately 3.5%/mm. The signal at the plateau changes little over 2 mm. Dividing the current signal at the high-gradient point by that at the plateau removes any variations in the reading due to source decay, timer miscalibration, or atmospheric density. Thus, the ratio of signals gives a sensitive indication of whether the unit accurately places the source to the correct location. Making measurements at two high-gradient points and the peak assesses not only the correct placement of the source at the one point but also the correct interval between. Use of this method requires measurement of the signal profile as a function of distance along the axis of the well chamber after initial verification of the source position using one of the other methods. Once put in place, this approach takes <1 minute. If the insert is left in the well chamber, the needle can be used for the safety checks, and this test can follow the safety checks without requiring re-entry into the room.

FIGURE 27.8. A special insert designed to assist in the evaluation of source positioning accuracy, with large lead cylinders separated by a plastic disc.

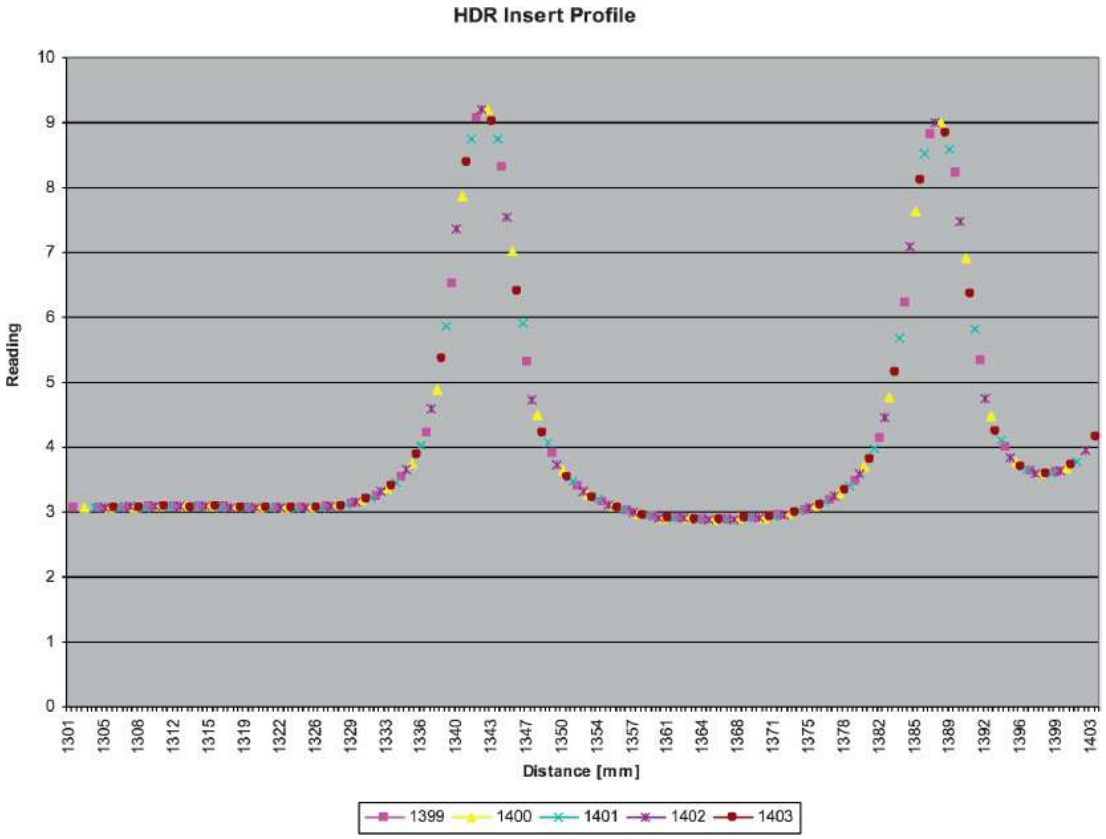

FIGURE 27.9. The signal produced as the source passes through the insert shown in Figure 27.8. Notice the high signal gradient that corresponds to the source centered on the plastic–lead interface. The color of the data points correspond to the starting dwell length as indicated in the legend. Five sets of measurements are required on this unit, with different starting dwell lengths, to have measurements every quarter millimeter.

The source position could be checked using radiochromic film, marking the intended position of the source in a catheter using the radiographic markers and then making an autoradiograph with the source. However, this method takes more time and carries a larger uncertainty than either of the two methods discussed above.

Dose Consistency

Correct dose delivery hinges on the proper operation of the timer controlling the exposure. The proper operation does *not* depend on the timer accurately keeping true clock time. The only important features of the timer are that it operates linearly and that its operation remains consistent over time. The daily QA generally needs only check two times to evaluate timer consistency and linearity, compared with the tests performed during the source exchange. The uncertainty in the measurement should be on the order of a few tenths of a second in order to

check the shorter times.

One technique for checking the timer observes the reading produced in a radiation detector as a function of the timer settings. To evaluate the timer, the measurement system must respond linearly to radiation dose and the setup provide a stable and reproducible geometry. A well chamber, such as that used for calibration, performs this function well. Such measurements in a well chamber include the effects of source decay and the source transit time. For the most part, source decay seldom deviates from the expected but should be checked because there have been sources with contaminant radionuclides that produce an anomalous decay. Because the reading varies directly with the set exposure time, these readings can form a check of the timer. The chamber reading needs a baseline, for example, a reading taken immediately after the initial calibration of the source. The expected reading can be tabulated as a function of day by correcting the initial reading by the decay factor, $e^{-0.693t/73.8\ \text{days}}$, where t is the time in days since the initial reading. The reading should remain within ±2% of the projected reading, values that also could be in the table. Deviations from the projected values indicate changes in the timer operation (linearity or consistency), changes in the unit's transit time, or anomalous decay. Further tests would be required to sort out the actual problem.

Source Strength Value

The value for the source strength at any time should be the same in the treatment planning computer as in the treatment unit computer to within 0.5%. The date and time in the treatment unit must be correct for the unit to calculate the source decay correctly. The format of the date, American or European, must be the same as that expected by the computer.

Initial Checks

Each source change requires a number of procedures in addition to the daily checks.

Safety Checks

The initial safety checks include the following:

Treatment unit backup batteries. In case of loss of power to the treatment unit, the machine has backup batteries to retract the source and save the record of the treatment up to the time of retraction. Checking the batteries entails initiating a source run, pulling the circuit breaker for power to the unit, and

verifying that the source retracts; the history is then saved, and the unit resumes the program where it left off when restarted after restoring the power.

In-room radiation monitor backup batteries. The in-room radiation monitor also has backup batteries allowing it to continue functioning in case of a power loss. Continued operation at such times becomes extremely important in case the source fails to retract. Verifying operation of these batteries simply requires unplugging the unit from the wall socket and performing the usual check for the monitor.

Dosimetry Checks

The following are the initial dosimetry checks:

Calibration. The accepted method for calibration of an HDR source uses a well-type ionization chamber that has been calibrated in terms of HDR source strength per unit current. The calibration factor for the same chamber will differ for LDR and HDR ^{192}Ir sources because of differences in source construction. The uncertainty in source strength calibrations using such chambers usually runs around 1% from national standards plus an additional 5% in the national standard with respect to absolute measures of energy absorbed per unit mass. The source strength is in terms of air kerma strength, S_K, with units of μGy m^2 h^{-1}, often called U for convenience.[21] This unit gives numbers that become very large, so sometimes units of mGy m^2 h^{-1} (called U_h) are used. Most treatment planning computers accommodate units of air kerma strength; however, many practitioners still relate better to source strength converted into curies, derived simply by multiplying S_K by a constant, which must be the same as that used by the manufacture in the treatment planning program.

Timer linearity. The verification for timer linearity uses several readings, R_i, for various increasing times, t_i, taken in the well chamber. The free-running reading rate can be defined as

$$\dot{R} = \frac{R_{i+1} - R_i}{t_{i+1} - t_i} \qquad (8)$$

and contains no effect from the source transit, which cancels during the subtractions. Taking approximately five readings covering the range of dwell times common in treatments gives four values for the free-running reading rate using adjacent times. These values should differ by <0.5%.

The transit time from the unit to the dwell position is hard to measure and is not important directly. What is important is that the transit time remains constant. An effective transit time can be defined as the time it would take to deliver the extra reading in the chamber because of the irradiation during the time the source moves into and then leaves the measurement dwell position, *if* the extra reading were delivered at the free-running reading rate. One expression for the effective transit time, t_ε, becomes

$$t_\varepsilon = \frac{R_i}{\dot{R}} - t_i. \tag{9}$$

An alternative expression for evaluating the timer linearity calculates ζ, defined as

$$\zeta = \frac{R_i / R_{i+1}}{(t_i - t_\varepsilon)/(t_{i+1} - t_\varepsilon)}. \tag{10}$$

In general, ζ should remain between 0.99 and 1.01.

Entry of data into computers. The new source strength must be entered into the treatment planning computer and the treatment unit computer. Special attention needs to be paid to selecting the units for the source strength, particularly if the system automatically defaults to given units.

Checks Just before and during Treatment

Other than the check performed on the treatment plan just before treatment, connecting the patient also requires care and verification. For most gynecologic applicators, the three parts of a tandem and ovoid set, or the tandem and ring, have coded connectors that only allow the correct transfer tubes to attach, and the transfer tubes also can only connect to the correct holes in the indexer. However, for implants with needles or catheters, no interlocking prevents mismatches between channels and catheter or needle tracks. For large implants on older units, the treatments often require first connecting the number of catheters equal to the number of channels and delivering the part of treatment that uses those channels. Those channels are then disconnected, and the next set of catheters is then connected to the indexers starting again with channel number 1. One of the most likely errors would be connecting a channel during the second set to a catheter from the first or vice versa. Newer treatment units often have enough channels to accommodate most large implants.

Also for interstitial implants, between fractions, the catheters often move from the position they occupied during the imaging used for treatment planning. Immediately before treatment, the catheters must be returned to their original position, for example, by snugging the buttons on one side to the skin.

During the treatment, the operator needs to watch for movement by the patient that could affect the treatment and ensure that the source moves through its program.

Checks after Treatment

At the end of a treatment, the operator verifies complete source retraction by taking the following steps:

- Noting the completion of treatment as indicated by the control console
- Observing the radiation monitors in the room
- Measuring the radiation levels at the patient using the handheld radiation detector
- Measuring the radiation levels at the treatment unit with the handheld detector

The last reading should be in front of the unit in line with the source path out of the shielding container.

DOSIMETRY AND TREATMENT PLANNING

Time Course of Procedures

As with LDR brachytherapy, treatment planning for HDR cases may follow different patterns, based on the treatment approach. For example, treatments of cervical cancer using a tandem and ovoid usually have the physician place the treatment appliance, followed by localization imaging and then dosimetric calculations. Less likely than with LDR approach, there can still be planning first based on an idealized application, such as a surface application. Some treatment planning may be interactive, such as with prostate implants, where dosimetry following needle placement can direct subsequent needle placement. Despite this range of options, in most HDR cases the treatment plan generation follows applicator placement, and that model will be assumed in this discussion.

Differences between Low and High Dose Rate Brachytherapy Treatment Planning

HDR brachytherapy treatment planning differs from LDR brachytherapy in three ways. The first difference results from the time course of the treatments. In

treatments of several sites, particularly most gynecologic applications and some methods for treatment of the prostate, the patient waits in the treatment position during the treatment plan generation. Most interstitial and intraluminal treatments differ little from the LDR varieties, with treatment plan generation performed with the patient elsewhere. For those cases with the patient waiting in the treatment position, time becomes an important factor. If the plan generation takes too long, the patient will begin moving with respect to the applicator even though both may be "immobilized." Additional problems with excessively long dosimetry sessions include patient discomfort (other than leading to movement) and cost of support staff such as anesthesiologists.

A second difference entails the quantities involved with the dose calculation. LDR applications often use source strength input by the user and calculate resulting dose rates based on the source configuration. The problem in many cases, particularly in interstitial implants, becomes selecting the dose rate isodose surface on which to base the treatment duration. The case may have many sources, possibly of various strengths, but only a single duration for all sources. HDR brachytherapy has one source strength and many different dwell times. In both cases, the dose calculation algorithm uses the product of the source strength and time at a given location as the basis for the resulting dose distribution.

The third difference concerns the role of quantities as input or output. As noted earlier, LDR calculations most often input the source strengths and calculate the resultant dose rate distribution. Sometimes the treatment duration is also specified, generating a dose distribution. HDR brachytherapy planning usually reverses the process, starting with the dose pattern desired and working backward to the dwell-time distribution necessary to achieve that dose, a process termed inverse planning. A common part of inverse planning is *optimization*, a process to achieve a treatment plan that satisfies some criteria.

Optimization

The term *optimization* implies finding a plan that maximizes some aspects of the dose distribution. Many approaches actually only address finding a set of dwell times that deliver a specified dose to specified locations. Other approaches also try to control the dose distribution more finely and possibly limit the dose to specified organs at risk (OAR). The umbrella of optimization covers many disparate processes.

Optimization Approaches

Optimization in brachytherapy has taken many forms. The approaches fall into general categories, although considerable controversy surrounds the classifications. Ezzell[22] presents an excellent review of optimization. The discussion here can only brush the surface of the topic. One listing of the categories with examples follows.

Stochastic approaches to optimization start from a distribution of dwell times for the selected dwell positions. The starting dwell-time distribution may be arbitrary, but information on typical solutions can reduce the time to solution. Through the initial set of dwell times, the program calculates a value for an *objective function* (OF). An OF assigns a numerical value to the solution set that allows ranking the set according to quality. The OF may be as simple as the difference between the value of dose calculated at a set of points and the dose desired. OFs often become more complicated, as in the following equation:

$$\mathrm{OF} = w_t(0.95D_{\mathrm{pre}} - D_{\mathrm{t,m}})_{D_{\mathrm{t,m}}<0.95D_{\mathrm{pre}}} + \sum_i w_{\mathrm{OAR},i}(\bar{D}_{\mathrm{OAR},i,\mathrm{calc}} - D_{\mathrm{OAR},i,\mathrm{limit}})^2_{\bar{D}_{\mathrm{OAR},i,\mathrm{calc}}>D_{\mathrm{OAR},i,\mathrm{limit}}} \quad (11)$$

In Eq. (11), D_{pre} represents the prescription dose and $D_{\mathrm{t,m}}$ stands for the minimum dose in the planning target volume. In this example, the person running the optimization wants to evaluate whether the dwell-time set results in part of the target receiving <95% of the prescribed dose and, if so, to keep track of how much less. The second term considers the average doses ($\bar{D}$) to each of the OAR and determines for each the amount over some limiting dose assigned for that organ. The objective function, OF, in this case is a penalty paid for the dwell-time distribution. The first term would be omitted as long as the minimum target dose equaled or exceeded 95% of the prescription dose, and the term for any of the OAR would be zero as long as the dose remained below the limiting value. The power of 2 in the exponent indicates tolerance of a little excess dose but imposes serious penalties for larger values. The weighting factors, *w*, allow a differentiation between the importance given to achieving the desired dose distribution and limiting the dose to a given organ at risk. In addition to the OF, the dwell-time set might also be subject to *hard constraints* that would reject the set outright if the target dose fell to <90% of the prescribed dose or an organ at risk exceeded a different, maximum limit. Because the value of the OF increases as the dose distribution gets worse, the program tries to minimize this function. Keep in mind that this equation only illustrates the concepts and is not intended

to serve as a model of a good OF.

The methodology for finding the best set of dwell times differs among the stochastic approaches. In *simulated annealing*,[23–26] random changes, often sizable, are made from an arbitrary initial solution for the dwell times of some or all of the dwell positions. After the changes and recalculation of the OF, the program holds on to the better of the two dwell-time sets. New random changes are made from the better set, and again, the sets are compared using the OF. As this process continues, the allowed changes become smaller, and the OF should improve as the process moves toward the solution—the set with the best OF. The process as described can fall into a local minimum for the OF, where any small change will make the OF worse, a very different solution would be better. The small changes could not get to better solution. To avoid such traps, the program periodically allows big jumps in the dwell times to investigate completely different regions of dwell times. If the new region does not seem promising because the OFs are worse, the program goes back to the better region.

Often, the value of the OF changes little with fairly large changes in individual dwell times in the neighborhood of the optimal solution. Going from a close dwell-time set to the true optimum can require a considerable amount of computer time and often more than getting close in the first place. Most programs contain a criterion for stopping the process once the OF finds an adequate solution instead of continuing to the true optimum.

Other stochastic approaches, such as the *genetic algorithm*,[27] use different search mechanisms, but the overall procedures tend to be similar.

A nonstochastic approach, *geometric optimization* solves for dwell times that would give the same doses to the vicinities around each of the dwell positions, based on several simplifying assumptions.[28] This approach recognizes that the dose near any dwell position results not only from the nearby dwell but also from the sum of the contributions from all the other sources. This method first calculates how much dose would be deposited to a dwell position from all the other dwell positions and then weights the dwell time at that dwell position under consideration by the inverse of this dose. Thus, each dwell position needs only make up for the difference between the dose it already receives from the other positions and the dose desired. The first step sets the relative dwell weight, τ_i (the relative dwell time, normalized as described later), for dwell position I, based on the dose contributions of the other dwell positions. Using the point-source formalism of AAPM Task Group 43[29,30]

$$\tau_i = \left[\sum_{j \neq i} \frac{g(r_{i \leftarrow j}) \cdot \varphi(r_{i \leftarrow j})}{r_{i \leftarrow j}^2} \right]^{-1}, \tag{12}$$

where $r_{i \leftarrow j}$ is the distance between dwell positions i and j, $g(r_{i \leftarrow j})$ is the radial dose function, and $\varphi(r_{i \leftarrow j})$ is the anisotropy factor. Commercial versions of this algorithm usually ignore the radial dose function, which remains within 2% of unity to a distance of 5 cm for ^{192}Ir, and the anisotropy factor, which falls within 3.5% of 0.98 over that same range. The errors from these omissions and the point-source approximation (inherent in the inverse-square relationship) remain smaller than errors that creep in later.

Determining the absolute dwell times then requires specifying the dose desired to a point or the average of several points. For the average dose to several points (indicated by q), the equation for the average dose to the points is

$$\bar{D}_{\text{initial pass}} = \frac{S_K \cdot \Lambda}{n} \sum_{q=n}^{1} \sum_{j=m}^{1} \frac{\tau_j \cdot g(r_{q \leftarrow j}) \cdot \varphi(r_{q \leftarrow j})}{r_{q \leftarrow i}^2}, \tag{13}$$

where S_K is the source strength in mGy m^2 h^{-1}, Λ is the dose rate constant in Gy cm^2/unit source strength, n is the number of dose points in the average, and m is the number of dwell positions, and t_j from Eq. (12) serves as the initial estimate of the dwell time at position j.

Adjusting $\bar{D}_{\text{initial pass}}$ to become $D_{\text{prescribed}}$ requires scaling the dwell times. Letting each of the tj be the time to deliver $D_{\text{prescribed}}$ and c be the scaling factor such that $t_j = c\tau_j$, then we have

$$c = \frac{\bar{D}_{\text{initial pass}}}{D_{\text{prescribed}}}. \tag{14}$$

This process calculated the doses to a dwell position assuming that all the dwell times were the same. That is not the case in Eq. (13), which means that the calculated dwell times are not quite correct. The uniformity could improve by iterating the process, at the sacrifice of its very high speed. The process also assumes that the implant, and particularly the dwell positions, matches the target volume.

Adjacent dwell positions along the same catheter track can produce the greatest effect on the dwell weights, resulting in isodose surfaces that tend to follow the catheters rather than conform to the shape of the implanted volume as

a whole. This is especially the case if the separation between dwell positions along a catheter is much less than the separation between catheters. To reduce this effect, a version of the algorithm neglects all other dwell positions along the same catheter track when calculating the dwell weights in a given catheter. This variation is called *volume optimization* because it tends to spread the doses throughout the implanted volume. The original version, which includes the contributions of all other dwell positions for the calculation of any dwell weight, is called *distance optimization* because the isodose surfaces tend to follow a catheter at a constant distance.

The analytic approach, also known as *point optimization* or *point-dose optimization*, attempts to solve algebraically for the set of dwell times that produce the desired dose distribution, as represented by a set of points, called *optimization points*, each with its own specified desired dose. In the most basic form, the specified doses and the dwell times establish a set of simultaneous equations of the form[31,32]

$$D_i = \sum_{j=1}^{m} C_{i,j} \cdot t_j, \qquad (15)$$

where D_i is the dose specified to point i, m is the number of dwell positions, t_j is the dwell time at position j, and the $C_{i,j}$ are factors that give the dose contribution at i because of the source at position j, with the sum over all sources. The source strength at each source position forms a variable (unknown), and each dose specification point yields an equation. Equal numbers of dwell times and dose points form a *determined* system with an exact solution. In more complex cases, there may be more optimization points than source positions, resulting in an *overdetermined* system (more equations than variables). This would be the situation in which optimization points were spread around the contour of a region of interest (ROI) and scattered through the volume. Faced with this situation, one can vary the source strengths to minimize the square of the differences between the desired and calculated doses at the optimization points. At the other extreme, a case may have more source positions than optimization points (more variables than equations), resulting in an *underdetermined* system. This situation most often happens with large implants and a minimum of optimization points or complicated gynecologic applicators with only a few dose control points. With this situation, the source strengths have no well-defined values; many solutions would possibly exist with the same value for the square of the difference between the doses desired and those calculated. Distinguishing

between the solutions requires some other criteria. One often is a minimization of the total dwell time, under the assumption that such would also minimize the integral dose to the patient.

Determined and overdetermined systems can (and often do) generate solutions with negative dwell times. Simply truncating the negative dwell times often results in a very unsatisfactory dose distribution. Avoiding this nonphysical situation also requires an additional criterion. One possible criterion minimizes the differences between adjacent source strengths. For m dwell positions, this term becomes

$$\delta_i = \sum_{j=1}^{n-1} \left(t_j - t_{j+1}\right)^2. \tag{16}$$

Including this term in the optimization limits the fluctuations between adjacent sources. To deliver a dose to the target volume requires a net positive total dwell time, and so limiting the amount of difference between the dwell times eventually results in all positive times. An additional condition for underdetermined systems selects solutions that minimize the total radiation to the patient as a whole, which depends directly on the total source strength. The final optimization becomes minimizing the chi-squared value in

$$X^2 = \sum_{i=1}^{m} w_i \left(D_i - C_{ij} \sum_{j=1}^{n} t_j \right)^2 + v \sum_{j=1}^{n-1} \left(t_j - t_{j+1}\right)^2 + u \sum_{j=1}^{n} t_j, \tag{17}$$

where, in addition to those quantities defined earlier, n is the number of dose points specified, w_i is the weighting given to the dose specification at point i (how much the operator wants the correct dose there), v represents the importance in minimizing the fluctuations between adjacent sources, and u represents the importance of minimizing the integral dose to the patient.

With a large number of optimization points or source positions, or both, the running of the program solving the equations becomes long, and approximations cut the calculation time greatly without significantly compromising the accuracy of the final dose distribution. By setting the dwell time

$$t_i = \sum_{k=1}^{p} a_k \cdot F_k\left(j-1\right), \tag{18}$$

where F is a fitting function, such as a polynomial or Fourier series of order p,

and a_k is the coefficient for the kth element, and substituting that into the X^2 Eq. (17), the optimization now need only solve for the fitting coefficients, presumably a much smaller set of values. An alternative approach to solving the equation follows Newton's method.[33,34]

Obviously, the selection of the optimization points becomes very important. The number of points must adequately describe the shape of the dose distribution desired. The dose distributions may satisfy the specifications established for the optimization points but leave portions of the target without dose specification points untreated. However, the points should avoid regions of large dose gradients because specification there can produce unexpected and inappropriate results.

In general, lower values for v in Eq. (17) allow better conformality of the dose distribution, and the optimum value often is that just sufficient to prevent negative dwell times. However, simply solving for the dose to specified points can produce an unwanted dose distribution, even when the points seem to follow normal guidelines. Thomadsen et al.[35] give an example similar to that in Figure 27.10. Here, the dose points mirror the basal dose points equidistant from the surrounding catheters. With a low value for v in the optimization equation, the simple solution places all of the source material in the center, bottom needle—not at all what was really desired. The situation could be avoided by limiting the dwell-time variations or using more dose points, particularly on the outside of the implant. Alternatively, performing a geometric optimization to obtain an approximate source distribution, followed by optimization on the points, also alleviates the problem.

The output of any optimization approach may leave the operator wanting to make modifications. One method commercially available works on the computer screen display of the dose distribution and allows the operator to "grab" a dose line on the display with the cursor and move the line to a desired location. These fine adjustments make changes that would be difficult to describe in the optimization routine's specifications. Most of the programs allow adjusting the impact of any change between changing all of the dwell times (scaling the distribution, making the whole larger or smaller) and changing a single dwell time (effecting very local changes). Even local changes, however, result in changes in image planes other than the one on which the change has made because the radiation carries the dose beyond the immediate locale.

Changes in the dose distribution to produce desired modifications can also produce unintended changes. Of particular concern would be expending the

prescription isodose surface and inadvertently also expending the higher-dose surfaces, possibly into a significant volume. During any manipulation of the isodose surfaces, the display should also show the higher doses. Assuming that most of the manipulation occurs with the 100% surface, the 150% should also be on display.

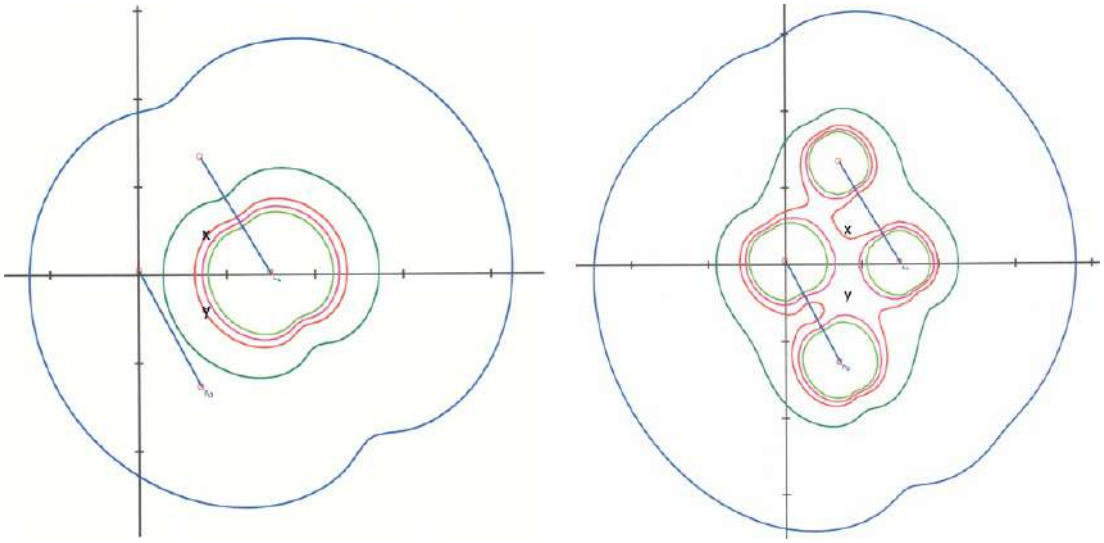

FIGURE 27.10. An example of potential optimization problem. **A:** The criterion was that the two optimization points (*X* and *Y*) receive the same dose, which was satisfied by a single active dwell position. **B:** Adding constraints on the dwell-time variation solved the problem. (Example inspired by van der Laarse R. Optimization of high dose rate brachytherapy. *Act Selectron User's Newsl* 1989;2:14–15.)

Evaluation of Dose Distributions

Optimization calculations compute relative dose distributions and require only spatial dose information. After establishing the shape of the dose distribution, the entire distribution must be raised or lowered to give the correct absolute dose to a specified point or the average at a number of specified points. This process requires some evaluation of the dose distribution.

Other than visually examining the isodose distribution resulting from the optimization routine, there are some tools that provide quantitative assessments of various aspects. Thomadsen[18] provides a fuller discussion.

Figure 27.11 shows a typical dose–volume histogram for an implant. The histogram provides the basis for many of the analytical quantities. Ideally, the target structure curve should follow the 100% (or 1.00) level (top of the graph) from the low doses on the left through the target dose, indicating that the entire target receives at least the target dose. In practice, such coverage often becomes challenging. The volume of the target receiving at least a dose "*x*" is indicated by

the symbol V_x, where the x can be either a percentage of the prescription dose or an absolute dose, but should be explicit. Alternatively, sometime the quantity of interest is the dose received by a volume "y," indicated as D_y, where y can be either the fraction of the ROI or an absolute volume. In this chapter (although not a very common practice), a preceding subscript indicates delimitations, such as confining the value to the planned target volume (PTV) or looking at the value through the entire universe ("total").

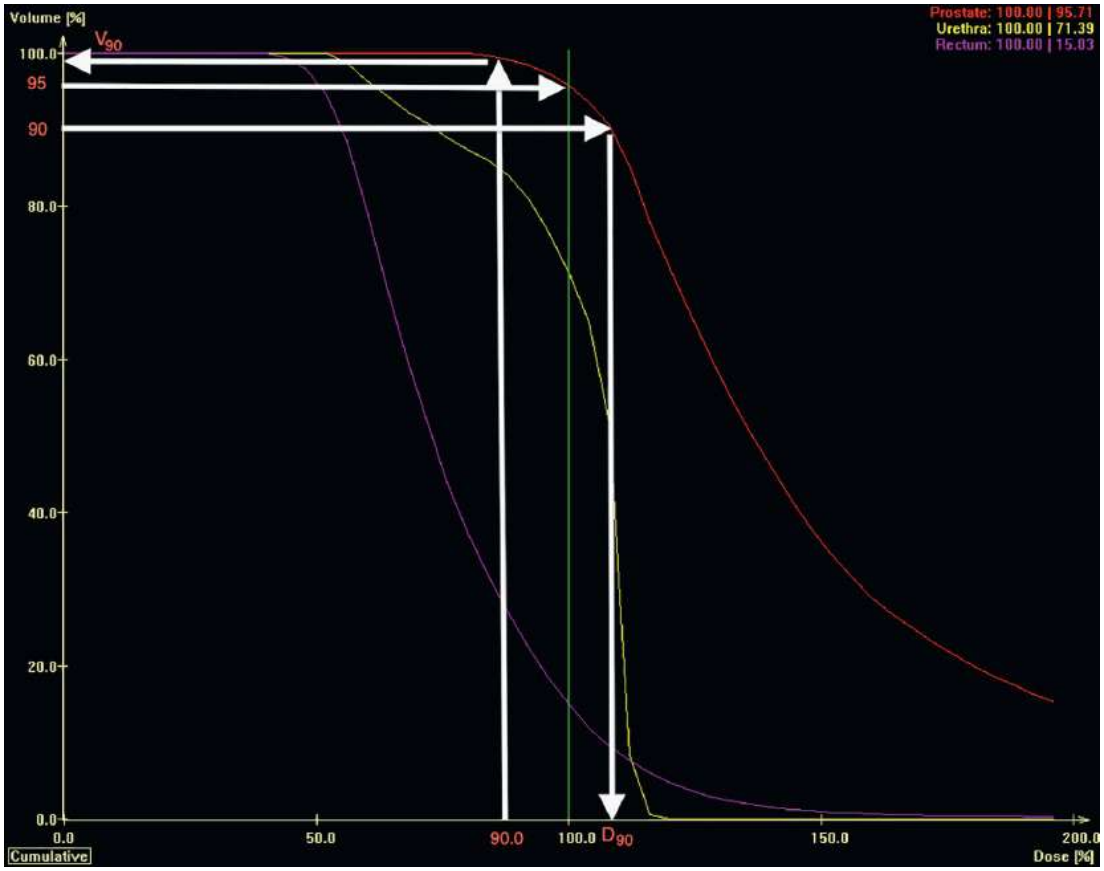

FIGURE 27.11. A dose–volume histogram (DVH) for a prostate implant. The *vertical green line* indicates that 95% of the prostate is to receive 100% of the prescribed dose. The fractional volume of the prostate receiving 90% of the prescribed dose, V_{90}, and the dose that covers 90% of the prostate, D_{90}, are also shown. This DVH also shows the volumes raised to specified fractions of the prescription dose for the rectum and bladder.

Competing treatment plans may have quite different features. Some quantities that can help condense some characteristics into values include the following. It should be noted that some of the quantities originally applied to the dose distribution in the absence of any regions of interest but have been adapted to the

modern situation in which volume images provide a context for assessment and evaluation. Unless indicated, the volumes are the fraction of the whole ROI.

Coverage is usually specified in terms of the faction of the CTV raised to a required dose. As an example, if it were felt that all the CTV should receive at least 95% of the prescribed dose, this would be specified as $_{CTV}V_{95\%}$=100%. It might also be desirable that in a given fraction, 90% of the CTV receive at least 5 Gy, or $_{CTV}D_{90\%}$=5 Gy.

High-dose volume (HDV)[36–38] is the volume of an ROI raised to a dose significantly higher than the target dose, often higher by a factor of 1.5. Symbolically, we have

$$\mathrm{HDV} = {}_{\mathrm{ROI}}V_{150\%}. \tag{19}$$

Dose nonuniformity ratio (DNR)[38–40] is the ratio of the CTV high-dose volume to that taken to at least the target dose:

$$\mathrm{DNR} = {}_{\mathrm{CTV}}V_{150\%} \,/\, {}_{\mathrm{CTV}}V_{100\%}. \tag{20}$$

Relative dose homogeneity index (HI)[38,39] is the fraction of the target volume receiving a dose between the target dose and the high-dose level:

$$\mathrm{HI} = {}_{\mathrm{CTV}}V_{150\%} - {}_{\mathrm{CTV}}V_{100\%}. \tag{21}$$

Rarely are both DNR and HI used together.

Conformation number or *conformal index* (CN or COIN)[41,42] is a measure of how well the dose distribution fits the target:

$$\mathrm{CN} = \frac{{}_{\mathrm{CTV}}V_{100\%}}{{}_{\mathrm{total}}V_{100\%}} \cdot \frac{{}_{\mathrm{CTV}}V_{100\%}}{{}_{\mathrm{CTV}}V}, \tag{22}$$

where all the volumes are absolute such as in cm^3.

Each of these quantities tells a small part of the dose distribution's entire story. Each can help in the evaluation of a dose distribution, and all, taken together, give a better picture. However, none of the indices—even together—captures the complexity and nuances of the total dose distribution. Inspection of the results of the optimization remains a necessity.

The *maximum significant dose* (MSD) refers to the highest-level isodose surface that encompasses more than one needle track. The dose very close to a needle track becomes very high, but the body seems to tolerate these small local volumes. The MSD provides a convenient criterion for when the high-dose

volumes become “significant” and likely to produce biologic consequences. For most implants, the MSD should remain <150% of the prescription dose, assuming that the prescription dose encompasses the target volume. For vary large volumes, the limiting value should decrease to about 125% of the prescription dose.[4]

Evaluation of the treatment plan quality also entails evaluating the doses to the OAR. This evaluation also most frequently uses quantities such as $_{\text{rectum}}D_{2\text{ cc}}$ as a review criterion. Limitations on the doses to normal-tissue structures are discussed in detail in Chapter 14 and in most of the chapters on clinical applications.

Quality Control of Treatment Plan

The use of HDR brachytherapy in the definitive management of gynecologic cancer,[2] early-stage breast cancer,[43,44] and prostate cancer[45] has made the HDR RAL a very common treatment modality in most radiotherapy clinics. Treatment planning systems for HDR RALs are now interfaced with multimodality images (computed tomography [CT], magnetic resonance imaging [MRI], and ultrasound) and sophisticated dose optimization software like inverse planning or interactive graphical optimizers, which enable the planner to maximize the dose uniformity while minimizing the implant volume needed to adequately cover the target volume and at the same time reduce the dose to the OAR. Such flexibility creates a challenge for the verification of the optimized calculations with practical manual calculation techniques. With the time constraint between HDR planning and the delivery of treatment while the patient is in the operating room, an efficient, precise, and easy method for checking the complex computer calculation is necessary for quality control of the treatment plan. Every institution should have an established quality control program that takes only a few minutes but at the same time gives a high probability of detecting significant errors, because the NRC considers a difference between the administered dose and calculated dose of 20% a reportable medical event.[46]

Simplistic models to verify computer calculations quickly have drawbacks because applicators or interstitial implants used in HDR treatments are complex in design, and simple point-dose or linear source calculations tend to fall apart in most circumstances.[17,47,48] Because all treatment planning systems have the capability of generating dose–volume histograms, it is logical that volume-based QA should be the choice. Das et al.[49,50] addressed this possibility and provided an easy and quick calculation check for most HDR interstitial and intracavitary

implants. Because HDR treatments are delivered through a wide variety of applicators, the study was divided into three categories:

- Single-catheter system, which includes tandem and cylinders and vaginal cylinders, as well as MammoSite balloons
- Two- and three-catheter systems, which include tandem and ovoid pairs or ovoid pairs only
- Multicatheter system for interstitial implants

SPECIAL CONSIDERATIONS

The following examples illustrate some of the aspects of the treatments that are unique for HDR applications. Other chapters discuss the actual therapies in more detail.

Cervical Cancer Brachytherapy

Intracavitary brachytherapy has been a major part of the treatment for cervical cancer for about 85 years, with a significant experience using HDR approaches since the mid-1980s. Of the advantages of HDR brachytherapy given earlier, several apply directly to these treatments, particularly the small size of the source and the concomitant smaller diameter of the intrauterine tandem, the greater stability of the treatment appliance and higher accuracy and relevance of the calculated dose distribution, and the ability to hold OAR away from the applicator and source track. Imaging plays a major role in these treatments, with the future likely seeing an increase in that role.[51] Ultrasound often provides guidance during the placement of the intrauterine tandem, particularly when the tumor obliterates the external cervical os and can help avoid perforation of the fundus. Fluoroscopy provides guidance during placement of the appliance, assisting in the assessment of applicator geometry (e.g., evaluating the centering of the tandem with the ovoids in both the anteroposterior and the lateral projections) and the positions of the rectum and bladder.

Imaging for gynecologic brachytherapy is evolving very rapidly, particularly for HDR approaches. Both the brachytherapy arm of the European Society for Therapeutic Radiology and Oncology (Groupe Européen de Curiethérapie [GEC-ESTRO]),[52–56] the American Brachytherapy Society (ABS) consensus guidelines for the locally advanced carcinoma to the cervix[57–59] and the International Commission on Radiation Units and Measurements (ICRU)[60] recommended moving toward image-based target prescriptions. Identifying the

target, that is, tumor tissue in the uterus, requires MRI, the only form of imaging that also reliably differentiates the uterus from other pelvic tissues. GEC-ESTRO defines a high-risk clinical target volume (CTV_{HR}) as any tumor detectable by physical examination or imaging plus the entire cervix. Typically, 95% of the prescription dose should cover 95% of the CTV_{HR} volume, written as CTV_{HR} $D_{95\%}$ = 95% $D_{Prescription}$. The formalism also defines an intermediate-risk clinical target volume (CTV_{IR}) based on the extent of disease at the time of diagnosis.* Generally, the CTV_{IR} should receive about two-thirds the dose of the CTV_{HR}. The recommended integrated dose to the CTV_{HR} in 2-Gy per fraction radiobiologic equivalence is 80 to 90 Gy depending on the tumor size including the external beam contribution. To maintain a connection to historic experience while prescribing the dose to a target volume, ICRU 89 recommends reporting the dose to the conventional point A, defined as per the American Brachytherapy Society.[57]

Although only MRI identifies the target and the uterus, CT images the rectum and the bladder well. Although using CT localization does not permit as detailed target information as MRI, it does allow moderate target definition and does facilitate determining the doses to the OAR when using conventional treatment prescriptions.[60] Dose calculations based on either CT or MRI often indicate that the maximum dose to the bladder falls 2 to 4 cm superior to the conventional point indicated following Report 38 of the International Commission on Radiation Units and Measurement (ICRU)[61] and may be two to four times the dose to the conventional point. The ICRU-indicated rectal point differs less than the bladder point, with the true maximum falling between 1 and 3 cm superiorly and the true maximum dose being one to three times the conventional point. The GEC-ESTRO and the ICRU 89 formalism specify the dose of interest to OAR in terms of volumes rather than points. For the rectum, bladder, and sigmoid, the point with the highest dose is found, and this point locates the volumes of interest. For each OAR, the minimum dose in the most highly irradiated 2-cm^3 volume is recorded, as is the minimum dose in the most highly irradiated 0.1-cm^3 volume.

The accuracy and precision of determining the dose matter much more in HDR intracavitary brachytherapy for the cervix than for LDR treatments for two reasons. The first concerns the precision of dose delivery. King et al.[62] demonstrated that the typical LDR tandem and ovoids move an average of 2 cm over the course of treatment. HDR tandems and ovoids move a maximum of 3

mm when not moving the patient.[48] Thus, the added precision of volume-imaged–based dose calculations would be lost in the general positional uncertainty of LDR intracavitary brachytherapy. In the second place, HDR applications not only can use the dosimetric accuracy, but they may require it. Because of the radiobiologic disadvantage of HDR brachytherapy, knowing the dose distribution with a high certainty is necessary to avoid complications.

Avoiding complications leads to several differences of the cervical applications with HDR compared to LDR brachytherapy. To prevent rectal complications, the dose to the rectum should remain <70% of the dose to the Manchester point A or the CTV_{HR}.[2,59]). Treating with the rectal retractor in place usually accomplishes this goal. As noted under the advantages of HDR brachytherapy, patients would not tolerate such a practice over the long durations with LDR applications. Adding distance to the bladder generally uses copious packing anterior to the ovoids, taking care not to let the packing slip between the ovoid surface and the superior or lateral fornices. An unpublished 1988 review of LDR cervical cases at the University of Wisconsin found the beginning of late complications in the superior bowel (fistulae) at about 13 years after treatment and that the prevalence increased continually with time out (unpublished). That problem with LDR treatments generated concern that the situation might be worse with HDR treatments because of the unfavorable radiobiology. With HDR, unlike LDR, the dose to the superior bowel can be reduced by not loading the tandem as high into the uterus and making the dose distribution more square than the LDR applications.[2]

Prostate Brachytherapy

Unlike most cancers, the α/β for prostate cancer is low, possibly as low as 1.2 Gy and lower than that for most normal tissues.[63,64] As discussed earlier, normally slow delivery of the radiation, such as with LDR treatments, allows normal tissues to recover better than tumors, whereas HDR causes a greater increase in the damage to the normal tissues than to tumors. When the relative size of the α/β inverts, as in prostate cancer, the advantages also invert. High doses per fraction cause a greater increase in damage to the tumor cells with an α/β of 2 than the normal-tissue cells with an α/β of 3. This situation makes HDR brachytherapy look attractive.[65,66]

Currently, the process for HDR treatments of the prostate follows the LDR model fairly closely. Ultrasound images provide guidance for the insertion of the catheters, although MRI guidance has also been reported and is likely to become

more common in the future.[67–69] Generally, placement of the catheters follows a pattern such as four around the urethra and then at 1- to 1.5-cm intervals around the periphery of the gland. The square-hole pattern complicates placement at regular intervals, but the final dose distribution is relatively insensitive to the exact location of the catheters. Commercial software exists to guide the user in the placement of the catheters, but those experienced in prostate implants probably perform as well without computer assistance.

After placement, the optimization routine calculates dwell times to achieve the criteria specified for the patient. The resultant dose distribution may still require adjustment through graphical optimization. On approval of the plan, the operator connects the needles to the treatment unit using the transfer tubes. Because the needles have no inherent numbering, great care must be taken during this process to ensure correct correlation between the needles in the patient and those in the treatment plan.

The location of the first dwell position in the needles would have been determined previously. Radiographing the needles with the x-ray markers in place forms one of the simplest methods. If the treatment unit does not seek the end of the needle to establish the first dwell position, all needles must be tested for uniformity of length.

Treating multiple fractions with the same insertion requires verification of the needle depth. Between fractions, the needles tend to work toward the surface and may need repositioning under ultrasound or fluoroscopic guidance. Marks on the needles where they enter a template also can serve as indicators of the needle for repositioning.

Breast Brachytherapy

Accelerated partial-breast irradiation (APBI) for breast cancer patients with HDR brachytherapy as monotherapy following lumpectomy has produced excellent local control rates and cosmesis.[49,70] Interstitial and intracavitary (catheter balloon) implants are used for this treatment modality. Usually within 8 weeks of lumpectomy and axillary nodal evaluation, the patient undergoes an interstitial implant with one of three methods: a prone, stereotactic, template method with digital mammographic guidance; a supine, ultrasound-guided technique; or a supine template guide CT technique, all three under local anesthesia. Because of the perceived technical challenge of multicatheter interstitial implants, alternative, intracavitary methods for APBI have been developed. One approach uses multiple catheters around the central catheter

within a balloon that is placed within the lumpectomy cavity closed, often under ultrasound guidance, and inflated with saline or diluted contrast medium. Two such systems are the Contura (SenoRx, Bard Biopsy System, Tempe, AZ) and multicatheter MammoSite (Hologic, Bedford, MA). An alternative is the SAVI device (Cienna Medical, Aliso Viejo, CA) that uses six to ten struts in a configuration that looks similar to an egg whisk to hold the tylectomy cavity open instead of a balloon. The struts also serve as the paths for the source travel. A new device consisting of a double balloon (Best Industries, Springfield, VA) contains a single central treatment catheter and four peripheral treatment catheters that can be customized for radiation dosage coverage. The inner balloon can be filled with 7 to 30 cc of saline to increase the separation of the peripheral catheters and an outer balloon that can be filled with 35 to 110 cc of saline to displace the breast tissue from the peripheral catheters. The multiple catheters of each of these devices allow some shaping of the dose distribution, but not comparable to that obtainable with the multicatheter, interstitial implants. Imaging of the balloon for its integrity, as well as rotation of the multiple-catheter devices, should be performed before the initiation of each treatment.

ACKNOWLEDGMENT

We thank Adam Uselmann and Liyong Lin for the artwork they contributed to this chapter.

CHAPTER 28

Clinical Aspects and Applications of High Dose Rate Brachytherapy

Subir Nag, Granger R. Scruggs, and John A. Kalapurakal

Brachytherapy has the advantage of delivering a high radiation dose to the tumor while sparing the surrounding normal tissues. Brachytherapy procedures were initially performed by inserting radioactive material directly into the tumor ("hot" loading), which resulted in high radiation exposure to the physicians performing the procedure. Manually afterloaded techniques were introduced to increase accuracy and reduce the radiation hazards. In afterloaded techniques, hollow needles, catheters, or applicators are first inserted into the tumor and then loaded with radioactive materials. The introduction of remote-controlled insertion of sources eliminated radiation exposure to visitors and medical personnel. In this technique, the patient is housed in a shielded room and the radiation therapist controls the treatment from outside the room. Hollow applicators, needles, or catheters are inserted into the tumor and connected by transfer tubes to the radioactive material, which is stored in a shielded safe within the high dose rate afterloader. The radiation source is driven through the transfer tubes and into the tumor by remote control. Currently, most brachytherapy procedures are performed using remote-controlled afterloading techniques.

Remote-controlled brachytherapy can be performed using low dose rate (LDR), medium dose rate (MDR), or high dose rate (HDR) techniques. Although, the International Commission on Radiation Units and Measurements (ICRU) definition No. 38 of HDR is >12 Gy/h,[1] the usual dose rate employed in current HDR brachytherapy units is about 100 to 300 Gy/h. HDR has the added advantage that the treatments take only a few minutes, which can be given on an outpatient basis with minimal risk of applicator movement and minimal patient discomfort. Additionally, use of a single-stepping source, as used in most modern HDR afterloaders, allows finely tuned optimization of dose distribution

by varying the dwell time at each dwell position. However, it should be emphasized that although optimization can improve the dose distribution, it should not be used to substitute for a poorly placed implant. Nag and Samsami[2] have provided examples of inappropriate optimization strategies that can lead to suboptimal dosimetry plans and clinical problems. HDR is normally given as a course of a number of fractionated HDR treatments, although it can be given as a single treatment, as in intraoperative HDR brachytherapy, if doses to the normal tissues can be sufficiently reduced by displacement or shielding. The advantages and disadvantages of HDR in comparison to LDR are enumerated in Table 28.1.

The advantages listed above have led to increased use of HDR worldwide; however, training and expertise are required for proper administration of these treatments. Guidelines and recommendations for the use of HDR at various sites have been published by the American Brachytherapy Society (ABS) originally between 1999 and 2001. In 2012, the ABS made updates to these guidelines and subsequently published them, much of which is summarized in this chapter[9–17] and the reader should refer to these publications for details. Controlled clinical trials are needed to critically evaluate the efficacy of these procedures.

RADIOBIOLOGIC PRINCIPLES OF HIGH DOSE RATE BRACHYTHERAPY

Most radiation oncologists are familiar with LDR brachytherapy. LDR (at 30 to 50 cGy/h) can be added to external beam radiation therapy (EBRT) doses (at 2 Gy/d) to obtain equivalent total doses. HDR brachytherapy is distinct from LDR brachytherapy, and radiation oncologists who are accustomed to LDR techniques must realize that experience in LDR cannot be automatically translated into expertise in HDR. It is important to review the current literature and survey the experiences of centers that have been performing HDR. When converting from LDR to HDR, one must keep the other parameters (chemotherapy, EBRT field/dose, dose-specification point, applicators, patient population, and so forth) the same, changing only the LDR to HDR.

Fractionation schemes for HDR are widely variable, and many radiation oncologists are not very familiar with the resultant biologic effects. Empirical methods such as the NSD (nominal standard dose), TDF (time–dose factor), or a dose reduction factor of 0.6 have been used in the past to convert HDR doses to LDR equivalent doses. The linear-quadratic (LQ) equation can be used to guide development of HDR doses and fractionation schedules.[18] However, the LQ

mathematical calculations are tedious and may not be practical on a day-to-day basis. Hence, a simplified computer program was developed by Nag and Gupta[19] to obtain the isoeffective doses to be used for HDR. The clinician needs only to enter the EBRT total dose and dose/fraction, HDR dose, and the number of HDR fractions. The computer program will automatically calculate the isoeffective doses for tumor and normal tissue effects. Isoeffective doses are expressed in clinically familiar terms, as if given at 2 Gy per fraction (EQD2), rather than as biologically equivalent doses (BED), which are unfamiliar to clinicians. Furthermore, a dose-modifying factor (DMF) can be applied to the normal tissues to account for the fact that doses to normal tissues are different from the doses to the tumor, thus providing a more realistic equivalent normal tissue effect. This program can be used to determine HDR doses that are equivalent to LDR brachytherapy doses (EQD2) used to treat various cancers. Alternatively, the program may be used to express the isoeffective dose of different HDR dose-fractionation regimens as shown for cervical cancer in Table 28.2. It is remarkable that the isoeffective doses for tumor effects for the various fractionation regimens used for early-stage cervical cancers are so similar, ranging from 82 to 85 Gy, whereas those used for advanced cancers are about 90 Gy (see Table 28.2). The isoeffective dose for normal tissue late effects depends on the assumed DMF (0.6, 0.7, or 0.9). For the fractionation scheme shown in Table 28.2, row 1, the equivalent late effect on normal tissue (bladder or rectum) would be 59.5, 71, or 98 Gy, respectively, if the doses to normal tissues were 60%, 70%, or 90% of the prescribed dose to point A.

Although the LQ biomathematical model can be helpful in determining isoeffective doses, it has many limitations that must be kept in mind when using the program. The LQ model accounts for the repair of sublethal damage, but it does not account for reoxygenation of hypoxic cells, reassortment within the cell cycle, or repopulation of tumor cells. These factors are generally small under normal circumstances. However, large doses per fraction do not allow reoxygenation of hypoxic tumor cells or reassortment of tumors from radioresistant S phase. Hence, a large radiation dose will preferentially kill radiosensitive cells, leaving a high number of hypoxic, radioresistant cells. Therefore, the computer program will overestimate the tumor effect of a single large dose per fraction (unless a resensitization factor is introduced).

TABLE 28.1 ADVANTAGES AND DISADVANTAGES OF HIGH DOSE RATE COMPARED WITH LOW DOSE RATE BRACHYTHERAPY

Advantages	Disadvantages
1. Radiation protection • HDR eliminates radiation exposure hazard for caregivers and visitors. Caregivers are able to provide optimal patient care without fear of radiation exposure. • HDR eliminates source preparation and transportation. • Because there is only one source, there is minimal risk of losing a radioactive source. 2. Allows shorter treatment times • There is less patient discomfort because prolonged bed rest is eliminated. • It is possible to treat patients who may not tolerate long periods of isolation and those who are at high risk for pulmonary embolism due to prolonged bed rest. • There is less risk of applicator movement during therapy. • There are reduced hospitalization costs because outpatient therapy is possible. • HDR may allow greater displacement of nearby normal tissues (by packing or retraction), which could potentially reduce morbidity. • It is possible to treat a larger number of patients in institutions that have a high volume of brachytherapy patients but insufficient inpatient facilities (e.g., in some developing countries). • Allow intraoperative treatments, which are completed while the patient is still in the operating room. 3. HDR sources are of smaller diameter than the cesium sources that are used for intracavitary LDR. • This reduces the need for dilatation of the cervix and therefore reduces the need for heavy sedation or general anesthesia. • High-risk patients who are unable to tolerate general anesthesia can be more safely treated. • HDR allows for interstitial, intraluminal, and percutaneous insertions. 4. HDR makes treatment dose distribution optimization possible • Variations of the dwell times of a single stepping source allow an almost infinite variation of the effective source	1. Radiobiologic • The short treatment times do not allow for the repair of sublethal damage in normal tissue or the redistribution of cells within the cell cycle or reoxygenation of the tumor cells; hence, multiple treatments are required. 2. Limited experience • Few centers in the United States have long-term (>20 y) experience. • Until recently, standardized treatment guidelines were not available; however, the American Brachytherapy Society (ABS) has provided guidelines for HDR at various sites.[3–8] 3. The economic disadvantage • The use of HDR brachytherapy as compared to manual afterloading techniques requires a large initial capital expenditure because the remote afterloaders cost about $400,000. • There are additional costs for a shielded room, and personnel costs are higher as the procedures are more labor intensive. 4. Greater potential risks • Because a high-activity source is used, there is greater potential harm if the machine malfunctions or if there is a calculation error. The short treatment times, compared to LDR, allow much less time to detect and correct errors.

	strengths, and the source position allows for greater control of the dose distribution and potentially less morbidity.

HDR, high dose rate; LDR, low dose rate.

The LQ equation does not take into account the proliferation of tumor cells. This factor is small if the treatments are performed over a short duration. However, if the treatments are highly protracted (e.g., there is a long time interval between EBRT and HDR), or in cases of tumors with high proliferation rates, the LQ model will overestimate the actual tumor effect. It also must be noted that individual α/β values are very variable. The α/β values for early reactions vary from 6 to 13 (the default in the program is set at 10); the α/β values for late reactions vary from 1 to 7 (default being set at 3), whereas α/β values for tumors vary from 0.4 to 13 (the default being set at 10). However, α/β values for a particular patient are not known and may vary even within the same tissue. The isoeffective doses obtained will therefore depend on the α/β values used for that particular calculation. The LQ model assumes complete repair between fractions. If the time interval between fractions is too short (<6 hours) or the half-time of repair is very long, the repair of normal tissues will be incomplete, and the LQ formula will underestimate the biologic effect. Hence, it is important to have sufficient time interval (at least 6 hours) between treatment fractions.

TABLE 28.2 AMERICAN BRACHYTHERAPY SOCIETY SUGGESTED DOSES OF EXTERNAL BEAM RADIATION THERAPY AND HIGH DOSE RATE BRACHYTHERAPY TO BE USED IN TREATING CERVICAL CANCER

Total EBRT Dose (Gy) at 1.8 Gy/Fraction	No. of HDR Fractions	HDR per Fraction (Gy)	Isoeffective Dose (Gy) for Tumor Effects[a]	Isoeffective Dose (Gy) for Late Effects with DMF = 0.7[b]	Isoeffective Dose (Gy) for Late Effects with DMF = 0.9[b]
45	4	7	83.9	74.2	90.1
45	5	6.0	84.3	73.4	88.6
45	6	5	81.8	70.5	83.7
45	5	5.5	79.8	69.6	82.6

[a] α/β ratio assumed for tumor = 10.
[b] α/β ratio assumed for normal tissue late effects = 3.
DMF, dose-modifying factor; EBRT, external beam radiation therapy; HDR, high dose rate.

The infinite variation of the dwell times that is possible with HDR (or pulsed dose rate) allows better optimization of the doses than can be achieved with LDR. Better packing or retraction of normal tissues is possible with HDR, because of the short treatment duration. This factor is not usually taken into account in the LQ model (unless the DMF is altered). Another difference not accounted for in the LQ model is that the dose stated in brachytherapy is generally the minimum tumor dose. The doses within the tumor are much higher. Hence, the effective dose (for tumor control probability) is much higher for brachytherapy than for EBRT.

In view of the many limitations of the LQ model, it must be stressed that, as with any mathematical model, the LQ model should be used judiciously only as a guide and should always be correlated with clinical judgment and outcome results. Because of the reasons mentioned above, caution is especially warranted whenever large fraction sizes, a short time interval between fractions, or highly protracted treatments are used.

Common Uses of High Dose Rate Brachytherapy

Although HDR brachytherapy has been used in almost every site in the body, it is now most commonly used to treat cancers of the cervix, endometrium, prostate, and breast. Less commonly treated sites for HDR include the lung, esophagus, bile duct, rectum, head and neck, skin, soft tissues, and blood vessels (coronary and peripheral arteries). HDR is generally used as a component of multimodality treatment that includes EBRT and/or chemotherapy and surgery. A summary of the clinical uses of HDR is included in this chapter, while the details of the physics and radiobiology of HDR are provided in other chapters.

Carcinoma of the Cervix

Brachytherapy is a necessary component in the curative treatment of cervical cancers.[10,11] However, an evaluation of the SEER data by Han et al.[20] revealed an overall decline in the utilization of brachytherapy for cervical cancer between 1988 and 2009 from 83% to 58%. Furthermore, it was found that brachytherapy resulted in higher cause-specific survival and overall survival. Gill et al. reported their analysis of the National Cancer Data Base of women with cervical cancer undergoing treatment from 2004 to 2011. It demonstrated a decrease in the use of brachytherapy from 96.7% to 86.1% with a simultaneous increase with the use of intensity-modulated radiation therapy (IMRT) and stereotactic body radiation therapy (SBRT) from 3.3% to 13.9%. The use of external boost

techniques resulted in inferior overall survival.[21] A practice patterns quality research study by Eifel et al.,[22] sampling 261 cases over 45 facilities between 2005 and 2007, revealed higher rates of EBRT use only without brachytherapy and protracted treatment beyond 10 weeks in nonacademic facilities compared to academic facilities. These findings across these various groups highlight our need to follow accepted treatment guidelines to provide our patients with the best possible outcome.

HDR brachytherapy has been utilized more frequently compared to LDR brachytherapy over the past few decades because of the ability to deliver therapy on an outpatient basis, avoidance of long-term bed rest, and avoidance of cervical dilation. Additionally, greater sparing of the rectum and bladder by temporary retraction, dose optimization, and integration with EBRT to the pelvis are possible.[23] These advantages must be counterbalanced with the greater number of treatments required (typically two to six treatments, lasting ~10 to 15 minutes each). An international survey published in 2012 revealed that 85% of centers now utilize HDR brachytherapy.[24] As LDR brachytherapy has been used for more than 100 years, it is imperative to analyze HDR brachytherapy, which has a much shorter history. A recent meta-analysis by Lee et al. compared treatment outcomes of LDR versus HDR for cervical cancer. Nearly 19,000 patients were analyzed, and there were no differences in 5-year overall survival, 5-year disease-free survival, pelvic recurrence, or rectal and bladder complication rates between HDR- and LDR-treated patients.[25]

The ABS recommends keeping the total duration of treatment (EBRT and HDR) to <8 weeks because prolongation adversely affects local control and survival.[10,11] To maintain this treatment duration, the HDR is interdigitated during the course of EBRT. However, it should be noted that neither EBRT nor chemotherapy is given on the day of an HDR treatment. Typically, if the tumor is small and the vaginal geometry is optimal, HDR brachytherapy begins approximately 2 to 3 weeks after starting EBRT. HDR is then continued one time per week with the EBRT given on the other 4 days of the week. If large tumor volume requires delaying the start of HDR brachytherapy, it may be necessary to perform two implants per week after the EBRT has been completed to keep the total treatment duration to <8 weeks.

The insertion of the applicator is performed under some form of sedation. The results of an international survey of gynecologic experts revealed that the most common form of sedation was general anesthesia (48%) followed by intravenous conscious sedation (28%), spinal anesthesia (27%), and oral pain medication

(14%).[24] At some institutions, a Smit sleeve is placed to facilitate insertion of the central tandem. It should be emphasized that rectal and bladder retraction (by the use of packing or retractors) is essential in HDR as it is for LDR. The use of an external immobilization device (EID) to fix the position of the applicator is controversial; some centers prefer to use an EID to fix the position of the applicators, whereas others feel that the use of the EID is detrimental. Various types of applicators (tandem and ovoid or ring being the most common) have been used and depend on the preference of the radiation oncologist as well as tumor response to initial therapy to select the most appropriate device.

Treatment Planning

Traditionally, the HDR dose was prescribed to an arbitrary applicator-based definition of point A.[26,27] However, point A does not necessarily reflect the dose to the tumor. The ABS recommends the use of image-based treatment planning in brachytherapy for carcinoma of the cervix and specifically 3D imaging, where available, to optimize treatment delivery to the tumor.[10] It is well established that magnetic resonance imaging (MRI) is superior to other current imaging modalities in delineating gross tumor involving the cervix and adjacent normal tissues.[28,29] The use of MRI can lead to better delineation of the target volume, which could translate to dose escalation for better tumor control while simultaneously limiting dose to normal tissues. As MRI is not uniformly accessible, transabdominal ultrasound[30] or computed tomography (CT) scan[10] has been used as a clinically acceptable alternative to MRI.

The gynecologic working group formed by the Groupe European de Curietherapie and European Society for Therapeutic Radiology and Oncology (GEC-ESTRO) in 2000 formulated and described new terminology regarding three-dimensional (3D) image-based treatment planning in cervical cancer brachytherapy. Their recommendations are summarized in Table 28.3.[31] This working group recognized that in most patients, there is significant change of gross tumor during combined modality treatment. Because of this, a fluid description of treatment volumes during the course of treatment is required to have a better understanding of dose–volume relationships throughout treatment and to more accurately compare treatments between institutions and patients. They devised definitions of gross tumor volume (GTV) at diagnosis and at each brachytherapy procedure as well as high-risk and intermediate-risk clinical target volumes (CTV). Each of these volumes would be determined via clinical examination and MRI (preferably T2 weighted) at their respective times during

the course of treatment. The CTVs are based on tumor load and represent risk of recurrence. Thus “high risk” (HR-CTV) is that which includes macroscopic tumor, “intermediate risk” (IR-CTV) is that which includes significant microscopic disease, and “low risk” (LR-CTV) is that which includes potential microscopic tumor spread. It is assumed that the low-risk region is successfully treated with surgery and/or external beam radiotherapy. Their recommendations were expanded in 2006 to include descriptions of dose–volume parameters for organs at risk and a stepwise procedure for transition from the traditional dose prescription (i.e., point A) to the 3D image-based volume prescription.[32] The group recommended for organs at risk that the minimum dose in the most irradiated tissue volumes of 0.1, 1, and 2 cm^3 be reported. In 2010, they published recommendations pertaining to applicator reconstruction with 3D image-based treatment planning and in 2012 recommendations regarding parameters for MR imaging for adaptive cervical brachytherapy.[33,34]

TABLE 28.3 GEC-ESTRO IMAGE-BASED PLANNING VOLUME DEFINITIONS FOR CERVICAL CANCER

Volume		Description
GTV_D	GTV at diagnosis	Macroscopic tumor extension at diagnosis as detected by clinical examination and visualized on MRI
$GTV_{B1,B2,B3...}$	GTV at each BT procedure	Macroscopic tumor extension at time of brachytherapy as detected by clinical examination and as visualized on MRI
HR $CTV_{B1,B2,B3...}$	High-risk CTV at each BT procedure	Includes $GTV_{B1,B2...}$, the whole cervix and presumed extracervical tumor extension at time of brachytherapy by means of clinical examination and by MRI
IR $CTV_{B1,B2,B3...}$	Intermediate-risk CTV at each BT procedure	Encompasses high-risk CTV with a safety margin of 5 to 15 mm (safety margin is chosen according to tumor size and location, potential tumor spread, tumor regression, and treatment strategy). The IR CTV is never less than GTV_D

BT, brachytherapy; CTV, clinical target volume; GEC-ESTRO, Groupe European de Curietherapie and European Society for Therapeutic Radiology and Oncology; GTV, gross tumor volume; HR, high risk; IR, intermediate risk; MRI, magnetic resonance imaging.

As over the last several years there has been a transition from 2D to 3D planning, the Gynecology Oncology Group set out to establish a contouring atlas for both CT-based and MRI-based treatment planning. They compiled contours performed by 23 expert gynecologic radiation oncologists on both CT and MRI for three separate cases and have made available a contouring atlas at

http://www.nrgoncology.org/Resources/ContouringAtlases/GYNCervicalBrachyt

The recommended combined EBRT and HDR dose to at least 90% (D90) of the HR-CTV is an isoeffective dose of 80 to 90 Gy.[11,31,32] The lower dose range can be utilized for early-stage disease (defined as nonbulky stage I or II < 4 cm in diameter) and the higher dose range is used for advanced stage disease (defined as stage I or IIA >4 cm in diameter or stage IIIB). The total pelvic sidewall dose recommendations are 50 to 55 Gy for smaller lesions and 55 to 60 Gy for larger ones. The ratio of EBRT to brachytherapy is dependent on the stage, with a larger EBRT dose used for the more advanced stages. Most centers use a schedule of approximately 5 to 7 Gy per fraction in four to six fractions (a smaller number of fractions is used by those using larger doses per fraction).[23,27,36,37] Some institutions use 8 to 9 Gy per fraction for two or three fractions.[38–41] These higher doses per fraction should be used with caution by experienced users. The HDR dose is also dependent on the stage of the disease and the dose of pelvic EBRT. While recognizing that many efficacious HDR fractionation schedules exist, the ABS suggestions and the isoeffective doses are given in Table 28.2 as a guide. These doses, while representing the doses to the traditional point A, correspond to the new HR-CTV D90 doses.

The University of Vienna has extensive experience with image-based dosimetry for intracavitary brachytherapy for cervical cancer. Their evaluations endorsed by the ABS have resulted in suggestions to keep the total isoeffective D2cc dose to the rectum and sigmoid <75 Gy and the bladder to <90 Gy.[42,43] As an example, in a patient who has received 45 Gy of EBRT and is planned to undergo five intracavitary brachytherapy treatments, the fractional HDR D2cc dose to the rectum and bladder should be kept to approximately <4.2 and <5.5 Gy, respectively. These doses would need to be altered based on the total EBRT dose and number of planned intracavitary brachytherapy treatments.

In certain clinical situations (e.g., a narrow fibrotic vagina, bulky tumors, the inability to enter the cervical os, extension to the lateral parametria or pelvic sidewall, lower vaginal extension, and suboptimal applicator placement), the normal tissue tolerance may be exceeded if the above doses are used. In these situations, either repacking or reoptimization may be attempted. If this fails to reduce the normal tissue doses, the HDR fraction size can be decreased (which requires an increase in the fraction number), or the EBRT dose increased while decreasing the HDR total dose. At our centers, we prefer to use an interstitial implant in these situations. In the event of reduced vaginal capacity and if an interstitial technique is not available, Sharma et al.[44] have described an

intracavitary technique that utilizes a central tandem with a single ovoid alternating with the contralateral ovoid with subsequent insertions.

Results of 3D Image-Based Treatment Planning

Over the last several years, there has been accumulating clinical evidence supporting 3D image-guided adaptive brachytherapy (IGABT) for cervical cancer. The University of Vienna has reported their results of utilization of MRI-based adaptive brachytherapy in accordance with GEC-ESTRO guidelines over the past decade. An initial report published in 2007 demonstrated improvement in complete remission and overall survival for patients with tumors > 5 cm between two separate time periods (1998–2000 and 2001–2003) reflecting the treatment planning changes employed by GEC-ESTRO guidelines.[45] Furthermore, grade 3 and 4 gastrointestinal and genitourinary (GU) complications decreased between the two time periods.[45] Dimopoulos et al.[46] performed a further analysis of this initial group of patients and found that a HRCTV D90 > 87 Gy resulted in a significantly lower local recurrence rate compared to a D90 of <87 Gy. They published updated results in 2011 evaluating 156 consecutively treated patients from 2001 to 2008. Three-year local control was 100% for IB, 96% for IIB, and 86% for IIIB. Three-year overall survival was 74% for IB, 78% for IIB, and 45% for IIIB. In addition, grade 3 + 4 late morbidity was only 3% to 4% at 5 years.[47]

The University of Pittsburgh has shown similar results. They evaluated 128 patients from 2007 to 2013 utilizing either CT or MRI after each application. Each patient was required to have at least 1 MRI for treatment planning. With a median follow-up of 24.4 months, 2-year local control was 91.6% and 2-year cancer-specific survival was 87.6%. Grade 3 or higher late toxicity at 2 years was 0.9%.[48]

Researchers at Aarhus University and Leiden University have published their comparative results of IGABT versus conventional brachytherapy (CBT). Aarhus University evaluated 140 consecutive patients treated with IGABT (2005–2011) and compared them to a prior cohort of 99 patients treated with brachytherapy based on x-ray imaging (1994–2000). Three-year actuarial local control for the IGABT group was 91%. No information regarding local control for the x-ray-based cohort was available. They also demonstrated an improvement in 3-year overall survival of 16% from 63% to 79% between the x-ray-based cohort and the IGABT cohort. There was also simultaneously a reduction in late morbidity by 50%.[49] Leiden University analyzed 126 patients

of whom 43 were treated with CBT between 2000 and 2007. The remaining 83 patients were treated with image-guided brachytherapy (IGBT) between 2007 and 2012. The IGBT group demonstrated improvement in complete remission, pelvic control, overall survival, and late morbidity. Complete remission was significantly higher in the IGBT group achieving 98.8% compared to 83.7% in the CBT group. Three-year overall survival was also significantly improved from 51% in the CBT group to 86% in the IGBT group. Three-year pelvic recurrence rate was 32% in the CBT group and 7% in the IGBT group. Simultaneously, 3-year high-grade late morbidity improved from 15.4% in the CBT group down to 8.4% in the IGBT group.[50]

In 2008, GEC-ESTRO began a study on MRI-based brachytherapy for cervical cancer in a prospective multicenter setting called EMBRACE (European study on MRI-guided brachytherapy in locally advanced cervical cancer). The goal of the study was to evaluate outcomes and feasibility of GEC-ESTRO recommendations. In addition, the group started a retrospective collection of data from 12 centers treated with IGABT entitled retroEMBRACE. Results of retroEMBRACE have been recently published. With 731 patients treated, 5-year actuarial local control was 98% for stage IB, 91% for stage IIB, and 75% for stage IIIB. Five-year actuarial overall survival was 83% for stage IB, 70% for stage IIB, and 42% for stage IIIB. Late grade 3 to 5 toxicity at 5 years ranged from 5% to 7% involving the bladder, gastrointestinal tract, and vagina.[51] In their report, they suggest that overall IGBT improves pelvic control by approximately 10% compared to 2D-based imaging.[51] Analyses of 488 patients evaluating the effects of tumor dose, volume of disease, and overall treatment time on local control were also recently reported. HR-CTV D90 of ≥85 Gy administered within 7 weeks provides a 3-year local control rate of more than 94% for tumors measuring up to 20 cm^3. This drops to 93% for tumors up to 30 cm^3 and 86% for tumors measuring up to 70 cm^3. IR-CTV D98 of ≥ 60 Gy and residual GTV (Res-GTV) D98 of ≥95 Gy had a significant impact on local control. They also found that a dose of 5 Gy delivered to the HR-CTV is required to achieve similar local control when overall treatment time is increased by 1 week. Furthermore, an additional 5 Gy to the HR-CTV is required to achieve similar local control with an increase of tumor volume by 10 cm^3.[52] It should be noted that some of the patients included in the retroEMBRACE evaluation are those patients previously described above from the University of Vienna and Aarhus University.

The investigators of the EMBRACE study have recently published results

regarding late rectal morbidity, late vaginal morbidity, quality of life, and early dosimetric evaluations.[53–57] In regard to late rectal morbidity, Mazeron et al. revealed that of 960 patients evaluated with a median follow-up of 25.4 months, the grade 3 rate was 1.6% and the grade 4 rate was 0.1%. There was a 12.5% risk of fistula at 3 years with a D_{2cc} of ≥75 Gy. There was a two times lower risk of proctitis with a D_{2cc} of <65 Gy. In regard to late vaginal morbidity, Kirchheiner et al. revealed that of 630 patients evaluated with a median follow-up of 24 months, the 2-year actuarial estimate of grade 2 or higher vaginal stenosis was 21%. The rectovaginal reference point was a risk factor with 20% risk at 65 Gy, 27% risk at 75 Gy, and 34% risk at 85 Gy. Additional risk factors included external beam radiation dose above 45 Gy and tumor extension into the vagina.

The American Brachytherapy Task Group published their review of literature of the clinical outcomes for cervical cancer patients treated with HDR brachytherapy in 16 prospective studies from 2000 to 2015. Of the patients treated with chemotherapy and radiation with HDR brachytherapy, the pelvic control, disease-free survival, and overall survival were 82%, 65%, and 70%, respectively, with at least 24-month follow-up. For these patients, the late grade 3 GU toxicity and late grade 3 gastrointestinal toxicity ranged from 2% to 20% and 1% to 11%, respectively. When comparing patients treated with chemotherapy, radiation, and image-based brachytherapy versus those utilizing the traditional point A dose prescription, there was a clinically significant improvement in both pelvic control and disease-free survival for those patients treated with image-based brachytherapy. The mean improvement was 3%.[58]

Additional studies have compared 3D IGBT to previous cohorts treated with traditional 2D planning and have shown improvements in local control[59,60] and reductions in toxicity[60,61] with 3D planning. Appropriate concerns on the feasibility of MRI-based treatment planning for brachytherapy include the increased cost of obtaining serial MRIs during a course of treatment (on average at least four to six during a normal course of treatment) and the limited availability and high cost of MRI-compatible applicator instrumentation for brachytherapy procedures. Table 28.4 summarizes the HDR fractionation and results of the published retrospective literature utilizing traditional treatment planning. Table 28.5 summarizes the results of recent literature utilizing 3D image–based treatment planning with the GEC-ESTRO recommendations. Although direct comparisons are difficult, it does give some insight to the variety of brachytherapy fractionation schedules used for cervical cancer.

In summary, the available data from recent trials suggest that 3D, image-based HDR brachytherapy of cervical cancer achieves superior tumor control with reduced morbidity.

Carcinoma of the Endometrium

HDR brachytherapy is commonly used for adjuvant treatment of the vaginal cuff after hysterectomy in patients with an intermediate or high risk for vaginal recurrence (high-grade, deep myometrial invasion or advanced stage). Additionally, brachytherapy may be used for primary treatment in inoperable endometrial carcinoma and for treatment of recurrences after hysterectomy.

TABLE 28.4 SUMMARY OF RETROSPECTIVE ANALYSIS OF HGH DOSE RATE BRACHYTHERAPY IN THE TREATMENT OF CERVICAL CANCER

Vaginal Cuff Irradiation

The standard management for operable carcinoma of the endometrium is total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH-BSO). Patients at high risk for vaginal recurrences (deep myometrial invasion, high histologic grade and stage, lymphovascular invasion, cervical or extrauterine spread, squamous cell or papillary histology) should receive radiation therapy. Two previous published randomized trials, Post Operative Radiation Therapy in Endometrial Carcinoma (PORTEC-1)[66,67] and GOG-99,[68] demonstrated general benefit of postoperative pelvic radiation therapy compared to observation in regard to local control with early-stage endometrial carcinoma and intermediate- to high-risk features for recurrence. Neither trial demonstrated improvement in survival. Following these two studies PORTEC-2[69] was undertaken to better answer how best to deliver adjuvant radiotherapy. As the majority of the recurrences in PORTEC-1 as well as GOG-99 occurred at the vaginal cuff in the observation arms, PORTEC-2 compared whole pelvic radiation therapy to vaginal cuff brachytherapy. Eligible patients for PORTEC-2 included patients 60 years or older with inner half myometrial invasion and histologic grade 3, outer half myometrial invasion, and histologic grade 1 or 2. Those with cervical glandular involvement and grade 1 or 2 histology, or cervical glandular involvement and grade 3 histology, and <50% myometrial invasion of any age were also eligible. The results of PORTEC-2 were published in 2010 and demonstrated that vaginal cuff recurrence was equal (1.8% vs. 1.6% at 5 years) in both arms. Additionally, it demonstrated that there were less acute grade one and two gastrointestinal toxicities with vaginal cuff brachytherapy (12.6% vs. 53.8%). This has led to an increase in the utilization of vaginal cuff brachytherapy alone in patients with a high intermediate risk of recurrence. A randomized study by Sorbe et al. was published in 2012 evaluating whole pelvic radiation with vaginal cuff brachytherapy versus vaginal cuff brachytherapy alone for patients with “medium-risk” endometrial cancer. “Medium-risk” was defined as FIGO stage I endometrioid histology grade 3 disease or grade 1 or 2 with ≥50% myometrial invasion or DNA aneuploidy. Five-year locoregionial relapse with combined treatment was 1.5% versus 5% with brachytherapy alone, which was statistically significant. Overall survival between the two groups was equivalent. There was a significant difference in late side effects between the two groups favoring brachytherapy alone.[70] There still remains some controversy as to which patients fall into the high intermediate-risk group or medium-risk group as the four mentioned studies had subtle differences in patient eligibility. Thus, clinical judgment is needed when evaluating patients

potentially eligible for vaginal cuff brachytherapy alone. The ABS released updated guidelines for vaginal brachytherapy in 2012, much of which is discussed below.[9] In addition, ASTRO with endorsement by the Society of Gynecological Oncologists published an executive summary in 2014 with regard to use of postoperative radiation for endometrial cancer with similar recommendations to the ABS as it pertains to vaginal brachytherapy.[71]

The American Brachytherapy Task Group published their review of the literature utilizing vaginal brachytherapy in various risk groups for overall early-stage endometrial cancer. Overall vaginal recurrence with the use of vaginal brachytherapy was 0% to 3.1%. In slightly higher-risk patients requiring whole pelvic radiation, the addition of vaginal brachytherapy has resulted in a vaginal recurrence rate ranging from 0% to 2.7%. Additional studies are needed though to better define when to use vaginal brachytherapy in addition to whole pelvic radiation. Although there are limited data regarding the use of vaginal brachytherapy in combination with chemotherapy and for treatment of high-risk histologies, in general, the vaginal recurrence rate is low. In regard to toxicity, their review of the literature revealed that the most common toxicity is vaginal atrophy/stenosis with a range of 0% to 5.2% for all severe toxicities.[72]

Technique

A vaginal cylinder is commonly used to deliver HDR brachytherapy. The largest diameter cylinder that comfortably fits the vagina should be used to increase the depth dose. The length of vaginal vault treated varies. Some treat the superior 3 or 5 cm, whereas others treat the superior half or two-thirds of the vagina.[9,69,73–75] For serous and clear cell histologies, treatment of the entire vaginal canal should be considered. The use of a single-line iridium 192 (^{192}Ir) source creates a dose inhomogeneity at the vaginal apex due to source anisotropy. However, the clinical significance of source anisotropy is debatable. The use of ovoids, circular rings, or an angled source may reduce the dose inhomogeneity at the apex created by the ^{192}Ir source anisotropy.[9] The applicator should be placed in the midline, as horizontal as possible and parallel to the longitudinal axis of the body for appropriate dose distribution. Placement of a radiopaque seed or clip at the vaginal apex helps to verify that the applicator is in contact with the vaginal apex on fluoroscopy or radiographs. However, these clips or seeds can sometimes fall off or migrate deep to the mucosa and, therefore, may not always indicate the position of the apex. Some centers prefer to use an EID to minimize movement; however, this is not mandatory. The use of

a multichannel vaginal applicator such as the Miami applicator or the inflatable Capri balloon applicator may allow the radiation oncologist to better sculpt the desired radiation dose distribution in 3D for the individual patient compared to a single-channel device.[76]

The dose distribution should be optimized to deliver the prescribed dose either at the vaginal surface or at 0.5 cm depth, depending on the institutional policy. It is important to place dose optimization points not only along the lateral aspect of the vaginal wall but also at specified points about the dome of the vaginal cylinder to avoid higher vaginal apex doses, which can lead to vaginal vault necrosis.[2] Regardless of the prescription method, doses to both the vaginal surface and at 0.5 cm depth should be reported.[9]

The dose per fraction used has varied from 4 to 7 Gy, and the number of fractions has varied from three to six with the interval between fractions ranging from 24 to 72 hours up to 1 to 2 weeks.[73,75,77–79] The lower doses per fraction are usually given either using a larger number of fractions or in combination with EBRT to the pelvis. Sorbe et al.[80] evaluated two fractionation schemes (2.5 Gy × 6 vs. 5 Gy × 6) in a randomized trial and found no difference in locoregional recurrence rates but an increase in vaginal shortening, mucosal atrophy, and bleeding in the 5 Gy per fraction arm. The ABS dose suggestions[81] for HDR alone or in combination with 45 Gy EBRT is given in Table 28.6. Because some institutions specify the dose to the vaginal surface and others specify the dose at 0.5-cm depth, suggested HDR doses have been given for both specification methods.

From retrospective analysis, the 5-year survival rates of HDR therapy vary from 72% to 97%, depending on the stage, grade, and depth of myometrial invasion.[73,75,77,82,83] The severe (grade III or IV) late complication rate is usually <2% and depends on the dose per fraction.[74,75,77,84,85]

Petereit and Peracey[37] published a literature review analyzing 1,800 cases of postoperative HDR brachytherapy alone in patients with low- to intermediate-risk endometrial cancer. They found an overall vaginal control rate of 99.3%. Late morbidity was significantly higher with isoeffective doses for late responding tissues exceeding 100 Gy. Patient education regarding the use of frequent vaginal dilation following HDR brachytherapy is important to minimize vaginal stenosis and sexual dysfunction.[86,87] The National Forum of Gynecological Oncology Nurses (NFGON) has published best practice guidelines for the use of vaginal dilators following radiation therapy treatments.[88]

Treatment of Recurrences at the Vaginal Cuff

A combination of pelvic EBRT and brachytherapy is generally used to treat recurrences at the vaginal cuff. With distal vaginal recurrences, the entire vagina and medial inguinal nodes are included in the EBRT field. Intracavitary vaginal brachytherapy should be used only for nonbulky recurrences (thickness < 5 mm after the completion of EBRT).[81] Interstitial brachytherapy is to be used for bulky recurrences (thickness > 5 mm after the completion of EBRT) and for previously irradiated patients.[15] Apical recurrences are often more extensive superiorly than can be judged on physical examination, thus favoring the use of interstitial brachytherapy. These patients are best treated at centers with considerable experience in interstitial brachytherapy. Radiopaque marker seeds or surgical clips should be placed at the margins of gross disease to delineate disease extent. If the relapse is limited to one wall of the vagina, consideration should be given to limiting the dose to the opposite wall. The ABS-suggested doses for HDR brachytherapy (in combination with 45 Gy EBRT) are provided in Table 28.7.[81]

TABLE 28.6 AMERICAN BRACHYTHERAPY SOCIETY SUGGESTED DOSES OF HIGH DOSE RATE BRACHYTHERAPY ALONE OR IN COMBINATION WITH PELVIC EXTERNAL BEAM RADIATION THERAPY TO BE USED FOR ADJUVANT TREATMENT OF POSTOPERATIVE ENDOMETRIAL CANCER

EBRT (Gy) at 1.8 Gy/Fraction	No. of HDR Fractions	HDR per Fraction (Gy)	Dose Specification Point

45	2	8.0	Vaginal surface
45	3	6.0	Vaginal surface

EBRT, external beam radiation therapy; HDR, high dose rate.

Inoperable Endometrial Carcinoma

Patients with adenocarcinoma of the endometrium who are not candidates for

surgery because of severe medical problems are treated with radiation therapy. A combination of pelvic EBRT and brachytherapy is preferred whenever possible. However, many of the conditions that do not allow surgery in these cases are also relative contraindications for EBRT and for LDR brachytherapy. In such cases, these patients may be treated with HDR alone.

The ABS released a consensus statement in 2015 with recommendations of treatment for medically inoperable endometrial cancer.[89] Numerous applicators can be used for treatment of primary endometrial cancer. The tandem and ovoid applicator, although often used, does not irradiate the uterine fundus homogeneously. Others have therefore used a curved tandem, turning it to the left and right in alternate insertions. A Y-shaped applicator irradiates the fundus more evenly. Other possibilities include modified Heyman capsules or multiple tandems. If CT or MRI is not available for treatment planning, then the dose is commonly specified at 2 cm from the source. However, the ABS recommends the use of CT- or MRI-based treatment planning with the latter the most preferable to ensure a more homogeneous dose to the entire myometrium. A volume-based approach is recommended with contouring the GTV as seen on T2-MRI sequences, CTV to include the entire uterus, cervix and upper 1 to 2 cm of vagina, and organs at risk. With respect to certain clinical situations, the ABS states that brachytherapy alone can be used for patients with stage I grade 1 or 2 endometrial cancer with minimal myometrial invasion as seen on MRI. In those same patients but with deep myometrial invasion, a combination of external beam radiation and brachytherapy is recommended. When MRI is not available or in patients with stage II or III disease, a combination of external beam radiation and brachytherapy is also recommended. The dose per fraction has ranged from 5 to 8.5 Gy, and three to six fractions are commonly employed.[90–93] The dose and/or the dose per fraction is reduced if EBRT is added. The ABS suggested doses for HDR brachytherapy alone or in combination with 45 or 50.4 Gy EBRT are given in Table 28.8.[89] The survival at 5 years for stage I disease is variable; however, some reports have revealed rates as high as 80%, which is slightly lower than that obtained by surgery.[92] Coon et al.[94] reported a 3-year overall survival of 83% for patients treated with 35 Gy HDR (treated twice a day) in five fractions without EBRT or with 20 Gy HDR in five fractions along with EBRT between 1997 and 2007. Some of these patients had higher stage disease. A later cohort treated at the same institution between 2007 and 2013 utilizing 3D image-based conformal treatment resulted in a 2-year overall survival of 94.4%.[95]

TABLE 28.7 AMERICAN BRACHYTHERAPY SOCIETY SUGGESTED DOSES OF HIGH DOSE RATE BRACHYTHERAPY TO BE USED IN COMBINATION WITH PELVIC EXTERNAL BEAM RADIATION THERAPY FOR TREATING VAGINAL CUFF RECURRENCES FROM ENDOMETRIAL CANCER

EBRT (Gy) at 1.8 Gy/Fraction	No. of HDR Fractions	HDR per Fraction (Gy)	Dose Specification

Carcinoma of the Prostate

Permanent implantation of iodine 125 (^{125}I) or palladium 103 (^{103}Pd) seeds has been the most common type of prostate brachytherapy. However, in recent years, HDR brachytherapy as a boost to EBRT has established itself as a way for escalating dose to the prostate. Several institutions have published their results

including one randomized study supporting the use of prostate HDR brachytherapy.[96–111] Table 28.9 lists these various studies. Different fractionation schemes have been used as seen in Table 28.9. In the one randomized study published to date with a median follow-up of 85 months, HDR brachytherapy boost significantly improved biochemical relapse-free survival compared to external beam radiation alone. The median time to relapse with an HDR boost was 116 months as compared to 74 months with EBRT alone.[112] One of the major advantages of HDR is that the dose distribution can be intraoperatively optimized by varying the dwell times at various dwell positions, potentially allowing reliable and reproducible delivery of the prescribed dose to the target volume while keeping the doses to normal structures (i.e., rectum, bladder, and urethra), within acceptable limits.[16,109] Another potential advantage of HDR brachytherapy in prostate cancer is the theoretical consideration that prostate cancer cells behave more like late-reacting tissue with a low α/β ratio and they should, therefore, respond more favorably to higher dose fractions rather than to the lower dose rate delivered in LDR brachytherapy.[114,115]

Patients with stages T1b to T3b prostate cancers without evidence of distant metastases are candidates for HDR brachytherapy as a boost to EBRT. Patients with distant metastases or a life expectancy of <5 years, or those who are medically unfit for anesthesia or in whom it is technically not feasible to implant the entire prostate should be excluded. Relative contraindications include large gland size (>60 cm^3), significant urinary obstructive symptoms, recent transurethral resection of the prostate (TURP) within the last 6 months, large TURP defects, infiltration of the external sphincter of the bladder neck, pubic arch interference, and a rectum–prostate distance on transrectal ultrasound of <5 mm.[16,109] These patients have, however, been implanted by experienced brachytherapists by using modified techniques. Absolute contraindications to HDR brachytherapy include a preexisting rectal fistula.[16]

EBRT, external beam radiation therapy; HDR, high dose rate.

Various implant techniques and treatment planning methods have been used. As in permanent seed implantation, the procedure is performed under general or spinal anesthesia. Transrectal ultrasound is utilized for catheter placement, and cystoscopy may be performed to exclude the urethra and bladder. At some institutions, real-time transrectal ultrasound-guided treatment planning is performed. Other institutions use CT-based treatment planning. Fiducial markers are placed in the prostate so that radiographic comparison of the markers to catheter location can be confirmed prior to each delivery of each treatment.[116] Typically, 15 to 17 catheters are placed (although some institutions have used fewer) with fraction doses ranging from 3 to 15 Gy prescribed to the prostate (CTV 1—clinical target volume) depending on the clinical situation. Additionally, it is recommended to identify the peripheral zone (CTV 2) and any areas of macroscopic tumor (CTV 3) so that these areas can preferentially receive a higher fractional dose by dose painting. As in permanent seed implantation, the D90, D100, V100, V150, and V200 should be reported. Simultaneously, the organs at risk should be contoured and the D2cc of the rectum and bladder and D0.1cc of the urethra should be reported.[109] The interested reader should review the GEC-ESTRO and ABS guidelines for more specific information.[16,109]

[b]Interpreted from table.
bNED, biologically without evidence of recurrence; GU/GI, genitourinary/gastrointestinal; HDR, high dose rate; NS, not stated.

Standard fractionation EBRT of 39.6 to 50.4 Gy or hypofractionated EBRT of 40 Gy in 16 fractions is given before, concurrently with, or after HDR brachytherapy. The minimum volume treated should include the entire prostate and seminal vesicles with a margin, with or without pelvic lymph nodes. The HDR dose is given in multiple fractions in one or two implant procedures. A variety of dose and fractionation schemes may be appropriate for same-stage disease as shown in Table 28.10.[96,98,99,101,102] The HDR fractions are generally given twice a day with a minimum of 6 hours between fractions. The most commonly encountered acute GU morbidities include urinary irritative symptoms, hematuria, hematospermia, and/or urinary retention, similar to LDR permanent implants.

HDR brachytherapy has also been used as monotherapy in a few centers, with dose fractionation ranging from 9.5 Gy × 4, 11.5 Gy × 3, 13.5 Gy × 2, and 19 Gy in a single fraction (Table 28.11).[117,118,120–122] The largest series to date is from Germany with 798 patients treated with either four fractions of 9.5 Gy each or three fractions of 11.5 Gy each. With a median follow-up of 52.8 months, the biochemical control at 60 months for low-risk patients, intermediate-risk

patients, and high-risk patients was 95%, 93%, and 93%, respectively.[121] Late grade 3 GU and gastrointestinal toxicity was 3.5% and 1.6%, respectively. These results compare favorably to traditional permanent seed implant.[123]

Treatment of recurrent prostate cancer as well as treatment of de novo prostate cancer in patients who have previously received pelvic radiation is challenging. HDR brachytherapy has been used as salvage therapy postprostatectomy, post-EBRT, as well as post permanent seed implant.[124–130] Overall patient numbers are low, so firm conclusions of its effectiveness are difficult; however, it does appear feasible in various clinical situations. Wojcieszek et al.[128] have reported their results of 83 patients utilizing HDR brachytherapy as salvage treatment for local recurrence following previous radiation therapy. Patients received three implants each delivering 10 Gy over a 4-week period. With a median follow-up of 41 months, 5-year overall survival was 86%. Late grade 3 GU toxicity was 13%, and there was no late grade 3 gastrointestinal toxicity. Yamada et al.[129] performed a phase II study evaluating salvage HDR monotherapy for patients with biopsy-proven recurrence following previous EBRT. Forty-two patients were enrolled and received a total dose of 3,200 cGy delivered over four fractions in a single implant. With a median follow-up of 36 months, the 5-year prostate-specific antigen biochemical relapse-free survival was 68.5%. One patient developed late grade 3 GU toxicity, and no patients developed late grade 3 gastrointestinal toxicity.

In a subset of men with localized focal prostate cancer, traditional definitive treatment with surgery and/or radiation may not be warranted. However, for some of these men, active surveillance is also not a desirable option. For these patients, the concept of focal therapy (destruction of the cancer with preservation of the surrounding organ) has emerged for prostate cancer just as it has been used in other disease sites. Improved imaging has allowed better localization of prostate cancer foci and thus the potential ability to better target these foci with localized treatment. Current modalities being investigated for focal therapy in prostate cancer include cryotherapy, high-intensity focused ultrasound, brachytherapy (both LDR and HDR), radiofrequency ablation, and photodynamic therapy (PDT).

HDR brachytherapy as a boost to EBRT for localized prostate cancer is being used more commonly, and its role has been well defined. Its use as monotherapy is increasing, and the early results are promising. Further studies are needed to more clearly define the role of HDR brachytherapy for recurrent disease after radical prostatectomy, previous EBRT, or permanent seed implant.

Breast

EBRT is the standard radiation modality used after lumpectomy in the conservative management of breast cancer. Over the past two decades, there has been an increase in use of brachytherapy as the sole modality of treatment[131–135] to decrease the 6-week treatment duration required for a course of EBRT to about 5 days. Table 28.12 lists the patients in whom an accelerated (4 to 5 days) brachytherapy treatment course can be an attractive alternative to 6 weeks of EBRT.[14] The ABS recommends a total dose of 34 Gy in 10 fractions to the CTV (lumpectomy site with 1 to 2 cm margin) when HDR brachytherapy is used as the sole modality.[136] The HDR treatments of 3.4 Gy are generally given at two fractions per day separated by at least 6 hours. This was also the dose used in a phase II RTOG trial[131] as well as in the phase III National Surgical Adjuvant Breast and Bowel Project (NSABP) B-39 Trial. Other prescriptive dosimetric parameters to be met recommended by the ABS include the following: (a) ≥90% of the CTV should receive ≥90% of the dose; (b) V_{150} and V_{200} should be <50 and <10 cm^3, respectively, for balloon catheters; and (c) maximum skin isodose should be <145% for balloon catheters.[136] Some investigators have evaluated ultrashort courses of accelerated partial breast irradiation. A fractionation scheme of 2,800 cGy delivered over four fractions in 2 days has been reported with acceptable toxicity rates.[137,138] Khan and colleagues[139] are planning a trial to evaluate a total dose of 2,250 cGy over three fractions in 2 to 3 days. Caution should be exercised with these ultrashort courses of accelerated partial breast irradiation until mature data are available.

The results of HDR brachytherapy as the sole modality are included in Table 28.13.[131–135,140–143,145–149] Depending on the selection criteria, final pathologic assessment is necessary to completely evaluate a patient for partial breast brachytherapy, and, therefore, the ABS does not advocate intraoperative treatment delivery at this time.[158] There are a variety of ways to deliver HDR brachytherapy including an interstitial multicatheter implant, a single lumen incracavitary balloon, a multilumen intracavitary balloon, struts, and an electronic balloon. The use of a variety of commercially available balloon applicators has simplified the brachytherapy procedure. To date, two randomized trials have published their results of partial breast irradiation utilizing HDR brachytherapy versus whole-breast irradiation. GEC-ESTRO conducted a noninferiority trial and randomized patients to whole-breast irradiation versus partial breast irradiation utilizing multicatheter interstitial brachytherapy.[144] The 5-year risk of ipsilateral breast recurrence was equal in both arms with <2%. In a

separate publication from the same trial, early side effects and patient compliance of 1,328 patients treated were reported.[159] Overall grade 3 early toxicity for all patients was limited to radiation dermatitis with a rate of 7% for whole-breast irradiation and 0.2% for partial breast irradiation. Polgar et al. reported their 10-year results of 258 patients treated on the Budapest randomized trial. A multicatheter interstitial implant was used for HDR brachytherapy. The 10-year rate of local recurrence was 5.9% for partial breast irradiation and 5.1% for whole-breast irradiation (P = .77). There was no difference in overall survival or cancer-specific survival or disease-free survival. An excellent or good cosmetic result was achieved in 81% of patients with partial breast irradiation versus 63% in patients treated with whole-breast irradiation (P < .01).[135]

TABLE 28.12 AMERICAN BRACHYTHERAPY SOCIETY ACCEPTABLE CRITERIA FOR ACCELERATED PARTIAL BREAST IRRADIATION

Indications for Brachytherapy as the Sole Modality	Indications for Brachytherapy as a Boost to EBRT
1. Age ≥ 50 years old 2. Size ≤ 3 cm 3. Histology: all invasive subtypes and DCIS 4. Estrogen receptor: positive or negative 5. Surgical margins negative 6. Lymphovascular space invasion negative 7. Nodal status negative	1. For patients with close, positive, or unknown margins 2. For patients with EIC 3. For younger patients 4. For deep tumor location in a large breast 5. For CTV of irregular thickness

CTV, clinical target volume; EBRT, external beam radiation therapy; EIC, extensive intraductal component.

In March 2005, the RTOG, in conjunction with the NSABP, opened a phase III randomized study (NSABP B-39) investigating standard whole-breast radiotherapy versus partial breast radiotherapy after lumpectomy for women with early-stage breast cancer. The partial breast treatment arm consists of three therapeutic options which are IMRT, HDR brachytherapy via MammoSite, Contura, or SAVI, and HDR brachytherapy via a multicatheter interstitial implant. The required dose for the brachytherapy treatment is 34 Gy given in 10 fractions over 5 days. The trial closed in April 2013 upon reaching its adjusted target accrual of 4,215 patients. It is hoped that over time, these large randomized studies will shed some light on the usefulness of partial breast irradiation and brachytherapy as a sole modality of treatment.

Various medical societies have published consensus statement guidelines for the selection of appropriate patients for breast brachytherapy as a sole modality treatment with slight variations.[14,160] According to the American Society of Therapeutic Radiology and Oncology (ASTRO) consensus statement, “Suitable” patients for accelerated partial breast irradiation include women 50 years of age and older, with unifocal tumors 2 cm in size or less, negative margins by at least 2 mm, and invasive ductal histology. The “Suitable” category also now includes patients with ductal carcinoma *in situ* who meet the following additional criteria: screening detected, low to intermediate nuclear grade, size ≤2.5 cm, and negative margins by at least 3 mm. The consensus statement also outlined criteria for “Cautionary” and “Unsuitable” candidates. The reader is encouraged to review the consensus statement for full details.[160] Thus far local control and cosmesis are similar to whole-breast EBRT with one group quoting 12-year follow-up.[132] However, further follow-up of clinical studies are required to define the most appropriate candidates for breast brachytherapy as a sole modality treatment and to determine the best delivery method of brachytherapy (multicatheter interstitial implant vs. balloon brachytherapy) in such patients.

A newer device, the Axxent (Xoft Inc., Sunnyvale, CA), uses a miniaturized x-ray source to deliver low-energy x-rays within a needle or catheter thereby mimicking HDR brachytherapy. The reduced radiation protection required for these devices because of limited penetration is a great advantage because it allows brachytherapy to be delivered in a nonshielded procedure room or a regular (unshielded) hospital operating suite. Although longer follow-up is needed to assess the risk of recurrence, early results with the use of this device for accelerated partial breast irradiation reveal that the procedure is tolerated well and grade 3 adverse events are minimal with 93.4% excellent or good cosmetic result at 1 year in one study evaluating 69 patients.[161–163]

[d]Includes 36 patients only.
EBRT, external beam radiation therapy; HDR, high dose rate; LDR, low dose rate; PDR, pulsed dose rate.

Brachytherapy has been used to boost the EBRT dose in select high-risk patients.[3,4] Data on the use of HDR as a boost are limited (see Table 28.13).[5,6,150–157] Polgar et al.[5] reported the results of a randomized trial involving 207 women with stage I or II breast cancer treated with breast-conserving surgery and whole-breast radiotherapy and subsequently randomized to either no further therapy or radiation boost to the tumor bed. The radiation boost consisted of either 16 Gy of electron irradiation or 12 to 14.5 Gy fractionated HDR brachytherapy. Fifty-two patients were treated with HDR brachytherapy, and the 5-year local tumor control rate was 91.4%. Excellent to good cosmesis was reported in 88.5% of patients. Similar results were noted in the group of patients receiving an electron irradiation boost. Because brachytherapy is an invasive procedure, it should be used selectively as a boosting technique. Situations in which brachytherapy may be advantageous as a boost are listed in Table 28.12. The brachytherapy boost can be given before or after EBRT, usually with a 1- to 2-week gap between EBRT and brachytherapy. The ABS recommends a dose-fractionation scheme that yields early and late effects approximately equivalent to those of 10 to 20 Gy LDR following 45 to 50 Gy EBRT.[164] Biomathematical models are often used to estimate equivalent HDR regimens.[18,19] For example, an HDR regimen of five fractions of 310 cGy per fraction should approximate the early and late effects of 20 Gy LDR delivered at 0.5 Gy/h. Although biomathematical models can be used to estimate the appropriate dose, there is no standardized HDR fractionation schedule that can be recommended for the use of HDR as a boost. Controlled clinical studies are required to further define the most appropriate doses to be used for boost treatment.

Use of interstitial HDR brachytherapy as neoadjuvant treatment in select

patients not amenable to breast-conserving surgery at presentation has been reported by Roddiger et al.[165] Fifty-three patients who were unable to undergo breast-conserving surgery because of either initial tumor size or an unfavorable breast–tumor ratio were treated with systemic chemotherapy and HDR brachytherapy with 5 Gy twice per day for 3 days (total dose 30 Gy). Of these patients, 56.6% went on to receive breast-conserving surgery, and with a median follow-up of 56 months, the local recurrence rate was 2%. Further studies are needed to fully define the roll of interstitial HDR brachytherapy as neoadjuvant treatment, but these results are encouraging.

Another clinical situation in which HDR brachytherapy has been evaluated is in the setting of salvage therapy to continue maintaining the breast in previously irradiated patients.[7,166] Current standard of care of recurrent disease following breast conservation is total mastectomy. Guix et al. reported their series of 36 patients who had previously been treated with lumpectomy, external beam radiation, and HDR brachytherapy boost who subsequently developed an ipsilateral breast recurrence and underwent excision only of the recurrence. Following excision, all patients underwent a HDR brachytherapy implant delivering 30 Gy in 12 fractions over 5 days. With a median follow-up of 89 months, 10-year local control was 89.4% and 10-year disease-free survival was 64.4%. They reported a 90.4% satisfactory cosmetic result.[166] GEC-ESTRO conducted a retrospective study and reported their results of 217 patients treated with multicatheter brachytherapy (low dose rate, pulsed dose rate, or high dose rate) following second conservative management for a local recurrence. Ten-year actuarial local recurrence rate was 7.2%.[7] Again although numbers are small, the possibility of continuing to provide breast conservation in the setting of recurrent disease is encouraging.

Endobronchial Radiation

The use of HDR brachytherapy is well established for palliation of cough, dyspnea, pain, and hemoptysis in patients with advanced or metastatic lung cancer. The use of brachytherapy as a boost to EBRT in curative cases should be restricted to a select group of patients who have predominantly endobronchial disease, are medically inoperable, or have small/occult carcinomas of the lung.

An initial bronchoscopy is performed to evaluate the airway and locate the site of obstruction. The updated ABS guidelines in 2016 further recommend CT imaging to evaluate for any potential extent of tumor beyond the bronchus as brachytherapy as an adjunct to external radiation would be preferable in such

cases.[13] Either a 5- or 6-French (Fr) catheter (inserted through the brush channel of the bronchoscope) can be used to deliver the brachytherapy. Use of a 6-Fr catheter allows the HDR source to negotiate tight curves, which is not possible with the 5-Fr catheter. If a 6-Fr catheter is used, a large bronchoscope (with brush channel diameter of at least 2.2 mm) is required. The bronchoscope can be connected to a teaching head or a video monitor so that the radiation oncologist can also visualize the lesion and the catheter. It is extremely important to note the distances between the proximal extent of the tumor and fixed structures such as the carina. The catheter is inserted through the brush channel of the bronchoscope, passed through the tumor, and lodged in one of the smaller bronchi. Fluoroscopic confirmation of the catheter's position is desirable. The radiation oncologist then pushes the afterloading catheter in while the pulmonologist slowly withdraws the bronchoscope. The use of fluoroscopy assists in keeping the catheter in place during this push–pull technique of bronchoscope removal. The catheter is then secured with tape at the nose, and its position is marked in ink to alert the radiation oncologist in case of displacement. As an additional precautionary measure, the external length of the catheter from the tip of the nostril is noted. If multiple catheters are to be used, the procedure is repeated, taking care to clearly label each catheter. The ABS recommends obtaining CT imaging to identify applicator location and subsequently treating the patient in the same position in which the CT was obtained. If multiple insertions are planned, then CT imaging should be obtained at each insertion. Utilization of CT for planning purposes may lead to decreased complications with better visualization of organs at risk.[167,168]

With the use of CT-based planning, the dose should be prescribed to a target volume keeping in mind dose to organs at risk. A fixed prescription point from the source is no longer recommended unless the clinical situation deems it appropriate and safe. When reporting dose, one should record the dose to the target volume, organs at risk, as well as at 1 cm from the center of the catheter.[13] Caution should be exercised when metallic stents are present as dose to the mucosa can be significantly increased from the stent surface.[169]

Palliative Endobronchial Brachytherapy

Candidates for palliative endobronchial brachytherapy include the following[13]:

- Patients with a significant endobronchial tumor component that causes symptoms such as shortness of breath, hemoptysis, persistent cough, and other signs of postobstructive pneumonitis. Tumors with a predominantly

endobronchial component are considered suitable, as opposed to extrinsic tumors that compress the bronchus or the trachea. Endobronchial brachytherapy can generally give quicker palliation of obstruction than EBRT. Furthermore, brachytherapy can be more convenient than 2 to 3 weeks of daily EBRT.

- Patients who are unable to tolerate any EBRT because of poor lung function.
- Patients with previous EBRT of sufficient total dose to preclude further EBRT.

A variety of doses have been successfully used by various centers. Retrospective reviews and randomized studies have found no difference in efficacy or survival with different fractionation regimens.[8,170–172] Table 28.14 lists the ABS recommended dose-fractionation schemes for endobronchial brachytherapy. These fractionation regimens have similar radiobiologic equivalence using the linear-quadratic model,[19] and there is no evidence of superiority for one regimen over the other. The benefits of fewer bronchoscopic applications should be weighed against the risks of higher dose per fraction. The interval between fractions is generally 1 to 2 weeks. If HDR is planned following palliative EBRT, then a reduced fractionation scheme is recommended. The brachytherapy dose should also be reduced when aggressive chemotherapy is given. Concomitant chemotherapy should be avoided during brachytherapy, unless it is in the context of a clinical trial.

The results from various centers (summarized in Table 28.15) show clinical improvement from 55% to 100% and bronchoscopy response from 57% to 100%.[170,171,174–183] Comparison of these results is difficult because of the differences in patient population and the variability in dose and fractionation employed. Complications of endobronchial brachytherapy include radiation bronchitis, stenosis, and fatal hemoptysis. Risk factors that increase complications include hypertension, chronic cardiac arrhythmias, chronic obstructive pulmonary disease (COPD), and cardiomyopathy.[184] Direct contact of the applicator to the tracheobronchial wall increases the risk of massive hemoptysis.[167]

Curative Endobronchial Brachytherapy

The standard, definitive therapy for unresectable lung cancer is a combination of chemotherapy and EBRT. Select patients (i.e., those with predominantly endobronchial tumor) may benefit from endobronchial brachytherapy, either alone or as a boost to EBRT.

The ideal patients for curative endobronchial radiation alone are those with occult carcinomas of the lung confined to the bronchus or trachea. Additionally, these patients tend to have early-stage disease and are medically inoperable because of decreased pulmonary function, advanced age, or refusal of surgery. Results of a few reported series are encouraging.[185–188] See Table 28.16. The largest series to date with 226 patients reported an 81% survival rate at 2 years utilizing four to six fractions of 5 to 7 Gy each.[188] Late complications did include a 5% fatal hemoptysis rate.

Endobronchial brachytherapy can be used in combination with EBRT for selected patients with inoperable non–small-cell lung carcinoma. In cases of postobstructive pneumonia or lung collapse, brachytherapy can be used to open the bronchus and aerate the lung such that the tumor volume is better defined. This allows some sparing of normal lung from the EBRT field. Muto et al.[189] performed a nonrandomized prospective study evaluating three endobronchial brachytherapy schemes concomitantly with EBRT on 320 patients with advanced inoperable non–small-cell lung cancer. Endobronchial brachytherapy consisted of either 10 Gy in one fraction, 14 Gy in two fractions, or 15 Gy in three fractions. Median survival for all patients was 11.1 months with a symptomatic response rate ranging from 82% to 94%. Complications were the least in the group of patients receiving 15 Gy in three fractions.

A Cochrane meta-analysis published in 2012 reviewing 14 randomized studies utilizing endobronchial brachytherapy in a variety of ways found no improvement in disease-free survival or overall survival when endobronchial brachytherapy was added to EBRT.[190] Based on this, the Cochrane review does not recommend endobronchial brachytherapy for routine use of radical treatment of lung cancer. When it is used, the ABS suggests an HDR dose of 10 to 15 Gy in two to three fractions as a boost to EBRT (either 60 Gy in 30 fractions or 45 Gy in 15 fractions).[13]

Brachytherapy Combined With Other Modalities

HDR brachytherapy in combination with either sublobar resection, metallic stent placement, PDT, or Yttrium-aluminum-garnet (YAG) laser has been described. McKenna et al.[191] reported their series of 48 patients who had poor pulmonary function not amenable to lobectomy who underwent wedge resection, lymph node dissection, and brachytherapy. Brachytherapy consisted of seven fractions of 350 cGy each prescribed to a depth of 1 cm delivered twice daily. Four recurrences were recorded with follow-up ranging from 1 to 27 months. Allison and colleagues[192] noted a significant improvement in Karnofsky performance status and pulmonary palliation with the use of a metallic stent placed in the endobronchial lumen followed by HDR brachytherapy of three 6 Gy fractions prescribed to a depth of 0.5 cm over a 2-week period. Finally, the use of HDR brachytherapy in combination with PDT or YAG laser has been described. Freitag et al.,[193] reported their results of 32 patients with bulky endobronchial non–small cell lung cancer treated initially with PDT followed 6 weeks later with five fractions (one per week) of 4 Gy each prescribed at a distance of 1 cm. Eighty-one percent of patients were free of endobronchial tumor at a mean follow-up of 24 months. Chella et al.[194] performed a small randomized trial comparing YAG laser alone versus YAG laser plus HDR brachytherapy in 29 patients. HDR brachytherapy consisted of three fractions (one per week) of 5 Gy each prescribed at a distance of 0.5 cm. Combination therapy resulted in a statistical improvement in period free from symptoms from 2.8 to 8.5 months. Disease progression-free period improved from 2.2 to 7.5 months as well.

Cancer of the Esophagus

Nonoperable definitive treatment of esophageal cancer has evolved over the last two decades to now frequently include concurrent EBRT and chemotherapy. HDR brachytherapy for palliative purposes has been evaluated in a few randomized trials and is well established, but its role in conjunction with concurrent EBRT and chemotherapy is less defined. HDR brachytherapy can be used either alone or in combination with EBRT.[195–202]

Brachytherapy is relatively simple to perform, because a single catheter is used for the treatment. A nasogastric tube or a specially designed esophageal applicator is used to deliver the treatments. The largest diameter applicator that can be inserted easily (either intraorally or intranasally) should be used to minimize the mucosal dose relative to the dose at depth. The site to be irradiated, which includes the tumor and a distal and proximal margin of 2 to 5 cm, can be confirmed by fluoroscopy or endoscopy. The ABS recommends an HDR dose of 10 Gy in two fractions, prescribed at 1 cm from the source, to boost 50 Gy EBRT.[195] HDR brachytherapy can be given before, concurrently with, or after EBRT. The advantage of giving brachytherapy after EBRT is that a more uniform dose can be delivered to the residual tumor after it has been reduced by EBRT. Brachytherapy given initially provides rapid relief of dysphagia. HDR brachytherapy at doses of 16 Gy in two fractions or 18 Gy in three fractions delivered weekly or every other day has been used without additional EBRT to palliate esophageal cancers.[198,199]

A few randomized studies have evaluated esophageal HDR brachytherapy and are summarized in Table 28.17. Historically, primary treatment of esophageal cancer included definitive radiotherapy. Results with external beam radiation alone in general were poor. For medically inoperable patients with submucosal esophageal cancer, external beam radiation with the addition of intraluminal brachytherapy is an attractive approach. Ishikawa et al.,[203] demonstrated a 5-year cause-specific survival of 86% with intraluminal brachytherapy compared to 62% with EBRT alone in a cohort of 56 patients. An update published in 2012 with additional patients demonstrated again a 5-year cause-specific survival of 85% with intraluminal HDR brachytherapy.[204]

In the palliative setting to relieve dysphagia, HDR brachytherapy is more defined. As was seen in definitive therapy, the combination of EBRT and HDR

brachytherapy as compared to EBRT alone has resulted in an improvement in relief of dysphagia as well as survival.

More recent studies have evaluated various HDR fractionation schemes as well as comparing HDR brachytherapy alone to combination EBRT and HDR brachytherapy. Sur et al.[199] evaluated three fractionation schemes given weekly (12 Gy in two fractions; 16 Gy in two fractions; 18 Gy in three fractions) among 172 patients with advanced esophageal cancer. The higher dose fractionation schemes had a trend toward improved dysphagia-free survival (25% to 38% at 12 months). Subsequently, a multicenter, prospective randomized study conducted under the auspices of the International Atomic Energy Agency (IAEA) evaluated two HDR regimens in 232 patients.[198] Patients were randomized to receive 18 Gy in three fractions over 5 days or 16 Gy in two fractions over 3 days. The authors concluded that dose fractions of 6 Gy × 3 and 8 Gy × 2 within 1 week gave similar results for dysphagia-free survival (~30% at 12 months), overall survival, and incidence of strictures and fistulae.

[a]Approximate dysphagia-free survival based on graph.
[b]Median survival.
EBRT, external beam radiation therapy; HDR, high dose rate.

The addition of EBRT to HDR brachytherapy has yielded mixed results. Sur

et al.[197] reported on a prospective pilot-randomized trial of 60 patients comparing HDR brachytherapy alone versus HDR brachytherapy plus EBRT for palliative treatment of advanced esophageal cancer. All patients received 16 Gy in two fractions over a 3-day period and then randomized to observation (group A) versus EBRT (group B) of 30 Gy in 10 fractions. At 12 months, there was no difference in dysphagia-free survival, overall survival, or incidence of strictures and fistulas for the two groups. However, the follow-up prospective multicenter randomized study in a larger patient group as reported by Rosenblatt et al.[196] utilizing the same regimen did show a sustained improvement in dysphagia-free survival at 12 months with the combined HDR brachytherapy and EBRT. There was no difference between the complication rates or overall survival between the two treatments.

In summary, retrospective studies as well as prospective, randomized clinical trials show that there is improved local control and survival when HDR brachytherapy is added to EBRT and that HDR brachytherapy alone can be used for palliation of advanced esophageal cancers. Because a high dose is delivered to the esophageal mucosa, side effects may include ulcerations, fistulae, and esophageal strictures. Additionally, the use of HDR brachytherapy as a boost to concurrent chemotherapy and EBRT has been evaluated.[205–208] Results have varied and thus caution should be exercised with this approach.

Biliary Cancers

Cholangiocarcinomas are rare malignancies and optimal adjuvant therapy remains unclear. A Surveillance, Epidemiology and End Results (SEER) database analysis suggested that brachytherapy may improve overall survival.[209] A recent Japanese study evaluating intraluminal brachytherapy in addition to EBRT for unresectable biliary tract cancer found an improvement in local control but no difference in overall survival.[210] The Mayo Clinic has described the use of HDR biliary brachytherapy in conjunction with neoadjuvant chemoradiotherapy prior to liver transplantation for unresectable perihilar cholangiocarcinoma.[211] Tumors of the bile duct are often unresectable and are treated palliatively by biliary drainage and EBRT. The biliary drainage tube can be accessed to provide brachytherapy to the area of obstruction either by LDR ^{192}Ir brachytherapy or by HDR brachytherapy[212–216] alone or in combination with EBRT. Although brachytherapy is commonly delivered through a transhepatic cholangiogram catheter, it has also been delivered using an endoscopic retrograde technique. A size 12-Fr biliary drainage catheter is

required to accommodate a 6-Fr HDR brachytherapy catheter. Therefore, the indwelling biliary drainage catheter is upsized to a size 12-Fr biliary drainage catheter, if required. Under fluoroscopy, the brachytherapy catheter is inserted into the biliary drainage catheter and advanced past the area of obstruction. A Tuohy-Borst (Y-shaped) adapter attached to the end of the biliary catheter allows concurrent external biliary drainage while holding the HDR catheter in place. The area of the obstruction is irradiated along with 1- to 2-cm proximal and distal margins. The dose per fraction delivered is variable, but approximately 5 Gy per fraction at a distance of 1 cm from the source is commonly used for three or four fractions (15 to 20 Gy total) to boost 45 Gy EBRT. If EBRT is not delivered, a palliative dose of 30 Gy in six fractions can be used. A phase 1 study from Italy established a recommended dose of 25 Gy in five fractions for palliative treatment.[217] Concurrent chemotherapy (5-FU) is often added. It is important to leave the biliary drainage catheter in place after therapy to minimize biliary stricture.

Head and Neck Cancers

Brachytherapy, especially using manually afterloaded ^{192}Ir, has been widely used to treat head and neck cancers. HDR brachytherapy has been used in selected cases to reduce radiation exposure and permit optimization as summarized in Table 28.18.[218–222,224–232] However, these advantages are offset by the need for multiple fractions because the head and neck area does not tolerate high doses per fraction. Both the ABS and GEC-ESTRO have separately published general recommendations of utilizing HDR brachytherapy in the various sites of head and neck cancer.[17,239]

The nasopharynx is a site within the head and neck area that is easily accessed by an intracavitary HDR applicator.[240] Levendag et al. have extensive

experience in treating nasopharyngeal lesions with HDR brachytherapy. They have shown that patients most suitable for a HDR brachytherapy boost are those with T1 and T2 lesions following 60 (T1, T2a) to 70 Gy (T2b) of EBRT. HDR doses of 18 Gy in six fractions are delivered by a special nasopharynx applicator. T3 and T4 lesions are better suited to be boosted with IMRT or stereotactic external beam techniques.[240]

The use of HDR brachytherapy catheters incorporated in removable dental molds allows repeated, highly reproducible, fractionated outpatient brachytherapy of superficial (<0.5-cm thick) tumors without requiring repeated catheter insertion into the tumor.[17] Suitable sites for mold therapy include the scalp, face, pinna, lip, buccal mucosa, maxillary antrum, hard palate, oral cavity, external auditory canal, and the orbital cavity after exenteration. HDR can be used as the sole modality or in conjunction with EBRT. A total HDR dose equivalent to about 60 Gy LDR (prescribed at 0.5-cm depth) is recommended when used as the sole modality.[17] The HDR can also be used as a boost to 45 to 50 Gy EBRT, in which case the HDR doses are appropriately reduced to LDR equivalent doses of 15 to 30 Gy. The actual HDR dose per fraction and number of fractions can be varied to suit individual situations (including site and treatment volume). Biomathematical (LQ) modeling can be used to assist in the conversion of LDR to HDR.[19]

Local regional recurrence remains the primary pattern of failure in head and neck cancers despite advancements in surgery and concurrent chemotherapy and EBRT. Surgical salvage is generally the preferred treatment, however, is not possible in all cases. EBRT is effective as salvage treatment but comes with high toxicity. HDR brachytherapy has been used in a few limited series for recurrent disease of previously irradiated patients. Various fractionation schemes with or without EBRT or surgical resection have been utilized. Initial results appear comparable to other modalities.[241–245]

Another innovative approach is the use of intraoperative HDR brachytherapy, which permits normal tissues to be retracted or shielded during brachytherapy. Intraoperative HDR brachytherapy can reach many sites in the head and neck area that are difficult to treat or are inaccessible by either LDR brachytherapy or intraoperative electron beam radiation. The catheters are removed immediately after the single dose of radiation, hence, minimizing inconvenience and permitting the use of brachytherapy in areas such as the base of skull.[224,228] Doses of 7.5 to 15 Gy are given when EBRT of 45 to 50 Gy can be added. In recurrent tumors where no further EBRT can be given, a single intraoperative

dose of 15 to 20 Gy can be given.[224,228]

An ABS Task Group recently published their review of the available literature of utilization of brachytherapy for head and neck cancers. Their review included LDR, PDR, and HDR. The most common applications of brachytherapy include the base of tongue, oral cavity, and nasopharynx. In general brachytherapy achieves good results; however, given the complexity of the anatomy, it should be performed in dedicated centers with high levels of expertise. The authors encourage the reader to review the ABS Task Group report for more details.[246]

Soft Tissue Sarcomas

Excellent results are obtained with a combination of wide excision of the tumor and adjuvant EBRT. However, irradiation of large volumes after surgery gives rise to morbidity, especially normal tissue fibrosis. To minimize morbidity, a few centers historically have used LDR brachytherapy.[247] The major problem with LDR brachytherapy of large volumes is the radiation exposure involved. Hence, a few centers have investigated the use of HDR brachytherapy for soft tissue sarcomas.[248–257] Most commonly interstitial brachytherapy catheters are placed immediately following surgical resection in the operating room, which gives the advantage of accurate tumor bed delineation as well as improved avoidance of adjacent critical normal structures. Radiopaque clips are used to indicate the margins. A 2- to 5-cm margin proximally and distally is used after gross excision of tumor along with 1 to 2 cm radially. The ABS recommends utilization of CT imaging for treatment planning purposes and using CTV D_{90} to assess the quality of the implant. In addition $D_{0.1cc}$, D_{1cc}, and D_{2cc} to critical structures should be recorded. Optimized treatment planning can be used to deliver a more homogeneous dose. Updated ABS recommendations recommend total doses of 30 to 54 Gy given twice daily in 2 to 4 Gy fractions over 4 to 7 days if the HDR is given alone.[12] If EBRT (45 to 50 Gy) is added, the brachytherapy dose is limited to 12 to 20 Gy in 2 to 4 Gy fractions over 2 to 3 days.[12] It is important to delay the start of brachytherapy for about 4 to 7 days after surgery to allow for wound healing.[12] An alternative technique not widely available is intraoperative HDR brachytherapy (HDR-IORT).[248,258] A HDR-IORT dose of 12 to 15 Gy is given to the tumor bed in a single fraction intraoperatively to boost EBRT doses of 45 to 50 Gy. Nerve tolerance to high dose per fraction is poor, and HDR should be used with caution when catheters have to be placed in contact with neurovascular structures. The ABS suggests the following interventions to minimize morbidity in soft tissue sarcomas[12]:

- When brachytherapy is used as adjuvant monotherapy, the source loading should start no sooner than 5 to 6 days after wound closure. However, the radioactive sources may be loaded earlier (as soon as 2 to 3 days after surgery) if doses of <20 Gy are given with brachytherapy as a supplement to EBRT.
- Minimize dose to normal tissues (e.g., gonads, breasts, thyroid, skin) whenever possible, especially in children and patients of childbearing age.
- Limit the allowable skin dose—the 40 Gy isodose line (LDR) to <25 cm^2 and the 25 Gy isodose line to <100 cm^2.

Outcome of nonrandomized studies using HDR doses in the range of 2 to 9 Gy per fraction given once or twice daily or single-fraction intraoperative HDR brachytherapy are outlined in Table 28.19.[248–260]

A recent nonrandomized study has demonstrated that IMRT achieved better local control over brachytherapy in patients with high-grade soft tissue sarcomas of the extremity and thus has questioned the use of brachytherapy in this patient population.[261] Despite this, HDR brachytherapy still has a role to play in the management of soft tissue sarcomas.

Pediatric Tumors

LDR brachytherapy has been used in children to reduce the deleterious effects of EBRT.[262] However, LDR brachytherapy is difficult to perform in young children and infants because they require prolonged sedation and immobilization with close monitoring, which increases the risk of radiation exposure to nursing staff and parents. HDR is therefore very appealing in infants and younger children and has undergone various trials.[263–265] The recommended dose for HDR as monotherapy is 36 Gy in 12 fractions given at 3 Gy per fraction (prescribed at 0.5 cm) twice a day.[263,265,266] The interval between fractions is at least 6 hours. Because the tissue planes are smaller in young children, catheter spacing and prescription points may have to be reduced.[263] There are no good published dose recommendations for HDR when used as a boost to EBRT. The LQ model[19] can be used to calculate a fractionation scheme equivalent to that of an LDR implant boost dose of 15 to 25 Gy (prescribed at 0.5 cm). The recommended dose for intraoperative HDR brachytherapy as a boost to EBRT is 10 to 15 Gy (prescribed at 0.5 cm), depending on the extent of residual disease.[267–269] According to the Intergroup Rhabdomyosarcoma Study (IRS), the standard EBRT dose for pediatric soft tissue sarcomas is 40 Gy for microscopic disease and 50 Gy for gross disease. Intraoperative HDR allows reduction in the dose of EBRT to 27 to 30 Gy so that concerns for impaired growth and organ function are greatly

reduced.[265,268,270] The results of HDR brachytherapy in the treatment of pediatric tumors are summarized in Table 28.20.[264,268,269,271–277] Although the long-term morbidity of HDR brachytherapy in young children is not fully known, one may expect preservation of organ functions similar to that seen with LDR brachytherapy.[278] Because of the complexities involved in pediatric HDR brachytherapy, it is recommended that the use of HDR brachytherapy in pediatric tumors be limited to centers that have experience with pediatric implants.[12] The availability of proton beam does not obviate the usefulness of brachytherapy as the former produces a high entrance dose, which can be deleterious to growing tissues, whereas brachytherapy dose distribution is more localized.

Skin Cancer

The widespread availability of HDR remote afterloading brachytherapy units allows the use of surface molds as an alternative to electron beam and for cases where surface irregularity, proximity to bone, or poor intrinsic tolerance of tissues do not allow for satisfactory treatment by electron beam. In addition to melanoma and nonmelanoma skin cancers, Merkel cell lesions, benign keloids, as well as Kaposi sarcomas have been treated with HDR brachytherapy. Indications for the use of radiotherapy for skin malignancies include primary treatment of tumor after biopsy, adjuvant treatment for close or positive surgical margins, high risk of recurrence following surgery, or treatment of recurrent tumors.[279] Pretherapy imaging to determine an appropriate applicator to encompass all of the disease is important and can often be accomplished with the use of MRI or CT. Newer technologies such as optical coherence tomography and confocal microscopy can potentially play a role in determining full tumor extent.[279] For most cases, a satisfactory mold can be made from 5-mm thick sheets of wax with the HDR catheters spaced 1 cm apart. A simpler alternative is to use commercially available surface template applicators (e.g., Freiburg flab from Nucletron Corp, Columbia, MD and HAM applicator from Mick Radionuclear Instruments Inc, Bronx, NY) that are used for intraoperative HDR brachytherapy.[280,281] The use of molds made of aquaplast allows greater conformity to curved surfaces like the scalp. Contraindications for the use of brachytherapy include invasion of the bone, extension of disease in the orbit or along facial planes, perineural invasion, and certain genetic diseases such as ataxia telangiectasia.[279]

[b]Surviving patients.
EBRT, external beam radiation therapy; F-HDR, fractionated high dose rate (given twice a day); IOERT, intraoperative electron beam radiation therapy; IOHDR, intraoperative high dose rate.

There is a wide range of recommended doses and fractionation schemes for treating skin cancer. An ABS working group determined that common fractionation schemes for surface applicators and custom molds include 40 Gy in eight fractions and 42 Gy in six fractions. These treatments are commonly delivered two to three times a week. For interstitial brachytherapy, the recommended dose is 30 Gy in 10 fractions delivered in a twice daily fashion.[279] The linear-quadratic radiobiologic model can be used to determine the total dose for a given fractionation scheme.[19] Kuribayashi et al.[282] reported 90% control rate postkeloidectomy utilizing 20 Gy in four fractions or 15 Gy in three fractions based on the site of the keloid. Kasper et al.[283] reported 100% complete response and local control at a median follow-up of 41.4 months for patients with Kaposi sarcoma utilizing a dose of 24 to 35 Gy in four to six fractions.

The respondents of a recent survey of members of the ABS to eight clinical scenarios of cutaneous squamous cell carcinoma and basal cell carcinoma generally prefer brachytherapy to external beam radiation mainly because of shorter treatment course, conformality of treatment, and shallow dose deposition. Tumor depth >3 mm, perineural invasion, or previous radiation were typical contraindications to brachytherapy. Median treatment margin was 5 mm and hypofractionation was preferred. The fewest fractions reported was 30 Gy in 5

fractions, whereas the most was 64 Gy in 32 fractions.[284]

INTRAOPERATIVE HIGH DOSE RATE BRACHYTHERAPY

Intraoperative high dose rate brachytherapy (IOHDR) is an extreme example of reduced fractionation in that only a single HDR brachytherapy dose is applied.[285] This results in an inherent radiobiologic disadvantage because the advantages of fractionation (repair of normal tissue damage, reoxygenation of hypoxic tumor cells, and movement of tumor cells from the radioresistant S phase to the more radiosensitive mitotic phase of the cell cycle) are lost. LQ model calculations show that there has to be a dose reduction of 20% to 25% to the late-reacting normal tissues for isoeffect. However, the dose reduction achieved by 1- to 4-cm displacement of normal tissue is much more (closer to 60% to 90% reduction).[280] Hence, HDR in these situations becomes advantageous. However, if such a dose reduction cannot be achieved in normal tissues, HDR brachytherapy becomes disadvantageous. Intraoperative HDR brachytherapy also has the advantage that normal tissues can be temporarily displaced and/or partially shielded during irradiation.

The ABS published a consensus report in 2017 for the use of IOHDR brachytherapy.[285] In IOHDR, the surgery is performed in a shielded operating room with remote anesthesia and a video monitoring system. Maximum surgical debulking is attempted whenever possible. Appropriate patients for IOHDR include those with close, microscopic, or positive margins and/or recurrent disease in a previously resected or previously irradiated region. The tumor bed is irradiated using special intraoperative applicators containing HDR catheters that are 1 cm apart and parallel to each other. The use of a fixed geometry applicator allows the patient to be treated without delay using preplanned dosimetry for the selected applicator. Normal tissues are either retracted from the high dose area or shielded. Doses of 10 to 20 Gy depending on treatment location are usually given as a single fraction over 10 to 30 minutes.[285] Dose is typically prescribed to either the surface of the applicator or to a depth of 3, 5, or 10 mm based on treatment location. The reader is encouraged to review the consensus report for more specific treatment details based on tumor location. The advantages of IOHDR brachytherapy over perioperative brachytherapy or electron beam intraoperative radiation therapy (IORT) are listed in Table 28.21. Unfortunately, the relative scarcity of shielded operating rooms has currently limited its availability to just a few centers.[285]

TABLE 28.21 ADVANTAGES OF SURGICAL DEBULKING WITH INTRAOPERATIVE HIGH DOSE RATE BRACHYTHERAPY OVER PERIOPERATIVE BRACHYTHERAPY OR ELECTRON BEAM INTRAOPERATIVE RADIATION THERAPY

Advantages over Perioperative Brachytherapy	Advantages over Electron Beam IORT
1. It is possible to use retraction or shielding to reduce the dose to normal tissues. 2. Normal structures can be temporarily moved while the radiation is given and then replaced in their normal position. For example, to access the base of skull, the maxilla can be removed and later regrafted. Ureters can be severed and then reimplanted into the bladder. During liver transplantation procedures, the liver hilum can be irradiated during the interval between the removal of the host liver and reimplantation of the donor liver. 3. The process is rapid. Using a surface applicator eliminates the needs to individually suture the catheters to the tumor bed. 4. HDR allows the treatment to be delivered at sites into which catheters cannot be sutured. 5. Because catheters are not left in the patient, there is no risk of catheter displacement, extrusion, or infection.	1. Electron beam IORT can only be delivered to areas accessible to the electron cone and, therefore, cannot treat steeply sloping surfaces, narrow cavities, or areas such as the diaphragm, pubis, and anterior abdominal wall. Intraoperative HDR brachytherapy has less anatomical constraints than electron beam IORT. 2. The HDR machine costs less than an electron beam linear accelerator. 3. Because the HDR afterloader can be transported between the radiation department and the operating room, dedicated equipment is not required.

HDR, high dose rate brachytherapy; IORT, intraoperative radiation therapy.

Reduction of Brachytherapy Errors

The International Commission on Radiological Protection (ICRP)[286] released Publication 97 in November 2005, which outlines quality assurance (QA) procedures necessary to prevent accidents with HDR brachytherapy. The ICRP gave general and specific recommendations for HDR brachytherapy programs which are summarized in Tables 28.22 and 28.23. The general recommendations include establishing a written comprehensive QA program, formation of a hospital radiation safety committee, external auditing of procedures, peer reviewing of each case, and reporting of every incident or accident. The specific recommendations cover a broad range of topics. Training in HDR brachytherapy should commence prior to acquisition of machines, follow a team approach, and should be sequential in the introduction of techniques with simpler techniques first followed by more complex treatments. For example, multiple plane flexible implants should not be attempted first. Transport regulations of sources should

be adhered to and performed by a factory-trained and certified operator. In addition, new sources should be measured in a calibrated well chamber to verify reported activity, at which time it is advisable to do a full commissioning including physics and mechanical QA checks. It is recommended that all systems of delivery (i.e., catheters) be close ended, that the step size at a particular center be constant (i.e., 5 mm) for all treatments, and that a dedicated self-contained brachytherapy suite exist to house all equipment. Prior to initiating treatment with the HDR machine a few standard procedures should be employed. These include manual insertion of a test wire to verify programmed treatment length and identify any kinks or obstructions, verifying applicator position with an appropriate imaging modality (i.e., fluoroscopy), and ensuring that all tubes outside the patient's body are as far away as possible to minimize unintended doses. Following treatment a survey of the patient by a portable radiation monitor is essential. Finally, emergency plans and security procedures should be in place and strictly adhered to. "false alarms" and "interlock failures" should be thoroughly investigated, and persons responsible for emergency procedures should remain in the vicinity of the brachytherapy suite during the entire treatment. In some countries, it is a requirement that both the clinician and physicist remain in the vicinity of the HDR suite. The possibility of theft of an HDR source for use as a weapon for nuclear terrorism is real, and the machine and source should be kept secure at all times. Particular attention should be paid if the facility or machine is decommissioned. It is believed that if a HDR brachytherapy center follows these general and specific recommendations, errors and accidents will be minimized.

TABLE 28.22 INTERNATIONAL COMMISSION ON RADIOLOGICAL PROTECTION PUBLICATION 97—PREVENTION OF HIGH DOSE RATE BRACHYTHERAPY ACCIDENTS—GENERAL RECOMMENDATIONS

1. Written comprehensive QA program.
2. Compliance to QA procedures will contribute to minimizing the occurrence of errors, both in number and magnitude.
3. Hospital Radiation Safety committee (QA committee) needs to exist and interact with regulatory and health authorities.
4. Maintenance is an indispensable component of QA.
5. External audits of procedures reinforce good and safe practice and identify potential causes of errors.
6. Peer review of each case improves quality.
7. Every incident or accident should be reported as required to the appropriate authority.

QA, quality assurance.

TABLE 28.23 INTERNATIONAL COMMISSION ON RADIOLOGICAL PROTECTION PUBLICATION 97—PREVENTION OF HIGH DOSE RATE BRACHYTHERAPY ACCIDENTS—SPECIFIC RECOMMENDATIONS

1. Training in an HDR center should commence prior to machine acquisition and should include the specific techniques to be used.
2. Training should be directed toward ensuring a team approach involving clinician, physicist, technician, and nurse.
3. Training and introduction of techniques should be sequential, commencing with simpler techniques before attempting more complex activities. Fixed geometry applicators and implants are less likely to result in errors.
4. Transport regulations should be adhered to and performed by a factory-trained and certified operator. This includes on-site container inspection for damage, removal of the old source and its transfer to the container, and installation of the new one into the safe.
5. New sources should be measured in a calibrated well chamber to verify the manufacturers reported activity and the results entered immediately into the software. At this time, it is advisable to do a full commissioning (physics and mechanical QA checks).
6. All systems of delivery must be closed ended (catheters, needles, and fine tubes).
7. Manual insertion of a test wire (check cable) clearly marked at the programmed treatment length before each treatment to ensure that the total length of the transfer tube plus applicator equals the programmed treatment length. A manual check cable also helps to identify any kinks or obstruction in the catheter or transfer tube.
8. The step size in a particular center should be kept constant (e.g., 5 mm) for all treatments to avoid errors of using incorrect step size.
9. Keeping all tubes outside of the body as far distant as possible from the patient's skin will help to minimize unintended doses.
10. Dedicated self-contained brachytherapy suite with adequate shielding housing all requirements is highly advisable.
11. Applicator positioning should be verified before each treatment.
12. So-called false alarms and interlock failures should be thoroughly investigated and appropriated action taken and repaired.
13. Survey of patient by portable radiation monitor after each treatment.
14. An emergency plan should be prepared and practiced with commencement of operations.
15. The person responsible for performing an emergency procedure should remain in the brachytherapy suite during the entire treatment.
16. The HDR machine and source should be kept secure at all times.

HDR, high dose rate; QA, quality assurance.

HIGH DOSE RATE BRACHYTHERAPY IN DEVELOPING COUNTRIES

HDR brachytherapy has special relevance for developing countries where resources may be scarce. In this regard, the IAEA has issued recommendations for the use of HDR brachytherapy in the developing countries.[287] A brief

summary is given here; however, readers interested in the details are referred to the original article. An HDR treatment system should be purchased as a complete unit that includes the ^{192}Ir radioactive source, source loading unit, applicators, treatment planning system, and control console. Infrastructure support may require additional or improved buildings and procurement of or access to new imaging facilities. A supportive budget is needed for quarterly source replacement and the annual maintenance necessary to keep the system operational. The radiation oncologist, medical physicist, and technologist should be specially trained before HDR can be introduced. Training for the oncologist and medical physicist is an ongoing process as new techniques or sites of treatment are introduced. Procedures for QA of patient treatment and the planning system must be introduced. Emergency procedures with adequate training of all associated personnel must be in place. The decision to select HDR in preference to alternate methods of brachytherapy is influenced by the ability of the machine to treat a wide variety of clinical sites. In departments with personnel and budgetary resources to support this equipment appropriately, economic advantage becomes evident only if large numbers of patients are treated. With HDR, it is possible to treat a large number of patients in institutions that have a high volume of brachytherapy patients but insufficient in-patient facilities for LDR brachytherapy or insufficient finances for the purchase of ^{125}I or ^{103}Pd seeds for permanent implants. Intangible benefits of source safety, personnel safety, and easy adaptation to fluctuating demand for treatments also require consideration when evaluating the need to introduce this treatment system.

TABLE 28.24 COMPARISON OF DIFFERENT BRACHYTHERAPY TECHNIQUES

	LDR ^{192}Ir	LDR Remote	MDR	PDR	HDR	IOHDR
Dose rate	Low	Low	Medium	High	High	High
Duration of each treatment	2–6 d	2–4 d	1 d	Minutes	Minutes	Minutes
Overall duration of treatment	2–6 d	2–4 d	1 d	2–4 d	3–5 wk	Minutes
Radiation hazards	High	Small	Small	Small	Small	Small
Availability (worldwide)	++	—	—	—	+	—
Ease of optimization	—	—	—	+	+	+
Dose as sole modality (Gy)	60	60	40	60	30–40	15–20
Dose as boost to EBRT	20–40	20–40	20–30	20–40	20–30	10–15

	(Gy)

EBRT, external beam radiation therapy; HDR, high dose rate; IOHDR, intraoperative high dose rate; LDR, low dose rate; MDR, medium dose rate; PDR, pulsed dose rate.

Of specific interest is locally advanced cervical cancer as most of these cases occur in low-income to middle-income countries. The ABS recently published recommendations for brachytherapy treatment in cervical cancer specifically for developing countries.[288] While the basic tenants and goals of overall management of cervical cancer are the same for developed and developing countries, the ABS guidelines recognize that traditional prescription points are still very relevant in countries where 3D imaging is limited. Furthermore, an emphasis is placed on the importance of pretreatment verification and checklists particularly when overseeing experienced personnel is limited.[288]

Summary

Although brachytherapy is a very effective modality, case selection and proper patient evaluation are essential. If the tumor is very large or widely metastatic, one is doomed to fail because of the physics of dose distribution in the former case and because of the biology of the tumor in the latter case. There are some differences between various brachytherapy modalities (Table 28.24). These differences should be kept in mind when selecting the brachytherapy modality in a particular situation. When HDR brachytherapy is used, the treatments must be executed carefully because the short treatment times do not allow any time for correction of errors, and mistakes can result in harm to patients. Hence, it is very important that all personnel involved in HDR brachytherapy be well trained and constantly alert. However, with proper case selection and delivery technique, HDR brachytherapy has great promise and convenience because of avoidance of radiation exposure, short treatment times, and outpatient therapy.

One of the disadvantages of HDR brachytherapy is that it requires a shielded room. A newer device, the Axxent (Xoft Inc., Sunnyvale, CA), uses a miniaturized x-ray source to deliver low-energy x-rays within a needle or catheter thereby mimicking HDR brachytherapy. The reduced radiation protection required for these devices because of limited penetration is a great advantage because it allows brachytherapy to be delivered in a nonshielded procedure room or a regular (unshielded) hospital operating suite. Currently, the Xoft-Axxent system has only a single channel and therefore has the limitation of being able to treat only small volume tumor beds. It is being used at a few centers in the United States to treat breast cancer via a balloon device similar to

the MammoSite balloon, the vaginal cuff with a single-channel cylinder applicator, and skin cancers with a surface applicator.[161,162,289,290]

There has been a recent decline in the utilization and interest and brachytherapy for various reasons including lack of facilities, training, and insufficient reimbursement. However, the inclusion of high-quality brachytherapy is imperative for good outcome in a number of malignancies. Continued education and awareness of the scope and value of brachytherapy is therefore essential.[291] It is hoped that with new emphasis on value and outcome, HDR brachytherapy will continue to expand over the coming years and that refinements in the integration of imaging (computed tomography, MRI, intraoperative ultrasonography), and optimization of dose distribution will foster this expansion.[31,292] The development of well-controlled randomized trials addressing issues of efficacy, toxicity, quality of life, and costs versus benefits will ultimately define the role of HDR brachytherapy in the therapeutic armamentarium.

CHAPTER 29

Radioimmunotherapy and Unsealed Radionuclide Therapy

Tod W. Speer

INTRODUCTION

The concept of a “magic bullet” or targeted therapy against a tumor was first proposed by Paul Ehrlich in 1898, ultimately allowing him to garner the Nobel Prize in 1908. As testimony to the complexities and challenges of his vision, it was not until a half a century later when radiolabeled antibodies were used in the clinic to target cancer. The modern exegesis for targeting agents does not limit the use of carrier molecules to mere antibodies. Successful targeting of tumor cells, with high affinity, can also be accomplished with antibody fragments, peptides, and affinity ligands. As the research and clinical arena ever so modestly disengage from intact antibodies as the carrier molecule for the radionuclide, the impact of the immune system has been somewhat abrogated. Hence, the “immunotherapy contribution” of “radioimmunotherapy” (RIT) has become less pronounced. Perhaps, a more appropriate term for this technology would be “targeted radionuclide therapy.”

To date, RIT has made significant progress secondary to advances in cell biology, immunology, radiation oncology, nuclear physics, and chemical technology. There are greater than 8 million cancer deaths worldwide and nearly 600,000 cancer deaths in the United States annually.[1,2] Millions of cancer patients each year exhaust available drug options and succumb to cancer. Current cancer drug development in the United States takes approximately 8 years and 1.3 billion dollars for FDA approval.[3] This process appears unsustainable.[4] RIT offers the potential to accelerate drug development. RIT exercises its cytotoxic action by delivering targeted molecular radiation to malignant tissue. Therefore, the success of RIT depends upon engineering a targeting construct that brings the radionuclide into close proximity of the target cell or tissue. The cytotoxic agent,

the radionuclide, is always the same. Of course, there is a selected differential of energy deposition into tissue, depending upon the specific chosen radionuclide. Standard drug development relies upon identifying a different target receptor or pathway that is prevalent within a particular type of cancer. Antibodies (or blocking agents) are then designed, over months or years, to interfere with the receptor or process. A cytotoxic evaluation is then performed. Not all antibodies are initially cytotoxic. Hence, the abovementioned timeline and cost prevail.

IMMUNOLOGY AND TARGETING CONSTRUCTS

Immunity refers to protection from disease or infectious agents.[5] Our immune system is composed of the cells and molecules responsible for the immune response, which can be divided into an early (1- to 12-hour) reaction, termed *innate immunity*, and a late (1- to >7-day) reaction, termed *adaptive immunity*. The innate immune system comprises biochemical and cellular mechanisms that exist prior to the introduction of a “foreign” or infectious agent and results in a rapid response. The innate immune system consists of epithelial barriers, phagocytic cells (neutrophils, macrophages), natural killer cells, the complement system, and cytokines. The adaptive immune system develops over time, becoming more effective with subsequent exposures of antigen. It exhibits the ability to “remember” and to respond more quickly with continued exposures to the same antigen. The adaptive immune system consists of lymphocytes and secreted antibodies. The adaptive immune system can be divided into humoral immunity and cell-mediated immunity. Concerning humoral immunity, B lymphocytes secrete antibodies for protection. With cell-mediated immunity, helper T lymphocytes either activate macrophages or cytotoxic T lymphocytes, which then directly destroy pathologic (infectious or malignant) cells.

It is well known that the host’s immune system is important for preventing the growth and development of cancer.[6] A large body of literature exists supporting the concept that the host immune system interacts with tumorigenesis and tumor progression. It has been shown in animal models and in the clinic that cancer immune surveillance is exceedingly important. For example, mice with an impaired innate or adaptive immune system will be more susceptible to develop chemically induced or spontaneous cancers. Additionally, the malignant transformation of cells in animals and humans, caused by the accumulation of somatic mutations and/or the deregulation of oncogenes or tumor suppressor genes, results in the expression of tumor antigens (TAs). These TAs are often

recognized by the immune system as documented by TA-specific T-cell precursors and natural killer cells, found in the peripheral blood of cancer patients, capable of killing tumor cells. Further evidence of cancer immune surveillance exists in patients with genetic or drug-induced immunosuppression. Transplant patients exhibit a predisposition for certain malignancies (squamous cell carcinoma, basal cell carcinoma, Kaposi sarcoma, melanoma, and lymphoma). Patients with Chédiak-Higashi and Wiskott-Aldrich syndrome demonstrate an increased rate of lymphoproliferative malignancies. Discontinuing immunosuppressive drugs in solid organ allograph patients with occult malignant melanoma has resulted in tumor regression.

Despite the evidence of cancer genesis and progression in immune-compromised hosts, the majority of cancers develop in seemingly immune-competent individuals. The last decades of research have revealed that cancer cells have developed means to avoid immune detection and surveillance, either through the selection of nonimmunogenic tumor cells or the active suppression of the immune response. It has therefore been rightfully suggested that “tumor immune escape” be added to Hanahan and Weinberg’s six hallmarks of cancer (self-sufficiency in growth signals, insensitivity to antigrowth signals, tissue invasion and metastasis, limitless replicative potential, sustained angiogenesis, and evasion of apoptosis). Interestingly, recent progress has been achieved utilizing drugs for immune checkpoint blockade therapy by targeting the programmed death protein (PD-1) with antibodies. Unfortunately, response rates have been limited.[7] Currently, the quest for the “Holy Grail” vaccine that turns the immune system against cancer remains elusive.[8]

The targets for RIT typically consist of tumor-associated antigens (TAAs) expressed on the surface of tumor cells or in the abnormal extracellular matrix. The reason for this is because the cytotoxic radionuclide must be delivered preferentially to malignant tissue and should avoid normal tissue. To date, >2,000 TAAs have been identified (http://www.re3data.org/repository/r3d100012052). One of the main methodologies used to identify TAAs is termed *SEREX* (serologic analysis of recombinant cDNA libraries). SEREX involves a bacteriophage recombinant cDNA expression library, prepared from various malignancies (isolated tumors or malignant cell lines) or testis tissue.[9] This cDNA expression library is transduced in *Escherichia coli* to produce a recombinant protein library. These various proteins (clones) are then tested against the serum from autologous cancer patients. Clones that react to IgG antibodies are identified and are then

further characterized as TAAs. Many of these SEREX-identified TAAs have been elucidated by other processes and laboratories. This has led to the concept of a finite number of TAAs that are produced in cancer patients and are potentially identified by the immune system. These finite TAAs are collectively referred to as the cancer immunome. SEREX-defined antigens, representing broad categories, may be organized as follows: mutational antigens, amplified or overexpressed antigens, differentiation antigens, and cancer/testis antigens. Within these categories, only a limited number of solid tumor TAAs have been used as targets for RIT (Table 29.1).

TABLE 29.1 SELECT TUMOR ANTIGEN TARGETS AND MONOCLONAL ANTIBODIES EVALUATED FOR SOLID TUMOR RADIOIMMUNOTHERAPY

Malignancy	Antigen	Antibody
Colorectal cancer	CEA	cT84.66, hMN-14, A5B7, TFT, IMP-288, CC49 B72.3, CC49, A33

CAIX/MN, carbonic anhydrase IX; CEA, carcinoembryonic antigen; EGFR, epidermal growth factor receptor; EpCAM, epithelial cell adhesion molecule; FAP, fibroblast-activating protein; MUC1, mucin 1; NCAM, neural cell adhesion molecule; PSMA, prostate-specific membrane antigen; TAG-72, tumor-associated glycoprotein.
Modified from Wong YC, Williams LE, Yazaki PJ. Radioimmunotherapy of colorectal cancer. In: Speer TW, ed. *Targeted radionuclide therapy*. Philadelphia: Lippincott Williams & Wilkins, 2011:325. With permission.

The ideal target for RIT-targeting constructs would be one that is overexpressed on cancer cells, is uniformly expressed, is not found to any significant level in normal tissue, is not shed into the circulation, and exhibits an important role in tumor growth and progression.[10] TAAs, as the name implies, are antigens “associated” with tumors but are also present in normal tissue. True tumor-specific antigens have not yet been identified and utilized. Overexpression is necessary because typical targeting constructs require antigen densities $\geq 10^5$ receptors on each cell for adequate targeting. A homogenous antigen expression is desired so that a uniform activity distribution of the radionuclide will result. Nonuniform activity distributions (heterogeneity of antigen in target tissue being one potential cause) will significantly lower the effectiveness of RIT by subsequently resulting in nonuniform or heterogeneous dose distributions.[11] This is particularly important for radionuclides with short path lengths of the emitted particles (i.e., Auger and α-particle emitters). Radionuclides with longer path lengths, such as high-energy β-emitters, can partly overcome the problem of nonuniform dose distributions through the crossfire effect. If the target antigen is significantly shed into the circulation, the targeting construct may bind and “complex” with the antigen. This will result in a more rapid clearance of the RIT

agent and a much less effective treatment. If the TAA has an important signaling role, then subsequent binding of the targeting construct will most likely add to the cytotoxicity of the radionuclide because of the blockade or promotion of intracellular signaling, potentially resulting in disruption of growth pathways important for tumor growth. Some TAAs (receptors) will internalize when bound by the targeting construct. In truth, most receptors internalize, although they do so at different rates. A rapid internalization process will have an impact on the type of radionuclide that is selected and potentially on the delivery strategy of the RIT agent.

A multitude of agents have been used as carriers (targeting constructs) for the targeted delivery of radiation to cancer. These consist of antibodies, antibody fragments, peptides, affibodies, aptamers, and nanostructures (i.e., liposomes, nanoparticles, microparticles, nanoshells, and minicells). By an exceedingly large margin, intact monoclonal antibodies (mAbs) have dominated the field of RIT as targeting constructs[12] (Fig. 29.1). In humans, there are five classes or isotypes of antibodies (IgA, IgD, IgE, IgG, and IgM). IgG is the most commonly used mAb for RIT because it is the most prevalent antibody in serum and has the longest serum half-life, typically measured in weeks (~23 days). IgG is further divided into four subtypes, $IgG_{1–4}$. IgG antibodies are large glycoprotein macromolecules, with an atomic mass of approximately 150,000 dalton (Da) or 150 kDa. The “y-shaped structure” (Fig. 29.1A) consists of two Fab fragments (antigen-binding fragment; ~50,000 Da each) and an Fc fragment (crystallizable fragment; ~50,000 Da).

The “tip” of each Fab fragment has a variable amino acid sequence, from one mAb to another. Accordingly, each tip is an antigen-binding site (ABS) and is responsible for antigen recognition. Each ABS forms a noncovalent bond (electrostatic forces, van der Waals forces, hydrophobic interactions, and hydrogen bonds) with the target or antigen. The specific region of an antigen, which binds to the ABS, is referred to as an epitope. It has been proposed that a million or more different antibodies exist in various individuals. Theoretically, $>10^9$ different antibodies can be produced. The outer core of the mAb consists of two identical light chains (outer portion of the Fab fragment) designated with an “L.” The inner core, consisting of the Fc region and the inner Fab region, is designated as heavy or “H.” Both the light and heavy chains contain homologous, 110 amino acid sequences that fold on one another and are connected by a disulfide bridge, resulting in “globular” motif or loop, called an Ig domain. There are three constant heavy domains (C_H1-3) and only one

constant light (C_L), one variable heavy (V_H), and one variable light (V_L) domain. The ABS consists of a V_L and a V_H region. Within each variable domain, there are three hypervariable regions (about 10 amino acid residues per hypervariable region) that form a three-dimensional surface that is "complementary" to the shape of the antigen surface; they are called complementarity determining regions (CDRs). A total of six CDRs come together to form the ABS. There are two ABS for each IgG mAb; hence, each IgG mAb is considered bivalent.

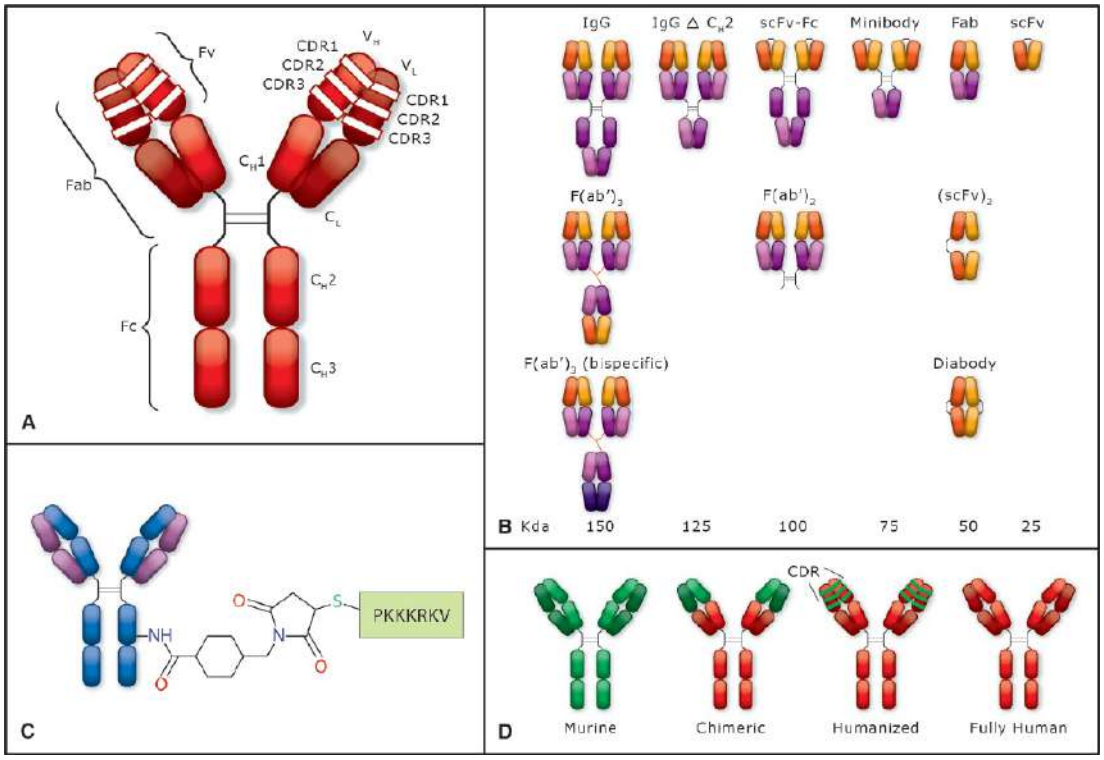

FIGURE 29.1. Antibody configurations for radioimmunotherapy. **A:** Typical structure of a humanized IgG antibody. **B:** Antibody fragments and size. **C:** Attachment of a nuclear localization signal. **D:** Humanization: *green* represents murine portion of IgG and *red* represents human portion. CDR, complementarity determining regions; CH, constant domain heavy chain; CL, constant domain light chain; Fab, antigen-binding fragment; F(ab') antigen-binding fragment (retaining a portion of the hinge region following enzymatic digestion); Fc, crystallizable fragment; Fv, variable fragment; PKKKRKV, amino acid sequence of nuclear localization signal; scFv, single-chain variable fragment.

Affinity refers to the strength of the bond between the ABS and the antigen. The strength of this bond is represented by the dissociation constant (K_d). Avidity refers to the overall strength of the ABS–antigen interaction, depending on both the affinity and the valency of the interaction. It should be noted that a high-affinity interaction can improve specific delivery of the RIT agent and

reduce overall dosing requirements. Increasing the affinity indefinitely, however, may decrease tumor penetration. It has been demonstrated that an affinity of 10^{-7} to 10^{-8} M is needed for tumor retention, whereas affinities in the range of $\geq 10^{-10}$ to 10^{-11} M will result in retention in normal tissue and asymmetric binding in tumor tissue, termed the *binding site barrier*.[13] The binding site barrier phenomenon may be at least partially overcome by increasing the antibody mass, or the overall delivered quantity of antibody.

Unconjugated antibodies—those not attached to a radionuclide or cytotoxic agent—will also mediate biologic activities. These activities may be mediated by the Fc region of the mAb or may be Fc independent. Fc-mediated interactions are termed *effector functions* and consist of antibody-dependent cell-mediated cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC).[5] Concerning ADCC, interaction of the Fc region of the antibody with Fc receptors (located on immune effector cells) results in the subsequent phagocytosis or lysis of the antibody-bound cancer cell. CDC is initiated by the interaction of soluble blood proteins and the Fc region. Epitope-dependent (Fc-independent) functions of the mAb may result in the inhibition of ligand binding, inhibition of ligand-induced dimerization, and inhibition of receptor shedding. These epitope-dependent functions are characteristic of modern-day biologics that target growth factor receptors, such as cetuximab and trastuzumab.

The original technology used to produce mAbs was first published by Kohler and Milstein in 1975 and is referred to as the hybridoma technique. The technique has propagated the use of murine mAbs for research and for therapy in the clinic. In fact, the two U.S. Food and Drug Administration (FDA) RIT agents used to treat non-Hodgkin lymphoma (NHL; ibritumomab tiuxetan and tositumomab) are murine mAbs. Although these agents are delivered as single instillations in patients typically with decreased immune recognition capabilities, there is a concern that human antiglobulin antibodies (HAGAs) will develop. If this phenomenon occurs in response to murine antibodies, then the resulting HAGAs will be called human antimouse antibodies (HAMAs). The formation of HAMAs will expedite blood clearance of the antibody and decrease targeting capabilities as well as potentially cause various adverse symptoms. Two main strategies, through the use of genetic engineering, have emerged[12] that reduce the immunogenicity of mAbs: (a) the production of antibody chimeras derived from both murine and human DNA and (b) the production of humanized or fully human antibodies (Fig. 29.1D). Chimeric antibodies retain murine V_H and V_L domains, whereas humanized antibodies retain murine CDRs. Fully human

antibodies retain no murine components. Although the development of HAGA may not be important after a single dose of mAb in lymphoma patients, HAGA will have a greater detrimental impact for patients with solid tumors when treated with RIT.[10] It has been well proven that as the antibody changes from murine to humanized, the immunogenicity is lessened. This concept is important so that multiple doses or fractions of RIT can be delivered. Current technology allows for the production of fully human mAbs. The concept of adding a nuclear localizing signal to bring the mAb from the cell surface or cytoplasm into the cell nucleus is shown in Figure 29.1C. In this setting, Auger-emitting radionuclides will be effective.

TABLE 29.2 TARGETING AND PHARMACOKINETICS OF INTACT IgG AND ANTIBODY FRAGMENTS

	IgG	F(ab')2	CH2 deletion	Minibody	Fab	Diabody	scFv
MW	150	100	120	80	50	40–50	20–25
Serum half-life	2–3 d[a]	1 d	Hours	Hours	Hours	Hours	1 hr
Metabolism	Liver	Liver	Liver	Liver	Kidney	Kidney	Kidney
Tumor uptake[b]	*****	****	***	***	**	**	*
Time to accretion	Days	1 d	Hours	Hours	Hours	Hours	1 h

[a]Serum half-life for fully human IgG is approximately 23 days.
[b]Tumor uptake values range from large (*****) to small (*).
MW, molecular weight (kDa).

Another factor that is critical and influences antibody targeting and pharmacokinetics is antibody molecular size (Fig. 29.1B). As stated previously, RIT has been less successful for treating solid tumors than hematologic malignancies. This is largely because of the lack of radiosensitivity of epithelial tumors (compared to hematologic malignancies) and the poor penetration of mAbs into large tumors. The decreased penetration of 150-kDa antibodies into large tumors is a direct result of increased tumor interstitial pressure, an aberrant tumor vasculature, and an abnormal tumor extracellular matrix.[14–17] Additionally, 150-kDa antibodies need longer periods of time to accrete into tumors and have long serum half-lives. When radiolabeled, a long serum half-life of the targeting construct will increase exposure of the bone marrow to radiation, which causes hematologic toxicity and limits the amount of antibody and radionuclide that can be given. To overcome some of these issues, methods have been used to generate antibody fragments of varying size and valency.

These smaller fragments exhibit superior tumor penetration and clear more rapidly from the circulation. However, if clearance from the circulation is too rapid, this can further limit tumor penetration. Table 29.2 summarizes these general concepts for targeting constructs of various molecular weights.

Although mAbs and their fragments represent the most commonly used targeting constructs for the delivery of a radionuclide to malignant tissue, other agents are either in use or are being investigated, consisting of peptides,[18–20] affibody molecules,[21,22] and aptamers.[23,24] Nanostructures are also being investigated as carriers of radionuclides.[12,25,26] In their unmodified form, the targeting capabilities of nanostructures are rather nonspecific.[27]

Peptides are amino acid sequences (typically 7 to 14 amino acids) that serve as opioids, hormones, sweeteners, protein substrate inhibitors, releasing factors, antibiotics, and cytoprotectors.[28] The overexpression of receptors that are specific for various peptides has led to the development of peptide-based radiopharmaceuticals. Somatostatin is one of the most common peptides and is overexpressed in a multitude of malignancies, including breast cancer, small cell lung cancer, medullary thyroid cancer, and neuroendocrine tumors (NETs). Somatostatin is rapidly degraded; however, its derivative, octreotide, is very stable. Octreoscan (indium-111 diethylenetriamine penta-acetic acid [^{111}In-DTPA]) has been shown to be highly diagnostic for NETs. Affibody molecules[22] are classified as affinity ligands or scaffold proteins that are approximately 7 to 9 kDa. These proteins are based on a 58 amino acid residue derived from staphylococcus protein A, which binds immunoglobulin. Various applications have been applied to affibody use, including radiolabeled targeting for therapy.

Aptamers are single-stranded DND or RNA oligonucleotides (8 to 12 kDa; 10 to 100 bases) that are selected *in vitro* from a random library by a process termed *SELEX* (systemic evolution of ligands by exponential enrichment). Aptamers are an attractive alternative to larger mAbs because they are chemically synthesized (do not require a biologic system such as mAbs), have a low cost of production, exhibit high affinities, have a small size, are rapidly cleared from the circulation, have an unlimited shelf life, exhibit rapid tissue penetration, and are nonimmunogenic.[23] Aptamers fold into unique secondary and tertiary structures that not only exhibit high affinities for targets, but can also gain entry into target cells. The basic SELEX process consists of exposing a target to a random single-strand nucleic acid library, selecting candidates that bind to the target, repeating the process to further select candidates with increasing affinity for the target, and sequencing the final candidates (Fig. 29.2). Variations of SELEX include

selecting aptamers that bind cells, internalize into cells, or are delivered *in vivo*, respectively, termed cell-SELEX, cell internalization SELEX, and *in vivo* SELEX. The basic configuration of an aptamer in a random library is a 5′ forward primer-binding site, a random region, and a 3′ reverse primer-binding site. The selected candidates can therefore undergo PCR amplification. The typical complexity of random library is between $1 \times 10^{13–24}$ different random sequences. For example, if the random region consists of 30 possible nucleotides, then potentially 1×10^{18} different aptamers will be available. In this particular example, 1×10^{18} represents a different aptamer or "key" for every grain of sand in the entire world. This is an amazingly large and diverse screening tool. The major detriment of using aptamers as targeting constructs for RIT is their short serum half-life (measured in minutes) secondary to nuclease degradation. Fortunately, research has shown that aptamers can be rendered nuclease resistant with the following modifications; 5′-modified uracil, 4′-thio, 2′-fluoro, 5′-*α*-P-borano, 2′-amino, 2′-deoxy-L-ribose, 5′-phosphorothio, 2′-methoxy, modification of bases.[29] Aptamers are amazingly versatile and can recognize nearly any type of target, from metal ions to whole cells and even entire organisms. Because of their chemical synthesis, aptamers seem to have a great chance of becoming a true tumor-specific and personalized delivery construct. Aptamers for cancer imaging or therapy are shown in Table 29.3.

THE PHYSICS AND RADIOBIOLOGY OF RADIOIMMUNOTHERAPY

RIT delivers radiation to the target tissue in a continuous, although declining, low–dose rate (LDR) fashion. Typical dose rates for RIT are in the range of 10 to 20 cGy per hour. The total dose delivered by RIT is low, in the range of 1,500 to 2,000 cGy, with an effective half-life of 24 to 72 hours. This can be compared to the high–dose rate (HDR) delivery of radiation by external beam radiation therapy (EBRT). EBRT typically will deliver radiation at a dose rate of 100 to 500 cGy per minute. This total dose range for RIT occurs despite overall very low percent injected doses (0.1% to 10.0%) that ultimately localize in target tissue.[30] Regardless, radiation-induced apoptosis still occurs.

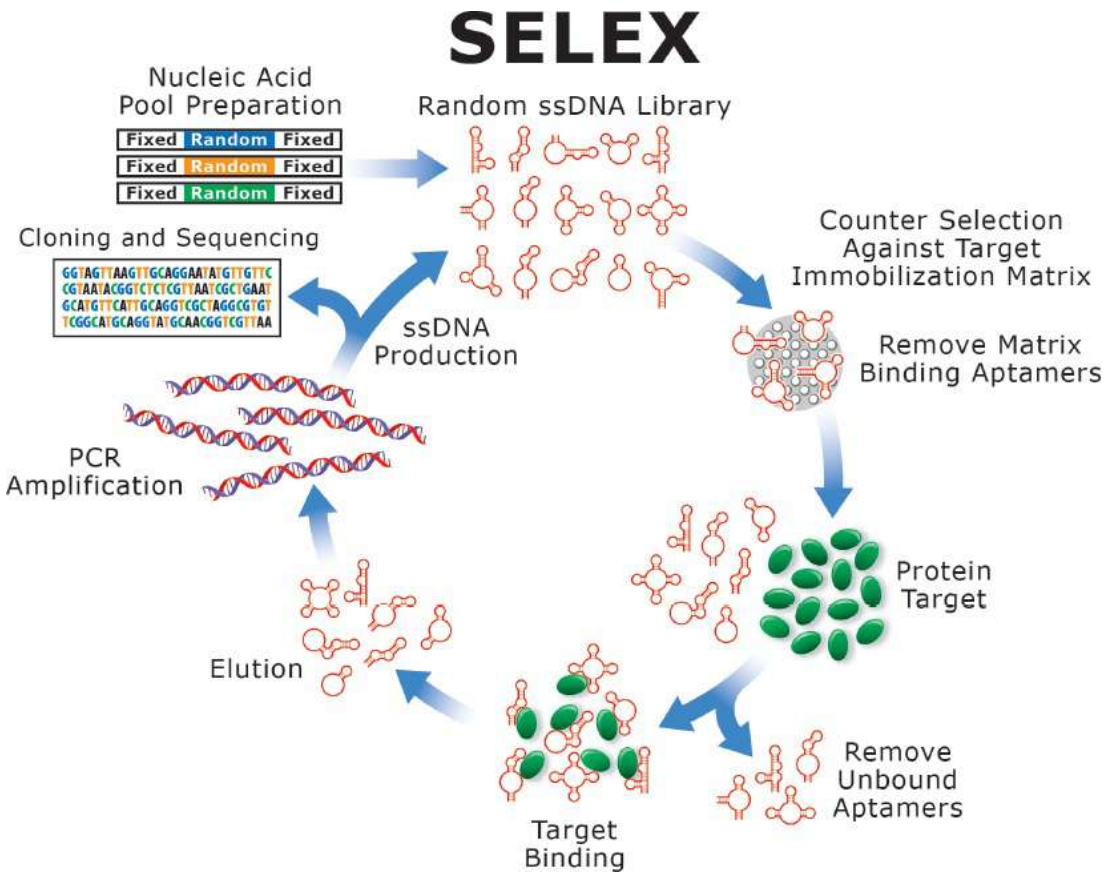

FIGURE 29.2. SELEX: A random ssDNA (or ssRNA) library is synthesized and exposed to laboratory equipment and target matrix. The aptamers that bind are considered nonspecific and are removed. The remaining aptamers are exposed to the target protein. Aptamers that don't bind are removed. Aptamers that bind the target are eluted and PCR amplified. Candidate "sense" strand aptamers are isolated and the SELEX process is repeated in order to refine the selection process. Final candidates are cloned and sequenced.

The most radiosensitive component of a cell is the DNA. Irradiation of tissue results in DNA damage. This damage may be either repaired or result in permanent damage. Permanent damage will cause cell death. By using a target-hit model, the tissue response end point of cell death may be used to relate absorbed dose of ionizing radiation to cell death. When the log surviving fraction of irradiated cells is plotted on the ordinate and the dose (Gy) is plotted on the abscissa, a cell survival curve is generated (Fig. 29.3). The "hit" that results in most lethal event is a double-strand break (DSB) of DNA. The mathematical term, α, represents the initial slope of the cell survival curve. It is a constant for a given tumor (or tissue) and can be thought of as the probability, per unit of absorbed dose, of creating a lethal DSB.[31] The target is the resulting DSB, and the cell survival versus absorbed dose is a pure exponential function:

$S = e^{-}\alpha D$ where S is the surviving cell fraction and D is the mean absorbed dose. Ionizing irradiation may also cause nonlethal single-strand breaks (SSBs). If these events accumulate, they may become lethal. The constant, β, is used to describe this phenomenon and represents the more distant, "linear" portion of the cell survival curve. The linear-quadratic (LQ) model combines the two processes into a continuously bending curve: $S = e^{\alpha D\text{-}\beta D^2}$

TABLE 29.3 APTAMERS FOR CANCER IMAGING AND THERAPY (PRECLINICAL AND CLINICAL)

Aptamer	Target	Condition	Radionuclide	Application
AS1411	Nucleolin	Renal cell carcinoma, non–small cell lung carcinoma, leukemia	None	Therapy
AS1411	Nucleolin	Glial tumor	^{67}Ga	Imaging
Sgc8	Protein tyrosine kinase 7 (PTK-7)	Leukemia	None	Therapy
TD05	Immunoglobulin μ heavy chains (IGHM)	Lymphoma, leukemia	None	Therapy
NOX-A12	CXCL12/SDF-1	Glioblastoma, multiple myeloma, solid tumors	None	Therapy
14-16	p68	Colon cancer	None	Therapy
TTA1	Tenascin-C	Glioblastoma	^{111}In, ^{18}F	Imaging
AptA, AptB	MUC1	Breast cancer	^{99m}Tc	Imaging
A9	PSMA	Prostate cancer	^{89}Zr	Imaging
A10	PSMA	Prostate cancer	^{225}Ac	Therapy
F3	hMMP-9	Various cancers, metastases	^{99m}Tc	Imaging
U2	EGFRvIII	Glioblastoma	^{188}Re	Imaging
E07	EGFR	EGFR-expressing cells	^{111}In	Imaging
Mini 15-8	ErbB2	HER2-expressing tumors	^{99m}Tc	Imaging
Apt3, Apt3–amine	CEA	CEA-expressing tumors	^{99m}Tc	Imaging
A30	HER3	Breast cancer	None	Therapy
TTA1	Tenascin-C	Breast, colon, lung, glioblastoma	^{99m}Tc	Imaging
5TR1	O-glycan-peptide	Breast, colon, lung, ovary, pancreatic	None (photodynamic therapy agent)	Therapy
J18	EGRF	EGFR-expressing tumors	None (gold	Therapy

			nanoparticles)	
Clone5	Sialyl Lewis X	Sialyl Lewis X–expressing tumors	None	Therapy
CTLA-4 aptamer	CTLA-4	CTLA-4 receptor	None	Therapy
A07	TGF-*β*	Chinese hamster ovary	None	Therapy
ST1571	PDGF *β*-receptor	Colon	None	Therapy
III.1	Pigpen	Glioblastoma	None	Therapy

CTLA-4, cytogenic T-cell antigen-4; CXCL2, C-X-C motif chemokine 12; EGFRvIII, epidermal growth factor receptor variant III; HER3, human epidermal growth factor-3; hMMP-9, human matrix metalloprotease-9; SDF-1, stromal cell–derived factor-1; TGF-*β*, transforming growth factor-*β*.

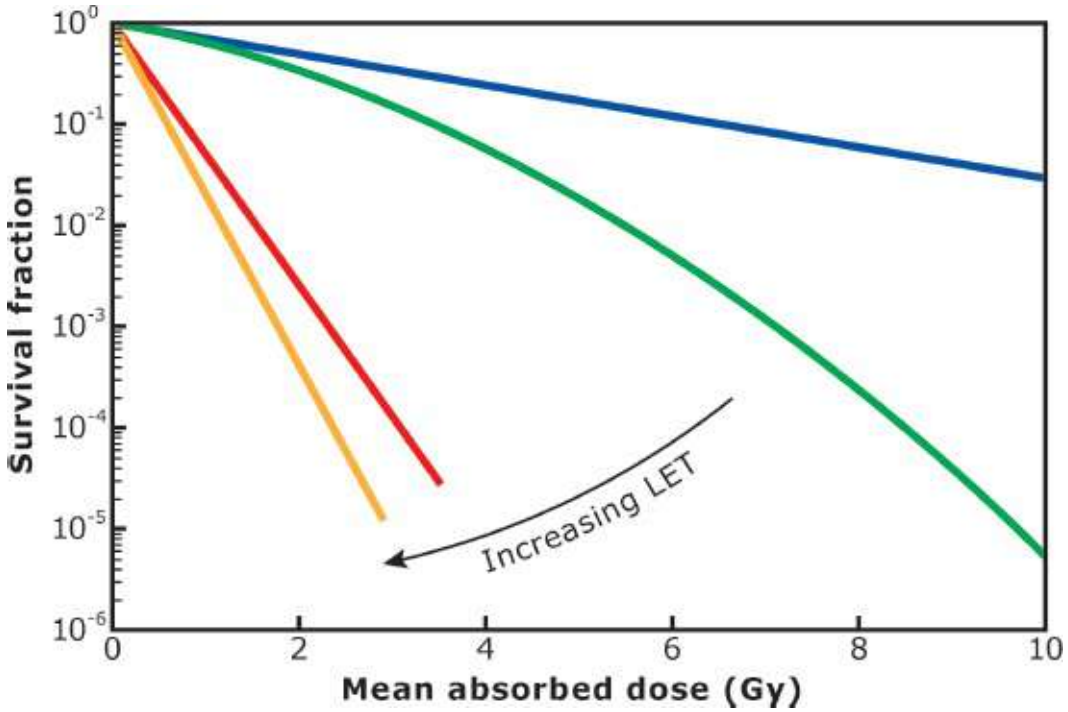

FIGURE 29.3. Cell survival curves following treatment with radiotherapy. The *blue curve* represents low–dose rate radiotherapy; the *green curve* represents high–dose rate radiotherapy. Increasing LET is represented by the *red line* (alpha particle radiation; RBE = 5) and *gold line* (Auger radiation; RBE = 7 to 9). (Adapted from Bernhardt P, Speer TW. Modeling the systemic cure with targeted radionuclide therapy. In: Speer TW, ed. *Targeted radionuclide therapy*. Philadelphia: Lippincott Williams & Wilkins, 2011:265. With permission.)

The shoulder on the cell survival curve is typically observed when HDR radiation is employed (green line in Fig. 29.3). In RIT, the dose rate is 1,000-fold lower; therefore, the quadratic portion of the curve will have a much lower impact on survival because many SSBs, considered sublethal damage, will be repaired during the more lengthy delivery of LDR radiation. This will result in a

"small" or absent observable shoulder and flattening of the cell survival curve. Thus, when estimating cell survival for RIT, α alone will define the radiosensitivity of the tumor (blue line in Fig. 29.3). Considering dose rate alone, RIT is approximately 20% less effective than HDR EBRT. Regardless, RIT does appear to be effective. This phenomenon can be attributed to many radiobiologic processes that appear to cause greater than predicted rates of apoptosis. These processes include low-dose/dose rate apoptosis, low-dose hyperradiosensitivity-increased radioresistance, inverse dose rate effect (G_2 synchronization), radiation-induced biologic bystander effect, and the crossfire effect.[30] The use of high-LET radiation, in the form of alpha particles or Auger electrons, will further increase cell kill.

TABLE 29.4 POTENTIAL RADIONUCLIDES FOR RADIOIMMUNOTHERAPY

Radionuclide	Physical Half-Life	E_{ave} (MeV)[a]	Maximum Range in Tissue	LET (keV/μm)	Approximate Cell Diameters
Beta-emitters		β-Particle		0.2	
Yttrium 90	2.7 d	2.19	12.0 mm		400–1,100
Iodine 131	8.0 d	0.28	2.0 mm		10–230
Lutetium 177	6.7 d	0.15	1.5 mm		4–180
Rhenium 186	3.7 d	0.36	3.6 mm		15–360
Rhenium 188	17.0 h	0.80	11.0 mm		200–1,000
Copper 67	2.6 d	0.18	2.8 mm		5–210
Phosphorus 32	14.3 d	0.70	7.6 mm		760
Phosphorus 33	25.3 d	0.08	0.6 mm		60
Holmium-166	1.1 d	1.86	8.4 mm		840
α-Emitters		*α- Particle*		*80*	
Bismuth-213	45.7 min	5.87	55–60 μm		5–6
Bismuth-212	60.6 min	6.09	60–70 μm		6–7
Astatine-211	7.2 h	5.87	55–60 μm		5–6
Actinium-225	9.92 d	5.83	60–90 μm		5–8
Terbium-149	4.12 h	3.97	30–60 μm		3–6
Low-Energy Electron Emitters (Auger)		*Low-Energy Electron*		*4–26*	
Iodine 125	60.1 d	0.030	2–500 nm		<1
Iodine 123	0.55 d	0.030	2–500 nm		<1
Gallium 67	3.26 d	0.009	2–500 nm		<1

Indium 111	2.80 d	0.026	2–500 nm	<1
Technetium 99m	6.01 h	0.018	2–500 nm	<1
Platinum-193m	4.33 d	0.053	2–500 nm	<1
Platinum-195m	4.02 d	0.063	2–500 nm	<1
Platinum-191	2.80 d	0.072	2–500 nm	<1
Antimony-119	38.9 h	0.028	2–500 nm	<1
Thallium 201	72.9 h	0.078	2–500 nm	<1
Bromine-77	57.0 h	0.012	2–500 nm	<1
Bromine-80m	4.4 h	0.013	2–500 nm	<1
Chromium 51	27.7 d	0.005	2–500 nm	<1

[a]When appropriate.
Data were obtained from Eckerman KF, Endo A. eds. *MIRD Radionuclide Data and Decay Schemes*. 2nd ed. SNM MIRD Committee, 2008.
E_{max}, maximum energy; LET, linear energy transfer.

Various radionuclides have been proposed for the use in RIT (Table 29.4), and their physical properties have been extensively reviewed in the nuclear medicine literature. They can be grouped into three basic categories depending on the type of emitted particulate radiation. Radionuclides that emit high-energy electrons are referred to as β-emitters. These electrons have maximum path lengths in tissue from 0.6 to 12.0 mm. This translates into a range of approximately 60 to 1,100 cell diameters. The most commonly used β-emitters for RIT are yttrium 90 [^{90}Y], iodine 131 [^{131}I], and lutetium 177 [^{177}Lu]. The maximum range of electrons in tissue for ^{90}Y and ^{131}I is 12 and 2 mm, respectively. It should be noted, however, that 90% of the electron energy is deposited over 5.2 mm for ^{90}Y and 0.7 mm for ^{131}I. This range of 90% energy deposition is referred to as the R_{90}. The most commonly used α-emitters for RIT are ^{211}At and ^{225}Ac. An α-particle is a helium nucleus that has a maximum range in tissue of 55 to 100 μm (5 to 10 cell diameters). Although it has a short range, the α-particle is very destructive and has a high linear energy transfer (LET). Low-energy electron emitters also emit radiation that is high LET and have path lengths between 2 and 500 nm (width of a double-strand helix). Auger emitters, such as ^{111}In or ^{125}I, are most effective if delivered to the nucleus of a cell or incorporated into the DNA. It has been mathematically postulated that it will only take 60 decays of ^{125}I, coupled to DNA, to reduce cell survival to 50%. For a patient with 1-g circulating micrometastatic disease, 1,000 decays in the malignant cells can produce a probable cure. This amount of radiation corresponds to 0.1-MBq injected activity. This represents 5 mSv per 1 year of background radiation for the average human.[32] To further place this in perspective, Auger emitters can be

safely injected into humans with an activity between 100 and 350 mCi, perhaps even at higher activities. It should be understood, 100 mCi = 3700 MBq; 1 MBq = 1,000,000 dps.

Because radionuclides have different energy spectra for their emitted particulate radiation, they will each interact with tissue and deposit their energy over varying distances. There is therefore a relation between the type of radionuclide, tumor size, absorbed dose, and ultimately tumor cure probability (TCP). If it is assumed that a tumor has a spherical volume and contains a uniform and identical activity concentration of a radionuclide, then the TCP can be calculated for different radionuclides and tumor size.[33] Figure 29.4 illustrates the relation between tumor mass and TCP for astatine-211 [^{211}At], lutetium 177 [^{177}Lu], ^{131}I, and ^{90}Y. As can be seen, there is an optimum tumor size for the different energy spectra for each radionuclide such that the TCP is maximized. If the tumor is small relative to the emission range, then much of the energy will be lost to the surrounding tissue and the absorbed dose will be low. As the tumor size increases, more energy is absorbed until the maximum TCP is reached. As the tumor further increases in size, the absorbed energy remains high, although fewer cells are affected by the radiation and TCP begins to decrease.[33] These observations move forward the concept of using multiple radionuclides, in the RIT process, that deposit their energies over different ranges in tissue. As a result, more energy could then be deposited into tumors of various sizes, potentially improving the therapeutic ratio.

Labeling the targeting construct with the appropriate radionuclide (radiochemistry) is exceedingly important and equally complex. Radionuclides are attached to targeting constructs by either using a “linker” molecule, termed a *bifunctional chelating agent* (BCA), or by a chemical reaction that forms a covalent bond between the radionuclide and the targeting construct. Three basic scientific fields converged to make radiochemistry a reality: coordination chemistry, directed biologic targeting, and the medical application of radiopharmaceuticals.[34] In general, metallic radionuclides will require a BCA for labeling, and radiohalogens will require a chemical reaction (halogenation). The most prevalent therapeutic radionuclides used in RIT are ^{90}Y (metallic radionuclide) and ^{131}I (radiohalogen). One of the most commonly used BCAs is DTPA—a polyaminopolycarboxylate straight chain ligand. Tiuxetan, a modified DTPA molecule, is used as a linker molecule to chelate ^{90}Y to ibritumomab (^{90}Y ibritumomab tiuxetan; Zevalin, Spectrum Pharmaceuticals, Henderson, NV). Tiuxetan forms a urea-type bond to the antibody (ibritumomab), and its five

carboxyl groups interact with and chelate ^{90}Y to form a stable coordination sphere. The halogenation reaction that bonds ^{131}I to a protein-targeting construct (^{131}I tositumomab; Bexxar, GlaxoSmithKline, Philadelphia, PA; discontinued 2013) is called iodination. Although there are many permutations of the iodination reaction, it basically inserts ^{131}I into a tyrosine group on the mAb without the need for a chelation molecule. Regardless of the required labeling technique, it is incumbent that a reasonably high labeling yield, unaltered biodistribution, stability of the radionuclide, and immunoreactivity are preserved.

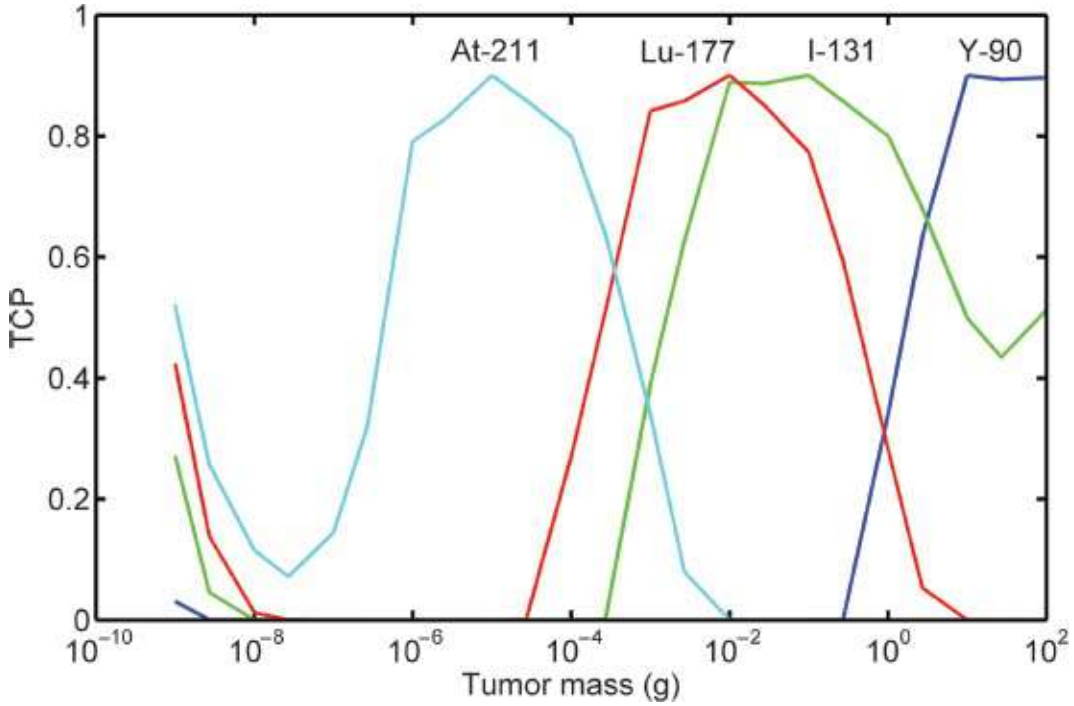

FIGURE 29.4. Tumor control probability (TCP) for various radionuclides. TCP = 0.9 versus tumor mass. The optimal TCP for various tumor masses when treated with ^{211}At, ^{177}Lu, ^{131}I, and ^{90}Y. This corresponds to approximately 10^{-5}, 10^{-2}, 0.1, and 10 g, respectively. (From Bernhardt P, Speer TW. Modeling the systemic cure with targeted radionuclide therapy. In: Speer TW, ed. *Targeted radionuclide therapy*. Philadelphia: Lippincott Williams & Wilkins, 2011:266. With permission.)

Historically, a single instillation or fraction of the RIT agent is delivered systemically (i.e., Zevalin and Bexxar). It is well known that although relatively effective for hematologic malignancies, RIT is much less effective for treating solid tumors. Therefore, a number of strategies are being developed that will potentially increase the effectiveness of RIT. These strategies include modulating the tumor microenvironment; using pretargeting techniques, extracorporeal

delivery, combined modality therapy (CMT), fractionation, and multiple radionuclides (radionuclide cocktail); increasing antibody mass (the amount of antibody delivered systemically); alteration of the physical properties (size and affinity) of the targeting construct; and employing different types of LET radiation (i.e., β-emitter vs. α-emitter). These strategies are designed to deliver more radiation to the tumor, make the radiation more cytotoxic, or decrease the exposure of radiation to bone marrow. As a result, the tumor to blood ratio will increase, and ultimately, the therapeutic ratio will increase. The pretargeting strategy warrants further discussion.[35,36]

Because radiolabeled mAbs take 2 to 3 days to localize or accrete into tumors, antibody-based RIT results in a prolonged exposure of the bone marrow to radiation, causing hematologic toxicity and rendering the bone marrow as the dose-limiting normal tissue. Accordingly, the tumor/blood ratios of mAb will only slightly favor the tumor. This situation can seriously limit the successful prospects of antibody-based RIT, especially for treating solid tumors. Smaller targeting constructs (antibody fragments, peptides, aptamers) can be used for RIT, and they will exhibit pharmacokinetics that result in a more rapid blood clearance allowing for the administration of higher activities. Unfortunately, because of the lower overall tumor accretion and retention of smaller constructs, the advantage of a more rapid blood clearance is usually offset. Therefore, the ideal delivery construct would manifest the high-affinity targeting properties of an intact mAb but exhibit the blood clearance pattern of a small molecular weight construct. This conventional wisdom is based upon using beta and alpha radionuclides, both of which will be toxic with long circulation times. If targeting constructs using Auger emitters can be engineered, the circulation time becomes rather immaterial as Auger radionuclides are only cytotoxic if internalized into cells. Because no known construct manifesting all of these attributes exists today, pretargeting strategies have been developed. The basic premise of pretargeting is to separate the delivery of a large, macromolecule-targeting construct (prolonged circulation time) from the delivery of a much smaller cytotoxic radioconjugate (more rapid circulation time). Two main approaches have been employed: a bispecific monoclonal antibody (bsmAb) system and a streptavidin–biotin system. In the bsmAb system (Fig. 29.5), a portion of the antibody has affinity for the tumor (antitumor), and another portion has affinity for the radionuclide carrier ligand or hapten–peptide (antihapten). Initially (step 1), a large “saturation” dose of the unlabeled bsmAb is administered, and the antibody localizes in the tumor over several days.

Occasionally, a clearing step is used to facilitate the clearance of the bsmAb from the circulation. Subsequently (step 2), a radionuclide conjugated to a hapten–peptide is administered that has high affinity for the antihapten portion of the bsmAb. This step results in a rapid distribution of the radionuclide in the tumor owing to the high affinity of the hapten–peptide for the bsmAb. Because the hapten–peptide has a small molecular weight, it will clear rapidly from the body and result in a low–bone marrow exposure to radiation. In the streptavidin–biotin system, streptavidin is conjugated to the initial pretargeting macromolecule, and biotin is conjugated to the radionuclide. Streptavidin and biotin have a very high affinity for each other (10^{15} M^{-1}). When either system is used, the tumor/blood ratios of the targeting agent are significantly increased, but there may be some advantages to the bsmAB system.[37,38]

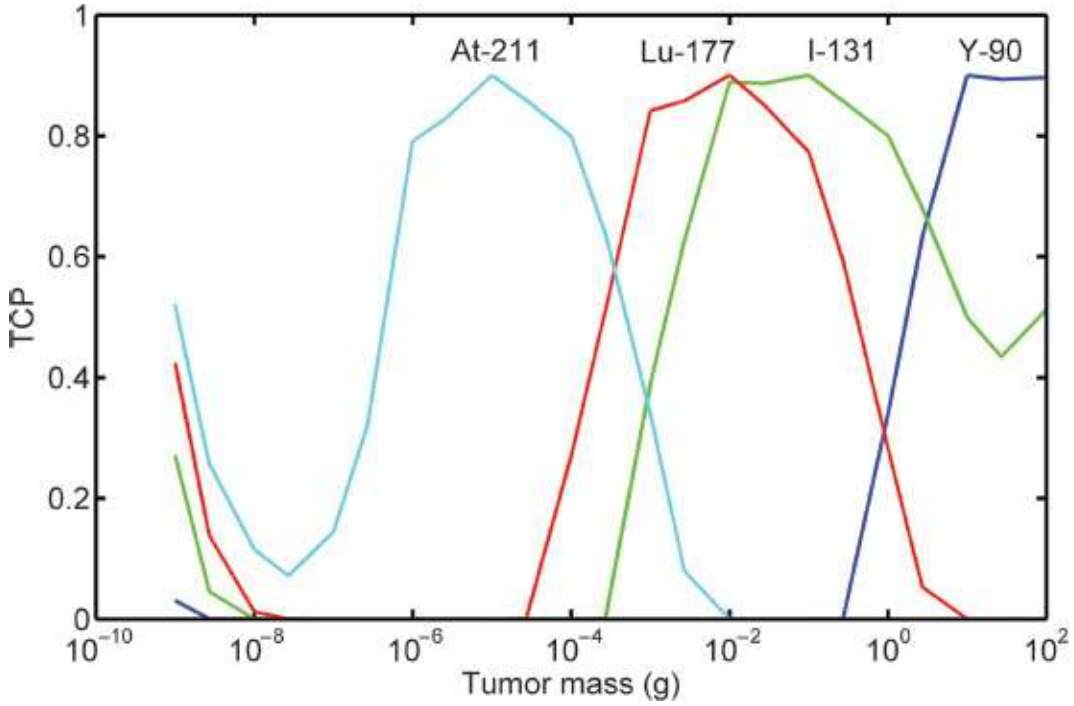

FIGURE 29.5. Bispecific pretargeting procedure. The bsMAb is injected, and over several days, it will localize in the tumor and clear from the blood. The bsMAb shown in this example is based on the dock-and-lock method for preparing recombinant bsMAb that has two binding arms for the tumor and one for the hapten. Once the molar concentration of the bsMAb is low enough, the radiolabeled hapten–peptide is given. The hapten–peptide has two haptens for more stable binding within the tumor, perhaps by cross-linking two adjacent bsMAb through a process known as the affinity enhancement system (AES). The peptide portion usually contains four to five D-amino acids with a single chelator bound to one of the amino acids that is used to capture the radionuclide. (From Sharkey RM, Goldenberg DM. Pretargeted radioimmunotherapy. In: Speer TW, ed. *Targeted radionuclide therapy*. Philadelphia: Lippincott Williams & Wilkins, 2011:194. With permission.)

CONJUGATED THERAPY

The current state of RIT continues to improve. The basic premise has been the delivery of targeted cytotoxic radiotherapy that is low dose, LDR, sparsely ionizing and delivered in a single fraction. Initially, this reality seemed to be a natural "fit" for hematologic malignancies that were sensitive to most types of radiation. However, for RIT to ultimately impact significantly upon the world of oncology, it is clear that current approaches need to be modified so that it can be applied to carcinomas. Zevalin and Bexxar were FDA-approved in 2002 and 2003, respectively, as RIT drugs to treat relapse follicular NHL for an end point of progression-free survival. Subsequently, Zevalin received an approved frontline indication (FIT trial). Bexxar was withdrawn from production by GlaxoSmithKline (GSK) in 2013. Currently, Zevalin is greatly underutilized because it has not shown a survival benefit for its respective indications and there are other competing drugs that are not radioactive and don't require close coordination with medical departments such as medical oncology, radiation oncology, and nuclear medicine. Table 29.5 lists FDA-approved and current phase III RIT drugs. Progress has been less sanguine for solid tumor malignancies, and phase III trials are lacking.[39,40] For the sake of clarity and brevity, this section will focus on clinically relevant phase II/III trials and U.S. FDA (or its international equivalent)-approved RIT therapeutics.

Hematologic Trials and Approved Therapeutic Agents

The National Comprehensive Cancer Network (NCCN) guidelines have recommended RIT for the following follicular lymphoma clinical situations: (1) first-line therapy for the elderly or infirm (Category 2B), (2) first-line consolidation (Category 2B), and (3) second-line (relapse/refractory) and subsequent therapy (Category 1). Initially, the NCCN guidelines rendered a Category 1 designation for first-line consolidation but downgraded this to Category 2B because of concerns about toxicity, although there is not a uniform consensus.[41] Zevalin continues to show very promising results for follicular lymphoma first-line monotherapy, diffuse large B-cell lymphoma and mantle cell lymphoma consolidation and second-line therapy, and transplantation studies. To date, however, none of these approaches have reached clinical phase III status. Zevalin has the only U.S. FDA approval for first-line consolidation and second-line therapy.

Currently, there is only one U.S. FDA-approved RIT agent in the United States: ^{90}Y ibritumomab tiuxetan (Zevalin; 2002). ^{131}I tositumomab (Bexxar;

2003) was removed from the market in 2013 by GSK. The demise of Bexxar was not because of lack of efficacy or toxicity, but because of unforeseen market pressure and financial decisions (http://www.xconomy.com/national/2013/08/26/why-good-drugs-sometimes-fail-in-the-market-the-bexxar-story/). Both will be briefly discussed as they represent common RIT paradigms. Zevalin has U.S. FDA approval for relapsed or refractory follicular NHL and as a frontline adjuvant agent for follicular NHL achieving a complete response (CR) or partial response (PR) to induction chemotherapy. Bexxar had U.S. FDA approval for the relapse or refractory setting as well as transformed NHL. Both are murine IgG mAbs that target the CD20 surface antigen on follicular NHL.[42] ^{90}Y ibritumomab tiuxetan utilizes ^{90}Y, a pure β-particle emitter with a physical half-life of 2.7 days. The β-particle has an energy of 2.3 MeV and a maximum tissue penetration of approximately 12.0 mm (R_{90} = 5.2 mm). Tiuxetan is a DTPA-type chelate that attaches ^{90}Y to the mAb, ibritumomab. Because there is no gamma emission in the spectrum of this isotope, it is not visualized by gamma camera scans. As a result, a biodistribution assessment cannot be performed. Therefore, a surrogate imaging radionuclide that emits gamma radiation ^{111}In is required. In contrast, ^{131}I tositumomab is a mixed β-/γ-emitter. The gamma spikes at 364 keV, and the beta emission has energy of 0.6 MeV. The maximum range in tissue of the β-particle is 2.3 mm (R_{90} = 0.7 mm). This agent can be imaged on gamma camera to calculate total body clearance.

TABLE 29.5 FDA-APPROVED AND CURRENT PHASE III RIT DRUGS

Drug Name	Targeting Construct	Target	Radionuclide	Disease	Pipel
Zevalin (Ibritumomab Tiuxetan)	IgG1 (Murine)	CD20	^{90}Y	NHL (low-grade follicular)	FDA 2
Bexxar[a] (Tositumomab)	IgG2a (Murine)	CD20	^{131}I	NHL (low grade follicular)	FDA 2
Lutathera (^{177}Lu–DOTATATE)	Octreotate peptide	Somatostatin receptor	^{177}Lu	Midgut neuroendocrine tumors	Phase con
Zevalin	IgG1 (murine)	CD20	^{90}Y	Relapse DLBCL/ASC transplant	Phase con
131I–chTNT	IgG1	Histone	^{131}I	Non–small cell lung	Phase

	chimeric murine	H1/DNA		cancer (postoperative)	con
Licartin (131I–Metuximab)	$F(ab')_2$	CD147	^{131}I	HCC with RFA	Phase con
Zevalin	IgG1 (Murine)	CD20	^{90}Y	Relapsed follicular NHL/consolidation	Phase rec (NC
Zevalin	IgG1 (Murine)	CD20	^{90}Y	Untreated follicular NHL	Phase rec (NC
Iomab-B (BC8-I-131)	IgG1 (Murine)	CD45	^{131}I	AML	Phase rec (NC
^{111}In–Pentetreotide	Octreotate peptide	Somatostatin receptor	^{111}In	Resected GI neuroendocrine tumors	Phase rec (NC
177Lu–Edotreotide	Octreotate peptide	Somatostatin receptor	^{177}Lu	GEP-NET	Phase rec (NC

[a]Withdrawn from production by GlaxoSmithKline in 2013.

For both agents, the treatment is delivered over 1 to 2 weeks. On day 1, both protocols deliver an infusion of nonradioactive (cold) anti-CD20 antibody (Zevalin employs rituximab; Bexxar employed tositumomab) designed to saturate the CD20 antigen sink (depletion of peripheral B cells and the binding of nonspecific sites in the liver and spleen) and provide antibody mass, which improves biodistribution and tumor targeting.[43,44] The administered activity for Zevalin is based on weight (0.4 mCi/kg for a platelet count ≥150,000; 0.3 mCi/kg for a platelet count of 100,000 to 149,000; maximum of 32 mCi). A single gamma scan (^{111}In ibritumomab tiuxetan) is used to confirm a normal biodistribution on days 3 to 4. A review of the Zevalin imaging registry reveals that only 0.6% of scans exhibited an altered biodistribution. Subsequently, the delivery of Zevalin has been simplified. Based upon the analysis of five trials, which revealed an altered biodistribution scan in only about 1% of patients, the FDA removed the requirement of the biodistribution scan. The administered activity for Bexxar was based on a calculated total body clearance (three scans over 1 week) that delivers a total-body (red bone marrow) dose of 75 cGy. This calculation is reduced to a total-body dose of 65 cGy for a platelet count <150,000. Eligible patients for Zevalin are also required to have an absolute neutrophil count (ANC) ≥1,500 and a bone marrow biopsy that reveals <25%

lymphoma involvement.

Relapse Setting

Multiple prospective clinical trials have provided evidence for the use of RIT for treating relapsed or refractory follicular NHL. Together, they represent >200 patients treated with either Zevalin or Bexxar. Both agents appear to suggest an overall response rate (ORR) of 60% to 80% and a CR rate of 20% to 50%. Zevalin trials have been extensively reviewed.[45,46]

A phase III study comparing Zevalin versus rituximab for patients with relapsed or refractory low-grade follicular B-cell NHL or transformed NHL was performed.[47] Patients were randomized to either a single intravenous (IV) dose of Zevalin 0.4 mCi/kg (n = 73) or IV rituximab 375 mg/m^2 weekly for four doses (n = 70). The RIT group was pretreated with two rituximab doses (250 mg/m^2) to improve biodistribution and tumor targeting. After the first rituximab dose on day 1, ^{111}In ibritumomab tiuxetan was administered to assess biodistribution and to aide in dosimetry. No patients received the therapeutic dose of ^{90}Y ibritumomab tiuxetan (Zevalin) if >20 or 3 Gy was calculated to any nontumor organ or the red marrow, respectively. Zevalin was administered after the second rituximab dose approximately 1 week (days 7 to 9) after the first dose of rituximab and (^{111})In ibritumomab tiuxetan. The administered activity of Zevalin was capped at 32 mCi. Patients in both arms of the study received two prior chemotherapy regimens. The ORR was 80% for Zevalin and 56% for rituximab (P = .002). The CR rates were 30% and 16% (P = .04), respectively, in the Zevalin and rituximab group. Durable responses ≥6 months were 64% versus 47% (P = .030) for Zevalin versus rituximab. The conclusion of the study was that RIT with Zevalin was well tolerated and resulted in statistically significant and clinically significant higher ORRs and CRs than rituximab alone.

Frontline Therapy

Considering the concerns about RIT for treating large bulky tumors (tumor penetration, overall required dose, nonuniform dose distributions), bringing RIT into a frontline therapeutic setting after induction chemotherapy and maximum cytoreduction would be the next logical direction. A phase III first-line indolent trial (FIT) of consolidation with Zevalin compared to no additional therapy after first remission was reported for follicular B-cell NHL.[48] Patients with CD20+ stage III/IV follicular B-cell NHL who achieved a PR or CR to induction chemotherapy were randomized to Zevalin (n = 208) or to the control arm,

representing no further treatment (n = 206). Prior to chemotherapy, patients had documented <25% bone marrow involvement. After induction chemotherapy, blood counts had to recover such that the ANC was ≥1.5, platelets were ≥150,000, and hemoglobin was ≥9. Patients in the Zevalin arm were treated with an activity of 0.4 mCi/kg; a maximum activity of 32 mCi was allowed. Although two doses of rituximab (250 mg/m^2) were used, an ^{111}In biodistribution scan was not required. The data were analyzed with a median follow-up of 3.5 years. Zevalin consolidation resulted in a median progression-free survival (PFS) advantage of 36.5 versus 13.3 months in the control arm (P < .0001). The PFS benefit was maintained in the Zevalin arm regardless if patients achieved a PR (29.3 vs. 6.2 months; P < .0001) or CR (53.9 vs. 29.5 months; P = .0154). The benefit of Zevalin consolidation was maintained across all Follicular Lymphoma International Prognostic Index (FLIPI) subgroups. In patients with a PR after induction chemotherapy, 77% were further converted to a CR when treated with Zevalin. This resulted in a final CR rate of 87% in the treatment arm, and this result compares well with established data. In the treatment arm, 90% of patients who were Bcl-2 positive converted to a negative status (90% molecular CR). Toxicity was well managed and primarily hematologic. A total of 8% of patients experienced a grade 3 to grade 4 infection. There were no treatment-related deaths. The FIT trial has been updated and with a median follow-up of 7.3 years ^{90}Y-ibritumomab consolidation results in a 3-year benefit in median PFS (41% vs. 22%; P < .001) and improves time to next treatment by 5.1 years (P < .001). Second malignancies were not statistically different.[49]

SOLID TUMOR TRIALS AND APPROVED THERAPEUTICS

Peptide receptor radionuclide therapy (PRRT) has been successfully used for greater than a decade to treat advanced NETs expressing somatostatin receptors. The most common PRRT agents are ^{177}Lu–DOTATATE and ^{90}Y–DOTATOC.[19,20] A phase III trial (NETTER-1) was performed, which randomized 229 patients with metastatic midgut NETs to either ^{177}Lu–DOTATATE (Lutathera) versus octreotide LAR (long-acting repeatable). The ^{177}Lu–DOTATATE was administered at an activity of 7.4 GBq (200 mCi) per infusion, every 8 weeks for a total of 4 doses. The ^{177}Lu–DOTATATE group exhibited a significant progression-free survival (P < .001) and overall survival (P = .004). Toxicity was acceptable.[50] Lutathera gained US FDA approval for somatostain receptor positive gastroenteropancreatic neuroendocrine tumors on

1/26/2018.

Lung cancer remains the leading cause of cancer mortality in the world. Clearly, new strategies are required to help improve local and systemic control. There are data to support the concept of targeting necrotic and hypoxic regions of tumors.[51] The selective targeting of dead or dying cells will allow a cytotoxic event of nearby malignant cells by the bystander and crossfire effect. Additionally, only one type of targeting construct needs to be manufactured to target many different types of malignancies. If the cell surface antigen does not internalize to any significant degree, then a typical targeting construct will remain on the cell surface. Because dead and dying cells (undergoing apoptosis) exhibit disruption of their cell membrane, constructs that target intracellular products of apoptosis will then be able to gain access to the cell cytoplasm and nucleus. Although several "dead cancer cell antigens" are under investigation, tumor necrosis therapy or treatment (TNT) has been investigated in human trials. TNT is an IgG_{2a} mAb that targets nuclear histones.[52]

A pivotal trial of iodine-131–chimeric tumor necrosis treatment (^{131}I-chTNT) in advanced lung cancer patients was performed.[53] A total of 107 patients (*n* = 97, non–small cell; *n* = 10, small cell) were enrolled from 1999 to 2002. All patients had failed at least one prior therapeutic regimen (mean = 3; range = 1 to 5), and 86.9% of the patients had stage III to stage IV disease at study entry. In all cases, the patients received two instillations of ^{131}I-chTNT administered over 2 to 4 weeks. Sixty-two patients received IV administrations, and 45 patients received intratumoral injections of ^{131}I-chTNT. IV administrations were delivered at an activity 0.8 mCi/kg, and intratumoral injections were delivered at an activity of 0.8 mCi/cm^3 of tumor size. In all patients (*n* = 107), the ORR was 34.6% (3.7% CR; 30.8% PR; 55.1% no change or stable disease; 10.3% progressive disease). Of the 62 patients receiving a systemic administration of ^{131}I-chTNT, the ORR was 35.5% (3.2% CR; 32.2% PR). Of the 45 patients receiving intratumoral injection of ^{131}I-chTNT, the ORR was 33.3% (5% CR; 20.9% PR). In 58 evaluable patients, the median survival was 11.7 months, and the 1-year survival rate was 41.4%. The average absorbed doses for tumor and normal lung were 8.45 and 2.35 Gy for patients receiving systemic ^{131}I-chTNT and 30.0 and 2.65 Gy for patients receiving intratumoral ^{131}I-chTNT. The major toxicity was hematologic and reversible. As expected, the hematologic toxicity was lower in the intratumoral injection group. In 2003, ^{131}I-chTNT was approved by the Chinese State Food and Drug Administration to treat refractory bronchogenic carcinoma.

A phase III trial was performed randomizing patients with stage II-IIIA non–small cell carcinoma of the lung, requiring chemoradiotherapy after surgery.[54] Group A included 49 patients treated with chemotherapy (docetaxel and cisplatin) and external beam radiotherapy. Group B included 47 treated with ^{131}I-chTNT and percutaneous microwave coagulation therapy (PMCT), with further chemotherapy. Survivals at 1 and 2 years for groups A and B were 80% and 49% versus 83% and 53% ($P < .05$). Adverse events and median survival were similar.

HCC, or liver carcinoma, represents a significant worldwide malignancy. Resection and orthotopic liver transplantation (OLT) represent the only potential curative options. In 1989, the Radiation Therapy Oncology Group (RTOG) reported its first and only phase III RIT trial comparing EBRT and chemotherapy to the same treatment plus ^{131}I antiferritin antibody. None of the patients receiving EBRT and chemotherapy only were converted to a resectable state. In a separate analysis, 11 patients crossing over from the EBRT and chemotherapy arm to further therapy with ^{131}I antiferritin antibody were converted to resection. There was, however, no significant difference in the initial "intent-to-treat" treatment arms based on response rate and survival.[55] Of course, the most promising role of RIT is in the treatment of minimal residual microscopic disease.

Licartin is an antibody fragment, $F(ab')_2$, that targets HAb18G/CD147, a HCC TAA. The safety and pharmacokinetics of Licartin (^{131}I metuximab) have been investigated in phase I/II trials.[56] Realizing that TRT is most suited for treating microscopic disease, Licartin was tested in the adjuvant setting for patients with HCC undergoing OLT.[57] A total of 60 patients with HCC who were undergoing OLT were randomized to Licartin (0.42 mCi/kg) for three fractions at 28-day intervals versus placebo. Analysis at 1 year post therapy revealed that the recurrence rate was significantly decreased by 30.4% ($P = .0174$) and the survival rate was significantly increased by 20.6% ($P = .0289$) in the Licartin group. No significant toxicities were observed. The Chinese State Food and Drug Administration has approved Licartin as adjuvant therapy after OLT for HCC in 2005. To my knowledge, this trial has not been updated.

A phase III trial of radiofrequency ablation (RFA) for unresectable HCC with or without Licartin was performed.[58] Patients received RFA followed by Licartin ($n = 62$) or RFA alone ($n = 65$). Adverse events were similar and minimal in both arms. The median time to recurrence was 17 and 10 months for the RFA/Licartin group and RFA-alone group, respectively ($P = .03$).

Currently, the most common antigen targets for CNS malignancies consist of the epidermal growth factor receptor (EGFR), tenascin, neural cell adhesion molecule (NCAM), placental alkaline phosphatase (PLAP), and phosphatidyl inositide. The EGFR is variably amplified in malignant tissue and is also present, to some extent, in benign tissue. Tenascin is an extracellular glycoprotein that is uniformly expressed in glioma, and NCAM is present on both benign and malignant glioma cells. Clinical trials using RIT to treat CNS malignancies have been extensively reviewed.[59] A phase III trial was reported in 2002.[60] A total of 12 patients with malignant glioma were randomized to surgical resection and radiotherapy (60 Gy) (n = 5) versus surgical resection, radiotherapy, and RIT (n = 7). The RIT agent was a ^{125}I-anti–EGFR antibody 425 that was administered intravenously in three weekly doses (50 mCi) beginning during week 4 of the EBRT. All patients in the treatment arm had a recurrence at the time of publication. Considering that the EGFR was not tested in submitted tissue, the trial had a small number of patients, and the 150-kDa antibody was administered intravenously, significant conclusions could not be drawn.

Most of the CNS RIT trials to date are of “dose searching pilot” or phase I design. The evolution of the trials has seen the delivery route move from systemic (intra-arterial or IV) to local instillation of the RIT agent into a surgically created resection cavity (SCRC). Even though the blood–brain barrier (BBB) is often disrupted by a rapidly growing CNS malignancy, this phenomenon is not well defined, and 150-kDa antibodies would still not likely cross to a significant degree, although there does appear to be an element of nonspecific uptake from a systemic delivery. As a result, studies using the systemic approach often deliver EBRT in conjunction with TRT. It has been well documented that EBRT will cause an increase in the permeability of the BBB and increase vascular leakage. Regardless, it has been disappointingly estimated that only 0.001% to 0.01% of the systemically delivered antibody will penetrate each gram of solid tumor. Furthermore, biopsy data have revealed that a single systemic injection of radiolabeled anti-EGFR antibody will deliver only 0.02% of the injected activity per gram of tumor, resulting in a dose of only 100 to 200 cGy.

Direct instillation of the TRT agent into the SCRC is an attractive alternative to the systemic approach. Unlike other malignant sites where the potential for systemic spread mandates a systemic approach, this is not the case for malignant gliomas. The local approach is accomplished by injecting or instilling the RIT agent directly into the SCRC via an Ommaya or Rickham catheter. Preliminary

dosimetry is performed to ensure localization within the surgical bed and that no direct communication with the ventricular system has occurred. Institutions using this technique have utilized murine, chimeric, or humanized mAbs attached to ^{131}I, ^{90}Y, ^{188}Re, and ^{211}At. Other important treatment variances include fractionation, pretargeting, and a combined modality approach using EBRT and chemotherapy. The success of this approach will depend on meaningful penetration of the RIT agent into the local brain parenchyma such that the mAbs (or targeting construct) can bind to areas of microscopic extension of malignant cells at some distance from the SCRC margin. It is still unknown as to what impact the healing process/inflammation at the surgical margin has on the success of antibody penetration. As well, it is well known that binding site barrier phenomena, interstitial tumor pressure, aberrant tumor vasculature, and a recusant extracellular tumor matrix will significantly impede antibody penetration.[61]

Hopkins et al.[62] obtained biopsy data from three patients with glioma who received two to three cycles of either ^{131}I or ^{90}Y-ERIC-1 (anti-NCAM antibody) directly instilled into a SCRC. Relevant assumptions were that the SCRCs were spherical, the radionuclide was spread evenly around the resection margin, 100% of the RIT agent was bound to its target, and diffusion into the resection margin was uniform. It was shown that “modest” diffusion occurred and the process was exponential. The peak dose occurred between 0.16 and 0.18 cm beyond the resection margin, and 4.4% to 5.8% of the peak dose was delivered to a depth of 2 cm. Of note, NCAM is expressed on benign and malignant cells and perhaps a more tumor-specific antigen would allow for greater depth of penetration. Certainly, smaller targeting constructs have been shown to penetrate to a greater depth in brain parenchyma compared to intact antibodies.[63] Using the same antibody, radiolabeled with ^{131}I and instilled into a SCRC, it was shown that diffusion occurred from 0.5 to 1.0 cm (single-photon emission computed tomography [SPECT]). The range of antibody binding to the target was 8% to 80% of total injected activity. Because the R_{95} (thickness of tissue where 95% of the β energy is deposited) for ^{131}I is only 0.992 mm, it was concluded that a more optimal radionuclide would potentially be ^{90}Y with an R_{95} of 5.94 mm.[64] Assuming a 2-cm SCRC and 100% binding, as much as 351 Gy could be delivered to the tumor with a single instillation of 18.2 mCi of ^{90}Y-ERIC-1. This calculation resulted in an impressive minimum tumor/whole-brain dose ratio of 140:1.

Using ^{131}I-81C6 (antitenascin mAB), dose-limiting toxicity was reached with

a single injection of 80 mCi for leptomeningeal disease (intrathecal delivery), 100 mCi for heavily pretreated and recurrent glioma (into SCRC), and 120 mCi for de novo glioma (into SCRC) also receiving EBRT and chemotherapy.[65] Using a standard, fixed, mCi dose, a wide range of absorbed doses (18 to 186 Gy) will be delivered to a depth of 2 cm beyond the SCRC margin.[66] On further analysis, an optimal dose of 44 Gy to 2 cm beyond SCRC was identified. Doses <44 Gy resulted in increased recurrence rates, and doses >44 Gy resulted in a higher rate of necrosis. A trend toward significant improvement in median survival was shown for patients receiving 40 to 48 Gy versus <40 Gy.[64] Refining the technique further, it was shown that 20 of the 21 patients could be successfully dosed to 44 Gy by varying the initial injection activity and considering the volume of the SCRC.[67] Zalutsky et al.[68] showed that a high-LET, α-emitting radioconjugate (^{211}At-ch81C6) could be safely delivered in a small cohort of glioma patients. Interestingly, histopathology appears to correlate with prognosis. Biopsy data from patients with a suspected recurrence, after receiving ^{131}I-labeled antitenascin 81C6 antibody, were analyzed. Three types of histologic patterns were evident: proliferative glioma, quiescent glioma, and negative for neoplasm. The median survival for each histopathologic pattern was 3.5, 15.0, and 27.5 months, respectively ($P < .0001$). Considering total dose (EBRT plus radiolabeled antibody), patients receiving <86 Gy or >86 Gy had median survivals of 7 and 19 months, respectively ($P < .002$).[69]

A review of the major RIT CNS trials[59] indicates that the range of maximum tolerated activity is between 10 and 120 mCi. There are many variables that could potentially account for the noted range. In general, by performing dosimetry for a given radionuclide delivery construct, a specific absorbed dose can be calculated to a predetermined depth from the SCRC margin. It has been shown that ^{131}I-antitenascin 81C6 can deliver 2,000, 90, and 34 Gy to the cavity interface, 1 cm depth and at 2 cm depth, respectively.[64,69] The median survival for TRT in treating glioma appears extremely favorable when compared to other treatment approaches. For de novo lesions, the median survival range is 50.9 to 57.6 months (three studies not reaching median survival at the time of the report) for anaplastic astrocytoma and 13.4 to 35.5 months for glioblastoma. For recurrent lesions, the median survival range is 13.0 to 52.0 months (one study not reaching median survival at the time of the report) for anaplastic astrocytoma and 14.0 to 25.0 months for glioblastoma.[59] Unlike sealed source brachytherapy, there appears to be a very low rate of CNS toxicity and a reduced subsequent need for surgical intervention to remove necrotic areas. Building upon Duke

University research, Bradmer Pharmaceuticals developed two clinical trials using the ^{131}I-antitenascin antibody (Neuradiab) for treating glioblastoma in the de novo (phase III) and recurrent setting (phase II). Because of lack of funding, the trials were discontinued in 2010.

Cotara (Peregrine Pharmaceuticals) is a ^{131}I-chTNT-1/B mAb used to treat high-grade glioma that is continuously instilled into the SCRC with positive pressure, using a technology termed convection-enhanced delivery (CED).[70] A phase II trial was performed treating high-grade glioma (37 recurrent glioblastomas, 8 de novo glioblastomas, 6 recurrent anaplastic astrocytomas). The Cotara infusions delivered between 90% and 110% of the prescribed activity with an acceptable safety profile.[71] A phase III trial is pending collaboration with a funding partner.

Initial promising investigations evaluated the long-term survival of patients with advanced ovarian cancer treated with RIT following cytoreductive surgery and platinum-based chemotherapy.[72] Eligibility criteria included patients with histologic evidence of ovarian cancer from stage IC to IV. The conclusion of this study was that a substantial proportion of patients who achieve a CR with conventional therapy can achieve a long-term survival benefit if treated with IP ^{90}Y-HMFG1.

A phase III study was subsequently performed.[73] This multinational (74 centers, 17 countries, recruiting patients between 1998 and 2003), open-label, randomized phase III study compared ^{90}Y-HMFG1 (against the MUC 1 antigen) plus standard treatment versus standard treatment alone in patients with epithelial ovarian cancer (EOC) who had attained a complete clinical remission after cytoreductive surgery and platinum-based chemotherapy. Stage IC to stage IV patients were screened (n = 844), of whom 447 with a negative second-look laparoscopy (SLL) were randomly assigned to receive either a single dose of ^{90}Y-HMFG1 plus standard treatment (224 patients) or standard treatment alone (223 patients). Patients in the active treatment (RIT) arm received an IP dose of 25 mg ^{90}Y-HMFG1 to provide 666 MBq (18 mCi)/m^2. After a median follow-up of 3.5 years, 70 patients had died in the active treatment arm compared with 61 patients in the control arm. Cox proportional hazards analysis of survival demonstrated no difference between treatment arms. In the RIT arm, 104 patients experienced relapse compared with 98 patients in the standard treatment arm. No difference in time to relapse was observed between the two study arms. The conclusion was that a single IP administration of ^{90}Y-HMFG1 to patients with EOC, who had a negative SLL after primary therapy, did not extend

survival or time to relapse. The reason for failure of the treatment could perhaps be explained by the choice of radionuclide. When treating microscopic disease with high-energy β-particles emitted from ^{90}Y, the electron will have too long of a range to deliver high enough energy to the tumor cell nuclei. It has been modeled that high-energy β-particle emissions will not deposit large amounts of energy (absorbed dose) into tumor spheroids below a certain size. However, there were other concerns about this study and these have been extensively reviewed.[74]

The patterns-of-failure analysis was eventually performed.[75] A total of 447 patients were included in the analysis with a median follow-up of 3.5 years. Relapse was seen in 104 of 224 patients in the RIT arm and 98 of 223 patients in the control arm. Significantly fewer IP ($P < .05$) and more extraperitoneal ($P < .05$) relapses occurred in the RIT arm. Time to IP recurrence was significantly longer ($P = .0019$), and time to extraperitoneal recurrence was significantly shorter for the RIT arm ($P < .001$). In a subset analysis, the impact of IP RIT on IP relapse-free survival was even greater and could only be seen in a subgroup of patients with residual disease after primary surgery. Although there was no survival benefit for ^{90}Y-HMFG1 IP instillation as consolidation treatment for EOC, an improved control of IP disease was found, which appeared to be offset by increased extraperitoneal recurrences. It was proposed that the transient myelosuppression (alteration of the immune system) induced by therapy with ^{90}Y-HMFG1 indirectly caused the greater number of extraperitoneal metastases. Most likely, this observation is simply the result of an alteration in the failure pattern owing to a greater number of patients in the treatment arm benefiting from a greater IP control, as distant metastases will not be observed because of overwhelming local symptoms. In addition, for reasons mentioned previously, it is possible that the treatment arm was skewed with more advanced disease.[74] Future trials should focus on both the IP and systemic delivery of RIT, using an appropriate radionuclide to target microscopic disease.

UNSEALED RADIONUCLIDE THERAPY

Unsealed radionuclide therapy (URT) refers to the medical application of radiopharmaceuticals that are not conjugated to a targeting agent and thereby localize in diseased tissue by virtue of biologic, chemical, or physical avidity.[76] These radionuclides are considered “unsealed” because they are not confined within a container that could be inserted or implanted into a tumor, as is

performed with conventional brachytherapy techniques. Because they are not conjugated to a traditional targeting construct, this class of therapeutics has also been referred to as “naked” radiopharmaceuticals. Oversight for the utilization of URT is governed by the U.S. FDA.[77] Safety issues, radioactive material shipping, and licensing are regulated by the U.S. Nuclear Regulatory Commission (NRC). A state may enter into an agreement with the NRC to perform its own regulation and to monitor of the use of radioactive material (agreement state), with the exception of fuel facilities and nuclear reactors. States that continue to allow monitoring by the NRC are referred to as nonagreement states. The NRC receives advice regarding radiopharmaceuticals from the Advisory Committee on the Medical Use of Isotopes (ACMUI). Regulations for the practice of nuclear medicine reside in U.S. NRC Title 10 of the Code of Federal Regulations, Parts 20 and 35. Part 20 largely governs the standards for radiation protection, and Part 35 governs the medical use of radioactive material.

Bone-seeking radiopharmaceuticals, used for palliation of painful bone metastases, represent one of the more common uses of URT. A few of the earlier radionuclides used for this purpose include phosphorus 32 [^{32}P], samarium 153 [^{153}Sm], and strontium 89 [(^{89})Sr];[78] however, newer agents are being investigated and are in various stages of development.[79–85] As with RIT, the radionuclides used in the application of URT can be classified as β-, α-, and Auger emitters. Many also emit gamma radiation, which can be used for imaging and dosimetry. The radionuclides used in URT target bone by either an intrinsic affinity (i.e., ^{89}Sr, radium-223 [^{223}Ra]) or by using bone-seeking phosphonate ligands attached to the radionuclide (i.e., samarium-153 ethylene diamine tetramethylene phosphonate [^{153}Sm-EDTMP] or rhenium-188 hydroxyethylidene diphosphate [^{188}Re-HEDP]).[82,86] Localization properties of individual agents and the clinical circumstances involved will determine routes of administration. These agents have been delivered by IV, intra-arterial, intracavitary, intra-articular (radiosynovectomy), and direct intralesional approaches. This variability of administration has been especially true for ^{32}P, which has been uniquely studied using IV, oral, IP, and intrathoracic routes.[87]

The initial use of a β-emitting radioisotope for the management of intractable malignant bone pain was reported in 1942. Because URT demonstrates a chemical affinity for bone, the predominant thrust of clinical investigation has been for primary and secondary malignancies of bone and bone marrow. Other target sites, however, have been considered. In some instances, these alternative

uses have remained a part of the therapeutic armamentarium; however, for many indications, the use of URT has yielded to nonradioactive approaches (corticosteroids, systemic chemotherapy, hormone therapy, analgesia, and surgery) and to EBRT. The lack of access to innovative candidate radionuclides, diminished trial participation, and absence of utilization and teaching from many training programs have further exacerbated the problem.[76] Regardless, a review of 15 randomized controlled trials (1,146 analyzed patients) comparing URT to placebo or another radionuclide for the treatment of metastatic bone pain confirms the efficacy of URT for pain management. This review also provides evidence that URT resulted in significant and complete pain relief during a 1- to 6-month period.[88] Practice guidelines have been established for URT,[89] and evidence-based guidelines for palliation of bone metastases include URT as a reasonable therapeutic option.[90]

The most common malignant sites that develop bone metastases are prostate, breast, and lung cancer.[78] URT exhibits increased targeting of bone in areas of osteoblastic activity and exerts this propensity because of a chemical similarity to calcium, which is classified as an alkaline earth metal in the periodic table (as are ^{89}Sr and ^{223}Ra). These therapeutic agents may either directly substitute for stable analogues in hydroxyapatite or may be chemisorbed on the hydroxyapatite surface of the phosphate moiety of phosphonate chelates.[86] Radionuclide decay profiles that include gamma emissions may be utilized for imaging and for documentation of therapeutic uptake in regions of bone pathology. Bone scans (technetium 99m [^{99m}Tc]) are typically performed to verify disseminated osseous disease. The intensity of uptake on pretherapeutic scanning does not necessarily coincide with therapeutic efficacy, and widely disseminated disease may actually produce “dilution” of dose and potentially reduced effectiveness.[86]

Regardless of the precise method of chemical or physical affinity, the agents studied for palliation of osseous metastatic bone pain fared better than placebos in randomized trials.[90] There is, however, limited evidence that the response or morbidity profile of the different radiopharmaceuticals varies significantly among themselves. Additionally, there is little evidence that dose escalation either in individual or cumulative doses will improve effectiveness. Sequenced administration has been investigated; however, if an initial intervention has not produced a significant level or duration of response, there is little evidence that additional administrations will increase effectiveness, but they may potentially increase morbidity.[86]

Rapid and significant localization in bone by all agents will generally limit

potential morbidity to myelosuppression, which in patients with adequate marrow reserve will usually be mild and be manifest initially within 1 week post administration with evidence of thrombocytopenia. Leukopenia may develop somewhat later; however, all side effects typically reverse without intervention within 8 to 10 weeks. Circulating isotope not immediately incorporated into bone is typically excreted in urine; therefore, patients with reduced renal function may not be ideal candidates for the agents and, if used, should have blood counts monitored carefully. Administration is routinely on an outpatient basis; thus, radiation protection measures for low-level radiation in urine should be practiced.

Palliative effects may be observed within 3 to 5 days but usually peak at approximately 7 to 10 days, and the beneficial effects may last for months. At this point in time, subsequent administrations may be considered. When used for management of bone pain, all bone-seeking radiopharmaceuticals can exhibit a flare in pain within 24 to 72 hours post injection that may last for 5 to 7 days. Appropriate analgesic management must be provided during this period. In the treatment of metastatic prostate cancer, prostate-specific antigen (PSA) levels may begin to decline within several days; however, the rapidity of decline, nadir of the PSA level, and duration of PSA response are not satisfactory predictors of improved outcomes.[86]

The bone-seeking agents have been and continue to be used primarily in metastatic prostate cancer, and evidence of effectiveness in breast and lung cancer is limited with responses noted primarily in osteoblastic metastases. Plain radiographs of symptomatic metastatic sites should be obtained prior to the use of systemic agents for palliation of bone pain. If there is evidence of possible impending fracture, stabilization and/or EBRT should be initiated prior to systemic radionuclide therapy. If painful vertebral metastasis is apparent clinically, CT or magnetic resonance imaging (MRI) of the painful vertebral segments should be obtained prior to administration of isotope to ensure that no epidural disease is present. If this pathology is discovered, EBRT or surgery should be carried out prior to systemic isotope therapy. IV administration of all agents should be carried out slowly over 1 to 5 minutes, through indwelling catheters with clear and unobstructed flow clearly validated, adequate hydration, and careful radiation precautions for patients and staff.

Radiopharmaceuticals

Iodine 131

Physical Properties: $t_{½}$ = 8.0 days; radiation decay: β (606 keV maximum and 190 keV mean); γ (364 keV).

Clinical Utility: Radioiodine ^{131}I was first used to treat benign thyroid disease in the late 1920s and early 1930s. The first reports of using ^{131}I to treat well-differentiated thyroid cancer (WDTC) were published in the 1940s.[91] To date, ^{131}I has become the standard of care, in conjunction with surgery, for the management of WDTC; its use and indications have been extensively reviewed.[92–94] Benign thyroid tissue (follicular cells) and certain thyroid carcinomas (follicular, papillary, and Hürthle cell carcinoma) will actively transport iodine into the cell via the sodium iodide symporter to initiate the synthesis thyroid hormone. As a result, this innate targeting system has been exploited for many decades to treat locally persistent, recurrent, or metastatic thyroid carcinoma. The majority of data concerning the treatment of WDTC with ^{131}I has been generated by large retrospective series of patients, with the resulting clinical data often spanning several decades. Frequently, these institutions used unchanged protocols and fixed activities for therapy. Regardless, considerable evidence exists concerning local control, decreased metastases, and a survival benefit when ^{131}I is used as part of the treatment regimen.[95–97]

In general, ^{131}I therapy for WDTC is considered either ablation or treatment. Ablation is the use of ^{131}I to sterilize normal remnant thyroid tissue or microscopic disease that remains after thyroidectomy. Treatment refers to the therapeutic application of ^{131}I against cancer persistence, local recurrence, or distant metastatic disease. Whereas the treatment aspect of ^{131}I is well accepted, ablation is more controversial.[98] Recent decades have revealed a decrease in mortality for WDTC, owing to the early diagnosis and aggressive treatment of WDTC with near-total thyroidectomy and ^{131}I ablation in selected patients at high risk for recurrence and mortality, followed by thyroid-stimulating hormone (TSH) suppression.[99] If it is determined that ablation will be performed, patients are placed on a low-iodine diet and TSH stimulation is performed by withholding thyroid hormone.[94] Standard fixed activities of 30 to 100 mCi are used for ablation, whereas higher activities in the range of 100 to 300 mCi are used for known residual disease, recurrence, or metastatic disease. If possible, patient-specific dosimetry should be used to determine the activity in the metastatic setting.[99] Using this approach, a dose <200 cGy is calculated to the blood (bone marrow) and ≤120 mCi of ^{131}I being retained after 48 hours. This can result in administered activities between 75 and 659 mCi without the

development of leukemia, permanent bone marrow suppression, or pulmonary fibrosis.[100] Diagnostic ^{131}I scanning and thyroglobulin measurement are required for follow-up.

Phosphorus 32

Physical Properties: $t_{½}$ = 14.3 days; radiation decay: β (1.71 MeV maximum and 1.69 MeV mean); γ (none).

Clinical Utility: Phosphorus 32 (^{32}P) represents one of the earliest agents in this class and perhaps is the most frequently studied for a wide variety of indications and routes of administration. In its aqueous form (Na_2PO_3), the agent was employed for the systemic therapy of chronic myelogenous leukemia and polycythemia vera. Orthopedic surgeons and rheumatologists have evaluated the agent for intra-articular management of persistent synovial effusions and hemarthroses secondary to hemophilia and leukemias.[101,102] The agent has been placed in indwelling catheters to treat CNS lesions.

The colloidal form of the agent (as chromic phosphate) became a standard modality for management of malignant pleural and peritoneal effusions in the 1960s and 1970s, driving numerous clinical investigations. Anecdotal reports suggesting significant activity were infrequently corroborated in randomized clinical trials. Following drainage of abdominal ascites or pleural effusions, up to 5 mCi of the agent was instilled and patients were placed in various positions to enhance distribution. The nature of the disease processes and prior therapy often predisposed patients to preinstillation adhesions with bowel or lung immobility, and distribution of the agent proved difficult. This indication has largely been replaced by instillations of various antibiotic or chemotherapeutic compounds.

Following identification of a subset of early-stage, high-risk ovarian cancer patients (FIGO stage Ia or Ib [grade 3], or stage 1c or II [any grade], or any stage I/II patient with clear cell histology), the Gynecologic Oncology Group (GOG), North Central Cancer Treatment Group (NCCTG), and Southwest Oncology Group (SWOG) undertook a randomized trial assigning patients to either a single dose of 15 mCi of IP ^{32}P or cyclophosphamide 1 g/m^2 and cisplatin 100 mg/m^2 every 21 days for three cycles. Prior to instillation of the radioactive material through multiperforated indwelling peritoneal dialysis catheters, ^{99m}Tc was instilled to ensure free flow and even distribution of the therapeutic agent. IP ^{32}P was administered within 10 days but not >6 weeks following laparotomy. Ten-year follow-up of the study population suggested a modest reduction in intra-abdominal recurrence rate for the chemotherapy population but only a

small and nonsignificant improvement in survival. These findings were corroborated by other reports.[103]

(^{32})P localization in bone created interest in the use of the orthophosphate form of the isotope for painful skeletal metastases with 85% of the administered dose ultimately incorporated into bone. However, priming regimens including androgenic agents prior to isotope administration were prolonged, beneficial results modest, and myelotoxicity significant; use of the agent for this indication is not ideal[104] and has largely been abandoned.

In the 1990s, a series of patients, treated with direct intralesional infusions of ^{32}P colloidal chromic phosphate for unresectable tumors of the liver, CNS, pancreas, and head and neck, was reported. Intense activity and doses were documented; however, improvements in local control and survival were inconclusive.[105] A randomized trial was performed on 30 patients with unresectable adenocarcinoma of the pancreas. The patients were randomized to 5-FU and EBRT with or without intratumoral ^{32}P. All patients received adjuvant gemcitabine. There was more liquefaction in the ^{32}P arm (78% vs. 8%). There was no difference in survival but an increase in serious adverse events in the ^{32}P arm.[106]

Strontium-89 Chloride (Metastron, GE Healthcare, Chalfont St. Giles, UK)

Physical Properties: $t_{½}$ = 50.5 days; radiation decay: β (1.463 MeV maximum and 0.583 MeV mean); γ (none).

^{89}Sr, a calcium analogue, is administered as an IV injection at doses of 4 mCi.

Clinical Utility: The Trans-Canada study randomized 126 patients with painful metastatic castrate-resistant prostate cancer to EBRT to painful bone sites with either ^{89}Sr or placebo.[107] A significant improvement in the following endpoints was noted in the ^{89}Sr arm: (1) intake of analgesics, (2) progression of pain, and (3) quality of life analysis. Multiple phase II and III trials have subsequently been performed using ^{89}Sr, showing favorable results. The conclusion of the review was that ^{89}Sr should be considered for the treatment of metastatic cancer where pain control is an issue and the bone scan shows activity. [108] The TRAPEZE trial is a prospective randomized trial comparing docetaxel alone or with zoledronic acid (ZA), ^{89}Sr, or both. Results revealed that ^{89}Sr combined with docetaxel significantly improved progression-free survival. [109]

Samarium-153 Lexidronam (Quadramet, Cytogen, Princeton, NJ)

Physical Properties: $t_{½}$ = 46.3 hours; radiation decay: β (0.81 MeV maximum and 0.23 MeV mean); γ (maximum energy 103 keV).

Clinical Utility: Samarium-153 EDTMP (^{153}Sm) is a bone-seeking agent consisting of radioactive samarium and a telephosphonate chelator, EDTMP. The recommended therapeutic dose is 1.0 mCi/kg, administered intravenously over a period of 1 minute through a secure indwelling catheter and followed by a saline flush. Extensive preclinical and clinical investigations have demonstrated the safety and effectiveness profile of ^{153}Sm-EDTMP.[110,111] Although primarily used alone, there is increasing interest in consideration of combination therapy with the bisphosphonates and taxane-based chemotherapeutics.

The use of ^{153}Sm-EDTMP has been evaluated in osseous metastases for primary osteosarcomas. Anderson et al.[112] investigated the use of gemcitabine as a radiosensitizer to increase ^{153}Sm-EDTMP effectiveness. Using 30 mCi/kg (average of 1,640 mCi), they found acceptable toxicity and objective response in 8 of 14 patients investigated. Treatment of osteosarcoma with ^{153}Sm has been further reviewed; 153Sm used as monotherapy or in combination with chemotherapy, stem cell transplant or EBRT.[153]

Radium-223 Chloride

Physical Properties: $t_{½}$ = 11.4 days; radiation decay: α (6 MeV maximum); γ (270 keV maximum).

Clinical Utility: The phase III ALSYMPCA (Alpharadin in Symptomatic Prostate Cancer Patients) trial confirmed the clinical utility of ^{223}Ra (Xofigo) for the treatment of castrate-resistant adenocarcinoma of the prostate. A total of 921 patients who had received, were not eligible to receive, or declined docetaxel were randomized 2:1 to receive six instillations of Xofigo (50 kBq/kg) every 4 weeks or placebo. Additionally, all patients received “best standard of care.” The primary end point was overall survival, and the secondary end points were time to first symptomatic skeletal event and various biochemical end points (median time to increase in alkaline phosphatase [AP] and PSA; ≥30% reduction in AP; normalization of AP). Entry criterion included castrate-resistant adenocarcinoma of the prostate (serum testosterone ≤1.7 nmol/L), at least two symptomatic bone metastases, no known visceral disease, PSA ≥5 with at least two consecutive rises, ECOG performance status of 0 to 2, malignant lymphadenopathy ≤3-cm short axis, and appropriate hematologic criteria (initial criteria per Bayer; ANC ≥1.5; platelet ≥100; hemoglobin ≥10). The overall survival in the Xofigo group

was 14.9 months versus 11.3 months in the placebo group (*P* < *.001*). All secondary end points had a benefit from Xofigo versus placebo (*P* < .001).[114] Subsequently, many questions regarding the use and sequencing of chemotherapy with Xofigo remained. In a prespecified subgroup analysis of the ALSYMPCA trial, Xofigo appeared to be equally effective before or after docetaxel, concerning overall survival.[115] A separate analysis of patients in the ALSYMPCA trial receiving chemotherapy after Xofigo was performed. The conclusion was that chemotherapy following Xofigo, regardless of prior docetaxel, is feasible and appears to be well tolerated.[116] Current areas of research include using higher activities per injection, increased overall number of doses, use in other nonprostate metastatic bone disease processes, and CMT with EBRT.

Rhenium-186 HEDP (Etidronate)

Physical Properties: $t_{½}$ = 3.8 days; radiation decay: β (1.07 MeV maximum and 0.336 mean); γ (0.137 MeV maximum).

Clinical Utility: Although not commercially available in the United States, ^{186}Rh-HEDP has been studied in phase I trials in Europe in association with autologous peripheral blood stem cell rescue in the management of hormone-refractory prostate cancer metastatic to bone. Phase I/II trials using ^{186}Rh-HEDP for castrate-resistant prostate cancer have indicated the potential for prolonged survival.[117]

Rhenium-188 HEDP (Etidronate)

Physical Properties: $t_{½}$ = 16.9 hours; radiation decay: β (2.1 MeV maximum and 0.779 mean); γ (0.155 MeV maximum and 0.061 mean).

Clinical Utility: Although not commercially available in the United States, ^{188}Re-HEDP has been studied in Europe for some time. The agent is produced by a generator similar to that used to produce ^{99m}Tc, enabling wide availability at relatively low cost. Liepe et al.[118] reported treatment of 46 patients with multiple bone metastases from breast and prostate cancer with pain. Thirty-one patients received ^{188}Re-HEDP (3,300 MBq) and 25 patients received ^{153}Sm-EDTMP (37 MBq/kg of body weight). All patients had a single injection of isotope. Patients with prostate cancer received hormone therapy for 6 months before isotope therapy and during the postisotope observation period. Thirty-nine patients received bisphosphonates for 6 months prior to study treatment with discontinuance of the agents 1 month prior to isotope administration. In

posttherapy evaluation, only the ^{188}Re-HEDP group had a statistically significant improvement in the Karnofsky performance score. Pain relief within 2 weeks of treatment was noted in 77% of the ^{188}Re-HEDP group and in 73% of the ^{153}Sm-EDTMP group. These results were not statistically significant, and there was no significant difference between responses in the patients with prostate or breast cancer. A brief flare reaction was noted in 17% of patients in both groups within 14 days of therapy, and the majority of patients demonstrated a maximum of grade I anemia within 12 weeks of therapy based on the 1979 WHO criteria. Grade I thrombocytopenia was noted in 2 patients with each isotope, and 1 patient in the ^{188}Re-HEDP group experienced grade II thrombocytopenia. Grade I leukopenia was noted in 1 patient in each group. All cases of thrombocytopenia and leukopenia reversed within 12 weeks after therapy. Similar findings have been reported by other investigators.[119,120]

FUTURE PERSPECTIVES

In order for RIT to be successful, quite simply, an increased dose of high-LET radiotherapy must be delivered to the tumor and a lower dose delivered to normal tissue:

- *Tumor Specificity*: To date, there are no true tumor-specific antigens or targets. This is important considering the toxicity of radionuclides. The field must move toward tumor-specific processes. This will result in greater doses to the tumor and less to normal tissue. For example, aptamers can be designed to target tumor cells and then counter selected against normal tissue to produce a “true” tumor-specific targeting construct.
- *High-LET Radiation*: Beta radiation is sparsely ionizing and may be effective against hematologic malignancies but not against solid tumors (carcinoma). High-LET radiation will be required to combat solid tumors. Alpha radiation will be very effective but potentially toxic. Auger radiation will be very effective with limited toxicity. The caveat, the Auger radionuclide, must enter the nucleus and/or bind DNA.
- *Fractionation*: Currently, the successful RIT agents (Zevalin, Bexxar) have been delivered in a single fraction. These agents however have treated radiosensitive hematologic malignancies. RIT must be delivered in multiple fractions for solid tumors. For example, platinum-based chemotherapy, used to treat germ cell tumors, was not curative as a single fraction. Multiple fractions were delivered with a noted “log fold” decrease in tumor markers with each fraction (cycle). Potentially survival advantageous results seem to be occurring

with the multiple fraction regimens of Xofigo and Lutathera.

- *Multiple Radionuclides*: Individual radionuclides deposit their energy over a known path length. In order to be maximally effective, radionuclides need to deposit their energy over a wide range of micrometastatic and tumor sizes. The effectiveness of multiple radionuclides seems to have come to fruition with peptide therapy (^{90}Y and ^{117}Lu). The use and incorporation of high-LET radionuclide are quite necessary. One can calculate that the following radionuclide combinations will encompass a subcellular level to tumor level coverage: ^{125}I, ^{33}P, ^{131}I, ^{32}P.

CHAPTER 30

Radiation Therapy and the Immune System

Chandan Guha, James W. Hodge, and Adam P. Dicker

RADIATION AND TUMOR IMMUNITY

Radiation therapy (RT) is an essential component of cancer care that is primarily intended to eliminate tumors and destroy cancer cells through irreparable DNA damage, resulting in cell death or cell cycle arrest. RT may have a palliative or curative effect either by reducing or eliminating tumor burden or by preventing cancer recurrence and metastasis. Whether the intent is cure or palliation, the goal of RT is direct tumor cell killing and/or modulation of tumor or stromal architecture. Radiation, however, is often insufficient to kill all tumor cells in a given mass because of (a) the need to limit damage to healthy tissues, (b) resistance of the tumor cells, and (c) lack of radiation kill at distant (metastatic) sites. Preclinical studies in numerous tumor models have shown that radiation exposure of tumor cells can elicit cell death while inducing some antitumor immunity in a process described as “immunogenic cell death”.[1,2] However, in clinical settings, immune responses elicited by radiation only rarely result in protective immunity.[3,4] Full and sustained clinical remissions are elusive for most patients receiving standard-of-care treatment. By contrast, immune-directed therapies can achieve clinical benefit in patients in which conventional therapy has failed. Perhaps, most strikingly, immune-based therapeutics can induce lasting or durable responses in subsets of patients with advanced diseases with no evidence of resistance development. It is expected that the demand for RT in early cancer treatment strategies will greatly increase by 2020 with the increasing age and diversity of the US population.[5] As a result, more innovative and effective RT options need to be developed that can be combined with immunotherapy (IT).

Currently, there is growing interest in combining RT with IT for treatment of

a broad range of malignancies, because as monotherapies neither IT nor RT may be sufficient to fully destroy tumors. There is evidence that IT is more beneficial when employed in combination with other standard therapies.[6,7] Radiation can act synergistically with IT to enhance immune responses, inhibit immunosuppression, and/or alter the phenotype of tumor cells, increasing their susceptibility to immune-mediated cytotoxicity.[8] RT can also enhance the potency of cancer vaccine approaches by exploiting the influencing natural antigen presentation pathways that induce sustained antitumor immune responses.[7] However, RT also induces immunosuppressive pathways within the tumor microenvironment that is detrimental to the generation of antitumoral immunity.[9–11]

Cancer cells express unique tumor antigens that include mutated oncoproteins, such as p53 and Ras; unique hybrid proteins expressed from translocated oncogenes, such as bcr-c-abl; and proteins that are expressed during embryogenesis, but are not expressed by normal adult tissues.[12] Some of these “oncofetal” proteins serve as epitopes for host humoral and cellular immune response, which could potentially eradicate cancer cells. The central tenet of T-cell–mediated adaptive immunity is antigen recognition by T-cell receptors (TCR) as peptides on MHC molecules. This depends upon processing of cellular and extracellular proteins by antigen-presenting cells (APCs) and presentation on cell surface MHC molecules. In case of CD8+ cytotoxic T lymphocytes (CTL), these peptides or epitopes are displayed at the cell surface bound to class I MHC molecules that are present in almost all cells. Class I MHC molecules display a “menu” of 8 to 10 amino acids of endogenous peptides that are derived from processing and degradation of cellular proteins in proteasomes and presented directly on the peptide-binding grooves of class I MHC as it is being assembled in the endoplasmic reticulum. Direct antigen presentation of peptides represents mostly degraded “self”-proteins and occasional “foreign” proteins, such as viral antigens from an infected cell or peptides from mutated oncogenes in cancer cells. However, tumors often have central defects in antigen processing and presentation, such as down-regulation of class I MHC molecules, thereby evading recognition by T cells. In contrast to most epithelial cells, professional APCs, such as dendritic cells (DCs), have the capacity to phagocytose exogenous proteins and present them on class II MHC molecules for recognition by CD4+ T cells. In special situations, DCs can phagocytose exogenous proteins but are able to process and transport peptides to the endoplasmic reticulum for cross-presentation on class I MHC molecules. In order to induce an effective

antitumoral immunity, first naïve T cells have to be primed by DCs, presenting tumor-derived peptides on class I and II MHC molecules. Upon appropriate priming and activation, CTLs would be able to recognize tumor cells if they present processed peptides on their cell surface class I MHC molecules.

Radiation-Mediated *In Situ* Vaccine

The concept that radiation-induced immune modulation may lead to the conversion of the primary tumor into an *in situ* vaccine was first described in a murine model of metastatic lung cancer where primary tumor irradiation in combination with systemic administration of Flt3 ligand (Flt3L) was able to not only control the primary tumor but result in suppression of metastatic progression and cure.[13] It was proposed that the release of putative tumor neoantigens and danger-associated molecular pattern (DAMP) signals by tumor irradiation (rather than surgical removal), synchronized with increased availability of APCs by expressing Flt3L, should prevent death of the tumor-bearing mice from distant metastasis.[13,14] Subsequently, it was shown that Flt3L can promote the abscopal effects of primary tumor irradiation in a murine breast tumor model.[15] The abscopal effect describes a condition in which the appropriate combination of host factors and tumor phenotype can lead to immune rejection of nonirradiated tumor cells or metastasis following local radiation of the primary tumor. Following irradiation of the tumor, the immune response may contribute not only to a local effect on the tumor but also to systemic rejection of metastases.[5]

Tumor antigens are released from dying tumor cells following treatment with chemotherapy or RT or from necrotic tumor cells from a growing tumor. The tumor antigens and cellular debris are normally engulfed by macrophages and neutrophils, as well as by professional APCs, such as DCs.[16] DCs are normally present as sentinels guarding the portal of entry of pathogens via skin and mucosal surfaces.[17,18] Although DCs are derived from hematopoietic stem cells, it is rarely present in circulating blood. However, systemic administration of cytokines, such as Flt3L and GM-CSF, can induce proliferation of immature DCs.[19,20] Following engulfment of the tumor antigens, the DCs process and present the peptide antigens on MHC molecules at the cell surface. Subsequently, if appropriate “danger” signals are present, the DCs are activated and antigen-loaded DCs migrate to draining lymph nodes. In lymph nodes, DCs interact with naïve CD4+ T helper cells (Th). CD40 ligand (CD40L) expressed at the surface of the helper T cells stimulates the maturation process of the

DCs.[21] Costimulatory interaction between mature DCs and the Th cells results in the release of cytokines, such as, IFN-gamma and IL-2, which leads to the proliferation of neo–antigen-specific CD8+ CTL. Furthermore, mature DCs can cross-present tumor antigenic peptides via class I MHC molecules to CD8+ naïve CTLs.[22–24] The CTLs, in turn, infiltrate the tumors at primary as well as metastatic sites, inducing death of the tumor cells.

Radiation-Associated DAMP Signals

Adaptive immune responses are induced and controlled by the innate immune system. Innate immune sensors respond to infectious pathogens or endogenous tissue damage through recognition of pathogen-associated molecular patterns (PAMP) or danger-associated molecular patterns (DAMPs), respectively. Radiation-induced tumor cell death releases tumor antigens and DAMPs, which can stimulate tumor-specific adaptive immune responses.[25]

One of the primary DAMPs, calreticulin (CRT), is exposed on the cell surface at the earliest stage of cell death followed by the well-known inside-out flipping of phosphatidylserine (PS), while at the later stage of apoptosis, cytoplasmic heat shock proteins (HSP) and the nuclear nonhistone high-mobility group box 1 (HMGB1) proteins are released.[26] CRT, PS, and the complement factor C1q serve as signals for phagocytosis by macrophages via binding to the scavenger receptor SRF-1 to facilitate clearance of dying cells and also to activate a proinflammatory immune response.[27,28] HSP60, HSP72, and HMGB1 are DAMPs recognized by the pattern recognition receptor toll-like receptor-4 (TLR-4), which stimulates subtypes of DCs to increase antigen cross-presentation and initiate antitumor cytotoxic responses.[25,29] Natural killer (NK) cell–mediated destruction of tumor cells may also be stimulated through radiation-induced DNA damage pathways via ataxia telangiectasia–mutated (ATM) protein and p53, which up-regulate expression of the nonclassical MHC-I molecules, MIC-A, MIC-B, and ULBP.[30] These proteins are high-affinity ligands to the activating NK cell receptor NKG2D and promote the efficient killing of tumor cells by NK cells. In addition, restoring p53 tumor expression in p53-deficient tumors can produce complete tumor regression due to p53-mediated cellular senescence, followed by up-regulation of inflammatory cytokines and induction of tumor-specific innate immune responses rather than by inducing apoptosis.[25]

Radiation-Enhanced Antigen Presentation

A crucial result of DAMP-induced inflammation is the activation of DCs and enhanced presentation of tumor-associated antigens (TAA) to T cells. According to the current model, tumor cells undergoing immunologic cell death (ICD) release both DAMPs and a variety of TAAs that are taken up, processed, and presented by APCs, primarily mature DCs. $CD11c^+$ myeloid DCs migrate to the tumor-draining lymph node where TAAs to $CD4^+$ T cells are present, which can differentiate to type 1 helper (Th1) T cells and stimulate CD8+ cytotoxic T cells (CTL), NK cells, and innate phagocytic responses. Within the tumor microenvironment, $CD8\alpha^+$ DCs, stimulated by DAMPs, such as HSPs or HMGB1 through TLR4, up-regulate MHC-I antigen cross-presentation, which can directly activate tumor-specific $CD8^+$ CTLs. Radiation exposure promotes alterations of multiple components of antigen presentation, including immunoproteasome subunits, peptide transporters, and protein chaperones to facilitate enhanced MHC-I–associated antigen presentation. RT also modulates the spectrum of peptides associated with MHC class I through a cascade of events, which include degradation of proteins damaged by radiation, increased peptide production, and improved antigen presentation.[31] Thus, the simultaneous release of DAMPs and TAAs in response to RT-induced tumor cell death leads to the powerful amplification of tumor-specific adaptive immune responses.

Antigen Cascade

Radiation promotes antigen cascade, or epitope spreading, described as a fundamental characteristic of the adaptive immune response in which the host responds not only to the specific peptide epitope used in the vaccine but also to other epitopes derived from the same tumor antigen. This phenomenon can also occur in ICD when DCs take up tumor-derived antigenic fragments and cross-present them with MHC class I to CTLs. Antigen cascade has been observed both in preclinical and clinical trials and, in some cases, has led to improved clinical outcome.[32]

Radiation-Induced Tumor Immune Modulation

RT in itself is not always successful at inducing tumor cell death and controlling tumor progression. Intrinsic radiosensitivity of tumor cells and limitations for dose delivery and localization often allow for survival of tumor clonogens. These constraints are sometimes dictated by the need to minimize toxicity of healthy tissue or by the inability of radiopharmaceutical agents to enter the tumor because of poor tumor vascularization.[28] Although sublethal doses of

radiation by definition are unable to induce complete cell death, numerous studies have established that lower doses of radiation can initiate a wide range of phenotypic changes in the surviving tumor cell population that collectively enhance their susceptibility to CTL-mediated killing, a process termed immunogenic modulation (IM).[7]

Primary characteristics of radiation-induced IM include the up-regulation of intercellular adhesion molecules, proapoptotic TNF family member receptors, and various costimulatory molecules, the down-regulation of antiapoptotic and prosurvival genes, and an overall increase in tumor antigen presentation.[5] Increased expression of adhesion molecules, such as intercellular adhesion molecule 1 (ICAM-1/CD54) and lymphocyte function–associated antigen 3 (LFA-3/CD58), enhances the ability of CTLs to form stable immunologic synapse and kill the targets via granzyme/perforin release. Expression of the TNF receptor family member Fas/CD95 further augments killing through interaction of Fas ligand expressed on CTLs. Radiation exposure also increases expression of a broad spectrum of molecules associated with antigen presentation, such as MHC-I surface expression, the chaperone proteins CRT and calnexin, and the production of TAAs, including carcinoembryonic antigen (CEA), mucin-1 (MUC-1), HER-2/*neu*, p53, and CA125. The final effect is increased loading of TAA peptides into MHC-I complexes that are recognized by tumor-reactive CTLs. Expression of costimulatory ligands such as B7-1 and B7-2, OX-40L, and 4-1BBL is also increased in irradiated human tumor cells[33,34] and critical to overcome tumor-specific anergy and sustain productive CTL responses.[35] Some of these costimulatory molecules have also been associated with reduced levels of regulatory T cells (Tregs), which may play an additional role in curbing immunosuppression.[35] Figure 30.1 illustrates the radiation-induced phenotypic changes of tumor cells during ICD or IM and how these changes can ultimately be exploited by a variety of immunotherapy (IT)treatment strategies that enhance tumor-specific effector responses.

Radiation-Induced Activation of Inflammatory Cytokines

Inflammatory cytokines are induced in tumor and stromal cells after genotoxic stress of RT. The efficacy of RT-induced tumor ablation requires the activation of type I interferon (IFN) expression in tumor-infiltrating DCs[36] via cytosolic DNA sensor cyclic GMP-AMP (cGAMP) synthase (cGAS) mediated sensing of DNA from irradiated tumor cells in DCs.[37] Many tumor cells evade immunosurveillance by inhibiting cytosolic DNA sensing in DCs. For example,

tumor cells express CD47 that acts as a “do-not-eat-me” signal for DCs. Inhibition of the CD47-signal regulatory protein alpha (SIRPalpha) axis by CD47 blockade activates NADPH oxidase NOX2 in DCs, thereby reducing the degradation of tumor mitochondrial DNA (mtDNA). mtDNA was recognized by cGAS in the DC cytosol, contributing to type I IFN production and antitumor adaptive immunity.[38] Recently, it was shown that a DNA exonuclease Trex1 was induced in some tumor cells after exposure to high-dose fractions (>12 to 18 Gy) of RT that attenuated their immunogenicity by degrading cytosolic DNA.[39] The cytosolic DNA sensor, cGAS, and its downstream effector, stimulator of interferon genes (STING), localize in micronuclei that are formed in irradiated cells after cell cycle progression through mitosis following double-stranded DNA breaks.[40] Inhibition of mitosis and micronuclei formation and/or cGAS–STING pathway impaired IFN signaling in tumor cells with loss of systemic tumor response after combination of RT and immune checkpoint blockade.[40] However, it is critical to note that there are redundant pathways for the activation of pattern recognition receptors (PRR) in tumor cells. For example, exosomal transfer of POL3-driven expression of endogenous RNA, RN7SL1, from stromal fibroblasts to breast cancer cells activates the PRR RIG-I and drives an inflammatory response that enhances tumor growth, metastasis, and therapy resistance.[41,42]

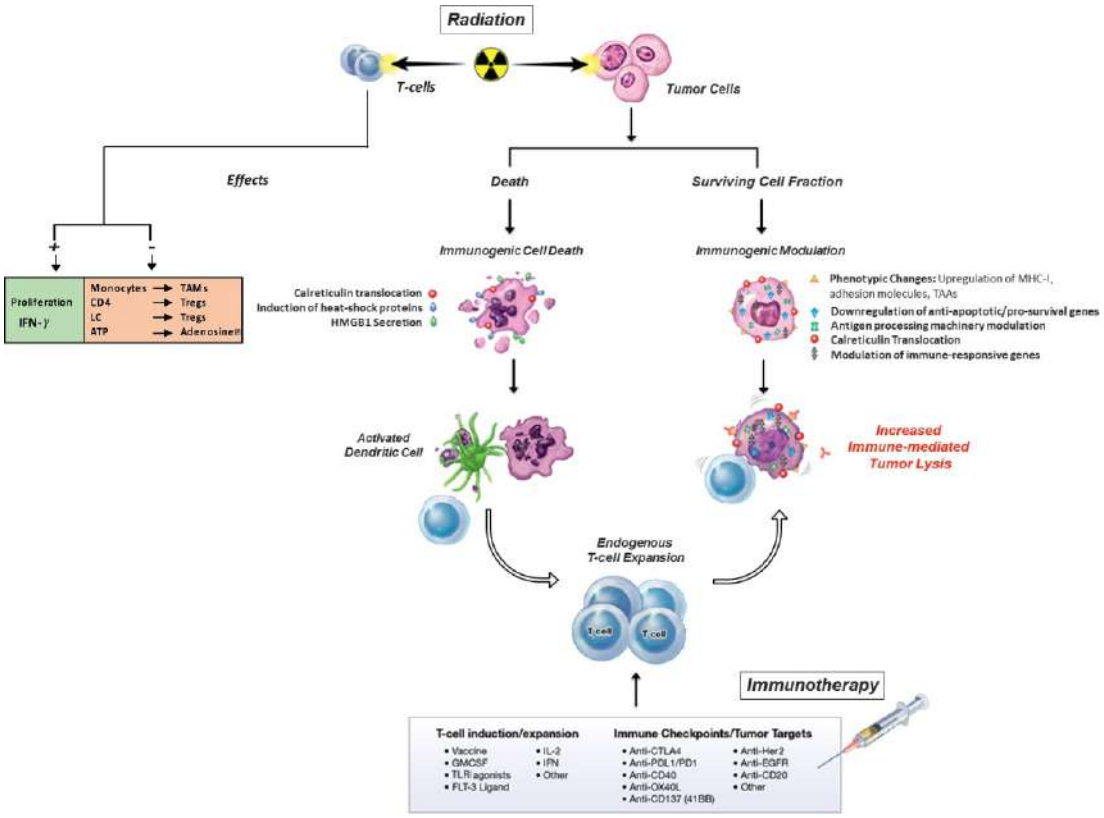

FIGURE 30.1. Radiation-induced immunogenic modulation may synergize with immunotherapy to effectively treat cancer. RT has been shown to increase T-cell proliferation as well as increase IFN-*γ* secretion. RT has also been shown to mediate negative effects on T-cell function: (1) RT-induced C-C chemokine receptor-2–expressing monocytes can be converted to immunosuppressive tumor-associated macrophages (TAMs) in the microenvironment; (2) RT-induced TGF*β* expression could convert infiltrating CD4 T cells to suppressive regulatory T cells (Tregs); (3) RT-induced Langerhans cells (LC) could promote Tregs; and (4) ATP released from dying tumor cells could be catabolized to adenosine, which supports Treg function. On the tumor side, RT modalities can induce a myriad of phenotyping changes in tumor cells that make them more susceptible to CTL-mediated lysis. Such changes can ultimately be exploited by a variety of immunotherapy treatment strategies that enhance tumor-specific effector responses.

THE RATIONALE OF COMBINING RT WITH IT

The rationale for combining RT and IT rests on the premise that ionizing radiation cannot only induce cell death directly but can also invoke an inflammatory response in tumor cells that will foster TAA presentation to overcome immunotolerance and stimulate a systemic immune response.[6,43,44] Evidence suggests that immune-mediated abscopal effect can be induced through a combined strategy of RT and immunotherapies, including effector cell enhancement, checkpoint inhibitors, and tumor vaccines. Radiation dose and

timing are crucial elements that determine the effectiveness of tumor immunity.[6]

Local Tumor Control following RT

Traditional view of local tumor control of irradiated tumors is thought to be mediated by radiation-induced cytotoxicity. However, several investigators demonstrated that RT-induced local tumor ablation largely depends upon T-cell immunity.[45,46] Ablative RT dramatically increases DC-induced T-cell priming in draining lymph nodes with activation of CD8+ CTLs that are essential in eradication of both the primary tumor and distant metastasis. These investigators further demonstrated that ablative RT-induced antitumoral immunity and tumor control were abrogated by conventional fractionated RT or adjuvant chemotherapy but greatly amplified by local IT.[46] Interestingly, addition of fractionated RT (3Gy × 10) to an ablative single-dose (30 Gy) RT abolished tumor control, even though the total dose was increased to 60 Gy, suggesting that protracted standard fractionation of RT inhibits the induction of antitumoral immunity by killing tumor-infiltrating lymphocytes.[45]

Radiation exposure can elicit a direct effect on MHC expression; however, TAAs stimulated by radiation can also up-regulate IFN-γ in the tumor, which has been shown to be necessary for radiation-induced MHC expression.[25] It has also been reported that RT directly modifies the phenotype of tumor cells making them more susceptible to immune-mediated cytotoxicity.[47] It has further been demonstrated that radiation promotes changes in the tumor microenvironment that reduce tumor burden and promote greater infiltration of effector cells.[48] The combination of radiation-induced local inflammation and tumor-specific effector T cells can change the tumor vasculature and phenotype, providing a robust mechanism of tumor control.

However, some reports have shown increased immunosuppressive properties of RT that include decrease in IL-12 production, leading to a negative effect on antigen presentation and an increase in the number of tumor-infiltrating Tregs.[25] RT induces the activation of TGFβ in the tumor, which is immunosuppressive and inhibits the generation of RT-mediated *in situ* tumor immunity.[49] RT can also promote the accumulation of tumor-infiltrating regulatory T cells (Treg cells), especially in melanoma.[9] These investigators demonstrated that specialized tissue-resident DCs, Langerhans cells (LC), were resistant to cell death after exposure to IR. Irradiated LCs up-regulated class II MHC molecules, migrated to draining lymph nodes, and primed the proliferation of immunosuppressive Tregs after RT. As explained above, activation of DCs is a critical effector of

anti-tumoral immunity, as DCs take up antigens from dying tumor cells and present them to T cells. However, macrophages also recognize and phagocytose dying tumor cells and can rapidly remove tumor antigens from the microenvironment. Because macrophages cannot cross-present TAA with MHC class I, phagocytic clearance of tumor cells may actually enhance regrowth of tumor cells through caspase 3–dependent stimulating signals and cancel out potential beneficial local and systemic immunostimulatory effects of ICD.[25] Therefore, one has to promote the immunostimulatory properties while inhibiting the immunosuppressive features of RT[11] for effective induction of antitumoral immunity and tumor control.

Systemic Tumor Control following RT

As previously discussed, radiation-induced immune modulation can lead to the abscopal effect, which can, not only eliminate irradiated primary tumors but also reduce the growth of secondary unirradiated tumors or render them more susceptible to further treatment strategies. TAAs may be weakly immunogenic because of the inherent tolerance of the adaptive immune system to self-antigens. RT may contribute to the breakdown of tolerance to endogenous TAAs.[7] In addition, RT-associated novel TAAs can include somatically mutated proteins, which are presented as neoantigens that could induce stronger cytotoxic responses, establishing a novel strategy for personalized tumor vaccination.[6] To overcome challenges of local deficiency of APCs in the tumor microenvironment, strategies to increase functional APCs in combination with RT are being developed to enhance tumor-specific immune response. The timing of administering a second form of IT relative to RT can be critical, as complete ablation of primary tumors could consequently remove the novel TAAs, thereby impeding sustained immune responses.[6]

Dose, timing, and schedule of RT are primary factors to consider for effective combined treatment with IT. There are many opportunities in the antitumor immune response for therapeutic intervention that would potentially enhance immune response. For example, cytokines and costimulatory molecules to enhance antigen presentation and CTL function can be introduced into the tumor environment following RT.[33] Further, physical, chemical, or molecular targeting of the tumor mass following immune response can reduce tumor burden, so that the immune response is not offset by local, tumor-associated immunosuppression.[6] Finally, pharmacologic inhibition of the PD-1/PD-L1 axis, CTLA-4, and other inhibitory checkpoints on activated T cells should result in a

more intense and sustained tumor-specific immune response.

Abscopal Effects Versus Survival in RT–Immunotherapy Clinical Trials

There is substantial clinical evidence of effective radiation-induced immune activation.[7] It has also been shown that tumor-specific T-cell populations were significantly increased in most colorectal cancer patients after completion of chemoradiation therapy and in most prostate cancer patients after RT. An increased population of Treg infiltration following treatment in colorectal patients potentially suggests that there is a threshold above which immunosuppressive side effects may prevail. Still, a beneficial abscopal effect has been reported in melanoma, lymphomas, hepatocellular carcinoma, and certain adenocarcinomas.[5]

These findings indicate that RT effectively stimulates immune responses through radiation-induced immune modulation, which as a result can translate into both local and systemic clinical benefits. Still, if the tumor burden is large enough, it may create enough immunosuppression to prevent successful immune intervention. In this case, studies suggest that local RT can also sufficiently reduce tumor burden to allow for further therapeutic intervention by IT, such as tumor vaccination or checkpoint blockade of inhibitory molecules.[5] By enhancing the frequency, magnitude, and character of the immune responses induced by RT with immunomodulatory agents, cancer patients should experience further improved outcomes.

A major impediment to the abscopal effect is that lymphocytes are highly radiosensitive.[50] However, several studies have demonstrated that RT can promote productive immune-mediated responses despite lymphocyte radiosensitivity. Preclinical studies have demonstrated increase of functional T cells that secrete IFN-γ upon tumor-specific peptide stimulation within the draining lymph nodes following tumor exposure to radiation.[50]

Clinical studies have further assessed the relationships between CTL, Tregs, and RT by analyzing levels of survivin in tumor cells following RT. Survivin is associated with tumor radioresistance and proliferation.[51] The results of these studies suggest that despite the radiosensitivity of lymphocytes, productive CTL responses may be enhanced following radiation because of the focal effect of RT, which does not impair systemic immune populations. The abscopal effect is infrequent in the clinical setting, seeming largely dependent on RT dose and timing. In many cases, cancer patients treated with RT do not exhibit a sufficient

enough immune response to elicit an improvement of progression-free or overall survival.[5]

RT TECHNIQUES

RT Dose and Fractionation

Traditional RT is considered locally immunosuppressive because of the rapid clearance of radiosensitive lymphocytes that reside within the field of radiation.[25,45] Fractionation lends the ability to administer a therapeutic dose of radiation to cancer cells while minimizing toxicity to surrounding healthy tissue. External beam radiation therapy (EBRT) can be delivered effectively in several ways: as a standard fractionation of 1.8 to 2.0 Gy daily for 5 to 9 weeks or as larger dose with fewer fractions (hypofractionated doses).[5] Preclinical studies have shown that conventional fractionation might diminish the immune response by eliminating infiltrating lymphocytes over time. Therefore, hypofractionated regimens have been favored to be used in combination with IT.

Normal tissue tolerance dictates the dose and fraction size of RT. With large fraction sizes, RT induces immunogenic cell death (ICD) and produces durable complete responses, which is dependent upon radiation-induced antitumoral immunity.[45,46] New RT technologies are being developed to avoid damage to healthy tissue while focusing high-dose heterogeneous radiation on the tumor. This follows the notion that a heterogeneous dose will lead to a similarly heterogeneous response by tumor cells.[8] RT-treated tumor cells can undergo several types of well-defined cell death, including necrosis, mitotic catastrophe, and ICD. However, cells that survive fractionated RT may be more susceptible to IM and therefore become better targets of tumor immunity.[9] As the dose of RT is reduced to avoid normal tissue toxicity, RT induces the cell surface expression of various immunomodulatory molecules that renders the surviving tumor cell susceptible to cytotoxic T-cell attack.[52] Therefore, subablative immunomodulatory RT doses can be combined with IT, such as tumor vaccines[52] and immune checkpoint blockade,[53] to achieve both local and systemic tumor control. It has been shown that from 1 Gy up to 25 Gy dose of radiation induces up-regulation of MHC class I expression in a dose-dependent manner. Irradiation also appears to accelerate degradation of existing proteins, leading to an increased intracellular peptide pool for MHC class I loading. Nonlethal radiation was also shown to activate the mammalian target of rapamycin (mTOR), resulting in increased protein synthesis and availability of

peptides for MHC class I loading.[5] The combination of these effects results in elevated TAA presentation on the surface of the tumor, which should further enhance TAA-specific responses. In contrast to RT doses that target the tumor cells, preclinical studies have demonstrated that very low-dose irradiation (0.5 Gy × 4) can reprogram macrophages and stimulate effective T-cell immunity against tumors.[54,55] Such novel low-dose tumor microenvironment modulating RT fractionation is being investigated in clinical trials. In summary, one could consider various RT fractionations as different immunomodulatory drugs with functions ranging from immunogenic ablation and immune modulation of tumor cells to modulation of the stromal cells of the tumor microenvironment.

Ablative Versus Immunomodulatory Doses for Antitumoral Immunity

Ablative RT can be delivered as hypofractionated regimen and in some cases as a single high-dose fraction of RT.[56] Single high-dose RT provides remarkably high rates of control for tumors that are otherwise not controlled by fractionated RT. In such cases, tumor control depends upon activation of acute acid sphingomyelinase-mediated endothelial cell injury.[57,58] Significant changes in vasculature have been observed after radiosurgery where obliteration of abnormal vasculature occurs months after irradiation, but is rarely seen below a single dose of 12 Gy rising with increasing doses above this threshold.[25] In contrast to ablative fractionation of RT, subablative RT fails to control tumor growth because of the recruitment of bone marrow–derived myeloid cells and vasculogenesis, partly mediated by HIF-1–dependent stromal cell–derived factor-1 (SDF-1) and its receptor, CXCR4.[59,60] Interestingly, the myeloid cells recruited in the tumor microenvironment by hypoxia-induced up-regulation of SDF-1 are immunosuppressive, and inhibition of CXCR4 using an inhibitor, AMD3100, inhibited tumor regrowth and lung metastasis and potentiated anti–programmed death receptor-1 immunotherapy in sorafenib-treated hepatocellular carcinoma in mice.[61] The circulating myeloid cell numbers are directly linked with tumor burden, and it correlates with primary tumor progression and recurrence. Ablative RT of tumors leads to a decline of the circulating myeloid cells and a decrease in spleen size in animals, indicating that RT may open a therapeutic window for IT at the time of minimal myeloid-induced immunosuppression.[62]

The role of dose fractionation, particularly single-fraction versus hypofractionated RT, in mediating abscopal effects of combination therapy of RT

and anti–CTLA-4 immune checkpoint blockade was studied in two murine models of solid tumors, breast and colon cancer.[53] In this report, fractionated RT (8 Gy × 3, or 6 Gy × 5 fractions in consecutive days) but not single-dose RT (20 Gy × 1) induced an abscopal effect when combined with anti–CTLA-4 therapy. These investigators further discovered that high doses (>12 to 18 Gy) of RT fail to induce an abscopal effect in combination with anti–CTLA-4 checkpoint blockade because of the breakdown of intratumoral cytosolic DNA by an exonuclease, Trex, which is induced in some tumor cells with higher doses of RT.[39] Thus, the expression of Trex after radiation exposure may guide the selection of RT dose and fractionation for IT. Despite these observations, it should be noted that the dose of RT selected in these reports was not ablative, and although abscopal effects were reported, the investigators did not describe the effect of these fractionation schedules on survival from spontaneous metastatic progression in these experiments. Thus, it would be prudent to test all types of RT fractionation in combination with clinical trials of RT and IT.

Partial Tumor Irradiation: Spatially Fractionated GRID Radiotherapy

Traditional methods of RT may not fully cover tumor burden at the maximum prescribed radiation dose because of the heterogeneity of tumor burden or possible toxicity to surrounding healthy tissue. Spatially fractionated GRID radiotherapy (SFGRT) is designed to partially cover the tumor volume with the prescribed dose of radiation in order to deplete local tumor burden and stimulate systemic immune response.[5] This was first achieved using 2-dimensional grid fields with orthovoltage beams allowing spatially alternated dose distribution. By using this approach, primarily for treatment of cancers with bulky tumors, successful clinical responses have been reported. Preclinical studies using this method have reported abscopal effects, suggesting that the SFGRT tumors may have elicited inhibitory factors through immune cells preventing tumor growth.[5]

More recent preclinical studies have used SFGRT modified as 3-D GRID in a similar scheme to compare effects of high-dose RT directed at total tumor volume versus partial tumor volumes. It was shown that high-dose RT directed to partial tumor volumes may produce immune stimulation because irradiating partial tumor volume with focused high-dose beams using lattice RT (3-D SFGRT) might induce secretion of immune-related cytokines and can activate the ceramide pathway to target the nonirradiated intratumoral environment as well as distant metastases.[63]

Types of RT

Photon RT

RT is traditionally delivered by photons, or x-rays. These particles are pure energy without mass. Because photon radiation is highly penetrating and peak radiation is deposited immediately upon entry into tissue, radiation is delivered to surrounding tissues as well as the tumor, also releasing a high exit energy. Although an effective strategy of reducing or eliminating local tumors, this type of irradiation cannot easily limit damage to healthy tissues.[64]

Particle RT

In contrast to photon RT, particle therapy deposits lower energy upon tissue entry and generates Bragg peak radiation that can be targeted primarily to the tumor. As the particles travel deeper into the tissue and progressively lose speed, the radiation dose they deliver to the surrounding tissue gradually increases. When they eventually stop at the tumor, a peak energy dose is released, also known as the Bragg peak.[65] Because of its ability to selectively target tumor tissue, proton radiation is particularly favorable in situations where it is necessary to limit the damage to adjacent healthy tissue. Recent advances in carbon ion radiotherapy (CIRT) have demonstrated an ability to deliver high linear energy transfer in a focused dose with the larger mass of carbon resulting in a decreased beam scattering, yielding a sharper, more focused dose distribution. Compared with traditional photon therapy, CIRT has less cell cycle–related radiosensitivity. These characteristics show promise for future developments in potential combination treatment strategies.[66,67] Preclinical evidence for induction of systemic antitumoral immunity by carbon ion RT has been reported in mouse models.[68–70] Both photon radiation and heavy particle radiation have already demonstrated significant antitumor efficacy and have been shown to capably increase CTL lysis of prostate, breast, and lung tumor cells regardless of their p53, triple-negative, or K-Ras mutational status.[28] Both forms of RT delivery have demonstrated immune-mediated cytotoxicity of tumors in preclinical studies, and although in early stages, all three forms of RT may demonstrate effective tumor control in various combinations with IT.

Heavy particle RT may also be administered via radiopharmaceuticals. Radium-223 dichloride (^{223}Ra) has recently received approval from the U.S. Food and Drug Administration (FDA) for the treatment of bone metastases in metastatic castration-resistant prostate cancer (mCRPC), and it is now being studied in other forms of cancers that metastasize to bone. Because of its

chemical similarity to calcium, ^{223}Ra forms complexes with the bone mineral hydroxyapatite at areas of increased osteoblastic activity.[64] This drug is now the preferred radionuclide for cancer therapy over the beta emitters strontium-89 (^{89}Sr) and samarium-153–EDTMP (Quadramet, ^{153}Sm), which fail to extend overall survival of patients with multifocal bone metastases.[71] Alpha particles are positively charged heavy particles, whereas beta particles are much smaller and take the form of either electrons or positrons. As a result, ^{223}Ra can deliver a greater dose of radiation in a more localized manner.[64] This is due to its shorter path length in soft tissue and bone and its higher linear energy transfer, which can be 2 to 3 orders of magnitude greater than that of beta emitters, leading to a higher frequency of complex DNA breaks that are more difficult to repair.

STRATEGIES TO COMBINE RT WITH IT

RT can be applied to several different IT strategies, including the use of costimulatory agonists and checkpoint inhibitors, cancer vaccines, and adoptive cell transfer (ACT) methods to boost effector immune responses and generate long-lasting antitumor immunologic memory. These strategies, when combined with RT, may be especially beneficial for patients who have failed RT alone or who have limited treatment options. Immunosurveillance mechanisms continuously eliminate tumor cells expressing mutated peptides on the cell surface class I MHC. During this process of immunoediting, tumors continue to evolve to evade T cells through a process of immune escape, suppression, and eventually co-option.[72] For cancer cure, ablative treatments, such as RT, have to be combined with IT so that an effective antitumoral immunity is generated and sustained to restore the cancer immunosurveillance network. A framework for combining RT with IT can be studied as part of the cancer immunity cycle,[73] where release of TAA from irradiated tumor cells could drive the process. The various steps of the RT-mediated cancer immunity cycle include (1) RT-induced release of cancer antigens (TAA), (2) antigen presentation by CD103+ DCs, (3) T-cell priming and activation in draining lymph nodes, (4) trafficking of activated T cells from DLN to blood, (5) infiltration of T cells into tumors, and (6) recognition and killing of cancer cells. For steps 1 and 2, RT and various tumor vaccines can be combined with immune adjuvants, including TLR agonist, STING ligands, and agonist anti-CD40. For step 3, agonistic antibodies that augment T-cell activation, such as anti-OX40, anti-CD27, and anti-CD137; cytokines, such as IL2 and IL12; as well as immune checkpoint blockade, such

as anti–CTLA-4 that acts in the immune priming phase, can be combined. To improve T-cell infiltration in tumors (steps 4 and 5), low-dose regimens of RT and anti-VEGF therapy can be applied. And finally, to improve cancer cell recognition and killing by tumor-infiltrating CTLs (step 6), epigenetic modulation could overcome immune ignorance and escape in tumor cells by inducing antigen presentation and class I MHC expression. At this stage, immune checkpoint blockade with anti-PD1, anti–PD-L1, anti-Tim3, and anti-LAG3 could overcome tumor-evasive strategies and reinvigorate exhausted T cells, in order to sustain a robust antitumoral immune response.

Dendritic Cell Vaccines

Dendritic cells (DCs) are the regulatory cornerstones of the immune system and, therefore, are highly attractive cellular targets of immunization.[74,75] The desired TAA can be introduced into DCs by either loading with a TAA-derived peptide, protein, or TAA-reactive anti-idiotype Ab; infecting with a viral vector, which encodes the TAA or its fragments; loading with apoptotic bodies from tumor cells; or fusing directly with a tumor cell.[76–78] However, there are major time and cost constraints hindering this process. Large amounts of peripheral blood mononuclear cells (PBMCs) must be obtained from the patient via leukopheresis. DC precursors must be purified and maintained in culture several days with cytokine supplementation. The cells must be reinfused into the patient following antigen exposure/loading. This is a highly individualized and laborious procedure. However, a successful strategy approved by the FDA involves immunization with sipuleucel-T (Provenge; Dendreon), an autologous DC vaccine loaded *ex vivo* with a recombinant fusion protein consisting of the tumor antigen prostatic acid phosphatase (PAP) linked to GM-CSF for patients with mCRPC.[79,80]

Various clinical trials have shown increased tumor immunity by DC vaccines in combination with RT. One phase I study evaluated the combination of RT plus injection of autologous immature DCs in 14 patients with advanced-stage/metastatic hepatoma and demonstrated improved tumor-specific immune responses in 7 out of 10 assessable patients.[81] Another recent trial reported results from 40 patients treated with an autologous DC-based vaccine in combination with conformal RT who had recurrent, metastatic, or locally advanced tumors of the head and neck, pancreas, lung, esophagus, or uterus. Results from this study also showed that the combination of DC-based vaccine and RT induces valuable clinical responses.[82]

The systemic effect of RT through DC expansion was demonstrated in a preclinical murine model of metastatic lung cancer and hepatocellular carcinoma using direct stimulation of DC proliferation by Fms-like tyrosine kinase receptor 3 ligand (Flt3L).[13,83] Expansion of the DC compartment with Flt3L in combination with RT augmented antitumor immunity. In follow-up studies, it was shown that the addition of CD40L to the radiation and Flt3L regimen increased the long-term survival of the treated mice to 84%.[84] Similar results were reported in lymphoma and mammary carcinoma studies, indicating that radiation enhanced the systemic effect of this IT in a broad range of tumors.

Tumor Vaccines (Viral, Bacterial, and Plasmid Vectors)

Advantages of vector-based vaccines include the ability of multiple genes (including genes for costimulatory molecules and cytokines) to be inserted, their economical aspects compared with other modes of therapy, their ability to infect APCs so that the antigens they express can be efficiently processed and presented, and the characteristic of viral and bacterial vectors to act as natural adjuvants, which can stimulate the host's immune response. Known limitations of these approaches include the development of host-induced immunity to the vector itself and safety concerns related to live vectors derived from originally virulent human pathogens.[32]

Viral Vectors

One of the most studied groups of vaccine vectors is the poxvirus group. Vaccinia virus, which was derived from a benign pox disease in cows, has been administered to more than 1 billion people and is responsible for the worldwide eradication of smallpox. As a result, smallpox vaccinations in the United States and most Western countries were halted approximately 40 years ago. However, most cancer patients are older than 40 and, therefore, have some level of pre-existing immunity to vaccinia virus.[32] For this reason, recombinant vaccinia viruses cannot be given multiple times in vaccine protocols. The poxvirus family contains the replication-incompetent modified vaccinia Ankara (MVA), a derivative of vaccinia virus. MVA is thought of as a safer alternative to the smallpox vaccine because it can infect mammalian cells but cannot replicate. Other replication-defective members of the poxvirus family are the avipox vectors (fowl pox and canarypox/ALVAC). These avipox vectors infect human cells and express their transgenes for 2 to 3 weeks before cell death; they are incapable of reinfecting cells. Clinical studies have shown that avipox-based

CEA vectors can be given to patients numerous times with a resulting increase in CEA-specific T-cell responses. Preclinical and clinical studies show that optimal use of recombinant vaccinia or MVA may be to prime the immune response, followed by boosting vaccinations with other vectors such as replication-defective pox vectors, peptides, or DNA.

Advantages of using vaccinia virus or the replication-incompetent MVA avipox are[7] large amounts of foreign DNA can be inserted into the vector and[5] proteins expressed in poxviruses are more immunogenic than the native protein, which is most likely a result of the inflammatory responses triggered against highly immunogenic poxvirus proteins. Several clinical trials with recombinant poxviruses containing TAAs such as CEA, MUC-1, PSA, and HPV have been completed, and others are ongoing.[32] In clinical trials, PANVAC (poxvirus-based vaccine encoding the tumor antigens CEA and MUC-1, along with three T-cell costimulatory molecules; TRICOM) demonstrated high progression-free survival relative to control groups.[85]

Adenovirus has also been proposed as a vector in recombinant vaccine design because its viral genome can be altered to accept foreign genes that are stably integrated. To produce recombinant adenovirus vectors, endogenous viral DNA sequences are typically deleted from replication-competent regions, which results in an attenuated form of the virus with potentially improved safety. A new viral vector gene delivery platform, adenovirus serotype-5 (Ad5) [E1-, E2b-], has been described. Human cells transfected with these adenovirus constructs were shown to express the encoded transgene(s) for more prolonged time *in vivo* compared to other adenovirus vector platforms.[86] In a phase I/II clinical trial, cohorts of patients with metastatic colorectal cancer (mCRC) were vaccinated with escalating doses of the adenovirus vector carrying a gene for the GI and liver cancer–associated CEA. CEA-directed T-cell responses were induced and patients exhibited evidence of a favorable survival probability.[32]

Yeast and Bacterial Vectors

Recombinant *Saccharomyces cerevisiae* is attractive as a vaccine vector because of its nontoxic and nonpathogenic characteristic. In addition, this recombinant yeast can be engineered in large batches to express multiple antigens. *S. cerevisiae* can be propagated and purified quickly, easily, and stably. Further, it has been shown to stimulate a robust immune response from the host to non–self-antigens. Bacterial vectors, derived from intracellular pathogens, such as *Salmonella* and *Listeria*, are advantageous for their natural ability to infect

APCs, such as macrophages. Once the bacterial vector is inside the cell, the exogenous tumor antigen is processed and presented with MHC class I through the natural endogenous peptide MHC class I presentation pathway without the requirement for antigen cross-presentation. Although these bacteria are potentially virulent in humans, several attenuated strains have been developed for safe clinical use.[32]

Plasmid DNA Vectors

DNA vaccination has emerged as an attractive immunotherapeutic approach against cancer because of its simplicity, stability, and safety. Results from numerous clinical trials have demonstrated that DNA vaccines are well tolerated by patients, do not trigger major adverse effects, and act as effective adjuvant CpG DNA patterns that can stimulate plasmacytoid DCs and B cells through TLR9. DNA vaccines are also very cost-effective and can be administered repeatedly for long-term protection. Despite all the practical advantages, DNA vaccines face challenges in inducing potent antigen-specific cellular immune responses as a result of immunotolerance against endogenous self-antigens in tumors. Strategies to enhance immunogenicity of DNA vaccines against self-antigens are currently being developed.[2,24]

RNA Vectors

RNA vaccines employ mRNA transcribed *in vitro* by a bacteriophage RNA polymerase and template DNA for the antigen(s) of interest. The mRNA is translated directly into the cytoplasm of host cells, and the antigens are presented to APCs in order to stimulate an immune response. DCs may also be loaded with mRNA of TAAs or tumor RNA for a more specialized response. Some RNA molecules can act as PAMP or DAMP and thereby exhibit adjuvant effects.

RNA vaccines have been employed in studies where expression of checkpoint inhibitors, such as PD-1, is silenced utilizing siRNA, showing improved vaccine efficacy. Further, RNA vaccines increased DC function in studies where tumor antigen mRNA with mRNA encoding for checkpoint molecules such as CTLA-4 and GITR were cotransfected, resulting in simultaneous TAA presentation and local checkpoint inhibition.[87]

Enhanced Effector Responses by Introduction of Cytokines or Costimulatory Molecules into the Tumor Microenvironment

Induction of antigen-specific T-cell responses requires both antigen presentation and expression of costimulatory molecules, B7-1/2, OX40L, or 41BBL, in DCs

that can interact with their cognate ligands/receptors on T cells.[25] Preclinical trials have shown that exposure of human prostate cancer cells to ionizing radiation increased expression of costimulatory ligands OX40L and 41BBL and decreased expression of PD-L1 molecules at all dose levels, thus enhancing CTL function.[33] These findings prompted the idea of localized expression of costimulatory molecules and/or cytokines within the tumor microenvironment should enhance the efficient activation of effector T cells. Introduction of B7-1/CD80, a costimulatory ligand of both the activating CD28 and inhibitory CTLA-4 receptors, into a tumor enhances antitumor immune responses. Similar positive results were achieved when cell adhesion molecules, such as ICAM-1 and (LFA)-3, were expressed in tumors. In clinical studies, recombinant vectors expressing a trio of costimulatory and cell adhesion molecules (B7-1, ICAM-1, and LFA-3; designated TRICOM) were directly injected into melanoma lesions, which enhanced tumor-specific CTL responses. Cytokines can also be introduced into the tumor mass using delivery vectors, as in the case of a recombinant vaccinia virus expressing GM-CSF directly injected into melanoma lesions.[32]

Tumor arrest and increased overall survival were shown in a murine sarcoma model when RT was administered with an agonistic antibody for OX40, which on activated T cells stimulates T-cell proliferation, effector differentiation, and expansion of the effector memory T-cell populations and also suppresses Treg function.[88] Inhibition of the inhibitory CTLA-4 engagement also enhanced effectiveness of RT in 4T1 murine mammary carcinoma resulting in diminished metastasis and increased survival. However, in this case, RT dose and timing were critical for CTLA-4 inhibition.[25]

A further study combined RT and agonist anti-CD40 antibody to treat B-cell lymphoma.[89] Although CD40 is an essential stimulatory molecule during T-/B-cell collaboration for high-affinity antibody responses, CD40 engagement is also known to play a role in macrophage activation and enhanced phagocytosis. On their own, each monotherapy was ineffective, but when RT and agonistic anti-CD40 were combined, long-term survival was reported.[89]

Recently, it has been shown that STING pathway activation is required in host APCs for spontaneous CD8+ T-cell activity targeting tumor-derived antigens. Production of IFN-β via this pathway contributes to the antitumor effect of radiation, which may be enhanced by adding a STING agonist. An *in vivo* study suggested that direct activation of the STING pathway in the tumor microenvironment by intratumoral injection of specific agonists might be an

effective therapeutic strategy to promote wide range T-cell priming against an individual's tumor antigen repertoire.[90] Intratumoral injection of synthetic STING agonists induced significant regression of established tumors in mice and suggested systemic immune responses, which prevented metastases. In separate studies of a murine genetically engineered model of pancreatic cancer, combination of IGRT with a novel STING ligand synergized the control of both local and distant tumors, indicating that inflammatory pathways activated by STING ligands generate a powerful adjuvant activity for enhancing adaptive immune responses to tumor antigens released by RT.[91] Intratumoral injection of STING agonists has demonstrated significant therapeutic effects in multiple mouse tumor models, including melanoma; colon, breast, and prostate cancer; and fibrosarcoma, suggesting that development of novel pharmacologic approaches to target STING activation within the tumor microenvironment deserves attention for clinical translation.[92,93]

Another study, which employed renal carcinoma with bilateral pulmonary metastases in a mouse model, observed that combined local irradiation of one lung with systemic IL-2 therapy reduced the tumor burden in both lungs more than was achieved by either monotherapy alone.[94,95] Local tumor irradiation was also combined with intratumoral injection of a novel immunocytokine, an IL2-linked tumor-specific antibody in preclinical murine models of melanoma, neuroblastoma, and head and neck squamous cell carcinoma.[96] This treatment showed complete regression of established tumors in most animals associated with an enhanced antibody-dependent cell-mediated cytotoxicity (ADCC) and a tumor-specific memory T-cell response. In mice bearing large primary tumors or disseminated metastases, the investigators administered a triple combination of intratumoral immunocytokine, RT, and systemic anti-CTLA-4 with eradication of large tumors and metastases and improved survival, thereby eliciting an *in situ* vaccination effect deserving potential clinical translation.[96]

Immune Checkpoint Therapy

One of the major impediments to tumor IT is the natural ability of most tumors to escape immune responses. Unlike most infectious immunity, tumor immunity must be continuously active for a long period of time, which frequently results in exhaustion of both $CD4^+$ and $CD8^+$ tumor-reactive T cells. Exhaustion is mediated by negative inhibitory interactions whereby either costimulatory ligands, such as B7-1/B7-2, bind to inhibitory receptor CTLA-4 or dedicated inhibitory receptors bind their cognate inhibitory ligands, as with PD-L1/PD-L2

to PD1, B7-H3 to Lag3, or Galectin to TIM3.[25] Targeted inhibition or activation of these interactions can be achieved with monoclonal antibodies (mAbs). To prevent CTL exhaustion, immune checkpoint mediators, such as CTLA-4 and PD1, on T cells and PD-L1, on tumor cells, are targeted with blocking antibodies.[97] Experimental evidence suggests that anti–CTLA-4 mAb facilitates T-cell proliferation and activation in the early phases of the response and reduces the suppressive function of Tregs. Clinical evidence has shown that fractionated RT combined with ipilimumab, an anti–CTLA-4 mAb, not only delayed tumor growth at the primary site but also significantly delayed tumor metastasis in melanoma patients. Several mAbs are also used in the clinic that block the PD-1/PD-L1/PD-L2 interactions either on T cells (anti-PD1 pembrolizumab) or on tumor cells (anti–PD-L1 avelumab). As PD1 expression is induced later in activated T cells, blockade of this pathway is particularly promising in restoring the functional competence of exhausted T cells.[97]

Fractionated RT could result in PD-L1 up-regulation on tumor cells in a variety of syngeneic mouse models of cancer via a mechanism of adaptive resistance-induced IFN-γ.[98] In a murine model of colon cancer, it was shown that the sequencing of anti–PD-L1 therapy was important for optimal therapeutic outcome, with concomitant but not sequential adjuvant administration with fractionated RT was required to improve survival. However, preclinical studies in murine models have limitations of lack of immunosurveillance in transplantation models. In a recently published phase III randomized clinical trial of consolidation therapy with anti–PD-L1 versus placebo after chemo-RT for stage II non–small cell lung cancer (NSCLC), the progression-free survival was significantly improved despite the use of anti–PD-L1 therapy after the completion of chemo-RT.[99]

Although immune checkpoint inhibitors result in impressive clinical response in a subset of patients, resistance may develop eventually. Optimal results will require combination of several immune checkpoint inhibitors. In a study of RT and anti–CTLA-4 therapy in melanoma, resistance developed due to up-regulation of PD-L1 on melanoma cells accompanied by T-cell exhaustion.[100] This highlighted the importance of combining anti–CTLA-4 and anti–PD-L1 therapy for optimal effects. Subsequent work by these investigators demonstrated that persistent type I and II IFN signaling induced PD-L1–dependent and PD-L1–independent adaptive resistance to immune checkpoint blockade. This resistance developed due to acquisition of a STAT1-related epigenomic changes in tumor cells with expression of IFN-stimulated genes and

ligands for multiple T-cell inhibitory receptors, such as TIM3, LAG3, Galectin-9, and TNFRSF14 (HVEM).[101] To overcome adaptive resistance, one could either combine multiple checkpoint inhibitors or pharmacologically inhibit chronic IFN signaling in a temporal fashion.

Adoptive Cell Transfer Approaches

Adoptive cell transfer (ACT) is an innovative new IT approach that involves genetic engineering of the patients' own immune cells to treat their cancer. The two major approaches include generation of TAA-specific TCR-expressing T cells and the creation of TAA-specific chimeric antigen receptor (CAR) T cells. Patient-derived tumor-specific T cells can be isolated *in vitro* by expanding rare populations of the patient's own T cells in the presence of tumor extracts and DCs or by transducing the T cells with genetically engineered TCR reactive with the TAA associated with the patient's MHC haplotype. Although this approach is highly personalized, it is also inherently slow and complicated. Alternatively, T cells can be transduced with a genetically engineered CAR where a TAA-specific antibody is fused to the signaling subunits of the TCR. This strategy takes advantage of the high-affinity, MHC-independent nature of antigen recognition of antibodies, thus opening the way to off-the-shelf, tumor-specific, but not individual patient-restricted, reagents.[102]

CAR T cells have recently shown success in the treatment of therapy-resistant B-cell acute lymphoblastic leukemia (B-ALL) and B-cell lymphoma and have been approved by the FDA for use against B-ALL. Despite the success of CAR T cells in blood cancers, their use to treat solid tumors is challenging, because of inefficient homing of T cells to tumor sites and the shortage of unique solid TAAs.[102] A preliminary study aimed to assess the effect of local irradiation in increasing CAR T-cell infiltration in EGFR-expressing solid tumors using a murine lung cancer model. Increased infiltration of EGFR-CAR T cells was observed in tumors that were irradiated compared to tumors treated with EGFR-CAR T cells alone, suggesting that radiation improved CAR T-cell infiltration, but further research will be needed to demonstrate the broader utility of this promising new technique.

CLINICAL CONSIDERATIONS FOR RT AND THE IMMUNE SYSTEM: LEARNING TO WORK TOGETHER

Radiation therapy can have paradoxical effects on the immune system. We

must learn to maximize the anti-cancer immune response when designing radiation treatments.

The excitement generated by the case reports of Postow[103] and others[104] demonstrating an abscopal effect of RT led to an unprecedented excitement of combinations with RT and immune checkpoint blockade. Other work with high-dose IL-2 suggested immune modulation combined with stereotactic body radiation could have significant clinical impact.[105] However, few reports have been able to replicate these dramatic results of Postow with RT and checkpoint inhibitors, which suggests that the clinical trial design may have significant implications when testing these combinations. However, there are retrospective data that suggest the clinical combination of RT and checkpoint inhibitor can have benefit. In this secondary analysis, patients were divided into subgroups to compare patients who previously received radiotherapy with patients who had not. Overall survival with pembrolizumab was significantly longer in patients who previously received any RT than in patients without previous radiotherapy (HR 0.58 [95% CI 0.36 to 0.94], $P = .026$; median overall survival 10.7 months [95% CI 6.5 to 18.9] vs. 5.3 months [2.7 to 7.7]) and for patients who previously received extracranial RT compared with those without previous extracranial RT (0.59 [95% CI 0.36 to 0.96], $P = .034$; median overall survival 11.6 months [95% CI 6.5 to 20.5] vs. 5.3 months [3.0 to 8.5]). Fifteen (63%) of 24 patients who had previously received thoracic RT had any recorded pulmonary toxicity versus 29 (40%) of 73 patients with no previous thoracic RT. Three (13%) patients with previous thoracic RT had treatment-related pulmonary toxicity compared with one (1%) of those without; frequency of grade 3 or worse treatment-related pulmonary toxicities was similar (one patient in each group). This is one of the few studies that suggest that previous treatment with RT in patients with advanced NSCLC results in longer progression-free survival and overall survival with pembrolizumab treatment than that seen in patients who did not have previous RT, with an acceptable safety profile.[106]

Recently, a phase 3 study compared anti–PD-L1 antibody, durvalumab, as consolidation therapy with placebo in patients with stage II NSCLC who did not have disease progression after two or more cycles of platinum-based chemoradiotherapy.[99] After a 2:1 ratio randomization, the median progression-free survival from randomization was 16.8 months (95% confidence interval [CI], 13.0 to 18.1) with durvalumab versus 5.6 months (95% CI, 4.6 to 7.8) with placebo ($P < .001$), and the 18-month progression-free survival rate was 44.2%

versus 27.0%. Without any significant increase in toxicity, the response rate was higher with durvalumab than with placebo (28.4% vs. 16.0%; $P < .001$), and the median duration of response was longer (72.8% vs. 46.8% of the patients had an ongoing response at 18 months). These impressive results will clearly set the new standard of care in NSCLC.

Clinical considerations when combining RT and IT include dose of radiation, fractions of radiation, scheduling of drug and radiation (neoadjuvant, concurrent, adjuvant), radiation field size, and concomitant use of systemic chemotherapy.[107] A review of current clinical trials from ClinicalTrials.gov combining RT and immune modulation reveals 60 trials are focused on either treatment of metastatic disease or localized disease. Within each of those categories, radiation is combined with either CTLA-4, PD-1, or both with a few trials examining the use of GM-CSF, TLR-9 agonist vaccines, or cell-based therapies.

Dose–Response Effect in Radiation Therapy

Today's radiation oncologists were bought up on the concept of "the more the better," encouraged on by Puck's seductive *in vitro* clonogenic cell survival curves that suggest an exponential relationship between radiation dose and cell kill.[108] Clinicians extrapolated these findings into the clinic, pursuing ever-higher radiation doses in the pursuit of local control and the sometimes-elusive cancer cure. In parallel to the concept of increased dose was enlarged radiation field size, seeking to destroy both the gross "macroscopic" tumor and "subclinical disease," especially small but at-risk regional lymph nodes. There is good evidence for the importance of irradiating "high-risk" lymphoid tissue in Hodgkin disease and cervical cancer, but the concept has influenced tumor planning in all cancer sites.

A number of key clinical trials from recent decades have contradicted these concepts. Although clearly a minimal dose of radiation is necessary (e.g., 60 Gy in glioblastoma and non–small cell lung cancer), attempts to escalate doses further have failed to deliver benefit in a range of cancers: esophageal, low-grade glioma, glioblastoma, and most recently non–small cell lung cancer.[109] Furthermore, large radiation fields are often poorly tolerated, especially in the context of concomitant chemotherapy. Theodore Puck succeeded in creating cell survival curves, where more radiation killed more cells, by developing techniques to grow cell monolayers *in vitro*. In doing so, he negated systemic effects and the role of the microenvironment.

What Is the Optimal Field Size? Lessons from Prostate and Pancreatic Cancer

We do not yet know the optimal dose and scheduling of radiation for combination with chemotherapy and IT. In prostate cancer, multiple randomized trials have indeed validated the concept of higher radiation dose achieving better tumor control.[110] However, the utility of larger radiation fields, that is, prophylactic irradiation of the whole pelvis, remains in doubt. A large cooperative group trial (RTOG 9413)[111] enrolled 1,323 patients in a two-by-two randomized trial seeking to assess the role of (1) whole-pelvic radiation compared to prostate radiation only and (2) neoadjuvant hormonal therapy compared to adjuvant therapy. Unfortunately, this trial did not succeed in providing clear answers, possibly because of an unexpected interaction between the size of the radiation field and hormonal therapy.[111] The trial RTOG 0924 is attempting to answer that question, which has still been elusive.

Pinkawa[112] provides important insight regarding why whole-pelvic irradiation may be less beneficial than expected in prostate cancer. Pinkawa et al. retrospectively reviewed hematologic changes during RT for prostate cancer. They noted that (1) RT significantly depressed all blood lineages in peripheral blood, especially lymphocytes, (2) these changes were prolonged—continuing at least 6 to 7 weeks following completion of therapy—(we do not know what happens at later time points), (3) whole-pelvic RT is more detrimental than prostate-only RT, and (4) neoadjuvant hormonal therapy decreased hemoglobin levels. Although endpoints in this study were confined to crude blood counts, we speculate that they reflect a detrimental impact on immune system function and tumor oxygenation, possibly explaining the disappointing results of RTOG 9413. In pancreatic cancer, the group led by Crittenden addressed this by analyzing the effect of neoadjuvant standard fractionated and hypofractionated chemoradiation on immune cells in patients with locally advanced and borderline resectable pancreatic adenocarcinoma. They found that standard fractionated chemoradiation resulted in a significant and extended loss of lymphocytes that was not explained by a lack of homeostatic cytokines or response to cytokines. By contrast, treatment with hypofractionated RT avoided the loss of lymphocytes associated with conventional fractionation.[113]

RT and the Immune System, Obstacles for Working Well Together

After many decades of basic research, the importance of the immune response in preventing and treating cancer is no longer controversial. For many years, we

have known that subjects with prolonged immunosuppression are at increased risk of developing cancers.[114–116] More recently, phase III randomized trials have demonstrated the efficacy of IT in metastatic melanoma, lung cancer, head and neck cancer, Hodgkin disease, and renal cell cancer, with trials under way in almost every disease site.

The relationship between RT and the immune system is complex. On the one hand, RT may augment the immune response, for example, by (1) killing cancer cells, increasing the tumor's antigenicity, and (2) rendering surviving tumor cells more susceptible to immune-mediated killing through increased MHC class I presentation. On the other hand, the immune system may help RT, eradicating residual disease inside and outside of the radiation field. The extreme demonstration of these interactions is the occasionally observed phenomenon when radiation can also reduce tumor growth outside the treatment field, the so-called abscopal effect.

As early as 1976, the effect of radiation on lymphocyte populations was appreciated.[117] Work by Stuart Grossman has suggested another mechanism through which radiation may suppress the immune response. They noted that in a range of cancers (high-grade glioma, squamous head and neck cancer, pancreatic adenocarcinoma—in both the locally advanced and adjuvant setting—non–small cell lung cancer), radiation/chemoradiation induces severe treatment-related lymphopenia. Furthermore, they correlated severe lymphopenia with early tumor progression in each of these disease settings.[118–127]

Looking only at crude blood counts may underestimate the effect of cytotoxic therapies on the immune system. Schuler et al.[128] examined lymphocyte subtypes in patients with head and neck cancer undergoing chemoradiation.[128] They found that chemoradiation decreased the overall number of circulating CD4 helper cells, but paradoxically increased the number of CD4+ CD39+ Treg that serves to dampen the immune response. Furthermore, they found that the increase in regulatory T cells persisted years after the conclusion of therapy.

It is often assumed that the effect of RT on peripheral blood counts is the result of bone marrow irradiation, where the normal stem cells are very sensitive to DNA damage. Work by Yovino proposes an alternative mechanism: Lymphopenia is caused by apoptosis of lymphocytes passing through the radiation field.[119] The authors estimate that during 6 weeks of partial brain irradiation in glioblastoma, 99% of lymphocytes receive at least 0.5 Gy, with a mean circulating lymphocyte dose of 2 Gy, sufficient to induce apoptosis in these highly sensitive cells. A molecular mechanism has been suggested by

Ellsworth et al.[123] that there is an absence of a compensatory increase in interleukin-7 levels. The failure to mount an appropriate homeostatic cytokine response may be responsible for the prolonged lymphopenia frequently observed in these patients, which may be highly dependent on field size and fractionation as the cytokine change was not observed by others.[113] RT-induced lymphopenia along with tumor-induced granulocytosis contributes to an increase in the neutrophil-to-lymphocyte (NLR) ratio, which has been validated in many studies as an independent prognosticator for overall survival in patients in clinical trials.[129]

Safety of Immune Modulation with RT

A number of reports have shown safety with the combination of immune checkpoint inhibitors and RT across different disease sites (cervix, head and neck, lung, brain[130] cancer, etc.). For single-agent PD-1/PD-L1 or CTLA-4, there appears to be no significant toxicity when added to RT. To date, there are very limited data regarding combinations of checkpoint inhibitors and RT; however, there are dozens of trials currently accruing. The diagnosis and management of immune-related adverse events in combination trials of RT and immune checkpoint blockade deserve special attention.[131]

Modulating the Immune System–Radiation Interaction

For many years, we have down-regulated the immune system by prescribing chemotherapy and steroids during RT. The expanding arsenal of immunomodulators (PD-1 inhibitors, tumor vaccines, ACT therapies) provides us with unprecedented opportunities to modulate and activate the immune system during RT. The challenges are immense, and investigators will need to choose the most appropriate patients, immunomodulators, and radiation therapies in order to succeed. Work by Pinkawa and others[112] informs us that despite the efficacy of RT in prostate cancer, its use is associated with relative lymphopenia and likely immunosuppression.

There is evidence in the metastatic disease space that a combinatorial immune approach would have the highest probability of success. One approach for designing radiation trials would be to use a neoadjuvant trial design to, first, determine optimal response by immune readout in the organ, and peripheral blood in patients with locally advanced disease, and, second, determine the clinical response in an expansion cohort of patients with oligo-/metastatic disease at presentation where appropriate. The following considerations

informed the trial design.

Preoperative chemotherapy and chemoradiotherapy are components of standard treatment paradigms for several solid tumors, including muscle invasive bladder cancer (≥T2), invasive breast cancer (≥T2), esophageal cancer (T1bN+ or T2-T4a and/ or N+), and rectal cancer (T3 or N+).[132–135] Pathologic responses determined at surgery provide clinical data including sensitivity to chemotherapy, potential need for adjuvant treatment, and for patients with pathologic complete response (pCR) and can correlate with survival.[132] Furthermore, intratumor and stromal molecular, hormonal, immunologic, and other changes, which evolve during preoperative therapy, can be comprehensively evaluated at the organ level following radical surgery and lymph node dissection. Fraction size should be guided by preclinical studies. One should avoid large radiation fields and prophylactic lymph node coverage or find ways to counter the radiation-induced lymphopenia. The schedule of drug and radiation should be based on data-driven preclinical experience. The primary objective for a phase I would be to determine the safety and tolerability of immune modulation combined with radiation. Secondary objectives could include evaluation of intratumoral immune responses and assessment of immune responses in peripheral blood samples. Expansion cohort would be in oligo-/metastatic patients.

Immune Profiling of Patients Undergoing Clinical Trials of RT and IT

Cancer therapy has been dictated by the histopathologic evaluation of tissue samples obtained during biopsy or surgical resection of the primary tumor. Despite traditional tumor staging using the AJCC/UICC-TNM classification, it is now recognized that clinical outcome can significantly vary among patients within the same stage. Several reports have alluded to the significance of the host immune system in controlling tumor progression. Within the same clinical stage, the type, density, and location of immune infiltrate in the tumor tissue could predict for the clinical outcome in patients with colorectal cancer.[136,137] Since this report, the immune infiltrates within tumors have been quantified by a methodology, termed an immunoscore of the tumor.[138,139] While tumor biopsies are critical to define the immunoscore, evaluation of an ongoing antitumoral immunity might require sampling of several biologic compartments, including the tumor, spleen, tumor-draining lymph nodes, bone marrow, and blood.[140] Clinical studies are beginning to define the immune profile of patients that can predict the clinical outcome of combination therapies with IT. While designing

clinical trials, tumor and circulating pharmacodynamic correlates of immune modulation should be carefully considered.[141] Although blood-based immune assays are highly valued, novel immune PET imaging is being developed to monitor CD8+ T-cell infiltration in tumors[142,143] and granzyme B PET imaging to assess CTL activity.[144] Studies have also been conducted in mouse models and patients using novel immune PET imaging of PD-L1.[145–148] Finally, PD-L1 expression is being monitored in circulating tumor cells as prognostic factors for survival in patients with head and neck[149] and lung cancer.[150]

Summary

The next generation of clinical trials led by radiation oncologists should tailor their treatments and determine RT dose, fraction, and field size, based not just on tumor-ablative considerations, but also with a view to maximizing the antitumor immune response. This will be guided by a comprehensive immune profile of the patient using functional imaging of the immune effector cells and immune checkpoint molecules, immunoscore of pathology, and circulating pharmacodynamic immune markers.

Theodore E. Yaeger

INTRODUCTION

The first report of *in vitro* cytotoxicity (in paramecium) was seen by combining visible light and an acridine drug in 1900.[1] That observation laid the foundation to begin reporting the results of combination topical eosin (a biologic stain) with visible light for treating a skin tumor.[2] Little progress in photodynamic therapy (PDT) ensued until about 1960 with the discovery—attributed to Lipson et al.[3]—of hematoporphyrin derivative (HpD). Samuel Schwartz[4] reported on a water-soluble mixture of porphyrins followed by a series of preclinical and then clinical investigations led by Dougherty et al.[5]

Despite deep historical origins and modern research investigations dating back 40 years, the clinical application of PDT still remains limited to specific clinical situations. In part, this has been due to the limited and superficial depth of cytotoxicity achieved with past photosensitizers and light delivery techniques. It is also due to the complexity of its application, requiring familiarity with safe photosensitizer administration coupled with the technical requirements for effective light delivery and, also, the optical expertise to prescribe and deliver an activating light energy for very specific indications.

Despite disadvantages, there are several compelling reasons to evaluate PDT as a major therapeutic approach in the management of cancer. PDT has the unique mechanism of action for allowing for nonoverlapping toxicities with traditional cancer therapeutics. As such, PDT does not exclude the subsequent administration of these treatment modalities. Technical advances with interstitial light delivery techniques (and advancements in modeling its dosimetry[6]) along with the clinical development of photosensitizers capable of absorbing and being activated at longer wavelengths now offer the potential for more penetrating and isolated cytotoxicity.[7] Unlike traditional chemotherapeutics and ionizing radiation therapy, there have not been any long-term genotoxic effects with the

use of PDT, an observation consistent with several *in vitro* studies.[8–10] The explosion in our understanding of tumor biology and the influence of the microenvironment has also provided tremendous insights into the development of novel strategies to explore the clinical efficacy of PDT, including its combination with biologic therapeutics. This also includes the potential for PDT to enhance the effects of traditional cancer therapeutics and its promising role to more effectively induce adaptive cell-mediated immunity.

PRINCIPLES OF PHOTODYNAMIC THERAPY

Photosensitizers

PDT represents a treatment modality that combines the selective photochemical activation of photosensitizers with electromagnetic radiation in the visible energy range (i.e., visible light). Photosensitizers (PS) may be given to the cancer patient either systemically, topically, or injected locally, but its specific chemical structure can significantly influence the effectiveness of a PDT treatment. These include influencing its biodistribution and subcellular localization along with how efficiently it absorbs light (referred to as its *molar extinction coefficient*) to generate reactive oxygen species (ROS), including singlet oxygen (referred to as its *quantum yield*) (Table 31.1). A PS with a low molar extinction coefficient will require large concentrations of the PS and light energy to be effectively delivered for photoactivation.

There are now many PS that have been discovered with most under preclinical evaluation but several receiving regulatory approval for clinical application in the United States, European Union, and other countries. The first PS to receive regulatory approval was a semipurified preparation of HpD known as Photofrin (porfimer sodium). Porfimer sodium represents a complex mixture of hematoporphyrin oligomers whose chemical composition has been difficult to reproduce consistently. It has an absorption peak at 630 nm with a relatively low molar extinction coefficient, thus requiring large concentrations of drug and light energy (fluence) to be delivered. It has also been shown to have a prolonged risk of skin photosensitivity reflecting its relative lack of selectivity. Although used routinely in clinical practice, these disadvantages have spurred ongoing PS development.

Several ideal characteristics have been well articulated in the area of PS development. These include the following: PS that has a well-established structure, ideally a pure compound with a constant composition and a stable

shelf life.

Without light activation, it should have little toxicity and tumor specificity when administered. With light, a PS with spectral absorption peaks demonstrates a high extinction coefficient when effectively activated. But, it is not entirely clear if the above is always desired. For example, a strong PS absorption at a specific wavelength can contribute to reduced light penetration, a phenomenon referred to as *self-shielding*. Moreover, potent PS such as temoporfin/mTHPC (Foscan) that thus require little drug and light for its efficient activation have been associated with significant complications necessitating even more vigilance to the light dosimetry (as defined below).[11] The wavelengths of a photosensitizer's absorption peaks also influence how the PS will be used clinically, with absorption at longer wavelengths (i.e., 700-nm range) offering deeper light penetration in human tissues. Lastly, some PS may undergo a process of *photobleaching*, whereby the PS in turn reacts with the singlet oxygen or other reactions created in the photoactivation process, limiting the ability to act as a PS. Typically, photobleaching decreases a photosensitizer's reactivity, which may or may not be desirable depending on the context of its clinical application.

Structurally, photosensitizers are generally classified as porphyrin-based or nonporphyrins with the former sharing a common backbone that consists of the tetrapyrrole ring. Other structural backbones that have demonstrated photosensitizing capabilities include the presence of four phenol rings and polycyclic ring compounds based on the pyrrole ring especially the tetrapyrrole PS. Extensive reviews are available regarding the specific physicochemical properties (i.e., primary structures, the presence of complexed heavy metals, and specific side chain substitutions) and the impact on its systemic biodistribution, cellular uptake, and photosensitizing properties.[7]

TABLE 31.1 FACTORS AFFECTING THE EFFICACY OF PHOTODYNAMIC THERAPY

Photosensitizer (PS)	Effectiveness of the tumor vasculature to deliver PS, extracellular and intracellular location of PS, PS extinction coefficient, singlet oxygen quantum yield, PS photobleaching
Light	Drug–light interval, fluence, fluence rate
Microenvironment	Oxygenation, status of immune system
Tumor response	Complex interaction between proapoptotic and prosurvival signals, angiogenic response

In general, the hydrophobic compounds with two or less negative charges have the ability to cross the plasma membrane. Otherwise, intracellular uptake is through active endocytosis. The charge of the hydrophobic PS can influence where a PS localizes with cationic charges (positive). This tends to localize to the mitochondria and anionic PS with a net charge of negative 2 or greater tending to localize in the lysosomes.[12] Cationic PS localizing to the mitochondria have been suggested to be more effective in mediating direct cytotoxicity.[13]

Tumor specificity is in part mediated by selective light administration and its natural energy attenuation. Specific extracellular and intracellular PS delivery is felt to further contribute to this process. Human tissue studies in patients receiving porfimer sodium–mediated intraperitoneal PDT have confirmed PS selectivity, even if limited.[14] Systemically administered photosensitizers (those with the tetrapyrrole backbone) will associate with serum proteins, including albumin and low-density lipoproteins (LDL). The association with LDL proteins has been suggested to be a potential mechanism that may contribute to specific tumor localization.[15] In this model, it has been proposed that tumor selectivity occurs due to a preferential up-regulation of LDL receptors in tumor cells because of the rapid plasma membrane turnover rate and the need for constituents in its biosynthesis. Alternatively, the functionally altered tumor vasculature resulting from overexpression of vascular endothelial growth factor[16] (VEGF) and its impaired lymphatic clearance of the extravasated PS have also been advanced as a functional mechanism.[17] Although it may lead to increased PS retention, the extracellular distribution of the PS can be inhomogeneous and can impact the effectiveness of a PDT treatment. The demonstrated direct tumor cell killing was a function of the distance from a tumor’s vascular supply.[18] In contrast, photosensitizers that tend to be located in the intravascular space can increase the effectiveness of PDT through mediating vascular damage and tumor infarction.[19]

The subcellular localization of a PS that can similarly influence the mechanism of cellular injury has been well-studied and recently summarized.[20] In general, photosensitizers that localize to the plasma membrane and lysosomes are likely to cause injury by necrosis. Those localizing to the mitochondria and endoplasmic reticulum are likely to initiate cell death by way of direct cell apoptosis.[5,21] However, mitochondrial injury can also mediate a necrotic cell death by mitochondrial membrane damage.[20]

Most photosensitizers tend not to accumulate in the nucleus, possibly

explaining the paucity of genotoxicity and observed carcinogenesis.[8,22] Although DNA damage has been reported in cell culture experiments for various photosensitizers,[8,10,23] for 5-aminolevulinic acid,[23,24] efficient DNA repair has also been observed. This suggests that the damage may not be sufficient to overwhelm a cell's repair capacity.[10,25] As PDT can mediate cell death through non-DNA targets, the potential mutagenic effects of any DNA injury are likely to be further limited by its cell death.

Photosensitizer Activation

Following photosensitizer administration, the drug–light interval (DLI) that is prescribed warrants consideration. Preclinical studies have demonstrated that varying the DLI can influence both the PS extracellular and intracellular localization.[19,26] In general, longer DLI will promote PS extravasation and intracellular uptake, provided it has a sufficient long pharmacokinetic lifetime. However, the passive targeting of either the vascular (short DLI) or tumor compartment can be compounded by the lipophilicity of the PS and associated proteins within the vasculature. Targeting both the vascular and tumor compartment with repeat PS administration, combining both a short DLI and a long DLI, can further improve the effectiveness of PDT. However, the order of the repeat PS administration and activation may be particularly important. Prescribing an initial short DLI that targets the vasculature can create subsequent hypoxia that limits the efficacy of the repeat PS with a long DLI.[19]

PS activation involves the absorption of wavelength-specific energy, causing specific changes in the electron energy states of the PS. Energy absorption can cause a PS electron to move from its ground state to a higher energy level or excited energy state. While in the excited energy state, transition back to the ground state may occur, with energy released in the form of fluorescence or heat dissipation. Thus, some of the light absorbed by a PS may be re-emitted at a different wavelength, allowing for fluorescence detection of the PS or *photodynamic diagnosis* (PDD). Figure 31.1 demonstrates the Jablonski energy diagram. It depicts the energy transitions that may occur with PDT. Two possible excited energy states may be possible, a singlet state (S1) and the triplet state (T1), which has a longer half-life. The distinction depends on the spin direction of the excited electron relative to its paired electron in the ground state. The triplet state has both electrons parallel to each other, and its ability to return to a ground state emitting fluorescence is impeded because of this spin direction.

Transition to the triplet state through a process referred to as *intersystem*

crossing is critical to the generation of cytotoxic ROS. This is largely due to the longer half-life of the triplet state that increases the probability of interacting with a nearby organic molecule (i.e., in the plasma membrane), generating reactive anions or cations that in turn may react with molecular oxygen generating ROS (referred to as a type I reaction). Alternatively, a PS in its triplet state may directly transfer its energy to molecular oxygen to form an excited state singlet oxygen ($^1O_2$) (type II reaction). Both types of reactions may occur simultaneously, though direct singlet oxygen production is felt to be the dominant mechanism of cytotoxicity.[27,28] Singlet oxygen within the cell has a limited half-life (estimated to be <0.04 μs) and thus a limited range of diffusion and activity (<0.02 μm).[22,29] As such, PS cytotoxicity is limited to its extracellular and intracellular (also, subcellular) localization and adjacent potential targets for reactivity.[22] For example, photosensitizers that tend to biodistribute or favor being localized in the vasculature will favor an antivascular necrotic mechanism of injury. The specific subcellular localization offers an added degree of specificity to its cytotoxicity.

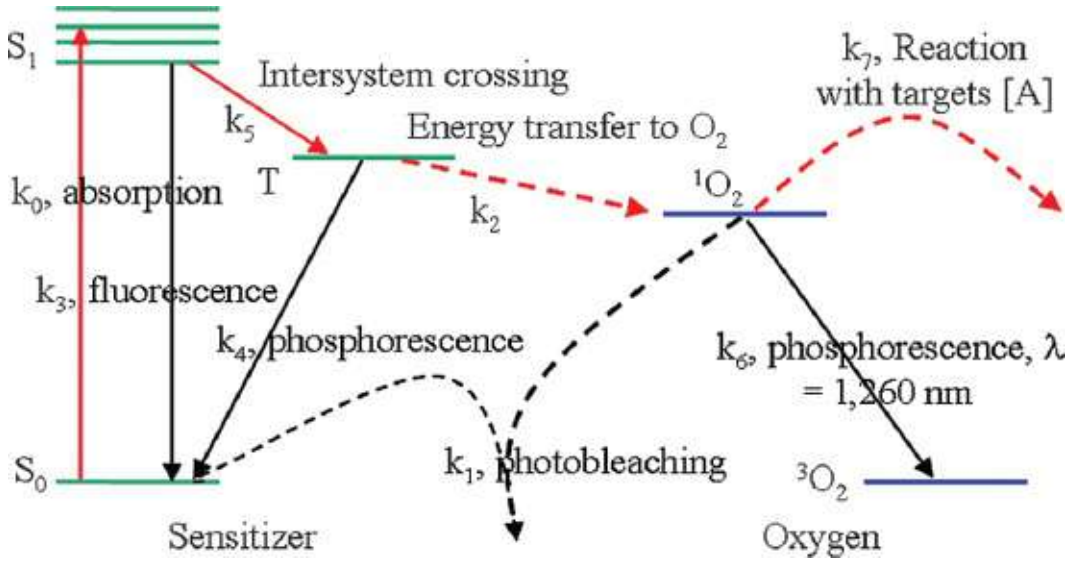

FIGURE 31.1. Jablonski energy diagram following type II photosensitizer activation.

Physics of Light Dosimetry

PDT is inherently a dynamic process. All three principal components—photosensitizer, light, and oxygen—interact dynamically over the time period of a PDT prescription.[5] As light interacts with human tissue, its energy distribution is influenced by surface reflection and with absorption and scatter at depth. Light scatter in human tissues can be affected by many factors. Tissue architecture and

geometry, plus heterogeneity at the histologic and cellular levels, can contribute to photon scattering, thus limiting the energy deposited at depth. Thus, it is important to recognize that light scatter is likely to be different from one tissue type to another. Although many factors remain to be fully characterized and accounted for in the prescription of PDT, it is presumed that selecting longer wavelengths for photoactivation can help to reduce photon scatter, thus increasing light penetration.

The deposition of light, or its *dosimetry*, is determined by the light source characteristics and the tissue optical properties, both on the cell surface and depth, in contrast to ionizing radiation. In turn, the tissue optical properties are influenced by the spatial distribution and concentration of both the photosensitizer and oxygen in the illuminated tissues. During illumination, the light dosimetry dynamically changes as the photodynamic process consumes oxygen and/or alters the blood flow.[30] For some photosensitizers, self-shielding can influence the light dosimetry at depth. Finally, the distribution of a photosensitizer may change as a result of photobleaching, a process whereby the photodynamic modification of the photosensitizer itself reduces the ability to further be photoactivated.

Quantifying the distribution of the light that is used in photoactivation is important biologically and for quality assurance reasons, as in the practice of ionizing radiation. The ability to relate the treatment outcome to the effective light fluence and its rate of delivery (*fluence rate*) facilitates an understanding of its relationship not only to the treatment outcome but also to any potential toxicities, as areas of high fluence and fluence rates have been associated with treatment toxicities.

Explicit dosimetry refers to the prediction of a singlet oxygen dose on the basis of measurable quantities that contribute to the photodynamic effect.[31] In clinical practice, the quantity most amenable to measurement is the PDT dose, defined as the light energy deposited to a photosensitizer. This quantity is proportional to the product of the absorption coefficient of the photosensitizer and light fluence. The absorption coefficient of the photosensitizer is, in turn, proportional to the photosensitizer concentration. PDT dose calculated in this way is a good predictor of outcome if one is operating in a drug- or light-limited situation when there is ample oxygen supply. To generally account for the oxygen effect, the concentration of reacted singlet oxygen (i.e., the concentration of reactions between singlet oxygen and molecular targets within the tumor cells) needs to be modeled as a function of PDT dose and tissue oxygenation. It

has been shown that the reacted singlet oxygen concentration can be expressed as the integration of the product of the PDT dose rate and the photosensitizer's singlet oxygen quantum yield.[32]

Implicit dosimetry refers to the use of photobleaching of the sensitizer as a measure of the light dose. For sensitizers where the photobleaching is mediated by singlet oxygen, it can be shown that on the microscopic scale, the fractional photobleaching is indicative of the concentration of singlet oxygen reactions induced by PDT.[33] Although the relationship to tissue response is more complex, photobleaching has been shown to be predictive of response in animal models[34] and used to design protocols for pain reduction during the treatment of patients.[35]

Accurate light dosimetry presents significant challenges in the clinic. It is relatively straightforward to measure the irradiance of light delivered to the surface of a tissue. The light absorbed by the sensitizer also includes the light scattered by tissue not too dissimilar from ionizing radiation. Like ionizing radiation, scattered light contribution may occur on a surface and is an important concept to consider in the practice of PDT. In hollow organs or any concave surface with surface secretions that further increase the reflective index, light can be reflected from one surface to another surface, to increase the effective surface light fluence rate. This effect is often referred to as the *integrating sphere effect*. In the extreme case, multiple reflections can significantly magnify the fluence rate within a hollow organ. This integrating sphere effect has been extensively modeled in the case of bladder treatment.[36] In complex concave mucosal surfaces such as in the head and neck, scattered light photons have been demonstrated to increase the effective fluence rate by factors of three- to fourfold.[37,38]

Light scattering also occurs within tissues, leading to a significant difference between the incident fluence rate that is delivered and the fluence rate within the tissue. In practice, the integrating sphere effect and multiple scattering within the tissue occur simultaneously. Accurate dosimetry requires accounting for both of these effects, ideally through real-time measurements using an isotropic light photon detector capable of capturing both directly incident and scattered light.[39] A comparison of measurements using fiber-based isotropic detectors and photodiode detectors (that capture only incident light) indicated significant difference in the measured light dose with significant variation in the contribution from scattered light.[40] Through measurements with a series of light sources and detectors, tissue optical properties can be assessed; however, PDT

treatment can significantly change the optical properties. This requires the ability to assess the optical properties in real time for an effective feedback to compensate for the influence of varying light transmission on the deposited light dose within the target tissue.[41,42] Recently, the first clinical experiences using an automated 18-channel system accommodating optical fibers for light delivery and monitoring were described in patients treated with temoporfin interstitial PDT.[6]

Biology of Photodynamic Therapy

Mechanisms of Tumor Cytotoxicity

PDT can induce cytotoxicity through all three death morphologies: apoptosis, autophagy, and necrosis. The multitude of signaling pathways (apoptotic and nonapoptotic) and the molecular interplay between various cell death pathways (balanced with the induction of prosurvival signals) that are activated with cellular photodynamic oxidative stress have been the focus of intense investigations and the subject of a recent extensive review.[20] Of these modes of cell death, apoptosis is a major pathway of PDT-mediated cytotoxicity. This reflects the near ubiquitous ability of PDT to induce mitochondrial injury.[43,44]

PDT can also induce cell injury through direct damage of the vascular endothelial cells. In turn, thrombus formation and the release of various vasoactive molecules, with an increase in the vascular permeability and deterioration of vascular status, ensue. Leukocyte infiltration further compounds this response, all contributing to secondary hypoxia[45] with ischemic cell death.[46] Preclinical studies also suggest that beyond direct tumor and vascular cytotoxicity, long-term cellular (tumor) control seems to require immune-competent subjects.[47]

Influence of the Tumor Microenvironment on the Photodynamic Therapy Response

As PDT is dependent on the presence and distribution of a photosensitizer, light, and oxygen, the *normal* tissue microenvironment (within which a tumor is located) can significantly determine the treatment response of the tumor to PDT. All three key PDT components are subject to effects from the tissue microenvironment. For example, tumor vascular density, permeability, or perfusion can affect photosensitizer delivery.[48] This undoubtedly contributes to the heterogeneities detected in photosensitizer levels in different tumors among different patients.[49–52] Tumor-associated hypoxia can limit PDT-created

damage.[53–56] Even the distribution of the treatment light is affected by the microenvironment because of differences in the penetration of red light as a function of the oxygenation status of hemoglobin. Compared to deoxyhemoglobin, oxygenated hemoglobin is less absorptive of red light (630 or 650 nm), thereby allowing deeper light penetration in tissues with a higher proportion of oxygenated hemoglobin.[57]

Much research has been performed on the dependence, as well as the effects, of PDT on tumor oxygenation. With conventional photosensitizers, the photochemical process can consume tissue oxygen faster than its delivery, leading to a hypoxic state that limits PDT-mediated cytotoxicity.[58–60] Moreover, intratumor heterogeneities in tumor oxygenation can have consequences to PDT-mediated cytotoxicity. This has been shown in murine studies that identify the presence of more severe PDT-created hypoxia in the base of subcutaneous tumors accompanied by a relative protection of this area from clonogenic cell death.[56]

PDT-mediated vascular effects are another cause of hypoxia during PDT. These effects can take the form of PDT-triggered vasoconstriction.[61] Additionally or alternatively, PDT can cause endothelial cell rounding, leading to intracellular gaps[62] and activation of the coagulation cascade. Ischemia then results, as leukocyte and platelet aggregation with secondary thrombosis within the vessels can further alter the blood flow.[61,63] Dynamic changes in tumor blood flow, including treatment-initiated decreases in the blood flow, have been observed for several photosensitizers including porfimer sodium, 5-aminolevulinic acid (5-ALA; Levulan), motexafin lutetium (Lutrin), verteporfin (Visudyne), palladium bacteriopherophorbide (Tookad), and 2-(1-hexyloxyethyl)-2-devinyl pyropheophorbide-a (HPPH; Photochlor).[61,64–70] In fact, PDT-triggered reductions in tumor blood flow during light delivery are not only therapy limiting but also directly correlate with outcome measures. Yu et al.[66] showed that the duration (long) and the slope (shallow) of the Photofrin-PDT–induced decrease in tumor blood flow correlated with the time-to-tumor regrowth (prolonged) in an animal. Similarly, Standish et al.[71] and Pham et al.[72] reported PDT-induced decreases in tumor blood flow and oxygen change (tissue hemoglobin oxygen saturation = $\%StO_2$), respectively, correlated with developing necrosis. These findings show the value in the development and application of noninvasive approaches to measure tumor blood flow during clinical applications of PDT.[67,73,74] Although PDT-induced ischemia can limit the effectiveness of PDT, in the setting of sufficient light and drug doses, the

persistent ischemia that is induced can provide incremental cytotoxicity and can improve the effectiveness.[46,75]

Experimental strategies directed at modulating the vascular response to PDT are also consistent with the importance of its contribution to the PDT effect. For example, inhibitors of nitric oxide have been effective in increasing tumor and vascular damage to porfimer sodium or ALA-PDT in a protocol-dependent manner.[76–78] Also, the vascular-disrupting agent, vadimezan (5,6-dimethylxanthenone-4-acetic acid; DMXAA), has been successful in improving PDT responses when administered in such a way as to decrease tumor perfusion after illumination.[68,79] It is even possible to deliver PDT in two fractions so that a vascular-damaging protocol follows one in which oxidative damage to tumor cells is the major cytotoxic mechanism.[19] This approach has been studied in preclinical models using verteporfin as photosensitizer by first employing a longer interval between drug administration and light delivery to allow drug accumulation in the tumor cells, leading to direct light-induced cytotoxicity, followed by a second round of drug administration and light delivery that utilizes a short DLI, which causes more extensive vascular damage because of drug localization in the blood vessels at the time of light delivery.[19] Similar observations have been reported with the photosensitizer MV6401.[26]

Tumor Stress Response to Photodynamic Therapy

The oxidative stress initiated with PDT can induce the expression of genes that can mediate various modes of cell death as well as survival signals. Using cDNA microarrays, the cellular effects of hypericin-mediated PDT were studied on the expression of a panel of genes involved in apoptosis, metabolism, and proliferation, among other cellular processes.[80] Twenty-five genes were significantly up-regulated by PDT, including dual specificity phosphatase-1 (DUSP1), which can induce apoptosis. The stress response proto-oncogene FOSB and JUN dimerize protein products to contribute transcription AP-1 (another effector - both positive and negative) to the cellular apoptosis response. Another important gene is MYC, which also codes for a proapoptotic transcription factor of c-MYC. Among the genes down-regulated by PDT were *THBS1*, whose protein product thrombospondin-1 is an effector of cell interaction with the extracellular matrix, angiogenesis, apoptosis, and cell migration; *ADAM10*, which codes for a family of cell surface proteins with roles in epithelial cell adhesion, migration, and proliferation; and several genes in the integrin family that mediate cell-to-cell and cell-to-matrix attachments, all

thereby facilitating signal transduction along pathways controlling apoptosis and metastasis, among other functions.[80]

In other studies, PDT-induced apoptosis was associated with activation of p38 in the mitogen-activated protein kinase (MAPK) family,[81–83] which along with its other family members (including ERK and JNK) regulates cell proliferation, differentiation, and survival. Furthermore, expression of proapoptotic and antiapoptotic proteins of the Bcl-2 family can also be modulated by PDT in a context-dependent matter, which depends on factors such as cell type and subcellular localization of photosensitizer.[81,84,85] Similarly, PDT-induced expression and phosphorylation of "survivin" (capable of inhibiting apoptosis through inhibiting caspase-9) have also been an active area of investigation to therapeutically improve PDT cytotoxicity.[86] Signal transduction in PDT-induced apoptosis, autophagy, and necrosis is an area of expanding interest, and, for the interested reader, several comprehensive reviews[20,87,88] are available on the current state of knowledge on this topic.

Immunologic Response to Photodynamic Therapy

The altered microenvironment generated by PDT can also serve to stimulate the host immune responses. Both the activation of a nonspecific and an adaptive antigen-specific immune response may be seen following PDT. These findings have raised considerable hopes that a localized treatment with PDT may lead to broader systemic oncologic benefits. For example, PDT-induced damage is associated with the local influx of neutrophils and other cell types, such as macrophages, natural killer cells, and dendritic cells, which contribute to local damage and inflammation while initiating a general systemic immune response.[89] Both preclinical and clinical studies show this to be accompanied by the release of immune-modulating factors, such as interleukin (IL) 1-β, tumor necrosis factor (TNF)-α, IL-6, IL-10, and granulocyte colony–stimulating factor (G-CSF).[90–92]

The resulting activation of the general immune response plays a major role in tumor control after PDT. Neutrophils are key to this process. *In vitro* studies demonstrate neutrophil adhesion to an extracellular matrix exposed by PDT-mediated endothelial cell damage.[93] *In vivo* studies find neutrophils attach to PDT-treated blood vessels.[94] In contrast, various approaches toward depleting neutrophil influx into the PDT-treated tissues have caused a detriment of therapeutic outcome.[95,96] In fact, a systemic neutrophilia is known to accompany PDT of various tumor types, sites, and photosensitization protocols.[97–99] PDT

can also activate the complement system with fixation of the complement C3 protein to tumor cells, which also promotes a strong neutrophilia. This serves not only to target cells for destruction by the nonspecific immune system but induces the release of proinflammatory mediators contributing to the migration of neutrophils.[100]

In addition to the induction of an innate immune response, PDT can also stimulate an adaptive cell-mediated immunity. In fact, these types of immune responses are intricately connected processes. It has been proposed that a critical aspect of PDT-induced adaptive immunity is the generation of a high antigen load causing tumor cell death. Tumor cell death is further promoted by the strong neutrophilia through the release of lysosomal enzymes, including myeloperoxidase. Strong neutrophilia also appears to be a critical factor for the development of PDT-induced adaptive immunity.[101] The AS neutrophils degranulate and release a family of mediators referred to as alarmins. *Alarmins* are a critical link between the inflammatory response and adaptive immunity as they are capable of recruiting and activating the maturation of antigen-presenting dendritic cells.[102] With a strong innate immune response, this antigen presentation can be more effectively recognized, inducing an adaptive cell-mediated immunologic response and memory.[103]

Dendritic cells (DCs) typically exist in the immature state within the tissue microenvironment. They actively survey and capture antigens and then migrate and present these to T cells in adjacent draining lymph nodes. For dendritic cells to mature and affect adaptive immunity, the expression of stimulatory molecules that are involved in antigen presentation to T cells is very important. Several aspects of the nonspecific or innate response include strong neutrophilia[101] and the release of damage-associated molecular patterns (DAMPs), which consist of various markers of normal tissue injury. Among these, the extracellular release of heat shock protein 70 (HSP-70) and its association with tumor antigens by PDT-treated cells appear to be particularly effective in being recognized by DCs through surface receptors that lead to their activation and maturation.[104]

HSPs, in particular HSP-70, have been a DAMP of particular interest in PDT for some time.[105] HSPs are molecular chaperones crucial for proper protein folding. HSPs can facilitate cell survival during intracellular functioning, but become immunostimulatory when extracellular or membrane bound.[106] In studies of PDT, HSP-70 is rapidly exposed on the surface of tumor cells treated *in vitro*,[107] and its antibody-based blockage served to inhibit maturation of dendritic cells.[108] Moreover, surface or extracellular expression of HSP-70 after

PDT has been shown to correlate with curative responses in temoporfin-treated murine tumors.[109] Research in these and other aspects of PDT-generated antitumor immunity has spawned interest in the use of PDT to develop cancer vaccines, the history and progress of which have been recently reviewed.[110]

Vascular Response to Photodynamic Therapy

The therapeutic benefits to be gained from PDT-created vascular damage and inflammation come with a cost. In a post-PDT, tumor microenvironment is characterized by inflammatory infiltrates, cytokine overexpression, arachidonic acid and eicosanoid production, and hypoxia. Then, there develops a strong proangiogenic stimulus to support the growth of new tumor blood vessels.[111] Such angiogenesis can counteract the intended effects of treatment by providing a means for delivery of oxygen and nutrients to tumor cells that escaped direct (oxidative) or secondary (vascular or immune mediated) damage by PDT. VEGF is one of the most common angiogenic molecules whose expression is stimulated by PDT, and its increase has been measured following PDT with a variety of photosensitizers and tumor models.[112–114] Moreover, studies of human tumors grown as murine xenografts find PDT to induce modest increases in host-derived (mouse) VEGF in addition to the increases in human VEGF that originate from the treated tumor.[115,116] The molecular mechanisms of PDT-initiated increases in VEGF can include increases in hypoxia-inducible factor (HIF)-1α, a transcription factor that promotes the activation of many hypoxia-responsive genes such as VEGF,[117,118] as well as activation of the p38 MAPK pathway.[119] In the case of the latter, an inhibitor of p38 MAPK significantly attenuated the PDT-induced increase in VEGF.[119]

Cyclooxygenase (COX) 2 is another proangiogenic molecule that is up-regulated by PDT under a variety of treatment conditions.[120–122] The COX-2 enzyme serves to catalyze the production of prostaglandin (PG) H_2, a substrate for multiple eicosanoid mediators (including additional prostaglandins and thromboxane) known to contribute to PDT-created ischemia.[123,124] The proangiogenic activity of COX-2 can be mediated through the enzyme's role in production of PGE_2, which in turn can promote increases in VEGF.[111] Moreover, PDT-stimulated proinflammatory cytokines such as IL-1β and TNF-α may also stimulate angiogenesis through a COX-2–dependent pathway. This is supported by findings that the decrease in PGE_2 after COX-2 inhibition is accompanied by a reduction in protein levels of IL-1β and TNF-α.[125]

Biologic Strategies to Improve Photodynamic Therapy Cytotoxicity

With improved understanding of the biologic and molecular mechanisms that underlie PDT-derived cytotoxicity has come the development of alternative, more effective approaches toward PDT delivery. These include the development of new targeted PS that exploit specific signatures or functions in diseased tissue in order to deliver, or even to activate, the PS.[126] These are commonly referred to as *PDT molecular beacons*, where the PS and a singlet oxygen–quenching or singlet oxygen–scavenging molecule are both coupled to a linker that can interact with a cancer-specific target.[127] In this way, the PS photoactivity is silenced because of the proximity of the singlet oxygen–quenching molecule. The PS is only capable of being photoactivated when the linker interacts with the cancer-specific target, which results in physical separation of the singlet oxygen–scavenging molecule from the PS. One example of a novel targeted linker includes an antisense oligonucleotide complementary to a target messenger RNA. The messenger RNA is conformationally restricted until the oligonucleotide interacts with its target.

Modulation of light delivery has also proven successful in mitigating the microenvironment limitations imposed by PDT. For example, lowering the fluence rate of light delivery can conserve tumor oxygenation during PDT, increasing direct tumor cell cytotoxicity as well as vascular and immune effects.[54,56–95,128–130] Similarly, fractionation of the light with or without repeat administration of the PS before each light fraction has improved treatment response in various preclinical protocols[45,131–135] and in early clinical studies.[136] Without repeat PS administration, preclinical studies suggest that the light fractionation is improving oxygenation[45] with more effective vascular injury[133] and necrosis.[132]

The duration of the light that is first administered[131] and the duration of time between each light fraction[132] may be particularly important in improving the oxygen delivery between light fractions. When the PS has been readministered before the second light fraction, a short DLI has demonstrated improved tumor control in preclinical models through vascular targeting with various photosensitizers such as verteporfin[19] MV6401[26] and m-tetra hydroxyphenylchlorin (mTHPC).[137]

As previously described, PDT causes cytotoxic oxidative stress and induces the expression of pleiotropic prosurvival molecules such as COX-2.[82] Understanding the mechanisms leading to prosurvival molecule induction is relevant to the design of more effective treatments. PDT in combination with

various targeted agents designed to reduce the effect of the tumor stress response has demonstrated improved tumor responses in various preclinical models. Antiangiogenic agents lead to decreases in VEGF expression after PDT,[113,138–140] along with improvements in tumor response.[112,113,115,117,138,141] Inhibition of HSP increases the curative potential of PDT through decreased expression of angiogenic and prosurvival proteins in the treated tumors,[142] whereas disruption of HSP-90 function *in vitro* leads to increases in PDT-induced apoptosis.[86] The COX-2 pathway has also been targeted in combination with PDT and can improve therapeutic outcome through inhibition of post-PDT angiogenesis, as well as, under some circumstances, through increases in direct PDT cytotoxicity.[125,143–145]

PRACTICE OF PHOTODYNAMIC THERAPY

Light Delivery and Dosimetry

The ability to achieve PS activation is dependent on effective administration of light not only with a wavelength that matches the spectral absorption of the PS but also on depositing a sufficient amount of energy to the target tissue (total fluence). Wavelengths >800 nm are unable to deposit sufficient energy to activate a PS. Delivering sufficient fluence is influenced not only by the technique of its administration (i.e., surface vs. interstitial) but also by the ability of the light energy to penetrate sufficiently at depth to treat the intended target volume. As light photons interact with tissue, photons scatter and are absorbed by endogenous chromophores such as hemoglobin, myoglobin, melanin, and cytochromes. Hemoglobin is especially important to consider. Hemoglobin has spectral absorption peaks < 600 nm (i.e., hemoglobin absorbs all colors except red), and its ability to absorb light energy is affected by its oxygenation status. Oxygenated hemoglobin is less likely to absorb between 600 and 800 nm compared to deoxygenated hemoglobin. Thus, most activating light that has been used for PDT has typically been between 600 and 800 nm, depending on the spectral absorption characteristics of the PS.

The rate at which the light energy is delivered (fluence rate) is also an important treatment factor that can affect the efficacy of PDT. It primarily affects the tissue microenvironment such as the vascular flow and oxygenation. In general, it is important to recognize that high fluence rates can rapidly consume and reduce the local oxygen levels such that it limits the efficacy of the remaining light fluence.[146] The prescribed fluence rate is typically based on the

power output of the light source, but surface and internal scattering of light photons may result in areas of higher fluence rates. Strategies to reduce the surface scatter effect or to modify the prescribed power output of the light source should be considered.

At present, the prescription of PDT used clinically remains limited to rudimentary power output calculations for surface illumination: That prescription dose is given in terms of the energy per unit area incident on the surface.

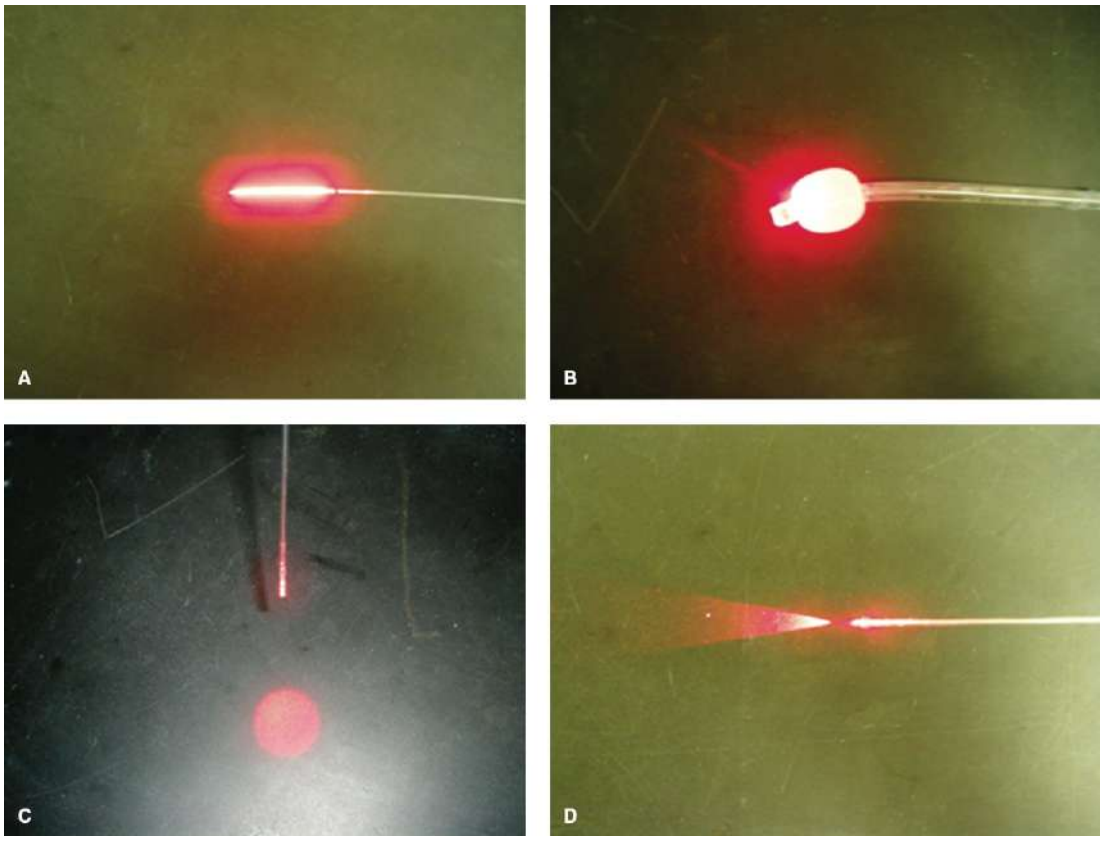

FIGURE 31.2. Various fiber-based light sources. These include a linear source **(A)**, an endotracheal tube–modified point source **(B)**, collimated light fiber **(C)**, and a flat-cut fiber **(D)**.

Various light delivery devices have been developed to perform PDT treatment. Most of them are fiberoptic based. These include linear source, endotracheal tube–modified point source, collimated light source, and flat-cut fiber (Fig. 31.2). The flat-cut and linear sources are suitable for inserting into the tissue for interstitial PDT application for the treatment of bulky tumors. In contrast, the collimated light source is suitable for superficial treatment.

It is therefore helpful to recognize that various illumination techniques may

be employed depending on the geometry of the target lesion that is to be treated. The most common clinical situation requires surface illumination. This is where several technical approaches may be considered. If the geometry of the target lesion is flat or may be modified to be a near flat surface, the use of a light fiber with a diffusing lens at the tip of the fiber (i.e., microlens) offers the ability to achieve homogeneous light distribution across the surface target. Inhomogeneities because of different distances between points on the surface of the target and the light source can result in different fluence rates and the total light dose (fluence) that is effectively delivered. Unlike ionizing radiation, the surface scattering of photons because of surface concavities or reflective surfaces (i.e., any adjacent metal surfaces) can further increase the risk of high surface dose inhomogeneities. In a similar manner, surface convexities may create regions of shadowing that can create regions of low fluence and fluence rate. Obviously, areas of high light fluence (and its fluence rate) could also contribute to an increased risk of normal tissue complications. But consider conversely, low fluence also decreases efficiency.

When the target lesion is cylindrical, a cylindrical diffusing fiber with the light dose prescribed along its length has commonly been used. However, it is important to note that where the target surface is not rigid (i.e., esophagus), mucosal folds that are not in apposition to the light fiber may become underdosed. To reduce this risk, the cylindrical diffusing fiber can be placed within a balloon diffuser that can be expanded to increase its surface apposition with the mucosal surface. Similar considerations can be applied to spherical surface targets such as the mucosa of the urinary bladder.

The use of a balloon diffuser may be helpful for certain complex three-dimensional surfaces, such as the lateral oral tongue and its adjacent floor of the mouth where the surface to be treated can be molded in apposition to the balloon diffuser. In such situations, it is important to verify that the mucosal surface is in direct contact with the balloon’s surface before the light is delivered. Other strategies for such complex three-dimensional surfaces may include dividing the target volume into separate targets and individually treating each area with a microlens (patching technique). With this approach, it is important to bear in mind that areas of potential overlap, when illuminated, may increase the risk of normal tissue complications. Other surface illumination techniques under development include a light “blanket” that attempts to mold the light source to such complex three-dimensional surfaces.

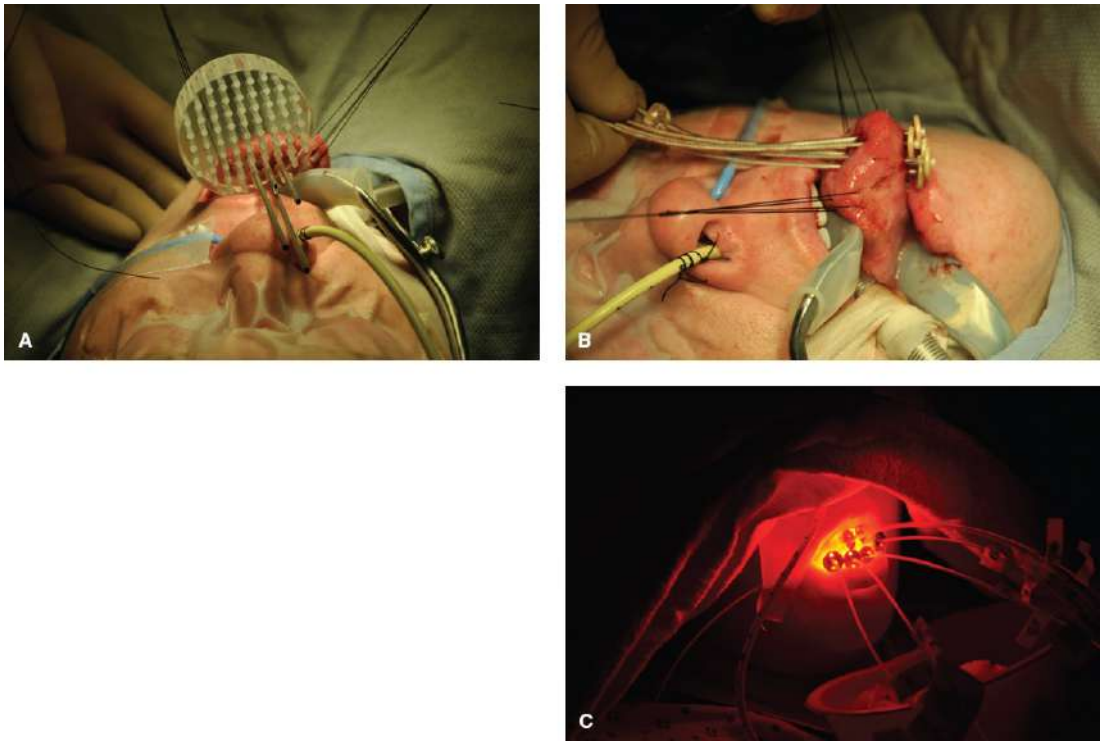

FIGURE 31.3. Example of an interstitial tongue photodynamic therapy implant. A traditional interstitial brachytherapy implant uses a template **(A)** to facilitate the placement of trocars guiding the insertion of hollow plastic catheters **(B)** that are modified for linear light sources **(C)**.

Interstitial light fibers can also be placed when volume illumination is required. As with interstitial brachytherapy techniques, the geometry of the light fibers can significantly affect the overall distribution and amount of light that is delivered. Thus, the use of rigid templates guiding the insertion of the trocar needles (Fig. 31.3) can be very helpful in ensuring accurate interfiber spacing. These templates may be used to facilitate the advancement of rigid trocar needles whose track can then be replaced with light fibers. Alternatively, traditional low dose rate afterloading plastic catheters may be used instead to allow the use of the needle track for both light detection fibers and treatment fibers where prescription is based on light dosimetry. The placement of the catheters can also facilitate several quality assurance measures. This can include verifying the geometry of the implant, allowing additional catheters to be placed or removed to optimize the geometry. It may also include verification or modification of the location of the light fiber in its catheter relative to the tumor volume.

Whether the optical properties of the tissue being treated are different by staging, the placement of the implant and its illumination is not clear. However,

where significant tissue trauma occurs with the placement of the implant, staging the illumination may offer some potential advantages especially where significant tissue bleeding with the introduction of the trocar needles has occurred. Other theoretical advantages may also include improved oxygenation of the implanted tissue, both improving the photosensitization process and reducing hemoglobin absorption of the activating light energy.

Although the optimal interstitial PDT prescription parameters remain to be defined, it is encouraging to see successful interstitial light implants being reported. For such results to become generalizable, the development of a robust and easy-to-use dosimetry system will be needed that will facilitate characterizing the impact of different prescription factors (i.e., intercatheter distance, fluence rate) on normal tissue complications and oncologic results.

Additional Technical Considerations

A significant property of the visible light energy used for photoactivation is its ability to reflect on a surface when light is delivered with a microlens technique. This can in turn increase the fluence and fluence rate delivered especially when the surface is concave and is often referred to as the *integrating sphere effect*. Strategies to minimize variables may include manipulating the surface geometry to reduce concavities and convexities (which can reduce the fluence delivered), removing surface mucosal secretions, using anticholinergics such as glycopyrrolate, and considering alternative illumination techniques. Where the target lesion lies adjacent to reflective metal surfaces that may be used in exposing and possibly flattening the target lesion, surface reflection may be blocked by placing surgical towels over these surfaces. Alternatively, these metal surfaces may be coated with a dark pigment. Similarly, surface scatter may increase the light that is delivered to the adjacent normal skin or mucosa adjacent but outside of the target lesion.

For small surface target lesions treated with a microlens technique, movement of the light fiber because of hand tremor can have a significant impact on the light dosimetry across a small surface area. For example, this is especially a concern when the glottic laryngeal mucosa is being illuminated while working down a laryngoscope. For these reasons, adding rigidity to the flexible light fiber by fixing it to a rigid stylet and immobilizing it with various commercially available fixation devices should be considered.

CLINICAL PHOTODYNAMIC THERAPY

The clinical study of PDT has been an active area of active investigation, despite only three PS being approved for clinical use in cancer management. These include porfimer sodium for the treatment of esophageal and lung cancers and superficial papillary bladder carcinomas, temoporfin for head and neck carcinomas, and ALA for skin actinic keratosis (AK) and basal cell carcinoma (BCC). Trials have generally established clinical activity and the potential for cure in the appropriate cancer application. Despite these efforts, rigorous clinical development of PDT is generally lacking and has not evaluated important comparative questions of its activity to established treatment modalities or, where more appropriate, its value as an adjunctive modality. In general, clinical investigations have also not established the optimal PDT treatment parameters. A comprehensive evaluation of the quality of evidence supporting PDT in clinical practice is referred to in the recent systematic review by Fayter et al.[147] However, the following examples are described.

Skin

The dermatologic applications of PDT are perhaps the most established and scientifically robust of all the anatomic sites for which PDT has been evaluated, with established consensus statements regarding its use.[148] The success of PDT for skin malignancies is a testament to both its strengths and its weakness, with a multitude of randomized trials having been completed for various nonmelanomatous skin malignancies leading to its U.S. Food and Drug Administration (FDA) approval for the management of BCCs and the premalignant nonhyperkeratotic AK.

PDT has been used extensively in the treatment of both premalignant and malignant skin tumors, typically with surface illumination.[148,149] PDT of nonhyperkeratotic AK, squamous cell carcinoma *in situ* (Bowen disease), and BCC can be performed using systemically administered porfimer sodium or topically applied aminolevulinic acid (ALA) and ALA derivatives such as methyl-ALA (MAL). For example, during a placebo controlled trial of PDT for actinic keratosis (AK), ALA-PDT showed a superior complete response (CR) as compared to a sham PDT technique coupled with the same carrier vehicle. That response rate was 87% versus only 13% with the sham (P = .001).[150] PDT for AK shows similar efficacy with less toxicity as compared to cryotherapy, topical 5-fluorouracil cream, or curettage, for example, a study in which 119 subjects with 1,501 AK lesions of the scalp and face were randomly assigned to receive MAL-PDT to either the left- or right-sided lesions, with cryotherapy used to treat

the contralateral side.[151] Twenty-four weeks after therapy, both treatment groups showed a high response rate (89% for MAL-PDT vs. 86% for cryotherapy; P = .2), but MAL-PDT showed superior cosmesis and patient preference. In contrast, the results for PDT of squamous cell carcinomas (SCC) of the skin using topical photosensitizers have been disappointing, with recurrence rates of >50%.[148,149] Perhaps, the most significant potential value of ALA-PDT may be its ability to prevent the development of nonmelanoma skin cancers in patients with AK, as recently demonstrated in a randomized trial of prophylactic ALA-PDT.[152]

Other indications for ALA-PDT include superficial and nodular BCC.[153–155] In a large single-institution series, high rates of local control (>90% complete response rate, <10% local failure at 3 to 5 years) can be achieved with PDT for superficial BCC. However, the response rate and local control rate for nodular BCC drop to 70% and 40%, respectively. In a multicenter randomized trial of MAL-PDT versus cryotherapy for superficial BCC, complete response rates at 3 months were 97% and 95%, with 22% and 20% 5-year recurrence rates for MAL-PDT and cryotherapy, respectively.[156] In this study, the excellent to good cosmetic outcome was 89% for MAL-PDT and 50% for cryotherapy. However, when topical PDT is compared to surgery for BCC, topical ALA or MAL-PDT consistently shows a small increase in recurrence rate as compared to surgery for both superficial and nodular BCC. However, the cosmetic outcomes for PDT are typically superior to surgery with good to excellent cosmetic outcome in >90% of PDT patients with PDT and 60% to 70% with surgery. In summary, PDT can be an appropriate and effective treatment alternative to cryosurgery or surgical excision for selected BCC. PDT is currently approved in the United States, Canada, and the European Union for the treatment of AK and approved in the European Union and Canada for treatment of BCC.

Brain

PDT has primarily been evaluated as adjunctive therapy treating the surgical bed often combined with its use for PDD as a fluorescent guide to (surgical) resection (FGR). Yang et al.[157] demonstrated that porfimer sodium fluorescence at 640 nm could be clearly visualized in the resection bed in patients with supratentorial gliomas not seen under white light. Biopsy of these areas of fluorescence confirmed the presence of residual tumor, thus demonstrating the concept of FGR. Similar high tumor specificity was also observed with hypericin-mediated FGR for glioblastoma multiforme (GBM)[158] and protoporphyrin-IX (PpIX) fluorescence (that was produced following

administration of the photosensitizer ALA) of the surgical bed in GBM patients.[159] All biopsies of fluorescent tissue contained GBM.[158,159] However, the benefits of just FGF could not be clearly demonstrated in a phase III study (n = 27) as all patients receiving ALA also had received porfimer sodium and received PDT to the surgical cavity. Eljamel et al.[159] demonstrated that the mean survival significantly increased with ALA-mediated FGR and porfimer sodium PDT (P < .01). However, in a phase III study of 322 patients with suspected malignant gliomas randomized to ALA-FGF or conventional surgery, Stummer et al.[160] reported an improved progression-free survival (41% vs. 21%, respectively; P = .0003) following a median survival of 35.5 months. No significant increased complications have been observed with photosensitizer-based PDD and FGR.[160]

Further evidence in support of PDT activity for GBM particularly comes from several institutional experiences where PDT was used to treat the resection cavity for various histologies, including newly diagnosed[161–163] and recurrent[162] GBM and anaplastic astrocytoma (AA).[161] Other histologies evaluated have also included malignant ependymomas[164] and meningiomas.[165] Muller and Wilson[163] reported the results of a retrospective institutional review of adjuvant porfimer sodium PDT (mean fluence of 58 J/cm^2 with only 18 patients receiving >100 J/cm^2) in 96 patients with supratentorial gliomas. Of these 96 patients, 49 patients presented with either newly diagnosed (n = 12) or recurrent (n = 37) GBM; a median survival of 8.25 and 7.25 months was reported, respectively. In contrast, Stylli et al.[162] reported a median survival of 14.3 and 14.9 months, respectively, with hematoporphyrin derivative (HpD)–mediated PDT. Though Muller and Wilson indicated that such differences may have been due to selection factors, they also suggest that this may be consistent with a dose–response effect. Stylli also reported a light dose effect on overall survival for both GBM and AA. This has formed the basis for an ongoing randomized trial of low versus high light dose porfimer sodium–mediated PDT as adjuvant therapy following surgical resection for supratentorial gliomas.[166]

Head and Neck

The evaluation of PDT for head and neck malignancies has typically been for head and neck squamous cell carcinomas (HNSCC). Case reports or series have also demonstrated that PDT may have activity for other histologies such as Kaposi sarcoma and salivary gland malignancies such as adenoid cystic carcinomas.[167] Although there have been significant numbers of clinical

evaluations of PDT in the management of HNSCC, the vast majority represent single-institutional experiences demonstrating activity either for definitive management or for palliation. Definitive management has typically evaluated surface illumination for premalignant dysplastic lesions or early primary invasive mucosa malignancies where the risk of nodal metastases was regarded as low. Common sites have included the oral cavity, larynx, nasopharynx,[37] and base of the tongue.[168]

Superficial premalignant mucosal lesions are attractive for PDT because of the ability to achieve wide-field mucosal ablation given the uncertainties that are commonly encountered in defining the peripheral extent of the lesion. For these reasons, treatment of the larynx is particularly attractive because of the defined nature of this anatomic site, where conservation therapies such as PDT can offer function-preserving advantages. Contemporary clinical experience suggests that this treatment approach can be effective in obtaining a complete response for the treated lesion, but long-term follow-up is limited.[169] However, this limitation is not dissimilar from other treatment modalities that have been used for mucosal dysplasia. To date, clinical experience has also included retrospective reviews[170] and several prospective studies of porfimer sodium,[171] temoporfin, and[172,173] topical[174] and systemic[136] ALA that have demonstrated high complete response rates typically >80%. Further research efforts are needed to define both the long-term infield and out-of-field relapse risks, and the risk of malignant transformation following PDT treatments is forthcoming.

Additionally, PDT for the treatment of superficial (*invasive*) carcinomas has also been evaluated, typically with porfimer sodium and temoporfin, especially with the EU regulatory approval of temoporfin for the palliative management of HNSCC. Prospective studies of porfimer sodium[171,175] and temoporfin[176] have demonstrated complete response rates typically >80%, with both surface and interstitial illumination techniques used. Long-term infield control rates have also been reported in approximately 70% to 90% of treated patients.[175,176]

The head and neck site has also been the main focus for the development of interstitial illumination techniques. These include the ability to treat deeper invasive carcinomas where the risk of nodal metastases remains low, such as early tongue carcinomas (see Fig. 31.2) or the promise of less toxic salvage therapy,[177] palliation of locoregional recurrences,[178,179] and the treatment of benign tumors such as vascular malformations,[180] which would otherwise require potentially debilitating surgery or the administration of high dose radiotherapy. Lastly, a potential role for intraoperative PDT using porfimer

sodium as adjuvant therapy following surgical resection for locoregionally recurrent HNSCC has been reported. With a minimum follow-up of 24 months, four of five treated patients were without locoregional recurrence or wound complications.[181]

Thorax

Since 1998, PDT has been FDA approved for the treatment of microinvasive endobronchial and advanced partially obstructing non–small cell lung cancer (NSCLC).[182] Endobronchial light delivery has typically been used limiting treatment to central lesions with techniques under development to extend PDT to treat peripheral lesions.[183] It has been used as definitive therapy in treating endobronchial occult or synchronous primary carcinomas where the bronchoscope-visible lesions are ≤1 cm in surface dimension with no clinical cartilage invasion. When PDT is attempted to treat larger tumors—without prior surgical debulking—it has largely been used for palliative indications.

Roentgenographically Occult Bronchogenic Non–Small Cell Lung Cancer

Fewer than 1% of patients with occult bronchogenic carcinoma that are endoscopically visible but lack cartilaginous invasion have metastatic lymph node involvement, indicating a potential for a less invasive focal therapy to be curative.[184] Investigators from the National Kinki Central Hospital for Chest Diseases used PDT to treat occult bronchogenic carcinoma in 25 patients with 29 lesions.[185] A complete remission was achieved in 72% of lesions, including 89% (17/19) of lesions ≤1 cm and 86% (18/21) of visible peripheral area lesions. In another series of 33 patients, with 40 clinically occult carcinomas treated with PDT, a complete response was achieved in all lesions ≤1 cm (n = 32).[186] Among the 39 occult lesions treated at Osaka Prefectural Habikino Hospital with PDT, a complete response was achieved in 64% of lesions, more in superficially infiltrating than for nodular lesions (76% vs. 43%).[187] Tohoku University Hospital investigators treated 48 medically operable patients with occult bronchogenic SCC with tumor lengths of ≤1 cm with PDT; they observed a complete response in 94% of patients and a 10-year overall survival rate of 71%.[188]

Radiographically Visible Early-Stage and Endobronchial Non–Small Cell Lung Cancer

Similar to roentgenologically occult bronchogenic carcinomas, early-stage and

endobronchial NSCLC can be effectively treated with PDT for patients unsuitable for surgical resection.

At Tokyo Medical University Hospital, 240 patients with 283 central lung cancer lesions were treated from 1980 to 1995 with PDT. The overall response rate was 99%, with a complete response in 40%. A complete response was achieved in 83% (79/95) of early-stage lesions, with a 94% (65/69) complete response rate for lesions <1 cm. Several institutional experiences also made similar observations of durable complete responses in over 75% of patients treated at a minimum of 12 months' follow-up.[189,190] However, the complete response rate fell to 54% (14/26) for lesions ≥1 cm and 38% (6/16) for lesions ≥2 cm (P = .00001).[191] A more recent report from Tokyo Medical University Hospital demonstrated that among 93 patients treated with PDT for 114 central early-stage lung cancers, as expected, the complete response rate was higher for lesions <1 cm (77/83) than ≥1 cm (18/31; 93% vs. 58%; P < .001). The recurrence rate was 12% for lesions <1 cm with an initial complete response to PDT, and many recurrences could successfully be salvaged with additional PDT.[192] In a review of 15 trials of 626 patients with 715 central early-stage bronchogenic cancers treated typically for surgery ineligibility patients, PDT-related toxicity was limited, with one PDT-related death (0.15%), photosensitivity skin reactions in 5% to 28%, respiratory complications in 0% to 18%, and nonfatal hemoptysis in 0% to 8%. A complete response was achieved in 30% to 100% of patients for a 2- to 120-month duration, and the 5-year overall survival was 61%.[193]

Synchronous multiple primary lung cancers occur in 1% to 15% of patients with lung malignancies and have been increasing in incidence because of improvements in imaging. These cases may warrant considerations for aggressive management. Incorporating PDT in the management of central lesions, especially when small in size, can significantly reduce the pulmonary morbidity. In a study of 22 patients with synchronous early lung cancers treated with PDT alone for each lesion (n = 11) or surgery for the more peripheral lesions and PDT for the more central lesions (n = 11), PDT achieved a complete response in all 39 central tumors at 2 months following therapy.[194] All patients were alive with variable follow-up of up to 5 years.

Advanced-Stage Non–Small Cell Lung Cancer

For patients with locally advanced or metastatic NSCLC, PDT has been used for palliation. In a randomized trial comparing PDT to neodymium:yttrium–

aluminum–garnet (Nd:YAG) laser therapy in the NSCLC patients with an obstructed airway, both PDT and Nd:YAG laser therapy were comparable with regard to symptom relief and response rates. The time to failure (P = .03) and the median survival (P = .007) were significantly longer in the cohort receiving PDT.[195] In combination with radiotherapy, prolonged response of the luminal tumor mass may be observed and thus warrants further investigation.[196,197]

Preoperative PDT has been reported in several small institutional series of patients with NSCLC. Although small in numbers, these series have independently observed that preoperative PDT may help reduce the extent of definitive resection needed for locally advanced NSCLC by downstaging patients who would otherwise require a pneumonectomy to undergo lobectomy instead or to convert patients originally deemed inoperable to be surgical candidates.[198–200] Okunaka et al.[198] reported on the results of 26 patients with NSCLC treated with preoperative PDT alone with the desired intent to reduce the extent of resection or convert inoperable disease to an operable status. These surgical goals were achieved in 85% of patients, with 4 of 5 originally inoperable patients converted to resectable, and 18 of 21 patients originally candidates only for pneumonectomy were able to undergo lobectomy. Ross et al.[199] reported on 41 patients with locally advanced NSCLC treated with induction PDT and chemotherapy or radiation therapy. PDT induction allowed 57% of initially unresectable patients to undergo definitive surgical resection and 27% of those initially deemed in need of pneumonectomy to undergo lobectomy. Pathologic downstaging occurred in 64%. Plus 46% of patients were alive at 3 years following therapy.

PDT has been used as part of multimodality management for patients with NSCLC with pleural spread. A phase II trial of 22 such patients at the University of Pennsylvania assessed the oncologic outcome of patients treated with surgery, achieving either a complete resection (n = 17) or partial tumor debulking (n = 3) followed by hemithoracic pleural PDT (porfimer sodium) (n = 20) or PDT alone (n = 2).[201] The 6-month local control rate for the cohort was 73.3% and the median overall survival was 21.7 months, suggesting promising activity.

Malignant Pleural Mesothelioma

The use of PDT to treat malignant pleural mesothelioma was pioneered at the National Cancer Institute in the 1980s and has since become integrated into multimodality therapy for mesothelioma.[202] In a National Cancer Institute phase I trial, 54 patients with pleural malignancies isolated to one hemithorax were

evaluated, including 40 patients with mesothelioma. Among the 42 patients who underwent optimal tumor debulking to ≤5 mm of residual tumor thickness followed by PDT, the PDT was relatively well tolerated. The median survival among mesothelioma patients was 10 months.[203] In the perioperative period, however, intraoperative PDT for mesothelioma can be associated with acute bleeding, severe generalized vascular atherosclerosis, generalized edema, intrathoracic fluid accumulation, respiratory distress, and death.[204]

In a phase II study at Roswell Park Cancer Institute, 40 patients underwent extrapleural pneumonectomy or pleurectomy followed by intracavitary PDT.[205] The median survival was significantly better for stage I and II patients (n = 13) than stage III and IV patients (n = 24; 36 months vs. 10 months; P < .0001). PDT dose was found to be independent prognostic indicators for survival (P < .009).[205] Dutch investigators treated 28 predominantly advanced-stage mesothelioma patients with pleuropneumonectomy followed by intraoperative PDT. Half of the patients in the cohort had persistent local tumor control for at least 9 months following PDT, and the median overall survival of the cohort was 10 months.[204] At the University of Pennsylvania, 28 patients with malignant pleural mesothelioma, including 86% with stage III and IV diseases, were treated from 2004 to 2008 with macroscopic complete resection and intraoperative PDT. Patients who underwent radical pleurectomy (n = 14) had a significantly improved median survival compared with those who underwent modified extrapleural pneumonectomy.[206]

The only randomized phase III trial assessing the role of PDT in the management of malignant pleural mesothelioma involved 63 patients at the National Cancer Institute undergoing maximum surgery, postoperative cisplatin, interferon α-2b, and tamoxifen with or without first-generation intraoperative intrapleural PDT (630 nm, porfimer sodium, 30 J/cm^2 using intraoperative real-time light dosimetry). Most patients (79%) had stage III disease. The median survival for the 15 nonoptimally cytoreduced patients with >5-mm residual disease was 7.2 months, compared to 14.4 months for the remaining 48 patients. However, PDT did not influence the pattern of recurrence, median survival (14.1 vs. 14.4 months), or median progression-free time (8.5 vs. 7.7 months).[207]

Gastrointestinal Malignancies

Photodynamic Therapy for Malignancies of the Gastrointestinal Tract

Of the gastrointestinal (GI) tract tumors that can be treated with PDT, Barrett

esophagus (BE) with dysplasia and early-stage esophageal cancer are the best studied.[208,209] Overholt et al.[210] demonstrated in a multicenter randomized trial that PDT for premalignant BE can eliminate dysplastic cells and is associated with a lower incidence of development of invasive carcinoma. In this trial, 208 patients were randomly assigned to receive either PDT with proton pump inhibitor (PPI) or PPI alone in a two-to-one randomization schema. PDT-treated patients received porfimer sodium (2 mg/kg) 40 to 50 hours prior to the first light delivery. Areas of BE were exposed to 130 J/cm with 630-nm light using a cylindrical fiberoptic diffuser encased in an inflated esophageal balloon so that the fiber would be centered and the esophageal folds flattened. Ninety-six to 120 hours later, a repeat endoscopy was performed to assess response, and an additional 50 J/cm could be given to areas of insufficient mucosal damage. If BE was found to persist on follow-up endoscopy, additional PDT treatments could be performed for a maximum of three total treatments given at least 3 months apart. All patients (in both arms) received omeprazole therapy at a dose of 20 mg given twice daily. The results of this trial showed that PDT plus PPI was superior to PPI alone, and the updated 5-year results confirm the long-term benefits with a 50% relative risk reduction in the incidence of invasive carcinoma.[211] At 5 years of follow-up, Overholt et al.[210] demonstrated that 77% of patients treated with PDT-PPI showed ablation of HGD versus 39% of patients treated with PPI alone ($P < .0001$). More significantly, 15% of the patients in the PDT-PPI arm showed progression to cancer versus 29% on the PPI arm ($P < .006$). The toxicity of the PDT-PPI treatment was esophageal stricture, with the majority of cases successfully managed with esophageal dilatation. Mucosal injury prior to PDT and repeat PDT treatments appears to increase this risk.[210,212]

PDT has also been studied in a variety of tumor types in the GI tract. Significant clinical efficacy has been observed in early studies of PDT for gastric,[213] early duodenal, and ampullary cancers.[214–216] Promising results have been achieved in the treatment of cholangiocarcinomas (CC). Early case reports and pilot studies of PDT for CC demonstrated significant promise.[217,218] In a randomized, controlled trial of stenting with or without PDT, the median survival of patients treated with PDT plus stenting was remarkable with 493 days compared with only 98 days in the stenting-alone group.[219] Other studies have shown similar results.[220–222] A multicenter clinical trial has been initiated to obtain regulatory approval in the United States and Canada.[223]

Other clinical applications of PDT in the GI tract have included unresectable pancreatic cancers[224] and numerous reports using PDT to eliminate colon polyps

as well as to palliate bulky colon and rectal cancers.[216,225–227] In addition, PDT may have efficacy in treating hepatocellular carcinoma. Early results have been promising, and a phase III study is currently under way to evaluate the efficacy of talaporfin-mediated PDT using interstitial LEDs compared with institution-specific standard treatment.[228]

Photodynamic Therapy for Intraperitoneal Malignancies

Peritoneal carcinomatosis presents a very difficult problem for standard cancer treatment modalities. The superficial nature of PDT combined with its ability to treat large surface areas seems to lend itself to this particular problem. However, adequate and homogeneous light distribution to all peritoneal surfaces remains an ongoing technical challenge. In a phase I trial of 70 subjects with predominantly recurrent ovarian carcinomatosis, intraoperative PDT following maximal surgical debulking resulted in a 76% complete cytologic response rate with tolerable toxicity.[229] In the follow-up of a phase II study, patients were enrolled and stratified according to cancer type (ovarian, gastrointestinal, or sarcoma) and given doses of porfimer sodium and light at a phase I previously defined maximally tolerated dose.[230] Other than capillary leak syndrome and skin photosensitivity, the complication rates were similar to the complication rates typically observed after similarly extensive surgery in the absence of PDT.[231] With a median follow-up of 51 months, the median failure-free survival and overall survival rates for the patients who received PDT were 3 and 22 months in ovarian cancer patients and 3.3 and 13.2 months in gastrointestinal cancer patients, respectively. Six months after therapy, the pathologic complete response rate was 3 of 33 (9.1%) and 2 of 37 (5.4%) for the patients with ovarian cancer and gastrointestinal cancer, respectively. These results in heavily pretreated patients suggest that PDT for peritoneal carcinomatosis may have some clinical benefit.

Genitourinary Malignancies

Photodynamic Therapy for Prostate Carcinomas

The role of interstitial PDT for prostate adenocarcinoma has been investigated by several groups studying various PS including temoporfin,[6,232] motexafin lutetium,[50,230,233] and padoporfin.[234] The majority of these phase I and II trials have been in patients with locally recurrent adenocarcinoma, typically following failure of radiotherapy. Several observations are implied: Traditional brachytherapy techniques can be adopted to administer diffusing light fibers with

potentially effective light delivery and oncologic efficacy. Oncologically, a dose–response relationship may exist. When higher light doses are delivered, the probability of acute tissue injury causes an increase in PSA in the first 24 hours posttreatment,[50] leading to a pathologic complete response[235] and possibly a more durable PSA response.[50]

At this time, the optimal light dose and other PDT prescription parameters remain to be determined. However, delivering a minimum and sufficient light fluence to 90% of the prostate clinical tumor volume (CTV) may be important.[235] This is further complicated by the significant patient heterogeneity[236,237] in the optical properties of the prostate that changes dynamically during the administration of the light.[6] However, analysis of the heterogeneity in the tissue injury as assessed by magnetic resonance imaging demonstrating light dosimetry may not be sufficient to completely predict for prostate and surrounding normal tissue injury or for the risk of urorectal fistulas.[238] That is, other factors such as the PS and oxygen concentrations and the effectiveness of the singlet oxygen generation along with variable patient factors may be important and remain subjects of ongoing investigation.[73] In the interim, careful attention to minimize trauma to the rectal wall[232] and the light dosimetry for interstitial PDT remains important. It may be prudent to establish a lower light fluence to the rectal wall as this tissue may have a lower intrinsic threshold for interstitial PDT injury.[238]

Photodynamic Therapy for Bladder Carcinomas

Bladder carcinomas are typically superficial and diffuse across the mucosa, lending to the application of intracavitary PDT. In fact, the first-generation photosensitizer hematoporphyrin and its derivative (HpD) were used as early as 1975. This developed the regulatory approval of the purified active component (porfimer sodium) for the treatment of recurrent superficial papillary carcinoma as seen in failed conventional intravesical therapy such as the bacille Calmette-Guérin (BCG). Several institutional experiences have demonstrated activity with HpD or porfimer sodium PDT to the whole bladder with high initial response rates of ≥70% with long-term (>2 years) control rates between 30% and 60%.[239–242] These response rates suggest comparable activity that was recently supported in a recent multicenter randomized study comparing BCG to porfimer sodium PDT in patients with superficial bladder carcinoma.[243] Bladder contracture because of fibrosis was observed to be a significant complication in the early experience of porfimer sodium PDT that was later demonstrated to be

reduced by measuring the light fluence on the surface and accounting for both the incident and scattered light.[244] Other strategies that reduced the risk of late bladder injury include porfimer sodium PDT with less penetrating light (514 nm),[245] reducing the porfimer sodium dose, the light dose administered,[239] and the use of topical ALA, which is a more superficial photosensitizer.[246,247]

CONCLUSION

A significant body of preclinical and clinical evidence supports the hypothesis that PDT could have important cytotoxicity, with cure possible in limited clinical applications as applied to malignancies. There has been a tremendous body of advancement in the physics of light dosimetry, sophistication of PS development for photodiagnosis and photoactivation, and the understanding of the cellular and microenvironment effects of PDT. These achievements may offer an array of potential translational opportunities. The advances for the indications and the efficacy of PDT when used alone and in combination with traditional therapeutics continue.

CHAPTER 32

Reirradiation

Carsten Nieder and Anthony E. Dragun

INTRODUCTION

A second course of radiotherapy to a previously treated, overlapping anatomic region poses considerable challenges if a high cumulative total dose is attempted. In palliative clinical scenarios, for example, painful bone metastases, such treatment is well established.[1,2] Occasional patients might even benefit from a third course. Reirradiation has been prescribed for locoregional relapse or second primary tumors, the latter often after very long time intervals, as well as benign diseases. Historical studies described how selected patients with cancer of the uterine cervix were reirradiated already before the Second World War.[3] The history of head and neck and brain tumor reirradiation also dates back many decades.[4,5] Despite this long-standing legacy, few prospective randomized clinical studies have provided high-level evidence clarifying the optimal approach toward previously irradiated tumors.[6] Phase II studies often included a single arm only.[7–14] Therefore, the clinical practice of reirradiation, prescribed as monotherapy or combined with other modalities,[9,13,15] is highly variable. Recent guidelines endorse repeat radiotherapy in selected patients.[16–19]

HISTORICAL PERSPECTIVE

At the Memorial Hospital New York (United States), about 11% of 1,574 patients with cervical cancer required further radiotherapy during the time period 1918 to 1931.[20] Only 2 of these patients survived more than 3 years, leading the author to conclude that “a lesion once fully and adequately irradiated cannot again be treated to advantage with radium or Roentgen therapy. Irradiation leads to tissue changes, largely in the nature of endarteritis and fibrosis, and further irradiation of such structures results in the formation of indolent chronic ulcers and sloughs, which are painful and extremely difficult to heal.” In 1956, Murphy

and Schmitz from Roswell Park Memorial Institute (United States) reported on treatment of failures following an apparently adequate course of radiation for cervical cancer.[3] They emphasized that “re-irradiation is particularly justified when a curative surgical approach would entail not only an appreciable mortality risk but also a high degree of permanent disability. Tissue changes resulting from previous radiotherapy do not contraindicate re-irradiation if cure or palliation is possible.” This study included 46 patients with squamous cell cancer treated between 1946 and 1950. Nine patients (20%) were alive at the time of reporting with a maximum follow-up of 8 years. The absolute 5-year survival with no evidence of cancer was 16%. Subjective and objective palliation was commonly recorded. Long-term survival was achieved exclusively in patients with limited pelvic recurrence in good physical condition.

Between 1940 and 1950, selected patients with nasopharyngeal cancer were reirradiated at the University of California School of Medicine in San Francisco (United States), as later reported by Fu et al.[5] External beam radiotherapy, brachytherapy, or combination therapy was prescribed. Actuarial 5-year survival was 41%. Six of 42 patients (14%) developed soft tissue necrosis and three (7%) osteoradionecrosis, all of whom minimally symptomatic. The authors’ preferred approach in patients with local and/or nodal recurrence was surgery followed by intracavitary radium therapy. For bulky, invasive lesions, a 3-week course of external beam radiotherapy was administered first.

In 1965, Kramer (Jefferson Medical College Hospital [United States]) provided a book chapter where he summarized factors to consider during decision-making.[21] These included the natural history of the tumor, its extent, the condition of the normal tissues, the details of the previous treatment, and the objective of the proposed reirradiation. He recommended that “an attempt must be made to determine whether the initial course of therapy has failed because of inadequate doses, geographical miss or radioresistance of the tumor. Previously irradiated tissues are compromised a priori to some extent, whether this is clinically obvious or not.” He advocated that radium needle implants were the first choice in certain accessible sites and concluded that “there is a definite place for re-irradiation, but patients must be selected most carefully if useless therapy is to be avoided.”

Stevens et al. used more modern technology in 100 patients with head and neck cancer treated with curative intent from 1964 to 1991.[22] These clinicians required presence of intact and nonulcerated mucosal surfaces and no more than minimal visible or palpable late effects from the prior irradiation. At least one-

third of patients evaluated were not accepted for reirradiation. In 82 patients, external beams only were used (1.8 to 2 Gy per day, 5 days per week, planned dose at least 50 Gy). Actuarial 5-year survival was 17% in case of recurrent and 37% in case of new primary tumors.

TISSUE TOLERANCE AND RECOVERY

General Aspects

Animal studies and clinical data on reirradiation of head and neck tumors, breast cancer, lung cancer, and others showed that acute skin and mucosal reactions after reirradiation were well within the range observed after the first course of radiotherapy.[8,23–27] If the previous treatment has caused persistent severe mucosal damage, reirradiation might be poorly tolerated. Clinical data related to many cancer types revealed that late complications were more frequent than anticipated after reirradiation to high cumulative doses. The majority of data is derived from head and neck cancer retreatment. Lee et al.[28] reported the data of 654 patients with recurrent nasopharyngeal carcinoma reirradiated with now outdated technology to moderate median initial and reirradiation doses of 60 Gy and 46 Gy, respectively, with a median interval of 2 years. For all complications combined, the actuarial incidence of symptomatic late sequelae was approximately 50% at 5 years. In a later analysis, the same group found that the major determinant of postretreatment complications was the severity of damage during the initial course.[29] Severe toxicity occurred also after intensity-modulated radiotherapy (IMRT), but no prospective randomized head-to-head comparison of salvage IMRT versus 3-D conformal RT is available.[30] In the IMRT study reported by Duprez et al.,[31] 84 patients were reirradiated to a median cumulative total dose of 130 Gy (median time interval 49.5 months, median reirradiation dose 69 Gy). Late toxicity was scored in 52 patients with at least 6 months of follow-up. Eight patients developed grade 3 or 4 late dysphagia, and three developed osteoradionecrosis. Overall, 30 different grade 3 or 4 late complications were recorded. Updated results from the University of Texas MD Anderson Cancer Center (n = 206, IMRT) revealed actuarial rates of grade ≥3 toxicity of 48% at 5 years, most often dysphagia and odynophagia.[32] Increased toxicity was associated with retreatment volume >50 cm^3. Stereotactic body reirradiation for recurrent head and neck cancer resulted in higher late toxicity rates if the larynx or hypopharynx was treated.[33] It is unrealistic to expect a zero risk of any severe late toxicity after IMRT or other highly

conformal techniques since certain parts of the mucosal and/or connective tissues will always be part of the planning target volume and receive high cumulative doses. Overall, the available literature indicates that mesenchymal tissues recover from radiation injury less than do rapidly reacting tissues like the epidermis and mucosa, at least in the head and neck region.

Large Arteries

Recent reports of high-dose reirradiation have also identified the large arteries as critical organs at risk (OAR). Evans et al.[34] analyzed the endpoint of grade 5 aortic toxicity in 35 patients with lung cancer. The median prescribed dose was 54 Gy in 1.8-Gy fractions and 60 Gy in 2-Gy fractions, respectively. The median interval between the two courses was 32 months. The median raw composite dose to 1 cm^3 of the aorta was 110 Gy. Toxicity developed in 25% of patients who received ≥120 Gy, but not in patients irradiated to lower cumulative doses. The issue of carotid blowout syndrome (CBOS) has been studied by Yamazaki et al..[35] They pooled data from 7 Japanese CyberKnife institutions and analyzed 381 patients. Of these, 32 (8.4%) developed CBOS after a median of 5 months from reirradiation. Twenty-two patients died (69%). Later, a predictive model (CBOS index) was developed, which includes carotid invasion of >180 degrees, presence of ulceration, and lymph node area irradiation (0 to 3 points).[36]

Lung/Thorax

In animal experiments, the lungs recover at least partially from occult injury, as reviewed in.[24] Experimental data on the trachea, bronchi, or esophagus are lacking. Most clinical series did not describe particular problems with these critical structures, except for stereotactic treatment of central lesions[37,38] and recurrent disease with infiltration or likely infiltration, where it is often difficult to determine the cause of fistula or hemoptysis (tumor progression vs. treatment toxicity). Table 32.1 shows different treatment regimens.

TABLE 32.1 PUBLISHED CONCEPTS FOR REIRRADIATION OF HEAD AND NECK (HN), LUNG, AND BRAIN TUMORS (WITH OR WITHOUT CONCOMITANT SYSTEMIC THERAPY)

Regimen	HN Tumors	Lung Tumors	Brain Tumors
External beam, conventional fractionation 1.8–2 Gy	x	x	x

Spinal Cord

The spinal cord has been studied in several experimental settings. Clinically applicable data were generated in adult rhesus monkeys by Ang et al.[39] The cervical spinal cord of these primates was irradiated with 2.2 Gy per fraction. The dose of the initial course was 44 Gy in all monkeys. Reirradiation dose was 57.2 Gy, given after 1-year (n = 16) or 2-year (n = 20) intervals, or 66 Gy, given after 2-year (n = 4) or 3-year (n = 14) intervals. Only 4 of 45 monkeys completing the required observation period (2 to 2.5 years after reirradiation, 3 to 5.5 years total) developed myelopathy. Fitting the data with a model, assuming that all (single course and reirradiation) dose–response curves were parallel, yielded recovery estimates of 33.6 Gy (76%), 37.6 Gy (85%), and 44.6 Gy (101%) of the initial dose, after 1, 2, and 3 years, respectively, at the 5% incidence level. Another way to look at these results is to estimate the total cumulative dose that can be tolerated, expressed in EQD_2 that is equivalent dose in 2-Gy fractions calculated using the linear-quadratic approach. For a time interval of 1, 2, and 3 years between the treatment courses, cumulative doses of 150%, 156%, and 167% of the first-line setting's tolerance dose appear possible. If true in humans, an initial exposure equivalent to 46 Gy in 2-Gy fractions (arbitrarily selected to represent 100% of the tolerance dose at the 5% myelopathy risk level because many institutions limit the spinal cord dose to lower levels than true tolerance) might be followed by an additional 23 to 24 Gy in 2-Gy fractions (50% of the tolerance dose) 1 or 2 years later. Clinical data from different institutions supporting this interpretation have been published. All available data from different published series including those reporting on myelopathy[40] were analyzed by Nieder et al.[41,42] Seventy-eight patients were

included and a risk prediction model was developed, based on time interval, cumulative dose, and presence or absence of any treatment course resulting in quite high spinal cord exposure. Besides cumulative dose, interval <6 months and total dose equivalent to >50 Gy in 2-Gy fractions in one of the two courses increase the risk of myelopathy. The introduction of stereotactic body radiotherapy (SBRT) has resulted in new challenges as such treatment typically is administered with few high-dose fractions or even single doses. Rather than irradiating complete spinal cord cross sections with homogeneous doses, small areas are exposed and steep dose gradients achieved. Medin et al.[43] developed a swine model where a 10-cm length of the spinal cord (C3-T1) was uniformly irradiated to 30 Gy in 10 fractions and reirradiated 1 year later with a single radiosurgery dose centered within the previously irradiated segment. Radiosurgery was delivered to a cylindrical volume approximately 5 cm in length and 2 cm in diameter, which was positioned laterally to the cervical spinal cord, resulting in a dose distribution with the 90%, 50%, and 10% isodose lines traversing the ipsilateral, central, and contralateral spinal cord, respectively. Follow-up after reirradiation was 1 year. Summarized briefly, pigs receiving radiosurgery 1 year following 30 Gy in 10 fractions were not at significantly higher risk of developing motor deficits than were pigs that received radiosurgery alone. Sahgal et al.[44] provided a recommendation of presumably safe stereotactic reirradiation doses after initial conventional radiotherapy (interval at least 5 months). A thecal sac point maximum P(max) EQD_2 of 20 to 25 Gy appeared to be safe provided the total P(max) EQD_2 does not exceed approximately 70 Gy, and the SBRT thecal sac P(max) EQD_2 constitutes no more than approximately 50% of the total normalized biologically equivalent dose. The feasibility of salvaging spinal metastases initially irradiated with SBRT, who subsequently progressed with imaging-confirmed local tumor progression, with a second SBRT course to the same level has recently been confirmed.[45]

Brain

In contrast to the spinal cord, no animal experiments on reirradiation of the brain are available. Clinical data mainly relate to temporal lobe injury after treatment of recurrent nasopharynx cancer[46] or reirradiation of glioma and brain metastases. Shepherd et al.[47] retreated glioma with fractionated stereotactic radiotherapy (5 fractions per week, 5 Gy per fraction) after a median initial dose of 55 Gy (Table 32.2). All patients treated with more than 40 Gy developed late

toxicity, whereas only 25% of those who received 30 to 40 Gy developed such adverse events. Several institutions have used reirradiation doses of 30 to 40 Gy with fraction sizes below 4 Gy with acceptable rates of toxicity,[58,62] and prospective trials with such regimens and a study comparing 5 fractions of 5 versus 7 Gy are in progress. Interstudy comparison between retrospective series is difficult because the literature is confounded by a lack of standardized recording of radiotherapy and outcome variables. In addition, some patients were treated at first and others at second or third progression. Recent prospective data from a multicenter study in 92 patients with recurrent high-grade gliomas suggest that reirradiation has no negative impact on health-related quality of life, comparable to other options such as surgery and chemotherapy.[63] Currently, there is no standard recommendation on what imaging modality has to be incorporated and what specific margins should be applied. The minimal consensus may be summarized as to confine gross tumor volume (GTV) definition to gadolinium-enhancing regions. The GLIAA (NOA 10) study (NCT01252459), an ongoing multicenter, prospective randomized, phase II clinical trial, evaluates the impact of FET-PET versus T1Gd-MRI target volume delineation on the outcome of patients with recurrent glioblastoma treated with high-precision radiation therapy (39 Gy, 3 Gy per fraction). As evident from the review of treated volumes with different modalities, such as single-dose and fractionated stereotactic irradiation, some institutions preferred hypofractionation for recurrences that others treated with a single dose. This finding reflects the lack of universally agreed dose constraints for reirradiation. In the randomized phase II NRG RTOG 1205 study of systemically administered bevacizumab with or without reirradiation, 35 Gy in 10 fractions was prescribed.[64] The maximum tumor diameter was 6 cm and the minimum time interval from previous radiotherapy 6 months. Brainstem, optic nerves, and chiasm were expanded with 3 mm to create planning organ at risk volumes (PRV). The maximum per protocol dose to 0.03 cm^3 PRV was 24 Gy (brainstem) and 20 Gy (optic nerves and chiasm), respectively. Acceptable variations included 30 and 25 Gy, respectively. Figure 32.1 shows a clinical example of a patient treated with conventionally fractionated reirradiation.

GBM, glioblastoma; WHO, World Health Organization.

Radiosurgery was systematically studied by the RTOG.[65,66] Adults with cerebral or cerebellar solitary nonbrainstem tumors ≤40 mm in maximum diameter were eligible. Initial radiosurgical doses were 18 Gy for tumors ≤20 mm, 15 Gy for that 21 to 30 mm, and 12 Gy for that 31 to 40 mm in maximum diameter. Dose was prescribed to the 50% to 90% isodose line. Doses were escalated in 3-Gy increments providing the incidence of irreversible grade 3 or any grade 4 or 5 RTOG central nervous system toxicity was <20% within 3 months of radiosurgery. Between 1990 and 1994, 156 analyzable patients were entered, 36% of whom had recurrent primary brain tumors (median prior dose 60 Gy) and 64% recurrent brain metastases (median prior dose 30 Gy). The median interval was 11 months and minimum 3 months. The maximum tolerated doses were 24, 18, and 15 Gy for tumors ≤20 mm, 21 to 30 mm, and 31 to 40 mm in maximum diameter, respectively. However, for tumors ≤20 mm, investigators' reluctance to escalate to 27 Gy, rather than excessive toxicity, determined the maximum tolerated dose. The actuarial incidence of radionecrosis was 5%, 8%, 9%, and 11% at 6, 12, 18, and 24 months following radiosurgery, respectively. Unacceptable toxicity was more likely in patients with larger tumors. Sneed et al.[67] reported that radiosurgery followed by a second radiosurgery for recurrent brain metastases resulted in a 20% 1-year cumulative incidence of symptomatic adverse radiation effect (median reirradiation dose 18 Gy, n = 72, crude risk 14%). Compared to patients who had not received prior radiosurgery to the same lesion, the hazard ratio (HR) for any adverse radiation effect was 5.05 (95% confidence interval [CI] 1.9 to 13.2). Another study of 46 retreated lesions reported symptomatic radiation necrosis in 24% (actuarial 1-year rate 29%),[68] whereas local control at 1 year was 79%.

In children with diffuse intrinsic pontine glioma, reirradiation at first progression (20 to 30 Gy) provided a significant benefit in median survival compared to systemic therapy or best supportive care (13.7 vs. 10.3 months, P = .04) in a matched-cohort analysis (n = 31 and 39, respectively). Clinical improvement was observed in 77% of reirradiated patients.[69] Grade 4 to 5 toxicity was not recorded.

Heart

Wondergem et al.[70] assessed the reirradiation tolerance of the heart at intervals of up to 9 months in a rat model by measuring cardiac function ex vivo 6 months after reirradiation. The cardiac tolerance dose was arbitrarily defined as the dose causing at least a 50% function loss in one-half of the treated animals (ED_{50}). Up

to a 6-month interval, the reirradiation ED_{50} was close to the single course ED_{50} but dropped significantly when the interval was longer than 6 months. The reirradiation tolerance also decreased with an increasing priming dose. A slow progression of damage induced by the priming dose is a plausible explanation for the decrease in tolerance with increasing time from the initial course. Systematic clinical data are not available.

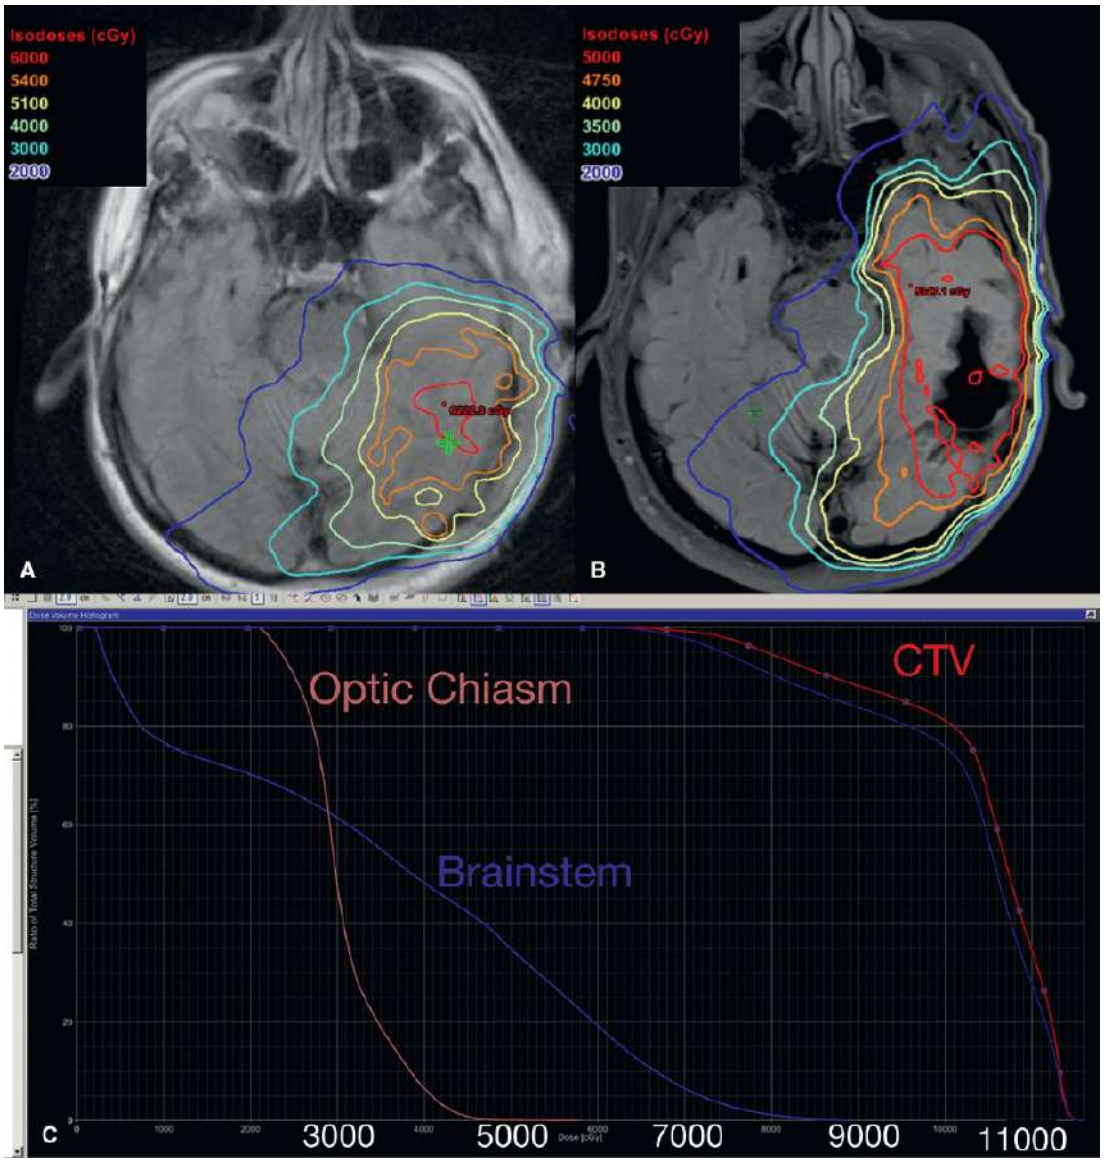

FIGURE 32.1. Representative axial slices from a T2-weighted fluid attenuation inversion recovery magnetic resonance image of a 66-year-old man with a left temporoparietal glioblastoma originally treated after surgical resection (panel **A**) to 60 Gy in 30 fractions with concurrent temozolomide. He subsequently had an in-field recurrence 4 years after the completion of his original treatment and was treated (panel **B**) to 50 Gy in 25 fractions. A dose–volume histogram is shown in panel **C**. Cumulative brainstem dose to 0.3 cm^3 was limited to 80 Gy. Treatment was

successfully delivered, and the patient continues to do well in follow-up. (Courtesy of Mark Amsbaugh, MD, University of Louisville School of Medicine, Louisville, KY.)

Kidney and Bladder

Experimental data caution also against whole-bladder reirradiation.[71] With respect to late bladder damage in mice (endpoint defined as >50% reduction in bladder volume, increased urination frequency at ≥27 weeks after reirradiation), no long-term recovery was observed in up to a 9-month interval. Unfortunately, neither experimental data for partial organ reirradiation nor larger clinical studies on bladder reexposure are available. Studies on mouse, rat, and pig kidneys suggested that radiation-induced toxicity progresses rather than recovers with time.[72,73]

SELECTED HEAD AND NECK CANCER STUDIES

The randomized Chinese phase 2 trial by Tian et al. that included 117 patients evaluated de-escalation of the biologically effective dose (BED) for late-responding normal tissues while maintaining the same BED for nasopharynx cancer cells.[26] This was accomplished by selecting a slightly hypofractionated experimental regimen (60 Gy in 27 fractions, IMRT), which was compared to a conventional regimen with 2-Gy fractions (total dose 68 Gy, IMRT) and longer overall treatment time. It was assumed that normal tissue sparing would result in less life-threatening toxicity and thus better overall survival, that is, a better therapeutic ratio. In principle, the results confirmed this hypothesis, with a 5-year overall survival rate of 44% versus 30%, but the difference was not statistically significant (P = .06). Interestingly, the small randomized phase 2 trial by Guan et al.[74] with 69 patients compared the winner arm from the Tian et al. study,[26] that is, 60 Gy in 27 fractions, to an experimental arm, which also included weekly chemotherapy with cisplatin 30 mg/m^2. Only 29% of patients had received radiochemotherapy before. In the investigational arm, more patients developed mucositis and grade 3 to 4 hematologic toxicity. Late toxicity was not significantly increased. Survival was significantly better in the combined-modality arm, P = .049. In the absence of phase 3 studies, these results suggest that chemoreirradiation might be an effective treatment option for recurrent nasopharynx cancer. Serious toxicity was not uncommon and, therefore, continued research efforts are necessary.

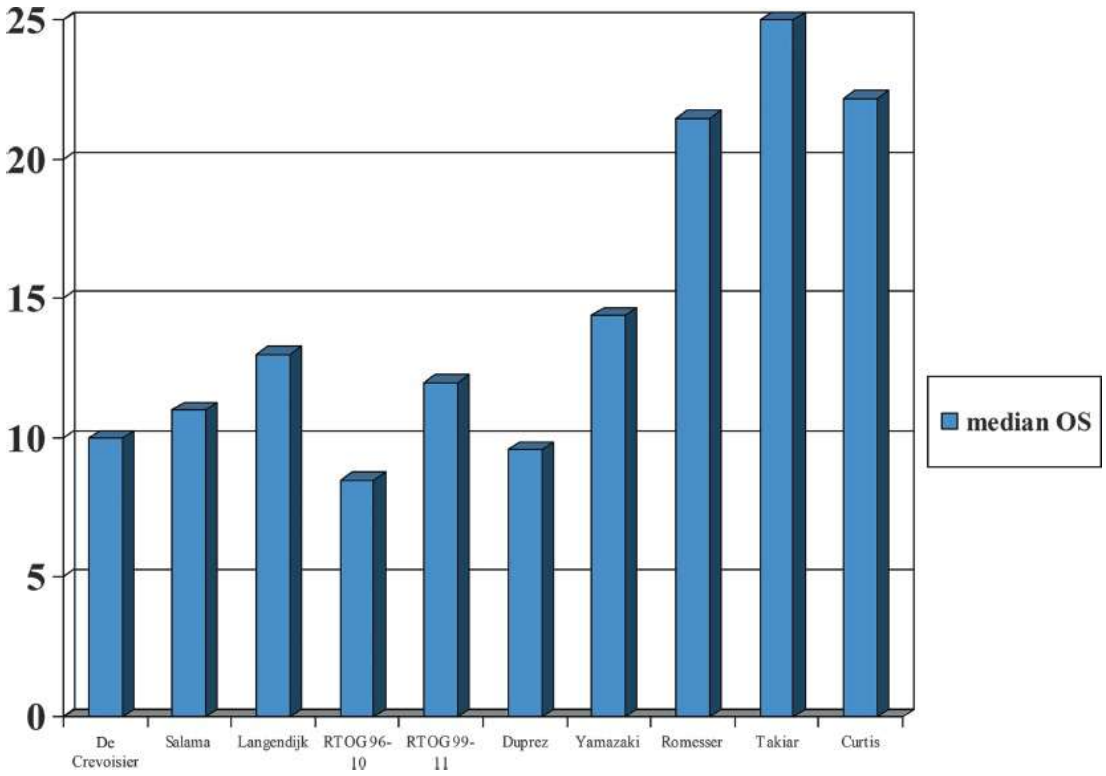

FIGURE 32.2. Median overall survival in months after reirradiation of head and neck cancers (selected studies[8,9,11,23,31,32,77–80]). The studies by Takiar et al.,[32] Romesser et al.,[78] and Curtis et al.[79] included mixed populations, that is, patients treated after salvage surgery or without resection.

The Groupe d'Oncologie Radiothérapie Tête et Cou/Groupe d'Étude des Tumeurs de la Tête et du Cou (GORTEC/GETTEC) reported on a prospective study in which 130 patients who underwent salvage surgery were randomly assigned to receive full-dose reirradiation (60 Gy) combined with concomitant chemotherapy (5-FU and hydroxyurea) versus no adjuvant treatment.[75] All patients underwent a macroscopic complete resection, and in the majority, the surgical margins were sufficient. A significant improvement with regard to the primary endpoint of locoregional tumor control (HR 2.73; 95% CI 1.66 to 4.51; P <.001) and disease-free survival (HR 1.68; 95% CI 1.13 to 2.50; P = .01) was observed in those patients that were assigned to receive postoperative chemoreirradiation compared to those that underwent surgery alone. However, this benefit in disease-free survival did not translate into a significant improvement of overall survival, which may be due to the higher incidence of distant metastases in the chemoreirradiation arm. The gain in locoregional tumor control and disease-free survival was achieved at the cost of significantly higher rates of grade 3 to 4 late side effects (39% vs. 10% at 2 years, respectively). It

should be noted that participants allocated to the wait-and-see arm could receive salvage chemoreirradiation at the time of locoregional recurrence after salvage surgery, which was the case in 25% of patients. This type of crossover reduces the likelihood of improved overall survival. Postoperative chemoreirradiation should be considered in selected cases, in particular given the very low locoregional control rate after salvage surgery alone, which was only 20% at 2 years. However, in the light of the high rate of late toxicity, the optimal postoperative regimen in the reirradiation setting has yet to be defined. Based on the results of this study, a wait-and-see policy could also be considered, in particular when patients suffer from severe late toxicities from the first course of treatment. Ho et al. in a retrospective comparison of primary closure to flap reconstruction (n = 59 and 37, respectively) reported that nonflap patients experienced significantly greater incidence of severe late toxicities (47.5 vs. 21.6%, P = .02), whereas acute toxicities and 5-year survival were comparable.[76]

As shown in Figure 32.2, median survival is limited,[8,9,11,23,31,32,77–80] but a proportion of patients experience long-term survival after reirradiation, a finding that has already been described in historical studies.[22,81] As highlighted by Stevens et al.,[22] actuarial 5-year survival was dependent on reirradiation setting, that is, 17% in case of recurrent and 37% in case of new primary tumors. Target volumes should be kept tight, and elective nodal irradiation should be avoided in order to minimize severe toxicity.[82]

BREAST CANCER

In-Breast Tumor Recurrence (IBTR) after Prior Breast-Conserving Surgery (BCS) and Whole-Breast Radiation Therapy (WBRT)

IBTR is expected to occur in approximately 5% to 10% of patients within 10 years after initial BCS + WBRT, equating to a cumulative risk of 0.5% to 1% per annum.[83] The most often recommended treatment for IBTR is salvage mastectomy, which imparts excellent locoregional control and 5-year survival rates.[84] Given the fact that there are subgroups of patients who refuse mastectomy after IBTR, a number of series have described the approach of repeat BCS alone, without additional reirradiation. In these studies, locoregional recurrence is unacceptably high, with rates approaching 40%,[17,85] as opposed to 10% following mastectomy.[84,86] Even so, radiation oncologists have generally shown a reluctance to offer reirradiation in the treatment of locally recurrent breast cancer.[87] However, with increase in technologic sophistication of radiation

therapy techniques over the last two decades, a number of studies have investigated the feasibility and efficacy of adding reirradiation to BCS for IBTR.

Table 32.3 shows a summary of modern series of repeat BCS and reirradiation in the setting of IBTR. The overwhelming majority of the data exists for partial breast irradiation (PBI) using interstitial, multicatheter brachytherapy with low dose rate (LDR), pulsed dose rate (PDR), or high dose rate (HDR) source techniques.[88–96] Pooled data from European experience using

all three of the aforementioned methods represent the largest study of this approach published to date.[96] In a total of 217 patients, this collaborative multi-institutional analysis from high-volume centers in Europe found that interstitial brachytherapy was very well tolerated with local control rates much more comparable to salvage mastectomy (93%) as well as good to excellent cosmetic outcome in the overwhelming majority of patients (85%). Simplified interstitial techniques using single-catheter balloon brachytherapy have been described with similar outcomes.[93]

An emerging technique to address the challenge of reirradiation after second BCS for IBTR was piloted by a European cooperative group that employed intraoperative radiation therapy (IORT) at the time of salvage lumpectomy.[89] IORT was delivered using a single dose of approximately 14 to 20 Gy, 50 kV x-rays delivered to the applicator surface using the Intrabeam device (Carl Zeiss, Oberkochen, Germany). In this small study of 17 patients, the treatment was well tolerated with no grade 3 or higher toxicity, 100% local control at 2 years, and excellent or good cosmetic outcome in 82% of patients.

In terms of breast reirradiation using external beam radiation therapy (EBRT), the data are fairly scant. The largest study of its kind published to date included 39 patients treated with electron beam radiotherapy directed at the tumor bed after repeat BCS.[88] At a median follow-up of over 4 years, the therapy was generally well tolerated with local control rates at 77% and good to excellent cosmetic outcome in 69% of patients. Interest in this commonly available modality has grown, and so a multi-institutional phase II trial of the safety and efficacy of repeat PBI using three-dimensional conformal radiotherapy has recently completed accrual of its targeted sample size of approximately 60 patients (NRG Oncology/RTOG 1014).[97] In this study, patients with small invasive or preinvasive lesions completely excised with negative surgical margins were treated with a regimen of accelerated hyperfractionated radiation therapy, twice daily over three treatment weeks (45 Gy in 30 fractions). Data from this trial will be forthcoming in the next few years, which will serve to increase the use and availability of breast reirradiation among centers that do not offer interstitial brachytherapy.

In the meantime, the only published consensus guidelines that exist to inform clinicians in routine practice come from the Breast Cancer Expert Panel of the German Society of Radiation Oncology (DEGRO).[17] This panel recommends that although mastectomy is regarded as a standard of care for patients with IBRT, a subset of patients may be appropriately offered reirradiation after a

second BCS. Since the largest experience to date exists for a multicatheter brachytherapy, other techniques such as EBRT or IORT should preferentially be performed on a clinical trial.

Management of Locoregional Recurrence after Prior Mastectomy and Postmastectomy Radiation Therapy (PMRT)

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) estimated that the addition of radiotherapy significantly reduced the 10-year risk of isolated local recurrence from approximately 25% to 7%.[98] The addition of modern systemic therapy has fortunately made this type of event even more rare. That does not diminish the clinical challenge that is experienced by physicians in cases of isolated chest wall or regional nodal recurrences in patients who have had prior PMRT. Published series that address this issue tend to be single institution and small experiences with heterogeneous mix of patients who are able to undergo upfront surgical resection of their disease and patients who have unresectable gross disease present at the time of therapy.[27,99–108]

A selection of the most modern published series in the reirradiation for chest wall recurrences is presented in Table 32.4. The overwhelming majority of investigators use concurrent hyperthermia (HT) combined with EBRT that is typically conventionally or hypofractionated.[27,99–104] Although HT is not available at a majority of radiotherapy centers, it does have a proven benefit in the treatment of advanced superficial local recurrences such as these. A randomized study from 2005 published by Jones et al. that examined the effect of HT found a statistically significant benefit, which was especially pronounced among the subset of patients who had been previously treated with full-dose radiation therapy.[102] In a large collaborative series published in 2002, Wahl et al. presented a cohort of 81 patients treated with reirradiation to a total median dose of 48 Gy.[103] The overwhelming majority of investigators used once-daily conventional fractionation, and just over half the patients were treated with concurrent HT and/or cytotoxic chemotherapy. The rate of grade 3 or higher toxicity was very low and the rate of local control at 1 year was approximately 66%.

[a]Clinical complete response rates for patients with gross disease at time of reirradiation.
[b]This trial included nonbreast superficial recurrences as well.
CT, cytotoxic chemotherapy; EBRT, external beam radiotherapy; HT, hyperthermia; N, number of patients; PMRT, postmastectomy radiotherapy.

Series that omit HT generally include fewer, more favorable patients treated for high-risk, microscopic disease post limited resection.[27,104,107] Local disease control rates are favorable, with lower rates of toxicity compared to combined hyperthermia. Although the majority of patients received concurrent cytotoxic chemotherapy, rates of distant disease failure were very high. The aforementioned DEGRO expert panel currently recommends the use of reirradiation both in cases of unresectable recurrences and after surgical

resection in high-risk patients.[17] This group recommends reirradiation with doses between 45 and 50 Gy in conventional fractionation, not exceeding cumulative doses of 100 to 110 Gy, and notes that HT can further improve tumor control in this population.

Isolated Regional Nodal Recurrences after Prior Radiotherapy

Isolated supraclavicular and/or axillary recurrences are very uncommon in breast cancer, especially after appropriate adjuvant radiation therapy in the up-front setting. These clinical scenarios, however, pose the most significant clinical challenges for physicians and patients alike, because of the difficulty in early diagnosis and high-risk surgical management. In these situations, the risk of injury to clinical OAR such as the brachial plexus from repeat radiotherapy must be weighed against the certain involvement of these structures because of direct invasion of progressive disease.

In the largest series of its kind, a multi-institutional study from the Netherlands, 42 patients with isolated supraclavicular recurrence treated with a combination of systemic and locoregional radiotherapy were examined.[109] The 5-year overall survival and disease-free survival rate were significantly worse than is seen with chest wall recurrences (38% and 22%, respectively). What is more striking is that outcomes were even worse for patients who did not receive radiotherapy as a component of their salvage treatment. Given the grim prognosis, there are small emerging series that address isolated nodal recurrences with combination of either concurrent or sequential chemotherapy and reirradiation[104,110,111] using IMRT techniques to median doses of 50 Gy. Even in these most conformal techniques, point doses to the brachial plexus are well above historically cited tolerance with cumulative doses in excess of 100 Gy.[110] Since overall survival in these patients is less than half that of patients with chest wall recurrences,[104] clinicians must weigh the risks of a tumor-induced plexopathy versus iatrogenic injury in each particular case.

Patients with isolated axillary recurrences tend to fare somewhat better because of the fact that they lend themselves more often to surgical excision and reirradiation without compromising the brachial plexus. In a series of axillary recurrences from the MD Anderson Cancer Center, the authors found that durable control was able to be achieved in 31/44 patients (70%).[112] Success was most often seen in patients who were able to undergo up-front surgery and multimodality therapy. Twenty percent of these patients had prior axillary radiotherapy, and the addition of reirradiation to the axilla significantly improved

local disease control (81% vs. 56%). As of now, the DEGRO expert panel acknowledges that in cases of isolated nodal recurrences, approximately 1/2 to 2/3 of patients will eventually develop distant metastatic disease. Durable locoregional control is more often achieved in patients with axillary nodal involvement only, and reirradiation improves local control and should be applied wherever feasible.[17]

DISCUSSION

Reirradiation should only be considered if the radiation tolerance of critical tissues or organs has not been exceeded during the first treatment, that is, after in-depth review of the initial plan and dose distribution, and assessment of organ status and side effects after the first treatment. Moreover, reasonable performance status, absence of other, less toxic treatment alternatives, and careful dose summation are prerequisites.[113,114] It is important to weigh the expected benefits against morbidity and compromised quality of life. Several studies, especially on lung and head and neck cancer, demonstrated that reirradiation can either cause or prevent a fatal outcome. In many scenarios including but not limited to pelvic tumors, the ability of reirradiation to palliate pain and other symptoms has repeatedly been confirmed[7,115,116] (Fig. 32.3). For many tissues, organs, and indications, an increasing body of clinical data is now emerging. These include settings with much higher single-course equivalent doses than previously prescribed, for example, stereotactic radiotherapy for early-stage lung cancer.[117] Nevertheless, little is known for a number of endpoints such as neurocognitive function, damage to endocrine organs, or reirradiation tolerance of pediatric patients.[118] Acutely responding tissues, in general, recover radiation changes practically completely within a few months and, therefore, can tolerate a repeat treatment course.

Clinical evidence suggests that fibrosis, impaired blood perfusion, and, in general, late normal tissue injury in humans continue to progress for many years and even decades. These findings have triggered a trend toward highly sophisticated, conformal image-guided reirradiation approaches aiming at better normal tissue sparing. Brachytherapy (including intraoperative administration[119–123]), stereotactic techniques, and proton and carbon ion beams are under clinical investigation.[124–127] Preliminary data suggest that these approaches are more successful than previous attempts to treat with neutrons or boron neutron capture therapy.[128–130] However, severe dysphagia and fatal

bleeding might still occur after proton beam reirradiation for head and neck cancer.[78,131,132] A treatment planning study in 25 patients, which compared intensity-modulated proton therapy (IMPT) and ion therapy (IMIT) reirradiation plans to a second subsequent dose of 70 Gy to photon therapy delivered with volumetric modulated arcs, reported a dosimetric benefit favoring carbon ions above proton therapy.[133] A previous, smaller study in 7 patients suggested that IMPT was not uniformly superior to helical TomoTherapy and recommended comparative treatment planning with different techniques.[134] It is hoped that models, which predict the risk of serious complications, might contribute to optimized patient selection, for example, the model for nasopharyngeal necrosis, which should be validated in future studies.[135] Proton beam reirradiation of non–small cell lung cancer was associated with 6 grade 5 toxicities in a multi-institutional study of 57 patients.[124] Increased overlap with the central airways, mean esophagus and heart dose, and simultaneous chemotherapy were risk factors for grade ≥3 toxicity.

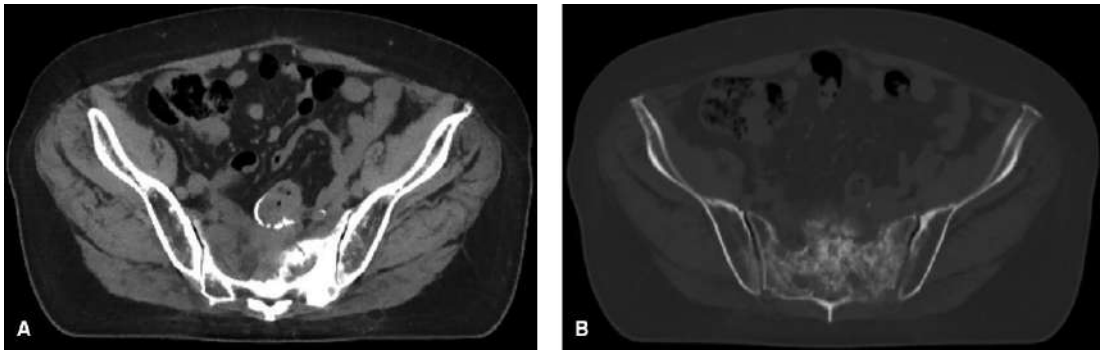

FIGURE 32.3. Representative axial slices from planning computed tomography (CT) images (soft tissue and bone window, panels **A** and **B**) of a 64-year-old female patient initially treated surgically for cancer in the sigmoid colon in 2013. She relapsed in the sacral bone in 2014 and received long-course chemoradiation (50 Gy in 25 fractions with concomitant capecitabine) without surgery. Owing to local progression, chemotherapy with an oxaliplatin/5-FU regimen was initiated in 2016. Because of increasing pain, reirradiation was offered in June 2016 (CT). A hyperfractionated regimen was chosen (1.25 Gy b.i.d., total dose 40 Gy) concomitant to capecitabine. Symptom improvement was achieved. At last follow-up in March 2017, no treatment-related toxicity was recorded.

While small target volumes can be treated with fraction sizes above 2 Gy, radiobiologic principles and retrospective data suggest that large volume reirradiation might be less toxic if hyperfractionation is employed.[115,116,136] Despite strong rationales, this logistically difficult approach has not been studied in randomized head-to-head comparisons to conventionally fractionated

reirradiation. Many institutions consider reirradiation for primary and secondary brain tumors; bone and lymph node metastases; head and neck, lung, breast, prostate, gynecologic, and rectal cancer; lymphoma; and soft tissue sarcoma. With regard to prostate cancer, several groups have started to investigate focal salvage therapies because whole-gland reirradiation has repeatedly been linked to a higher risk of late toxicity.[137] Very few reports were published regarding hepatic, pancreatic, and esophageal tumors.[138–141]

CHAPTER 33

Global Radiation Oncology

Timothy P. Hanna and C. Norman Coleman

INTRODUCTION

Global radiation oncology links the discipline of radiation oncology to global health, where the latter may be defined as "… an area for study, research, and practice that places a priority on improving health and achieving equity in health for all people worldwide."[1] This chapter will provide an overview of the unique challenges to providing radiation oncology in low-income and middle-income countries (LMIC). It will also provide reasons for hope that the global challenge of cancer can be met. Low-income countries had a 2015 per capita gross national income of US$1,025 or less, and for middle-income countries, the range was US$1,026 to $12,475.[2] Nations falling into these income groups are sometimes described as developing countries.

GLOBAL BURDEN OF DISEASE

In 2015, an estimated 16% of all deaths worldwide were due to cancer.[3] In comparison to the worldwide burden of cancer, cardiovascular disease and other chronic conditions are responsible for, respectively, 32% and 24% of deaths globally. In total, 71% of mortality worldwide is the result of noncommunicable disease. Seventy-six percent of these deaths occur in low- and middle-income countries.[3] In low-income countries, where deaths from communicable disease and other related causes are common, noncommunicable disease is already responsible for nearly 40% of all deaths.[3]

In 2012, 57% of cancers worldwide occurred in less developed countries, as did 65% of all cancer deaths.[4,5] The burden of cancer in LMIC relates to increasing life expectancy in LMIC, population growth patterns, and rising incidence of risk factors for chronic diseases in LMIC.[6,7] For example, an estimated 65% of people ≥60 years of age lived in less developed countries in

2011, and this is expected to rise to 79% by 2050.[6] The growing burden of cancer and other noncommunicable diseases in LMIC represents a significant epidemiologic transition and a dual challenge for disease control efforts.

EPIDEMIOLOGY OF CANCER WORLDWIDE

Worldwide, there were 14.1 million new cases of cancer and 8.2 million cancer deaths in 2012.[8] Lung cancer is the most common cause of cancer worldwide (1.8 million new cases in 2012), followed by breast cancer (1.7 million) and colorectal cancer (1.4 million) (Fig. 33.1).[4] Lung cancer is also the most common cause of cancer death, with 1.6 million deaths in 2012.[4] Liver cancer (0.74 million) and gastric cancer (0.72 million) are the second and third most common causes of cancer death, respectively. Age-standardized incidence rates of cancer in developed countries are nearly double the rates in LMIC, though mortality rates are far more similar. These findings reflect variation in prevalence and distribution of major risk factors and limitations in early detection and treatment resources in LMIC.[9]

Although cervix cancer is the 11th most commonly diagnosed cancer among women in developed countries, it is second only to breast cancer in developing nations.[4] This reflects a lack of sufficient prevention of cervical cancer in many LMIC. Cervix cancer is an extremely common cancer in Latin America, Sub-Saharan Africa, and parts of Asia such as India (Fig. 33.2).[4] Gastric cancer and hepatocellular carcinoma are also common in many LMIC, with 43% of all cases of gastric cancer in the world occurring in China alone (Fig. 33.2).[4] Kaposi sarcoma is a common cancer in Sub-Saharan Africa,[10] and esophageal cancer has the highest incidence rates worldwide in regions of Asia and Africa.[4] Oral cancer has a high incidence in South Asia, particularly among men.[11]

Among nine common modifiable risk factors for cancer, tobacco smoking is associated with the largest proportion of attributable risk.[12] There are one billion smokers globally, and 80% live in LMIC.[13] With large populations and high tobacco use in China and India, tobacco is an extremely important risk factor for cancer in Asia.[14] In general, many LMIC have demonstrated increased tobacco use during the past three decades. National consumption continues to rise in many countries, and in others, a peak occurred in the 1980s and 1990s.[15] History has shown a 30- to 40-year delay between the peak in smoking rates in a population and the peak in tobacco-related mortality.[16] Thus, an increasing rate of tobacco-related malignancies is expected in LMIC during the next half

century.[17,18]

Over 26% of cancers in developing countries are attributed to infectious causes.[19] Hepatitis B is a major risk factor for hepatocellular carcinoma in LMIC. Other factors are hepatitis C[20] and aflatoxin produced from *Aspergillus* in certain poorly preserved foods.[21] Human papillomavirus (HPV) and *Helicobacter pylori* are important etiologic agents, and there are numerous other infectious agents relevant to cancer in the developing world. These include Epstein-Barr virus, human immunodeficiency virus (HIV), schistosomiasis, human T-cell leukemia virus type 1 (HTLV-1), and human herpesvirus 8 (HHV-8).[19,22] The prevalence of infectious causes is notable given the preventability of many of these causes through public health measures (e.g., hepatitis B, HPV vaccines).

There are a number of other factors that are relevant to patterns of global cancer incidence. Diet[23] and obesity are risk factors for some cancers.[24] This is notable given increasing trends in unhealthy diet and sedentary lifestyle among LMIC.[25] The impact of genetic polymorphisms on patterns of global cancer incidence has not been fully elucidated, but there is some suggestion of their relevance.[26,27] Similarly, the role of occupational and environmental exposures to cancer in LMIC requires continued exploration.[28]

In many LMIC, cancer often presents in advanced stages, due to factors such as lack of comprehensive screening and poor access to effective treatments.[29] As a result, case fatality rates are much higher in LMIC, with rates for breast and cervical cancer in low-income countries being more than double rates in high-income countries.[30] Overall, about half of all cancers in LMIC require radiotherapy.[31,32] With cervical cancer being so common in LMIC and the high frequency of advanced cancer presentations requiring local therapy, radiation therapy has an extremely important role in LMIC. Accordingly, the World Health Organization considers linear accelerators, remote afterloading brachytherapy systems, and their supporting technologies as priority medical devices for cancer management.[33] The following sections will describe radiation oncology in LMIC in terms of access, quality, and economics.

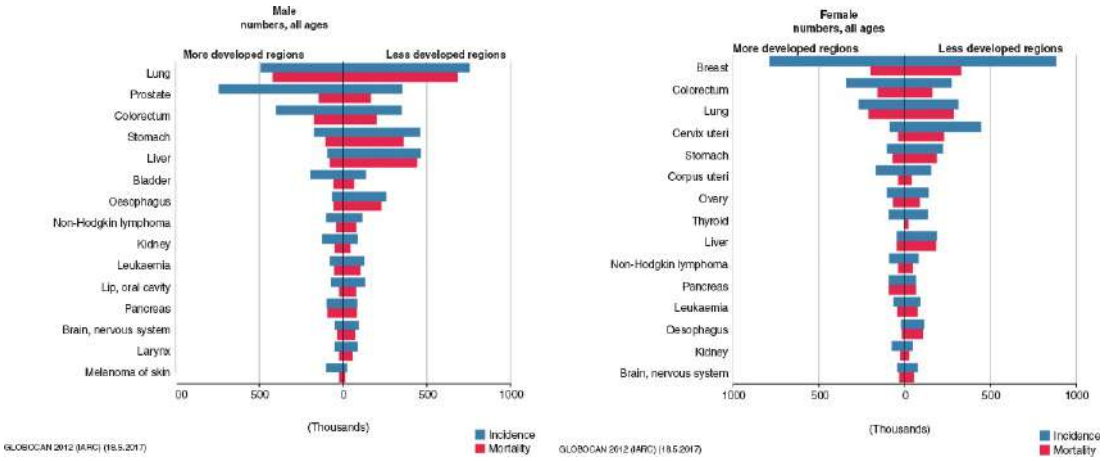

FIGURE 33.1. Estimated number of new cancer cases (incidence) and deaths (mortality) worldwide in 2012. Data are shown for more developed and less developed countries by top 15 cancer sites and sex, ranked by global cancer incidence. (Reproduced with permission from Ferlay J, Soerjomataram I, Ervik M, et al. *GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11* [*Internet*]. Lyon, France: International Agency for Research on Cancer, 2013. Available from: http://gco.iarc.fr/today/home, accessed on 8/03/2018.)

GLOBAL STATUS OF ACCESS TO RADIATION THERAPY

Access to radiation therapy is a multifactorial issue. Availability of machines and personnel for treatment is a key part of access to care. Other considerations include spatial accessibility, acceptability, affordability, accommodation, and awareness.[34,35] The most pertinent elements of access to radiation therapy in LMIC are discussed here.

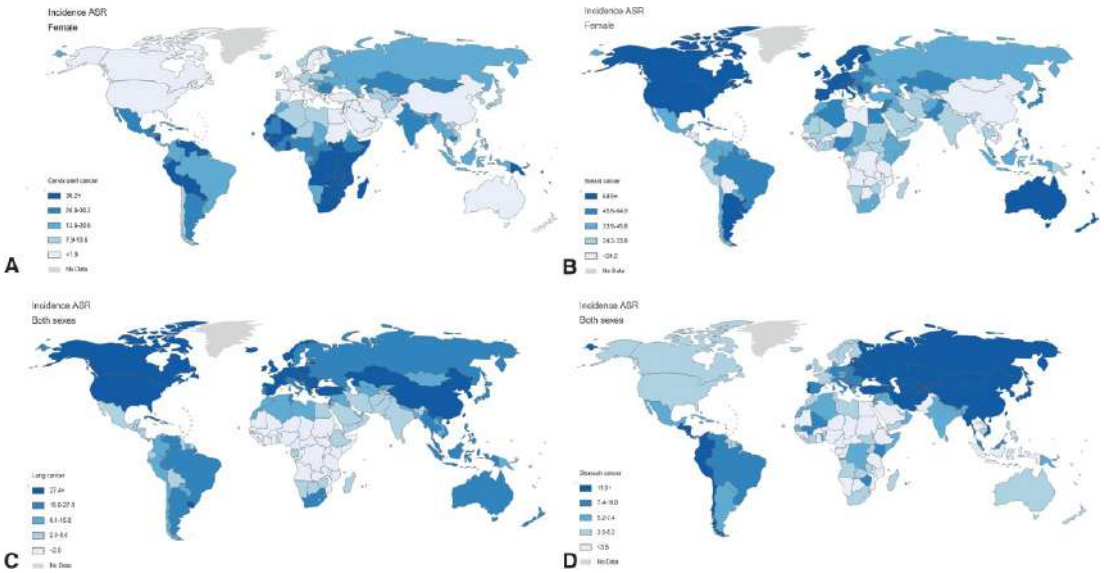

FIGURE 33.2. Global variation in estimated age-standardized cancer incidence per 10^5 in 2012 for specific cancers based on International Agency for Research on

Cancer statistics. Incidence is grouped with higher incidence indicated by darker color. Rates for both sexes are shown for lung and stomach cancer. **A:** Cervix cancer rates are highest in Latin America, Sub-Saharan Africa, and parts of Asia including India. **B:** Breast cancer rates are high among high-income countries. Among low- and middle-income countries, rates are high in parts of Latin America and lower in parts of Africa and Asia. **C:** Lung cancer rates are high in both developed and developing parts of the world, including China, Southeast Asian countries, and parts of South America. **D:** Rates of stomach cancer are highest in East Asia. High rates are found in Latin America, other parts of Asia, and Eastern Europe. (Reproduced with permission from Ferlay J, Soerjomataram I, Ervik M, et al. *GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11* [*Internet*]. Lyon, France: International Agency for Research on Cancer, 2013. Available from: http://gco.iarc.fr/today/home, accessed on 8/03/2018.)

Availability of equipment and personnel for radiation therapy is a common limiting factor in LMIC. Less than 5% of global medical spending on cancer is in LMIC.[36] This is despite LMIC containing over 80% of the world's population[6] and almost 80% of the world's premature death, disability, and ill health from cancer.[37] Insufficient medical training programs make it difficult to address the lack of key personnel for radiation oncology.[38–42] International Atomic Energy Agency (IAEA) data suggest that LMIC only have about a third of the world's 13,136 megavoltage radiation therapy units despite an estimated need for more than double the current number.[43,44] There are currently at least 36 countries with no known machines, mostly in Africa.[44]

The greatest limitations in machine supply are strongly associated with low national economic status (Fig. 33.3).[31] Given the expected rise in cancer incidence in LMIC, these large mismatches between need and availability will only increase if current machine supply is not improved. In addition to machine availability, one must also consider the need for other physical resources. These include clinical space, bunkers, other equipment (brachytherapy, simulation, immobilization, treatment planning, beam modification, dosimetry, quality assurance), a reliable power supply for linear accelerators, and the availability of parts (and technical support) for machine maintenance and repair.[45]

The state of radiation therapy resources varies between LMIC and regions.[39,42,46,47] Some selected examples are provided for illustration. In 1999, Levin et al.[47] documented the availability and distribution of radiation therapy equipment in Africa. Only 22 of 56 countries in Africa were confidently known to have megavoltage radiation therapy facilities. In total, more than 400 million Africans had effectively no access to radiation therapy. Although machine supply has since increased, there are still dramatic shortfalls in machine supply in Sub-Saharan Africa.[43,44]

In the Asia and Pacific Region, Tatsuzaki and Levin[39] found an 82-fold variation in the number of megavoltage machines per million population for 1999. China's and India's machine supply has increased in recent years, though capacity is still well below what is needed to treat all patients (Table 33.1).[5,43,48] Workforce resources vary considerably between countries, and most countries have less than two radiation oncologists per 1,000 incident cancers annually.[5,40,43] More physicists are required if radiotherapy capacity is to expand in the Asia Pacific region.[40]

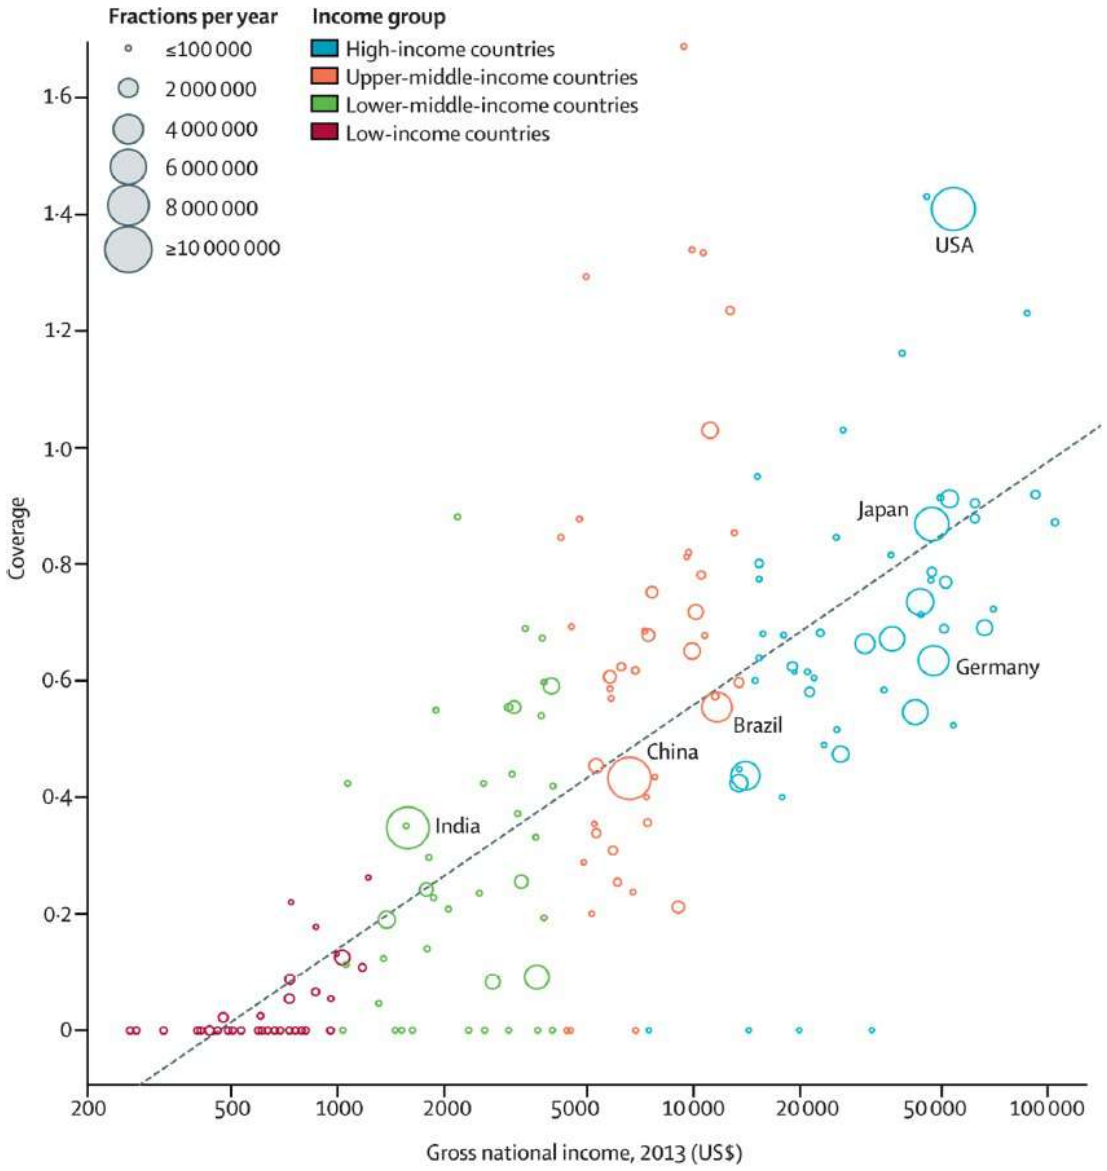

FIGURE 33.3. Radiotherapy coverage according to country gross national income per capita. Each *circle* represents a single country. The diameter corresponds to the actual annual number of fractions delivered by each country. Color corresponds to country income group. Coverage is reported assuming an 8-hour operating day.

n.a., not available.

[a]2009 data. As a simple estimate, countries with more than 1,000 new cancers annually per radiation machine most likely have a shortfall of radiation machines. 2010 gross national income per capita information provided by the World Bank Group (Atlas method) (http://data.worldbank.org/about/country-classifications). 2010 population data from the World Population Prospects 2010 revision (http://esa.un.org/unpd/wpp/index.htm). Projected cancer incidence in 2010 from GLOBOCAN 2008 (http://globocan.iarc.fr/). Reported number of megavoltage radiation machines from Directory of Radiotherapy Centers (DIRAC) August 2011 (http://www-naweb.iaea.org/nahu/dirac/default.shtm).

In the era of multidisciplinary cancer therapy, for instance, for head and neck squamous cell carcinoma, availability of other elements of diagnosis and therapy such as surgical oncology, medical oncology, oncology nursing, pathology,

radiology, rehabilitation, supportive care, and palliative care are all important to effective cancer management.[49] Without adequate pathology and radiology, it is not possible to effectively diagnose cancer and distinguish curative from palliative cases. The need for surgical capacity is especially noted, given its central role in curative treatment of the most common cancers globally, especially in their early stages. The Lancet Oncology Commission on Global Cancer Surgery reported that despite over 80% of cancer cases needing surgery globally, less than 25% of cancer patients get safe, affordable, or timely surgery.[50] Access to palliative care, including pain control for moderate to severe pain, is also a major issue. The World Health Organization (WHO) estimates 5 billion people live in countries with limited or no access to narcotic analgesics and other controlled substances, with an estimated 5.5 million patients with terminal cancer dying each year without adequate treatment.[51]

Spatial accessibility refers to the geographic accessibility of medical treatments. Available information suggests spatial accessibility is a major issue in LMIC.[43,52] With radiation therapy centers often in large cities, rural populations may face substantial financial challenges when traveling into cities for the duration of radiation treatment.

Acceptability of available options can impact an individual's willingness to take advantage of services and adhere to recommended therapies. For example, a small study from Cameroon found beliefs, fears, cultural factors, and awareness were among explanations for delay in seeking medical attention for cancer.[53] Values surrounding effects of pelvic radiation treatment on fertility, loss of hair with some chemotherapy, and anatomic changes associated with surgery such as mastectomy are some potential factors in need of further description and quantification in LMIC. Culturally appropriate cancer control plans sensitive to a region's social and political concerns are needed, including initiatives to overcome stigma and improve awareness.[54]

Affordability of radiation therapy and other forms of cancer therapy are a major concern in LMIC.[55] Households often have limited or no health insurance coverage, especially in low-income and lower-middle-income countries and more often among the poor in LMIC.[56,57] This is notable as cancer-related publicly funded health care may be inadequate or nonexistent. The cost of travel to the nearest cancer center can itself be another major financial obstacle, and costs of staying for the length of radiation treatment in another location can mean lost income and more cost to the patient and family.[55] A family may lose additional income because of caregiver absence from work.[55,58]

Awareness of the basic cancer principles and the value of cancer screening and early detection may limit timely access to cancer services for the public in LMIC. A large Union for International Cancer Control (UICC) survey of multiple LMIC found substantial lack of awareness of common preventable causes of cancer and found that a quarter or more of respondents in Asia and Africa did not think cancer could be cured.[59] Limited awareness of principles of cancer diagnosis and appropriate referral among nonspecialist health care workers may be further limiting factors for access to cancer treatment. Health care worker training in oncologic principles may be extremely basic or insufficient in some cases.[60]

QUALITY OF RADIATION ONCOLOGY IN LOW- AND MIDDLE-INCOME COUNTRIES

Key dimensions of quality are described by the Institute of Medicine as safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity.[61] Quality can be assessed through consideration of a health system's structure, process, and outcomes.[62] Elements of structure are physical resources, human resources, and organizational structure. Limitations in physical and human resources in LMIC have already been described. The access issues that relate to late presentation and failure to receive indicated treatment arguably have the greatest impact on outcomes and quality of radiation therapy in LMIC. Quality may be further degraded by the inequitable access of the few available resources between country and city and rich and poor.

The organizational structure of health care in LMIC has historically revolved around communicable disease, nutritional deficiencies, and child and maternal health. The additional burden of noncommunicable disease in LMIC, commonly cancer, cardiovascular disease, chronic lung disease, and mental illness, impose a major strain on current resources and health care models. Other issues may include political or social instability, conflict, corruption, and fragmented service provision. Challenges to the structure of cancer control in limited-resource settings may also include insufficient priority of cancer control among some governments and donor agencies with many competing priorities. Cancer infrastructure may be considered expensive. However, health investment is not a zero-sum game. There is a global need for sustainable local health care infrastructure relevant to all conditions, and focusing on cancer can help catalyze its development. Moreover, though prevention must be part of this, it is

emphasized that targets set by WHO for reducing mortality from NCDs by 2025 will not be met by prevention alone.[63] Effective cancer control requires prevention, timely and accurate diagnosis, and access to treatment. The immediate need for cancer care once a diagnosis is made, and that cancer is a problem in upper-income countries altogether makes it a good focal point for investment in LMIC.

The process of health care refers to what occurs while care is provided. For radiation oncology, this includes technical elements of quality assurance, treatment prescription, treatment planning, and treatment delivery. It also includes the integration of multidisciplinary services needed alongside radiation oncology for effective cancer management. A major process issue in some countries is system-related delay in diagnosis.[64,65] This contributes to high rates of advanced disease at presentation. System-related diagnostic delay can relate to weak or nonexistent referral systems or limited resources for diagnosis. It is compounded by patient-related delay in seeking medical attention because of previously described access issues.[66] The additional impact on delay because of waiting times for radiation following radiation oncology consultation may be substantial.[67]

The technical process of radiotherapy is a vital element of quality. For this reason, the IAEA and WHO have maintained a postal dose audit program using thermoluminescent devices (TLDs). A report focusing on measurements from LMIC found acceptable results, with most machines calibrated within the ±5% dose acceptance limit. Sixteen percent of machines registered measurements outside this range in the first round of testing, with 93% measuring dose within 5% of the standard after the second round.[68] Notably, a dosimetric audit in Latin America and the Caribbean suggested an association between on-duty medical physics support and acceptable TLD results.[69] This emphasizes the importance of adequate staffing to a radiation department’s quality assurance process.

Current reports are too limited to comment on the quality of general patterns of the radiation oncology clinical process in LMIC. There are most certainly specific opportunities for gains. Taking advantage of hypofractionation to increase throughput where there is supportive evidence has not always occurred, as one survey on patterns of palliative radiation for bone metastasis in Africa suggests.[70] Implementation of multidisciplinary decision-making among oncologists in LMIC is important but not always present.[71,72] Treatment refusal or nonadherence by patients can be a major issue in some cases and is an important area for quality improvement where it exists.[52,58,73] Audits of the

clinical decision-making and the treatment-planning process may provide a useful means of ensuring patient safety, improving processes, and creating opportunities for continuing education.[74,75] This is particularly important with the introduction of technology at new locations. For example, initial experience with this approach in a new radiation therapy center in an Asian developing country found suboptimal management in 52% of cases.[74]

Adverse event rates in LMIC treating with radiation are largely unknown. A report examining the risk profile of radiation therapy for the WHO could not identify any detailed reports of adverse events from Africa or Asia.[76] It is important to highlight the need for adverse event recording and reporting for the purpose of patient safety and quality improvement for all countries utilizing radiation therapy.

Finally, quality of radiation oncology in LMIC relates to outcomes. Of all cancer outcomes, there is the most information on survival. Generally, overall survival for cancer patients is lower, and sometimes dramatically so, for populations in LMIC. In a large multinational series from the International Agency for Research on Cancer (IARC), 5-year age-standardized relative survival for cervix cancer was 79% in Seoul, South Korea, but 46% in Mumbai, India; 22% in The Gambia; and only 13% in Kampala, Uganda.[77] Similarly, for breast cancer, survival rates ranged from 90% in Hong Kong SAR to 13% in The Gambia. When absolute survival was stratified by extent of disease, in many cases, treatment outcomes were still inferior in regions with less developed health services compared to regions with more developed services (e.g., local and regional extent breast cancer and larynx cancer). This may reflect access and quality issues in diagnosis, treatment, and follow-up and/or limitations of the available data.

ECONOMICS OF RADIATION THERAPY IN LOW- AND MIDDLE-INCOME COUNTRIES

In 2013, The Global Task Force on Radiotherapy for Cancer Control (GTFRCC) was commissioned by the Union for International Cancer Control to determine the investment needed to achieve equitable access to radiotherapy in LMIC by 2035.[31] This was a broad collaborative effort, involving radiation oncologists, physicists, industry, economists, and global health experts. GTFRCC published their findings as a Lancet Oncology Commission, as part of the Lancet Cancer Campaign. Dramatic shortfalls in radiotherapy coverage were evident (Fig.

33.3). The cost of scaling up radiotherapy services 2015 to 2035 was estimated to be US$26.6 billion in low-income countries, $62.6 billion in lower-middle-income countries, and $94.8 billion in upper-middle-income countries. By comparison, 1 year of immunotherapy (budgeted at $295,000 per patient), for the current burden of metastatic cancer in the United States, would cost an estimated $174 billion.[78]

What could be gained by investment in radiotherapy for LMIC? The GTFRCC estimated that scaling up radiotherapy from observed levels in 2015 to 2035 could save 26.9 million life-years in LMIC over the lifetime of patients receiving treatment. Moreover, the estimated net economic benefit derived from investment in radiotherapy 2015 to 2035 was found to be substantial. These estimates utilized a full-income method, which is rooted in societal or individual willingness to pay to avoid a shortened life expectancy. Investment in radiotherapy could produce a net benefit of $265.2 million in low-income countries, $38·5 billion in lower-middle-income countries, and $239·3 billion in upper-middle-income countries.

Undoubtedly, applications of various radiation therapy techniques and modern equipment will yield opportunities to maximize the cost–benefit ratio of radiation treatment in LMIC. The GTFRCC found economic benefits from efficiency gains in radiotherapy delivery could be substantial. These efficiency gains included automation of treatment planning and quality assurance.[31] Hypofractionation yields opportunities to treat more patients with the same supply of equipment.[79] Hypofractionation for cervical cancer and lung cancer are examples of identified areas for research.[80–82] Investigation of brachytherapy or intraoperative radiation therapy (IORT) may provide means of delivering adjuvant treatments rapidly. High–dose-rate (HDR) brachytherapy markedly increases patient throughput (e.g., for cervical cancer) compared to low–dose-rate (LDR) brachytherapy per machine.[83] An IAEA study of accelerated radiation therapy for head and neck cancer in LMIC suggests an opportunity for increasing effectiveness of treatment without increasing departmental resources, though with increased, but tolerable, acute toxicity.[84] It should be emphasized that prevention and early detection are critical to reducing the number of people diagnosed with cancer and the number of advanced cancers requiring more complex, multimodality treatments.

TRANSLATING KNOWLEDGE INTO ACTION

Recognized priorities for action fall into six categories: (a) advocacy, (b) investment, (c) planning, (d) capacity building, (e) quality, and (f) innovation.[57,85–90] The varying resources, priorities, and disease burden seen in countries at different stages of development mean that there is no single solution that will apply in all cases. In low-income countries with extreme resource limitations, a strategy focusing on cost-effective prevention, raising awareness of cancer within the population, monitoring of process and outcomes, good palliative care, and focused early detection and treatment goals would be a reasonable starting point.[87]

Advocacy

An international coalition to support cancer control and cancer care in LMIC is emerging. The UICC plays an important role as an umbrella organization for advocacy, notably commissioning the GTFRCC, whose efforts have been described above. The GTFRCC called for action on five items: (a) population-based cancer control plans, (b) expansion of access to radiotherapy, (c) human resources for radiotherapy, (d) sustainable financing to expand access to radiotherapy, and (e) align radiotherapy access with universal health coverage.[31] We will elaborate on some of these items in review of the six priority categories for action covered in this section.

Other groups involved in advocacy range from international agencies (e.g., IAEA, WHO, IARC), to national organizations (e.g., US National Cancer Institute), to professional groups (e.g., American Society for Radiation Oncology [ASTRO], European Society for Radiotherapy and Oncology [ESTRO], American Society of Clinical Oncology [ASCO], International Organization for Medical Physics [IOMP]), to nongovernmental organizations (NGOs) (e.g., International Network for Cancer Treatment and Research [INCTR], Axios International, AfrOx, American Cancer Society), to academic institutions and hospitals (e.g., the Global Task Force on Expanded Access to Cancer Care and Control in Developing Countries [GTF.CCC] convened by Harvard, St. Jude Children's Research Hospital). Through the advocacy of the UICC and many other partners (e.g., NCD Alliance), the 2011 Political Declaration[91] of the United Nations High-Level Meeting on the Prevention and Control of Noncommunicable Diseases was an important acknowledgment by governments of the global problem of cancer and other noncommunicable diseases. It was also a substantial step toward specific and concerted action by the international community.

Investment

Substantial investment is required, though the potential return on investment is substantial. The GTFRCC has called for $46 billion of investment by 2025 to establish radiotherapy infrastructure and training in LMIC.[31] Particularly in middle-income countries, incorporation of cancer care into public health insurance for those living in poverty is an important goal to meet.[57,92] The GTFRCC set a target for 80% of LMIC to include radiotherapy services as part of their universal health coverage by 2020. Given the shortage of national funding for cancer care in poorer countries, international private and public donor support and advocacy on pricing will be notably important in improving access to cancer therapy.

Planning

Development of radiation therapy capacity cannot occur in isolation. Radiation therapy resources must be integrated into a broader context of multidisciplinary cancer control and into a functional health system capable of tackling the double burden of communicable and noncommunicable diseases afflicting LMIC.[93] For this reason, the GTFRCC called for population-based cancer control plans, with a target of 80% of countries with cancer plans that include radiotherapy by 2020. A national cancer control plan and collection of cancer registry and health data are central in organizing resources in an equitable and appropriate fashion.[94] Notably, the GTF. CCC has published an important resource for planning, advocacy, and priority setting entitled *Closing the Cancer Divide: A Blueprint to Expand Access in Low and Middle Income Countries*.[95]

Prevention (e.g., tobacco control, hepatitis B and HPV vaccination) and early detection are crucial in reducing the burden of advanced cancers in LMIC. When early detection and prevention are combined with timely access to effective cancer therapy, there is great potential for dramatically reducing deaths from cancer in LMIC as well as minimizing national costs of cancer therapy.[57]

The IAEA plays a prominent role in quality assurance, safety standards, and dose calibration of radiation therapy equipment internationally. It has also been involved in numerous technical cooperation projects and radiation therapy clinical trials in LMIC. In 2004, the IAEA launched the Program of Action for Cancer Treatment (PACT) to widen the scope of its work in radiation therapy planning and capacity building. Its wide-ranging plan started with the development of sustainable demonstration radiation treatment sites in six countries throughout the developing world (Albania, Nicaragua, Sri Lanka,

Tanzania, Vietnam, and Yemen).

At a global level, breast cancer guidelines stratified by availability of resources have been developed through the Breast Health Global Initiative.[96] This is a useful paradigm for developing resource-appropriate and stepwise, scalable goals and guidelines for cancer care that is being adopted for other cancers.[97] A related approach has been used by the IAEA to describe additional resource requirements, benefits, and risks for specific approaches in lung cancer treatment, including curative and palliative radiation.[98]

Developing innovative means of organizing and funding cancer services is needed. The IAEA's PACT program offers opportunities to identify successful models of service delivery and planning. A model of radiotherapy service provision utilizing geographically dispersed telemedicine-linked sites with varying levels of capacity has also been proposed by an Indian group to maximize available resources.[99] Another concept that is being explored is utilizing community health workers and primary care to expand cancer-related service provision. Proposed activities are cancer prevention, early detection, some treatment (e.g., systemic therapy), palliation, and follow-up.[57]

Capacity Building

The importance of improving human resources for radiation oncology and oncology in general cannot be overstated given the global workforce shortage of trained health care professionals. Some initial efforts have been made in developing curricula and educational approaches specific to the discipline of radiation medicine.[100–102] The IAEA has been notably involved in these efforts. The issue of loss of trained staff from developing to developed countries is especially important to consider in developing educational programs. Urban regions in LMIC may have high-level expertise that can be utilized in developing national or regional training programs. A complementary approach is online training. This is the approach of the Virtual University for Cancer Control and Regional Training Network (VUCCnet) initiative in Africa. A growing number of cancer centers, regional groups, and specific nations have been involved in twinning projects building capacity for cancer therapy in limited-resource countries. These initiatives have been particularly strong in pediatric oncology, with demonstrated success.[103,104] They provide an appealing means for broad participation in improving cancer control in LMIC.

Surge in career interest and opportunities. In the last 5 or so years, particularly following the United Nations declaration on the importance of

addressing noncommunicable diseases in 2011,[91] there has been a surge in interest in radiation and clinical oncology in making global health an integral part of a career. With support from visionary senior leadership, much of the initiative has been undertaken by trainees and early career leaders in defining a career path[105,106] and for establishing resources for idea sharing and opportunities for clinical rotations.[107] The International Cancer Expert Corps (ICEC) has established an Early Career Leaders Working Group and Fund[108] to provide support for small grants for global health projects. The hurdle that must be overcome is the issue of how one supports a career in global health because it is not a revenue-generating activity. This can be surmounted with both the appreciation of the need for service as an essential component of a career in health care and also the tangible and intangible benefits to institutions and individuals that come from establishing a means of sustainable service to society. New creative paradigms have the potential to bring in interest and investment in global health from a wide range of economic sectors[109] including science, education, economics, and industry. The data from the GTFRCC[31] indicate that treating cancer provides economic as well as health benefits and is, indeed, a wise investment.

What is obvious is that visionary leaders interested in (a) innovation in career path development, (b) enhancing the capability of existing technology and creating new robust technology and connectivity, and (c) expanding the scope of what is a *bona fide* medical career are needed to address the gap in global cancer care in both capacity and capability. This will represent a paradigm shift to address an issue of health care inequality that is morally unacceptable, requiring immediate attention with effective action and a sustainable commitment to a problem that will take decades to solve.

Indigenous populations in Upper-Income Countries (UICs). Expanding the number of stakeholders in global health will benefit those in need and also may enhance the interest and investment from resource-rich countries (UICs) including a recognition that they have similar problems within their own country. Optimism for investment in global health by radiation oncology over the last few years is the result of remarkable interest by trainees and early career leaders and understanding that this is not simply a problem in the developing world. The level of interest is demonstrated by two very recent reviews, in Clinical Oncology[110] and Seminars in Radiation Oncology.[111]

Indigenous populations in UICs, particularly people living in geographically isolated or remote regions, have economic, social and societal issues that are

often quite similar to the underserved in LMIC.[112] As in LMIC, there is less screening, less care and presentation with more advanced stages of disease. Although there is substantial overlap in terms of access and the need for care between indigenous and indigent populations and in the social determinants of health, a distinction is being made between indigent populations in urban centers who are near medical facilities but with limited access often because of other reasons, compared to geographically isolated indigenous people who may be many miles away and for whom physical access to facilities is limited by distance, expense and the need to be at home to care for families. Success is possible when investment is made, as demonstrated in the Walking Forward Program[113] and the Native Navigators and the Cancer Continuum (NNACC).[114] Indeed in the National Cancer Institute's Cancer Disparities Research Partnership Program, the program with the Lakota Sioux demonstrated that clinical and translational research can be accomplished.[115,116] The Union for International Cancer Control has included an indigenous populations session in its last two World Congress meetings, with participation from Australia, New Zealand, Canada and the United States.

What is critical to remember is that the health care disparities within geographically remote indigenous populations are also suffered by nonindigenous people who are neighbors of the tribes so that they, too, benefit from investment in cancer care. Addressing this common need serves to build a link among the local communities. For those seeking investment from UICs for global health, there is an advantage in including indigenous populations among the needs for LMIC. This approach serves to make the investment more immediate to those in UICs and helps address the frequently raised question as to why invest abroad when problems exist at home.

Quality

Embedded within the themes of investment, planning, and capacity building is the implicit theme of structure-related quality improvement. Process-related initiatives in quality are another very important part of ensuring optimal outcomes. These are often referred to indirectly (e.g., safety, effectiveness, patient-centeredness, timeliness, efficiency, equity).[61] Quality improvement relating to process and organizational structure is important as it holds the potential for improving some outcomes more rapidly than other drivers of health, such as economic growth.[117] One important element of quality for radiation oncology in LMIC is safety, given the potential for unsafe treatment to negate

any benefit of available treatment.[118] Safety includes the clinical process and the various elements of technical quality assurance, maintenance, worker safety, public safety, and source security.[119,120] Safety requires investment in appropriate dosimetry equipment, sufficiently trained human resources, and time for quality assurance activities.[120] Internal and external audits, peer review, regulation, accreditation, certification, checklists, adverse event reporting, common protocols, quality improvement, and independent checking are examples of interventions ensuring safety and quality assurance in radiation oncology.[76,121,122]

Innovation

There are many fundamental questions that remain unanswered for cancer in LMIC. It cannot be assumed that approaches to treating cancer from developed settings will produce the same results when applied in other countries. Considerations include potential differences in disease bulk, malnutrition, rates of chronic infections such as HIV/tuberculosis/hepatitis B, and genetic polymorphisms affecting disease biology and treatment response.[123–127] There are many unknowns in cancer epidemiology and basic science, and, as mentioned, more health services research is emphatically needed into areas such as access, quality, and economics.[94]

International research partnerships are essential in the interconnected and interdependent world we live in.[128] Many LMIC have quite advanced resources to sustain research activities; for instance, a number of clinical trials for cervical cancer radiotherapy have occurred in India (e.g., HDR vs. LDR brachytherapy, radiation vs. chemoradiation).[129,130] India is also home of the Advanced Center for Treatment, Research and Education in Cancer (ACTREC), part of the Tata Memorial Center. Regional research collaborations are developing, for example, the Forum for Nuclear Cooperation in Asia (FNCA). In addition, of note, a number of research/teaching twinning partnerships between UICs and LMIC have been formed.[103,104,131] Supporting research on cancer by investigators in the developing world is important as it can build local research capacity and provide a means of adapting scientific knowledge to local circumstances to meet national health priorities.[128] The US National Cancer Institute has also been involved with numerous international collaborations. Protocol-driven clinical research can also strengthen local treatment capacity. The INCTR has been involved in designing clinical trials relevant to developing world situations, as has the IAEA.

What should be implicit in capacity building is the capability of the workforce and also of the technology to provide state-of-the-art care. It is debated about what is the best technology for the developing world between the relative simplicity of cobalt-60 and the more sophisticated ability of linear accelerators, which are dependent on effective physical infrastructure. Logically, a range of technologies is needed[132] including brachytherapy. However, to fill the enormous gap in global cancer care, it is imperative to look forward toward longer-term solutions because although incremental steps and small projects are useful, innovative systems solutions are necessary to reach the necessary capacity and capability. This includes increasing the opportunities for a career in global health and recruiting, training, and retaining people willing to serve within challenging environments. Detailed discussions for issues raised in the sections in this chapter on capacity and capability building are in recent radiation oncology reviews mentioned above, in Clinical Oncology[110] and Seminars in Radiation Oncology.[111]

New paradigms in global health. An example of novel partnerships emerged from the White House's Interagency Working Group on Alternatives to High-Activity Radioactive Sources[133] that brought together experts interested in reducing the availability of potentially dangerous radiation sources (including medical radionuclides of cobalt-60 and cesium-137), along with radiation oncologists and medical physicists and also groups interested in nuclear nonproliferation. Pomper et al. developed a new concept "Treatment, Not Terror" that highlights the importance in providing safe alternatives to radionuclides which for cobalt-60 requires expertise for delivering linear accelerator treatment.[134] The relatively lower initial cost of cobalt-60 is offset by a very high cost of disposal of the source at the end of its useful life, a number that is often not included in the purchase price. Certainly, treatment with both cobalt and linear accelerators is important for cancer care; however, as the huge shortage of capacity is addressed, it is worthwhile to look toward the future with improvements possible in technology, telecommunications, economic models, and efficient use of expert personnel. Recognizing the need for improved infrastructure to support linear accelerators, a workshop was recently conducted by the ICEC in Geneva at CERN[135] to address this complex topic. This included people with expertise in accelerator design, technology modularization, telemedicine, industrial design, and education/training. Task groups will address unique solutions for training, education, the use of current technology, and the potential for innovative technology. Feain et al. have highlighted new

approaches to radiation technology for LMIC including software, information management, and technologic solutions.[136]

CONCLUSION

Cancer in the developing world is an urgent problem, reaching critical proportions. Almost 60% of all cancer cases occur in the developing world. Vast numbers of people in LMIC have either limited access or no access to radiation therapy. At a time when new gains in oncology outcomes in the developed world are often incremental, oncologists have the chance to help make some of the largest survival gains in history in the developing world. In addition, the potential for health care gains through cancer prevention and early detection, and for the relief of suffering through palliative care is enormous. Global access to quality cancer care is a moral imperative. The challenge will now be to deliver this in a thoughtful and contextually appropriate way.

CHAPTER 34

Chemical Modifiers of Radiation Response

Yvonne Marie Mowery, David S. Yoo, and David M. Brizel

INTRODUCTION

Chemical agents have been administered in conjunction with radiation therapy (RT) for both the enhancement of antitumor therapeutic efficacy and the amelioration of treatment-induced toxicity. Two concepts are fundamental to understanding the rationale for chemical modification of radiation response and to interpreting the studies that have addressed this issue. The first is the therapeutic ratio (TR), which is defined as the TCP/NTCP where TCP is the tumor control probability and NTCP is the normal tissue complication probability. Both of these parameters have sigmoid dose–response curves (Fig. 34.1). The horizontal separation between these two curves for any given treatment will often determine its overall utility. As the separation between these curves increases, the likelihood becomes greater that the treatment will be effective without causing an unacceptable level of morbidity. Conversely, when the two curves are closer together, the treatment may be less effective while causing an unacceptable level of morbidity.

The second concept is the efficacy/toxicity profile of the putative chemical modifier, which can directly affect the TR. A radiosensitizing agent that exacerbates toxicity to the same extent that it improves efficacy (shifting both NTCP and TCP curves to the left) may leave the TR unchanged or worsened and not be clinically practical. Conversely, a radioprotective agent that also reduces RT efficacy against the tumor (shifting both NTCP and TCP curves to the right) also may not affect or even reduce the TR. The intrinsic toxicity of a radioprotector must also be considered when reduction of NTCP is the primary goal of a given chemical modification strategy. A compound that causes significant side effects of its own may render it unsuitable even if it can reduce

the treatment-induced toxicity in question. This chapter will explore chemical radiosensitization and radioprotective strategies. The primary focus will be on treatments that have been clinically tested in head and neck cancer in order to amplify these concepts.

CHEMICAL RADIOSENSITIZATION

The Oxygen Effect

Tumor cell killing is produced by direct ionizations within critical cellular targets as well as by the indirect effect of energy deposited in other cellular molecules including water. Ionizing radiation generates free radicals, which can lead to cellular death via the creation of single-strand and double-strand breaks in DNA. This damage can be fixed or repaired by the chemical processes of oxidation and reduction, respectively.[1] The addition of molecular oxygen to target free radicals produces altered chemical structures that are potentially lethal. Tumor hypoxia reduces radiosensitivity *in vitro* and *in vivo*.[2,3] Well-oxygenated cells (partial pressure of oxygen or P_{O_2} > 10 mm Hg) are approximately 2.5 times more sensitive to a given dose of ionizing radiation than their hypoxic counterparts.

Clinical data clearly demonstrate the existence of tumor hypoxia in head and neck cancer[4,5] and extremely strong correlations between hypoxia and both infield treatment failure and overall survival (Figs. 34.2 and 34.3).[6,7] This effect is independent of presenting stage of disease.[7] Tumor hypoxia has also been correlated with local and distant recurrence in carcinoma of the cervix treated with surgery[8,9] or RT[10] and with distant failure in soft tissue sarcomas treated with surgery and adjuvant RT.[11]

Augmentation of Tumor Oxygenation

Therapeutic attempts to overcome the deleterious effect of tumor hypoxia have followed three general lines of investigation: increased delivery of oxygen to tumor, preferential sensitization of hypoxic cells with oxygen-mimetic agents, or cytotoxic agents that selectively target hypoxic tumor cells. Hemoglobin concentration is the major determinant of the oxygen delivery capability of blood to tissue. Hemoglobin oxygen saturation exceeds 90% when the arterial P_{O_2} is >70 mm Hg. Still, oxygen is relatively insoluble in plasma under normobaric conditions. Under hyperbaric conditions, considerable quantities of oxygen can be dissolved into plasma and thus be potentially available for

delivery to hypoxic tissues.

Clinical trials of hyperbaric oxygen (HBO) and RT were conducted from the 1950s to the 1970s. Trials conducted in patients with cancers of the central nervous system,[12] lung,[13] bladder,[14] and skin[15] showed no benefit from the addition of HBO. Randomized trials conducted in carcinoma of the cervix[16] and head and neck[17,18] did, however, show improvements in locoregional control and overall survival. The cumbersome logistics associated with HBO delivery in conjunction with RT necessitated the utilization of nonconventional hypofractionated treatment regimens. This reality has prevented HBO from being incorporated into routine clinical use.

Carbogen (95% oxygen [O_2]/5% carbon dioxide [CO_2]) breathing, with or without concurrent nicotinamide administration, has also been utilized in attempts to improve tumor oxygenation and enhance RT response. The rationale for CO_2 addition in the gas breathing mixture is the generation of a mild acidosis that shifts the oxyhemoglobin association curve to the right, facilitating more unloading of oxygen into the most hypoxic tissues. The rationale for adding nicotinamide, a vitamin B derivative, is based on preclinical studies showing enhancement of tumor blood flow.[19,20] Polarographic electrode assessments in cervix and head and neck cancer have demonstrated that carbogen breathing and nicotinamide administration improve tumor oxygenation in some patients.[21–23]

A randomized trial of hyperfractionated RT with or without carbogen was conducted at the University of Florida from 1996 to 2002.[24] The study included patients with T2 to T4 squamous cell carcinoma of the oropharynx, larynx, and hypopharynx and was designed to detect a 20% improvement in a 2-year local control in the carbogen arm relative to the RT alone arm, with a 15% improvement in a 4-year cause-specific survival. Virtually all enrolled patients in both arms completed their prescribed courses of treatment. The addition of carbogen to RT did not appear to improve any of the planned end points of this trial. Most important, however, was the fact that while the design of this trial called for the enrollment of 675 patients, only 101 were entered over a 5-year period. The trial was therefore significantly underpowered in terms of its ability to detect the desired treatment effects. The inability to accrue patients also called into question the overall viability of strategies utilizing carbogen.

The use of accelerated RT with carbogen inhalation and nicotinamide (ARCON) was tested in a phase II trial of 215 head and neck cancer patients.[25] Ninety-seven percent had stage III or IV disease, and the primary tumor site was laryngeal in 46%, hypopharyngeal in 23%, and oropharyngeal in 23%. Full

compliance with carbogen breathing during RT was obtained in 88% of patients. Nicotinamide was administered 1 to 1.5 hours prior to RT at 60 to 80 mg/kg. Nicotinamide-induced nausea and vomiting necessitated discontinuation of the drug in 10% of patients receiving the lower dose and 31% of patients receiving the higher dose. Five-year locoregional control rates were 48% for hypopharynx primaries, 77% for larynx, and 72% for oropharynx primaries.[26] A subsequent phase III trial randomized 345 patients with cT2–T4 laryngeal squamous cell carcinoma to ARCON versus accelerated RT.[27] Local tumor control did not differ between treatment arms, but 5-year regional control was significantly higher with ARCON compared to accelerated RT alone (93% vs. 86%, respectively; $P = .04$). A subgroup analysis indicated that this beneficial effect of ARCON is limited to patients with tumors having a high hypoxic fraction.

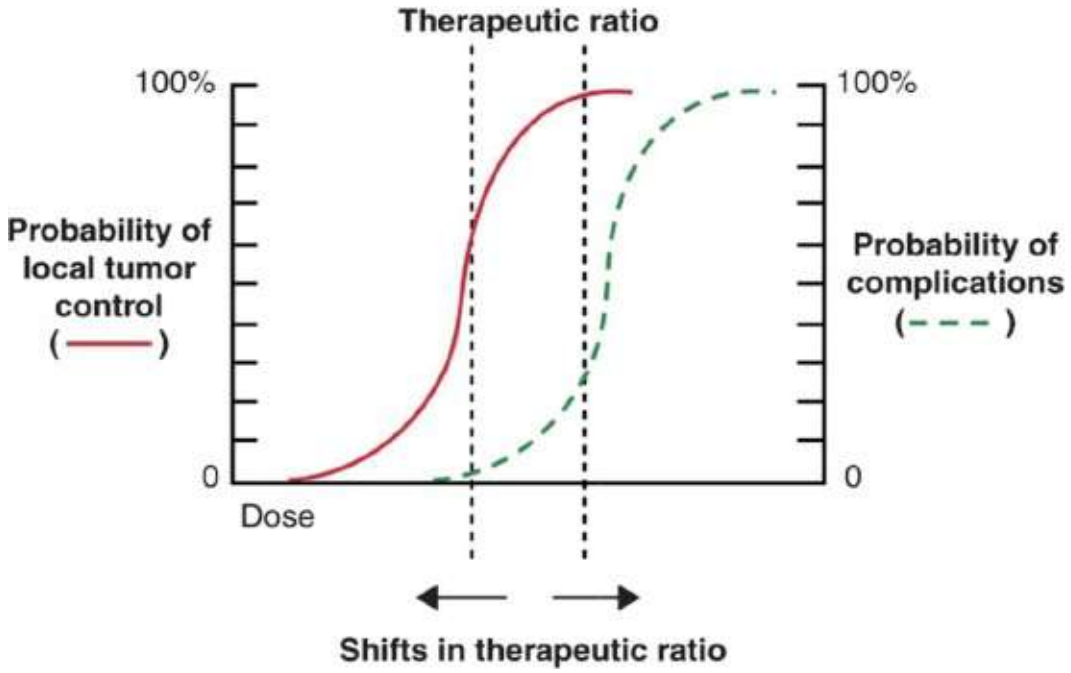

FIGURE 34.1. A graphic representation of the therapeutic index (TI). The tumor control probability (TCP) is to the left of the normal tissue complication probability (NTCP), and both are displayed as sigmoid dose–response curves. Larger separations are indicative of higher TIs. Ideally, normal tissue protection strategies would move the NTCP curve to the right without compromising TCP (moving the TCP curve to the right). Ideal therapeutic intensification strategies would move the TCP curve to the left without worsening NTCP (moving the NTCP curve to the left).

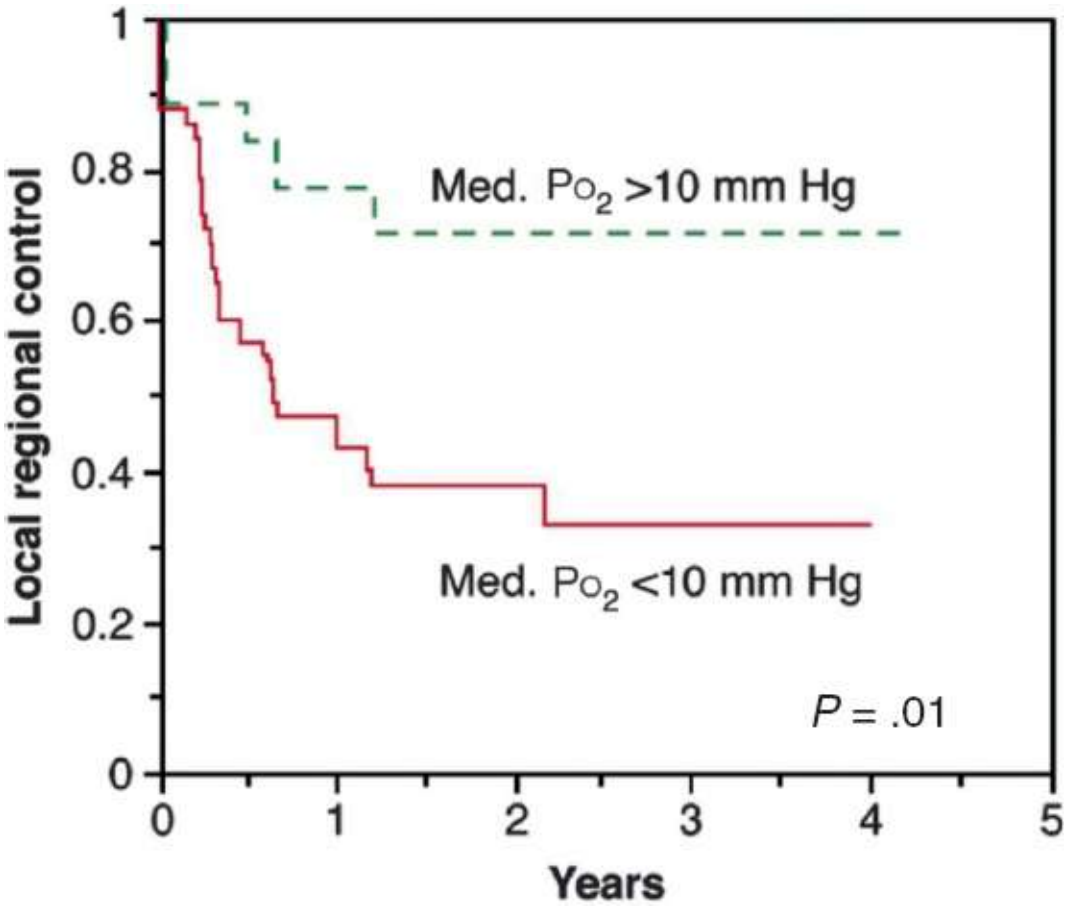

FIGURE 34.2. The correlation between pretreatment head and neck tumor oxygenation and locoregional disease control after radiation therapy with or without concurrent chemotherapy. *Dashed line* represents tumor median partial pressure of oxygen (P_{O_2}) > 10 mm Hg. *Solid line* represents tumor median P_{O_2} < 10 mm Hg.

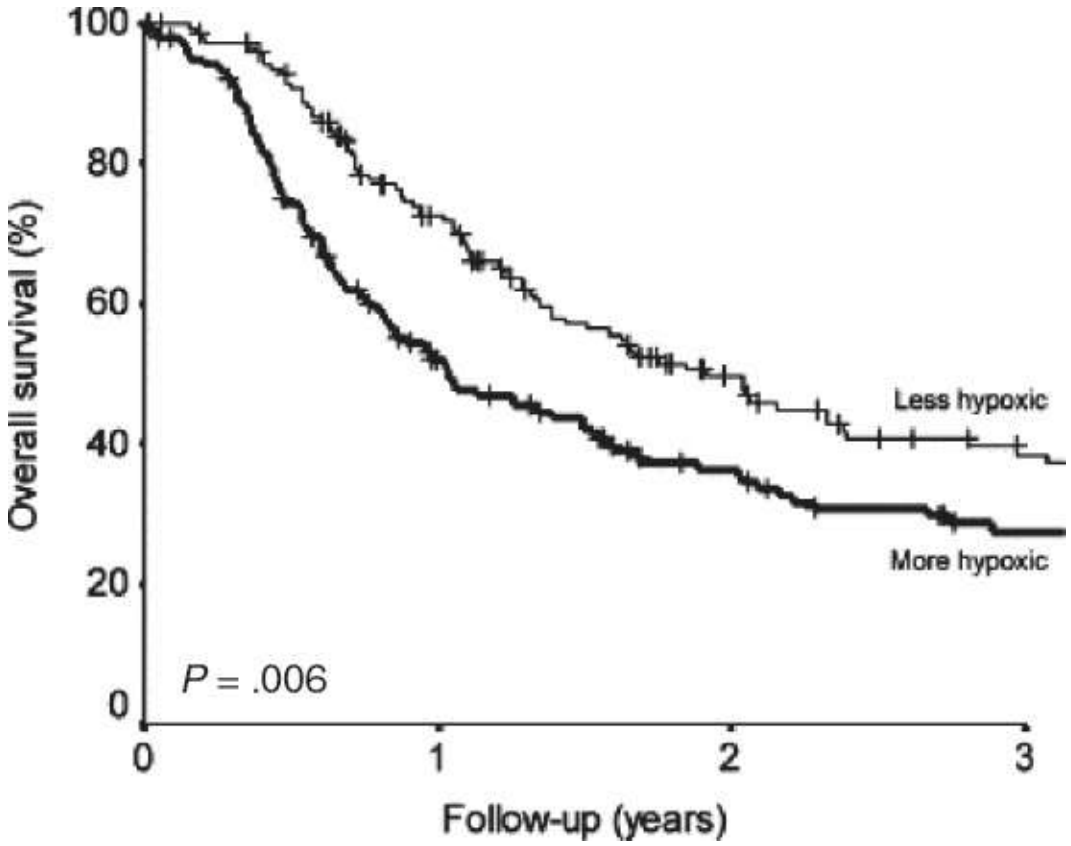

FIGURE 34.3. The correlation between actuarial overall survival for head and neck cancer patients with tumor hypoxia. Patients (*n* = 397) received definitive radiation therapy, with or without chemotherapy and/or surgical resection. *Thin line* represents patients with tumor fraction of PO_2 values ≤ 2.5 mm Hg ($HP_{2.5}$) below 20%. *Bold line* represents patients with $HP_{2.5}$ ≥ 20%.

Allosteric modifiers of hemoglobin structure have been identified that can shift the oxyhemoglobin dissociation curve to the right and increase O_2 delivery to hypoxic tissues.[28] One such compound, RSR13, (efaproxiral) has been tested in animal models and shown to improve tumor oxygenation[29] and enhance the effectiveness of RT.[30] A phase III open-label trial of whole-brain RT and oxygen breathing with or without daily infusion of efaproxiral was conducted in 538 patients with brain metastases.[31] Fifty-four percent of the patients had metastatic non–small cell lung cancer, and 20% had metastatic breast cancer. Overall, no improvement in survival was detected. A planned subset analysis suggested significant improvement in median survival time in breast cancer patients with sufficient levels of efaproxiral in their erythrocytes.[32] However, the phase III ENRICH trial, which examined efaproxiral and supplemental oxygen with whole-brain RT (30 Gy in 10 fractions) in 368 breast cancer patients with brain metastases, showed no significant difference in overall survival.[33]

Anemia is a very powerful adverse prognostic factor in various malignancies, including carcinomas of the lung,[34] cervix,[35] and head and neck.[36–38] Polarographic electrode oxygen measurements in head and neck cancer have demonstrated that anemic patients are significantly more likely to have poorly oxygenated tumors than nonanemic patients, but significant tumor hypoxia has also been detected in patients who are not anemic.[6,39] Whether correction or prevention of anemia with blood transfusions or erythropoiesis-stimulating agents can improve treatment outcomes has been investigated in multiple studies.

The use of blood transfusions in cervical cancer patients gained traction after an initial publication from Princess Margaret Hospital showing an improvement in pelvic control and cure rates associated with correction of anemia.[40] However, subsequent publications from the same group showed no survival benefit to transfusion when the data were critically reexamined and analyzed on an intent-to-treat basis.[41] In head and neck cancer patients, studies suggest that blood transfusions may have a negative effect on survival.[42,43]

Correction of anemia via erythropoietin (EPO) administration was evaluated in a double-blind, placebo-controlled randomized trial in 351 head and neck patients treated with RT.[44] The primary end point was locoregional progression-free survival. Eighty-two percent of patients (n = 54) who received EPO maintained hemoglobin >14 g/dL (women) or 15 g/dL (men), whereas only 15% of the patients in the placebo arm attained this benchmark. The relative risk of locoregional progression, however, was 1.62 in the EPO arm compared to placebo (P = .0008), with a similar detriment seen for survival in those patients who received EPO (relative risk 1.39; P = .02). A systematic review pooling data from five randomized studies with a total of 1,397 patients showed significantly worse overall survival in head and neck cancer patients with the addition of EPO to RT (odds ratio 0.73; P = .005).[45] These poorer outcomes may have been the result of overcorrection of hemoglobin levels with increased thromboembolic events.[46] Tumor cells have also been found to express EPO receptors, with stimulation of downstream signaling pathways that may promote a more invasive phenotype.[47,48]

Sensitization of Hypoxic Cells

Electron-affinic compounds can oxidize radiation-induced free radical damage in the cell to produce increased kill.[49] The use of these agents would be particularly attractive in the hypoxic tumor microenvironment, where low oxygen

concentrations impair the effectiveness of RT. The 2-nitroimidazoles are one such class of compounds that are metabolized into their active form under hypoxic conditions. Misonidazole, the prototype 2-nitroimidazole, was tested in two randomized trials. The Danish Head and Neck Cancer Study 2 (DAHANCA-2) performed a double-blind randomized trial evaluating the effect of misonidazole given in two drug schedules with split-course irradiation in the treatment of carcinoma of the larynx and pharynx.[50] Patients were stratified according to tumor site (larynx vs. pharynx), nodal status, and institution. The total misonidazole dose was 11 g/m^2. The study assessed 626 patients. Overall, the misonidazole group did not have significantly better local tumor control than the placebo group. Serious peripheral neuropathy, the dose-limiting toxicity of all nitroimidazole compounds, occurred in 26% of misonidazole-treated patients. The European Organisation for Research and Treatment of Cancer (EORTC) conducted a randomized study of conventional fractionation RT versus modified fractionation RT (three fractions per day) with or without misonidazole in 523 advanced head and neck cancer patients. No differences were seen in treatment outcome.[51]

Etanidazole (SR2508) is an analog of misonidazole with lower lipid solubility and less neurotoxicity in phase II studies in head and neck cancer.[52] A Radiation Therapy Oncology Group (RTOG) phase III study with etanidazole in head and neck tumors included 521 patients who received conventionally fractionated irradiation with or without etanidazole 2 mg/m^2 delivered three times per week.[53] Of those on the etanidazole arm, 77% received at least 14 doses of the drug. No grade 3 or 4 central nervous system or peripheral neuropathy was observed. The 2-year actuarial local tumor control was 40% in each arm, and the survival was 41% and 43%, respectively, in the irradiation alone and the irradiation plus etanidazole arms. A similar study of 374 patients performed in Europe did not show any overall benefit to treatment with etanidazole but did demonstrate increased neurotoxicity in the patients who received the drug.[54]

Nimorazole is a 5-nitroimidazole of the same structural class as metronidazole.[55] Its dose-limiting toxicity is nausea and vomiting; however, the drug can be administered with each radiation treatment. DAHANCA conducted a phase III trial of nimorazole (1.2 g/m^2 vs. placebo) for squamous cell cancer of the supraglottic larynx and pharynx.[56] There was a statistically significant improvement in locoregional tumor control (49% vs. 33% at 5 years; $P = .002$) but not for survival, which is consistent with the DAHANCA misonidazole trial. The use of nimorazole has become the standard of care (SOC) in Denmark but

has not been adopted in other countries. An international multicenter phase II randomized trial of nimorazole with accelerated radiation therapy for stage I to IV head and neck squamous cell carcinoma (excluding nasopharynx and stage I to II larynx) failed to meet accrual goals, enrolling only 104 of a planned 600 patients.[57] Although premature closure resulted in this trial being underpowered, there was a trend toward reduced 18-month locoregional failure with nimorazole (33% vs. 51% in control group, $P = .1$). The difference in overall death (19%; 95% CI, −3% to 42%; $P = .1$) also favored nimorazole but did not meet statistical significance. NIMRAD (NCT01950689) is an ongoing randomized, placebo-controlled phase III trial in the United Kingdom assessing nimorazole with a 6-week course of intensity-modulated radiation therapy for locally advanced head and neck cancer patients not suitable for concurrent cetuximab or chemotherapy.[58] Initial results are anticipated in June 2020.

Pharmacologic Targeting of Hypoxic Cells

Mitomycin C (MMC) is an alkylating agent metabolized in regions of low oxygen concentration and preferentially cytotoxic to hypoxic cells. MMC plays an integral role in conjunction with RT and 5-FU (fluorouracil) in the definitive nonsurgical management of squamous cell carcinomas of the anus.[59] Yale University investigators examined the concurrent use of MMC in 195 head and neck cancer patients treated on two randomized trials.[60] Their treatment program consisted of 68 Gy with or without MMC on days 1 and 43 of RT. Locoregional recurrence-free survival was improved with the addition of MMC from 54% to 76% ($P = .003$). Overall survival improved from 42% to 48%, but this was not statistically significant. The majority of patients in these trials received adjuvant postoperative or preoperative irradiation. Only 74 (38%) received definitive primary RT, and the benefit from the addition of MMC in this subset is unclear.

A three-armed randomized trial conducted by the University of Vienna compared conventionally fractionated (CF) RT (2 Gy daily to 70 Gy) against variation of continuous hyperfractionated accelerated RT with or without MMC (V-CHART + MMC and V-CHART, respectively).[61] RT was given as an initial 2.5-Gy fraction followed by 1.65 Gy twice a day to a total dose of 55.3 Gy in 17 days. MMC was given as a 20-mg/m^2 bolus on day 5 of RT. Of the 239 patients enrolled, 85% had T3 or T4 primaries and 79% had nodal involvement. Three-year actuarial locoregional control was 48% for V-CHART plus MMC versus 32% for V-CHART and 31% for CF ($P = .05$ and .03, respectively). Survival including death from all causes was also improved to 41% in the V-CHART plus

MMC arm as compared with 31% for V-CHART and 24% for CF (P = .03). The incidence of confluent mucositis was 90% in both experimental arms as compared with 33% in the CF arm. The median time to complete resolution of mucositis was 6 to 7 weeks in all three arms. Grade 3 or 4 hematologic toxicity, primarily thrombocytopenia, developed in 18% of the V-CHART plus MMC patients.

Porfiromycin, a derivative of MMC, provides greater differential cytotoxicity between hypoxic and oxygenated cells *in vitro*.[62] The Yale investigators also conducted a phase III study that compared patients treated with conventionally fractionated radiation plus MMC versus radiation plus porfiromycin.[63] Hematologic and nonhematologic toxicities were equivalent in the two treatment arms. With a median follow-up >6 years, MMC was superior to porfiromycin with respect to 5-year local relapse-free survival (91.6% vs. 72.7%; P = .01), locoregional relapse-free survival (82% vs. 65.3%; P = .05), and disease-free survival (72.8% vs. 52.9%; P = .03). There were no significant differences between the two arms with respect to overall survival (49% vs. 54%) or distant metastasis-free rate (80% vs. 76%). Their data supported the continued use of MMC as an adjunct to radiation therapy in advanced head and neck cancer. However, this regimen is no longer used on a routine basis.

Tirapazamine (also known as SR-4233; WIN 59075; 3-amino-1,2,4-benzotriazine 1,4-dioxide) is a bioreductive agent preferentially cytotoxic to hypoxic cells *in vitro*. Twenty-five to 200 times more drug is required to produce the same level of cell killing in aerobic compared to anaerobic conditions.[64,65] Under hypoxic conditions, a free radical one-electron reduction product rapidly forms and is believed to be the toxic species, causing oxidative damage to pyrimidines and inducing DNA strand breaks.[66] Analysis of DNA and chromosomal breaks following hypoxic exposure to tirapazamine suggests that DNA double-strand breaks are the primary lesions involved in cell death.

This bioreductive agent differs from oxygen-mimetic sensitizers, such as the nitroimidazoles, in that it is itself cytotoxic to hypoxic tissues. Therefore, unlike the oxygen-mimetic sensitizers, tirapazamine-mediated therapeutic enhancement occurs whether the drug is given before or after irradiation.[67,68] In fractionated radiation therapy of murine tumors, tirapazamine is as effective as, if not superior to, etanidazole.[69] The efficacy of this radiation modifier depends on the number of “effective doses” that can be administered during a course of radiation therapy and the presence of hypoxic tumor cells.[70] Tirapazamine can also enhance the cytotoxicity of cisplatin.[71]

Rischin et al. investigated the use of concurrent tirapazamine, cisplatin, and RT in advanced head and neck cancer in a series of trials. A phase I trial established the dosing schedule for tirapazamine given with RT and cisplatin.[72] A randomized phase II study compared RT with cisplatin/tirapazamine versus RT with cisplatin/5-FU and suggested a benefit in the tirapazamine treatment arm (3-year locoregional failure-free survival 84% vs. 66%; P = .07).[73] Tumor hypoxia imaging was performed with 18-fluorodeoxyglucose-misonidazole positron emission tomography (PET) scanning in 45 of the patients on these studies.[74] Hypoxia was identified in primary or nodal sites in 71% of the patients. Eight of thirteen (62%) patients with hypoxic tumors who received cisplatin/5-FU experienced subsequent locoregional failure compared to only 1/19 (5%) patients with hypoxic tumors who received tirapazamine (hazard ratio [HR] = 15; P = .001). Only 1 of 10 patients with nonhypoxic tumors who received cisplatin/5-FU had a locoregional failure. These findings strongly suggested that the benefit of tirapazamine resulted from improved treatment efficacy against tumor hypoxia.

Two phase III trials were initiated to validate the use of tirapazamine in head and neck cancer. The HeadSTART study enrolled 861 patients and compared standard fractionation RT (70 Gy) with concurrent cisplatin/tirapazamine versus concurrent cisplatin alone.[75] The primary endpoint was overall survival, with 2-year rates of 65.7% in the cisplatin alone arm and 66.2% in the cisplatin/tirapazamine cohort. No differences were seen in failure-free survival, time to locoregional failure, or quality of life. Of note, the patients in this study were not selected based on the presence of tumor hypoxia. Moreover, 12% had major RT planning deficiencies, with those patients having significantly worse locoregional control and overall survival compared to those in protocol compliance.[76] A second trial with a planned enrollment of 550 patients was closed prior to completion of accrual because of an excess number of early deaths in the cisplatin/tirapazamine arm.[77]

Hyperthermia

Hyperthermia (HT) involves elevation of tissue temperature, typically to 40°C to 45°C, for a therapeutic effect.[78] Although HT monotherapy can result in some cells being killed, it has been more widely used for its radiosensitizing effect in tumors. Physiologic changes induced by HT include increased perfusion causing tissue reoxygenation and altered metabolism associated with reduced oxygen consumption. This improved oxygenation confers increased tumor radiation

sensitivity and is correlated with pathologic complete response in soft tissue sarcoma patients undergoing preoperative irradiation and HT.[79] In addition, cells are particularly sensitive to HT under conditions associated with radioresistance, including hypoxia, low pH, and presence in S phase of the cell cycle. Heat may also interfere with repair of radiation-induced DNA damage.[80,81] The thermal enhancement ratio (TER) quantifies the synergistic effect of HT and RT. TER is defined as the ratio of RT dose without HT to the isoeffective RT dose with HT: TER = RT dose without HT/RT dose for equivalent effect with HT. TER is >1 for most tumor types when HT is administered within 2 hours of RT (Fig. 34.4).[82]

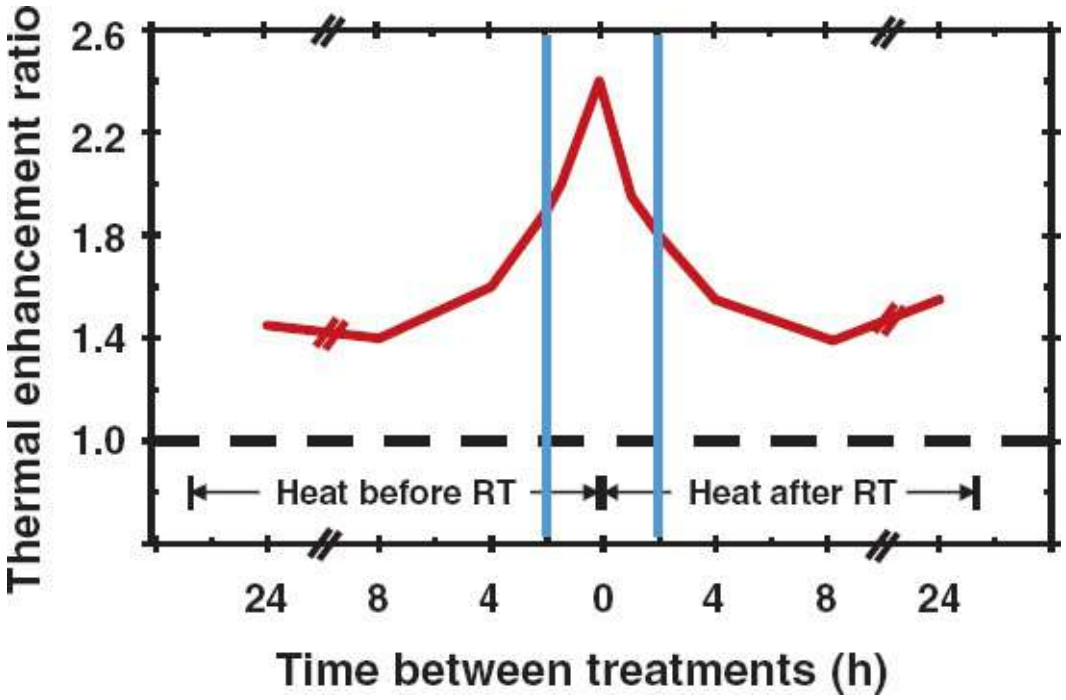

FIGURE 34.4. The effect of timing for combined hyperthermia and radiation therapy on the thermal enhancement ratio. The thermal enhancement ratio (ratio of radiation dose for radiation therapy alone and radiation therapy with hyperthermia to produce the same effect) was determined in several murine tumor models, and compiled results are shown. The greatest thermal enhancement ratio occurs when hyperthermia is performed within 2 hours before or after radiation therapy. (Adapted from Horsman MR, Overgaard J. Hyperthermia: a potent enhancer of radiotherapy. *Clin Oncol* 2007;19[6]:418–426, with permission.)

Several randomized clinical trials have assessed RT with HT compared to RT alone. Results have been mixed, but a meta-analysis suggests overall improved tumor response with combined RT and HT for multiple tumor types (Table 34.1).[82,83] Combined RT and HT have been most widely studied for head and

neck cancer and cervical cancer, largely because of the association between tumor hypoxia and poor clinical outcomes in these diseases as discussed above. The Dutch Deep Hyperthermia Group performed the largest randomized controlled trial comparing RT alone to RT with HT in patients with locally advanced bladder, cervical, or rectal cancer. HT was administered once weekly within 1 to 4 hours of RT for five total treatments. Complete response rates were significantly higher with RT and HT compared to RT alone (55% vs. 39%, respectively; $P < .001$), and local control duration was longer with combined therapy. On multivariate analysis adjusting for age, tumor site, and tumor size/stage, RT combined with HT was also associated with reduced death (relative HR, 0.74; 95% CI, 0.57 to 0.97; $P = .03$). Acute and late radiation toxicity did not differ by treatment group.[84] Although results with combined HT and RT have been promising, enthusiasm for HT has waned due in large part to technical challenges in uniformly heating tumors, particularly at deep-seated locations.[85]

Chemotherapy

Chemotherapeutic agents are often utilized in conjunction with radiation therapy for their radiosensitizing effect.[86,87] Concurrent chemoradiation with platinum agents, particularly cisplatin, improves survival in numerous malignancies including head and neck cancer,[88,89] cervical cancer,[90,91] and lung cancer.[92] Multiple potential mechanisms for platinum-induced radiosensitization have been proposed, including blocking DNA repair and inducing cell cycle arrest.[86,93] Several clinical trials are investigating the addition of new agents to cisplatin-based chemoradiation. For example, the ribonucleotide reductase inhibitor triapine showed promise in a phase II clinical trial for cervical cancer,[94] and a randomized phase II trial is ongoing (NCT02466971). Taxanes are also widely employed with radiation therapy for the treatment of head and neck cancer, lung cancer, and esophageal cancer. These drugs facilitate radiation-induced cell killing by synchronizing cell cycle and causing cell cycle arrest in the radiosensitive G2/M phase.[95–97] Fluoropyrimidines such as 5-fluorouracil are commonly administered concurrently with radiation therapy for gastrointestinal malignancies because of their radiosensitizing effect. Slowed repair of radiation-induced double-strand breaks and alteration of cell cycle progression by fluoropyrimidines likely result in radiosensitization.[98] Although mechanistic understanding of the interactions between radiation therapy and chemotherapy remains poorly understood, combined chemoradiation has dramatically

improved outcomes for multiple malignancies.[87]

TABLE 34.1 META-ANALYSIS OF RANDOMIZED CLINICAL TRIALS COMPARING RADIATION THERAPY ALONE WITH RADIATION THERAPY AND HYPERTHERMIA

Tumor Type	Number of Trials	Patient Number	LR Control, RT + HT	LR Control, RT Only	Odds Ratio (95% CI)
Advanced breast	2	143	68%	67%	1.06 (0.52–2.14)
Prostate	1	49	81%	79%	1.16 (0.28–4.77)
Mixed	3	442	39%	34%	1.24 (0.84–1.82)
Head and neck	5	274	51%	33%	2.08 (1.28–3.39)
Rectum	2	258	19%	9%	2.27 (1.08–4.76)
Chest wall	4	276	59%	38%	2.37 (1.46–3.86)
Bladder	1	101	73%	51%	2.61 (1.14–5.98)
Melanoma	1	128	56%	31%	2.81 (1.36–5.80)
Cervix	4	248	77%	52%	3.05 (1.77–5.27)
All	**23**	**1,919**	**52%**	**38%**	**1.80 (1.50–2.16)**

CI, confidence interval; HT, hyperthermia; LR, locoregional; RT, radiation therapy.

Biologic Modifiers of Radiation Response

Overexpression of the epidermal growth factor receptor 1 (EGFR-1) is associated with an adverse outcome in squamous head and neck cancer.[99] Cetuximab (C225) is a chimeric monoclonal antibody to EGFR. Preclinical studies have demonstrated that cetuximab sensitizes cells to the cytotoxic effects of ionizing irradiation.[100,101] Preliminary studies demonstrated that this drug could be safely administered in conjunction with a course of RT for head and neck cancer.[102] An open-label phase III trial tested the impact of weekly injections of cetuximab added to a course of RT alone.[103] Most patients received accelerated fractionation with concomitant boost, although hyperfractionation

and standard fractionation schemes were also permitted. Oral cavity primary tumors were ineligible for enrollment. Two-year locoregional control increased from 48% with RT to 56% with RT and cetuximab (P = .02). The incidence of distant metastatic recurrence was the same in both treatment arms. The initial survival advantage seen with the addition of cetuximab to RT has persisted, with updated 5-year overall survival rates of 45.6% versus 36.4% (P = .018).[104]

This trial provided an important proof of principle that adding a biologically targeted agent to a physically targeted modality can improve therapeutic outcome, and enhanced locoregional control can lead to enhanced survival. One-third of the patients enrolled had stage III disease, however, and thus had less advanced disease with more favorable prognoses than a significant proportion of patients who typically undergo chemoradiotherapy (CRT). A more favorable prognosis and improved treatment response has also been seen in patients with oropharyngeal squamous cell cancers associated with the human papillomavirus (HPV).[105] Whether RT with cetuximab is as effective or less toxic than RT with cisplatin in this select population is being examined by the phase III RTOG 1016 study and De-ESCALaTE trial. RTOG 1016 (NCT01302834) has closed to accrual after enrollment of 987 patients, but survival results will not be available for several years. Similarly, De-ESCALaTE (NCT01874171) has enrolled 334 patients, but estimated final collection date is February 2019 for the primary outcome of acute and late toxicity. A phase II Italian trial comparing cetuximab to weekly cisplatin (40 mg/m^2) for stage III to IVB head and neck squamous cell carcinoma was closed early because of slow accrual (n = 70 of planned 130 patients). Serious adverse events were more common among patients receiving cetuximab compared to cisplatin (19% vs. 3%, P = .044). Two-year overall survival rates were similar in both arms (68% for cetuximab and 78% for cisplatin).[106]

A separate phase III study, RTOG 0522, randomized patients with locally advanced head and neck cancer to receive RT and concurrent cisplatin with or without cetuximab.[107] Treatment intensification with the addition of cetuximab to CRT did not improve 2-year progression-free or overall survival. Patients with p16-positive oropharyngeal cancer had better progression-free and overall survival than p16-negative oropharyngeal cancer patients. No significant interaction was present between p16 status and treatment, although there was a trend toward worse overall survival for p16-positive patients receiving cetuximab (HR 1.42, P = .13). Toxicity was more pronounced in patients who received cisplatin and cetuximab. Still, EGFR inhibition remains a very active

area of investigation in head and neck cancer. Agents currently in clinical trial include fully humanized monoclonal antibodies and orally administered small molecule inhibitors of the tyrosine kinase domains of the EGFR family of receptors.

CHEMICAL RADIOPROTECTION

The protection of normal tissues from the deleterious effects of radiation is a critical component in the development of a comprehensive treatment plan. Strategies for the accomplishment of this aim include the physical manipulation of the beam, modification of the fractionation schedule, and pharmacologic manipulation of the radiation response. Physical radiation protection rests on the principle of exclusion of normal tissue from the high-dose region and may be accomplished by contouring the shape of the radiation beam, the use of multiple treatment fields, the use of different beam energies, and modulation of the dose delivery from each beam (intensity-modulated radiation therapy [IMRT]). Modified fractionation typically uses multiple fractions of treatment per day as opposed to the conventional once-daily paradigm in order to exploit the differing radiation repair capabilities of normal tissues as opposed to tumors. Physical modification of the treatment beam and altered fractionation are discussed elsewhere.

Protection

Pharmacologic radioprotection itself can be classified into three categories: protection, mitigation, and treatment. The direct cytotoxicity of ionizing irradiation results from the generation of free radicals that cause DNA strand breaks and lead to mitotic cell death. Amifostine (WR2721; Ethyol, Medimmune, Inc., Gaithersburg, MD) is the prototype pharmacologic radioprotector that functions via free radical scavenging. Amifostine is a thiol-containing prodrug that preferentially accumulates in the kidneys and salivary glands where it is metabolized to its active moiety, WR1065.[108]

An open-label phase III randomized trial was conducted from 1995 to 1997 to assess the ability of this drug to reduce the incidence of grade 2 or higher acute and late xerostomia and grade 3 or higher acute mucositis.[109] Patients enrolled in this trial received curative intent or adjuvant postoperative irradiation without concurrent chemotherapy. All treatment was delivered with conventional once-daily fractionation of 1.8 to 2.0 Gy. Curative intent delivery consisted of 66 to 70

Gy total dose, and postoperative irradiation was delivered at 50 to 60 Gy total dose depending on the patient's assessed risk for recurrence. IMRT was not utilized, and inclusion of >75% of both parotid glands was required for inclusion in the study. Those patients who were randomized to receive amifostine were given a daily dose of 200 mg/m^2 intravenously for 15 to 30 minutes every day prior to each fraction of RT.

Three hundred and three patients were enrolled in this trial, and minimum follow-up was 2 years. Amifostine did not reduce the incidence of grade 3 mucositis but did significantly reduce the incidence of acute and long-term grade >2 xerostomia. One-year post-RT, the incidence was 34% versus 56% for patients who had received amifostine versus those who had not (P = .002). Unstimulated saliva production >0.1 g was also more common in patients who had received amifostine (72% vs. 49%; P = .003). Two years post-RT, amifostine use was still associated with a significantly lower incidence of xerostomia, although the magnitude of benefit was lower (19% vs. 36%; P = .05). The lower incidences in both groups of patients also suggest some late recovery of salivary function. Reinforcing this idea of late recovery of salivary function is the fact that the percentage of patients who did not receive amifostine but who could exceed the >0.1 g of unstimulated saliva threshold had increased to 57%.[110]

Severe toxicity (CTCAE grade >3) attributable to amifostine occurred in <10% of patients in this trial and consisted of nausea and vomiting and transient hypotension. Nearly two-thirds of the patients had less severe grades of these side effects. Drug-related toxicity did cause approximately 20% of patients to discontinue amifostine prior to completing RT. Subcutaneous administration of the drug causes less nausea, vomiting, and hypotension than intravenous dosing but is associated with an increased risk of cutaneous toxicity, which again causes 15% to 20% of patients to be unable to complete a full course of amifostine in conjunction with their radiation.[111] The incidence of severe cutaneous toxicity, including erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis, is 6 to 9 in 100,000.[112]

A criticism of this trial is that it was underpowered to detect a very small compromise in survival caused by amifostine (tumor protection).[113] This argument is correct but overlooks the reality that absolute refutation of a small compromise of antitumor efficacy attributable to amifostine would have required an equivalence trial. Demonstration that amifostine reduced survival from a hypothetical 45% to 40% (P = .05; 80% power) would have necessitated >1,200 patients per study arm.[114] Such large studies have rarely been performed in head

and neck cancer, because patient resources are too scarce. The largest randomized head and neck trial ever conducted, RTOG 9003, required 8 years to enroll 1,113 patients into four treatment arms.[115] A meta-analysis of amifostine that used individual patient data from 12 trials and 1,119 patients examined the impact of this drug on survival in patients treated with RT or CRT. The majority of patients (65%) had head and neck cancers, with 33% lung cancers and 2% pelvic carcinomas. The hazard ratio of death was 0.98 (95% confidence interval, 0.84 to 1.14; $P = .78$).[116]

The potential of amifostine as a protector against radiation-induced esophagitis during the treatment of non–small cell lung cancer was studied in a randomized trial conducted by the RTOG.[117,118] No reduction in the incidence of grade 3 esophagitis was observed, although less swallowing dysfunction occurred in the patients who received amifostine. Part of the explanation for this absence may be attributable to the study design, which utilized a hyperfractionated radiation schedule 5 days per week (69.6 Gy total dose) and concurrent carboplatin/paclitaxel. Amifostine 500 mg intravenous was delivered 4 days per week prior to the afternoon fraction only. Moreover, 28% of the patients did not complete the full course of the drug either because of toxicity or refusal. Consequently, approximately 50% of the RT was delivered in the absence of the radioprotective drug in those patients who were randomized to receive it. Preclinical study of amifostine delivered daily in conjunction with fractionated lung and esophageal irradiation has demonstrated morphologic and immunohistochemical evidence of radioprotection.[119–121]

Amifostine is approved by the U.S. Food and Drug Administration for xerostomia in the setting of RT alone. The majority of both curative intent and adjuvant postoperative RT for head and neck cancers, with large target volumes that put the parotid glands at risk, are now delivered in conjunction with concurrent chemotherapy. Small phase II and III trials suggest that amifostine has a cytoprotective benefit in the chemoradiation setting, but level 1 evidence is lacking.[122,123] Moreover, the widespread adoption of IMRT with its ability to spare one or both parotid glands and reduce the incidence of xerostomia compared to conventional, non-IMRT techniques has further reduced the role for this drug.[124] The utility of amifostine in conjunction with IMRT has been investigated in small settings with inconclusive results.[125]

Superoxide dismutase (SOD) mimetics represent a new class of radioprotectors that are currently under active investigation. These drugs convert the radiation-induced toxic reactive oxygen species superoxide anion (O_2^-) to

hydrogen peroxide and molecular oxygen to mitigate radiation-induced toxicity. Similarly, these drugs interact with other potentially damaging reactive oxygen and reactive nitrogen species. A phase Ib/IIa clinical trial of the SOD mimetic GC4419 in patients with oral cavity or oropharyngeal cancer showed delayed development of oral mucositis, as well as reduced severity, incidence, and duration.[126] An ongoing randomized phase II clinical trial (NCT02508389) is assessing the effect of GC4419 administered prior to radiation therapy on oral mucositis during treatment of locally advanced head and neck cancer. Another SOD mimetic, Mn(III)meso-tetrakis(N-n-butoxyethylpyridinium-2-yl)porphyrin (MnBuOE), has been shown to mitigate oral mucositis, xerostomia, and salivary gland fibrosis in preclinical models.[127,128] Mice treated subcutaneously with MnBuOE twice daily or three times per week for 1 week prior to single-fraction radiation therapy to the oral cavity and ventral neck, followed by continued MnBuOE dosing after RT, exhibited significantly decreased incidence and severity of oral mucositis. This was demonstrated by fluorescence molecular tomography assessing cathepsin activity as a marker of mucositis (Fig. 34.5).[104] Stimulated saliva production was also significantly greater in mice treated with MnBuOE compared to saline control at 2 to 4 and 11 weeks post radiation therapy. At 6 and 12 weeks post radiation therapy, significantly decreased salivary gland fibrosis was observed in MnBuOE-treated mice.[127,128] Importantly, MnBuOE does not appear to protect tumor cells from RT. In FaDu flank models of head and neck cancer, MnBuOE with RT resulted in further slowing of tumor growth[127] or no change in radiation-induced tumor growth delay.[128] Analogs of MnBuOE have also been shown to reduce radiation-induced erectile dysfunction[129] and pulmonary injury in mice.[130–132] A phase Ia-b clinical trial is ongoing to investigate the effect of MnBuOE (also known as BMX-001) on mucositis and xerostomia in patients with locally advanced head and neck cancer (NCT02990468). A phase I/II trial is also assessing MnBuOE in glioblastoma patients receiving concurrent RT and temozolomide to determine the maximum tolerated dose and assess median overall survival compared to historical controls (NCT02655601). Initial safety and efficacy results from the GC4419 and MnBuOE clinical trials are anticipated in early 2019.

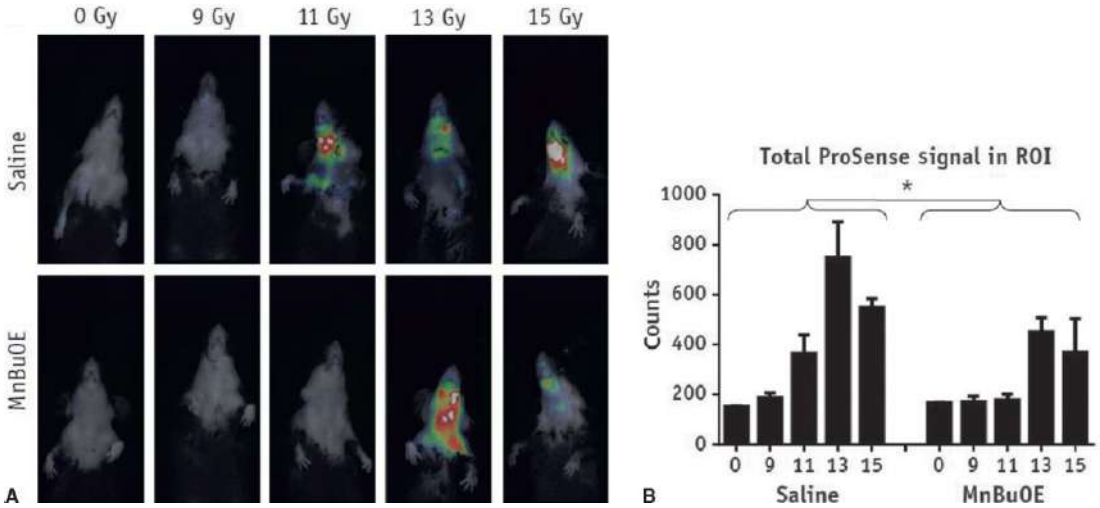

FIGURE 34.5. Reduced severity of mucositis for mice treated with MnBuOE compared to saline prior to and after single-fraction radiation therapy. **A:** Demonstrates fluorescence molecular tomography images using a probe that fluoresces after cleavage by cathepsins and plasmin as a marker for mucositis. **B:** Quantification of fluorescence in saline- and MnBuOE-treated mice. ROI, region of interest.

Mitigation

Administration of compounds that mitigate damage caused by previous radiation exposure constitutes a different approach to the management of radiation-induced toxicity. This strategy contrasts to the classical free radical scavenging radioprotective mechanism of drugs such as amifostine. The leading drug under development in this category is palifermin. Palifermin is a recombinant human keratinocyte growth factor that belongs to the fibroblast growth factor (FGF-7) family of cytokines. It stimulates cellular proliferation and differentiation in a variety of epithelial tissues including mucosa throughout the alimentary tract, salivary glands, and type II pneumocytes. Palifermin also regulates intrinsic glutathione-mediated cytoprotective mechanisms. Administration of palifermin in preclinical rodent models leads to a significant thickening of oral tongue mucosa.[133] Preclinical studies of fractionated RT have revealed that the administration of palifermin leads to increases in the dose of RT necessary to induce ulcerative mucositis and to reductions in the duration of this ulceration when it does occur.[134,135] Parotid gland production of saliva is also preserved when palifermin is administered in the setting of RT in preclinical systems. Preclinical evaluation of palifermin in a rodent model has also demonstrated that administration of a single dose of this drug after completion of a course of fractionated thoracic irradiation significantly reduces the severity and duration of pneumonitis and the severity of pulmonary fibrosis.[136]

The ability of palifermin to reduce mucositis in a clinical setting has been tested in a pivotal phase III double-blind placebo-controlled trial of patients with non-Hodgkin lymphoma undergoing bone marrow transplantation.[137] The bone marrow ablative regimen consisted of 12 Gy of total body irradiation (TBI) given at 1.5 Gy twice a day. Thereafter, etoposide (VP-16) and cyclophosphamide were administered. Palifermin was delivered prior to the initiation of TBI and again after the completion of chemotherapy, which also corresponded to 5 days after the completion of TBI. The dose schedule of palifermin was 60 mcg/kg/d three times for both administrations. This trial enrolled 212 patients who were equally divided between the placebo and palifermin arms. The World Health Organization (WHO) scoring system was used. The incidence of grade 3 or 4 mucositis approached 90% in the placebo arm as opposed to approximately 60% in the palifermin arm. For those patients who developed this level of toxicity, the duration was significantly reduced from 10.4 days in the placebo arm to 3.7 days in the palifermin arm ($P < .001$). Grade 3 mucositis developed in 62% of the placebo arm patients and only 20% of the palifermin arm patients ($P < .001$). Mean duration of grade 4 mucositis was reduced from 6.2 to 3.3 days with the use of this drug ($P < .001$).

A phase II study examined the safety and efficacy of palifermin in locally advanced head and neck cancer patients.[138] Patients were randomized 2 to 1 between palifermin and placebo. Palifermin was delivered at a dose of 60 mcg/kg. Institutions had the discretion to deliver RT via conventional once-daily 2-Gy fractions or with an accelerated hyperfractionated regimen of 1.25 Gy twice daily. One hundred patients were enrolled, of whom 34 received accelerated hyperfractionation and the remainder received standard fractionation. The first dose was delivered prior to the initiation of CRT and then every Friday afternoon after the last fraction of radiation. Two additional doses of palifermin were given 1 and 2 weeks after the completion of RT for a total of 10 doses of the drug. Palifermin did not reduce the incidence or duration of mucosal or salivary gland toxicity. The subset of patients receiving hyperfractionated radiation, however, showed significant improvements in the duration and severity of mucositis (Fig. 34.6). They also had improved swallowing function and less salivary gland toxicity relative to patients who received placebo.

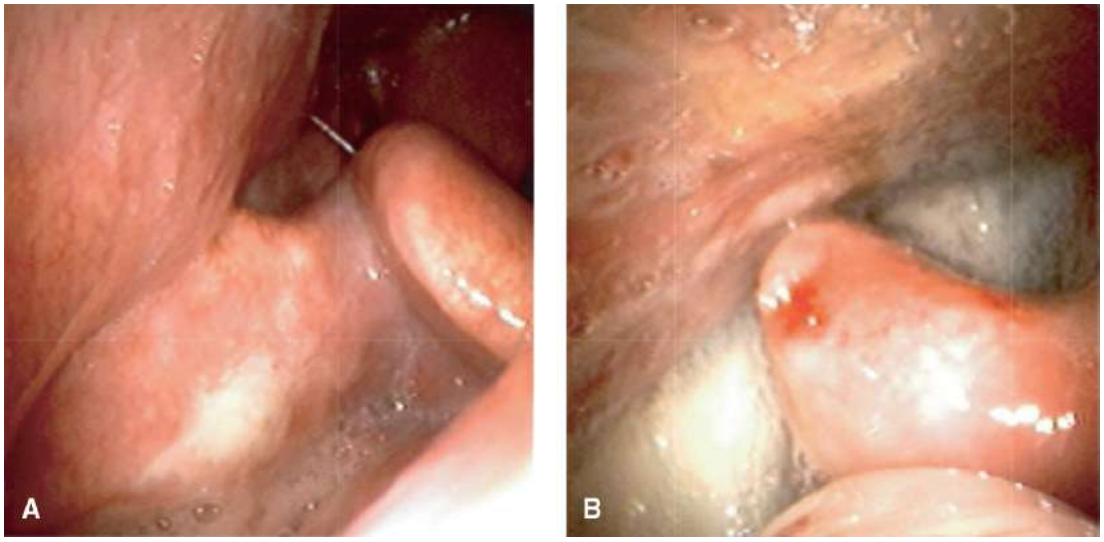

FIGURE 34.6. Confluent mucositis induced by concurrent chemoradiation in the base of tongue and supraglottic larynx regions. **A:** Demonstrates normal mucosa prior to the initiation of treatment. **B:** Demonstrates the pseudomembranous exudate, hemorrhage, and edema that are characteristic of this confluent mucositis.

A subsequent randomized phase III study examined a higher dose of palifermin at 180 mcg/kg to reduce oral mucositis in 188 patients with locally advanced head and neck cancer treated with CRT.[139] Palifermin was administered prior to starting CRT and once weekly for 7 weeks. The incidence of severe oral mucositis, the primary endpoint, was significantly lower in the palifermin arm compared to placebo (54% vs. 69%; P = .041). Both overall survival and progression-free survival were similar as well. However, no statistically significant differences emerged in secondary efficacy end points such as narcotic doses and duration of treatment breaks. A similar randomized phase III study examined palifermin at 120 mcg/kg in 186 head and neck cancer patients treated with postoperative CRT.[140] Palifermin again reduced the time to development and duration of WHO grade 3 or 4 oral mucositis without differences in patient-reported pain scores, treatment breaks, or efficacy. The precise role for palifermin in the management of head and neck cancer remains to be established.

Treatment

Radioprotectors and radiation mitigators are both designed to minimize the risk of clonogenic death of normal cells and subsequent disruption of the protective mucosal barrier. Head and neck RT also initiates a local cytokine cascade, which includes interleukin-1 and interleukin-6 and tumor necrosis factor-α (TNF-α). An inflammatory response results, which contributes to the ultimate anatomic

disruption of the mucosa. Secondary bacterial and fungal overgrowths are thought to exacerbate the local pathophysiology.

Sucralfate, a basic aluminum salt of sucrose, is used in the treatment of peptic ulcer disease. It provides a protective coating to ulcerated tissue by means of binding to exposed proteins in damaged cells.[141] It also stimulates mucus production, mitosis, and surface migration of cells. Sucralfate has been tested in several double-blind placebo-controlled randomized trials. Despite the attractive conceptual nature of using it to ameliorate mucositis, the clinical data do not show any benefit from sucralfate.[142–144]

Benzydamine hydrochloride is a nonsteroidal anti-inflammatory drug that also possesses antimicrobial activity.[145] It is a potent inhibitor of TNF-α.[146] Expression of this proinflammatory cytokine is upregulated in mucosal tissue of the head and neck regions, with peak levels typically at approximately 20 Gy (conventionally fractionated) just prior to the first signs of mucosal ulceration. The ability of benzydamine to reduce mucositis during head and neck RT was tested in a randomized double-blind placebo-controlled trial.[147] The primary endpoint of this trial was the area under the curve for the mean mucositis score over a cumulative RT dose up to a total dose of 50 Gy. Secondary end points included use of concomitant pain medication, oral pain at rest and with eating, body weight, and the use of enteral nutritional support.

Benzydamine therapy resulted in a 30% reduction in mucosal erythema and ulceration. Most of this benefit was observed once doses >25 Gy had been delivered. One-third of the benzydamine patients did not develop any mucosal ulceration, compared with only 18% of the placebo-treated patients (P = .04). There was a nonsignificant trend toward reduction in mouth pain at rest for the patients who received benzydamine. Importantly, benzydamine was no more effective than placebo with respect to the reduction of pain during meals. Cumulative weight loss during RT was equivalent in the two treatment groups. There was no difference in the proportion of patients who required enteral nutritional support between the two treatment arms.

The data from the benzydamine trials suggest that this agent is active against mucositis but are inconclusive regarding whether it has any clinical role in treating this condition. There was no significant benefit regarding the functional sequelae of mucositis. Mucosal assessment was not performed beyond 50 Gy, and most patients received RT doses of 64 to 74 Gy. The study design may thus explain the discordance between the improvement in the anatomic assessment of mucosal integrity associated with benzydamine and the lack of any functional

benefit, as the latter parameters were assessed throughout a patient's entire course of RT. The most severe mucositis during a course of head and neck RT occurs beyond the 50 Gy level. Fewer than 10% of the patients enrolled in this trial received concurrent chemotherapy, even though most of them had stage III or IV disease. Concurrent CRT has become the SOC for most patients with this extent of disease. Consequently, the clinical value of benzydamine has not been proven for patients receiving high-dose RT with or without concurrent chemotherapy.

Endogenous oral flora may exacerbate the mucosal inflammatory process once the mucosal integrity is disrupted. Secondary infections may prolong the course of mucositis and compromise overall patient well-being. Protegrins are naturally occurring peptides that have broad-spectrum antimicrobial activity.[148] Iseganan is a synthetic analog of this class of compounds. A placebo-controlled trial in patients receiving chemotherapy suggested that iseganan reduced the incidence of ulcerative stomatitis and decreased both mouth pain and swallowing difficulty.[149]

A phase III double-blind, placebo-controlled trial was subsequently conducted to test this concept in patients receiving head and neck RT.[150] This trial mandated that a minimum dose of 60 Gy be delivered but allowed different fractionation schemes. Forty percent of the patients enrolled received concurrent chemotherapy. The study contained three treatment arms: SOC oral hygiene only, placebo plus SOC, and iseganan plus SOC. Iseganan and placebo were equivalent to one another with respect to all end points in the trial. Interestingly, both iseganan and placebo arms were superior to SOC oral hygiene alone. Two-thirds of the patients in both arms had confluent mucositis compared with 79% in the SOC alone arm ($P = .02$). Only 2% of the SOC patients had no mucosal ulceration versus 9% in both the iseganan and placebo arms ($P = .04$). Peak mouth pain and difficulty swallowing were also significantly worse for the patients assigned to SOC alone. RT dose reductions were also significantly more common in the SOC patients.

The iseganan trial showed no benefit from the administration of the study drug. It did, however, reveal the importance of adherence to a strict regimen of oral hygiene during head and neck RT. Patients on both the drug and placebo arms were instructed to swish and gargle prior to each administration of study drug. They also maintained study diaries to help ensure adequate compliance with administration of the study drug. These interventions were not performed in the patients assigned to SOC alone. This trial provides an important foundation

in the evaluation of new therapies for mucositis through its demonstration of the value of organized and systematic attention to the maintenance of good oral hygiene throughout a course of head and neck RT.

SUMMARY

The chemical modification of radiation response both for enhancing treatment efficacy and reducing therapy-induced toxicity remains an area of active investigation. Promising candidates identified in preclinical and early-phase trials have been less successful in randomized phase III settings. Attempts to improve treatment efficacy by augmenting tumor oxygen delivery have a mixed record of success. The use of drugs that are preferentially cytotoxic to hypoxic cells holds promise, although improved tools to identify those patients most likely to benefit from targeted therapy are needed. Proof of principle for chemical radioprotection has been established in salivary glands but not elsewhere and is associated with significant toxicity in its own right. Growth factor utilization appears to protect against treatment-induced mucositis but not to an extent to change clinical practice. As RT regimens evolve and new technologic advances continue to improve treatment delivery, investigators will continue to seek agents that optimize the TR.

CHAPTER 35

Oncologic Imaging and Oncologic Anatomy

Junzo P. Chino, Chris R. Kelsey, Jared D. Christensen, and Lawrence B. Marks

INTRODUCTION

This chapter addresses two topics central to the management of patients with cancer: oncologic anatomy and oncologic imaging. Although these topics are relevant for all specialties involved in the treatment of cancer, they are particularly germane for radiation oncologists. A sound understanding of anatomy, especially pertaining to malignant processes, facilitates interpretation of imaging studies. Likewise, understanding the advantages and limitations of individual imaging modalities assists in defining rational clinical target volumes (CTVs) that maximize the therapeutic ratio.

Advances in diagnostic imaging have increased our ability to visualize macroscopic disease, referred to as gross tumor volume (GTV). Imaging is currently unable to identify microscopic tumor extension around a primary tumor or occult nodal involvement. A CTV is created to account for both of these uncertainties (Table 35.1). A rational definition of the CTV should reflect the clinician's knowledge regarding the patterns of spread for each particular cancer. This involves both local spread around the primary site and patterns of lymphatic drainage. Appropriate expansion of a GTV to a CTV minimizes the risk of local failure (i.e., marginal miss) while reducing the risk of complications by avoiding regions at low risk of involvement (Fig. 35.1).

Radiation treatment planning has undergone considerable evolution during the past 30 years. With conventional planning, the physician conceives of beam orientations and aperture shapes based on the interpretation of available clinical and diagnostic information, including three-dimensional (3D) imaging data such as computed tomography (CT) or magnetic resonance imaging (MRI). The beam

is then applied to the patient using a fluoroscopy-based conventional simulator, relying on an understanding of tumor and normal tissue anatomy and its association with fluoroscopic bony anatomy and surface anatomy. Relatively generous margins are used to account for inherent uncertainties of the process.

With 3-D treatment planning, anatomic information from a planning CT scan is transferred to a computer where the images are segmented to define the tumor and normal tissues. Software allows this 3-D information to be displayed and viewed from any orientation. Beam orientation and shape are chosen to encompass the target, yet minimize, as much as possible, normal tissue exposure. Thus, 3-D planning tools allow the 3-D anatomy to be more accurately incorporated into the planning process than with conventional techniques. The computer allows the planner to use beam orientations that are nonstandard (e.g., nonaxial beams). Beam apertures are typically smaller than with conventional simulation because of reduced uncertainty in the entire process. The prior specification of the beam angle and aperture by the treatment team is known as "forward planning." Current technology also allows data from other imaging modalities (MRI, positron emission tomography [PET], etc.) to be fused with the planning CT dataset and hence considered in the planning process. It is advantageous to position the patient similarly during the imaging and treatment planning scans to facilitate accurate image correlation.

TABLE 35.1 VOLUME DEFINITIONS FOR RADIATION THERAPY PLANNING

Structure	Defined	Method of Assessment
Gross tumor volume (GTV)	Palpable or visible disease	Physical examination, imaging studies
Clinical target volume (CTV)	GTV + expansion for microscopic spread	Knowledge of patterns of spread (oncologic anatomy)
Planning target volume (PTV)	CTV + expansion for setup error and organ motion	Imaging studies (fluoroscopy or 4D CT to define degree of motion) and reproducibility/stability of mobilization/localization systems

4D, four dimensional; CT, computed tomography.

Intensity-modulated radiation therapy (IMRT) and other more conformal

technologies require the clinician to explicitly delineate target volumes, including elective nodal basins and avoidance structures. The introduction of IMRT has revolutionized radiation treatment planning and, in the process, has required clinicians to become more proficient in 3-D anatomy and malignant patterns of spread. The prespecification of the intended target of radiotherapy, the organs at risk of treatment, and the dosimetric goals or constraints of therapy is known as “inverse planning,” as the beams’ apertures and fluencies are determined afterward by an optimization algorithm.

There has been great progress in the last decade with the development of consensus guidelines for target and critical organ delineation in most disease sites (Table 35.2). While some of the volume definitions may be conceived primarily based on expert opinion, they facilitate the rational demarcation of nodal stations at risk, reporting of patterns of spread and failure, and communication with surgical colleagues. Certainly, these guidelines and atlases provide the fundament upon which future work may be built, and should be seen as living works, refined and revised on a regular basis, preferably with reference to recurrence/spread patterns (as was recently performed for bladder cancer).[1] These guidelines should complement, and not replace, the judgment of the treating physician, as anatomic variations, prior surgery, and unusual patterns of disease spread can invalidate the applicability of an atlas to an individual patient.

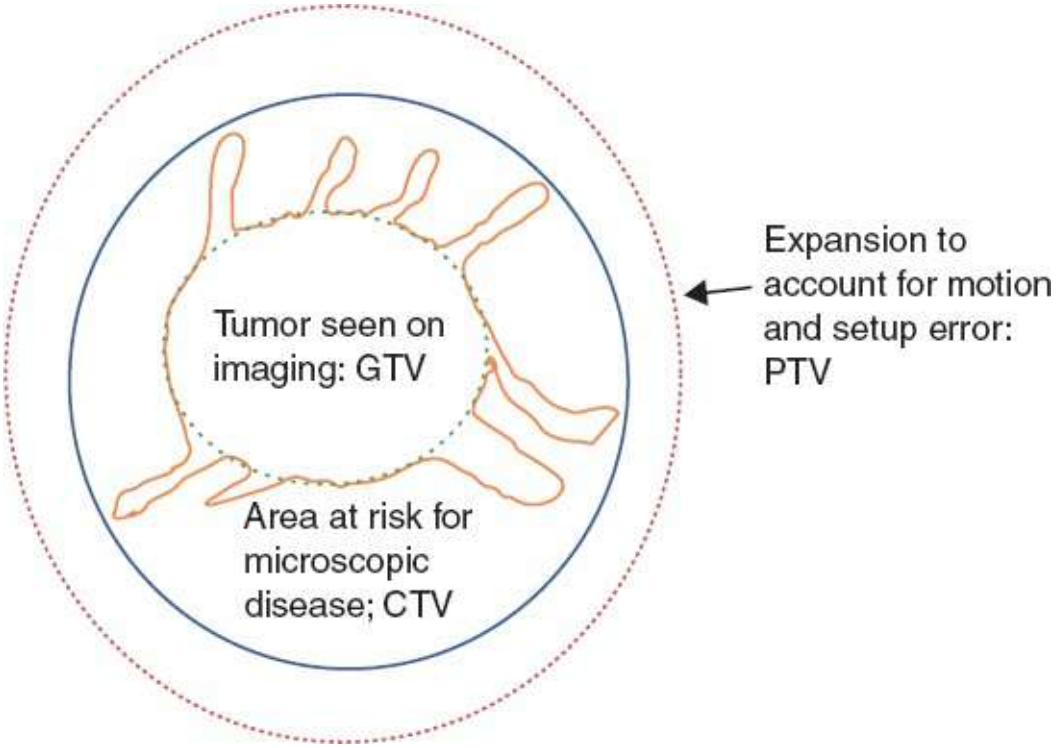

FIGURE 35.1. Gross disease identified with imaging is depicted, along with appropriate expansions to encompass surrounding microscopic disease (CTV) and setup/motion uncertainties (PTV). GTV, gross tumor volume.

One of the risks of 3-D and IMRT is a false sense of security in the accuracy of imaging to portray the *in vivo* extent of disease. Further, imaging obtained at the time of initial treatment planning may not be representative of the *in vivo* anatomy throughout a course of therapy spanning several weeks. Indeed, there have been published examples of inferior outcomes with highly conformal treatment planning.[2,3] Modern imaging tools are clearly not perfect. The rapid embrace of newer technologies to visualize gross tumor and to address uncertainties related to organ motion and setup errors may be counterproductive if relied on too heavily in the treatment planning process. It is possible, if not likely, that microscopic tumor has been sterilized at the edge of radiotherapy fields that were expanded to account for setup errors and organ motion (i.e., not expanded with the intent of covering the microscopic disease). Further, the clinical history or examination and imaging may be discordant, and one needs to be careful not to be overly reliant on imaging when defining target volumes. For example, in a patient with cancer of the nasopharynx with cranial nerve deficits, the target volume should include the corresponding anatomic site of likely extension, even in the absence of an abnormality on imaging. Thus, a sound understanding of oncologic anatomy and imaging modalities is vital in the treatment planning process.

IMAGING MODALITIES

Radiologic imaging is an integral component in the management of cancer patients. Imaging is utilized in the diagnosis and initial staging of disease, treatment planning, and posttreatment surveillance. Radiation oncologists must be familiar with the available imaging modalities and understand the appropriate utilization and limitations of each, which often varies based on the tumor site and study indication. In particular, a general sense of the sensitivity, specificity, and positive and negative predictive values of an imaging study helps the clinician assimilate and interpret imaging information that can be misleading or even contradictory. A detailed review of each imaging modality and its associated physics is beyond the scope of this chapter; however, a general overview of the imaging modalities most frequently utilized in clinical practice is provided, with disease-specific applications addressed in the systems-based anatomy sections.

Radiography

Conventional radiography creates a two-dimensional gray-scale image produced by the differential attenuation of x-rays that pass through soft tissues of varying density. Tissues that are very dense, such as bone, will absorb (attenuate) more x-rays than tissues that are less dense, such as lung. The energy loss of source x-rays identified at the x-ray detector is directly proportional to tissue density resulting in a processed image where highly dense objects appear bright and less dense objects are dark. Radiographs are therefore best suited to detect pathology when a lesion differs greatly in density from adjacent structures, such as a soft tissue mass surrounded by aerated lung or a lytic lesion surrounded by dense bone. Radiographs have excellent spatial resolution: the ability to detect a small object within a given volume. However, they are suboptimal when there are only subtle differences in tissue density. Even large lesions can be missed if they are of similar density to surrounding structures. Further, given that radiographs are only two-dimensional, determining spatial relationships to adjacent structures is limited. Radiographs may help identify an abnormality, but additional imaging modalities are often required for further characterization. Although conventional radiography has limited utility in oncologic imaging, its basic principles underlie more advanced imaging modalities such as CT.

Cross-Sectional Imaging

CT, MRI, and ultrasound (US) generate two-dimensional cross-sectional images.

The benefits of cross-sectional imaging include visualization of superimposed structures obscured on planar images, improved anatomic detail of individual organs and their precise relationship to adjacent structures, and the ability to perform multiplanar reconstructions. Some applications, such as Doppler US and cine cardiac MRI, provide functional information in addition to morphologic information and can be acquired in real time and have varying indications for image-guided procedures. For these reasons, cross-sectional modalities are the mainstay of oncologic imaging.

Computed Tomography

CT generates cross-sectional images from the transmission of radiation through tissue. A patient lies on the scanner table within a gantry that houses an x-ray generator opposite multiple rows of detectors, hence the term *multidetector CT* (MDCT). Current generation scanners (e.g., 64, 128, and 256 detector arrays) are able to acquire high-resolution image data much faster because of improvements in the number of detectors and computer processing. As the gantry rotates, the detectors measure x-ray transmission through the rotation, or slice. The patient is moved through the scanner as the gantry rotates, resulting in a helical or spiral course at a very thin slice thickness, typically 0.625 mm. The spatial and temporal data from multiple projections are then processed by a Fourier transform mechanism generating two-dimensional axial images. The thin-slice volume dataset is isotropic, meaning that images can be reconstructed in orthogonal and oblique planes without a loss in image quality. Furthermore, thin-slice acquisition improves contrast resolution and decreases partial volume artifacts, thereby improving imaging quality and accuracy.

Images are displayed within a matrix composed of voxels, each representing a volume of radiodensity that is quantified by a linear attenuation value called a Hounsfield unit (HU). Each voxel is assigned an HU in the range of −1,000 to 1,000 corresponding to a shade of gray that represents the attenuation difference between a given material and water. By convention, air is the least dense material with an HU value of −1,000, whereas water has an HU value of 0. Soft tissues have a range of attenuation with typical HU values as follows: fat (−120), blood (30), muscle (40), and bone (>300). HU analysis is more accurate than visual assessment of tissue composition and is particularly useful in characterizing enhancement postcontrast administration, a feature critical in the assessment of many solid organ lesions.

Both intravenous (IV) and oral contrast agents may be utilized to improve

spatial resolution. Oral contrast agents are routinely used for abdominal and pelvic imaging to distinguish bowel from adjacent organs, lymph nodes, and tumors. The use of an intravascular contrast agent during CT depends on the study indication, target organ, and patient status. IV contrast agents contain variable concentrations of iodine compounds that attenuate, or absorb, x-rays, which allows for enhanced detection of vascular structures. Administration of IV contrast media is required for thorough assessment of vessels (e.g., aorta, pulmonary arteries), solid organs (e.g., liver, kidneys), and characterization of lesion vascularity. Contrast-enhanced CT is often necessary to detect solid organ metastases (e.g., liver, adrenal gland, brain). Contrast is usually not necessary for routine pulmonary imaging because of the inherent contrast of solid lesions within a background of aerated lung, although it does improve the characterization of hilar lymph nodes.

Given that the administration of contrast media can alter tissue attenuation, the HU value of a lesion or tissue may differ depending on whether the study was performed with or without contrast and based on the timing of image acquisition (e.g., arterial vs. portal venous phase). HUs are used during radiation treatment planning dose calculations; therefore, both IV and bowel contrast can affect these calculations. If indicated, the HU within a structure enhanced by contrast (e.g., the bladder when planning for prostate cancer treatment) can be set to an alternate value prior to dose calculations. A similar phenomenon often occurs when materials with a high atomic number are within the scanned volume. These materials (e.g., dental fillings, hip prostheses) can cause artifacts that can make it challenging to accurately segment the image or affect dose calculations. The latter can also be corrected by setting the HU within the affected area to the desired value.

IV contrast agents are excreted through the kidneys, are nephrotoxic, and are not typically administered to patients with impaired renal function (glomerular filtration rate [GFR] < 60, creatine [Cr] < 2.0, though institutional policies vary) unless on dialysis or out of emergent medical necessity. IV contrast media should also not be given to patients with a known contrast allergy resulting in anaphylaxis or laryngeal edema. More minor reactions, such as pruritus, are not an absolute contraindication, and contrast may be administered following a proper steroid pretreatment protocol. Alternative imaging modalities should be considered if a contrast-enhanced study is required in the setting of a severe contrast allergy. An allergy to shellfish is not considered a contraindication to iodinated contrast administration.[4–6]

In part because of its availability, rapid acquisition, and high-yield anatomic data, CT has become one of the most widely used medical imaging modalities in the United States, with over 85 million scans performed annually, and it serves as the core modality for oncologic imaging.[7,8] Although CT is noninvasive, it is not entirely benign. CT utilizes radiation to generate images, and although dose modulation and optimal scanning parameters can significantly reduce patient radiation exposure, the cumulative effects of CT radiation are of clinical concern. Alternative imaging modalities should always be considered and performed in lieu of CT when appropriate.

Magnetic Resonance Imaging

MRI generates cross-sectional images without ionizing radiation. MRI utilizes strong magnets to generate images, typically 1.5 or 3.0 T for clinical applications. A 3.0 T magnet is 60,000 times greater than the earth's magnetic field. The magnetic field uniformly aligns the nuclei of hydrogen protons within tissue. Applying a radiofrequency (RF) pulse sequence and gradient to the magnetic field disrupts this alignment and equilibrium. When the RF pulse is removed, the protons realign, or relax, within the field and emit a measurable resonance radio signal. The detected radio signals, referred to as *echoes* or *spin echoes*, are then used to generate an image. The most important tissue properties for image generation are the proton density, the spin-lattice relaxation time (T1), and the spin–spin relaxation time (T2). Different tissues have different proton density and relaxation times, absorbing and releasing radio wave energy at different rates, which in part accounts for the high tissue contrast obtained by MRI.

Different RF pulse sequences can accentuate different tissue characteristics by varying parameters such as the repetition time (TR)—the time between RF pulses in the sequence, which determines how much time protons have to realign within the magnetic field—and the echo time (TE)—the time between the RF pulse and the peak returning signal. TR and TE dramatically affect image contrast and determine which tissue properties are selected. T1-weighted images, in which fluid is dark and fat is bright, are generally good at depicting anatomy; T1-weighted images are generated by selecting short TR (typically ≤800 ms) and short TE values (≤30 ms). T2-weighted images, in which fluid is bright and fat is dark, are fluid-sensitive and can depict areas of pathology; T2-weighted images are generated by selecting long TR (≥2,000 ms) and long TE values (≥60 ms) (Table 35.3). Scan sequences are composed of variations in RF pulses and TR

and TE settings. Although these vary by MRI scanner manufacturer using proprietary names, the underlying principles are similar. Common sequence techniques include the following:

TABLE 35.3 MAGNETIC RESONANCE IMAGING SIGNAL INTENSITIES (SPIN-ECHO IMAGING)

	T1WI	T2WI	FLAIR
Cerebrospinal fluid	Dark	Bright	Dark
Fat[a]	Bright	Dark	Bright
Solid mass (tumor)	Dark	Bright	Bright
Edema	Dark	Bright	Bright
Cyst	Dark	Bright	Dark

[a]Fat is bright on T2 fast spin-echo (FSE) or gradient echo sequences.
Bright, hyperintense; dark, hypointense; FLAIR, fluid-attenuation inversion recovery; T1WI, T1-weighted image; T2WI, T2-weighted image.

Spin-echo (SE) sequences produce standard T1- and T2-weighted images.

Multiple spin-echo (MSE) sequences allow for faster image acquisition and are also referred to as turbo spin echo, fast spin echo, or rapid-acquisition relaxation-enhanced imaging. The signal intensity and image quality are less than that of conventional SE sequences. Furthermore, fat is bright on MSE T2-weighted images, which can limit sensitivity for detecting pathology. Fat-suppression techniques can be used to offset this limitation. Fast low-angle acquisition with relaxation enhancement and half-Fourier acquisition single-shot turbo SE sequences are MSE variations.

Inversion recovery (IR) pulse sequences emphasize differences in T1 properties of tissues. A time of inversion (TI) is added to the sequence that can be set to target-specific tissues. Short time of IR sequences suppress tissues with short T1 relaxation times, such as fat, and enhance tissues with high T2 properties, such as fluid, resulting in added tissue contrast. The opposite effect may be achieved with fluid-attenuation IR sequences. In addition to IR, tissue suppression may be achieved with fat or fluid saturation and opposed-imaging techniques.

Gradient-recalled echo (GRE) pulse sequences are used for rapid image acquisition, which minimizes motion artifact associated with breathing, the cardiac cycle, vessel pulsation, and bowel peristalsis. GRE sequences have low tissue contrast, with the exception of flowing blood, which is bright in signal, and are therefore ideal for cardiac and vascular applications. Fast

low-angle shot (FLASH) and true fast imaging with steady-state precession (FISP) are examples of this technique.

Although the inherent tissue contrast with MRI is excellent, the administration of contrast media can further improve the detection of pathology and subtle differences in tissue properties. Gadolinium chelates are the most commonly used MRI contrast agents, which, like the iodinated CT equivalents, are confined to the vasculature and do not cross an intact blood–brain barrier. Gadolinium is a heavy metal ion with paramagnetic effects that shorten T1 and T2 relaxation times. Although there are flow-related techniques for vascular imaging that do not require contrast media (e.g., time of flight imaging), the use of a contrast agent is essential for characterizing tissue perfusion. Once considered safe for patients with impaired renal function, the use of gadolinium-based contrast agents has now been associated with nephrogenic systemic fibrosis (NSF), a debilitating and potentially fatal condition of fibrin deposition within the skin and other organs.[5,9] Although the precise mechanism is not understood, patients with severe renal dysfunction (GFR < 30) who receive gadolinium-based contrast media are at increased risk of developing NSF. Additional contributing factors may include an underlying inflammatory state, utilizing higher doses of gadolinium, or repeated dosing over short intervals.[10] Careful patient evaluation, including a risk/benefit analysis, should be performed before administering gadolinium-based contrast agents in patients with impaired renal function.

One of the advantages of MRI over CT is that it can provide functional in addition to anatomic information. This is particularly beneficial in oncologic imaging. MRI techniques allow for tissue diffusion and perfusion imaging, quantification of blood flow by velocity phase encoding, and magnetic resonance proton spectroscopy, which provides biochemical quantification of tissues. DCE (dynamic contrast-enhanced) MRI uses sequential images after contrast delivery to calculate a transfer constant k^{trans}. In situations with low vascular permeability, the constant will be driven by the rate of transfer across the vessel wall into the extracellular space; however, with high permeability, k^{trans} will be proportional to blood flow. Pretreatment k^{trans} may predict for poor outcome with head and neck cancers, though a high k^{trans} may conversely be associated with residual disease cervical cancer.[11,12] Thus, this functional imaging technique may have differing applications in clinical scenario, reflecting the complexity of the tumor and its microenvironment.

Diffusion-weighted imaging (DW or DWI) MRI measures brownian motion within the cellular microenvironment and calculates an apparent diffusion coefficient (ADC) map. A region of low intensity in an ADC map reflects restricted diffusion, a state that may correlated with increased cellularity, as seen with malignancy or fibrosis. This may improve the specificity of breast MRIs for differentiating malignancy from benign processes and even predicting the grade of the lesion.[13] DWI MRI has also improved the detection rate of hepatic lesions and differentiates between benign and malignant processes.[14] Conversely, high pretreatment ADC in cervical cancers may be associated with poorer eventual disease-free survival, again reflecting how functional imaging may be revealing a complex interaction in the tumor microenvironment.[15]

As with other imaging techniques, MRI has modality-specific artifacts that can limit image quality. Motion artifact can be problematic with MRI because of long scan times and breath-holding required with some sequences. Chemical shift artifact results in a loss of signal at the interface of tissues with highly variable contrast properties. MRI is also sensitive to magnetic field distortions that can produce artifacts. Susceptibility artifact is one of the most common problems with MRI and is frequently attributable to objects that alter the magnetic field such as metallic hardware or devices, resulting in signal voids or distortion of MRI images. The magnetization of such objects also presents a safety hazard as items can overheat or become displaced, resulting in serious harm or injury. Patients must be carefully screened to ensure that any medical devices or surgical hardware are MRI compliant.

Ultrasonography

US is an imaging modality utilizing pulse-echo techniques rather than radiation to produce an image. The US transducer coverts electrical energy into a high-frequency pulse that is transmitted through tissues. The pulse interacts at tissue interfaces, generating a reflected echo signal that is detected by the transducer. The returning sound waves are transformed into a gray-scale image in real time. Image quality is, in large part, determined by the pulse frequency. High-frequency transducers (5 to 12 MHz) produce high-resolution images but have limited ability to penetrate tissue. Therefore, they are best suited to imaging superficial structures such as the breast or thyroid. Low-frequency transducers (1 to 3.5 MHz) generate lower-quality images but have better tissue penetration and are most often used for imaging abdominal and pelvic organs. The degree to which tissues are visualized by US is called *echogenicity*. Fat is highly

echogenic (bright), whereas fluid-containing structures, such as simple cysts, are anechoic (dark).

The quality of US images is highly dependent upon the user. Variability in experience can be problematic in the performance, reproducibility, and interpretation of US exams. Furthermore, US is prone to artifacts. Bone almost completely absorbs sound waves, resulting in acoustic shadowing that completely obscures tissues located beyond the bone. Air is also problematic as it almost completely reflects sound waves, leaving little pulse energy to penetrate tissues deep to the air. The application of a water-soluble gel between the transducer and the patient's skin eliminates air at the skin surface and ensures transmission of the US beam. Artifacts secondary to air markedly limit evaluation of lesions near the lung or bowel. In contrast to air, fluid readily transmits sound and makes an excellent "acoustic window" for imaging. This is the reason that patients are encouraged to drink plenty of fluids prior to a pelvic US examination—so that the bladder is fully distended.

Color Doppler US is an important adjunct to conventional gray-scale sonography. The Doppler effect is a change in frequency of returning sound waves reflected by a moving object, such as flowing blood. If blood flows away from the transducer, the echo frequency decreases, whereas if blood flows toward the transducer, the echo frequency increases. The change in frequency is directly proportional to the flow velocity and produces a color overlay in areas of flow on the standard gray-scale US image. Color Doppler US is useful in characterizing blood flow within lesions and assisting in image-guided procedures.

TABLE 35.4 ENDOSCOPIC ULTRASOUND WALL LAYERS OF THE ESOPHAGUS

Layer	EUS Characteristic	Histologic Layer	AJCC T Stage
1	Hyperechoic	Superficial mucosa	T1 *m*
2	Hypoechoic	Deep mucosa	T1 *m*
3	Hyperechoic	Submucosa	T1 *sm*
4	Hypoechoic	Muscularis propria	T2
5	Hyperechoic	Subserosa, serosa, adventitia	T3

AJCC, American Joint Committee on Cancer; EUS, endoscopic ultrasound; m, mucosa; sm, submucosa.

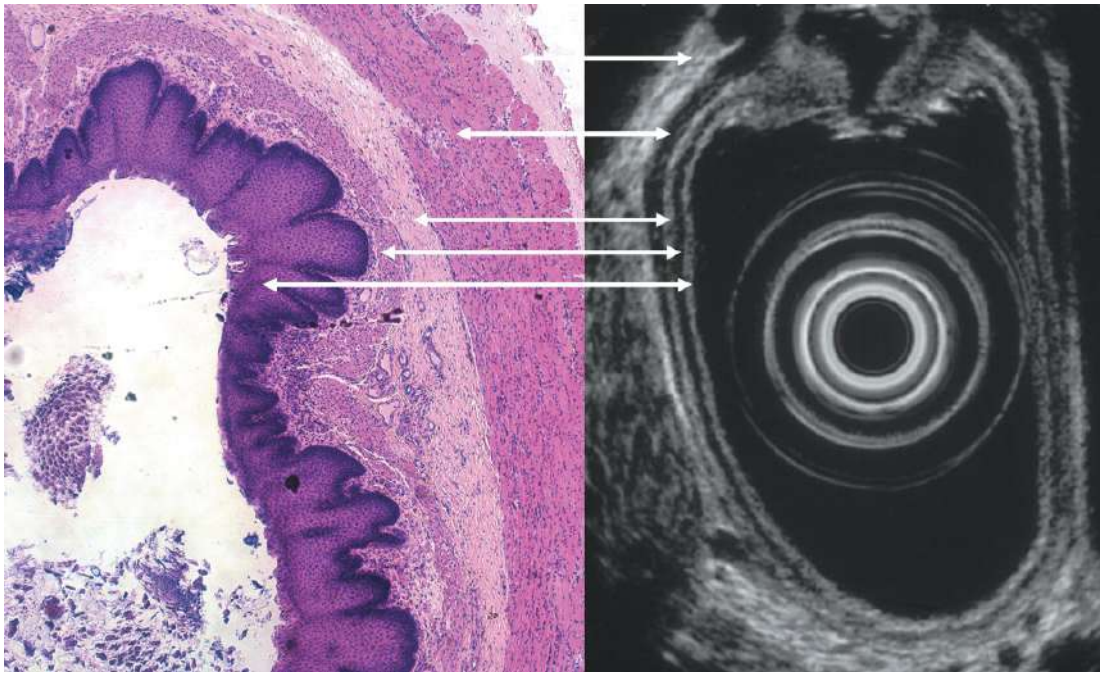

FIGURE 35.2. Axial endoscopic ultrasound image *(right)* and histologic specimen *(left)* from a normal esophagus. The endoscopic ultrasound layers and histologic layers of the esophagus are correlated (see Table 35.4). (Endoscopic ultrasound image courtesy of Dr. Frank Gress. Histologic image courtesy of Dr. Daniel Goodenough.)

Endoscopic ultrasound (EUS) was introduced in the early 1980s and has become an important tool in oncologic staging. It allows for high-resolution images of internal structures not typically accessible by high-frequency transducers by passing the probe through bowel or airways. It is most widely applied in the setting of gastrointestinal (GI) malignancies, especially esophageal and rectal carcinomas. A 5 to 12 MHz transducer can readily identify five of the layers of the GI tract (Table 35.4 and Fig. 35.2).[16] Higher-frequency transducers can identify additional layers, such as the muscularis mucosa and lamina propria of the esophagus, which has important staging implications. EUS is also utilized for characterization and image-guided sampling of regional lymph nodes in GI or bronchopulmonary disease. The ability of EUS to predict the tumor (T) stage is generally superior to its ability to predict the node (N) stage, although some imaging patterns of nodal involvement are recognized. Normal lymph nodes are usually ovoid, <10 mm in short axis, and have a homogeneous but variable echogenic appearance that may be isoechoic, hyperechoic, or hypoechoic to surrounding tissues. An echogenic (bright) center is common and represents the normal fatty hilum. Suspicious lymph nodes are typically round, >10 mm in short axis, have distinct margins, and are often hypoechoic. If all four features

are present, the likelihood of malignancy is 80% to 100%.[17] There is, however, considerable overlap between benign and malignant features of lymph nodes on EUS in addition to wide interobserver variability. Tissue sampling is therefore recommended for accurate staging. When describing clinical T and N staging by EUS, the prefix *u* should be utilized (e.g., uT3N1).

Nuclear Imaging

Although radiographic and cross-sectional studies provide important anatomic information regarding pathologic processes, nuclear radiology provides physiologic information based on the distribution of an injected or ingested radiopharmaceutical. Radiopharmaceuticals consist of a radioactive substrate (radionuclide, radioisotope, or radiotracer) that is coupled with a physiologically active compound or analog. For example, technetium-99m is a radioisotope that is coupled to pertechnetate, water-soluble ion salt that is targeted for imaging of the thyroid, bladder, stomach, and colon, among other organs. The timing of imaging depends on the kinetics of absorption, metabolism, and half-life of the radionuclide. Gamma rays emitted by nuclear decay of the radionuclide are then detected using a γ-camera corresponding to radiotracer activity that is described in terms of uptake.

There are numerous available nuclear imaging studies that take advantage of differing radiopharmaceuticals for oncologic imaging. Many of these play a primary role in the management of oncology patients with specific malignancies. However, the primary nuclear imaging studies relevant to general oncologic imaging are PET and bone scintigraphy. These studies have broad application for many malignant processes in the diagnosis, staging, and surveillance of disease.

Positron Emission Tomography

Although several radionuclides for PET are available, the most common is 18-fluorodeoxyglucose (FDG). FDG is a glucose analog that concentrates in areas of high metabolic activity. Tumor cells are often highly metabolic, with rapid cell division and an increased number of glucose transporters. However, FDG uptake is not specific for malignancy and accumulates in any cell with increased metabolic activity, including myocardium, gastric mucosa, brain tissue, thyroid, and salivary glands, which limits PET evaluation of these organs. Furthermore, FDG tracer is excreted within the urinary system; therefore, activity within the kidneys, collecting system, and bladder can obscure malignancy of these structures. Notwithstanding these limitations, PET-CT has become the preferred

imaging modality for clinical staging, facilitating the characterization of benign versus malignant pathology, detecting sites of unsuspected disease, identifying optimal sites for tissue sampling, assessing treatment response, and monitoring for recurrence for multiple malignancies.

Initially performed in isolation, PET is now routinely obtained in conjunction with CT. PET-CT combines the physiologic assessment of PET with the anatomic assessment of CT, resulting in improved diagnostic accuracy.[18] PET and CT may be obtained independently on the same day but are more commonly performed on a combined PET-CT scanner, which more precisely aligns the two imaging datasets for fusion such that the patient does not have to move between examinations. Patients must fast for 4 to 6 hours prior to scanning in order to limit metabolic activity within the GI tract. Blood glucose levels should be well controlled (<150 mg/dL) to limit glucose receptor competition with FDG, as high glucose levels can result in a false-negative scan. Speech and motion should be restricted to minimize muscle uptake, which could obscure pathology. Approximately 1 hour following FDG administration, a CT scan is performed immediately followed by PET imaging, which can take up to 60 minutes. CT and PET datasets are then reconstructed in separate axial, coronal, and sagittal series, as well as fused PET-CT images.

FDG uptake is nonspecific, localizing to any tissue with increased metabolic activity. Although most malignant tumors are hypermetabolic relative to normal tissues, nonmalignant processes also concentrate FDG, including foci of infection, inflammation, and benign neoplasms. FDG uptake is quantified by the standard uptake value (SUV). Most malignant tumors have a maximum SUV > 2.5, whereas physiologic uptake is typically <2.5. SUVs are not absolute and can be affected by the timing of imaging, improper attenuation correction, partial volume affects, patient weight, FDG dose, and factors affecting FDG uptake, as previously described. It is therefore difficult to accurately compare SUVs between scans. However, if care is taken to ensure that variables between studies are similar, such as performing the examination on the same scanner with similar patient preparation, FDG dosing, and image timing, comparing SUVs between studies may be reliable. Clinical studies to date have documented that under such uniform conditions, changes in SUV have prognostic value, indicating that most tumors responding to therapy show a 20% to 40% decrease in SUV early in course of treatment.[19–22]

The registration of CT and PET has led to novel ways of quantifying the burden of disease. Total lesion glycolysis (TLG), for example, is calculated by

multiplying the mean SUV in a segmented lesion by the volume of said lesion. This metric essentially weights the volume of disease by its metabolic activity in an attempt to reflect the true burden and has been associated with worse prognosis in non–small cell lung cancer (NSCLC).[23] Metabolic tumor volume (MTV), on the other hand, is a measure of tumor volume only counting voxels above a certain SUV threshold, either relative (such as a percentage of SUVmax) or an absolute SUV value. Higher pretreatment MTV is associated with poorer eventual outcome in head and neck cancers.[24]

Other radionuclides with potential application to oncologists include ^{18}F-fluoromisonidazole (F-MISO), ^{18}F-fluoroazaomycin arabinoside (F-FAZA), and copper-64 diacetyl-bisN4-methylthiosemicarbazone (^{64}Cu-ATSM), all of which have different mechanisms of colocating to intratumoral hypoxic regions.[25] As hypoxia is a driver of both prosurvival factors such as HIF-1α, and resistance to radiotherapy, these agents are of considerable research interest, though not yet of routine clinical utility.

Bone Scintigraphy

Normal bone undergoes continuous remodeling, maintaining a balance between osteoblastic and osteoclastic activity. Most bone metastases originate as intramedullary lesions, having gained access to the bone through the vasculature. As the lesions enlarge, reactive osteoblastic and osteoclastic activity results in characteristic radiographic changes indicative of bone metastases (sclerotic, lytic, or mixed lesions). Rapidly growing metastases tend to produce lytic lesions, whereas more slowly growing metastases typically produce sclerotic (or blastic) lesions. Metastases from multiple myeloma, thyroid cancer, and renal cell carcinoma are predominantly lytic, whereas blastic lesions are associated with breast and prostate cancers. The primary utility of bone scintigraphy in oncologic imaging is the detection of osseous metastatic disease.

Bone scintigraphy or bone scan imaging utilizes radiopharmaceuticals composed of bisphosphonates, the most common of which is the radionuclide technetium-99m methylene diphosphonate (^{99m}Tc-MDP). ^{99m}Tc-MDP localizes to areas of new bone mineralization, which occurs in a wide array of bone pathology and is therefore highly sensitive to osseous disease, but is not very specific. Although a 30% to 50% reduction in bone density must occur before bone metastases are detected on radiographs, as little as 5% to 10% change is required to detect such on a bone scan.[26,27] Furthermore, bone scans are relatively inexpensive, convenient, and visualize the entire skeleton, including

sites that are difficult to assess on plain films (e.g., ribs, sternum, scapula, sacrum). Reported sensitivities range from 62% to 100% with similar specificity rates (78% to 100%).[28]

Two primary patterns of radiotracer activity can be associated with malignancy: increased or decreased activity. Increased uptake occurs in areas of increased blood flow and osteoblastic activity; this is a common finding in metabolically active tumors and small sclerotic metastatic foci. Decreased radiotracer activity occurs as a "cold" area on bone scan and is associated with lytic bone disease and aggressive tumors that outgrow their blood supply. Rapidly progressing and purely lytic disease are the main causes of false-negative findings on bone scintigraphy, whereas false-positive findings can be related to trauma, healing, benign bone tumors, or arthritic changes. The false-positive rate of planar bone scintigraphy can be reduced by the use of single photon emission CT (SPECT), which can be obtained in conjunction with conventional CT or MRI for more precise localization of disease.[29,30]

Bone metastases are considered "nonmeasurable" using the Response Evaluation Criteria in Solid Tumors (RECIST).[31] Although a decrease in the intensity of radionuclide uptake is often ascribed to a response to treatment and an increase is attributed to progressive disease, several points must be considered. First, tumor treatment response may cause a "flare phenomenon," resulting in increased bone scan uptake secondary to new osteoblastic activity concomitant with new bone formation. This may be falsely attributed to progressive disease. Similarly, lytic lesions that were previously "cold" on bone scan can transform into "hot" spots (areas of uptake) after treatment. Second, rapidly progressive disease with overwhelming bone destruction without new bone formation can be misinterpreted as stable or responding disease on bone scan.

Many patients are at low risk of harboring occult osseous metastatic disease, and, in the absence of symptoms, a bone scan can be omitted from the staging workup. In prostate cancer, only approximately 1% of patients with a prostate-specific antigen (PSA) <10 will have a positive bone scan.[32,33] Patients with a Gleason score ≤7 and a PSA of 10 to 20 have a similar low risk of bone metastases.[34] In these patients, a bone scan should be omitted in the absence of symptoms. Similarly, a bone scan may be omitted in asymptomatic patients with node-negative breast cancer and lung cancer. Although studies have shown that MRI may be more sensitive than bone scans, especially for vertebral metastases, whole-body MRI is impractical and bone scintigraphy is considered sufficiently

sensitive that MRI should be reserved for equivocal bone scans in the context of high clinical suspicion or for patients with positive bone scans but low clinical suspicion. Like MRI, PET has been shown to be more sensitive than scintigraphy for the diagnosis of osseous metastatic disease with sensitivity of 91% and 75% and specificity values of 96% and 95%, respectively.[35] FDG-PET also provides earlier detection of metastases than bone scans, attributable to the fact that increased glucose metabolism in neoplastic cells occurs prior to increased osteogenesis (required for bone scintigraphy uptake). PET also has the advantage of providing more comprehensive imaging in that it can detect soft tissue metastases in addition to bone disease, whereas scintigraphy only evaluates osseous structures. As a general rule, patients with isolated osteoblastic metastases may be monitored by serial bone scans, whereas other clinical scenarios are likely best suited for PET.

Radiomics

Radiomics is a burgeoning field, combining large databases of radiographic data (usually of CT, MRI, or PET orgin) with high-throughput computing capabilities to detect emergent patterns of data associated with clinically relevant outcomes.[36] It borrows its name and much of its terminology from genomics and proteomics, utilizing similar computational techniques to detect signatures within the data, which may correlate to underlying tumor biology. An example of this is texture analysis, which derives several features of the intensity of not only a single voxel but its relationship to all neighboring voxels, which may potentially derive quantifiable measures of tumor heterogeneity, necrosis, and hypoxia.[37] However, it is worth noting that not only does it borrow its terminology with genomics, it similarly is susceptible to multiple comparisons and testing. When hundreds if not thousands of values can be derived from a finite pool of clinical data, the chances of spuriously positive correlations is quite high. It is incumbent, therefore, on all research in this promising field to externally validate all findings prior to clinical application.

BRAIN AND SPINE

Oncologic Anatomy

The Brain

The central nervous system consists of the brain and spinal cord. Both are covered with three meningeal layers—the dura mater, arachnoid mater, and pia

mater. Meningiomas are the most common tumors arising from the meninges. They arise from arachnoid cells but are typically affixed to the underside of the dura mater. They are well-circumscribed tumors that do not typically invade the underlying brain parenchyma. Thus, when planning a course of radiation therapy, only minimal margins are required to account for surrounding microscopic disease extent in the direction of the brain parenchyma. Many meningiomas will have a linear area of enhancement on MRI, extending from the tumor along the dura. This so-called dural tail is generally not felt to represent direct extension of tumor but rather vascular congestion within the dura, leading to the characteristic enhancement.[38,39] Thus, enlarging the target volumes to include this linear area of enhancement is probably unnecessary unless other imaging abnormalities are apparent (e.g., nodularity).

The arachnoid mater and pia mater are considered the leptomeninges with the intervening space (subarachnoid space) filled with cerebrospinal fluid (CSF). Cancer can breach the CSF space through several routes, including hematogenous spread (via the Batson venous plexus or the arterial system) or by direct extension. Once cancer breaches the subarachnoid space, the entire craniospinal axis is at risk, and tumor deposits can lead to increased intracranial pressure, cranial nerve deficits, radiculopathies, and seizures. Leptomeningeal involvement occurs most frequently with pediatric brain tumors (e.g., medulloblastoma), acute lymphoblastic leukemia, and some solid cancers (e.g., breast cancer, melanoma, and lung cancer in particular).[40]

The major units of the brain include the cerebral hemispheres, diencephalon, cerebellum, and brainstem. The cerebral hemispheres consist of the frontal, parietal, temporal, and occipital lobes, basal ganglia, and lateral ventricles. The diencephalon includes the thalamus, hypothalamus, and third ventricle. The brainstem consists of the midbrain, the pons, and the medulla oblongata. The fourth ventricle lies between the pons and the cerebellum. Although more than half of pediatric brain tumors arise in the posterior fossa (cerebellum and brainstem), the vast majority of primary brain tumors in adults arise in the cerebral hemispheres or diencephalon.

The hippocampus is a portion of the limbic system in the deep medial temporal lobes bilaterally and plays important parts in the development and maintenance of memory. It is also a region that is seldom a site of metastatic disease and therefore a potential region that may be spared to improve the therapeutic ratio of whole-brain radiotherapy. It has been demonstrated that there is a dose-dependent atrophy of the hippocampus after radiation therapy and a

dose-dependent decline in neurocognitive function.[41,42] A phase II trial from the RTOG demonstrated less cognitive decline in subjects treated with hippocampal-sparing whole-brain radiation compared to historical controls, demonstrating both feasibility and a significant signal for further study.[43]

Cranial Nerves

The cranial nerves consist of 12 paired nerves whose nuclei (with the exception of CN I) are located in the brainstem and upper spinal cord. They are termed cranial nerves because they exit the cranium through foramina in the base of skull and are encased by sheaths formed from the meninges. Nerve pathways connecting the cerebral cortex with the cranial nerves are complex. Although spinal motor neurons are innervated by the corticospinal tracts, many of the lower motor neurons in the brainstem are innervated by the corticobulbar tracts. These upper motor neurons innervate the cranial motor nuclei bilaterally (with some exceptions), in contrast to the nerves within the corticospinal tracts, which largely cross in the medulla leading to contralateral innervation.

Multiple tumors, both benign and malignant, commonly involve the cranial nerves, leading to serious neurologic deficits. Some of the more common include meningiomas involving the optic nerves (CN II), vestibular schwannomas (CN VIII), parotid gland tumors (CN VII), nasopharyngeal carcinoma (NPC) (multiple), and brainstem gliomas (multiple).

The classic presenting symptoms of diffuse pontine gliomas illustrate the intricate anatomy of the pons. A unilateral lesion in the ventral pons with involvement of the pyramidal tracts (upper motor neurons) might cause contralateral motor weakness in the arms or legs. In addition, cranial nerves within the pons might also be affected, unilaterally, without complete paralysis because of bilateral innervation of the cranial nerves by fibers in the corticobulbar tracts. Ataxia, denoting impairment of coordination without weakness, can be caused by involvement of fibers projecting from the pons to the cerebellum within the middle cerebellar peduncle. Through this pathway, the cerebellum receives a copy of the information for muscle movement that the corticospinal tracts relay to lower motor neurons, facilitating the complicated act of coordination.

The cranial nerves should also be carefully examined when evaluating a patient with NPC. One-fifth of patients with NPC present with symptoms of cranial nerve involvement (Table 35.5). The most commonly involved cranial nerves are the abducent nerve (CN VI) and the trigeminal nerve (CN V). CN VI

originates in the ventral aspect of the brainstem, ascends on the clivus, and crosses the internal carotid artery near the superior aspect of foramen lacerum before entering the cavernous sinus. It then exits the skull through the superior orbital fissure. The motor and sensory nerve roots of CN V exit the pons and pass underneath the free edge of the tentorium cerebelli into the Meckel cave, forming the trigeminal (gasserian) ganglion. From the ganglion, V_1 and V_2 enter the cavernous sinus and subsequently exit the skull through the superior orbital fissure and foramen rotundum, respectively. V_3 exits the skull through foramen ovale.

The nasopharynx is in close proximity to foramen lacerum, rotundum, and ovale, explaining the frequent tumor involvement of CN V and VI. Invasion superiorly to the foramen lacerum and involvement of the trigeminal ganglion could lead to dysfunction in all three branches of CN V. In fact, most patients with NPC and CN V involvement have isolated deficits of V_2 or V_3. This occurs because of extension into foramen rotundum and ovale, respectively (Fig. 35.3). After gaining access to the middle cranial fossa, NPC may extend superiorly into the cavernous sinus. Four cranial nerves, including two branches of CN V, pass through the cavernous sinus. Within the sinus, the oculomotor nerve (CN III) is located most superiorly, whereas the maxillary nerve (CN V_2) is located most inferiorly. One would suspect that cranial nerves located more superiorly in the cavernous sinus would be involved less frequently than those located closer to the base of skull. This is consistent with what is observed clinically (see Table 35.5).

TABLE 35.5 MAJOR FORAMINA AND OTHER APERTURES IN THE CRANIAL FOSSAE AND THEIR PRIMARY CONTENTS AND CLINICAL ASSOCIATION WITH NASOPHARYNGEAL CANCER

Foramina/Opening	Contents	Frequency of Involvement by NPC (152) (%)
Anterior Cranial Fossa		
Foramina in cribriform plate	Axons of olfactory cells (CN I)	0
Middle Cranial Fossa		
Optic canal	Optic nerve (CN II) Ophthalmic artery	6
Superior orbital fissure	Oculomotor nerve (CN III)	9

	Trochlear nerve (CN IV)	17
	Abducent nerve (CN VI)	44
	Ophthalmic nerve (CN V_1)	45
Foramen rotundum	Maxillary nerve (CN V_2)	67
Foramen ovale	Mandibular nerve (CN V_3)	48
Foramen spinosum	Meningeal branch of CN V_3	14
	Middle meningeal artery/vein	
Foramen lacerum	Internal carotid artery[a]	
Petrous Portion of the Temporal Bone		
Internal acoustic meatus	Facial nerve (CN VII)[b]	
	Vestibulocochlear nerve (CN VIII)	9
	Labyrinthine artery	0
Posterior Cranial Fossa		
Jugular foramen	Glossopharyngeal nerve (CN IX)	20
	Vagus nerve (CN X)	20
	Spinal accessory nerve (CN XI)	14
	Internal jugular vein (superior bulb)	
Foramen magnum	Spinal roots of spinal accessory nerve (CN XI)	14
	Medulla	
	Vertebral artery	
	Anterior/posterior spinal artery	
Hypoglossal canal	Hypoglossal nerve (CN XII)	24

[a]After entering the skull through the carotid canal.
[b]The facial nerve exits the skull through the stylomastoid foramen.
NPC, nasopharyngeal carcinoma.

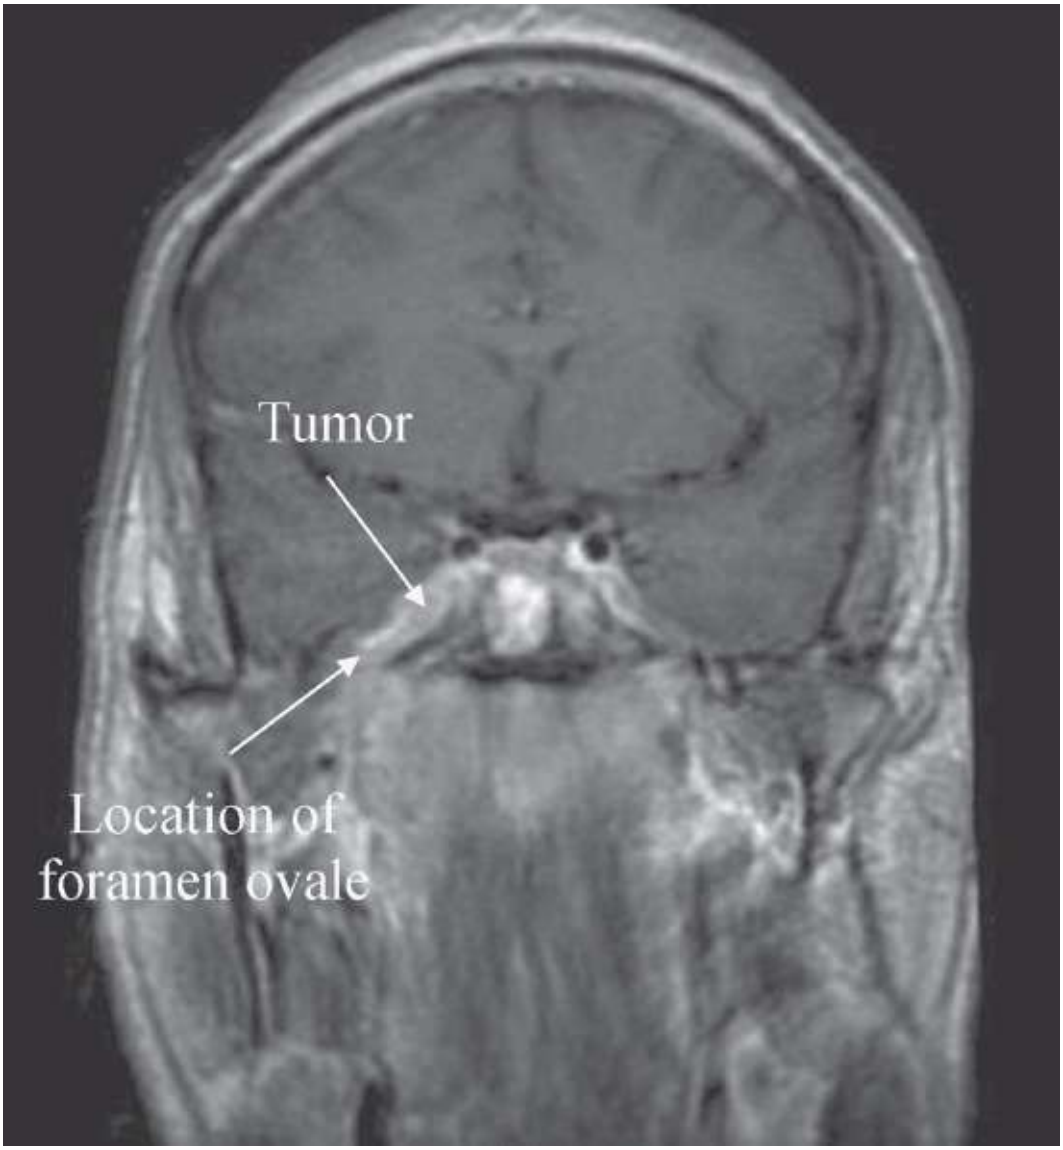

FIGURE 35.3. Coronal T1 magnetic resonance image with contrast demonstrating nasopharyngeal carcinoma extending through foramen ovale into Meckel cave.

Lower cranial nerve involvement can occur without intracranial extension. The fossa of Rosenmüller is the most common site of origin of NPC. The lateral border of the fossa of Rosenmüller is the pharyngeal space. Direct tumor extension laterally into the parapharyngeal space or lymphatic metastases to high parapharyngeal lymph nodes can affect the cranial nerves exiting the jugular foramen (CN IX, X, and XI) and hypoglossal canal (CN XII). This may result in loss of the gag reflex (CN IX), hoarseness or dysphagia (CN X), atrophy or paralysis of trapezius and sternocleidomastoid (CN XI), as well as tongue deviation (CN XII).

Spine

The vertebral column typically consists of 33 bones (7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal). The sacral and coccygeal vertebral bodies are fused. Although all individuals have seven cervical vertebral bodies, variations in the number of the other vertebral levels are occasionally observed. The spinal cord is housed within the spinal canal and encased by the meninges. Spinal cord levels do not correspond with levels of the vertebral column. In adults, the spinal cord typically ends at the L1-2 interspace (termed the *conus medullaris*). In an infant, the spinal cord terminates at L2 or L3. However, the spinal nerves continue to descend within the spinal canal (termed the cauda equina). The subarachnoid space, containing CSF, typically extends to the second sacral vertebral body. At this level, the meninges fuse together and extend caudally as the filum terminale, which anchors the spinal cord to the coccyx. These anatomical issues have implications when evaluating a patient with spinal cord compression, when designing craniospinal fields, and when setting up palliative spine fields.

Oncologic Imaging

Intracranial Metastases

Approximately 50% of adult intracranial neoplasms are metastatic, with lung, breast, melanoma, renal, and colon cancers being the most common, in order of decreasing frequency. Among individual primaries, melanoma is associated with the highest frequency of brain metastases.[44,45] Most metastases gain access to the brain through the vasculature and typically arise at the junction of the gray and white matter, presumably because the caliber of blood vessels decreases at this point, acting as a trap for tumor emboli.[45] Approximately 80% of brain metastases are found in the cerebral hemispheres, with less frequent involvement of the cerebellum (15%) and brainstem (5%), reflecting their smaller volume and blood flow.

The detection of brain metastases is an important part of initial staging. Furthermore, because of improved treatment strategies and overall cancer survival, the overall incidence of brain metastases is increasing. The preferred imaging modality for the diagnosis of intracranial metastasis is contrast-enhanced MRI. Brain metastases are typically well circumscribed and avidly enhance (Fig. 35.4). They are also typically associated with a disproportionate amount of surrounding edema best depicted on T2-weighted sequences. MRI is more sensitive than CT in detecting intracranial metastases, and approximately

20% of patients with solitary metastatic lesions by CT show multiple lesions on MRI.[46] Furthermore, for patients with a single brain metastasis detected with a conventional single-dose MRI-contrasted study, triple-dose studies will depict additional metastases in up to 25% of patients.[47] The detection of multiple lesions aids in directing appropriate treatment and helps to distinguish metastases from primary brain tumors, which are more commonly solitary.

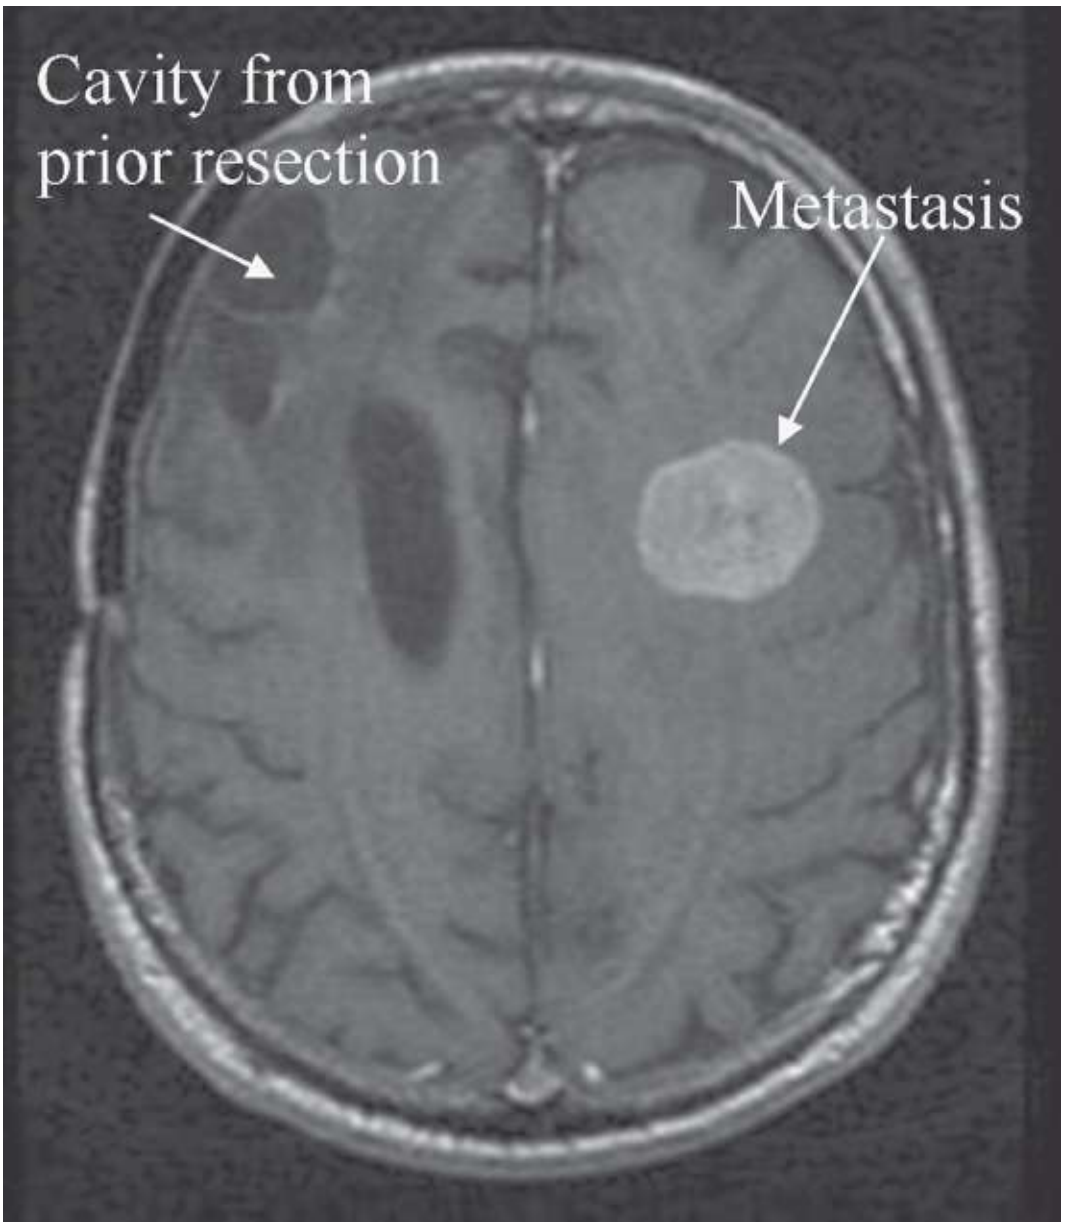

FIGURE 35.4. Axial T1 magnetic resonance image with contrast demonstrating a 2.5-cm melanoma brain metastasis in the left frontal lobe. Note the prior resection cavity in the right frontal lobe.

Primary Brain Malignancy

Primary brain tumors account for approximately 50% of adult intracranial masses, of which half are malignant. The most common malignant primary brain tumor in adults is glioblastoma multiforme (GBM), which usually arises in the cerebral hemispheres. Compared with CT, MRI is more accurate in delineating the local gross extent of disease. In a series of 52 patients with primary brain tumors, the MRI signal abnormality was larger than that identified by CT in 62% of patients. Furthermore, 10 patients with equivocal CT scans had clear abnormalities on MRI.[48] GBMs are characterized by an expansile mass that is iso- to hypointense to surrounding tissue on T1-weighted images, with central necrosis and peripheral ring enhancement postcontrast administration. T2-weighted imaging shows a heterogeneous mass with high signal of the tumor nidus and surrounding T2-signal abnormality corresponding to vasogenic edema, in which malignant cells are known to frequently reside.[49] Central areas of low signal reflect a combination of blood products, necrosis, and vascular flow voids.

GBM most commonly grows along white matter tracts and does not typically involve the dura or skull. GBM is one of two entities that may spread into the contralateral cerebral hemisphere via tracts of the corpus callosum; central nervous system lymphoma is the other. Other potential routes of spread, including subependymal extension with CSF contamination or hematogenous dissemination, are possible but unusual.

Advanced imaging techniques are also beneficial in characterizing intracranial malignancy. Magnetic resonance spectroscopy (MRS) provides metabolic and biochemical information about tumors in relation to normal brain tissue by quantifying five metabolite peaks: choline (Cho)-containing compounds, Cr, *N*-acetylaspartate (NAA), lactate, and lipid: the Cho peak reflects cell membrane turnover, Cr is a surrogate for energy synthesis, and NAA is a marker exclusive to neuronal cells. Lactate is detected in necrotic tumors and infarcted tissue and results from anaerobic metabolism. Lipid peaks are produced by cellular and myelin breakdown products. The hallmark spectroscopic pattern of brain tumors is an increase in Cho-containing compounds and a decrease in NAA relative to normal brain tissue. MRS can also aid in the evaluation of tumor type and grade. High-grade gliomas tend to exhibit higher Cho:Cr and Cho:NAA ratios. High-grade gliomas also typically have higher lipid and lactate peaks as the result of necrosis.[50] MRS can also distinguish metastatic disease from high-grade gliomas, particularly when combined with perfusion MRI.[51] Differentiating radiation necrosis from

recurrent or progressive tumor remains a significant challenge in imaging, though delayed contrast extravasation (DCE) MRI has shown early promise in differentiating between active tumor (fast extravasation) and benigh processes (slow extravasation).[52]

Conventional PET-CT has limited utility in the assessment of brain neoplasms because of the high metabolic rate of normal brain tissue. However, delayed-phase PET, performed approximately 3.5 hours following FDG injection, allows for washout of FDG from normal brain cells, whereas abnormal tissue retains FDG. Delayed phase PET has been shown to be beneficial in detecting both primary and metastatic brain lesions as well as differentiating between residual or recurrent tumor and radiation necrosis following treatment.[53,54] The development of new radioisotopes for neurologic applications, such as ^{11}C-methionine for targeting gliomas, has demonstrated clinical utility and advantages over FDG and might have similar utility in metastases. Many of these new tracers target different cellular processes such as apoptosis, angiogenesis, and hypoxia; the latter being of particular prognostic importance as hypoxic tissue is less sensitive to chemotherapies.[55] The utility of delayed phase PET may be further enhanced through fusion with MRI.[56]

Spinal Metastases

Osseous metastases are common in many malignancies, and the vertebral bodies are frequently involved because of the vascular distribution to the spine. MRI is more sensitive at detecting early vertebral body metastases than both radiographs and CT as it can image changes within the marrow space before cortical destruction occurs. Given that PET has similar sensitivity as MRI for osseous metastatic disease, is performed as part of routine staging, and can image the entire body, MRI is reserved for troubleshooting, such as determining extent of invasion into adjacent tissues. One notable exception is the use of urgent MRI for identification of cord compression in the setting of acute neurologic compromise. In this situation, it is often the T2-weighted sequences that are most useful: the high-signal CSF provides contrast to identify disease encroaching into the spinal canal. Spinal cord edema can also be identified. One should consider screening the entire spine when evaluating for cord compression.

Spinal cord compression is often considered an oncologic emergency, because the longer the duration of symptoms, the less likely the patient will regain function. Thus, therapy is often instituted emergently in these cases (e.g., with radiation, steroids, surgery, or sometimes chemotherapy in sensitive tumors).

There is often discordance between the imaging and clinical examination findings. It is the *clinical* findings that determine the acuity of the situation rather than the imaging findings. A radiologic finding of cord compression certainly warrants a timley evaluation, but does not necessarily warrant emergent intervention in the absence of symptoms.

HEAD AND NECK

Oncologic Anatomy

The anatomy of the head and neck is complex, and it is important that oncologists have an intimate understanding of the location, function, and radiographic appearance of the various subsites. The potential for significant morbidity associated with local tumor progression and recurrence in the head and neck region, as well as the associated late effects of curative treatment, necessitates attention to detail. The impact of anatomy is such that the Accreditation Council for Graduate Medical Education mandates cadaver lab experience for otolaryngology residency.

Lymphatic Drainage of the Head and Neck

The lymphatics in the head and neck region largely proceed in an orderly fashion from sites in the upper aerodigestive tract into the common jugular chains, which eventually empty into systemic circulation near the junction of the internal jugular and subclavian veins. There are notable exceptions to this orderly drainage that can influence radiation treatment planning. In order to discuss this in a systematic fashion, the lymphatic basins of the neck are divided into six distinct levels, with surgical and radiographic boundaries.[57]

Level I is defined as both the submental basins (level IA) and the submandibular basins (level IB) and receive drainage from the oral cavity, although this basin may also be at risk from other sites in the setting of advanced nodal disease (N2b or greater). Level II contains the upper jugular nodes, extending from the C1 vertebral body to the hyoid bone, including the contents of the carotid sheath and the space deep to the sternocleidomastoid muscle (SCM). Level II is subdivided into anterior (level IIA) and posterior (level IIB) regions, as defined by the posterior border of the jugular vein. Level II contains the jugulodigastric node at the level of the jugular vein as it crosses the posterior belly of the digastric muscle and is a common lymphatic pathway for the majority of the upper aerodigestive tract. Level III follows the carotid sheath and

space posterior to the SCM from the hyoid bone to the cricoid and receives efferent lymph drainage from level II. Level IV continues to follow the same jugular chain to the level of the clavicle. Level V contains the posterior triangle of the neck, boarded by the trapezius posteriorly, the SCM anteriorly, and the clavicle inferiorly, and is at particular risk for nasopharyngeal primaries. Level VI are the prelaryngeal lymph nodes (delphian nodes), which extend from the inferior edge of the thyroid cartilage to the sternal notch, bounded laterally by the sternal heads of the SCM. Level VI is at risk in laryngeal cancers with subglottic or transglottic extension and for hypopharyngeal cancers with esophageal extension.[58]

In addition, there are two other regions not included in this level classification that are worthy of consideration. Just superior to level II, following the carotid sheath to the skull base are the junctional or retrostyloid nodes, which may be at risk when there is ipsilateral nodal disease. Medial to these nodes and to level II lie the retropharygeal nodes (or nodes of Rouviere), which lie in the regions anterior to the prevertebral fascia, which in turn surrounds the longus capitis and the longus colli muscles. The retropharyngeal nodes extend superiorly to the skull base and inferiorly to the hyoid bone and are at risk of cancers arising from the nasopharynx, posterior pharyngeal wall, and the pyriform sinus.[59]

The Oral Cavity

The oral cavity encompasses three major subsites: the oral tongue, the floor of mouth, and the buccal mucosa. Carcinomas originating from the oral tongue have potential to spread locally through the intrinsic and extrinsic muscles of the tongue, inferiorly to the floor of mouth, and posteriorly to the anterior tonsillar pillar. For the floor of mouth, the genioglossus, geniohyoid, and root muscles of the tongue are at risk for local disease spread, as well as levels IA and IB of the neck, laterally to the alveolar ridge and mandible. Tumors of the buccal mucosa may extend superiorly to the infratemporal fossa, inferiorly to the submandibular region, anteriorly to the lip commissure, and posteriorly to the retromolar trigone.[59]

Nasopharynx, Oropharynx, and Hypopharynx

The nasopharynx is bounded superiorly and posteriorly by the sphenoid sinus, clivus, and the prevertebral fascia of C1 and C2. The parapharyngeal space lies laterally to the nasopharynx, which in turn is bounded laterally by the medial pterygoid muscle. The parapharyngeal space offers few anatomic barriers for the

direct invasion of tumors superiorly and laterally to the base of skull, resulting in cranial nerve deficits as noted above. The eustachian tube empties into the nasopharynx at the torus tubarius; just posterior to the torus is the pharyngeal recess (or fossa of Rosenmüller), a fold of mucosa that is a frequent site for primary malignancies of this region.

The oropharynx anteriorly is bounded by the base of tongue, laterally by the tonsils, superiorly by the soft palate, and posteriorly by the posterior pharynx. Tumors arising from the base of tongue are often difficult to assess for extent of disease; therefore, the entire base of tongue, proximal oral tongue, and vallecula are at risk for subclinical disease. MRI may aid in delineation of the GTV for this site.[60] Tonsillar cancers may involve the base of tongue, palate, and buccal mucosa, although in locally advanced cases, they may also involve the nasopharynx, parapharyngeal space, and pterygoid muscles. Soft palate tumors may extend laterally to the tonsillar pillars and superiorly to the pterygopalatine fossa.

The pharyngeal constrictor muscles (PCM) lie along the posterior aspect of the naso- and oropharynx, bounded by the parapharyngeal space. The PCM may be further divided into (1) the superior PCM starting at the occipital condyle to the hyoid; (2) the middle PCM, starting 0.5 cm superior to the hyoid and ending at the inferior edge of the hyoid; and (3) the inferior PCM, which continues from the inferior aspect of the hyoid to the esophagus. The middle PCM was initially implicated as an organ at risk, with dose–volume metrics associated with late swallowing problems.[61] Since then, dose to other swallowing structures such as the genioglossus, mylo-geniohyoid complex, the anterior digastric, and the superior PCM have also been implicated in later dysphagia.[62]

Carcinoma arising from the posterior and lateral pharyngeal walls may spread superiorly to the nasopharynx and inferiorly to the hypopharynx. Similarly, primaries of the hypopharynx may spread superiorly through the oropharynx and nasopharynx. Malignancies of the pyriform sinus may also place the ipsilateral larynx at risk.

Larynx

The larynx is subdivided into three anatomic regions: the supraglottis (containing the epiglottis, the arytenoid and aryepiglottic folds, and the ventricular bands or false cords), the glottis (a 1-cm plane extending inferiorly from the lateral margin of the ventricle, including the true vocal cords and commissures), and the subglottis (from the inferior border of the glottis to the

inferior aspect of the cricoid). The true cords have essentially no lymphatic drainage, allowing for focal treatment of a limited primary tumor without elective nodal treatment. In contrast, the supraglottic larynx has a rich and bilateral lymphatic system, requiring either dissection or elective nodal radiotherapy for even early primary tumors. The subglottis is a rare site of primary tumors and may invade locally into soft tissue as well as metastasize to laryngeal and tracheal lymphatics.

Oncologic Imaging

For cancer of the head and neck, staging relies on careful physical examination, fiberoptic and direct laryngoscopy, directed biopsies, and integration of imaging modalities. Contrast-enhanced CT is the standard imaging modality for carcinomas of the head and neck region (Fig. 35.5). MRI may be a superior imaging modality for evaluating the extent of primary tumors of the oral cavity, oropharynx, and nasopharynx.[63] Novel approaches with MRI have shown promise in evaluating tumor responses to treatment by measuring physiologic changes within the tumor. Dynamic contrast-enhanced MRI may give insight into the vascular permeability (k-trans) in the tumor microenvironment; k-trans is found to be significantly higher in complete responders to concurrent chemoradiation therapy and therefore may be a predictor of treatment response.[64,65] Diffusion-weighted MRI may also provide information about the cellularity of a tumor mass or involved lymph node; an increase in the ADC (corresponding to a decrease in cellularity) during chemoradiation has been correlated with improved 2-year local control in one series.[66]

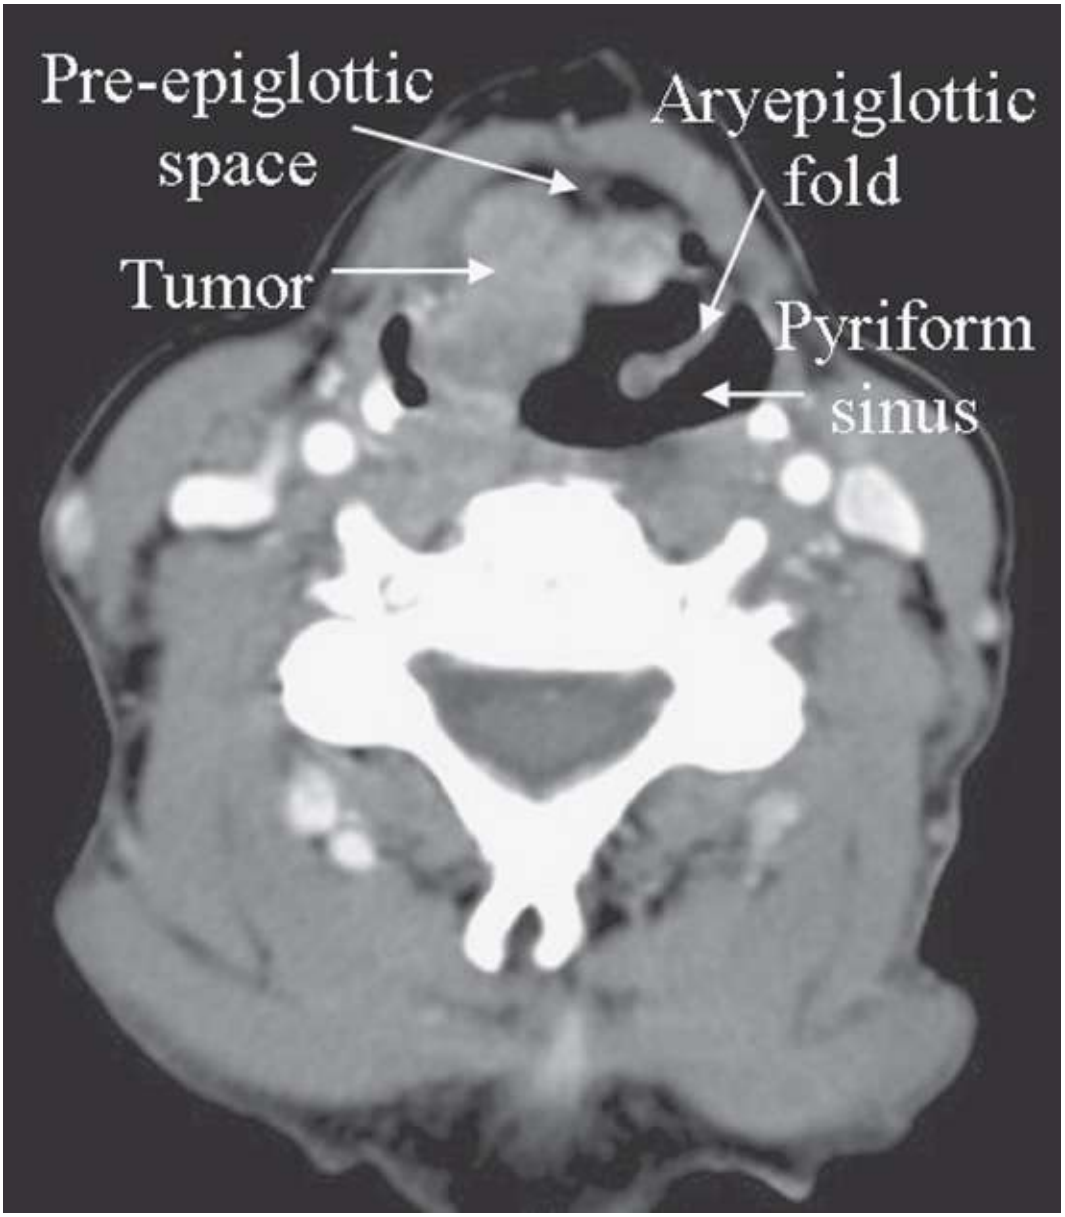

FIGURE 35.5. Axial computed tomography image demonstrating a squamous cell carcinoma involving the right aryepiglottic fold with anterior extension into the pre-epiglottic space.

FDG-PET imaging for head and neck cancer has been useful as an adjunct to MRI and CT, particularly in clarifying the significance of intermediate lesions. In one series, the addition of FDG-PET imaging improved the accuracy of tumor delineation from 40% to 70% with MRI or CT alone to 97% to 100%, altering the management of 23% of the patient under study.[67] Another series found FDG-PET to have a sensitivity of 88% in determining the primary tumor and a sensitivity of 82% and specificity of 100% for lymph node metastases.[68]

However, in initial staging, no noninvasive imaging modality has a high enough negative predictive value to forgo appropriate dissection or elective nodal irradiation when the characteristics of the primary tumor suggest a significant risk of spread. That is in contrast to the value of FDG-PET after chemoradiation for the detection of residual nodal disease. The sensitivity for detection of persistent disease was 96% with a specificity of 72% in a posttreatment series, with a negative predictive value in some series as high as 99%, allowing for the abandonment of routine posttreatment neck dissections in patients with a complete clinical and PET response.[69,70] Novel PET tracers such as Cu64-ATSM and F18-misonidasole, designed to evaluate hypoxia within the tumor, may also prove to be clinically useful.[71]

THE BRACHIAL PLEXUS

Oncologic Anatomy

The brachial plexus originates from the primary rami of the C5 through the T1 vertebral levels and joins to form three nerve trunks (upper, middle, and lower) in the neck. These trunks divide as they course beneath the clavicle, forming three cords (lateral, medial, and posterior) in close approximation to the axillary artery, posterior to the pectoralis minor. The cords then form the three primary terminal nerves for the arm (the median, ulnar, and radial nerves) as well as the musculocutaneous nerve. These peripheral nerves are of particular importance because of the significant morbidity associated with injury, either from tumor invasion or from treatment-related toxicity. As the plexus traverses the neck and axilla, it is of particular relevance when treating tumors of the head and neck, upper thorax, and breast.

Oncologic Imaging

Identifying the brachial plexus is difficult on CT imaging and may be most directly visualized on MRI.[72,73] However, one may accurately contour the position of the trunks, divisions, and cords on noncontrast CT imaging based on bony, muscular, and vascular landmarks.[74] The method put forward by Hall et al. begins contouring at the origination of the vertebral foramina of C5 through T1. The anterior and middle scalene muscles are then identified, with the trunks lying in the space between these muscles. The middle scalene will end at the superior aspect of the first rib just as the divisions of the plexus will be joining with the axillary artery as a neurovascular bundle. The artery then can be

followed laterally as a surrogate for the remainder of the cords into the upper arm. Of interest to breast treatment, the course of the plexus will be brought superior and lateral with the upper arm with abduction, though still constrained by its course underneath the clavicle (Fig. 35.6).

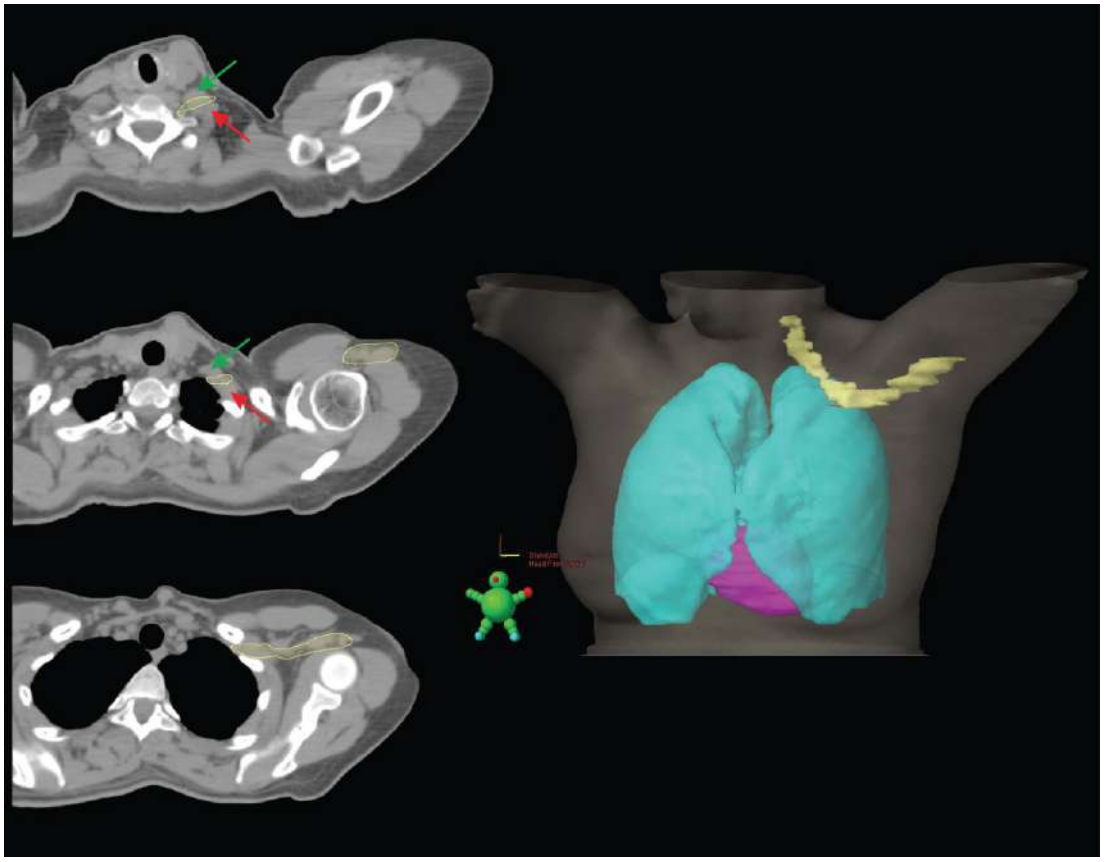

FIGURE 35.6. The brachial plexus (*yellow contour*) is delineated on axial computed tomography images on a woman undergoing treatment to the left breast. The anterior scalene (*green arrow*) and middle scalene (*red arrow*) are identified. The brachial plexus is delineated in the space between these muscles, originating at the C5-T1 roots and continuing to the axillary neurovascular bundle. The course of the plexus is contoured more distally than clinically necessary to emphasize the course and location when the arm is abducted.

THE THORAX

Oncologic Anatomy

The thorax consists of the superior part of the trunk and contains several important structures including the heart, lungs, esophagus, and pleura. Primary tumors of the heart are extremely rare. On the other hand, lung cancer is the leading cause of cancer mortality in the United States and the incidence of

esophageal carcinoma is rising. Other common malignancies that arise in the thorax include malignant pleural mesothelioma, thymic malignancies, and Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).

There are many clinically relevant anatomical issues when evaluating patients with cancers of the thorax, particularly lung cancer. These include (a) lobe-specific patterns of lymphatic spread, (b) the complex anatomy surrounding the lung apex, (c) the extent of the pleural space, (d) esophageal landmarks, and (e) thymic architecture.

Patterns of Lymphatic Spread

Lung cancer, both non–small cell and small cell histologies, frequently metastasize to regional lymph nodes. A basic understanding of mediastinal lymph node stations and lobe-specific lymphatic spread is helpful when evaluating and planning treatment for patients with lung cancer. The mediastinal nodes are a complex system, and it is challenging to predict where lymph node metastases will develop. However, these basic patterns provide a framework for customizing local treatment approaches (surgery and radiation therapy).

Both anatomical and clinical studies have shown that bronchogenic tumors frequently spread directly into mediastinal lymph nodes, bypassing intrapulmonary and hilar lymph nodes. This phenomenon appears to occur more frequently for upper lobe tumors.[75] For right-sided tumors, these pathways most frequently lead to ipsilateral paratracheal and subcarinal lymph node stations. For left-sided tumors, particularly those arising in the left upper lobe, direct spread to para-aortic and aortopulmonary (AP) window stations predominates. Second, right lung segments drain predominantly into the ipsilateral mediastinum. Conversely, left lung tumors commonly spread to both sides of the mediastinum,[75–77] especially left lower lobe tumors. Third, direct passageways to the supraclavicular fossa exist but are rare. Clinically, supraclavicular failures are uncommon and are usually associated with failure in upper paratracheal lymph node stations.[78] Fourth, most clinical studies have shown that subcarinal lymph nodes are frequently involved by both upper and lower lobe tumors.

The Superior Sulcus

The superior sulcus of the lung is surrounded by multiple critical structures. The subclavian artery and vein pass anterior to the lung apex, the brachial plexus and its branches cross over the apex of the lung toward the arm, and the stellate ganglia lie posteriorly alongside the exiting nerve roots of the lower cervical and

upper thoracic spine. Other structures that can be involved by superior sulcus tumors include the vertebral bodies, trachea, and esophagus. Patients with superior sulcus tumors present with a variety of presentations (arm edema, hand weakness, sensory deficits, and/or Horner syndrome) related to the local extent of their disease.

The Pleura

The lungs are enclosed within a pleural sac. The visceral pleura is adherent to all of the surfaces of the lung, including the individual lobes where the pleura extends into the fissures. The parietal pleura is adherent to the thoracic wall, mediastinum, and diaphragm. The pleural recesses are potential spaces where portions of opposed parietal pleura are in contact during quiet respiration (Fig. 35.7). The inferior extension of the costodiaphragmatic recess can be easily underestimated, as can the medial extent of the costomediastinal recess (see Fig. 35.7). The inferior aspect of the costodiaphragmatic recess often extends to the level of the midkidney. The posteromedial extent of the pleura often wraps anteriorly over the descending aorta.

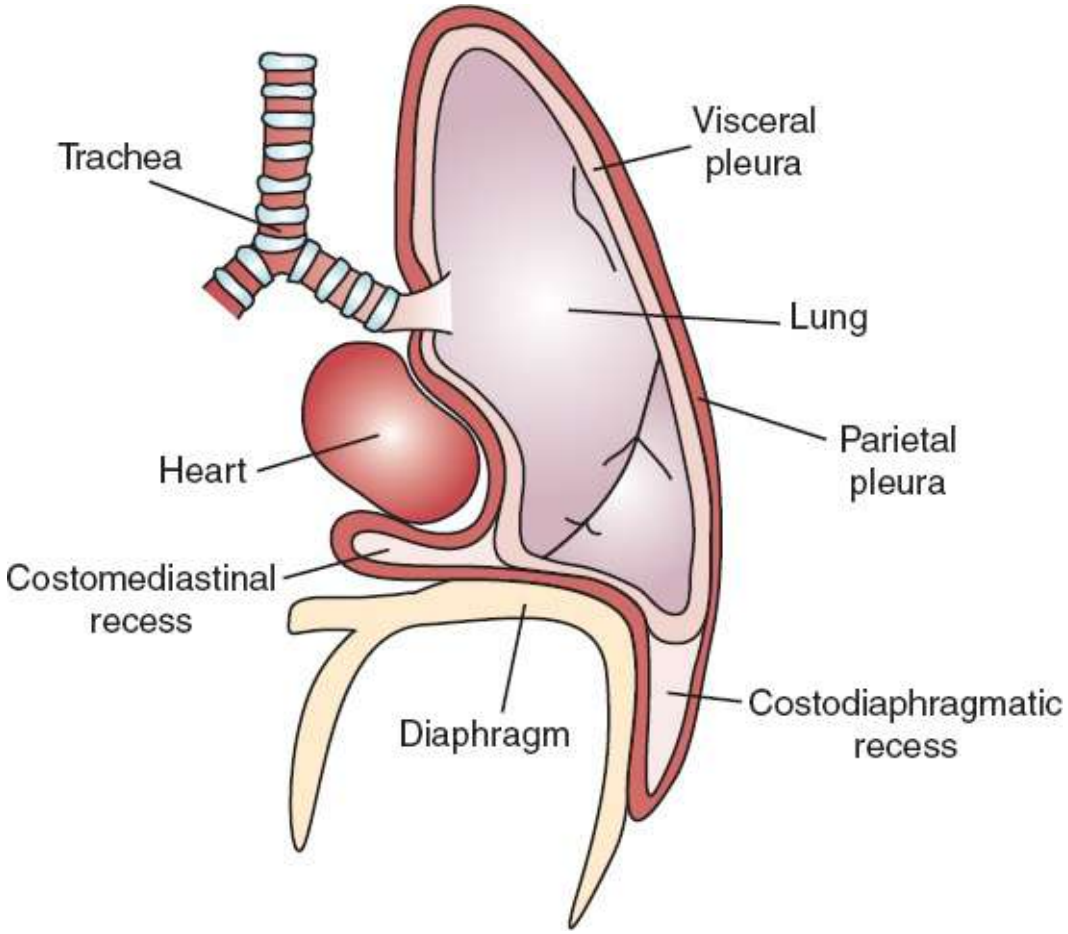

FIGURE 35.7. The extent of the pleura is illustrated. Note the inferior extension of the costodiaphragmatic recess and the medial extension of the costomediastinal recesses. (Courtesy of the University of Bristol, Centre for Applied Anatomy.)

Malignant mesothelioma is a rare pleural neoplasm associated with prior asbestos exposure. Pathologically, it can be categorized into epithelial, sarcomatoid, and mixed histologic subtypes. Mesothelioma initially involves the pleura and grows by contiguous spread from the pleural space into the lung, chest wall, mediastinum, pericardium, and diaphragm. The extent of the pleural spaces has implications for postoperative radiation target volumes (Fig. 35.8).

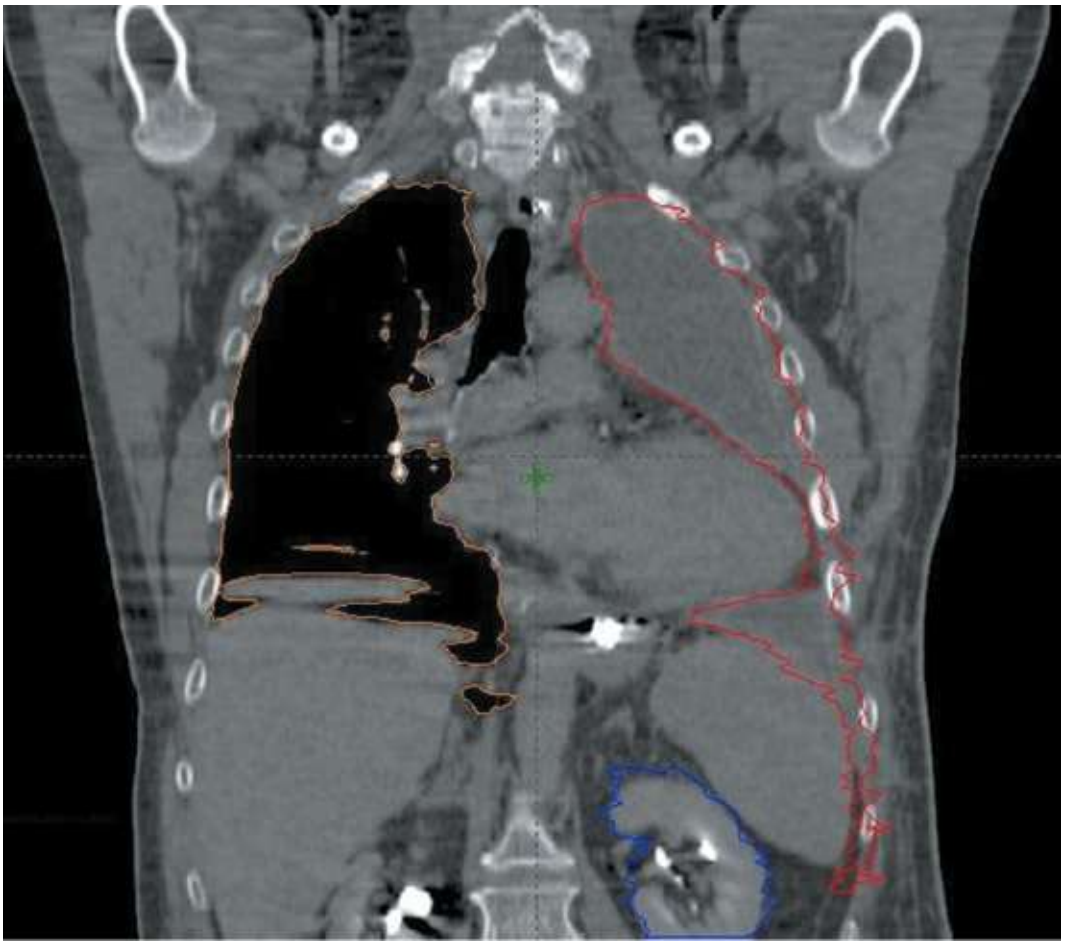

FIGURE 35.8. Digitally reconstructed coronal image from a treatment planning computed tomography scan illustrating the inferior extent of the costodiaphragmatic recess, which extends to the level of the midkidney. The patient had previously undergone an extrapleural pneumonectomy at which time metallic clips were placed, demarcating the inferior extent of the recess. The clinical target volume is illustrated in *red.*

Esophageal Anatomy

The esophagus extends from the cricopharyngeus muscle at the level of the cricoid cartilage to the gastroesophageal junction in the abdomen. The cervical esophagus extends from the cricopharyngeus muscle (~15 cm from the incisors) to the level of the thoracic inlet (~18 cm from the incisors). The thoracic esophagus extends from the thoracic inlet to the diaphragm and is sometimes divided into upper, middle, and lower sections. The carina is located at approximately 25 cm from the incisors and the gastroesophageal junction is located at approximately 40 cm. These general numbers are helpful when planning radiation fields based on staging studies that include endoscopy, EUS, and PET.

Thymus Architecture

The thymus is an encapsulated, bilobed gland situated in the superior anterior mediastinum and is involved in adaptive immunity. Although prominent in size during infancy and early childhood, it begins to involute during adolescence. The thymus decreases significantly in size in most patients after administration of chemotherapy but typically regrows during the recovery phase, sometimes to a larger size than at baseline.[79]

The thymus gland is composed of both lymphocytes and epithelial cells. Thymic neoplasms are a common cause of anterior mediastinal masses. Thymomas and thymic carcinomas arise from epithelial elements within the thymus. Primary mediastinal (thymic) large B-cell lymphoma arises from B-cells within the thymus and T-cell lymphoblastic lymphomas arise from T-cells within the thymus.

Thymomas are the second most common primary mediastinal neoplasm in adults following lymphoma and are classified on a histologic spectrum from thymoma to thymic carcinoma. Once thymomas extend through the capsule, they can invade other regional structures, including the lungs and great vessels, sometimes rendering them inoperable. The thymus gland lies within the pleural envelope. The most common pattern of spread is within the pleural and pericardial spaces. Lymphatic and hematogenous metastases are rare.

Oncologic Imaging

Non–Small Cell Lung Cancer

Treatment decisions are often predicated on the status of the mediastinum in patients with operable NSCLC. Patients with operable disease, without mediastinal involvement, generally proceed directly to resection, whereas those with mediastinal lymph node involvement typically receive induction therapy or definitive chemoradiotherapy. The historical noninvasive staging tool has been CT. In general, the sensitivity and specificity of CT are less than optimal with a false-positive rate of approximately 40% and a false-negative rate of 20%[80–82] (Table 35.6). Thus, mediastinoscopy or endobronchial ultrasound (EBUS) is often utilized to pathologically stage the mediastinum. These procedures are associated with a low rate of morbidity. Nevertheless, if noninvasive studies prove to be highly accurate, invasive mediastinal staging might be avoided in some patients.

Numerous studies and meta-analyses[80–82,88,89] have assessed the ability of CT, PET, and integrated PET-CT to accurately stage the mediastinum in patients

with NSCLC (see Table 35.6). Although significant heterogeneity exists among the individual studies, several conclusions can be drawn. First, the positive predictive value of CT is poor (around 50%). PET and PET-CT are somewhat better (80% to 90%). Still, 10% to 20% of patients with PET abnormalities in the mediastinum will have no evidence of disease at mediastinoscopy, although insufficient sampling may be explanatory in some cases. Therefore, many still advocate mediastinoscopy in the setting of a positive PET. The negative predictive value of PET and PET-CT appears to be better, especially when there are no enlarged lymph nodes visible on CT.[90] Nonetheless, most guidelines recommend invasive mediastinal staging prior to resection given the inherent limitations of PET.

TABLE 35.6 "ACCURACY" OF COMPUTED TOMOGRAPHY AND POSITRON EMISSION TOMOGRAPHY FOR MEDIASTINAL STAGING OF NON–SMALL CELL LUNG CANCER

End Point	Toloza et al.[83]	Gould et al.[84]	Dwamena et al.[85]	Darling et al.[86] (%)	Bille et al.[87] (%)
Computed Tomography (CT)					
Sensitivity	0.57	0.61	0.60		
Specificity	0.82	0.79	0.77		
Positive predictive value	0.56		0.50		
Negative predictive value	0.83		0.85		
Positron Emission Tomography (PET)					
Sensitivity	0.84	0.85	0.79		
Specificity	0.89	0.90	0.91		
Positive predictive value	0.79		0.90		
Negative predictive value	0.93		0.93		
Positron Emission Tomography/Computed Tomography (PET/CT)					
Sensitivity				70	54
Specificity				94	92
Positive predictive value				64	74
Negative predictive value				95	82

Localization of the esophagus is important during treatment planning of lung

cancer. The esophagus is often well visualized on CT. However, its course can be tortuous and its exact location is often uncertain. Having the patient swallow dilute contrast during the planning CT can assist in localization of the esophagus. The heart and spinal canal (as a surrogate for the spinal cord) are also well seen on CT. The substructures of the heart, however, are often challenging to define on CT. If one were to try to preferentially spare or consider the dose to cardiac substructures, an MRI or nuclear medicine cardiac image might provide additional information.

Esophageal Carcinoma

The most commonly used staging tools for esophageal carcinoma are barium swallow, EUS, CT, and PET. EUS, as previously discussed, is the most accurate modality to assess depth of invasion (T stage) but is less accurate in assessing nodal involvement (N stage) (Fig. 35.9). The ability to perform fine-needle aspiration biopsies of suspicious nodes, primarily disease in the celiac axis, has increased the ability of EUS to stage regional nodes. The reported accuracy of EUS for T and N stage is approximately 85% to 90% and 75%, respectively.[91,92] CT is primarily used to assess for metastatic disease. It is fairly unreliable in predicting T or N stage. The optimal role of PET in esophageal cancer staging is undefined, but it is generally used to evaluate for local or regional nodal disease and distant metastases. However, the sensitivity of PET for local or regional nodal disease does not appear to be superior to EUS.[93] PET may be most helpful in detecting distant metastases and differentiating patients who have residual disease after neoadjuvant chemoradiotherapy, requiring surgical resection, from those who are complete responders and may be spared the morbidity of surgery.[94]

Mesothelioma

CT best evaluates suspected mesothelioma for initial diagnosis and surgical planning. The characteristic CT appearance is focal or diffuse nodular pleural thickening, which demonstrates enhancement post contrast administration.[95] MRI is not routinely used in the diagnosis of mesothelioma but is a complementary modality with better sensitivity than CT for depicting chest wall, diaphragmatic, and pericardial invasion.[96] PET is often performed for staging to detect distant and nodal metastases. However, it can also be helpful in establishing the initial diagnosis when CT findings are subtle, as even small foci of disease are typically highly FDG-avid.

Superior Sulcus

Superior sulcus tumors are NSCLCs that arise in the apex of the lungs and invade surrounding structures such as the chest wall, vertebral bodies, and/or brachial plexus. Imaging plays a crucial role in the diagnosis and staging of superior sulcus tumors including CT, MRI, and/or PET-CT. CT is best to define the primary tumor and detect rib or vertebral body invasion. CT may also identify suspicious pulmonary nodules that may be below the threshold for PET detection. Contrast-enhanced MRI using T1-weighted sequences is best for determining resectability by assessing the brachial plexus.[97] The primary role of PET is to identify distant and nodal metastases.

Thymic Malignancy

Thymic neoplasms often go undetected until they are quite large and become symptomatic, at which time they may be depicted as a mediastinal mass on chest radiography. The role of imaging is to diagnose and stage patients. With respect to thymoma, this involves detecting local invasion and distant disease, thereby identifying patients who may benefit from neoadjuvant therapy prior to resection (e.g. Masaoka stage III or IV). Contrast-enhanced CT is best for characterizing thymomas and detecting local invasion. High-grade tumors tend to be larger in size, have irregular margins, enhance heterogeneously, and have regions of necrosis; mediastinal lymphadenopathy may also be present. Direct invasion into the pleura, pericardium, and vessels is often difficult to detect by CT unless extensive. A preserved fat plane between tumor and adjacent structures is a negative predictor of invasion; however, this finding has poor positive predictive value.[98] Therefore, mere contiguity of tumor with a structure or loss of normal anatomic planes is not sufficient to preclude surgical resection. CT features that have been correlated with stage III or greater disease include primary tumor size 7 cm or larger, lobulated margins, and infiltrative changes of the mediastinal fat surrounding the mass.[99]

THE BREAST

Oncologic Anatomy

Breasts are present in both males and females, although they are only well developed in the latter with the onset of puberty. In the male, generally only a few ducts are present, which nonetheless can rarely develop into malignancy, particularly in the context of *BRCA2* mutations.[100] In the female, the breast originates from a roughly circular base or bed extending from the lateral border of the sternum to the midaxillary line from medial to lateral and from the second through sixth ribs superior to inferior. The upper outer quadrant extends along the pectoralis major toward the axilla, forming the axillary tail of Spence. This is also the most frequent quadrant for primary breast cancer (~40%), which may be simply due the additional breast tissue associated with the tail.[101] Just posterior to the breast is the retromammary space, consisting of loose connective tissue, allowing for movement on the breast on the chest wall. Two-thirds of the breast rests on the deep pectoral fascia, which lies over the pectoralis major; the remainder rests on the fascia of the serratus anterior.

The breast tissue consists of lactiferous ducts that each drain 15 to 20

mammary gland lobules, and it is these ducts that are the origin of the majority of both noninvasive (ductal carcinoma *in situ*) and invasive disease (invasive ductal carcinoma). The breast is then anchored to the skin by suspensory ligaments (or Cooper ligaments) and interspersed with fat lobules. These ligamentous attachments to the skin become more prominent with breast edema or congestion due to tumor involving the dermal lymphatics, resulting in the characteristic appearance of peau d'orange.

The lymphatic drainage of the breast is primarily to the axilla, although the upper outer quadrant may drain to the intermediary intrapectoral nodes (or Rotter nodes) lying between the pectoralis major and pectoralis minor muscles, and the inner quadrants may drain to the internal mammary nodes (IMN). The axilla is divided into three sections with relation to the pectoralis minor muscle; the nodes found inferolateral to the muscle are termed level I, those beneath the muscle are termed level II, and those medial to the muscle are level III. Level I and II are generally removed in a standard axillary dissection, whereas the level III and the subsequent infraclavicular and supraclavicular basins are generally not considered resectable and are the target of radiotherapy if the more proximal basins have disease.

In a study of the location of sentinel nodes from various breast quadrants, the majority of drainage in all breast quadrants was to the axilla, and isolated drainage to the IMN was very rare (<6% in any quadrant).[102] However, identification of an additional IMN sentinel was found in 10% to 50% of cases dependent on quadrant (the upper outer quadrant was lowest at 10%, and the lower inner quadrant was most frequent at 52%). In surgical series in which the IMNs were routinely dissected, the incidence of isolated IMN disease was limited to 5% to 15%.[103–105] The risk of involvement increased when the axilla was also involved (20% to 55%), dependent on the axillary disease burden and location of the involved quadrant of the breast (Table 35.7). When IMNs were involved, the majority were located in the first three intercostal interspaces (first interspace 80%, second 75%, third 40%, and fourth 5%).[105] A margin of 4 mm medially and laterally to the internal mammary vessels encompasses the 90% of nodes in this region and may be a reasonable CTV for treatment.[109] That stated, irradiation of the IMN nodes remains controversial, though recent randomized data has found a modest benefit in terms of disease-free and cancer-specific survival when IMN and medial supraclavicular fields are treated.[110,111]

TABLE 35.7 RISK OF INTERNAL MAMMARY LYMPH NODE

INVOLVEMENT BASED ON STATUS OF AXILLA AND LOCATION WITHIN THE BREAST

Scenario	Livingston and Arlen[106] (%)	Urban and Marjani[107] (%)	Noguchi et al.[108] (%)
Negative axilla	8	8	5
Outer quadrant primary	5	10	ns
Medial/central primary	14	16	ns
Positive axilla	33	52	35
Outer quadrant primary	23	43	ns
Medial/central primary	48	55	ns
1–3 + axillary nodes	ns	ns	20
≥4 + axillary nodes	ns	ns	52

ns, not stated.

Oncologic Imaging

Mammography remains the preferred imaging modality for the diagnosis and follow-up of both invasive and noninvasive disease. Multiple randomized trials have shown that screening mammography reduces the risk of breast cancer mortality by 20% to 35% in women aged 50 to 69.[112–115] The efficacy of screening in younger women (aged 40 to 49) and elderly women (aged 70 or older) is less certain. Most published guidelines suggest initiating screening at age 40. Screening mammography includes two standard views of each breast: a craniocaudal (CC) view and a mediolateral oblique (MLO) view. These images are taken at approximately 45-degree angulation to each other (i.e., they are not orthogonal). Although the CC view is oriented in the long axis of the patient (i.e., superior/inferior), the MLO is oriented in the medial-superior/lateral-inferior direction. The MLO view increases visualization of the upper outer quadrant and tail of the breast, whereas the CC view ensures adequate visualization of the inferior and medial aspects of the breast. Additional views, such as spot compression, can be utilized to further evaluate suspicious lesions.

The majority of women (~95%) with abnormalities on a screening mammogram do not have breast cancer; thus, the positive predictive value is low. Overall, the sensitivity of screening mammography is approximately 75% (i.e., 25% of women diagnosed with breast cancer have a history of a normal mammogram 12 to 24 months prior to diagnosis). Sensitivity and specificity

vary widely depending on breast density; for fatty versus dense fibroglandular breasts, reported sensitivities are 87% versus 63%, whereas specificities are 92% versus 68%, respectively.[116–118] Furthermore, sensitivity and specificity differ between screen-film versus digital mammography, with digital systems generally having higher diagnostic accuracy in women with dense breast tissue compared to film mammography.[119]

Systematic interpretation and unambiguous reporting is important for any screening study. Given the prevalence of breast malignancy and its clinical implications, the Breast Imaging Reporting and Data System (BI-RADS) was developed and constitutes guidelines for standardized reporting and quality assurance of screening mammography within the United States (Table 35.8). Mammographers are ahead of their radiology colleagues in this regard as the BI-RADS system affords a clear unambiguous means of quantifying the "suspiciousness" of mammographic findings. Systems similar to BI-RADS would be helpful for other imaging modalities as a means to reduce the risks of misunderstanding and miscommunication between radiologists and other care providers.

TABLE 35.8 BREAST IMAGING REPORTING AND DATA SYSTEM (BIRADS) CATEGORIES USED FOR MAMMOGRAPHY EXAMINATIONS AND RISK OF MALIGNANCY

Assessment Category	Assessment	Definition	Risk of Malignancy
0	Need additional imaging evaluation	A lesion is noted for which additional imaging is needed	n/a
1	Negative	Breasts appear normal	<0.1%
2	Benign finding	A negative mammogram result but the radiologist wishes to describe a finding	<0.1%
3	Probably benign finding; short-interval follow-up suggested	Lesion with a high probability of being benign	<2%
4	Suspicious abnormality—biopsy should be considered	A lesion is noted for which the radiologist has sufficient concern to recommend a biopsy	25%–50%
5	Highly suggestive of malignancy	A lesion is noted that has a high probability of being cancer	75%–99%

n/a, not available.

Features of concern for malignancy at mammography include a focal mass, irregular borders, and microcalcifications. Spiculation can be due to invasion into, or reactive changes within, the surrounding breast parenchyma. However, spiculated masses can also be secondary to fat necrosis, postoperative scarring, or other nonmalignant processes. Calcifications associated with ductal carcinoma *in situ* or invasive carcinoma are typically pleomorphic (heterogeneous) in appearance and clustered in a localized area (Fig. 35.10). Linear, branching calcifications are suggestive of intraductal carcinoma. Round, well-circumscribed lesions, with or without coarse calcifications, are often benign.

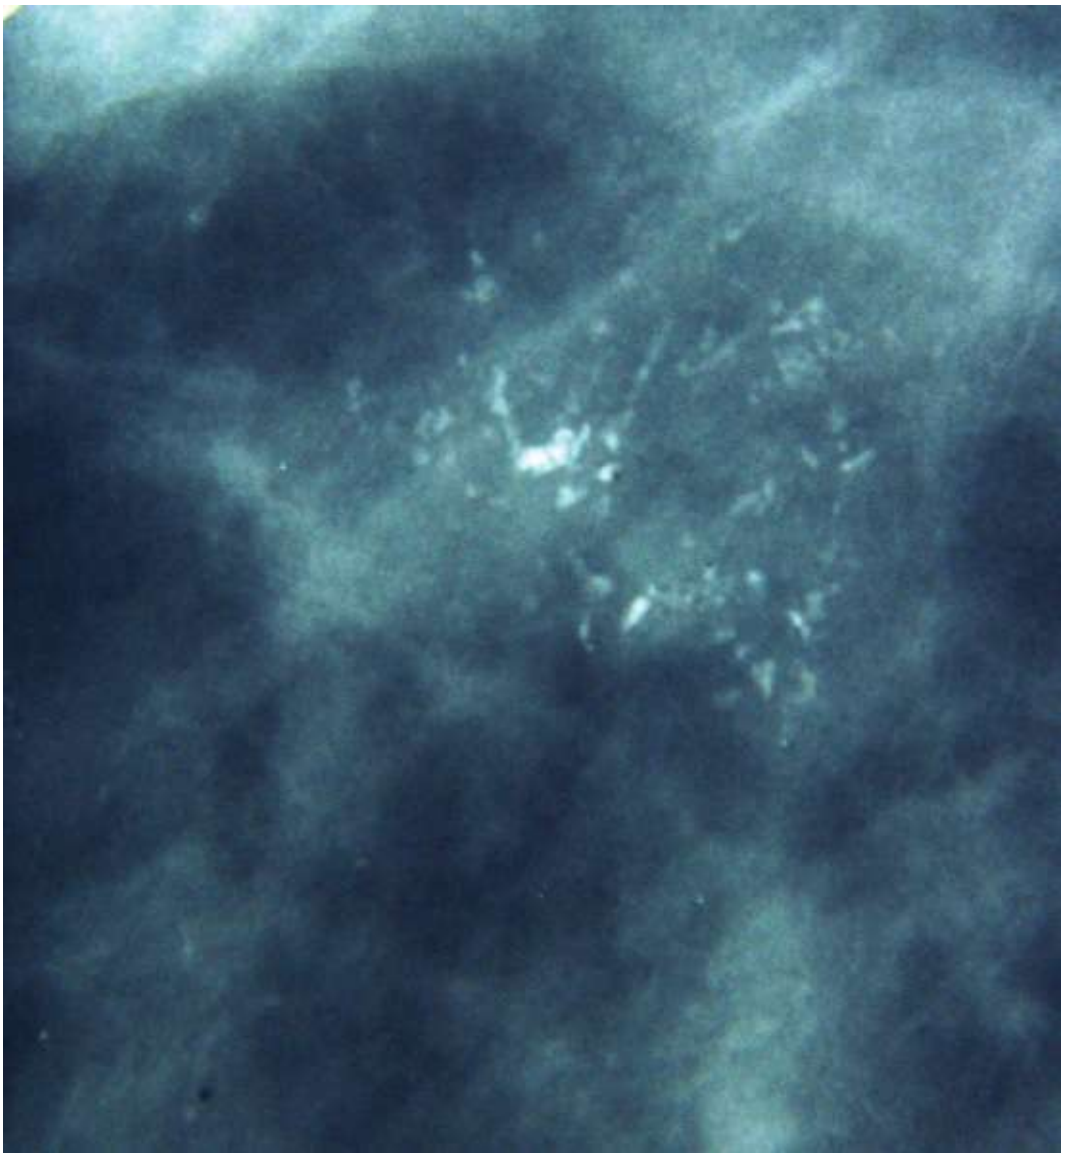

FIGURE 35.10. Clustered, pleomorphic calcifications visualized on mammography. The patient was found to have ductal carcinoma *in situ.*

Abnormalities on screening mammogram are generally followed with a diagnostic mammogram, in which supplemental and magnified views may be obtained to detect and characterize microcalcifications. Breast US is often performed to further characterize suspicious lesions, guide core biopsy, and assess regional lymph nodes. It is most helpful in differentiating fluid-filled cysts from solid tumors. MRI is not routinely recommended for upfront screening, except in patients with dense breast tissue and those at very high risk for primary breast malignancy, including those with *BRCA* mutations or women who received chest radiation therapy at a young age (typically <30 years old).[120] In addition to T1 and T2 lesion characteristics, patterns of MRI enhancement and washout kinetics are beneficial in evaluating concerning lesions. MRI can also be used for biopsy image guidance. After biopsy confirmation of disease, MRI has been examined in an attempt to better diagnose multifocal or contralateral disease preoperatively. One trial found contralateral cancers on MRI in 3% of their cohort, at the cost of performing a biopsy in 12%.[121] Preoperative MRI, however, did not improve the requirement for reoperation in a randomized UK trial.[122] The only clinically relevant outcome that routine use of preoperative MRI appears to have changed is that more women are having mastectomies as opposed to breast conservation.[123]

Digital tomosynthesis is a method of generating three-dimensional breast imaging from several planar x-ray images taken at differing angles. It is distinct from CT in that the resolution is much higher, consistent with conventional mammography, the images are not taken in axial sections, and only a limited rotational angle is utilized. Generally, digital tomosynthesis appears to result in higher cancer detection rates, with fewer false positives, as it allows for distinguishing overlapping lesions, that may confound planar imaging.[124] As such, it is beginning to supplement screening for high-risk individuals, particularly those in follow-up after radiation treatment.[125]

THE ABDOMEN

Oncologic Anatomy

Many diverse malignancies arise from abdominal structures. The most common are epithelial cancers of the stomach, pancreas, colon, liver, kidney, and biliary tract, including the gallbladder. Cancers of the kidney and colon are not often

managed with radiation therapy and are not discussed further. Several relevant anatomical issues include (a) site-specific patterns of lymphatic spread for gastric cancer, (b) local disease extension of pancreatic cancer rendering a tumor inoperable, and (c) anatomy of the biliary tree.

Gastric Cancer: Patterns of Lymphatic Spread

The stomach is a distensible organ located in the left upper abdomen. It is classically divided into four parts: the gastroesophageal junction (cardia), fundus, body, and pylorus (antrum). Although the incidence of epithelial malignancies of the distal stomach has declined in Western countries over the past century, the incidence of malignancies of the gastroesophageal junction is increasing. Lymph node involvement is common in gastric cancer, likely because of the extensive submucosal and subserosal lymphatic networks. This rich lymphatic network places all lymph node regions within the abdomen at risk of harboring regional metastases, irrespective of the part of the stomach involved. However, some general patterns have been observed, which can facilitate rational radiation treatment planning for gastric cancer.

For tumors within the stomach, the perigastric region located along the greater and lesser curvatures of the stomach are typically the initial draining lymph node basin. The other primary lymph node regions are those along the three arterial branches of the celiac axis (common hepatic, left gastric, splenic). Secondary and tertiary drainage sites include lymph nodes in the hepatoduodenal, peripancreatic, para-aortic, mesenteric, and middle colic region.

A large surgical series from Japan demonstrated that the most common site of lymph node involvement was along the lesser and greater curvature (perigastrics), regardless of the part of the stomach involved (11% to 40%).[126] As expected, lymph node involvement around the cardia was unusual for distal stomach tumors (0% to 7%) but common for proximal tumors (13% to 31%). Similarly, infrapyloric lymph nodes were commonly involved for distant gastric cancers (49%) but rare for proximal tumors (3%). Other common sites of lymph node involvement included those along the left gastric artery (19% to 23%), common hepatic artery (7% to 25%, greatest for distal tumors), and celiac axis (8% to 13%). The risk of splenic hilar involvement has varied among surgical series but is generally highest for proximal tumors.[127,128] Based on these and other data, guidelines have been published outlining proposed radiation fields for gastric cancer based on site of involvement within the stomach.[129,130]

Pancreas

The pancreas is an elongated digestive gland posterior to the stomach. It is classically divided into four parts: the head, neck, body, and tail. The pancreatic head is nestled within the curve of the duodenum and this is where most pancreatic carcinomas arise. The pancreas has a rich lymphatic network and is in close proximity to multiple other abdominal organs and structures, making surgical resection difficult and negatively affecting long-term cure rates (resectability is the most important prognostic factor).

Biliary Tree

Hepatocytes within the liver secrete bile (an important agent for digestion) into bile canaliculi, the initial branches of the intrahepatic duct system. These canaliculi drain bile into larger and larger channels that eventually become the left and right hepatic ducts, draining bile from the left and right lobes of the liver, respectively. These exit the liver from the porta hepatis and join to form the common hepatic duct (~4 cm in length). The cystic duct joins the common hepatic duct to form the common bile duct (~10 cm in length). The common bile duct extends to, and empties into, the duodenum. It lies alongside the hepatic artery and portal vein.

Biliary tract cancers include adenocarcinomas of the gallbladder and bile ducts, the latter referred to as cholangiocarcinomas. Cholangiocarcinomas include intrahepatic, perihilar, and distant extrahepatic biliary malignancies. Klatskin tumors are perihilar tumors that involve the bifurcation of the common hepatic duct. Both resectability and prognosis increase for more distally located biliary tumors.

Oncologic Imaging

Pancreatic Cancer

The pancreas can be imaged with US, CT, and MRI. MDCT with IV contrast and thin-section reconstructions optimize pancreatic tissue characterization and allow for detection of small tumors as well as vascular and ductal invasion. CT also defines the surgical anatomy to determine resectability and can detect regional and distant metastases (Fig. 35.11).

Adenocarcinoma of the pancreas most frequently arises in the head of the gland, to the right of the superior mesenteric or portal vein. It usually appears as a hypodense mass relative to the normally enhancing pancreas. Surgical resection typically provides the only chance of cure, and CT with thin-section

reconstructions and IV contrast enhancement is an important technique to assess resectability. Encasement of the superior mesenteric artery (SMA) or celiac trunk defines an unresectable T4 tumor. On the other hand, the presence of a fat plane around the celiac trunk and SMA, along with a patent superior mesenteric or portal vein, defines potentially resectable disease. Borderline cases include those with tumor abutment on the SMA, severe unilateral superior mesenteric vein (SMV) or portal vein impingement, or adjacent organ invasion. CT does not, however, detect small volume peritoneal or surface liver metastases that can be identified with laparoscopy. Oral contrast during radiation planning scans can be helpful to define the stomach and duodenum. MRI may be performed when CT findings are equivocal or there is a contraindication to administering iodinated contrast; however, there is no diagnostic advantage of MRI over contrast-enhanced CT (sensitivity of 84% vs. 86%, respectively).[131] The role of FDG-PET for pancreatic cancer diagnosis and staging remains uncertain and is not routinely performed.

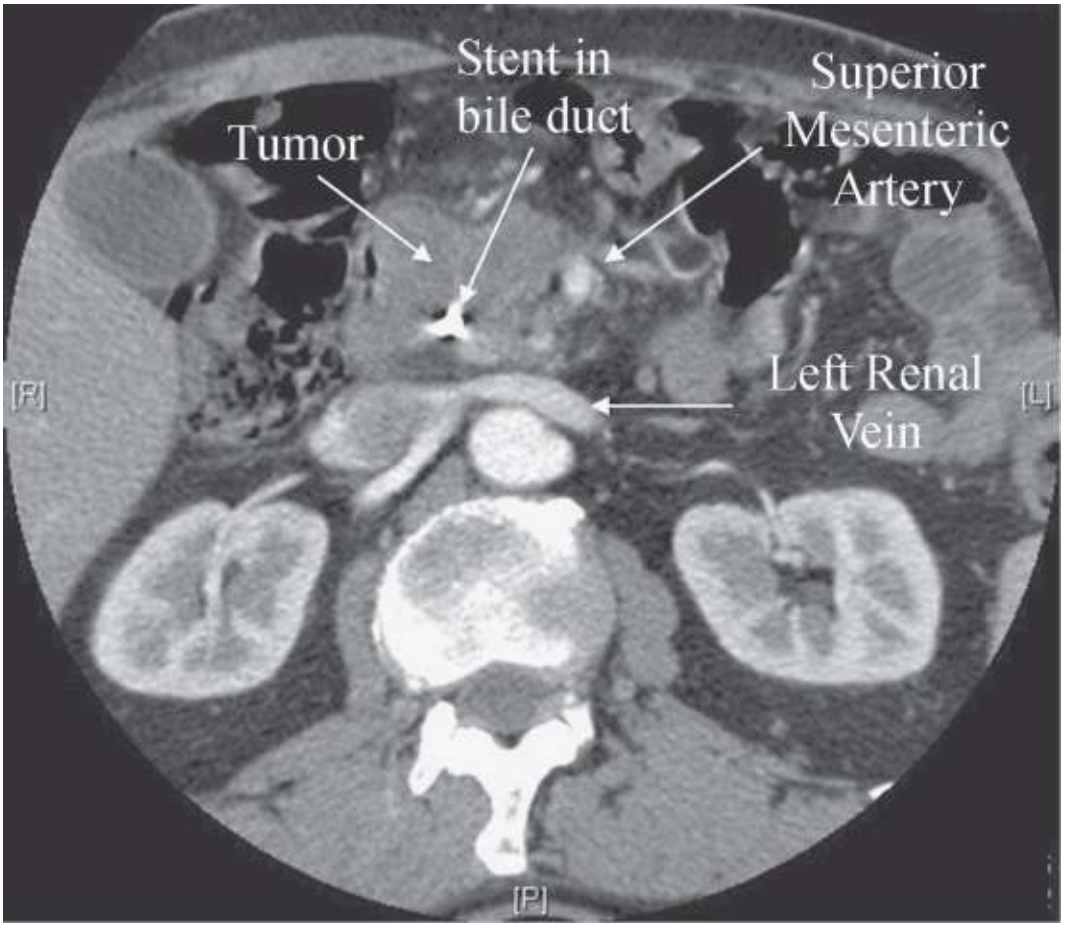

FIGURE 35.11. Axial computed tomography image demonstrating an

adenocarcinoma of the pancreatic head with tumor abutting the superior mesenteric artery.

Hepatic Imaging

MDCT with IV contrast allows for morphologic characterization of the liver and biliary system. The administration of IV contrast is essential as many hepatic tumors are of similar attenuation as normal liver parenchyma and are not identifiable until central necrosis is present. MDCT with contrast is performed in both arterial and portal-venous phases of enhancement. This allows for detection of both early- and late-enhancing lesions, as well as characterization of enhancement patterns that can differentiate between benign and malignant disease. For example, hemangiomas are classically low attenuating on noncontrast images, have peripheral enhancement on the arterial phase, and demonstrate central filling on portal-venous phase imaging. Hepatocellular carcinoma is the most common primary hepatic malignancy and is characteristically hypervascular with pronounced enhancement throughout the solid tumor components on arterial phase images and diminished enhancement on the portal-venous phase. Contrast-enhanced CT can also identify invasion of tumor into the portal and hepatic veins and is frequently associated with portal vein thrombosis. As with other malignancies, PET is recommended for staging and identification of extrahepatic disease.

The liver is one of the most common sites of metastatic disease for many cancers. In patients with a known extrahepatic primary malignancy, evaluation of the liver is an important part of staging. Contrast-enhanced CT has a high sensitivity (73%) and specificity (96%) for detecting hepatic metastases.[132] MDCT of the liver for metastatic disease is typically performed with biphasic technique. Although most metastases are identified on the portal-venous phase, some hypervascular tumors (e.g., melanoma, renal cell carcinoma) may only be identified on arterial phase imaging. MRI has similar accuracy for the diagnosis of hepatic metastases as CT and may be performed in patients with an allergy to iodinated contrast media. However, CT outperforms MRI in detecting extrahepatic lesions, particularly within the lungs.

Biliary Imaging

US is typically the initial imaging study for patients with suspected biliary or pancreatic disease. The primary goals of evaluation include assessment for biliary and pancreatic ductal dilatation (abnormal is >3 mm), identify the presence of stones, characterize the gallbladder wall, and exclude a pancreatic

head mass. US does not, however, image the entire pancreatic and biliary ductal system. In the presence of an US abnormality, further imaging is required.

Endoscopic retrograde cholangiopancreatography (ERCP) is a minimally invasive procedure that involves passing an endoscope into the duodenum and cannulating the main bile duct at the ampulla of Vater. Contrast is then infused to image both the biliary and pancreatic ductal system. In addition to being minimally invasive, ERCP carries risks associated with conscious sedation and can induce pancreatitis in 1.3% to 8.6% of patients.[133] Any evidence of biliary obstruction in the absence of calculi typically prompts further evaluation with cross-sectional imaging to exclude malignancy. ERCP can directly visualize ampullary carcinomas and permits tissue diagnosis achieved using needle aspiration, brush cytology, or forceps biopsy. ERCP may also provide palliation via stent placement in the setting of known obstructive biliary malignancy.

Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive method of imaging the intra- and extrahepatic biliary and pancreatic ducts. MRCP does not require IV contrast; imaging relies heavily on T2-weighted sequences and high-resolution techniques resulting in the pancreatic and biliary ducts appearing very bright while surrounding tissues are dark in signal.[134] MRCP and ERCP have similar sensitivities and specificities in detecting ductal obstruction in the setting of malignancy, although MRCP is better at defining the anatomical extent and type of tumor involved (pancreatic vs. cholangiocarcinoma).[135,136]

Normal Tissue

During RT planning for cancers of the upper abdomen, consideration of the dose to the kidneys may be important. The kidneys are well visualized on CT. However, regional differences in kidney function cannot be readily assessed on CT. Nuclear medicine renal scans provide quantitative information regarding delivery of fluid into the kidneys from the bloodstream, concentration of wastes in the kidney, and excretion from the kidneys into the ureters and filling of the bladder. This information is useful when significant portions of one or both kidneys will be exposed to doses of RT expected to cause regional dysfunction. The liver, stomach, and small bowel are other organs whose location is often important to consider during RT planning. These are usually well seen on CT, although the use of oral contrast can be helpful.

THE PELVIC LYMPH NODES

Oncologic Anatomy

The lymphatic drainage of pelvic organs follows the iliac vessels throughout their branching within the pelvis. Most superiorly within the pelvis, the common iliac chains receive the majority of lymph drainage from intrapelvic organs, which then empty to the para-aortic chains superiorly in the region of the bifurcation of the abdominal aorta. The gonadal veins and arteries are notable exceptions to this orderly flow of lymph from the pelvis and are discussed separately below. Also of note, the rectum, sigmoid, and distal colon have a separate path for lymphatic metastasis via the inferior mesenteric chain to the preaortic basin.

The common iliac pathway receives lymphatic drainage from three primary routes: the external iliac chain, the internal iliac chain, and the presacral chain. The external iliac pathway begins at the point where the femoral vessels cross the inguinal ligament to become the external iliac chains, which courses more proximally to the common bifurcation. The internal iliac chain (also termed the hypogastric chain) is a more complex plexus, flowing back from the distal elaborations of the same artery. Just as these branches of the internal iliac vessels provide blood supply for the pelvic organs, the corresponding lymph node chains provide the majority of lymph drainage. The obturator nodes are part of the internal iliac system and may be found at the point in which the obturator vessels perforate the obturator internus muscle. Radiographically these nodes lay medial to the femoral head, just superior to the bony obturator foramen. The presacral chain is located just anterior to the sacrum and receives lymphatic drainage from the rectum, the cervix, and posterior vagina in the female and the prostate in the male.[137,138]

The testicles have an interesting lymphatic drainage that differs with laterality, essentially mirroring the differences in venous drainage of the two testicles. On the right, the testicle drains into the para-aortic nodes along the lower portion of the inferior vena cava at about the level of L3-L4 following the left testicular vein. On the left, the testicle drains to the renal hilar nodes following the left testicular vein.

Oncologic Imaging

CT is the current preferred means of identifying vessels within the pelvis and is an acceptable method of delineating the pelvic lymph node basins for elective radiotherapy. A 7-mm margin may be applied to the internal and external iliac vessels to arrive at a nodal CTV, with uninvolved bone, muscle (such as the

psoas), and bowel excluded from the volume. The 7-mm margin was developed by investigators in London, who determined the minimum margin on CT visible vessels needed to cover 95% of all nodes identified using ultrasmall iron oxide particles (USPIO) as an MRI contrast agent.[139,140] Special care, however, should be taken to include visualized lymph nodes, even if they lie outside of this margin.

Symmetric expansion margins on vessels are not, however, adequate in the para-aortic regions or the inguinals. In the para-aortic region, the most common location for nodal involvement includes region to the left of the aorta, a basin that extends to the medial margin of the psoas muscle.[141] This region is frequently inadequately covered by a symmetric expansion. Similarly in the inguinal region, nodes lie medial to the femoral neurovascular bundle, often at a distance ≥2 cm. In this region, the space bounded by the regional musculature is the preferred CTV volume.[142]

One centimeter of soft tissue anterior to the sacrum, bridging between the common and internal nodal CTVs, should be added when presacral coverage is desired. The Radiation Therapy Oncology Group has release several atlases to aid the clinician in the contouring of pelvic CTVs that are available at its website. With 3D CT imaging, bony landmarks may not be the ideal determinant of block or multileaf collimator shapes when treating the pelvis.[143,144]

THE RECTUM

Oncologic Anatomy

The rectum is the final, straight portion of the large bowel, measuring approximately 12 cm in length, beginning at the transition from the sigmoid colon with the fusion of the tenia into the circumferential longitudinal muscle. It terminates with the ampulla, leading to the anal canal and dentate (or pectinate) line. Posteriorly, the entire rectum is extraperitoneal, whereas anteriorly, the peritoneal reflection occurs at approximately 7 to 9 cm from the anal verge in males at the posterior aspect of the bladder (superior to the prostate) and 5 to 8 cm from the verge in females, forming the rectouterine pouch (or pouch of Douglas). Below this point, the distal third of the rectum is entirely extraperitoneal.

The mesorectum is the supportive mesentery of the rectum, lying in the extraperitoneal space between the rectum anteriorly and sacrum posteriorly. It is of critical importance as a potential area of both direct and lymphatic spread of

rectal cancers. High-quality total mesorectal excision with sharp dissection has been associated with excellent local control when compared to blunt dissections. However, this has not obviated the need for perioperative radiation therapy, as demonstrated by an increase in local recurrences if this is omitted.[145–147]

Oncologic Imaging

Endorectal US is the preferred nonsurgical staging tool for determining the T stage of rectal malignancy, with an overall accuracy of approximately 85% to 90%.[148] US is probably not needed in cases where there is a large mass with clear extension into the deep portions of the wall (or surrounding tissues) based on CT or examination. There is some tendency to overstage T2 lesions as T3 (beyond the muscularis propria); however, the accuracy remains superior to other imaging modalities.[149] The nodal staging accuracy is somewhat less at approximately 80%, which is comparable to results with either MRI or CT. Accurate staging is critical when determining treatment for rectal cancer. Although surgery alone is sufficient for patients with stage I disease, surgery and chemoradiotherapy are indicated for patients with stage II or III tumors. The German Rectal Cancer Study Group showed that preoperative chemoradiotherapy is associated with improved local control with less acute and late toxicity than postoperative chemoradiotherapy.[150] In this study, 18% of patients in the immediate surgery group, believed to have stage II or III disease by EUS, were found to have stage I disease after surgical resection. Thus, further improvements in preoperative staging are needed to appropriately select patients for neoadjuvant therapy.

THE BLADDER AND URETHRA

Oncologic Anatomy

The bladder is a distensible muscular organ, which may be contained completely within the pelvis when empty or may extend far into the abdominal cavity with distention. The trigone is the posterior and inferior portion of the bladder, defined by the two ureteral orifices posteriorly and the urethral orifice inferiorly. The trigone remains fixed at the base with distension, while the superior most surface expands to accommodate urine. Because of this distensibility, this bladder is surrounded by loose connective tissue and fat. Anterior to the bladder, this loose connective tissue is termed the space of Retzius or retropubic space.

The urethra inferiorly has a short course to the introitus in the female,

measuring approximately 4 to 5 cm in length. In the male, it is approximately 20 cm in length and traverses the prostate and penis to the meatus.

The lymphatic drainage of the base and posterior wall of the bladder may preferentially drain to the obturator and internal iliac basins via anterior pathways. In contrast, the external iliac chain may receive primary drainage from the lateral and superior bladder wall, and tumors arising from the bladder neck may also spread to the presacral nodal basins.

Oncologic Imaging

Bladder tumors are often inadequately evaluated with conventional imaging techniques such as radiographic IV urograms and US. CT urography is useful for the diagnosis of superficial tumors but provides limited visualization of the depth of tumor invasion within the bladder wall. PET has limited utility in the primary diagnosis because of urinary excretion of FDG that can obscure bladder disease. Notwithstanding, PET is still performed as part of staging in order to identify distant metastases. Given the imaging limitations, cystoscopy with biopsy is the preferred method of confirming diagnosis and characterizing the primary tumor stage. Regional nodal involvement is best initially characterized by contrast-enhanced CT; however, the role of MRI is evolving, particularly for evaluation of lymph nodes utilizing novel contrast agents including USPIO.[151]

CERVIX, UTERUS, AND OVARIES

Oncologic Anatomy

The uterus lies between the bladder anteriorly and the rectum posteriorly, covered by a layer of peritoneum. Laterally lie the fallopian tubes and ovaries, which are anchored medially by the ovarian ligament (or utero-ovarian ligament) and laterally by the suspensory ligament of the ovary (or infundibulopelvic [IP] ligament). The ovarian arteries originate from the abdominal aorta, just inferior to the renal vessels, following a course anterior to the psoas on the left and crossing anterior to the inferior vena cava to the psoas on the right, both sides crossing anterior to the ureter and then crossing medially with the IP ligament to the ovaries. The fold of the peritoneum over the uterus continues laterally over these structures, forming the broad ligament. Similar to the testes, the right ovarian vein drains to the inferior vena cava, whereas the left ovary drains to the left renal vein.

The uterine corpus or body is the cephalad two-thirds of the organ and is lined

internally by the endometrium, which varies in thickness by the menstrual cycle and by menopausal status. The middle muscular layer, the myometrium, is primarily smooth muscle. The final outer layer is the serosa or perimetrium and is continuous with the peritoneum. The caudal one-third of the organ is the uterine cervix, which consists of firm connective tissue, approximately one-half of which extends into the vagina. The intravaginal portion is lined by nonkeratinized squamous epithelium (the ectocervix), whereas the cervical canal is lined by columnar epithelium (the endocervix).

Lateral to the uterine cervix and corpus is the parametrium that caudally consists of the paracervical tissue, including the cardinal ligament, uterine artery and vein, and the ureter as it courses anteriorly to the bladder. This caudal portion of the parametrium is of importance for evaluation of lateral spread of cervical cancer and can be staged on physical examination by the bimanual examination and, perhaps more importantly, with the rectovaginal examination, where the examining rectal finger can palpate these structures. Cephalad to this, the parametrium continues as the broad ligament, terminating at the suspensory ligament of the ovary. Posteriorly the cervix is anchored to the sacrum via the uterosacral ligament, which classically attaches at the third sacral foramen, although MRI studies would suggest a fair amount of individual variation.[152]

Oncologic Imaging

MRI of the pelvis is the most useful modality outside of the physical examination to determine the extent of disease within the uterus and cervix with an accuracy of approximately 85%.[153,154] For endometrial carcinoma, T2- and postcontrast T1-weighted sequences are beneficial in staging, such as identifying the primary tumor, extent of invasion, and involvement of regional pelvic lymph nodes. In the setting of cervical cancer, T2-weighted sequences are often the most useful in determining the extent of disease and are preferred for MRI-guided brachytherapy.[155] Either CT or MRI may be used for image-guided brachytherapy to potentially improve central disease control and reduce toxicity. However, CT systematically provides larger estimates of target size compared to MRI, particularly in the lateral extent.[156,157] US can be useful during intracavitary brachytherapy to ensure the proper placement of a uterine tandem and prevent uterine perforation.

FIGURE 35.12. Positron emission tomography imaging of a patient with cervical cancer showing an 18-fluorodeoxyglucose-avid left external iliac lymph node.

PET-CT has been proven to be sensitive and specific in the evaluation of lymph nodes within the pelvic and para-aortic chains with squamous cell carcinoma of the cervix (sensitivity ~85%, and specificity 95% for para-aortic nodes), although it is less well studied in endometrial and other primary gynecologic sites[158] (Fig. 35.12). Investigators from Washington University have extensively studied FDG-PET in cervical cancer, showing that the initial maximum SUV of the primary tumor is predictive of response to treatment.[159] Additionally, they found that a complete metabolic response to treatment was highly predictive of progression free survival (PFS); at 3 years, with complete response, PFS was 78% versus 33% in partial responders and 0% with PET progression.[160] The prognostic significance of PET response to treatment has been confirmed by investigators in Melbourne.[83]

PROSTATE

Oncologic Anatomy

The prostate lies in the center of the male pelvis, with its widest portion, the base, in close approximation to the bladder neck superiorly, narrowing to the apex inferiorly, supported by the urogenital diaphragm (UGD). Posteriorly, the

gland is closely related to the ampulla of the rectum. The seminal vesicles are located superior to the prostate and extend somewhat laterally and posteriorly and are immediately posterior to the posterior wall of the bladder. Anteriorly lies the retropubic space filled with fat.

Within the prostate five distinct zones exist: the peripheral zone, the central zone, the transitional zone, the periurethral glandular tissue, and the anterior fibromuscular stroma.[84] The peripheral zone accounts for the majority of the gland (70% of glandular tissue) as well as the majority of cancers (60% to 70%). The peripheral zone is located posteriorly and laterally within the gland. This zone is hyperintense on T2 MRI and care should be taken to include it when treatment planning with MRI. The central zone accounts for an additional 25% of glandular tissue and lies near the origin of the seminal vesicles, accounting for 10% of cancers. The transitional zone surrounds the urethra cephalad to the insertion of the ejaculatory duct, may hypertrophy with age, and is the origin of 10% to 20% of cancer within the prostate.

The Batson venous plexus is a series of valveless veins anterior to the vertebral bodies that received drainage from the deep pelvic veins and prostate gland.[85,86] It has been postulated that because of the lack of valves, this may represent a pathway of spread for metastases and provide an anatomic basis for the propensity of prostate cancer to involve the lumbosacral vertebral bodies.

The T staging of prostate cancer remains based primarily on the physical examination, where the examining rectal finger may palpate the size and extent of discrete ridges and nodules within the gland. It is important to palpate and document the presence of the lateral sulci of the gland, as evidence of effacement is highly suggestive of extracapsular extension (ECE) of disease. The examiner should also attempt to palpate the base of the seminal vesicles, although this is not always possible given body habitus and individual anatomy.

Oncologic Imaging

Transrectal US is invaluable for guiding biopsies for diagnosis of disease; however, it has limited specificity and sensitivity (~40% to 50%) for determination of seminal vesicle involvement and ECE. CT has similar limitations, as the prostate gland has similar attenuation characteristics as the anterior and lateral venous plexus, the inferior UGD, and the bladder wall superiorly. CT can detect gross extracapsular disease, identify distant metastases, and determine suspicious pelvic nodes and is currently the standard for defining pelvic radiation target volumes, if indicated. If CT alone is used for definition of

the prostate for treatment planning, the penile bulb may provide a useful reference point for ascertaining the apex of the gland, which lies approximately 15 to 18 mm superior to the bulb, although there is significant interpatient variation.[87] A retrograde urethrogram can be useful to identify the inferior aspect of the UGD and aid in the delineation of the apex approximately 12 to 15 mm superiorly.

MRI may be the optimal imaging modality for evaluation of the prostate itself and is an invaluable aid in treatment planning. As noted previously, the zonal anatomy of the prostate is only visible on T2-weighted imaging, and the apex can be clearly distinguished from the UGD and other neighboring structures (Fig. 35.13). The joint maximum sensitivity and specificity of determining extraprostatic disease on MRI is approximately 70%, although this may be improved with endorectal coils.[106,107] Because of the increased tissue contrast, planning based on MRI results in a reduction of interobserver variability and a reduction in the volume of the prostate contours.[108] In general, the prostate identified on CT is larger than that identified on MRI. Therefore, with MRI-based treatment planning, the accurate delineation of the GTV is more important (compared to CT where the GTV tends be likely slightly overestimated).

Multiparametric MRI (mpMRI) consists of obtaining multiple T1, T2 weighted conventional sequences, in combination with DWI, DCE, and MR-spectroscopy. Combining the unique characteristics of each of these sequences (discussed in the MRI section above) has led to an increased specificity (>90%) of lesion location both within prostate and in detecting disease extension outside of the capsule.[161,162] As such, this collection of sequences has become useful for directing biopsies and driving treatment decisions and conceivably can be used to direct the purposeful delivery of a heterogeneous RT dose to the prostate gland.

Targeted imaging has long been of interest in prostate cancer, beginning with ProstaScint (Cytogen Corp, Princeton, NJ) imaging, which utilized a radiolabeled monoclonal antibody indium-111 capromab pendetide to identify sites of local or metastatic disease.[163] Unfortunately, in clinical practice, it was neither sufficiently specific or sensitive to be of significant utility. However, the use of prostate-specific PET radiopharmaceuticals such as choline ^{11}C, fluciclovine ^{18}F, and ^{68}Ga prostate-specific membrane antigen (^{68}Ga-PSMA) have had more success in identifying occult metastatic prostate cancer. ^{68}Ga-PSMA PET in particular has shown promise, with both a sensitivity and specificity of 86%.[164]

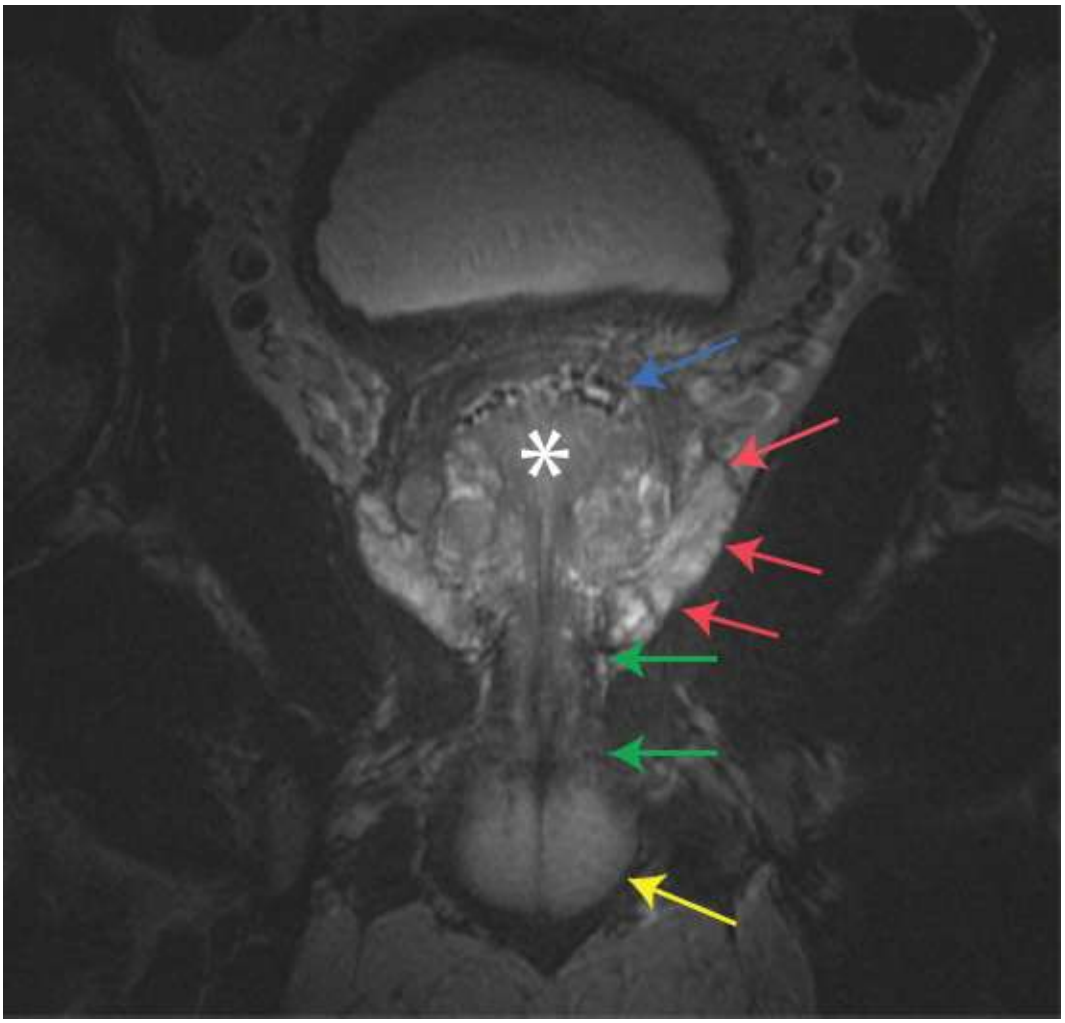

FIGURE 35.13. A coronal T2-weighted magnetic resonance image demonstrating the anatomy of the prostate. The regional anatomy is labeled as follows: the asterisk (*) is the central gland—a combination of the central zone and transitional zone; *red arrows* indicate the peripheral zone (PZ); *blue arrows* indicate the seminal vesicles (SV) and their insertion in the base; *green arrows* indicate the urogenital diaphragm (UGD); *yellow arrows* indicate the penile bulb (PB).

Prostate imaging and pathologic analyses can be somewhat discordant. The lesions seen on imaging can often appear focal. However, prostatectomy specimens usually demonstrate the microscopic presence of cancer in multiple regions of the gland. Thus, attempts to severely restrict the therapeutic radiation dose distribution to focal areas of the prostate need to be done with care.

The normal rectum and bladder are commonly avoided structures during pelvic RT, and their location relative to surrounding tissues can be readily determined on planning CT. The interface between the bladder and prostate can be challenging and may be improved with placement of contrast agents within the bladder.

THE LYMPHATIC SYSTEM

Oncologic Anatomy

The lymphatic system is a component of the circulatory system, and wherever arteries and veins pass, lymphatic vessels are also present (with the notable exceptions of the placenta and central nervous system). In the central nervous system, lymph is carried within perivascular lymph sheaths, as opposed to actual lymphatic vessels. The lymphatic system includes lymphatic vessels, lymph nodes, lymphatic organs such as the spleen, and the lymphocytes themselves. The lymphatic system is a loosely organized system but generally follows somewhat predictable paths. Small lymphatic vessels form within the tissues of the body, drain into one or more lymph nodes, and eventually drain into larger lymph trunks. These unite to form either the thoracic duct or right lymphatic duct, which empties into the venous system at the subclavian vein–internal jugular vein junction. The lymphatics are primarily involved in returning plasma from the interstitial space to the venous system, although they are also involved in absorption and transport of fat and in defense mechanisms. Radiation oncologists must become versed in an understanding of site-specific lymphatic spread.

The primary tumors arising from the lymphatic system are leukemias and lymphomas. Leukemias are primarily managed with chemotherapy, although radiation therapy is often utilized in the setting of stem cell transplantation (total body irradiation), central nervous system involvement (cranial or craniospinal irradiation), or in palliative settings. Lymphomas consist of multiple distinct entities that are often managed with chemotherapy and/or radiation therapy.

Oncologic Imaging

Nodal Metastases

The accurate identification and characterization of lymph nodes have important diagnostic, therapeutic, and prognostic implications in patients with cancer. Prior to the advent of cross-sectional imaging, bipedal lymphangiography was the standard test for evaluating and staging nodal disease in the abdomen and pelvis. CT and PET-CT have supplanted lymphangiography.

Lymphoma

The current WHO classification of lymphoid neoplasms consists of nearly a hundred distinct entities.[165] Further, lymphomas can arise virtually anywhere in the body, including both nodal and extranodal sites. Consequently,

comprehensive imaging withPET-CT plays an integral role in the staging and management of both HL and many NHL. Current guidelines recommend that PET-CT be employed for initial staging of all lymphomas that are FDG-avid.[166] CT alone is appropriate for the minority that are not, such as chronic lymphocytic leukemia/small lymphocytic lymphoma. Postchemotherapy response assessment with PET-CT is also standard and should utilize the Deauville criteria.[167] A negative (Deauville 1-3) PET-CT scan after chemotherapy does not necessarily mean that all disease has been eradicated, simply that an excellent response was achieved (Fig. 35.14). This point has been confirmed in randomized trials of HL, where patients were randomized to observation or consolidation RT after achieving a complete response by PET-CT after chemotherapy. Even in the setting of a negative postchemo PET, consolidation RT still decreased the risk of recurrence.[168]

Summary

The term *oncoanatomy* describes the fusion of clinical oncology and anatomy, for the betterment of both. The successful practice of radiation oncology requires a thorough understanding of anatomy. Likewise, the study of malignancy and observations regarding spread of malignant tumors aids in the understanding and instruction of anatomy. Radiation oncologists have a unique opportunity to assist in the instruction of anatomy. For most medical students, gross anatomy is an early first-year course before significant clinical experience is obtained. Over the ensuing years of medical school and residency, much of this knowledge is lost as it is not routinely applied during clinical practice. It is incumbent on those who seek advanced training in fields such as surgery, radiology, and radiation oncology to again become students of anatomy, as the successful practice of such disciplines requires an in-depth understanding of anatomical principles.

A multi-institutional oncoanatomy course has been described.[169–171] It currently consists of a bimonthly conference where the anatomy of a particular disease site is reviewed along with pertinent clinical implications. Following this didactic session, the presentation continues in the gross anatomy suite where anatomy faculty demonstrate on prosections. This course is attended by medical students, residents, and faculty members from multiple disciplines. The expertise of all involved contributes to a valuable educational environment. Recently, a similar Canadian national anatomy and radiology and contouring boot camp has been developed, drawing radiation oncology residents from 10 universities, demonstrating improved understanding of anatomy and radiology, critical for

successful practice.[172]

CHAPTER 36

Basic Concepts of Chemotherapy and Irradiation Interaction

D. Nathan Kim, Michael Story, and Hak Choy

For decades, radiation therapy has been a major treatment modality for locally or regionally confined cancers. The rate of treatment failure is still high, particularly for large tumors or advanced disease. Technologic improvements in radiation therapy have continuously been made that allow delivery of higher radiation doses to the tumor or lower doses to normal tissues and in the implementation of strategies that modulate the biologic response of tumors or normal tissues to radiation. These strategies include altered fractionation scheduling including extreme hypofractionation (e.g., stereotactic body radiotherapy, stereotactic radiosurgery [SRS]), combined modality treatments using chemical or biologic agents, and, more recently, targeting molecular processes and signaling pathways that have become dysregulated in cancer cells.

The combination of chemotherapeutic drugs with radiation has perhaps had one of the strongest impacts on current cancer radiation therapy practice. This is particularly true for concurrent chemoradiation therapy, which has been shown in many recent clinical trials to be superior to radiation therapy alone in controlling locoregional disease and in improving patient survival. Combining chemotherapeutic drugs with radiation therapy has a strong biologic rationale. Such agents reduce the number of cells in tumors undergoing radiation therapy by their independent cytotoxic action and by rendering tumor cells more susceptible to killing by ionizing radiation. An additional benefit of combined treatment is that chemotherapeutic drugs, by virtue of their systemic activity, may also act on metastatic disease. Most drugs have been chosen for combination with radiation therapy based on their known clinical activity in particular disease sites. Alternatively, agents that are effective in overcoming resistance mechanisms associated with radiation therapy could be chosen. There have been clinical successes with concurrent chemoradiation therapy using

traditional drugs, such as cisplatin and 5-fluorouracil (5-FU), and these studies have led to extensive research on exploring newer chemotherapeutic agents for their interactions with radiation. A number of potent chemotherapeutic agents, subsequently, have entered clinical trials or practice. These agents were selected after preclinical studies demonstrated that they are potent enhancers of the radiation response and thus might further improve the therapeutic outcome of chemoradiation therapy. There are also molecular targeting strategies aimed at improving the efficacy of radiation therapy. In this era, there is significant explosion of activity revolving around the exciting and emerging data suggesting potential benefit to combining immunotherapy agents with radiation therapy. This chapter reviews the biologic rationale and principles fundamental to the use of chemotherapy, molecular targeted agents, and immunotherapy in conjunction with radiation treatments and discusses mechanistic interactions between drugs and radiation, the knowledge of which is essential in developing the optimal treatment strategies and designing appropriate clinical trials. It also provides a brief overview of current treatment applications and advances in the clinic. Owing to limited space, this review is far from comprehensive; additional information can be found in other reviews on this subject.[1–11]

THERAPEUTIC INDEX

Both radiation and chemotherapeutic drugs are cytotoxic to tumor and normal tissue cells. This lack of specificity is a major limitation in their use when applied either as individual treatments or in combination. Radiation inflicts damage to tumor and normal tissues in the radiation treatment field, whereas drugs, because of their systemic action, can affect any tissue in the body. Damage is often accentuated when the two agents are combined and when they affect the same tissue. In general, both the antitumor effectiveness and the severity of normal tissue damage produced by either radiation or drugs are increased as their dose is increased. This dose–effect relationship is sigmoidal and enables estimation of the therapeutic index (ratio), which is defined as the ratio between the doses (radiation, drug) that produce the same level (probability) of antitumor efficacy and normal tissue damage. To be therapeutically beneficial, the therapeutic ratio must be positive (>1); that is, individual agents or their combination must be more effective against tumors than normal tissues. To define therapeutic benefit in clinical settings, many factors must be taken into account, such as whether the treatment is curative or

palliative, which tissues are dose limiting (critical tissues), what degree of tissue damage is acceptable, and so forth. The balance between a given level of antitumor efficacy and acceptable normal tissue complications gives a measure of the therapeutic ratio of a treatment.

EXPLOITABLE STRATEGIES IN CHEMORADIATION THERAPY

The goals of combining chemotherapeutic drugs with radiation therapy are to increase patient survival by improving locoregional tumor control, decrease or eliminate distant metastases, or both while preserving organ and tissue integrity and function. Combined modality treatment can further improve positive therapeutic outcome of individual treatments through a number of specific strategies, which Steel and Peckham[12] classified into four groups: “spatial cooperation,” independent toxicity, enhancement of tumor response, and protection of normal tissues.

Spatial cooperation was the initial rationale for combining chemotherapy with radiation therapy, in which the action of radiation and chemotherapeutic drugs is directed toward different anatomic sites. Localized tumors would be the domain of radiation therapy because large doses of radiation can be given. On the other hand, chemotherapeutic drugs are likely to be more effective in eliminating disseminated micrometastases than in eradicating larger primary tumors. Thus, the cooperation between radiation and chemotherapy is achieved through the independent action of two agents. Spatial cooperation is the basis for adjuvant chemoradiation therapy, in which radiation is given first to control the primary tumor and chemotherapy is given later to cope with micrometastases. The concept of spatial cooperation is also applied in the treatment of hematologic malignancies that have spread to “sanctuary” sites, such as the brain. These sites are poorly accessible to chemotherapeutic agents, and thus, they are more appropriately treated with radiation therapy.

Independent toxicity is another important strategy for increasing the therapeutic ratio of chemoradiation therapy. Normal tissue toxicity is the main dose-limiting factor for both chemotherapy and radiation therapy. Therefore, combinations of radiation and drugs would be better tolerated if drugs were selected such that toxicities to specific cell types and tissues do not overlap with, or minimally add to, radiation-induced toxicities. This strategy requires a thorough knowledge of drug toxicity, underlying mechanisms, and drug

pharmacokinetics. Another strategy in chemoradiation therapy is to exploit the ability of chemotherapeutic agents to *enhance tumor radioresponse*. The enhancement denotes the existence of some type of interaction between drugs and radiation at the molecular, cellular, or pathophysiologic (microenvironmental, metabolic) level, resulting in an antitumor effect greater than would be expected on the basis of additive actions. Many mechanisms may be involved in drug–radiation interactions leading to tumor radio enhancement, and some of them are elaborated on further in the text. The enhancement must be selective or preferential to tumors compared with critical normal tissues to achieve therapeutic gain. The ability of chemotherapeutic agents to enhance tumor radioresponse by counteracting determinants associated with tumor radioresistance is a major rationale for concurrent radiation therapy.

An additional strategy is to *protect normal tissues* so that higher doses of radiation can be delivered to the tumor. This can be achieved through technical improvements in radiation delivery or administration of chemical or biologic agents that selectively or preferentially protect normal tissues against the damage by radiation or drugs. A separate section in this chapter discusses radioprotectors in more detail.

ASSESSMENT OF DRUG–RADIATION INTERACTION

Any drug considered for use in combination with radiation therapy needs to undergo preclinical evaluation for its interaction with radiation both in *in vitro* cell culture systems and *in vivo*, with the aim of assessing antitumor activity and normal tissue toxicity. The interaction between two agents is more easily defined and quantified *in vitro* because complete cell survival curves are readily obtained. The *in vitro* cell survival assay measures the ability of cells to produce colonies of a defined minimum size. Cell survival is determined after treatment with a drug or radiation alone, given at different doses, or after treatment with both agents, in which case the cells are exposed to the drug before, during, or after irradiation. Survival curves are usually plots of the surviving fraction of cells on a logarithmic scale and the dose of radiation or drugs on a linear scale.

The cell survival curve after irradiation characteristically has a “shoulder” of varying width that denotes the capacity of cells to repair radiation damage. The curves that describe survival after chemotherapeutic agents show much more variation both in absolute sensitivity to drugs and their shape than those after radiation, all depending on the drug tested. Some curves possess shoulders, some

lack them, and some show resistant “tails” at higher drug doses. The tails denote the existence of cell subpopulations resistant to chemotherapeutic agents.

To assess the effect of the drug on cell radiosensitivity, the combined drug–radiation curve is commonly plotted after the cytotoxicity produced by the drug alone is excluded (“normalized”). The radiation cell survival curve is not changed if the drug does not influence cell radiosensitivity regardless of whether the drug is cytotoxic on its own. In this case, the cytotoxicity of the drug contributes only to the overall cell killing by the combined treatment (*additive effect*) of both agents. Chemotherapeutic agents may interact with radiation by altering cell radiosensitivity such that the combination results in a *supra-additive* or *subadditive effect*, depending on whether the cell killing is greater or smaller than the sum of cell killings produced by individual agents. Drugs may eliminate the shoulder on the radiation survival curve, implying that drugs can inhibit cell repair from radiation damage, or they may change the slope of the exponential portion of the survival curve. A steeper slope indicates increased sensitization to radiation, whereas a shallower slope indicates protection.

Because of non–linear dose-related characteristics in cell killing by both chemotherapeutic agents and radiation, the effects of the combined treatment are best assessed using the “isobologram,” an isoeffect plot for the dose response to the combination of two agents[12] (Fig. 36.1). Dose–response curves are determined for each agent to generate the isobologram, an envelope of additivity, which denotes expected additive response over a range of doses of the agents used. If the interaction between drugs and radiation is supra-additive or synergistic (i.e., the effect is caused by lower doses of the two agents than the envelope of additivity would predict), the effect is shown at the left side of the envelope. In contrast, the effect of the subadditive or antagonistic interaction is shown to the right of the envelope: the effect required higher doses of the two agents than predicted. The width of the envelope of additivity depends on the degree of the nonlinearity in the dose response to individual agents. The envelope is wider as the degree of nonlinearity increases. In the case of a linear dose–response relationship for each agent, which is rare, the isobologram is also linear, represented by a single straight line.

In vitro testing is often followed by *in vivo* exploration of drug–radiation interactions, which allows assessment of the combined treatment on both tumors and normal tissues. This is essential for determination of therapeutic gain, as discussed earlier in this chapter. Syngeneic animal tumors or human tumor xenografts in nude mice are most often used for this purpose. The efficacy of the

treatment is determined by the extent of tumor growth delay or the rate of tumor cure. In normal tissues, the effect of chemotherapeutic drugs on radiation response of acutely and late-responding tissues can be assessed using a variety of available assays. Some of these assays are clonogenic, such as the jejunal crypt assay, where the endpoint depends directly on the reproductive integrity of individual cells. More frequently, however, dose–response relationships for normal tissues are based on functional endpoints (such as breathing rate in lung damage and paralysis in spinal cord damage). These endpoints tend to reflect the minimum number of functional cells remaining in tissues or organs and not the proportion of cells retaining reproductive integrity.

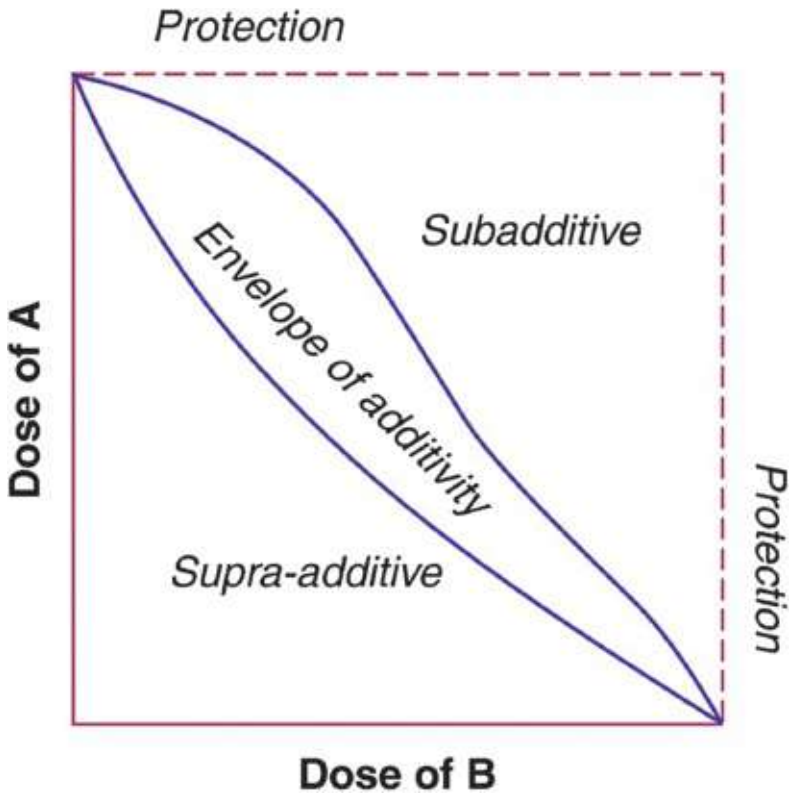

FIGURE 36.1. An isobologram for two agents when their dose–response curves are nonlinear. The isobologram shows the envelope of additivity and regions of supra-additivity and subadditivity. MECHANISTIC CONSIDERATIONS IN DRUG–RADIATION INTERACTIONS

Increasing Initial Radiation Damage

Radiation induces many different lesions in the DNA molecule, which is the critical target for radiation damage. The lesions consist of single-strand breaks (SSBs), double-strand breaks (DSBs), base damage, DNA–DNA and DNA–protein cross-links, and so forth. DSBs and chromosome aberrations that occur in association with or as a consequence of DSBs are usually considered to be the principal damage that results in cell death.[13] Any agent that makes DNA more susceptible to radiation damage may enhance cell killing. Certain drugs, such as halogenated pyrimidines, incorporate into DNA and make it more susceptible to radiation damage.[14]

Inhibition of Cellular Repair

Both sublethal[15] and potentially lethal[16,17] damage inflicted by radiation can be repaired. Although sublethal damage repair (SLDR) denotes the increase in cell survival when the radiation dose is split into two fractions of radiation separated by a time interval, potentially lethal damage repair (PLDR) designates the increase in cell survival as the result of postirradiation environmental conditions. SLDR is rapid, with a half-time of approximately 1 hour, and is complete within 4 to 6 hours after irradiation. This time between two radiation fractions allows radiation-induced DSBs in DNA to rejoin and repair. SLDR is expressed as the restitution of the shoulder on the cell survival curve for the second dose. PLDR occurs when environmental conditions prevent cells from dividing for several hours, such as keeping *in vitro* growing cells in plateau phase after irradiation. Preventing cells from division allows the completion of repair of DNA lesions that would have been lethal had DNA undergone replication within several hours after irradiation. PLDR is considered to be a major determinant responsible for radioresistance in some tumor types, such as melanomas. The repair can be achieved through restoration of damaged molecules by reducing species that donate electrons to oxidized substrates or through involvement of enzymes mediating homologous and nonhomologous recombination repair of DNA DSBs, base excision repair of base damage, and nucleotide excision repair of DNA–protein cross-links.

Many chemotherapeutic agents used in chemoradiation therapy interact with cellular repair mechanisms and inhibit repair and hence may enhance cell or tissue response to radiation. The aforementioned halogenated pyrimidines enhance cell radiosensitivity not only through increasing initial radiation damage but also by inhibiting cellular repair.[14,18] Nucleoside analogs, such as gemcitabine, are a class of chemotherapeutic agents potent in inhibiting the

repair of radiation-induced DNA and chromosome damage.[19,20] They have been shown strongly to enhance tumor radioresponse in preclinical studies and have been, and are continuing to be, extensively investigated for such activity in patients with cancer.[21,22]

Cell Cycle Redistribution

Both chemotherapeutic agents and radiation are more effective against proliferating than nonproliferating cells. Their cytotoxic action further depends on the position of cells in the cell cycle. Cell cycle dependency in response to radiation was first described almost 40 years ago.[23] Terasima and Tolmach[23] reported that the sensitivity of the cell response to radiation varied widely depending on which phase of the cell cycle the cells were in at the time of irradiation and that cells in the G_2 and M cell cycle phases were approximately three times more sensitive than cells in the S-phase. The exact reason for this variability is still unknown.

The influence of the cell cycle on cell response to cytotoxic agents can be therapeutically exploited in chemoradiation therapy using cell cycle redistribution strategies. For example, some chemotherapeutic drugs, such as taxanes, can block transition of cells through mitosis, with the result that cells accumulate in the radiosensitive G_2 and M phases of the cell cycle. Radiation delivered at the time of significant accumulation of cells in both the G_2 and M phases results in enhanced radioresponse of cells *in vitro*[24,25] and of tumors *in vivo*.[26,27] However, this cell cycle mechanism of taxane-induced enhancement of tumor radioresponse is dominant only in tumors that are resistant to paclitaxel or docetaxel as a single treatment. Although tumor growth in taxane-resistant tumors is not substantially affected by the drug, tumors do exhibit significant transient accumulation of cells in mitosis 6 to 12 hours after the treatment.[27] Taxanes also enhance the radioresponse of tumors that respond by significant tumor growth delay to taxanes given as a single treatment modality, but a major mechanism for radio enhancement in such tumors is reoxygenation of radioresistant hypoxic cells, as discussed later.[26]

Elimination of the radioresistant S-phase cells by the chemotherapeutic agents may be another cell cycle redistribution strategy in chemoradiation therapy. Nucleoside analogs, such as fludarabine or gemcitabine, are good examples of the agents that become incorporated into S-phase cells and eliminate them by inducing apoptosis.[19,21] In addition to purging S-phase cells, the analogs induce the surviving cells to undergo parasynchronous movement to accumulate in the

G_2 and M phases of the cell cycle between 1 and 2 days after drug administration, a time when the highest enhancement of tumor radioresponse was observed.[21] Tumors with a high cell growth fraction are likely to respond better to the cell cycle redistribution strategy in chemoradiation therapy than tumors with a low cell growth fraction.

Counteracting Hypoxia-Associated Tumor Radioresistance

Solid malignant tumors usually are characterized by defective vascularization, both in the number of blood vessels and vessel function. Because of this, blood supply to tumor cells is inadequate, cells lack oxygen and nutrients, and multiple tumor microregions become hypoxic, acidic, and eventually necrotic. Hypoxia occurs at distances from blood vessels larger than 100 to 150 μm. The hypoxic cell content in tumors varies widely and can be more than 50%. The presence of hypoxia makes tumors more aggressive (hypoxia is conducive to the emergence of more virulent tumor cell variants and stimulates metastatic spread[28,29] and more resistant to radiation as well as most chemotherapeutic agents. Hypoxic cells are 2.5 to 3 times more resistant to radiation than well-oxygenated cells. The fact that hypoxia may be a cure-limiting factor in radiation therapy, at least in some clinical situations, is suggested by the findings that reduced hemoglobin levels[30] and low tumor pO_2,[31,32] are associated with higher treatment failure rates. Also, there are reports showing that local tumor control by radiation therapy can be improved by the use of hypoxic cell radiosensitizers[33] or hyperbaric oxygen.[34,35] With respect to the effects of chemotherapy, hypoxic regions are less accessible to chemotherapeutic drugs; in addition, hypoxic tumor cells are either nonproliferating or they proliferate poorly and as such do not respond well to drugs.

Combining chemotherapeutic agents with radiation therapy can reduce or eliminate hypoxia or its negative influence on tumor radioresponse. Most chemotherapeutic drugs preferentially kill proliferating cells, primarily found in well-oxygenated regions of the tumor. Because these regions are located close to blood vessels, they are easily accessible to chemotherapeutic agents. Destruction of tumor cells in these areas leads to an increased oxygen supply to hypoxic regions and hence reoxygenates hypoxic tumor cells. Massive loss of cells after chemotherapy lowers the interstitial pressure, which then allows the reopening of previously closed capillaries and the re-establishment of blood supply. It also causes tumor shrinkage so that previously hypoxic areas are closer to capillaries and thus accessible to oxygen. Finally, by eliminating oxygenated cells, more

oxygen becomes available to cells that survived chemotherapy. It was recently shown that tumor reoxygenation is a major mechanism underlying the enhancement of tumor radioresponse induced by taxanes in tumors sensitive to these drugs.[26]

Another approach to counteract the negative impact of hypoxia is selective killing of hypoxic cells through bioreductive drugs, such as tirapazamine,[28] which undergo reductive activation in a hypoxic milieu, rendering them cytotoxic. A related possibility is to exploit the acidic state (low pH) of tumors, which develops as a result of hypoxia-driven anaerobic metabolism that produces lactic acid,[36] through the use of drugs that selectively accumulate in acidic environments or become activated by a low pH.[37]

The use of agents that selectively radiosensitize hypoxic cells to reduce their negative impact has been considered and tested in clinical trials. These drugs increase radiation damage by mimicking the effect of oxygen. Many clinical trials have tested these drugs, particularly misonidazole, in combination with radiation therapy, but few of them have shown an improved treatment outcome. The exception is nimorazole, which also does not elicit the neurotoxicity commonly associated with hypoxic cell sensitizers that prevented the delivery of clinically effective doses of these agents.[38]

Inhibition of Tumor Cell Repopulation

The constant balance between cell production and cell loss maintains the integrity of normal tissues. When this balance is perturbed by cytotoxic action of chemotherapeutic drugs or radiation, the integrity of tissues is re-established by an increased rate of cell production. The cell loss after each fraction of radiation during radiation therapy induces compensatory cell regeneration (repopulation), the extent of which determines tissue tolerance to radiation therapy. In contrast to normal tissues, malignant tumors are characterized by an imbalance between cell production and cell loss in favor of cell production. As with normal tissues, tumors also respond to radiation- or drug-induced cell loss with a compensatory regenerative response. Preclinical studies provided ample evidence demonstrating that the rate of cell proliferation in tumors treated by radiation or chemotherapeutic drugs is higher than that in untreated tumors.[39–41] This increased rate of treatment-induced cell proliferation is commonly termed *accelerated repopulation*. Accelerated repopulation of tumor clonogens has been shown to occur during clinical radiation therapy as well. Withers et al.[42] showed that the total dose of radiation needed to control 50% of head and neck

carcinomas progressively increased with time whenever radiation therapy treatment was prolonged beyond 1 month. This increase in radiation dose required to achieve tumor control was greater than what would be anticipated based on the pretreatment tumor volume doubling time of approximately 60 days for head and neck tumors. The increase was attributed to accelerated repopulation, and it was estimated to average approximately 0.6 Gy/day[42] but may be as high as 1 Gy/day.[43]

Although accelerated cell proliferation is beneficial for normal tissues because it spares them from radiation damage, it has an adverse impact on tumor control by radiation therapy or chemotherapy. Chemotherapeutic drugs, because of their cytotoxic or cytostatic activity, can reduce the rate of proliferation when given concurrently with radiation therapy and hence increase the effectiveness of the treatment. Caution must be taken to select drugs that preferentially affect rapidly proliferating cells and preferentially localize in malignant tumors. However, the main limitation of concurrent chemoradiation therapy is the enhanced toxicity of rapidly dividing normal tissues because most available chemotherapeutic agents show poor tumor selectivity. Moreover, accelerated repopulation induced by chemotherapeutic drugs may have a negative influence on the outcome of tumor response to radiation when drugs are used in induction or neoadjuvant chemotherapy protocols. In this strategy, chemotherapy precedes radiation therapy. Treatment outcomes after induction chemotherapy followed by radiation therapy have not been overly encouraging in terms of both local tumor control and patient survival, even if a large proportion of tumors initially responded with total or partial clinical regression by the time of radiation therapy implementation. Some experimental evidence suggests that the drug-induced accelerated cell repopulation can actually make the tumor more difficult to control with radiation.[39,40]

Other Potential Interactions

Modulation of Immunogenic Mechanism of Cell Death with Radiation

In the past decade, there has been significant advance in the understanding of the molecular signals involved in immunogenic cell death. Traditionally, radiation therapy was thought to have immunosuppressive potential, particularly if significant amounts of bone/bone marrow were in the treatment field. However, even as early as 1979, preclinical studies have demonstrated the potential importance of having an immune competent host to produce effective antitumor

effects by radiation.[44] In another preclinical study where higher dose of radiation (15 to 20 Gy) was used to treat implanted mouse melanoma B16 tumor, it was determined that these tumors only responded when implanted in immunocompetent hosts, whereas tumors in mice that were immunocompromised (nude mice), or in mice where CD8+ T cells were depleted, failed to respond to high-dose radiotherapy.[45] Several studies have suggested the potential importance of CD8+ T-cell infiltration as it relates to radiotherapy-mediated immune effects.[8] Additional preclinical and clinical studies have demonstrated that radiotherapy therapy (RT) may also exert tumoricidal effects both in the irradiated region and outside of the radiation field, through immune-mediated mechanisms.[9] There is now evidence to suggest that radiation and some chemotherapy agents can induce steps that can lead to immunogenic cell death. It has been demonstrated that radiotherapy can release and/or lead to expression of new antigens with immune adjuvant-like effects and has been suggested that this can convert irradiated cancer into an in situ vaccine that elicits tumor-specific T cells.[9] This “vaccination” can lead to immune memory, which becomes a powerful weapon against not only the irradiated tumor but also against nonirradiated tumor sites (e.g., abscopal effect), and potentially against cancer cells that later emerge after a period from dormancy.[9]

Preclinical and clinical data supports the notion that radiation can augment innate and adaptive immune response to increase the tumoricidal effects on the antigenic cancer cells that had previously escaped immune surveillance likely through immunosuppressive mechanisms. Mechanisms for immune enhancement by RT is suggested to involve (a) increased tumor-associated antigen (TAA) release, (b) initiation of release of danger-associated molecular patterns (DAMPs—calreticulin, ATP, HMGB1), which leads to activation of antigen-presenting cell (APC), (c) improved dendritic cell (DC) function, and (d) enhanced T-cell priming.[8] Radiotherapy is thought to lead to creation of an inflammatory microenvironment that is conducive to maturation of APCs and to T-cell activation. Chemokine expressions are induced resulting in chemotaxis of T cells to the tumor microenvironment. Signals driving migration of APCs to draining lymph nodes lead to T-cell priming and initiation of systemic response.[8] Signals driving migration of APCs to draining lymph nodes lead to T-cell priming and initiation of systemic response.[8] Radiotherapy can modulate the priming of adaptive immune response against tumors by increasing antigen release by cancer cells, increased antigen uptake by DCs, and increases DC maturation. DC maturation is required in order for DCs to migrate to the

draining lymph nodes to initiate an immune response. Radiation is also shown to increase recruitment of cytotoxic CD8+ T-cell infiltration by inducing chemokine expression, and by vascular normalization, which can lead to enhancement of tumor regression.[11] Inflammatory environment and recruitment of T cells to this microenvironment also may help sensitize cancers that are typically resistant to PD-L1 therapy.

Radiation can also facilitate increased recognition and killing of tumors by T cells in part by inducing MHC expression on cancer cells, and in some tumors, by up-regulation of cell death ligand Fas. In addition, radiation could increase recognition of tumor stroma and lead to destruction of this environment by cytotoxic T cells. Radiation also has been shown to sensitize cancer cells to recognition by natural killer (NK) cells.

Alternatively, radiotherapy also induces modulators of tumor immune response, by recruitment of immune suppressive factors, including myeloid-derived suppressor cells (MDSCs), tumor-associated macrophages, and regulatory T cells (Tregs). Studies would suggest that increase in myeloid cells would be protective of irradiated tumors by fostering a pro-growth environment and by inhibiting antitumor immune effects.[11] Radiotherapy can also lead to galectin-1 expression, which can lead to systemic lymphopenia,[46] and can up-regulate PD-L1 in tumor microenvironment,[47] which can lead to tumor escape mechanism from T cells. These dual effects (stimulation and suppression) of immune response by radiotherapy likely contributed to the overall lack of significant immune response unless radiotherapy is used in conjunction with an appropriate immune modulating agent.

It is recognized that tumors can suppress the antitumor immune response by multiple mechanisms, including production of inhibitory cytokines, recruitment of immunosuppressive immune cells, and up-regulation of immune checkpoints, which are molecules that enhance (costimulatory molecules) or inhibit the immune response.[48] Different strategies for harnessing immune response to exert its effect on tumors include development of receptors that can activate or block the inhibition of the immune response and lead to T-cell stimulation (Fig. 36.2).[49] Of these strategies, significant increase in understanding of checkpoints, molecules that shuts down the immune system as a means of immune suppression in tumors, have led to development of a novel clinically relevant paradigm for cancer therapy. Checkpoint inhibition as a method for inhibiting immunosuppressing mechanisms have been investigated for potential therapeutic gain. The two most studied immune checkpoint inhibitor class are strategies that

inhibit cytotoxic T lymphocyte antigen-4 (CTLA-4) and programmed death 1 (PD1).[50]

CTLA-4 is expressed on helper CD4+ T cells and T regulatory cells. It has a high affinity for binding B7-1 and B7-2 and prevents these from binding to CD28, a costimulatory receptor. CTLA-4 can also deliver inhibitory signal to CD8+ T cells and can increase the immunosuppressive activity of Tregs. Therefore, antibodies that effectively block CTLA-4 will lead to B7 ligands binding to CD28, enhance the expansion of effector CD8+ T-cell response, and prevents Treg, all of which leads to increased immune effects on tumor.[11] PD1 is expressed on effector T cells and typically acts in the tumor microenvironment. PD1 can be up-regulated by activated T cells and binds to ligands PD-L1 and PD-L2. Cytokines such as interferon gamma can induce the expression of PD-L1 on epithelial cells and tumor cells. PD-L2 are primarily expressed on DCs and macrophages. This binding can lead to apoptotic death of effector T cells, which can lead to exhaustion of antitumor response.[11] A number of preclinical studies have demonstrated that combining radiation therapy with CTLA-4 and PD1 inhibition is a promising novel strategy for cancer therapy.[11] There are preclinical data, and early clinical data suggesting that combining RT and checkpoint inhibiting immunotherapy can lead to synergistic immune effects both locally and in nonirradiated sites (synergistic enhancement of the abscopal effect).[10] Preclinical and early clinical studies also support continued investigation in to the use of radiation with other immune strategies including cytokine therapy (e.g., interleukin-2 [IL-2]) and vaccine therapy.[10] The furthest clinically developed CTLA-4 and PD-L1 inhibitors as these pertain to clinically applicable radiation-related immune effects are discussed in section on “Using Radiotherapy to Improve the Local and Distal Tumoricidal Effects of Immunotherapy, A Novel Paradigm in Combined Modality Therapy” below.

Molecular Signaling Pathways That May Be Responsible for Radioresistance

Significant strides have been made in elucidating molecular pathways that may be involved in resistance to cytotoxic therapy including radiation treatments. These molecular determinants are being scrutinized in preclinical and clinical settings as potential targets for cancer therapy, of which some agents are being studied for the potential for enhancing radiation effects.[51] For example, the efficacy of combining the epidermal growth factor receptor (EGFR) inhibitor cetuximab with radiation therapy has been demonstrated in randomized clinical studies in head and neck cancer patients.[52] Molecular targeting has become an immensely important topic, and effective integration of these strategies with radiation therapy to foster improved efficacy of therapy is an active area of investigation. This topic is further discussed in significant detail in the section to follow.

Targeting the Tumor Microenvironment

Tumor microenvironment has been postulated as being a potential therapeutic target for cancer therapy. Tumor microenvironment is a complex system of many cell types including endothelial cells, smooth muscle cells, fibroblasts, and cells involved with the immune system (lymphocytes, macrophages, etc.).[53] Among these different cells that make up the different components of the tumor microenvironment, the most studied preclinically and clinically are the cells that make up the tumor microvasculature. Preclinical studies have suggested the potential role for radiosensitization of the tumor microvasculature using compounds directed at targeting angiogenesis.[54] Clinical studies have been performed with efforts to combine antiangiogenic agents with radiation therapy, with mixed results.[54] Studies are ongoing, as many antiangiogenic agents are approved for cancer therapy, and are detailed in the section on antiangiogenic agents.

Cancer Stem Cells

Cancer stem cells are defined as being cells within a tumor that possess the capacity to self-renew and generate the heterogeneous lineages of cancer cells that make up the tumor.[55] Cancer stem cells as a source of radiation resistance for solid tumors is an area of active investigation. Potential for the need to eradicate cancer stem cells for effective cure by radiotherapy has been postulated, and although radioresistance of cancer stem cells has been noted in *in vitro* studies,[56] this notion has been challenged as some have demonstrated radiosensitivity of cancer stem cells.[57] But, if in fact cancer stem cells are radioresistant, one possible strategy may be to identify molecular pathways that could influence cancer stem cell radiosensitivity and investigate the use of such agents in combination with radiotherapy at different stages during the course of therapy.[58]

Combined Chemoradiation to Induce Immunogenic Cell Death Pathway

Some have proposed that achievement of immunogenic cell death may be another mechanism of improved outcomes seen with concurrent chemoradiation therapy.[9] Drug repositioning refers to the utilization of a known compound in a novel indication and new mode of activity leading to innovative therapy.[59] It has been proposed that cancer cell immunogenicity might be recovered through "repositioning"[59,60] achieved through concurrent use of chemotherapy with

radiation. In this concept, it is suggested that radiation and chemotherapy used together may complement one another and fulfill requirements for successful signaling of the immunogenic cell death pathway leading to more than additive outcomes and even noticeable improvements in nonlocoregional outcomes.

Improving Systemic Therapy Outcome by Cytoreduction of Gross Metastases with Local SBRT

Another proposed mechanism of improving outcomes with use of systemic agents with radiotherapy has been suggested involving patients with limited metastatic disease. This mechanism suggests that stereotactic body radiotherapy technique (SBRT) could be used to cytoreduce gross disease in patients with limited number of metastatic sites, at the onset of initiation of systemic therapy. This was based on studies suggesting that most failures after chemotherapy for non–small cell lung cancer (NSCLC) occur at the original gross disease and that most patients have metastases that are amenable to SBRT.[61] In a proof of principle study, a single-arm phase II trial of SBRT in patients with 6 or less metastatic site, with erlotinib systemic therapy beginning 1 week prior, and administered during, and after SBRT, was conducted.[62] This study demonstrated a remarkable progression-free survival (PFS) (14.7 months) and overall survival (OS) (20.4 months) as compared to historical patients with similar presentation. Furthermore, pattern of relapse was shifted, with failures occurring at new sites as opposed to the preexisting local sites. This suggests a potential novel mechanism for improving outcome of patients with limited metastatic disease, by combining cytoreductive SBRT with systemic treatments.

TIMING OF DRUG ADMINISTRATION IN RELATION TO RADIATION THERAPY

Most clinical chemoradiation therapy regimens evolved empirically: increasingly, information from preclinical studies is being considered in planning the optimal timing of drug administration in relation to radiation therapy. Depending on the principal aim of the therapy, drugs are administered before (*induction* or *neoadjuvant chemotherapy*), during (*concurrent* or *concomitant chemotherapy*), or after (*adjuvant chemotherapy*) the course of radiation therapy. The advantages and disadvantages of each approach are summarized in Table 36.1.

In regard to the primary tumor, induction chemotherapy may reduce the

number of clonogenic cells and cause the reoxygenation of the surviving hypoxic cells, both of which render tumors more controllable by radiation. In addition, chemotherapy-induced tumor shrinkage may allow the use of smaller radiation fields, in which case less normal tissue is exposed and damaged by radiation. This treatment approach is often used in the therapy of solid tumors in children and of lymphomas. Induction chemotherapy precedes radiation therapy for a few weeks to a few months, which improves tolerability of the combined treatment.

Induction chemotherapy has resulted in therapeutic improvement in a number of clinical trials compared with radiation therapy, but in general, the therapeutic benefits are below expectations. A number of factors could account for this, including accelerated proliferation of tumor cell clonogens and selection or induction of drug-resistant cells that are cross-resistant to radiation. The preclinical findings provide solid evidence for the existence of accelerated repopulation in tumors treated with chemotherapeutic agents. On the other hand, although development of drug resistance is a significant problem in chemotherapy, the evidence that cells that acquire drug resistance are also resistant to radiation is not convincing.

TABLE 36.1 ADVANTAGES AND DISADVANTAGES OF DIFFERENT CHEMORADIATION SEQUENCING STRATEGIES

Strategy	Advantages	Disadvantages
Sequential chemoradiation	• Least toxic • Maximizes systemic therapy • Smaller radiation fields if induction shrinks tumor	• Increased treatment time • Lack of local synergy
Concurrent chemoradiation	• Shorter treatment time • Radiation enhancement	• Compromised systemic therapy • Increased toxicity • No cytoreduction of tumor
Concurrent chemoradiation and adjuvant chemotherapy	• Maximizes systemic therapy • Radiation enhancement • Both local and distant therapy delivered up front	• Increased toxicity • Increased treatment time • Difficult to complete chemotherapy after chemoradiation
Induction chemotherapy and concurrent chemoradiation	• Maximizes systemic therapy • Radiation enhancement	• Increased toxicity • Increased treatment time • Difficult to complete chemoradiation after induction

When chemotherapy is given during a course of radiation therapy, it is referred to as *concurrent chemotherapy*. This form of treatment is intended to cope with both disseminated lesions and the primary tumor, but it takes advantage of drug–radiation interactions to maximize tumor radioresponse. The drug scheduling in relation to individual radiation fractions is highly important, and the selection of optimal timing of drug administration must be based on mechanisms of tumor radio enhancement by a given drug, the drug's normal tissue toxicity, and the conditions under which the highest enhancement is achieved. The data from preclinical studies can greatly contribute to the selection of the most optimal schedules. For example, it has been demonstrated that murine tumors sensitive to taxanes show enhanced radioresponse, but the best effect is achieved if drug treatment precedes radiation by 1 to 3 days.[26] A major mechanism for tumor radio enhancement was reoxygenation of hypoxic cells. Based on this preclinical information, one would anticipate that in clinical protocols such tumors would best respond to a bolus of a taxane given once or twice weekly during radiation therapy. In contrast, tumors resistant to taxanes on their own would call for daily administration of a taxane because they show accumulation of radiosensitive G_2- and M-phase cells 6 to 12 hours after drug administration. If the objective is to counteract rapid repopulation of tumor cell clonogens induced by radiation, then administration of cell cycle–specific chemotherapeutic agents during the second half of radiation therapy, when accelerated repopulation is more expressed, might be more effective. At present, the enhancement in normal tissue complications remains the major limitation of concurrently combining chemotherapy with radiation therapy. Nevertheless, as is made evident later in the text, concurrent chemoradiation therapy has provided better clinical results both in terms of local tumor control and patient survival than have other modes of chemoradiation therapy combinations.[63,64]

Adjuvant chemotherapy designates a treatment modality in which chemotherapeutic drugs are given some time after completion of radiation therapy. The primary objective is to eradicate disseminated disease; however, the control of the primary tumor may also be improved by the ability of drugs to deal with tumor cells that survived radiation.

INTERACTION OF SPECIFIC CHEMOTHERAPIES AND RADIATION IN THE TREATMENT OF CANCER

This section provides an overview of the evidence that exists for combining particular chemotherapies with radiation. In many cases, the level of support that exists for combined therapy mirrors the age of the drug. However, as would be expected, newer drugs have generally been subject to more rigorous preclinical assessment of their efficacy before their introduction into the clinical setting (Table 36.2).

Platinum-Based Drugs

This group of compounds, distinguished from most others by its metallic element base, has come to be recognized as one of the most potent chemotherapies available to date. Cisplatin (*cis*-diamminedichloroplatinum II), which is the prototype drug, has been acknowledged to be a potent radiosensitizer for many years and has a significant role in clinical practice to date. Preclinical work done using murine models by Rosenberg et al.[80] in the late 1960s showed that cisplatin is an effective antitumor chemotherapy. Subsequent efforts have shown that its primary mechanism of inhibition of tumor growth appears to involve the inhibition of DNA synthesis by formation of DNA cross-links.[81,82] Another secondary mechanism includes the inhibition of transcription elongation by DNA interstrand cross-links.[83]

Work on nonmammalian systems first demonstrated the radiosensitizing abilities of platinum-based compounds.[84–86] This was confirmed in several mammalian systems as well.[65,87,88] This makes inherent sense because these platinum compounds have a high electron affinity and react preferentially with hydrated electrons. The exact mechanism for the increased cell death seen with combinations of ionizing radiation and platinum drugs is not known for certain; however, the evidence would seem to point to the inhibition of PLDR[66] and to the radiosensitization of hypoxic tumor cells.[89] Cisplatin-free radical–mediated sensitization may involve the ability to scavenge free electrons formed by the interaction between radiation and DNA. The reduction of the platinum moiety may serve to stabilize DNA damage that would otherwise be repairable.[90] Greater than additive effects of cisplatin and radiation are seen in tumor models most reliably when the drug is administered with fractionated radiation,[90] explained by its inhibition of SLDR. Bladder cancer, head and neck cancer, lung cancer, esophageal cancer, and cervix cancer are some of the disease sites where cisplatinum is approved for use in combination with radiation therapy.

TABLE 36.2 MECHANISMS OF CHEMOTHERAPY-INDUCED

RADIATION SENSITIZATION

Class of Compound	Mechanism of Radiosensitization	References
Platinum-based compounds	Inhibition of DNA synthesis Inhibition of transcription elongation by DNA interstrand cross-links Inhibition of repair of radiation-induced DNA damage	65–68
Taxanes	Cellular arrest in the G_2M phase of the cell cycle Induction of apoptosis Reoxygenation of tumor cells	26,27,69,70
Topoisomerase I inhibitors	Inhibition of repair of radiation-induced DNA strand breaks Redistribution into G_2 phase of the cell cycle Conversion of radiation-induced SSBs into DSBs	71–73
Hypoxic cell cytotoxins	Complementary cytotoxicity with radiation on euoxic and hypoxic tumor cells	74,75
Antimetabolites	Nucleotide pool perturbation Lowering apoptotic threshold Cell cycle redistribution Tumor cell reoxygenation	19,20,76,77
Temozolomide	DNA repair inhibition (radiosensitization effect may be subject to MGMT status)	78,79

Carboplatin, a second-generation platinum compound with a different toxicity profile, has also been studied as a radiosensitizer.[67,68] Mechanism of action also involves interfering with function of DNA by producing interstrand DNA cross-links. Carboplatin tends to have less nephrotoxic or neurotoxic effects compared to cisplatin, but hematologic toxicity is slightly increased. Its potential efficacy as a radiosensitizer has allowed for its incorporation into regimens used in several randomized trials including but not limited to landmark trials which allowed for its indication for use in esophageal cancer, head and neck cancer, and lung cancer. Oxaliplatin, although sharing a similar mode of action as other platinum compounds, has been shown to have activity in cisplatin-resistant systems *in vitro*.[4] One potential explanation for this is that oxaliplatin is not affected by loss of mismatch repair, which leads to cisplatin resistance *in vitro*,[91] and there are those who postulate that adducts formed by oxaliplatin are less well recognized by DNA repair systems.[92] Whether oxaliplatin is truly active against cisplatin-resistant cancer clinically is an area of active investigation.[93] Despite encouraging findings in phase I to II rectal cancer studies, phase III studies integrating neoadjuvant oxaliplatin with 5-FU or capecitabine with

radiotherapy, with the exception of the CAO/ARO/AIO-04 study, have yielded negative findings (STAR-01, ACCORD 12, NSABP R04, PETACC-6).[94] In esophageal cancer, oxaliplatin-based chemoradiation therapy, although did not demonstrate improvement in efficacy over cisplatinum/5-FU–based regimen, was suggested to be a more convenient regimen and was not found to be more toxic.[95] Oxaliplatin-based regimens with radiation therapy are being further studied in additional randomized phase II studies in comparison to carboplatin-based regimen (NEOSCOPE and PROTECT-1402).[94,96]

Antimicrotubules

Taxanes

The radiosensitizing properties of plant-derived chemotherapeutic agents, the taxanes, have been studied extensively in both preclinical models and in clinical trials. Paclitaxel (Taxol) and docetaxel (Taxotere) act as mitotic spindle inhibitors through their promotion of microtubule assembly and inhibition of disaggregation.[97] Both taxanes bind to the *N*-terminal 31–amino-acid sequence of the *β*-tubulin subunit of cellular tubulin polymers, stabilizing the polymers by shifting the dynamic equilibrium that exists between tubulin dimers and microtubules in favor of the polymerized state.[98,99] Although there is preclinical evidence that docetaxel has both a higher affinity for the tubulin-binding site and greater *in vitro* cytotoxicity than paclitaxel, this has not necessarily translated into greater clinical efficacy because the toxicity profiles of the two drugs also differ.[100,101]

The administration of a taxane leads to cellular arrest in the G_2/M phase of the cell cycle, which is the precise point associated with increased sensitivity to the lethal effects of ionizing radiation.[102] Early laboratory studies with a human lung cancer cell line[25] and human astrocytoma cells[24] bore out the prospect of significant radiosensitization, with relative enhancement ratios in the 1.48 to 1.8 range when paclitaxel was administered before irradiation.

The exact conditions used in various studies appear to determine the strength of the interaction between radiation and paclitaxel because subadditive effects have been seen in addition to the more widely reported additive and supra-additive effects.[27] In general, enhancement of radiation effects is seen when proliferating cells have been incubated with moderate concentrations of paclitaxel for 24 hours before irradiation. Conditions leading to a less-than-optimal response include paclitaxel-mediated G_1 arrest, wherein a more resistant cell subpopulation counteracts the effects of a G_2/M block; paclitaxel-induced

cell cycle effects such as the G_2/M block in cells destined to die before irradiation; and incubation conditions insufficient to exert cellular effects. The fact that nonproliferating cells are also sensitized to the effects of radiation by the use of paclitaxel suggests that mechanisms other than the cell cycle arrest in the G_2/M phase underlie paclitaxel's sensitizing abilities.

Paclitaxel also acts to induce programmed cell death; work from the M.D. Anderson Cancer Center[27] has examined the relationship between mitotic arrest, apoptosis, and the antineoplastic activity of paclitaxel in 16 murine tumors. Single-dose paclitaxel (40 mg/kg) induced mitotic arrest to varying degrees in all tumors; however, apoptosis was induced in only 50% of tumors. This study also revealed that pretreatment levels of apoptosis correlated with both paclitaxel-induced apoptosis and tumor growth delay. Therefore, both the pretreatment apoptotic rate and paclitaxel-induced apoptotic rate could potentially act as predictors of the response to paclitaxel.

Milas et al.[27] summarized observations that showed that (a) there was massive loss of tumor cells though the apoptotic pathway was restricted to the perivascular region, and (b) radio enhancement occurring during this period of cell loss became even more impressive when apoptotic cells were removed from the tumor. Experiments in which tumor xenografts were treated with paclitaxel and exposed to radiation under hypoxic or air-ambient conditions were pursued.[26] It was found that the creation of hypoxic conditions greatly reduced the efficacy of paclitaxel in its enhancement of radioresponse. It appears that a combination of cell cycle effects, drug-induced reoxygenation, and drug-induced apoptosis underlies paclitaxel's radiosensitizing abilities.

Docetaxel has also been found to be a respectable radiosensitizer in both *in vitro*[69] and *in vivo* models.[70] Radiation response in the presence of docetaxel was examined in three different cell lines that have widely different responses to radiation alone.[103] Their findings suggest that the p53 status of tumor cells may have a profound effect on the radiosensitizing effects of a taxane. Other novel taxanes and analogs that continue to attract the interest of investigators for their potential to enhance radiation effects include Abraxane, paclitaxel poliglumex, larotaxel, cabazitaxel,[104,105] and orally available taxanes.[106]

Antimetabolites

5-Fluorouracil

The radiosensitizing properties of 5-FU has been known for years.[107] Several mechanisms have been proposed for the cytotoxicity of this drug:

a. Its incorporation into RNA, which leads to a disruption of RNA function
b. Inhibition of thymidylate synthase function and subsequently of DNA synthesis
c. Direct incorporation of the drug into DNA

It is believed that a combination of these effects underlies its radiosensitizing properties.[108] Optimization of its schedule of delivery is crucial to obtaining an effect with this combination, and it is accepted that cytotoxic doses of 5-FU are needed to obtain a radiosensitizing effect. In general, it is thought that a continuous infusion of the drug is needed to obtain the desired drug levels after irradiation.[109] Long-standing clinical experience with this drug bears out much of the laboratory studies of its effectiveness as a radiation sensitizer. Gastrointestinal tract cancers, bladder cancer, and head and neck cancers are some of the disease sites where 5-FU–based combined modality therapy with radiation is used as standard of care.

Capecitabine

Capecitabine is an oral prodrug of 5-FU. It is converted to its cytotoxic form in three enzymatic steps, the last of which is mediated by thymidine phosphorylase. One of the potential advantages of this mechanism for increasing tumor cytotoxicity is that thymidine phosphorylase is overexpressed in tumor tissues. Interestingly, radiation has been shown to stimulate expression of thymidine phosphorylase, which provides a further rationale for considering combined therapy with radiation treatments.[110] Capecitabine was shown to be safe to replace 5-FU in chemoradiotherapy regimen for rectal cancer.[111] It is being used in the combined modality setting as standard therapy, and in clinical trials, for many tumor types (including but not limited to rectal cancer, gastric cancer, esophageal cancer) requiring fluorouracil-based chemoradiation.

Gemcitabine

Gemcitabine is another nucleoside analog that acts as a very potent radiosensitizer. The biologic action of gemcitabine is due almost completely to its effects on DNA metabolism. Early studies of this drug in leukemic cell lines found that notable decreases in cellular deoxynucleotide triphosphates occurred with the use of the drug.[112]

Direct incorporation of the drug into DNA and drug-induced apoptosis are also thought to underlie its cytotoxicity.[112] The metabolism of gemcitabine in the cell is complex, and it is able to potentiate its cytotoxicity as a sole therapy.[112]

Depending on the conditions, relative enhancement ratios in the range of 1.1 to 2.5 have been reported.

Gemcitabine is S-phase specific and as such should be selectively toxic to proliferating cells,[113] decreasing the amount of proliferation that can occur during fractionated radiation therapy. In addition, cell cycle redistribution induced by these agents may improve cell kill by allowing more cells to be treated in the more sensitive parts of the cell cycle.[114] As DNA synthesis inhibitors, these drugs may act to inhibit the repair of radiation-induced DNA damage.[19] Finally, as DNA chain terminators, they may serve to trigger the apoptotic response.[20]

There is strong preclinical evidence to suggest that the radiosensitizing abilities of gemcitabine are intimately linked to cellular deoxyadenosine triphosphate levels.[20] Interesting results from Latz et al.[76] show quite clearly that cells that are pretreated with gemcitabine no longer show a progressive increase in radioresistance as they progress toward DNA replication, and sensitization, therefore, appears to be greatest in the S-phase.

Milas et al.[21] found the largest enhancement of growth delay when gemcitabine was delivered 24 to 60 hours before irradiation in a murine sarcoma tumor model. The use of gemcitabine with radiation also decreased the risk for development of lung metastases in those mice that attained durable local control (73% in the radiation-alone group vs. 40% in the combined modality group), which was confirmed in a second study with a larger number of mice.[77] This preclinical work is supportive of the principles of combined modality therapy in that better local control translated into decreased systemic spread of tumor cells. The same authors also report a dose-dependent increase in the apoptotic rate after the administration of gemcitabine,[21] which they believe correlates with the elimination of the more radioresistant S-phase population of cells and a redistribution of the remaining cells into more radiosensitive parts of the cell cycle. They also report that reoxygenation of the resistant hypoxic fraction of tumor cells is a mechanism for the radiosensitizing action of gemcitabine.[77]

In summary, the preclinical evidence suggests that gemcitabine acts through several mechanisms (nucleotide pool perturbation, lowering of the apoptotic threshold, cell cycle redistribution, and tumor cell reoxygenation) to enhance the effect of ionizing radiation on tumors. Clinical experience has shown that this drug is indeed a potent sensitizer with the potential for significant toxicity as well as improvement in tumor control when combined with radiation.[115–121]

Pemetrexed

Pemetrexed is a novel multitargeted agent, exerting its effect via simultaneous inhibition of multiple folate-requiring enzymes, including thymidylate synthase, dihydrofolate reductase, and glycinamide ribonucleotide formyl-transferase.[122] Pemetrexed has shown synergistic activity with radiation treatments, likely because of interference with DNA synthesis.[123] There are indications that radiosensitization by pemetrexed is not cell cycle phase specific[124] *in vitro*. Others have suggested that a combination of radiation therapy and pemetrexed results in supra-additive effects, which may be in part because of apoptosis induction.[125] Phase III study in NSCLC has demonstrated nonsuperiority for pemetrexed–cisplatin with radiation, compared to cisplatin-etoposide and radiation, and although trial closed early because of futility, it is considered to be a potential alternative regimen.[126]

Topoisomerase I Inhibitors

Camptothecin is a plant alkaloid obtained from the *Camptotheca acuminata* tree. Its initial clinical evaluation in the 1960s and 1970s was abandoned because of severe and unpredictable hemorrhagic cystitis.[127,128] Camptothecin and its derivatives (e.g., irinotecan, topotecan, 9-aminocamptothecin, SN-38) target DNA topoisomerase I.[129–131] This enzyme relaxes both positively and negatively supercoiled DNA and allows for diverse essential cellular processes, including replication and transcription, to proceed. In the presence of camptothecin, a camptothecin–topoisomerase I–DNA complex becomes stabilized with the 5′-phosphoryl terminus of the enzyme-catalyzed DNA SSB bound covalently to a tyrosine residue of topoisomerase I. These stabilized cleavable complexes interact with the advancing replication fork during the S-phase or during unscheduled DNA replication after genomic stress and cause the conversion of SSBs into irreversible DNA DSBs, resulting in cell death.[130]

Several investigators have reported that camptothecin enhances the cytotoxic effect of radiation *in vitro* and *in vivo*.[71–73] Chen et al.[72] showed that cells exposed to 20(S)-10,11 methylenedioxy-camptothecin before or during radiation had sensitization ratios of 1.6, whereas those treated with the drug after radiation had substantially less enhancement of radiation-induced DNA damage. There are several hypotheses regarding the mechanism of interaction between radiation and irinotecan: (a) inhibition of topoisomerase I by irinotecan leads to inhibition of repair of radiation-induced DNA strand breaks; (b) irinotecan causes a redistribution of the cells into the more radiosensitive G_2 phase of the cell cycle;

(c) topoisomerase I–DNA adducts are trapped by irinotecan at the sites of radiation-induced SSBs, leading to their conversion into DSBs.[132] Although there is currently insufficient evidence to identify the underlying mechanism with certainty, the primary mechanism involved with radiosensitization may depend on which camptothecin derivative is being used.

Data from *in vivo* experiments demonstrate that combination 9-aminocamptothecin and irradiation is more effective when fractionated, compared with single doses.[133] There is also evidence for circadian-dependent cytotoxicity and radiation sensitization when camptothecin derivatives like 9-aminocamptothecin are used as radiation sensitizers.[133] The integration of this group of drugs into clinical treatments with radiation therapy has been explored in NSCLC and brain tumors.[134–137]

Alkylating Agents

Temozolomide

Temozolomide is a second-generation alkylating agent, which is orally administered, is readily bioavailable, and demonstrates broad-spectrum activity in a variety of difficult-to-treat malignancies including glioma and melanoma.[138] It is unique in its ability to cross the blood–brain barrier (about 30% to 40% of plasma concentration found in CSF). *In vitro* studies demonstrate increased inhibition of cell growth in combination with radiotherapy.[139] Radiosensitization appears to occur via inhibition of DNA repair, leading to an increase in mitotic catastrophe.[78] It has proven efficacy as a first-line therapy for glioblastoma multiforme (GBM) patients in conjunction with radiotherapy based on a randomized phase III clinical study demonstrating survival benefit.[140] Temozolomide spontaneously converts to the reactive methylating agent 5-(3-methyl-1-triazeno)imidazole-4-carboxamide (MTIC) and transfers methyl groups to DNA, the most important one being at the O6 position of guanine, an important site for DNA alkylation.[141] The MGMT gene encodes a DNA repair protein that removes the alkyl group from the O6 position of guanine, and high MGMT activity levels abrogate the effectiveness of alkylating agents. *In vitro*, temozolomide enhances the radiation response most effectively in MGMT-negative glioblastomas, and likely because of decreased double-strand DNA repair capacity and increased DNA DSB damage, which occurs when the combination of temozolomide and radiation therapy was administered.[79] Analysis of a randomized study by the European Organization for Research and Treatment of Cancer (EORTC) and National Cancer Institute of Canada (NCIC)

demonstrated that loss of MGMT expression by promoter methylation is correlated with a better outcome after treatment with radiation and temozolomide.[142] Temozolomide and radiation combination is considered the backbone standard therapy for newly diagnosed GBM, upon which combination of additional new investigational agents are being studied.

Other Agents

Mitomycin-C

Mitomycin-C is a quinone, whose mechanisms of action include inhibition of DNA and RNA synthesis.[143] When combined with radiation, the rationale for the use of mitomycin-C is based on its ability to target hypoxic cells that are known to be relatively radiation resistant.[144] There is preclinical evidence to suggest that mitomycin-C administered before irradiation leads to a supra-additive interaction.[74,145] The postulated mechanisms of action for supra-additivity include prevention of repopulation and hypoxic cell sensitization, although the definitive action is not fully elucidated. Given that normal tissues are not hypoxic, the selective targeting of this cell population with mitomycin-C has the potential to improve cures without compromising normal tissue complication rates. The use of mitomycin-C is limited by its hematologic toxicities. Mitomycin-C combined with radiation therapy remains the standard-of-care therapy for anal carcinoma based on multiple clinical studies.[146]

Hypoxic Sensitizers

Tirapazamine

Investigators have pursued a similar strategy as outlined previously with the development of tirapazamine, a hypoxic cell cytotoxin.[28,75] Brown[75] has discovered that tirapazamine, which is a benzotriazine di-*N*-oxide, is toxic to hypoxic cells at concentrations much lower than what is needed to radiosensitize cells. It has the greatest differential toxicity known between hypoxic and well-oxygenated cells. Essentially, this drug functions through its intracellular reduction to form a highly reactive radical capable of causing both SSBs and DSBs.[147] In the presence of oxygen, a free electron is absorbed, and the compound is back-oxidized to the parent compound with the concomitant release of a superoxide radical, which is much less cytotoxic than the tirapazamine radical. Clinical trials are ongoing or have been completed in multiple tumor sites including cervix, head and neck, GBM, and lung malignancies (small cell lung cancer).[148–160] Although most studies have demonstrated a reasonable

toxicity profile, several studies have suggested caution in the appropriate selection of a dose and delivery regimen when combining tirapazamine to a standard chemoradiation regimen.[152,155,161]

Fairly promising earlier phase studied led to phase III studies in head and neck and cervical cancer. A phase III study by the Trans-Tasman group (TROG 02.02) suggested no significant improvement in survival outcome in locally advanced head and neck cancer patients, unselected for hypoxia, with the addition of tirapazamine to a standard platinum-based chemoradiation regimen.[158] A subset analysis of the phase II study from the TransTasman Group suggested that tumors with a hypoxic component as assessed by 18F fluoromisonidazole positron emission tomography (FMISO-PET) imaging had a higher likelihood of locoregional failure, whereas an improvement in local control was identified for those treated with the addition of tirapazamine, suggesting that it specifically targets hypoxic tumor cells.[154] Similarly, GOG phase III trial studying the role of addition of tirapazamine to platinum-based radiation therapy in cervical cancer was closed early and demonstrated no improvement in survival outcomes with the addition of tirapazamine.[161] Study was closed early because of lack of available study drug and limits future development of this drug.[161–163]

Nimorazole

Nimorazole is another hypoxic cell radiosensitizer belonging to a class of chemical known as 5-nitroimidazoles, with less neuropathic toxicity than misonidazole; it has demonstrated improved tumor control outcome and tolerability with radiotherapy, in supraglottic laryngeal and pharyngeal tumors in the DAHANCA 5 study.[38] A randomized multicenter study, IAEA-HypoX study with nimorazole and concomitant accelerated radiotherapy in head and neck squamous cell carcinoma, was attempted but closed prematurely in 2014 because of poor recruitment (100 of the intended 600 patients were accrued).[30] Although closed early, it suggested an improvement in locoregional tumor control with the addition of nimorazole. Additional ongoing trials include NIMRAD, a phase III study of addition of nimorazole to radiotherapy in patients with locally advanced head and neck cancer not suitable for chemotherapy or cetuximab.[163] EORTC has opened a phase III multicenter study of radiation with or without nimorazole using a 15-gene signature for hypoxia in the treatment of head and neck squamous cell carcinoma. DAHANCA 30, a randomized noninferiority study of hypoxia-profile guided selection of patients who are predicted to be

nonresponders to chemoradiotherapy with or without nimorazole, is recruiting patients.

EMERGING STRATEGIES FOR IMPROVEMENT OF CHEMORADIATION THERAPY

In spite of increasing therapeutic achievements of chemoradiation therapy, the use of this form of therapy is still very much restricted by its narrow therapeutic index. The available agents are either insufficiently effective on their own or in combination with radiation against tumors, or normal tissue toxicity prevents the use of effective doses of drugs or radiation. Significant research efforts, both preclinical and clinical, have been undertaken to improve chemoradiation therapy. They include developing more selective and more effective chemotherapeutic agents, incorporating additional agents into chemoradiation therapy that protect normal tissues from injury by drugs or radiation, and improving the technique of radiation therapy delivery to minimize treatment of adjacent normal tissue while maximizing tumor dose delivery.

Increasing Antitumor Efficacy of Chemotherapeutic Drugs

A number of newer chemotherapeutic agents are being developed with the goal of enhancing antitumor effects by improving on the selective targeting of tumor cells via strategies such as chemical modification of known compounds including agents currently in use with radiation therapy because of their radiosensitizing properties.

Approaches for improvement of drug safety, convenience, or efficacy could include chemical modifications or modifications of the formulation of a known drug. One example is that of Abraxane (nab-paclitaxel, ABI-007). Abraxane is a 130-nM particle form of paclitaxel that is bound to albumin and is solvent free. This avoids the need for Cremophor-based vehicles and lowers the risk of hypersensitivity reactions.[104] Such vehicles have the potential for altered pharmacokinetics by drug entrapment, leading to decreased drug clearance, decreased volume of distribution, and ultimately nonlinear pharmacokinetics. Interestingly, Abraxane has been demonstrated to have higher antitumor activity compared to Taxol in preclinical studies. This is in part mediated via utilization of albumin receptor–mediated endothelial transport, which leads to higher intracellular accumulation compared to standard paclitaxel.[164] Clinically, Abraxane has shown demonstrated efficacy in metastatic breast cancer in a phase

III study.[165] Phase I/II studies in advanced NSCLC, melanoma, bladder cancer, high-risk prostate cancer, and gynecologic malignancy have been reported.[165–176] Preclinical studies have demonstrated Abraxane to have radiosensitizing properties.[177] Therefore, there is significant interest in determining the potential efficacy of Abraxane in disease sites where combined therapy with taxanes and radiation has demonstrated therapeutic advantage. Phase I and phase I/II study of nab-paclitaxel with radiation in lung cancer and head and neck cancer have been completed and reported demonstrating tolerability.[178,179]

Another approach to make current chemotherapeutic drugs more effective against tumors and at the same time less toxic to normal tissues is compound modification via conjugation with water-soluble polymeric drugs, such as polyglutamic acid. These conjugates accumulate in tumors and release the active drug into the tumor in high concentrations and for a longer time. The enhancement in uptake by and prolongation of drug release in tumors are thought to be due to the enhanced permeability and retention effect of macromolecular compounds in solid tumors.[180,181] The abnormal vasculature in tumors is porous to macromolecules, but high concentrations of drug can build up in tumors owing to inadequate lymphatic drainage, whereas polymer–drug conjugates are confined to the bloodstream in normal tissue.[180] This leads to improved spatial localization of the cytotoxic drug within tumor. A promising polyglutamic acid–paclitaxel conjugate (paclitaxel poliglumex) was developed. It is less toxic, more effective against tumors, and more enhancing of tumor radioresponse in preclinical studies than unconjugated paclitaxel.[181,182] Furthermore, there are *in vivo* laboratory data suggesting that radiation adds to the accumulation of drug within tumors by modification of tumor vasculature.[183] Therefore, multiple mechanisms for spatial localization and cooperation, including inherent drug properties, radiation modification of vasculature, and radiation-based targeting of sites within the body, could make this an attractive strategy for combining this agent with radiation treatments. Clinical trials in esophageal cancer (phase II), gastric cancer (phase I), and glioblastoma without MGMT methylation (phase II) have been reported in combination with radiation treatments.[184–186]

Normal Tissue Protection

Because normal tissue toxicity represents a major limitation of concurrent chemoradiation therapy, every effort must be taken to prevent or minimize

complications. This could be achieved through the incorporation into the treatment of radioprotective or chemoprotective agents or through improvements of radiation delivery. A number of chemical and biologic compounds are available that exhibited either selective or preferential protection of normal tissues in preclinical *in vivo* testing.[187–191] In addition, there are many candidate compounds, particularly extracts from plants used in traditional medicine settings, that are undergoing *in vitro* evaluation.[192–194] The most commonly tested radioprotectors are thiol compounds, such as WR-2721 (amifostine), a prodrug that must be converted *in vivo* to its active metabolite WR-1065. Amifostine is currently the only Food and Drug Administration (FDA)-approved radioprotector. The principal mechanisms of protection by these agents include scavenging of free radicals generated by ionizing radiation and some chemotherapy agents, such as alkylating agents, and donating hydrogen atoms to facilitate direct chemical repair of DNA damage. However, amifostine modulates transcriptional regulation of genes involved in apoptosis, cell cycle regulation, and DNA repair as well.[195] The protector is taken up preferentially by normal tissues, where the entry into cells is accomplished by active transport. In contrast, the drug diffuses passively into tumors, where its availability is also reduced by deficient tumor vasculature. Amifostine has been shown to reduce normal tissue toxicity in a number of clinical settings, including protection of salivary glands in head and neck radiation therapy,[196,197] prevention of acute and late normal tissue toxicities from chemoradiation in cancers of the head and neck,[198] and the esophagus in chemoradiation therapy of lung cancer,[199,200] without adversely affecting tumor response to treatment. The drug significantly protects against cisplatin-induced nephrotoxicity, ototoxicity, and neuropathy.

Emerging Strategies to Improve Radiation Therapy

Technology-Based Strategies

Several technologic strategies to improve the efficacy and decrease the toxicity of radiation therapy have been developed. These advances include improvements in radiation therapy delivery, such as three-dimensional treatment planning, conformational radiation therapy, intensity-modulated radiation therapy (IMRT), and image-guided radiation therapy (IGRT). Use of heavy particles, such as protons or carbons, which have a more favorable beam profile, is another approach likely to minimize the toxicity, and combining such treatments with chemotherapy may lead to enhancement of the effectiveness of not only radiation therapy but also chemoradiation treatments. The principle primarily

exploited with this would be that of maximizing spatial localization, with technologic advances and/or heavy particles being used to maximize radiation therapy's spatial localization. Further advances in imaging, with the advent of molecular-based imaging applications in oncology, will lead to further refinement of IGRT techniques. Because there are significant discussions of three-dimensional conformational radiation therapy (3DCRT), IMRT, IGRT, and heavy particles detailed in other chapters, we refer readers to those chapters for more in-depth discussion.

Altering Fractionation Schemes to Improve Therapeutic Ratio for Chemoradiation Treatments

Accelerated fractionation regimens are designed to counteract tumor repopulation, and accelerated fractionation with concomitant boost technique has shown superiority in terms of local control over the standard fractionation regimen in a large randomized study for head and neck cancer patients.[201] Head and neck cancer remains one of the best paradigms for effectiveness of accelerated fractionation methods in clinical use. However, when combined with chemotherapy, a benefit to accelerated fractionation over standard fractionation was not demonstrated.[202]

Hyperfractionation is another strategy aimed at increasing the tumoricidal dose by delivering smaller doses/fractions, which allows a higher total dose to be administered as smaller doses/fractions lead to improved tolerance of late-responding normal tissues.[102] The efficacy of hyperfractionation over standard fractionation has been demonstrated in several disease sites, including lung and head and neck cancer.[201,203,204] In head and neck cancer, hyperfractionated radiation therapy with chemotherapy has yielded superior outcomes compared to hyperfractionated RT alone[205]; however, there has been no trial to demonstrate superiority of hyperfractionated RT and chemotherapy compared to conventional RT and chemotherapy. Perhaps, given the limited success of concurrent therapy, methods of combining systemic agents sequentially either before or after radiation treatments with altered fractionation can be considered.

THE CLINICAL EXPERIENCE WITH CHEMORADIATION IN CANCER THERAPY

The level of clinical experience with the combination of radiation and chemotherapy has increased dramatically during the years. In many tumor types,

the sequencing and method of administration of the combination have been very important in attaining improved outcomes seen in randomized trials. Improved local control and better OS rates have resulted from combination therapy in a number of diseases, including rectal cancer, limited-stage small cell lung cancer, locally advanced NSCLC, esophageal cancer, gastric cancer, cervical cancer, glioblastoma, and rhabdomyosarcomas. Equally important are the successes seen in the realm of organ preservation in sarcomas of the extremity, bladder cancers, carcinomas of the anal canal, head and neck cancers, and breast cancer.

As the role for combined modality therapy and studies leading to such for each of the tumor types are well represented in individual chapters addressing the disease site, readers will be referred to individual disease site chapters in the text for details. Briefly summarized in Table 36.3, however, are some representative disease sites in adult malignancies, where combined modality therapy with chemotherapy and/or targeted biologic agents and radiation therapy is accepted as the standard of care. The table also summarizes the commonly used systemic agent for these different disease sites. As one can see, the list, while not comprehensive, is certainly extensive and impressive, and the clinical impact that combined modality therapy has had in each of these disease sites cannot be understated.

TABLE 36.3 CHEMORADIATION THERAPY AS STANDARD OF CARE BY SELECTED DISEASE SITES

Disease Site	Commonly Used Chemotherapeutic Agents	Sequencing and Intent of Therapy	Benefit of Combined Modality Approach
Locally advanced head and neck cancer	Cisplatin, 5-FU, hydroxyurea, carboplatin, cetuximab	• Definitive concurrent • Postoperative concurrent	Definitive: organ preservation/survival benefit Postoperative: DFS/LRC benefit; OS benefit in subset of patients
Glioblastoma multiforme	Temozolomide	• Postoperative concurrent • Definitive concurrent in unresectable cases	Overall survival
Locally advanced/unresectable non–small cell lung cancer	Cisplatin, Carboplatin, Paclitaxel, Etoposide,	• Definitive concurrent • Sequential	Overall survival

	Vinblastine		
Limited-stage small cell lung cancer	Cisplatin/etoposide	• Definitive concurrent	Overall survival
Esophageal cancer	Cisplatin/5-FU	• Preoperative concurrent • Definitive concurrent	Local control, overall survival
Gastric cancer	5-FU, Leucovorin	• Postoperative concurrent	Overall survival
Pancreatic cancer	5-FU, Gemcitabine	• Postoperative concurrent • Definitive concurrent in unresectable patients	Locoregional control, possibly survival
Locally advanced rectal cancer	5-FU, Xeloda	• Preoperative concurrent	Improved sphincter preservation, improved DFS
Anal cancer	5-FU, mitomycin C	• Definitive concurrent	Improved colostomy free survival
Cervical cancer	Cisplatin, 5-FU, hydroxyurea	• Definitive concurrent	Overall survival benefit
Bladder cancer	Cisplatin, 5-FU, mitomycin C	• Definitive concurrent	Bladder preservation

TABLE 36.4 REPRESENTATIVE LONG-TERM TOXICITY OF COMBINED CHEMORADIATION THERAPY

Agent	Toxicity	Mechanism	References
Bleomycin	Pneumonitis/pulmonary fibrosis	Undefined but related to total drug dose and effects on pulmonary macrophages, type I and II alveolar cells; effects/lethality exacerbated by the administration of radiation.	206–208
Actinomycin D	Hepatopathy	Altered liver function postradiation leads to decreased metabolism of agents, including actinomycin, which in turn worsens the hepatopathy.	209,210
Doxorubicin	Cardiomyopathy	There is an additive interaction between doxorubicin and radiation with recall of radiation effects occurring. Primary radiation effect is on the endothelial cell, whereas doxorubicin affects the connective tissue stroma of the myocardium.	211–214

Methotrexate	Leukoencephalopathy	Methotrexate may cause this syndrome on its own. Radiation effects on the blood–brain barrier and the choroid plexus can alter methotrexate clearance, leading to higher levels in the brain. Effects are increased when both modalities are used.	215–217
Cisplatin	Sensorineural hearing loss	Although cisplatinum alone can cause this, reports suggests radiation therapy concurrently with cisplatin may contribute to sensorineural hearing loss.	218–221

As outcomes in each of the solid tumors improve with concurrent therapy, we need to become cognizant of the potential for significant long-term toxicity from combination chemoradiation and do our best to minimize the risks that these side effects pose to patient survival and quality of life. Several well-documented chemoradiation-imposed late effects are summarized in Table 36.4.

MOLECULAR TARGETED THERAPIES: NEW AGENTS AND NOVEL PARADIGMS FOR OPTIMIZING COMBINED MODALITY THERAPY

Discoveries in molecular biology have identified a number of molecular pathways involving receptors, enzymes, or growth factors that may be responsible for resistance of cancer cells to radiation or other cytotoxic agents and as such may serve as targets for augmentation of radiation response or chemotherapy response. It is becoming more evident that with advances in the understanding of the molecular processes that are associated with various malignancies, a molecular profile of a tumor may prove to be as important as its pathologic profile. Further classification of a patient's tumor molecular profile should, among other things, aid in selection of the appropriate targeted agents. The challenge for radiation oncologists in this molecular era is determining what would be the best method of integrating cytotoxic radiation treatments with a molecular-based therapeutic plan.

Among this expanding list of molecular targets are epidermal growth factor (EGF) and its receptor (EGFR); vascular endothelial growth factor (VEGF) and its receptor (VEGFR); mammalian target of rapamycin (mTOR); anaplastic lymphoma kinase (ALK) fusion proteins; heat shock protein 90 (hsp90); poly(adenosine diphosphate [ADP]-ribose) polymerase (PARP); mutated *ras*;

histone deacetylase (HDAC) inhibitors; cell cycle checkpoint control proteins such as checkpoint kinase 1 (CHK1); a number of the DNA repair enzymes, including DNA-dependent protein kinase (DNA-PK), ataxia telangiectasia mutated (ATM), and RAD51; the proteasome; angiogenic molecules; and various other molecules that regulate different steps in their signal transduction pathways.[222] Several agents have now gained FDA approval for cancer therapy in patients, and many are undergoing clinical trials to determine their efficacy when used in combination with radiation therapy. Some agents are potentially single-pathway targets, and others are able to target multiple molecular signaling pathways. Some molecular strategies to improve chemoradiation therapy are shown in Table 36.5. The most clinically advanced of these strategies include agents targeting EGFR, VEGF and VEGFR, and ALK1 pathways. The scope of this section will be a discussion of some relevant molecularly targeted agents that have been FDA approved for use and which hold promise for use in conjunction with radiation treatments.

TABLE 36.5 MOLECULAR TARGETING POSSIBILITIES IN COMBINATION WITH CHEMO/RADIATION OR RADIATION

Class	Agents	Status in Combination with XRT (Published)
Epidermal growth factor receptor inhibitors	Cetuximab	HN cancer—phase III NSCLC—phase III Other sites—phase I/II
	Gefitinib	NSCLC—phase III Other sites—phase I/II
	Erlotinib	Phase I/II
	Afatinib	None reported
Antiangiogenics	Bevacizumab	GBM—phase III Other sites—phase I/II
	Thalidomide	Brain metastases—phase III Other sites—phase I/II
Multitargeted tyrosine kinase inhibitors (TKIs)	Sunitinib (inhibits PDGFR, VEGFR, KIT, RET, CSF-1R, FLT3)	Phase I, II
	Sorafenib (inhibits Raf kinase, PDGF, VEGFR2/3, cKit)	Phase I, II
	Pazopanib (inhibits VEGFR1–3, PDFR-alpha, beta, c-Kit, FGFR-1, FGFR-3, Lck, c-Fms)	Phase I

mTOR inhibitors	Temsirolimus	Phase I
	Everolimus	Phase I, II
ALK inhibitor	Crizotinib	None reported
HDAC inhibitors	Vorinostat	Phase I
DNA repair	Romidepsin	None reported
	Veliparib	Phase I
	Olaparib	None reported
	Niraparib	None reported
	Rucaparib	None reported

Epidermal Growth Factor Receptor

Targeting EGFR is one of the current model paradigms for the combination of molecular-based therapy and radiation. EGFR is also known as ErbB1, a member of the ErbB family of receptor tyrosine kinases, which also includes ErbB2 (HER2/neu). EGFR is a 170-kD transmembrane glycoprotein with an intracellular domain possessing intrinsic tyrosine kinase activity. On binding to a ligand, such as EGF or transforming growth factor-*α*, EGFR undergoes autophosphorylation and initiates transduction signals regulating cell division, metastases, angiogenesis, proliferation, and differentiation. EGFR plays an important role in tumor growth and response to cytotoxic agents, including ionizing radiation. The receptor is frequently expressed in high levels in many types of cancer, which is often associated with more aggressive tumors, poor patient prognosis, and tumor resistance to treatment with cytotoxic agents including radiation.[223–227] *In vitro* experimental studies have provided solid evidence linking EGFR with resistance to cytotoxic drugs. Although transfection of EGFR into tumor cells increases their resistance to drugs[228] and radiation,[229] the blockade of the EGFR-mediated signaling pathway with antibodies to EGFR enhances the sensitivity of tumor cells to drugs[226] and ionizing radiation.[230] *In vivo* studies have shown that blockade of EGFR, such as with cetuximab, anti-EGFR monoclonal antibody (mAB), or interference with its downstream signaling processes, can improve tumor treatment with both chemotherapeutic agents and radiation.[231,232] Furthermore, overexpression of constitutively active EGFR vIII has been correlated with enhanced radioresistance.[233]

Broadly speaking, the two most developed strategies for inhibiting EGFR include the use of mABs against EGFR and small molecule tyrosine kinase inhibitors (TKIs). Cetuximab and panitumumab are examples of mABs, and their mechanism includes blocking the extracellular binding domain, thus inhibiting dimer formation. TKIs such as gefitinib or erlotinib target the intracellular tyrosine kinase domain. However, the activity of EGFR is

complicated by the signal diversity because of the formation of homo- and heterodimers with other members of the ErbB family and by the specific autophosphorylation patterns within each ErbB family member. This is further compounded by the identification of specific mutations within EGFR that confer sensitivity to certain EGFR inhibitors. The approach of combining an anti-EGFR therapy with cytotoxic agents including radiation in the treatment of patients with cancer remains an area of active investigation,[52,234–238] and some of these key agents warrant further discussion.

Cetuximab (Erbitux)

Cetuximab is a chimeric mouse anti-EGFR mAB and is perhaps the most widely studied and developed mAB in this class. It has been studied in a large randomized phase III trial for locally advanced head and neck squamous cell carcinoma patients. This study included 424 patients treated with either radiation therapy alone or radiation therapy with concurrent cetuximab. Median survival was nearly doubled (49 months vs. 29 months, P = .03), and PFS and locoregional control were both improved with the addition of cetuximab.[52] This resulted in FDA approval in 2006 for use of cetuximab in combination with radiation treatments for locoregionally advanced head and neck cancer.

However, studies of combining cetuximab with established chemoradiation regimen have been relatively unsuccessful at improving outcomes. Radiation Therapy Oncology Group (RTOG) 0522 is a randomized study comparing the addition of cetuximab to standard concurrent cisplatinum and radiation treatments in head and neck cancer patients. This study demonstrated no benefit to addition of cetuximab, increased grade 3 to 4 acute toxicity events, and more frequent interruptions in radiotherapy.[239] Outcomes also did not differ by EGFR expression in this study. For esophageal cancer, potential role of cetuximab being added to chemoradiation therapy were studied in a multicenter, phase II/III randomized trial (SCOPE1), and randomized phase III trial (RTOG 0436). SCOPE1 demonstrated worse outcomes with worse toxicities and inferior survival outcomes with cetuximab.[240] RTOG 0436 demonstrated no improvement in outcomes with addition of cetuximab.[241]

Interestingly, recent phase II studies for stage III NSCLC were reported by the RTOG 0324 and Cancer and Leukemia Group B (CALGB) groups.[120,242] In the randomized phase II CALGB study, two novel chemotherapy regimens in combination with concurrent radiation therapy were investigated in stage III NSCLC patients. The first group received carboplatin (area under the curve

[AUC] = 5) and pemetrexed (500 mg/m^2) every 21 days for four cycles with 70 Gy of RT. The second group received the same with the addition of cetuximab. Both groups received four cycles of pemetrexed as consolidation therapy. The primary endpoint was 18-month survival with a goal of ≥55%, at which point the regimens would be deemed worthy of further study. The carboplatin/pemetrexed/RT arm demonstrated 18-month OS of 58% and the group with cetuximab, 54%. The combination of thoracic radiation, pemetrexed, and carboplatin, with or without cetuximab, was demonstrated to be feasible and fairly well tolerated.[120]

In the RTOG study, patients were treated with a combination of Taxol, carboplatin, and cetuximab (225 mg/m^2) for six weekly cycles, with 63 Gy of daily radiation therapy. All patients received a loading dose (400 mg/m^2) of cetuximab 1 week prior to RT, and patients received carboplatin/Taxol/cetuximab for two additional cycles after completion of radiation treatments. This study demonstrated median survival of 22.7 months and 2-year OS of 49.3%.[242] Because of these very promising results, cetuximab was included in the RTOG 0617 trial, which was initially designed to compare two different radiation doses (60 Gy vs. 74 Gy) with concurrent chemotherapy. Randomization includes chemotherapy + cetuximab + RT versus chemotherapy + RT, followed by adjuvant chemotherapy versus chemotherapy + cetuximab. In addition to demonstrating 74 Gy was not better than 60 Gy, addition of cetuximab to concurrent chemoradiation and consolidation treatment provided no benefit in OS in this study. However, in a planned retrospective analysis of prospectively collected pathologic specimens, high EGFR expressing patients demonstrated OS benefit (42 months vs. 21.2 months) with the addition of cetuximab (P = .032), whereas low EGFR expressing patients might have had a detriment (19.5 months vs. 29.6 months) with cetuximab (P = .056).[243]

Therefore, cetuximab has not clearly demonstrated benefit when combined with chemoradiation therapy. Efforts are under way to determine if there may be certain subgroups of patients that may benefit from cetuximab and radiation combination, in the presence or absence of chemotherapy, such as in EGFR high expression patients, HPV+ head and neck cancer population, or HIV+ anal carcinoma patients.

Panitumumab (Vectibix)

Panitumumab is a fully human mAB to EGFR, which received FDA approval in 2006 for treatment of EGFR expressing metastatic colorectal cancer with disease

progression on chemotherapy and has been determined to be noninferior to cetuximab for refractory metastatic colorectal cancer patient treatments.[244] Clinical studies of panitumumab combined with radiotherapy have been reported for esophageal, rectal, head and neck, and pancreatic cancer, most of which did not show significant improvement in outcomes or increased toxicity with the use of this agent with standard radiotherapy +/− chemotherapy regimens.[245–254] For locally advanced distal esophageal cancers, neoadjuvant use of panitumumab with docetaxel/platinum chemotherapy and radiation was found to be toxic, and evaluation in an unselected population was not recommended based on a phase II study (ACOSOG Z4051).[247] In a phase II study of resectable esophageal cancer, preoperative therapy with carboplatinum/paclitaxel/radiation was tolerated, but could not improve on the preset criterion of pCR rate of 40% (PACT study).[246] In a phase II study, the use of panitumumab with RT in preop setting, in KRAS wild-type locally advanced rectal cancer, demonstrated modest pCR rates and failed to meet the primary endpoint of this study.[248] In a preop study of panitumumab with capecitabine and radiotherapy in KRAS wild-type rectal cancer patients, high near complete or complete response rates were noted, but increased toxicity (diarrhea, anastomotic leakage).[251] In a phase II study of panitumumab with oxaliplatin/5-FU and radiotherapy as preoperative therapy for rectal cancer patients (StarPan/STAR-02 Study), toxicity was high, particularly with high incidence of grade 3 to 4 diarrhea, including one toxic death because of diarrhea.[252] In a randomized phase II trial (CONCERT-2) of panitumumab with RT versus chemoradiotherapy, cisplatinum-based chemoradiotherapy yielded better tumor control compared to the panitumumab/RT therapy.[245] The use of chemoradiotherapy with or without panitumumab was studied in locally advanced head and neck cancer patients in a randomized phase II trial (CONCERT-1), and the addition of panitumumab did not confer significant benefit to chemoradiotherapy.[249] Phase III trial of cisplatin-based chemoradiotherapy versus accelerated radiotherapy with panitumumab for locoregionally advanced head and neck cancer was reported and was not able to show a noninferiority with the panitumumab-based regimen and also did not lead to improvement in quality of life or swallowing.[255,256] Phase I trial of panitumumab addition to standard gemcitabine-based chemoradiation for locally advanced pancreatic cancer demonstrated MTD of panitumumab of 1.5 mg/kg and was found to have overall manageable toxicity with potential clinical efficacy in the treated cohorts.[250]

Gefitinib (Iressa)

Gefitinib is approved for use as a single agent in the treatment of chemotherapy-refractory NSCLC.[229] It is known to inhibit primarily the EGFR tyrosine kinase but also has shown some activity for HER-2 kinase, albeit at a much lower level.[229] This agent demonstrated promise in phase II studies ("Iressa" dose evaluation in advanced lung cancer [IDEAL-1] and IDEAL-2),[257,258] but had disappointing results in phase III trials (Iressa NSCLC trial assessing combination treatment [INTACT-1] and INTACT-2), where it failed to demonstrate additional benefit to standard chemotherapy for advanced lung cancer patients.[259,260] However, a subset of patients were noted to have a significant response to gefitinib, and subsequently this led to the discovery that mutations in the EGFR tyrosine kinase domain may predict for a positive response to gefitinib.[261,262] Since then, studies involving gefitinib and combined modality therapy have also been reported.

The Southwest Oncology Group performed a large phase III trial where stage III NSCLC patients were treated with standard chemoradiation therapy, and after consolidation with docetaxel for three cycles, patients were randomized to maintenance therapy with a placebo or gefitinib 250 mg/day. This was an unselected patient population. At interim analysis, patients on the gefitinib maintenance arm had a worse OS, and therefore the study was closed.[238] CALGB 30106[263] was a phase II study designed to evaluate the addition of gefitinib to sequential or concurrent chemoradiotherapy in patients with unresectable NSCLC. Patients were categorized into poor-risk (performance status [PS] ≥ 2, weight loss ≥ 5%) and good-risk stratum (PS 0 to 1, weight loss < 5%). All patients received induction chemotherapy with two cycles of carboplatin (AUC = 6) and paclitaxel (200 mg/m^2), plus gefitinib 250 mg from days 1 to 21. Gefitinib was removed from induction in May 2004 when a randomized phase III trial did not demonstrate benefit to adding gefitinib with chemotherapy. The poor-risk group received 66 Gy of RT delivered in 33 fractions, with gefitinib 250 mg/day. Good-risk stratum patients received the same RT and gefitinib but also received weekly carboplatin (AUC = 2) and paclitaxel (50 mg/m^2). Consolidation gefitinib was given until progression. For the poor-risk stratum, PFS was 13.4 months, and median OS was 19 months. For the good-risk stratum, PFS was 9.2 months, and median OS was 13 months. Thirteen of 45 tumors had activating EGFR mutations, and two of 13 had T790M mutations. Seven of 45 tumors had KRAS mutations. When analyzed by these molecular phenotypes, no significant difference in outcome was noted.

Interestingly, the poor-risk stratum who received radiation + gefitinib after induction chemotherapy demonstrated promising survival and PFS outcomes. This will lead to further studies designed to elucidate the role of gefitinib and radiation therapy in poor performance status patients with stage III NSCLC. Meanwhile, the good-risk stratum patients did not demonstrate a very good outcome, suggesting that the addition of gefitinib to the chemoradiation therapy regimen may not be beneficial. This is consistent with studies of erlotinib and chemoradiation therapy.[264]

Erlotinib (Tarceva)

Erlotinib is also an EGFR TKI that has been approved for use by the FDA. Erlotinib is a potent inhibitor of EGFR autophosphorylation and, like gefitinib, also has some activity against HER-2. It also seems to be a fairly potent inhibitor of signaling mediated by the mutant EGFR vIII.[229] Findings from two large phase III studies, the Tarceva Lung Cancer Investigation (TALENT)[265] and Tarceva Responses in Conjunction with Paclitaxel and Carboplatin (TRIBUTE)[266] trials, demonstrated no significant benefit of the addition of erlotinib to chemotherapy to OS in patients with advanced lung cancer.[265,266] Similar to the gefitinib studies, the lack of a demonstrable global benefit to erlotinib pointed to the need for stringent patient selection criteria. In the TRIBUTE study, addition of erlotinib to carboplatin and Taxol improved PFS and OS only in a subset of never smokers. NCIC conducted a phase III study of patients with stage IIIB or IV NSCLC who had failed one to two prior chemotherapy regimens. OS was improved with erlotinib over placebo (6.7 months vs. 4.7 months), and response rate, time to symptomatic progression, and PFS were also improved.[267] Meanwhile, erlotinib has been studied in combination with gemcitabine for advanced pancreatic cancer patients demonstrating an OS benefit (median 6.24 months vs. 5.91 months) compared to gemcitabine alone[268] by NCIC.

Because EGFR TKIs appear to be most effective in never smokers and those with EGFR mutations, these issues were studied in a phase II study (CALGB 30406), which to date has only been reported in abstract form. This study evaluated patients who were never/light smokers. Patients were randomized to erlotinib alone or erlotinib with carboplatin and paclitaxel. At a median follow-up of 30 months, there was no statistically significant difference in PFS with the addition of erlotinib. However, patients with EGFR mutations had significantly improved PFS and OS in both treatment groups compared to patients who did

not harbor the EGFR mutation.[269] There have been a few phase I and II studies that examine the combination of erlotinib and radiation therapy. For instance, adding erlotinib to radiation therapy and temozolomide has been studied for GBM in a phase I/II setting. The North Central Cancer Treatment Group (NCCTG) demonstrated no significant benefit for the addition of erlotinib,[270] and Cleveland Clinic's phase II study demonstrated detrimental effects.[271] Interestingly, a phase II study by Prados et al.[272] demonstrated superior median survival compared to historical controls treated without erlotinib (19.3 months), with good tolerance to therapy. Erlotinib with chemoradiation (gemcitabine, paclitaxel, and radiation) demonstrated tolerability in a phase I study for locally advanced inoperable pancreatic cancer patients,[273,274] and another study demonstrated tolerability of IMRT-based radiation therapy with erlotinib and capecitabine for pancreatic cancer patients in the postoperative setting.[275] A phase I study of the combination of chemoradiation therapy with erlotinib has been completed in cervical squamous cell carcinoma and a phase II study in locally advanced esophageal cancer, both demonstrating the feasibility of such approaches.[276,277]

In head and neck cancer patients, the addition of erlotinib has been studied with chemoradiation both in newly diagnosed patients and in early phase trials for reirradiation of patients with recurrent head and neck cancer.[278–280] The group from the Sarah Cannon consortium has recently reported on a phase II study of erlotinib, bevacizumab, and radiation therapy and the feasibility of such an approach in a community-based setting with a high level of efficacy and tolerability.[281]

Choong et al.[264] reported on a ping-pong–design phase I study of erlotinib with chemoradiotherapy in patients with NSCLC. One group received induction carboplatin and paclitaxel followed by carboplatin/paclitaxel/radiation + erlotinib, whereas a second group received cisplatin/etoposide/radiation + erlotinib followed by Taxotere. The erlotinib dose was escalated from 50 to 150 mg in three levels in each arm. Median survival in each group was 13.7 and 10.2 months, respectively, with patients who developed rash having an improvement in OS and PFS. This study demonstrated tolerability for such a regimen but with fairly disappointing survival data, once again pointing to the need for improved patient selection when using EGFR-based treatments.

In addition to lung and head and neck cancers, erlotinib and radiation therapy has been investigated in early phase studies for other disease sites including pancreatic cancer, gliomas, brain metastases, esophageal cancer, rectal

cancer.[282–284]

Afatinib (Gilotrif)

Afatinib is an orally administered irreversible inhibitor of ErbB family of tyrosine kinases. It binds to EGFR, Her2 and Her4 irreversibly inhibiting tyrosine kinase autophosphorylation. It has been approved for first-line use in metastatic NSCLC patients who have EGFR exon 19 deletions or exon 21 substitution mutations. It demonstrated benefit in PFS but not OS when compared to gefitinib for patients with EGFR mutations, and OS benefit when compared to chemotherapy in patients with exon 19 deletions. It also demonstrated benefit in second-line treatment of advanced NSCLC patients regardless of EGFR mutation status when compared to erlotinib.[285] Afatinib in combination with chemotherapy and/or radiation therapy is being investigated in head and neck cancer, GBM, and EGFR mutant NSCLC.

Summary

Several studies have demonstrated the feasibility and tolerability of combining EGFR inhibitors with chemoradiation therapy in different tumor types. Of note, the importance of molecular profiling and patient selection, such as EGFR mutation status and smoking status in predicting the efficacy of an anti-EGFR–based regimen, has become apparent. Some studies have demonstrated potential for increased toxicity when these regimens are incorporated with chemoradiotherapy. Future studies involving anti-EGFR treatments in combination with radiation treatments should also incorporate such stringent patient selection criteria to maximize the chance of providing a benefit for the appropriate patients. Finally, when combining EGFR inhibitors with radiation, the efficacy and toxicity may vary by tumor type, molecular profile, use of chemotherapy, and the sequencing of the EGFR inhibitor therapy with respect to radiation treatments.

Antiangiogenesis

The formation of tumor vasculature, a prerequisite for progressive tumor growth, is initiated and sustained by angiogenic mediators secreted by tumor cells and cells from the surrounding stroma. Many different angiogenic factors have been identified, including VEGF/vascular permeability factor, members of the fibroblast growth factor (FGF) family, platelet-derived growth factor (PDGF), interleukin-8, and prostaglandins. In addition to angiogenic factors, tumors secrete substances that inhibit angiogenesis, such as angiostatin, endostatin,

thrombospondin-1, and interferons, so that the final outcome of angiogenesis (and hence tumor growth) depends on the balance between proangiogenic and antiangiogenic activities.

Inhibitors of angiogenesis have undergone extensive preclinical testing, with some agents moving into clinical trials. However, as monotherapeutic agents, the early agents have not been as promising as their preclinical evaluations had suggested.[286] Even though it was assumed that an antiangiogenic agent would impair the efficacy of radiation therapy via the enhancement of hypoxia, early evidence for radiation therapy in combination with angiostatin showed both improved oxygenation and reduced oxygenation.[287–289] However, the first clinical trial with a specific inhibitor of angiogenesis, angiostatin, showed a synergistic effect.[290] Since then, the role of specific factors in vascular growth and maintenance has become clearer. VEGF receptors, in particular, play a critical role in vascular integrity, including angiogenesis and endothelial cell survival, via their tyrosine kinase activities.[291] VEGF expression induces endothelial cell proliferation by creating a vascular sprout that subsequently organizes into a capillary tube.[292,293] VEGF also promotes angiogenesis through the formation of a hyperpermeable immature vascular network.[294] VEGF expression is enhanced following radiation, which is likely a survival response for vascular endothelial cells, ultimately in support of tumor survival. Receptor tyrosine kinases, EGFR in particular, up-regulate VEGF, and cyclo-oxygenase-2 (COX-2) inhibitors limit the up-regulation of VEGF by prostaglandins. One proposed mechanism for resistance to a specific targeted antiangiogenic agent such as VEGF or VEGF receptor inhibitors is that tumor cells may be able to up-regulate alternate angiogenic factors such as PDGF and FGF.[295] Therefore, multitargeted agents that can inhibit multiple pathways have been developed and are also under investigation.

A model of normalization of tumor vasculature has been described by Jain.[296] In this model, proangiogenic factors from tumors can cause abnormal neovascularization, and inhibition of tumor angiogenesis transiently normalizes the tumor vasculature. This, therefore, has the counterintuitive effect of decreasing tumor hypoxia and improving effectiveness of radiation therapy. Preclinical studies and a phase I study of bevacizumab, 5-FU, and radiation therapy preoperatively in locally advanced rectal cancer patients also supported this notion.[297]

There are other biologic mechanisms associated with angiogenesis that suggest combining radiation treatments with antiangiogenic agents, including

induction of expression of DNA repair enzymes and targeting of the tumor microenvironment with combined modality therapy. Data from a number of preclinical studies suggest that at higher doses of radiation, tumor radiosensitivity is directly linked to efficacy of endothelial cell death[298] and that the conventional fractionation dose (~2 Gy) may not be effective at targeting endothelial cells.[54] However, in preclinical studies, endothelial cell apoptosis may be induced at lower radiation doses by the addition of antiangiogenic drugs or by blocking targets such as PI3K/AKT pathways, which are activated by ionizing radiation on endothelial cells.[299] Finally, radioresistance of some tumors is thought to be mediated in part by the presence of cancer stem cells, which secrete significant amounts of VEGF,[300] and raises the question of whether these tumor cells can become a more sensitive target to radiation treatments when combined with antiangiogenic agents.[301]

Antiangiogenic compounds can also be broadly classified as mABs or TKIs. The most clinically developed agents that have been FDA approved include the mAB bevacizumab and the TKIs sorafenib, sunitinib, and pazopanib.

Bevacizumab

Bevacizumab is a recombinant humanized mAB that targets VEGF to inhibit its interaction with the VEGF receptor.[302] It has a long circulating half-life after intravenous infusion of up to 21 days. Bevacizumab was the first drug to receive approval by FDA when used as first-line therapy with 5-FU in patients with advanced colorectal cancer. It has since demonstrated efficacy and activity in NSCLC, renal cell carcinoma, GBM, and ovarian cancer.[54] A number of studies have also been performed in different disease sites with bevacizumab in conjunction with radiation therapy.

Phase I and II studies with rectal cancer have demonstrated feasibility, and recommendations for appropriate doses to be used with radiation and 5-FU or capecitabine have been established.[303–306] A phase II study of bevacizumab, capecitabine, and radiotherapy for locally advanced rectal cancer in the preoperative setting was reported. Twenty-five patients with clinically staged T3N1 or T3N0 rectal cancer received 50.4 Gy with bevacizumab every 2 weeks (5 mg/kg) and capecitabine 900 mg/m^2 orally bid followed by surgery. Thirty-two percent of patients had pathologic complete response, and 24% of patients had <10% viable tumor cells in the specimen. Three wound complications required surgical interventions.[307] Thirty-two patients were enrolled in a phase I/II study of neoadjuvant bevacizumab, radiation therapy, and fluorouracil in

advanced rectal cancer.[304] This treatment yielded 5-year OS and local control of 100% and 5-year disease-free survival of 75%. Toxicity was acceptable, and bevacizumab was shown to decrease tumor interstitial fluid pressure. Biomarkers showed significant correlation to outcome. Phase I and II studies by Crane et al.[308] have been performed of bevacizumab with capecitabine-based chemotherapy and radiation treatments for pancreatic cancer.[308,309] In the phase II study RTOG 0411, overall median survival was not compromised, but there was a 35.4% rate of grade 3 or greater gastrointestinal-related toxicity (22% during chemoradiation therapy and 13.4% during maintenance chemotherapy). However, there was a significant correlation with grade 3 toxicity during the chemoradiation therapy phase and protocol deviation in terms of generous treatment volumes. A need for prospective quality assurance in future trials was recommended.[308] Phase I and I/II study of bevacizumab, fluorouracil-based radiation, with erlotinib have been completed with encouraging pathologic complete response rate and with demonstration of good tolerability in neoadjuvant setting for locally advanced rectal cancer patients.[282,283]

Efforts to improve the therapeutic ratio by addition of bevacizumab to chemoradiation therapy have been attempted in multiple studies for both small cell lung cancer and NSCLC patients. Unfortunately, these studies have demonstrated that this regimen was associated with an incidence of tracheoesophageal fistula in both small cell and NSCLC settings.[310]

A number of studies using bevacizumab have been reported for CNS malignancies. Findings of phase II studies showing promise for addition of bevacizumab to temozolomide/radiation therapy regiment for gliomas[311,312] led to development of two phase III studies to investigate this approach in patients with newly diagnosed GBM. In the RTOG 0825 study, Bevacizumab or placebo began during week 4 of radiotherapy and was continued for up to 12 cycles of maintenance chemotherapy.[313] No significant difference in duration of OS between bevacizumab and placebo was found. PFS was longer in the bevacizumab group (10.7 months vs. 7.3 months). With bevacizumab, toxicity was increased, and over time, increased symptom burden, worse quality of life, and decline in neurocognitive function. The AvaGlio study randomized patients with newly diagnosed glioblastoma to receive bevacizumab versus placebo concurrently with radiotherapy and temozolomide, and was followed by maintenance bevacizumab and temozolomide.[314] Similar to the RTOG study, bevacizumab did not improve survival and increased the rate of adverse events. However, PFS and maintenance of baseline quality of life and performance

status were observed.

Studies of reirradiation of recurrent high-grade gliomas with radiotherapy/fractionated stereotactic radiotherapy have been reported demonstrating feasibility/tolerability and potential efficacy of this approach.[315–319] Additional clinical trials investigating this approach are ongoing for recurrent gliomas.

The University of Chicago group has published phase I and phase II studies combining bevacizumab with 5-FU and hydroxyurea-based radiation therapy in advanced head and neck cancer patients.[320,321] In the phase I study, bevacizumab at 10 mg/m^2 was reported to be integratable in this chemoradiotherapy regimen, but five patients with fistula formation and four with ulceration/tissue necrosis were reported. It was felt that the fistula and tissue necrosis could have been bevacizumab related. The randomized phase II study enrolled 26 patients with newly diagnosed T4N0/1 head and neck cancers. Patients received hydroxyurea, 5-FU, and bid radiotherapy with or without bevacizumab (10 mg/kg every 14 days). Unexpectedly, there was significant locoregional progression seen in the bevacizumab arm. Two patients died during therapy, and one died shortly after therapy. This led to study termination, and it was felt that addition of bevacizumab to chemoradiotherapy should be limited to clinical trials for head and neck squamous cell carcinoma. However, addition of bevacizumab to standard chemoradiation in nasopharyngeal carcinoma was studied in a phase II multi-institutional trial (RTOG 0615).[322] In this study, addition of bevacizumab was deemed to be feasible, with possibility of delaying progression of subclinical distant disease reported. Randomized phase III study is needed to substantiate these findings.

Thalidomide

Thalidomide is an agent that was originally marketed as a sedative and was initially taken off the market because of concerns of teratogenicity. There has been a resurgence in use and interest in this agent, as it has since been found to have potent immunomodulatory effects as well as antiangiogenic properties.[323] Although its effects are not limited to angiogenesis, there are suggestions that thalidomide stimulates vessel maturation with implications for vascular normalization, which may be an important strategy for antineoplastic therapy.[324] Therefore, the use of thalidomide with or without radiation therapy has been investigated in both preclinical and clinical settings.[325]

A phase III study (RTOG 0118) was performed to study the efficacy of

WBRT (37.5 Gy in 15 fractions) when combined with thalidomide, in patients with 4 or more, or large (>4 cm) tumor, or midbrain brain metastases. Median survival was 3.4 months for both arms (with or without thalidomide), and thalidomide was not well tolerated in this population (48% of patients discontinued thalidomide because of side effects).[326] The efficacy of thalidomide, temozolomide, and 30 Gy in 10 fractions of whole-brain radiation therapy was studied in patients with brain metastases from melanoma. The efficacy was found to be low, and further therapy with this approach was not recommended.[327] A phase II study of thalidomide and radiation in children with newly diagnosed brainstem gliomas and GBM also yielded negative results.[328] A phase II study of temozolomide and thalidomide in patients with newly diagnosed GBM did not demonstrate significant improvement compared to temozolomide alone.[329] Similarly, concurrent thalidomide during radiotherapy of hepatocellular carcinoma did not demonstrate additional benefits in a phase II setting.[330] Eastern Cooperative Oncology Group (ECOG) 3598 was a randomized study comparing chemoradiation therapy ± thalidomide in patients with stage III NSCLC. There was no difference in PFS or OS with the addition of thalidomide.[331]

Summary of Antiangiogenesis Agents

It is clear from these studies that the efficacy and safety of antiangiogenic agents in combination with radiation and chemoradiation therapy, while promising in many regards, need to be approached with great caution. It also appears that the location of the tumor and agents used in combination with radiation and antiangiogenic agents such as bevacizumab may factor into determining the feasibility and tolerability of such regimens. The potential for improved efficacy over chemoradiation therapy has been raised in particular for gastrointestinal, nasopharyngeal, and CNS malignancies, and further larger studies to help clarify the potential role for antiangiogenic agents in chemoradiation therapy are needed.

Multitargeted Tyrosine Kinase Inhibitors

Several TKI agents have been developed that have demonstrable antitumor and antiangiogenesis activities. These include sorafenib (Nexavar), sunitinib (Sutent), and pazopanib (Votrient). All three agents are approved for use in treatment of patients with advanced renal cell carcinoma. Preclinical studies have demonstrated promising findings when combining multitargeted receptor

TKIs with radiation therapy.[299,332–338]

Sunitinib

Sunitinib is an oral, multitargeted receptor TKI, which was approved by the FDA for treatment of advanced renal cell carcinoma, imatinib-resistant gastrointestinal stromal tumor (GIST) in January of 2006, and pancreatic cancer (unresectable progressive neuroendocrine tumors). Its targets include platelet-derived growth factor receptor (PDGFR), VEGFR, KIT, RET, CSF-1R, and flt3. Several preclinical studies have suggested that sunitinib may be an appropriate agent to consider for use in combination with radiation therapy for a number of solid tumors.[299,335–338] In the clinical setting, a few studies have been reported to date, mostly phase I and phase II studies. Some representative studies are as follows.

Wuthrick et al.[339] have completed a phase I trial of 37.5 mg of sunitinib daily with radiation therapy (doses ranged from 14 to 70 Gy [1.8 to 3.5 Gy per fraction]) in 15 patients with primary (n = 3) and metastatic (n = 12) CNS malignancies.[339] Six patients developed grade 2 or less toxicities, and grade 3 toxicities occurred in seven patients. No grade 3 to 5 intracerebral hemorrhagic events or hypertensive events were reported. Two grade 5 adverse events attributed to disease progression were reported. With a median follow-up of 34.2 months, 13% achieved partial response, 60% had stable disease, and 13% had progressive disease. Six-month PFS for patients with brain metastasis was 58%. The authors recommended consideration for further phase II studies. Phase II trial of concurrent sunitinib, temozolomide, and radiation therapy for GBM patients with an unmethylated MGMT gene promoter is currently recruiting patients in Canada. A phase I trial of sunitinib and radiation therapy for preoperative treatment of soft tissue sarcoma from the German interdisciplinary sarcoma group (GISG-03) has been reported. Two-dose levels of sunitinib (25 and 37.5 mg) were studied with radiation therapy (1.8 Gy × 28 fractions), with surgery scheduled 5 to 8 weeks postneoadjuvant treatments.[340] Of 9 patients enrolled (6 and first dose level and 3 at second dose level), 1 had partial response, 7 had stable disease, and 1 had progressive disease. Pathologic evaluation revealed ≥95% tumor necrosis in 3/9 specimens. 37.5 mg was the recommended dose for subsequent studies. However, in another phase IB/II study of sunitinib with neoadjuvant radiation therapy (50.4 Gy in 28 fractions), combination of sunitinib at 50 mg/day for 2 weeks followed by concurrent 25 mg/day during radiation and dose level −1 where patients received 37.5 mg 2 weeks before and concurrent with RT, both resulted in unacceptable toxicities

(primarily liver, hematologic) and premature study closure.[341] Addition of radiation therapy may not be completely implicated in these toxicities, particularly liver when treatment was delivered to extremity where liver was not exposed to radiation. Whether this was due to the sunitinib delivered prior to concurrent/RT is not fully clear. In nonmetastatic high-risk prostate cancer, phase I study of sunitinib with androgen deprivation therapy and radiation therapy (treatment to only prostate and seminal vesicles to 75.6 Gy in 42 fractions) demonstrated that 24 mg/day dose of sunitinib should be considered for phase II study.[342]

Kao et al.[343] reported on a phase I study designed to determine the safety and maximum-tolerated dose of concurrent sunitinib and radiation therapy using image-guided technologies for patients with oligometastases (one to five sites) from renal cell carcinoma. The most common treatment sites were bone, liver, and lung. Sunitinib was given at 25 to 37.5 mg/day with either 40 or 50 Gy of radiation therapy delivered in 10 fractions in a ping-pong design of either sunitinib or radiotherapy dose escalation. Twenty-one patients with 36 metastatic lesions were enrolled. No dose-limiting toxicity (DLT) was noted for sunitinib at 37.5 mg plus 40 Gy. At 37.5 mg sunitinib with 50 Gy, and 50 mg sunitinib with 50 Gy, one out of ten patients, and two out of five patients, respectively, experienced DLTs (grade 4 myelosuppression and grade 3 nausea). The 1-year OS rate was 75%, and PFS rate was 44%. They proceeded to a phase II trial for sunitinib at 37.5 mg/day and a 50-Gy/10 fraction dose regimen, with tumor types treated including head and neck, liver, lung, kidney, and prostate cancers.[344] Local control and distant control at 18 months were 75% and 52%, respectively, with PFS and OS of 56% and 71% reported. Incidence of acute grade ≥ 3 toxicities was 28%, most commonly myelosuppression, bleeding, and abnormal liver function test findings.

Sorafenib

Sorafenib is a small-molecule TKI that has been approved for treatment of advanced renal cell carcinoma, hepatocellular carcinoma, and thyroid cancer. It is also a multikinase inhibitor of Raf kinase, PDGF, VEGFR2 and R3, and cKit.[345] Conflicting reports of efficacy and tolerability are reported in early phase studies with radiation therapy.

Phase I trial of sorafenib and SRS for patients with 1 to 4 brain metastases has been reported.[346] In a 3 + 3 dose escalation trial design, dose level 1 (400 mg/day) and dose level 2 (400 mg twice per day) starting 5 to 7 days prior to

SRS, and continued for 14 days after SRS, was tolerated. In an expansion cohort of 17 patients treated with dose level 2, 6 grade 3 toxicities were reported, all of which were attributable to sorafenib, and not to the combination treatment. Recommended phase II dose for sorafenib with SRS was 400 mg twice daily. For unresectable liver metastases, a phase I trial of radiation therapy with sorafenib was reported, for SBRT or whole liver radiotherapy (WLRT).[347] Sorafenib was delivered for 4 weeks, with radiotherapy delivered during weeks 2 to 3, and 3 escalating dose levels from 200 to 400 mg twice daily was studied. Depending on effective liver volume irradiated (<80% vs. >80%), radiation dose was either 30 or 60 Gy in 6 fractions (n = 18) versus 21.6 Gy in 6 fractions (n = 15), respectively. In both strata, MTD (defined as liver toxicity grade 3+ or grade 4+ treatment related toxicity) was not reached. Grade 3+ toxicity was seen in 33% of patients at a median of 10 days. Two patients undergoing WLRT died, from nonclassic liver toxicity in the 21.6 Gy in 6 fraction group. The investigators concluded that the Sorafenib with 21.6 Gy in 6 fractions to the whole liver was with unacceptably high rates of liver toxicity. SBRT was sorafenib was deemed tolerable, efficacy was not felt to be sufficient to merit further clinical evaluation. Similarly, phase I study of sorafenib with SBRT for hepatocellular carcinoma demonstrated significant toxicity if significant volume of liver was irradiated, and not recommended outside of a clinical trial.[348] In the only reported phase II study of sorafenib and radiation therapy for unresectable hepatocellular carcinoma, 40 patients were enrolled and sorafenib was administered at 400 mg twice daily, starting with radiation therapy (40 to 60 Gy, median 50 Gy), and continued till progression.[349] Fifty-five percent patients achieved complete or partial remission, and 2-year infield PFS was 39%. However, 6 patients (15%) developed treatment-related grade 3+ hepatic toxicity during the sequential phase, and 3 of these were fatal, and investigators advised caution with this regimen. RTOG 1112 is a phase III clinical trial investigating sorafenib versus sorafenib with SBRT for liver cancer, currently recruiting patients.

In cervical cancer patients, a phase I study of 13 patients with stage IB to IIIB cervical cancer, with sorafenib administered for 7 days prior to start of cisplatin/radiation treatments, suggested that sorafenib might increase tumor hypoxia, raising concerns for potential to impair radiation efficacy when added to standard chemo/RT regimen.[350] In high-grade glioma, sorafenib dose escalation (200 mg daily, 200 mg bid, and 400 mg bid) was studied with temozolomide and radiation therapy as first-line therapy, and MTD was

established at 200 mg bid.[351] Efficacy in this limited number of patients was moderate, and therefore, further study with chemoradiation in high-grade glioma was not recommended. In pancreatic cancer, a phase I study of dose escalation of sorafenib (starting at 200 mg/day up to 400 mg twice daily), with concurrent radiation therapy and gemcitabine, enrolled 27 patients.[352] Maximum tolerated dose was 400 mg twice daily. Addition of sorafenib seemed to have modest clinical activity, except in patients with angiogenesis genes polymorphisms (VEGF-A-2578AA, -1498CC, and -1154AA), with these patients having median OS of 21.6 months versus 14.7 months for others. This study suggested that select VEGF-A/VEGF-R2 genotypes may be associated with improved outcomes.

In rectal cancer, preoperative 5-FU and sorafenib with external beam radiation therapy (50.4 Gy in 28 fractions) was studied, with sorafenib dose starting at 200 mg daily with dose escalation planned up to 400 mg po bid to determine MTD.[353] Seventeen patients were enrolled. Because of acute toxicities in the initial phase of the study, protocol was amended to administer chemotherapy and sorafenib on days 1 to 5 only. With the amended protocol, primary grade 3 toxicity was hypertension in 2 patients at the 200 mg/day dose and 1 patient at the 400 mg bid dose. One patient had grade 3 liver function elevation at 400 mg, and no grade 4 toxicities were observed. No perioperative complications were reported. Pathologic complete response rate was 33%, and downstaging observed in 85.7% of patients.

A phase I trial of sorafenib with radiation therapy delivered preoperatively to extremity soft tissue sarcoma has been reported.[354] Two dose escalation cohorts for sorafenib were 200 mg/daily and 200 and 400 mg daily, with sorafenib delivered during the entire course of radiation therapy (50 Gy in 25 daily fractions) as tolerated. All tumors in this study were located in the lower extremity. Eight patients were enrolled. Two out of five patients at second dose level developed DLT, with grade 3 rash. Other grade 3 toxicities included anemia, perirectal abscess, and supraventricular tachycardia, with total of 4/8 patients having developed grade 3 toxicities. Radiation-related toxicities and postsurgical complications (3 grade 3 wound complications) were felt to be comparable to those treated historically without sorafenib. Complete pathologic response was noted in 38% of patients. Investigators recommended further studies using dose level 1 of sorafenib. Phase II trials of sorafenib with radiation therapy for soft tissue sarcoma are in progress.

Pazopanib

Pazopanib is also a multitargeted TKI that was approved by the FDA in October 2009 and inhibits the intracellular tyrosine kinase portion of VEGFR1–3, PDGFR-α and -β, c-Kit, FGF receptor-1 (FGFR-1), FGFR-3, Lck, and c-Fms.[355] Phase I study of preoperative radiation therapy with pazopanib in patients with locally advanced soft tissue sarcoma of the extremities has been reported.[356] Twelve patients were enrolled with 11 evaluable. Dose of pazopanib was escalated from 400 to 600 to 800 mg/day, for 6 weeks given with radiation therapy (50 Gy in 25 fractions) starting day 8. No increased toxicity inside radiation field was reported, but 2/10 patients (in the 400 and 600 mg cohorts) demonstrated delayed wound healing after surgery. Pathologic complete response was noted in 4/10 cases. Grade 3 hepatotoxicity, which led to pazopanib interruption, was noted in 27% of the cases. In these cases, liver was not in the radiation field. The same group is conducting a phase II study using once daily 800 mg oral pazopanib with radiation therapy in preoperative treatment of sarcoma in extremities, trunk chest wall, and head and neck regions (PASART-2). There is also a multigroup phase II/III trial currently recruiting patients studying the potential role of preoperative pazopanib (or chemotherapy) with radiation in adult and pediatric nonrhabdomyosarcoma soft tissue sarcoma patients (COG-NRG ARST 1321).

Mammalian Target of Rapamycin

The mTOR pathway has been shown to be dysregulated in a number of solid tumors.[357] A number of rapamycin analogs exist and have been approved by the FDA, such as temsirolimus (Torisel) or everolimus (Afinitor), which inhibits mTOR. Temsirolimus is approved for treating patients with advanced renal cell carcinoma. Everolimus is approved for treatment of patients with advanced renal cell carcinoma that has progressed after other therapies, advanced breast cancer, subependymal giant cell astrocytoma (in adults and children who have tuberous sclerosis and are not amenable to surgery), and progressive well-differentiated neuroendocrine tumors of GI or lung origin. The potential for radiosensitization effects of these agents has been studied in a preclinical setting in a number of different cancer types.[358–366]

Temsirolimus

Temsirolimus was studied in combination with chemoradiation therapy in newly diagnosed GBM patients in a dose-escalation phase I study.[367] Unfortunately,

concomitant and adjuvant use of temsirolimus was associated with a high rate (3 of 12 patients) of grade 4/5 infections. This was reduced with antibiotic prophylaxis and by limiting the duration of temsirolimus therapy. Therefore, based on this study, a dose of 50 mg/week of temsirolimus combined with radiation and temozolomide is the recommended phase II dose and schedule. In a phase I study, temsirolimus was studied with thoracic radiation in patients who were candidates for palliative radiotherapy.[368] Patients who were candidates for definitive chemoradiotherapy were excluded. Temsirolimus dose levels were 20 mg/week and 25 mg/week, and −1 dose level was at 15 mg/week, using 3 + 3 design. Radiation dose was 35 Gy in 14 daily fractions. Ten patients were enrolled. Maximum tolerated dose was determined to be 15 mg/weekly. At the first dose level of 20 mg/week, 1 patient experienced grade 3 pneumonitis (day 10), grade 4 fatigue, and grade 4 lymphopenia and was able to complete radiotherapy after discontinuation of temsirolimus. Another patient died after 2 doses of temsirolimus and 3 fractions of radiation. Although death was more likely to be related to cancer progression, per protocol definition, was considered DLT. At the 15 mg/week dose level, one-third patient developed pulmonary hemorrhage from a fungating right main stem bronchus mass after only 2 radiation treatments (5 Gy). With enrollment of 3 additional patients, no additional DLTs occurred. Of the 8 evaluable patients, 3 had partial response, and 2 had stable disease.

Everolimus

The North Central Cancer Treatment Group has also reported a phase I trial of everolimus and temozolomide in combination with radiation therapy in newly diagnosed GBM patients.[369] Eighteen patients were enrolled, and everolimus was well tolerated. The recommended dose for the phase II study is 70 mg/week in combination with standard temozolomide/radiation therapy. RTOG 0913 is a phase 1 study of everolimus in combination with radiation therapy and temozolomide in patients with newly diagnosed GBM. Everolimus was escalated from 2.5 to 5 to 10 mg/day in combination with 60 Gy in 30 fractions radiation therapy and temozolomide. Adjuvant temozolomide and concurrent everolimus was then given at an established dose of 10 mg/day. In this study, everolimus dose was escalated to 10 mg/day as MTD. In a multi-institutional NCCTG phase II trial (N057K), 70 mg/week everolimus was started 1 week prior to radiation/temozolomide and given concurrently and followed by adjuvant temozolomide until disease progression.[370] One hundred patients were enrolled.

Fourteen percent had grade 4 hematologic toxicities, 12% had at least one grade 3 nonhematologic toxicity, and one treatment-related death was reported. One-year OS was 64%, and median time to progression was 6.4 months. On molecular imaging response assessment, responders were less likely to have alterations within the PI3K/AKT/mTOR or tuberous sclerosis complex/neurofibromatosis type 1 pathway compared to nonresponders, which did not translate into durable outcomes, and survival benefit was not seen as compared to historical controls.

In an adjuvant therapy setting, the use of bevacizumab/everolimus after concurrent radiation/temozolomide for GBM has been reported demonstrating feasibility and efficacy, with median PFS of 11.3 months, and median OS of 13.9 months reported.[371] In head and neck cancer, phase I study of everolimus with weekly cisplatinum (30 mg/kg) and IMRT-based radiation therapy was reported, with maximum tolerated dose of everolimus of 5 mg/day.[372] Phase I study of everolimus with thoracic radiation for NSCLC has been reported.[373] In this study, everolimus dose was escalated either weekly (10, 20, or 50 mg) or daily (2.5, 5, or 10 mg), with everolimus starting 1 week prior to radiation, and for 3.5 weeks after end of radiotherapy. Radiation dose was 66 Gy in 2 Gy/daily fractions. Twenty-six patients were enrolled from two centers. In the weekly group (n = 14), dose was escalated to MTD of 50 mg/week, with 1 patient experiencing DLT with grade 2 interstitial pneumonitis at 20 mg/week dose at week 10 of therapy. Addition of 6 patients to this dose group, and further 3 patients in the 50 mg/week group, did not demonstrate any further DLTs. In the daily group (n = 11), 1 DLT of grade 2 pneumonitis at week 6, with subsequent fatal outcome (1 month after interruption of treatment), was noted at 2.5 mg/day dose. Expansion at this dose level to 6 patients demonstrated no further DLTs, and dose increased to 5 mg/day. At this level, grade 3 pneumonitis at week 11, grade 4 dyspnea at week 9, and grade 3 esophagitis with associated dysphagia at week 5 were reported. Because of this (2/5 patients with DLT), further recruitment was stopped, and MTD determined to be 50 mg/week. Overall, 5 patients with grade 3 to 4 pneumonitis related to treatments were reported. Of 22 patients assessable for response, 41% partial response and 32% stable disease, with 2-year OS and PFS of 31% and 12%, respectively, were reported. Investigators recommend for further studies, weekly dose of 50 mg/week, with caution for monitoring for pulmonary toxicity.

Further studies of mTOR inhibitors with radiation therapy are ongoing, with special emphasis in trying to determine molecular markers of response to

therapy to better select patients who may have improved outcome with the use of mTOR inhibitor therapy. Studies involving the use of agents inhibiting the signaling pathway downstream of mTOR are also in development.

Anaplastic Lymphoma Kinase Inhibitors

ALK fusion protein results in constitutive activation of ALK tyrosine kinase. Although studies specifically addressing ALK inhibitors with radiation therapy have not yet been reported, because of the impact this molecular has made in the NSCLC therapy paradigm, this topic will be briefly discussed. Soda et al.[374] discovered the fusion of the ALK gene with echinoderm microtubule-associated protein like 4 (ELM4-ALK). This *ELM4–ALK* fusion oncogene has become a very important potential biomarker for patients with NSCLC. The frequency of *ALK* rearrangement ranges from 3% to 7% in unselected NSCLC patients. Furthermore, similar to EGFR mutations, this rearrangement is seen more frequently in adenocarcinomas and patients with never or light smoking history. *ALK* rearrangements appear to be mutually exclusive with *EGFR* and *KRAS* mutations.[375] Several ALK inhibitors have been identified, and the furthest developed is crizotinib. Crizotinib was initially designed as an MET inhibitor but has been found to be clinically effective as an ALK inhibitor in NSCLC patients harboring *ALK* rearrangements.[375] In a phase I trial of 82 patients selected for ALK rearrangement (out of over 1,500 patients), an impressive response rate of 57% was noted.[376] Crizotinib has demonstrated efficacy in patients with ALK rearrangement in randomized trials. When compared to pemetrexed or docetaxel single-agent chemotherapy, crizotinib demonstrated improved median PFS of 7.7 months versus 3 months in patients previously treated with platinum-based chemotherapy regimen.[377] Objective response rate was improved, but OS benefit was not seen, presumably because of cross over study design, where patients progressing on chemotherapy were allowed to cross over to crizotinib. In another study of chemotherapy naïve patients, 343 patients were randomized to crizotinib versus platinum and pemetrexed chemotherapy, with cross over permitted.[378] PFS was significantly improved with crizotinib (10.9 months vs. 7 months), once again with OS not showing significant difference, likely because of cross over being permitted to the crizotinib treatment.

Although extremely effective, patients develop resistance to crizotinib within first few years of therapy. In one-third of resistant cases, tumors have acquired a secondary mutation within the ALK tyrosine kinase domain, most commonly, L1196M mutation, followed by G1269A mutations. Other mutations also exist

including the G1202R mutation, which confers significant resistance to not only crizotinib but also to next-generation ALK inhibitors. Second-generation ALK inhibitor includes ceritinib, which is approved for use in patients that have progressed or are not tolerant of crizotinib.[379] Ceritinib has been shown to yield improved outcomes in patients compared to chemotherapy both in the upfront setting[380] and in those who have progressed on crizotinib (presentation at ESMO 2016, Sacagliotti et al.).[381] Alectinib is another second-generation ALK inhibitor that has activity in crizotinib-resistant disease, and also reported to have better activity for brain metastases.[382–384] It is approved for use in crizotinib-resistant or crizotinib-intolerant patients. Brigatinib, another next-generation agent, was approved by FDA for use in patients with metastatic NSCLC progressed on crizotinib on April 2017.

There are no significant data to suggest a radiosensitizing or synergistic effect when combined with radiation therapy concurrently, but sequential use of crizotinib with a chemoradiation regimen is being explored in a randomized phase II study for stage III NSCLC patients (NCT01822496). A phase I study aimed at determining safety and activity of crizotinib with temozolomide and radiation therapy for newly diagnosed GBM is also recruiting patients in Spain.

Histone Deacetylase Inhibitors

HDACs contribute to oncogenic transformation, and involvement of acetylation and HDAC activity in cancer development provides a mechanistic rationale for considering HDAC inhibitors as an anticancer therapy. Inhibitors of HDAC relax chromatin structure. This can lead to increased radiosensitivity through enhanced DNA damage.[385,386] However, some HDAC inhibitors have also been shown to down-regulate the expression of both EGFR and ErbB2 and to inhibit PI3K and AKT signaling,[387–389] all strong potentiators of tumor cell survival and modulators of DNA DSB repair.[390] This combination of DNA damage enhancement, inhibition of DNA repair, and down-regulation of strong survival highlights the utility of agents that attack multiple signaling pathways.

The most clinically developed HDAC inhibitors include vorinostat and romidepsin, both of which have FDA approval for use in cutaneous T-cell lymphoma (CTCL). Although their indications are supported by data suggesting activity in hematologic malignancies, studies in solid tumors have also been reported. Preclinical studies of radiation therapy and HDAC inhibitors have been reported in squamous cells, medulloblastoma cells, breast cancer brain metastatic cells, colorectal models, GBM cells, pancreatic cells, neuroblastoma

cells, osteosarcoma, and rhabdomyosarcoma cells.[387,391–402] Of note, 18 HDAC enzymes have been identified and classified into four groups (classes I through IV).

Vorinostat is a hydroxamic acid multi-HDAC inhibitor that blocks the enzymatic activity of both class I and II HDACs at low nanomolar concentrations.[398] Vorinostat is active in inducing differentiation, cell growth arrest, or apoptosis in a wide variety of transformed cells in preclinical studies.[398] Vorinostat is FDA approved for treatment of CTCL that has persisted, progressed, or recurred after treatment with other first-line agents. Therefore, primary efficacy of vorinostat has been demonstrated in hematologic malignancies. However, it is also being studied in a number of different solid tumor types with mixed success (NSCLC, colorectal cancer, breast cancer, prostate cancer, GBM) in phase I and II clinical settings in combination with other standard cytotoxic agents, including radiation therapy.[403–407] Ree et al.[397] reported on combining vorinostat with pelvic palliative radiotherapy for gastrointestinal carcinoma patients. Sixteen patients were evaluable. Patients received palliative radiotherapy (30 Gy in 10 fractions) with escalating vorinostat dose, administered orally daily 3 hours before each radiotherapy fraction. Maximum tolerated dose was determined to be 300 mg/day. Histone hyperacetylation was detected, indicating biologic activity of vorinostat.

Phase I study of vorinostat for brain metastases has been reported.[408] Vorinostat was administered by mouth during whole-brain radiation therapy (37.5 Gy in 15 fractions), escalated from 200 to 400 mg/day. Seventeen patients were enrolled. There were no specific treatment-related grade 3+ toxicities, with one death in the 400-mg cohort because of pulmonary embolus, which was unlikely to be related, but was conservatively classified as DLT. Recommended dose for further phase II study was 300 mg/day.

Romidepsin is a novel HDAC inhibitor with recent FDA approval for treatment of CTCL, approved as second-line therapy.[409] Studies in small cell lung cancer, recurrent glioma, and castrate-resistant prostate cancer have been performed with mixed success.[410–412] As yet, there are no completed and published studies demonstrating efficacy of romidepsin in combination with radiation treatments.

Miscellaneous Molecular Targets

K-Ras

Activating mutations in the ras oncogene are found in many tumors including the

lungs, colon, head and neck, glioblastoma, pancreas, and others. The overall rate of ras mutations in human cancers is 25% to 30%, but for some cancers, the mutation rate can be quite high. These activating mutations drive key intracellular signaling pathways that confer proliferative and survival advantages to tumor cells, including radioresistance, through the chronic activation of the PI3K and the Ras/MAP kinase pathways.[413–415] Ras must be prenylated in order to be membrane bound, where it becomes active. Prenylation can occur by two enzymatic processes, farnesylation and geranylgeranylation. Inhibitors of farnesylation, specifically farnesyltransferase inhibitors (FTIs), have had some success in limiting the negative impact of ras activation, particularly in inhibiting tumor cell radioresistance *in vitro* and *in vivo*.[29,413,416–418] FTIs selectively affect tumors because the *ras* genes in normal tissues are not mutated. The activity of FTIs has had limited success, partly because of the activity against a given ras species, H-ras versus n-Ras or K-ras, and partly because of the FTI resistance of geranylgeranylated K-ras.[413,416,419–421] However, new compounds that target both farnesylation and geranylgeranylation have been shown to be effective in preclinical studies, and new molecular targets for radiosensitization by FTIs have been identified,[415,422] which may enhance their clinical utility.

Targeting DNA

Many therapy agents target the DNA of cells, preferably tumor cells. This can be through DNA damage induction, inhibition of cell cycle traversal, or inhibition of DNA replication, for example, and targeting the enzymes that manage the integrity of the DNA of cells represents a sound therapeutic strategy. Furthermore, differences between tumor and normal cells in cell cycle checkpoint controls, DNA repair capabilities, and even chromatin architecture have been identified that could be taken advantage of by combined therapies.

There are multiple strategies to targeting DNA repair pathways with drugs or small molecules. First, DNA damage must be sensed, and there are several key enzymes that are considered damage sensors. The most established sensors are telomeric repeat-binding factor 2 (TRF2), the Mre11-Rad50-Nbs1 (MRN) complex, and ATM.[423,424] These proteins set off the cascade of events that alter chromatin, recruit repair enzymes to the break site, and initiate cell cycle checkpoint control following DNA damage. ATM inhibitors, for example, have been studied in preclinical setting showing significant radiosensitizing effects, but a challenge that remains is the potential for normal tissue toxicity when used in combined modality therapy with radiation.[425] Key regulatory proteins within

each of these areas are being successfully targeted in preclinical studies. Examples include a specific inhibitor of ATM, Ku55933, which has shown enhanced radiosensitivity in *in vitro* experiments,[426] small molecules that reconstitute the wild-type p53 protein structure in mutant p53 molecules,[427] and radiotherapy combined with adenoviral wild-type p53 delivered *in vivo* by liposomal carriers in clinical trials for lung cancer.[428] Preclinical evaluations of compounds that target DNA repair components directly, particularly when combined with radiation and radiosensitizing compounds such as cisplatin or gemcitabine, are ongoing. Inhibitors of DNA-PKcs, a critical enzyme in nonhomologous end joining (NHEJ), have been successful in preclinical studies on tumor cell lines; however, a treatment advantage for normal tissue may provide a challenge.[429–434]

There are novel therapeutic targets within the DNA repair pathway known as *homologous recombination* (HR). For instance, RAD51 and BRCA1/2 defective cell lines are radiosensitive, and antisense strategies against RAD51 have been used against a number of cancer cell lines. Interestingly, targeting HR may have a distinct advantage over the NHEJ pathway. NHEJ occurs throughout the cell cycle, whereas HR is considered to be a dominant repair pathway during the S and G_2 phases of the cell cycle because of the need for a template strand of DNA. This implies that for most normal tissues, where there is little to no cellular turnover and where NHEJ is the dominant DNA repair pathway, there would be a survival advantage compared to tumors where cells are traversing the cell cycle and are more likely to be found in the S or G_2 phase. Specific inhibitors such as small interfering RNA (siRNA), antisense, small molecules, and antibodies that target DNA repair are still relatively new, and although the *in vitro* data are encouraging, clinical efficacy remains to be seen. Other DNA damage response targets include CHK1, which functions in HR repair, and WEE1, a cell cycle kinase which leads to G2 cell cycle arrest in response to DNA damage.[425] Inhibitors for WEE1 and CHK1 have been identified demonstrating promising preclinical data with radiation inhibitors have been identified. AZD1775 (MK1775), a potent WEE1 inhibitor, has been studied in solid tumors in phase I trial[435] and additional studies with phase 1 trial in combination with RT/temodar in GBM, pancreatic cancer, head and neck cancer, and younger patients with diffuse intrinsic pontine gliomas ongoing. Clinical trials studying CHK1 inhibitors, including MK-8776, SRA737, prexasertib are ongoing. PARP is an enzyme whose specific function is to repair SSBs, and with recent advances in agents that block this pathway, a discussion of such agents is

warranted. PARP catalyzes the transfer of ADP-ribose units from intracellular NAD^+ to nuclear receptor proteins, leading to the formation of ADP-ribose polymers. Nicotinamide was the first PARP inhibitor identified, and since then second-generation PARP inhibitors have been developed. Although significant current interest is in the role of PARP inhibitors in BRCA-deficient tumors, they have also been studied as chemosensitizers. Therefore, initial studies primarily were based on nonselected tumor types to determine the efficacy of PARP inhibition in combination with chemotherapy agents. However, because radiotherapy damages cells by causing DNA breaks, and PARP inhibitors impair DNA repair mechanisms, studies in combination with radiation therapy have been performed *in vitro* and *in vivo* demonstrating effectiveness in cancer cell lines, including glioma cells.[436–439] Furthermore, with exciting preclinical data suggesting that PARP inhibitors may have a significantly and selectively high impact in BRCA-deficient cells,[440,441] a new paradigm for a clinical trial was born in which patients with BRCA mutations or BRCA-ness were selected for treatment with PARP inhibitors.[442,443] BRCA-ness refers to abnormal function of BRCA1/2 genes, or other genes implicated in similar DNA repair pathways to BRCA1 and BRCA2, which is seen in triple-negative breast cancer patients, for example, without necessarily having the hereditary mutations.[443] After encouraging preclinical data in solid tumors with chemotherapy, and particularly in selected tumor cells with BRCA deficiency, multiple PARP inhibitors have been studied or are being studied in solid tumors, including breast cancer, ovarian cancer, and lung cancer. Three PARP inhibitors have now received FDA approval, olaparib (Lynparza, AstraZeneca), rucaparib (Rubraca, Clovis Oncology), and niraparib (Zejula, Tesaro). Olaparib has been approved for advanced ovarian cancer patients who have been treated with at least three types of chemotherapy. Rucaparib is approved for use in advanced ovarian cancer patients, previously treated with two or more chemotherapy regimens, and have BRCA mutation. Niraparib is approved for ovarian, fallopian tube, or primary peritoneal cancer, to be used as maintenance treatment for patients who are in complete or partial response to platinum-based chemotherapy. Two other agents furthest along in development without FDA approval include veliparib and talazoparib. Veliparib failed to improve outcome in NSCLC and triple negative breast cancer in phase III studies, and the phase III trial of gynecologic malignancies is still recruiting patients. Talazoparib is currently undergoing phase III study for patients with BRCA mutations with locally advanced or metastatic breast cancer (EMBRACA study).

Of note, Veliparib is a PARP inhibitor that appears to cross the blood–brain barrier, and its efficacy in combination with whole-brain radiation for brain metastases and with temozolomide and radiation for patients with primary brain tumors has been investigated in phase I studies. For patients with brain metastases, veliparib's dose was escalated from 10 mg bid up to 300 mg bid given concurrently during the radiation therapy course.[444] WBRT was administered as either 37.5 Gy in 2.5 Gy/daily treatments or 30 Gy in 3 Gy/day treatments. Three DLTs occurred—two at 150 mg veliparib, one of which was grade 3 hypokalemia and the other a grade 3 hyponatremia. After review, dose escalation was continued. One DLT of grade 4 posterior reversible encephalopathy syndrome occurred at 200 mg bid. At the 300 mg bid, five of eight subjects experienced AEs of nausea and or vomiting, with two events leading to discontinuation of drug. Although not meeting criteria for DLT, because 300 mg bid was not well tolerated, recommended phase II dose for veliparib was determined to be 200 mg bid with 30 Gy in 10 fractions (the most common radiation combination at higher doses).

A phase I study of veliparib in combination with low-dose fractionated whole abdominal radiation therapy in patients with advanced solid malignancies and peritoneal carcinomatosis has been reported.[445] In this study, patients were treated with veliparib (from 40 mg bid, up to 160 mg bid) for 3 cycles. Radiation consisted of 21.6 Gy in 36 fractions (0.6 Gy twice daily on days 1 and 5 for weeks 1 to 3 of each cycle). Overall, the regimen was deemed tolerable and in some patients, particularly those with ovarian and fallopian cancer, appeared to prolong disease stability. Other disease sites studied with veliparib and radiation therapy include rectal cancer (phase I/II), inflammatory or locoregionally recurrent breast cancer (phase I), unresectable pancreatic cancer (phase I), NSCLC (phase I/II), brain metastases from NSCLC (phase II), and GBM (phase I/II).

Several phase I studies combining olaparib with radiotherapy for triple negative breast cancer, soft tissue sarcoma, head and neck cancer, esophageal cancer, and NSCLC are actively recruiting patients or under development. Niraparib is being investigated for use with Radium 223 radiopharmaceutical for hormone-resistant prostate cancer bone metastases patients in the phase I setting (NCT03076203). There are no studies reported or ongoing with rucaparib with radiation therapy.

Era of Personalized Medicine Using Molecularly Tailored

Therapeutics

Although high-impact molecular discoveries and effective combined modality treatment realizations have been of significant importance in the field of oncology, another area that has made significant strides and impact on cancer therapeutics is the concept of molecular selection of patients for appropriate therapy. One of the first such examples is in the field of breast cancer where hormonal therapy and Herceptin treatments are selectively given to patients whose tumors demonstrate appropriate molecular criteria (estrogen receptor positivity and HER2/neu positivity).[446] Other examples include imatinib for treatment of patients with c-kit harboring GIST tumors,[447] anti-EGFR therapy for lung cancer patients with EGFR tyrosine kinase mutations, crizotinib for lung cancer patients with ALK fusion gene translocation, and the predictive value of KRAS mutation status for anti-EGFR therapy for patients with metastatic colorectal cancer.[448] Meanwhile, abundant studies are in progress and/or have been performed to attempt to determine biomarkers that may provide prognostic or therapeutic information. Multigene assays (Oncotype DX),[449] for example, are already in use in clinical practice for patients with breast cancer. Genomic signatures or biomarkers of response to chemotherapy of tumor, to survival, or to metastatic potential of tumor have been studied.[450] Similarly, efforts to study and identify biomarkers for radiation response, sensitivity, resistance, or toxicity are being investigated.

USING RADIOTHERAPY TO IMPROVE THE LOCAL AND DISTAL TUMORICIDAL EFFECTS OF IMMUNOTHERAPY, A NOVEL PARADIGM IN COMBINED MODALITY THERAPY

Radiation therapy's potential to improve clinical response of immunotherapy has gained tremendous momentum for clinical trial development, based on positive results from preclinical and early clinical data. There are numerous clinical trials investigating this approach, in part because of the increasing number of novel immunotherapy agents gaining FDA approval for indications for cancer therapy. In this section, we review some key radiation issues to consider when combining immune agents with radiotherapy, and some of the agents being pursued actively for such combined modality clinical trials.

RT Factors Influencing Immune Response

When considering use of RT with immunotherapy, one must consider the

optimal dose of radiotherapy, the timing of radiotherapy, and the volume of area irradiated, potential role of particle therapy, as these are all important factors that could potentially affect the ability of RT/immunotherapy combination to yield successful outcomes. In addition, one size may not fit all in terms of these parameters, and some of these may prove to be dependent on tumor histology.

When considering combining immunotherapy with RT, one must consider the volume of area that will be encompassed by RT. Radiation therapy has been traditionally used for treatment of regional areas when clinically indicated and has in many disease sites, and for many disease sites, such treatment has remained a standard of care. Although this may provide benefit for impacting regional control by treatment of microscopic or gross nodal disease burden, it may counteract the immune response, as lymph nodes, and T cells would be negatively affected by the radiation and ultimately may potentially reduce the cytotoxic effects that would be mediated by immune mechanisms. Concurrent chemotherapy could further lead to this issue. Therefore, a delicate balance may be required in considering the need to irradiate potential disease burden in the lymph node regions versus impacting immune effects. Such issues will need to be considered and studied carefully when designing clinical trials aimed at implementing immunotherapy in conjunction with standard definitive radiotherapy. A potential concept could include trials where only the gross disease is treated with RT, when studied in conjunction with immunotherapeutic agents, particularly in disease sites where ENI is already safely omitted.

Another important RT factor to consider is the appropriate dose per fraction and number of fractions that should be delivered when combined with immunotherapy. Some preclinical data would support consideration of use of higher dose/fraction as a more optimal dose regimen when considering immune effects.[451] Some studies would suggest fractionation to some degree may be beneficial, whereas others did not. For example, when combined with anti-CTLA-4, 8 Gy × 3, and to a lesser degree 6 Gy × 5 fractions demonstrated improved local and abscopal effects compared to mice treated with single fraction of 20 Gy.[452] However, other preclinical studies have demonstrated immune response or stimulatory effects with single-fraction regimen.[453] In another preclinical study of mice-bearing murine melanoma tumors, radiation dose up to 15 Gy was studied for tumor control and immune response effects and demonstrated that 7.5 Gy/fraction gave the best tumor control and tumor immunity while maintaining low Treg numbers.[454] 5 Gy in this study was not immunostimulatory, suggesting a potential threshold dose above which immune

effects are manifested. Authors proposed that the optimal immunogenic effect may be a balance of increasing cross-priming while not increasing Treg cell numbers, which in their study was best accomplished with 7.5 Gy × 2 fractions. Biologic rationale for higher dose per fraction include potential for increased induction of necrosis and senescence,[455] which are thought to be associated with inflammation, and increased release of DAMP.[456,457] Relatively larger dose of RT (8 Gy) has also been shown to induce Fas-receptors, which could lead to activation of T cells.[457] One would also need to consider the mechanism of immune agent being used in conjunction with RT. Preclinical study of anti-CD137 and anti CD-40 antibodies combined with either 12 Gy in 1 fraction, or 4 Gy × 4 fractions, or 5 Gy × 4 fractions in breast cancer preclinical model demonstrated that PD-1 expression and targeting of this checkpoint with anti-PD-1 antibodies were required for combination treatment with anti-CD137 and RT to be effective.[458,459] Furthermore, the fractionated radiation regimens were less effective than that 12 Gy regimen. Another study of 30 Gy in 1 fraction versus fractionated treatments (30 Gy in 10 fractions) demonstrated higher dose/fraction RT led to intense T-cell tumor infiltration compared to fractionated regimen in weakly immunogenic colon tumors in preclinical setting.[460] In other tumor types, such as lymphoma, prostate cancer, and renal cell bone metastases in the clinical setting, there are reports that conventional dose per fraction (2 Gy × 2 fractions, 70 Gy in 1.8 to 2 Gy/fractions, and 45 to 50 Gy in 1.8 to 2 Gy/fractions) in combination with immune therapy elicited a positive clinical response.[461–463] Therefore, preclinical and clinical studies would suggest that there is a complexity in determining optimal dose and fractions for optimal radiation/immunotherapy interactions. This may depend on the tumor type, the tumor microenvironment, and the mechanism of action of immunotherapy agent being utilized.[8,451]

Another intriguing line of investigation to determine the additional potential benefit that particle therapy may have over conventional photon-based RT as it pertains to immunomodulation/activation. Preclinical studies suggest in animal studies that DC injection and carbon ion combination conferred augmentation of immunogenicity of tumor cells through maturation of DCs, which stimulates antitumor immunity and led to reduction in lung metastases.[464] Preclinical studies and development of clinical trials to determine the potential role of particle therapy with immunotherapy are areas of active investigation.

From a practical point of view, given the potential benefit for use of hypofractionated radiation favoring a higher dose/fraction regimen that has been

seen in some of the preclinical studies, clinically relevant and available radiation modality may include SRS and SBRT, which typically employs larger dose/fraction in limited total fractions (typically 1 to 5 fractions) to a smaller treatment area. Regional nodal exposure would be limited with SBRT treatments. As SBRT and SRS are also frequently being used in the setting of limited extracranial and intracranial metastases/oligometastases, respectively, combining with immunotherapy may provide not only a local control advantage but can be studied to explore improvements in distant control rates. Therefore, there is significant excitement for design and implementation of clinical trials using SRS/SBRT as well as conventional fractionated RT in combination with available immunotherapy. Given the preclinical data, the appropriate dose, fractionation, treatment volume, and timing of SRS/SBRT treatments in relation to the immune agent, tumor type, and treatment site will need to be carefully considered and preferably systematically studied in the clinical setting.

Clinical Experiences

Immune agents, most of which have received recent FDA approval for cancer therapy, include cytokines (IL-2, interferon-alpha-2b), oncolytic virus therapy (T-VEC), dendritic-cell vaccine (Sipuleucel-T), and checkpoint inhibitors (ipilimumab, nivolumab, pembrolizumab, atezolizumab, durvalumab, avelumab). These agents and their current FDA-approved indications are listed in Table 36.6. Many additional agents are in the pipeline undergoing active preclinical/and clinical studies. In terms of combined therapy with radiotherapy, a large number of clinical trials are ongoing to attempt to further elucidate the potential role of RT/SBRT with these agents. However, thus far, only a handful of studies or case reports demonstrating the potential safety or efficacy of combining immune agents with RT are published. Some of the more relevant class of immune agents and published studies in conjunction with RT are reviewed below.

Vaccines

Rationale for vaccine therapy would be to boost the immune response and to overcome the baseline established immune tolerance that provided escape for the tumor. Multiple approaches for vaccine therapy have been developed including peptide-based therapy, DNA-based vaccines, and DC-based approaches.

Few studies of peptide vaccine with radiation have been reported. A randomized phase II clinical trial of use of a standard radiotherapy with or

without poxviral vaccine encoding PSA was studied in 30 patients with localized prostate cancer. RT was delivered between fourth and sixth vaccinations.[465] The vaccine regimen was safely deliverable with majority of patients demonstrating PSA-specific cellular immune response to the vaccine. However, on long-term follow-up, including patients treated with adjuvant standard or low-dose IL-2 regimen, there was no specific difference in terms of PSA outcome or toxicity with addition of vaccine, and limited long-term immune response was seen.[466] Tecemotide (L-BLP25) is a vaccine to tumor antigen MUC-1 that has been studied in a randomized phase III study for unresectable NSCLC patients undergoing chemoradiation therapy. The outcome of the study demonstrated no survival advantage to the vaccine when evaluating all patients but suggested potential benefit for patients undergoing concurrent chemoradiotherapy but not sequential chemoradiotherapy.[467] Update of the study demonstrated continued benefit in the concurrent chemoradiotherapy arm, but not the sequential chemoradiotherapy arm, and in addition, exploratory biomarker study demonstrated that high sMUC1 and ANA, but not neutrophil/lymphocyte ratio, lymphocyte count, and HLA, correlated with possible benefit for tecemotide.[468] Further studies in NSCLC have been discontinued by manufacturers, but studies in prostate and rectal cancer are being pursued.

Combining DNA vaccines with RT is an area of investigation. INO-3112 is a novel vaccine for HPV-16 and -18, combined with a proprietary immune activator expression IL-12. This compound is being studied in conjunction with concomitant chemoradiotherapy in patients with locally advanced cervical as a randomized phase II study with a safety run-in component. ADXS11-001 is another nucleic acid vaccine based on HPV protein E7, which is being evaluated in conjunction with chemoradiotherapy for HPV-related anal cancer patients.

Dendritic cell vaccine therapy aims to elicit immune response by infusion of DCs loaded with TAAs. Although several DC vaccines have been developed, the only one with FDA approval is Sipuleucel-T (PROVENGE), which is a DC enriched with prostatic acid phosphatase/GM–CSF fusion protein and approved for use in asymptomatic men with metastatic castration-resistant prostate cancer (CRPC) based on OS benefit, despite lack of disease progression benefit.[469] Several phase II trials studying the potential role of combining RT or SBRT with Sipuleucel-T are ongoing. Other DC vaccines showing promise with standard radiotherapy include EGFRvIII-targeted DC vaccine for newly diagnosed glioma patients[470] and algenpantucel-L, an allogenic pancreatic cancer vaccine, results of which are available for phase II experience with adjuvant radiochemotherapy

for pancreatic cancer patients with promising results.[471] Algenpantucel-L has been further studied in phase III trial (IMPRESS trial) with chemoradiotherapy with initial results announced on May 2016 of unfortunately negative unimpressive findings. Another method of DC therapy being explored is use of intratumoral injection of DC with neoadjuvant radiotherapy for soft tissue sarcoma, which in phase I trial demonstrated safety and induction of antitumor immune response.[472]

TABLE 36.6 REPRESENTATIVE FDA-APPROVED IMMUNE AGENTS

Category	Immune Agent	Target or Immune Mechanism	FDA-Approved Indications
Checkpoint inhibitors	Nivolumab (Opdivo)	Anti-PD1	Urothelial carcinoma, head and neck carcinoma, classical Hodgkin lymphoma, renal cell carcinoma, non–small cell lung cancer, melanoma
	Pembrolizumab (KEYTRUDA)	Anti-PD1	Hodgkin lymphoma, non–small cell lung cancer, head and neck cancer, melanoma
	Atezolizumab (TECENTRIQ)	Anti-PD-L1	Urothelial carcinoma, non–small cell lung cancer
	Durvalumab (IMFINZI)	Anti-PD-L1	Urothelial carcinoma
	Avelumab (BAVENCIO)	Anti-PD-L1	Urothelial carcinoma, Merkel cell carcinoma
	Ipilimumab	Anti-CTLA-4	Melanoma
Cytokines	Interleukin-2	T-cell growth factor and central regulator of immune function	Melanoma, renal cell carcinoma
	Interferon-alpha-2b	Activation of immune cells	Melanoma, hairy cell leukemia, non-Hodgkin lymphoma (aggressive follicular type), AIDS-related Kaposi sarcoma
Oncolytic virus	T-VEC (IMLYGIC) (talimogene laherparepvec)	Oncolytic virus therapy that initiates systemic antitumor immune response	Unresectable/recurrent cutaneous, subcutaneous, and nodal melanoma
Vaccine	Sipuleucel-T (PROVENGE)	Stimulates T-cell response against prostatic acid	Metastatic prostate cancer (CRPC)

Cytokines

IL-2 was approved for use in adults with metastatic melanoma in 1988 and is also approved for use in metastatic renal cell carcinoma. A small percentage of patients are found to have durable response with this agent.[473] Based on preclinical evidence of efficacy of RT with IL-2, clinical studies have been explored, and some of these have been reported. Phase I study from National Cancer Institute enrolling 14 patients with metastatic melanoma and at least two sites of measurable disease is reported. All patients received local RT of 10 to 20 Gy in 5 Gy/fraction dose given twice daily, followed by high dose IL-2. Although tolerable, this particular radiation regimen did not seem to improve antitumor effects.[474] In a phase I study of SBRT and high-dose IL2, patients with metastatic melanoma (n = 7), or renal cell carcinoma (n = 5), patients received 1 to 3 doses of SBRT (20 Gy/fraction) with IL-2 to commence 3 days after completion of SBRT. Five out of seven patients with melanoma had CR or PR, and 3/5 with renal cell had PR. One of twelve patient achieved CR. All irradiated metastases had response with none recurring at the time of their publication.

Checkpoint Inhibitors

Excitement of efficacy of immune checkpoint inhibitors and successful FDA approval of several agents in the past half-decade, along with significant preclinical studies demonstrating rationale and potential for increasing efficacy of these immune agents with the addition of radiotherapy, have led to development of multiple clinical trials. Currently, there are over 90 phase I or II studies[475] exploring this concept in a number of disease sites, predominantly in the metastatic setting. Only studies with ipilimumab have been completed and reported in publication form to date.

Ipilimumab is the first in class of anti-CTLA-4 strategy, to receive FDA approval in 2011. A case report demonstrated in a melanoma patient the potential efficacy of 9.5 Gy × 3 fractions regimen in combination with ipilimumab (anti CTLA-4 antibody).[476] Retrospective series of patients undergoing SRS for melanoma brain metastases who also received ipilimumab has been reported.[477] Of 42 patients in this series, 15 received SRS during, 19 before, and 12 after ipilimumab. Patients treated with SRS during or before ipilimumab had better OS and less regional recurrence. Interestingly, a temporary increase in tumor size was also noted.[477] Overall tolerability was felt to be reasonable, with 20% of

patients having grade 3+ toxicity. Although not designed to evaluate for abscopal effect, one patient demonstrated a potential abscopal effect after SRS. Ipilimumab has been studied in metastatic prostate patients with or without 8 Gy × 1 fraction radiation therapy. In an open-label multicenter phase I/II study, ipilimumab was dose escalated from 3 to 10 mg/kg +/− radiotherapy. In the phase II portion, the 10 mg/kg dose of ipilimumab was given with (n = 34) or without (n = 16) radiotherapy. This regimen was reported to be tolerable and demonstrated efficacy.[478]

Phase III trial of patients with CRPC with bone metastases was conducted, where patients received 8 Gy × 1 fraction of radiation followed by either 10 mg/kg of ipilimumab or placebo.[478] Although clear cut OS could not be made for use of ipilimumab, there was significant signs that drug may be active, particularly in certain subset of patients with more favorable prognosis, and felt that the drug requires further investigation. Most common grade 3+ adverse events were immune related, occurring in 26% in the ipilimumab group versus 3% in the placebo group. These events included diarrhea, fatigue, anemia, and colitis. Four deaths occurred due to toxic effects of ipilimumab.

Summary

Driven by strong preclinical data, a large number of clinical trials aimed at determining safety and efficacy of combining radiation with novel immune agents are actively ongoing. With this enthusiasm will be required a careful and systemic approach to careful and deliberate design of clinical trials aimed at determining the answers to many remaining questions at hand. These include determination of tumor types and tumor sites that would benefit most from radiotherapy, determination of biomarkers for response to combined RT/immune therapy, and careful dose escalation studies to determine the appropriate total dose and dose/fraction for each disease sites being considered for immune-radiotherapy. In addition, as immune therapy agents have a significantly different toxicity profile compared to other traditional systemic agents, which when combined with RT may have less predictable events in terms of severity and timing of onset, one would have to carefully study these toxicities under the auspices of prospective clinical trials. Some of the limited available experiences of potential adverse events related to combined use of immunotherapy and SBRT has been reviewed.[479] This study overall demonstrated that there were very limited data on combined SBRT with ipilimumab, nivolumab, and pembrolizumab. We await results from currently ongoing and to be developed

prospective studies to properly define the potential toxicity profiles when using immunotherapy agents in combination with RT/SBRT. The next decade should provide significant clinical data that may help define a novel paradigm for combining radiotherapy with immune therapy to impact not only local but hopefully distal disease outcomes.

CONCLUDING REMARKS

The combination of chemotherapy and radiation therapy has become a common strategic practice in the therapy of locally advanced cancers, with emphasis on the concurrent delivery of both modalities. Improvements in treatment outcome in terms of both local control and patient survival have been achieved with traditional chemotherapeutic agents such as cisplatin and 5-FU. However, there is considerable room for improvement of the combined treatment strategies. Selection of the most effective drug or the optimal treatment approach remains a significant challenge.

Newer chemotherapies, novel molecularly based targeted therapeutic agents, and immunotherapeutic agents are becoming available at an increasing rate. These agents have high potential for increasing the therapeutic effectiveness when used in conjunction with radiation therapy, and therefore, their evaluation —both in the laboratory and in the clinic, in combination with radiation therapy —is essential for improvement of cancer treatment. Preclinical studies not only provide a biologic rationale for the use of a given drug with radiation but also are able to generate information that is critical to the design of effective treatment schedules in clinical settings. Studies of the mechanisms of immune agents/molecular agents/chemotherapy–radiation therapy interaction at the genetic–molecular, cellular, distal (abscopal—in case of immunotherapy), and tumor (or normal tissue) microenvironmental levels are essential for obtaining clear insight into the radiomodulating/immunomodulating potential of these agents, and their ability to increase radiotherapeutic/immunotherapeutic effects.

Biomarkers, molecular therapeutics, immunotherapy advances, advanced imaging technology, and advances in understanding of effective chemotherapy/immunotherapy and radiation treatment integration have led to an era where personalized medicine for cancer therapy is becoming a reality. Many studies have pointed toward the need for careful patient selection when designing clinical trials incorporating molecular targeted agents. Effective biomarker development and integration of such into clinical trial design are

essential as it becomes more and more clear that cancer is truly a heterogeneous entity. There are certainly challenges that we can anticipate along the way toward an era of personalized medicine. For example, once numerous biomarkers have been elucidated, how will we decide which biomarkers are most important to test for further clinical trials? Furthermore, how will these studies be financed? In the era of tenuous health care finances, will we have the funds to implement the needed studies and be able to support payment for all the novel drugs coming out of the pipeline?

Finally, despite significant improvements rendered to cancer therapy in the past decades, it is sobering to realize that cancer, particularly when advanced, remains a deadly disease for many. As we embark on this era of abundant and emerging immunotherapeutics, molecular therapeutics, novel chemotherapeutic agents, better-established chemoradiation regimens, and more sophisticated imaging technology and radiation delivery methods, it will be essential to design well-thought-out and effective combined modality-therapy clinical trials to further improve the odds in the battle against cancer.

Section III

Clinical Radiation Oncology

PART A

Skin

CHAPTER 37

Skin

William M. Mendenhall, Anthony A. Mancuso, Jessica M. Kirwan, Peter T. Dziegielewski, and Christiana M. Shaw

The purpose of this chapter is to discuss cutaneous carcinoma and melanoma. Uncommon cutaneous malignancies, such as angiosarcoma and dermatofibrosarcoma protuberans, will be addressed elsewhere. Most skin cancers are managed surgically. Because of the functional and/or cosmetic deficits that may occur after surgery for skin cancers of the head and neck, the discussion will occasionally focus on lesions in this area.

Skin cancer is the most common of all malignancies. The American Cancer Society estimates that approximately two million basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs) are diagnosed annually in the United States, although the precise number is unknown because they are not reported.[1] The risk for carcinoma of the skin increases with sun exposure. A low incidence occurs in those with Fitzpatrick skin type V or VI; a corresponding increase occurs in those with Fitzpatrick skin types I and II. The mortality rate is about 1,800 per year, or 0.45%.

Several conditions are associated with carcinoma of the skin, including the following:

- Actinic exposure
- Ionizing radiation
- Scar (e.g., burn scar)
- Chronic infection or draining of sinus or fistulous tract (e.g., pilonidal sinus)
- Immune disorders
  - Chronic lymphocytic leukemia
  - Solid organ transplant patients
  - Discoid lupus erythematosus
- Chemicals
  - Arsenicals (herbicides, pesticides)
  - Psoralens and ultraviolet light (PUVA) treatment for psoriasis

- Nitrates
- Tars, oils, and paraffins

- Hereditary disorders
  - Xeroderma pigmentosum
  - Basal cell nevus syndrome
  - Albinism
  - Congenital epidermolysis bullosa

Melanoma is less common than BCCs and SCCs. Siegel et al.[2] estimated that approximately 76,380 melanomas will be diagnosed in the United States in 2016 and that about 10,130 deaths owing to the disease will occur.

ANATOMY

The epidermis is thinner in the face than in most portions of the body, measuring approximately 0.04 mm. No consistent change in the thickness of the epidermis occurs with increasing age, and no difference in skin thickness exists between men and women. The layers of the epidermis from superficial to deep are

- Stratum corneum
- Stratum lucidum
- Stratum granulosum
- Stratum spinosum
- Stratum basale

It is important to know these layers to understand the origin and behavior of a particular type of skin cancer.

The dermis, which contains the blood and lymphatic vessels, adnexa, hair follicles, sweat glands, and sebaceous glands, is 1 to 2 mm thick; the dermis of the eyelid is thinner, ≤0.6 mm. Beneath the dermis lies the subcutaneous tissue containing the fat and the superficial fascia. No distinct transition occurs from the dermis to the subcutaneous layer.

Lymphatics

No lymphatics exist in the epidermis. A superficial capillary lymphatic plexus lies in the dermis and is without valves.[3] The deep lymphatic trunks in the dermis and subcutaneous tissues have valves. The density of the capillary lymphatics has been noted to be about the same in all areas, except the sole of the foot and palm of the hand, where it is denser. Observation suggests that SCCs and melanomas occurring on the skin of the temple are particularly prone

to develop lymphatic metastasis.[4] During the healing of wounds, such as incisions or burns, a regeneration of lymphatic capillaries across the scar occurs, similar to the regrowth of small blood vessels.[3]

The first-echelon lymph nodes for carcinomas of the face and scalp are the superficial network of lymph nodes that form a ring around the top of the neck: submental (level IA), submandibular (level IB), intraparotid or preauricular, postauricular (mastoid), and occipital lymph nodes as well as inconstant facial lymph nodes. The first echelon is highly associated with the exact location of the cancer on the face.

PATHOLOGY

The most common carcinomas of the skin are BCC (65%), SCC (30%), a variant of BCC or SCC, and the adnexal carcinomas. Merkel cell carcinoma (MCC) is a rare neuroendocrine malignancy arising in the skin that was first described by Toker[5] in 1972. Verrucous carcinoma, a variant of SCC, occurs most often on the foot and is rare in the head and neck area. Carcinoma *in situ* (CIS) occurs frequently in the head and neck. Perineural invasion (PNI) is observed in 2% to 3% of patients with BCCs and SCCs.[6]

Noncutaneous carcinomas (e.g., renal cell carcinoma) may metastasize to the skin and subcutaneous tissues.

Basal Cell Carcinoma

The common BCC, which arises from the basal layer of the epithelium, may have a variety of growth patterns merge into one another in the same tumor, and the different names applied to the gross and microscopic appearances have clinical implications. The morphea type (sclerosing BCC) shows little surface disease and a marked infiltrating pattern; it is an important subtype because of the higher risk for recurrence. Microcystic BCC is a histologic variant of BCC that exhibits the same natural history as the more common variety. Some lesions will have mixed BCC and SCC (basosquamous cell carcinoma or metatypical BCC). Melanin pigment may be seen on both gross and microscopic examination of BCC.

Squamous Cell Carcinoma

SCC and its variants (i.e., verrucous carcinoma, spindle cell SCC) are similar histologically to SCC occurring in other sites. Most are well differentiated. Evans and Smith[7] identified two categories of spindle cell tumors of skin: one

was composed of SCC mixed with a spindle cell component; the other was predominantly spindle cells. The spindle cell component is similar in both groups; mitoses, giant cells, and epithelioid cells may be seen.

Keratoacanthoma

Keratoacanthoma is a benign tumor of the skin that grossly resembles a cystic BCC and microscopically resembles SCC or squamous papilloma. Part of the difficulty in histologic diagnosis is owing to an inadequate biopsy specimen. Ackerman[8] concluded that "the diagnosis of keratoacanthoma can only be made with absolute certainty by biologic behavior in the form of eventual involution."

Adnexal Carcinoma

Carcinomas may arise from the epithelium of the sweat glands, sebaceous glands, or hair follicles and microscopically resemble the tissue of origin. Carcinoma of the sweat gland can arise from either the eccrine or apocrine glands; however, no reliable histologic criteria exist to differentiate the origin. It is difficult to distinguish between benign tumors and malignant carcinomas of the sweat gland in the absence of metastases. The differential diagnosis includes adenocarcinoma metastatic to skin and BCCs and SCCs with an adenoid cystic growth pattern. They are frequently misdiagnosed at the time of the first biopsy. Malignant trichilemmoma arising from hair follicles is extremely rare.

Microcystic adnexal carcinoma (sclerosing sweat duct carcinoma) is a rare variant of adnexal carcinoma first described in 1982. The lesion usually presents on the upper lip or skin of the periorbital area as an indurated plaque without direct invasion of the overlying epidermis. It often appears as a subcutaneous nodule. It tends to be slow growing and locally invasive.[9–11] Microcystic adnexal carcinoma exhibits a propensity for local recurrence after excision and is associated with PNI; lymph node metastases are rare. The role of radiation therapy (RT) in the treatment of this rare malignancy is undefined.

Merkel Cell Carcinoma

MCC is a small cell neuroendocrine carcinoma arising in the skin. It has been found to be associated with polyomavirus infection. As in neuroendocrine carcinomas arising in other primary sites, MCC produces a neuron-specific enolase and has been found to contain membrane-bound neurosecretory granules within the tumor cell. In the past, the correct diagnosis often was not obtained until an extensive recurrence was noted. MCC was often misdiagnosed as BCC, lymphoma, adnexal carcinoma, or carcinoma metastatic to the skin from another

primary site (i.e., small cell carcinoma of the lung or medullary carcinoma of the thyroid).[12]

Melanoma

Melanoma arises from melanocytes, which are present in the epidermis as well as in other parts of the body including the eye and respiratory, gastrointestinal, and genitourinary tracts.

PATTERNS OF SPREAD

The patterns of spread for individual anatomic sites are outlined in the Selection of Treatment Modality section. Some lesions remain confined to the epidermis (CIS) and may involve a large area of skin. Large *in situ* lesions occur more often on the trunk; however, small areas of CIS are common on the head and neck.

Basal Cell and Squamous Cell Carcinomas

Both BCC and SCC usually are well differentiated, and most have an indolent growth with distinct margins; a small proportion are poorly differentiated and grow rapidly. BCC occurs more frequently around the central portion of the face, whereas SCC occurs more often on the ears, preauricular and temporal area, scalp, and skin of the neck.

Most lesions remain superficial and invade the adjacent epidermis in a circumferential growth pattern. Invasion of the dermis usually is confined to the superficial (papillary) dermis. Eventually, penetration of the reticular dermis, subcutaneous tissues, and other underlying structures occurs. A few skin carcinomas tend to grow beneath the skin, and the surface lesion gives little indication of their extensive growth; this is more often seen in recurrent tumors. Most early BCCs and SCCs show an orderly invasion of the superficial dermis, which allows successful local therapy. Both BCCs and SCCs invade cartilage and bone, develop PNI, and eventually enter the lymphatics, although the latter is not common. BCC, in particular, has a low incidence of lymphatic involvement unless it is recurrent (0.05%), whereas the incidence of lymph node spread for SCC is estimated to be at least 10% to 15%. As the size and age of the lesion increase, the potential for lymphatic spread increases.

SCCs may develop distant metastases, whereas BCCs rarely produce metastases. BCC tend to be locally invasive and destructive. A variant of BCC known as basosquamous cell carcinoma acts more aggressively than does BCC

and has a propensity for lymphatic spread.

Metatypical BCC is intermediate between BCC and SCC as far as recurrence rates and the risk of metastases.[13]

Spindle cell tumors of the skin have a gross appearance and growth pattern similar to SCCs.

Carcinoma of the Sweat Gland

Carcinoma of the sweat gland occurs with equal frequency in males and females. It predominantly affects elderly people, although it may occur even in early adulthood. The lesion is generally a subcutaneous nodular mass, which may be solitary or multiple, and the larger lesions may be ulcerated. Carcinoma of the sweat gland most often occurs on the eyelid, face, and scalp. The growth rate varies from indolent to rapid. The tumor may be present for several years with little change and then suddenly begin to enlarge. PNI is frequent. Regional and distant metastases may develop. Scalp lesions are the ones most likely to develop metastases to regional lymph nodes.

Recurrence after excision is frequent, and often multiple recurrences are reported.[14,15] Little information exists on the response to RT.[15] In our limited experience, carcinoma of the sweat gland is sufficiently radioresponsive to justify RT, particularly in association with excision.

The mucin-producing sweat gland adenocarcinoma is a rare tumor. The eyelid is the primary site in about one-half of cases and the face and scalp in another one-fourth of cases. The tumor presents most often in middle-aged men. Wright and Font[16] reported 21 cases that originated on the eyelid. Eight patients (38%) developed one or more local recurrences, one patient died with extensive persistent disease in the face after a 15-year interval, and only one patient had metastasis to the submandibular lymph nodes successfully treated by radical neck dissection.[16] Regional or distant metastasis is a relatively infrequent event for lesions arising in the head and neck area.

Sebaceous Gland Carcinoma

Sebaceous gland carcinoma is rare. It occurs most often on the eyelids, predominantly on the upper lid in elderly women, although the lower lid and caruncle are also sites of origin; it may occur on other parts of the head and neck skin as well. It is often indolent in its growth; however, it may be locally aggressive and develop regional and distant metastases. Local recurrence is common after excision because the lesions often have significant deep and

lateral spread beyond the obvious lesion. Metastasis to regional lymph nodes is reported in about 20% of cases, and a small percentage of patients develop distant metastases.[17] Inadequate treatment often occurs because of incorrect histologic diagnosis.

Keratoacanthoma

Keratoacanthoma benign lesions start as a firm, round skin nodule and grow to 1 to 2 cm in a short time, usually a few weeks. As the lesion matures, the center becomes separate and can be removed, revealing a small crater. The lesion occurs most often in the exposed area of the head and neck. Keratoacanthoma is an unlikely diagnosis for a lesion of the lip vermilion. Typically, keratoacanthoma is twice as common in men as women. It occurs most often in patients older than 40 years of age, although it may be seen as early as the second decade of life.

Basal Cell Nevus Syndrome

The basal cell nevus syndrome (aka Gorlin syndrome) is an autosomal dominant disorder with a high level of penetrance but a variable clinical picture. The clinical syndrome may be composed of any or all of the following:

- Multiple BCCs (differing only in their tendency to develop at an early age and on unexposed skin areas)
- Jaw cysts (common)
- Palmar or plantar pits
- Skeletal abnormalities (short fingers, hypertelorism)
- Ectopic calcification
- Eye muscle palsies
- Hamartomas
- Epidermal cysts

The age at onset is frequently in the second or third decade of life, and a family history is often positive for the disorder.[18]

Merkel Cell Carcinoma

MCC occurs primarily in white men between 60 and 80 years of age.[19] The lesion often presents as a painless, raised skin nodule or mass that is red, pink, or blue and may have diffuse margins and is covered with an intact epidermis. Most lesions are ≤2 cm in size at diagnosis.[19] Human polyomavirus is thought to be etiologic in a significant proportion of patients; human polyomavirus DNA in the

MCC cells may be associated with an improved prognosis.[19]

MCC displays an aggressive growth pattern. Mojica et al.[20] reported on 1,665 patients from the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) database and observed the following extent of disease at diagnosis: localized, 55%; positive regional nodes, 31%; distant metastases, 6%; and no data, 8%.

Melanoma

Melanoma is more aggressive and prone to metastasize to regional lymph nodes and exhibit hematogenous dissemination compared with BCC and SCC. The likelihood of regional and/or distant metastases is related to the depth of invasion of the primary tumor. The incidence of positive sentinel lymph node biopsies (SLNBs) versus depth of penetration is depicted in Table 37.1.

Lymphatics

The overall risk of lymphatic metastases is estimated to be 10% to 15% for cutaneous SCC of the skin. The risk increases with the size of the lesion, depth of the penetration, histologic grade, and recurrence.

The risk of lymph node metastases from previously untreated BCCs is <1% and is not related to size, depth of penetration, or histologic subtype; the risk increases for recurrent BCCs, especially those with multiple recurrences over several years. Lymph node metastases, however, are seen on rare occasions without a history of recurrence, and an interval of several years may occur between the treatment of the primary lesion and the appearance of involvement in lymph nodes. When they do occur, lymph node metastases often are solitary.

CLINICAL PICTURE

Presenting Symptoms

The common history for BCC or SCC is a slowly enlarging growth on or just beneath the skin surface. Often a history exists of a sore that will not completely heal. Other symptoms such as bleeding or pain are unusual until the lesion becomes large, and even then symptoms are relatively mild and infrequent. Patients with PNI may complain of paresthesia, especially the sensation of worms crawling under skin (formication). PNI is usually observed with midface lesions and most often involves cranial nerves V2 and/or VII.[6] Advanced, neglected lesions with bone and cartilage destruction, orbit invasion, and

regional metastases may be seen; these advanced lesions often produce few, if any, symptoms, and patients simply delay consulting a physician.

TABLE 37.1 PRIMARY DEPTH OF INVASION VERSUS SENTINEL LYMPH NODE BIOPSY POSITIVITY

Melanomas usually present as a pigmented skin lesion associated with a change in color, shape, and/or size. Although most probably arise de novo, some may arise in a previously benign nevus. Occasionally, patients present with regional or distant metastases without an apparent primary tumor.

Physical Examination

The site, size, and mobility of the primary lesion is always documented. Depending on location, evidence of PNI is assessed as well as any findings that might suggest involvement of underlying bone or cartilage. The regional lymph nodes must be carefully examined, even though they are not often involved. Because of the infrequent appearance of regional lymphatic metastases, and because cases of skin cancer often are not followed diligently, lymph node metastases frequently are missed. Although lymphatic metastases may appear within a few months of the management of the primary lesion, in some cases,

many years intervene before the regional lymph nodes become apparent. It is not at all unusual for ≥5 years to intervene between the primary lesion and the appearance of metastases. Patients with chronic lymphocytic leukemia and concomitant skin cancer often have enlarged lymph nodes from both processes and may have elements of SCC and leukemia in the same lymph nodes.

METHODS OF DIAGNOSIS AND STAGING

Biopsy should be performed on the majority of lesions before deciding on treatment. We do not always insist on biopsy for elderly patients who have a typical skin carcinoma and are to be treated by RT.

Small lesions occurring on the free skin areas (i.e., not involving the eyelid, ear, or periorbital areas) usually can undergo biopsy and be treated simultaneously with surgical excision. Larger lesions, or those involving areas where functional or cosmetic deficit might occur from excision, first undergo biopsy with a small incisional biopsy or with a skin punch. Shave biopsies are also often used, except in pigmented lesions where a melanoma is suspected. For the diagnosis and staging of a melanoma, a full-thickness skin biopsy (such as with a punch) is needed. Biopsy with a skin punch should include the subcutaneous fat; punch biopsy is contraindicated when differentiating between keratoacanthoma and SCC because of the small sample size.

The following is a partial list of conditions to be considered in the differential diagnosis of BCC and SCC:

- Senile keratosis
- Keratoacanthoma
- Nonpigmented nevi
- Melanoma
- Cutaneous horn
- Psoriasis
- Lymphoma (mycosis fungoides)
- Soft tissue sarcomas (dermatofibrosarcoma protuberans)
- Hemangiosarcoma
- Metastatic carcinoma
- Adnexal carcinoma of skin
- MCC

Staging

The 2017 American Joint Committee on Cancer (AJCC) systems for SCC of the head and neck and melanoma are depicted in Tables 37.2 and 37.3, respectively.[21] BCC and SCC outside of the head and neck was not included in the AJCC Staging Manual for 2017. Although there is an AJCC staging system for MCC, we prefer the Yiengpruksawan system for this rare entity because of its simplicity: stage I, localized; stage II, regional lymph node metastases; and stage III, distant metastases.[22]

TABLE 37.2 2017 AJCC STAGING SYSTEM FOR SQUAMOUS CELL CARCINOMAS OF THE HEAD AND NECK

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumor smaller than 2 cm in greatest dimension
T2	Tumor 2 cm or larger, but smaller than 4 cm in greatest dimension
T3	Tumor 4 cm or larger in maximum dimension of minor bone erosion or perineural invasion or deep invasion[a]
T4	Tumor with gross cortical bone/marrow, skull base invasion, and/or skull base foramen invasion
T4a	Tumor with gross cortical bone/marrow invasion
T4b	Tumor with skull base invasion and/or skull base foramen involvement
Regional Nodes Lymph (N)	
NX	Regional lymph cannot nodes be assessed
N0	No regional node lymph metastases
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and extranodal extension (ENE)(−)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−); or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−); or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2a	Metastasis in a single ipsilateral lymph node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)
N2b	Metastasis in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2c	Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); or metastasis in any node(s) and clinically overt ENE [ENE(+)]
N3a	Metastases in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in any node(s) and ENE(+)
Distant Metastasis (M)	

M0	No distant metastases		
M1	Distant metastases		
Stage	***T***	***N***	***M***
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0

Diagnostic Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are only necessary in a carefully chosen group of patients being treated for skin cancer. CT is the primary modality for showing bone invasion and nodal metastases, although MRI is often useful in determining muscular or bony invasion in large or neglected lesions, and is superior to CT for demonstrating PNI.[23] Positron emission tomography (PET) is useful to detect regional and distant metastases in patients with MCC and melanoma, but should be restricted to patients for are found to be node-positive.

TABLE 37.3 2017 AJCC STAGING SYSTEM FOR MELANOMA

Primary Tumor (T)

T Category	Thickness	Ulceration Status

TX	Primary tumor thickness cannot be assessed (e.g., diagnosis by curettage)	
T0	No evidence of primary tumor (e.g., unknown primary or completely regressed melanoma)	
Tis	Melanoma *in situ*	
T1	<0.8 mm	Unknown or unspecified
T1a	<0.8 mm	Without ulceration
T1b	<0.8 mm 0.8–1.0 mm	With ulceration With or without ulceration
T2	>1.0–2.0 mm	Unknown or unspecified
T2a	>1.0–2.0 mm	Without ulceration1
T2b	>1.0–2.0 mm	With ulceration
T3	>2.0–4.0 mm	Unknown or unspecified
T3a	>2.0–4.0 mm	Without ulceration
T3b	>2.0–4.0 mm	With ulceration
T4	>4.0 mm	Unknown or unspecified
T4a	>4.0 mm	Without ulceration
T4b	>4.0 mm	With ulceration
Regional Lymph Node (N)—Extent of regional lymph node and/or lymphatic metastasis		
N Category	Number of tumor-involved regional lymph node	Presence of in-transit, satellite, and/or microsatellite metastases
NX	Regional nodes not assessed (e.g., SLN biopsy not performed, regional nodes previously removed for another reason) **Exception:** pathologic N category is not required for T1 melanomas, use cN	No
N0	No regional metastases detected	No
N1	One tumor-involved node or in-transit, satellite, and/or microsatellite metastases with no tumor-involved nodes	
N1a	One clinically occult (i.e., detected by SLN biopsy)	No
N1b	One clinically detected	No
N1c	No regional lymph node disease	Yes
N2	Two or three tumor-involved nodes or in-transit, satellite, and/or microsatellite metastases with one tumor-involved node	
N2a	Two or three clinically occult (i.e., detected by SLN biopsy)	No
N2b	Two or three, at least one of which was clinically detected	No
N2c	One clinically occult or clinically detected	Yes
N3	Four or more tumor-involved nodes or in-transit, satellite, and/or microsatellite metastases with two or more tumor-involved	
N3a	Four or more clinically occult (i.e., detected by SLN biopsy)	No

N3b	Four or more, at least one of which was clinically detected, or presence of any number of matted nodes	No
N3c	Two or more clinically occult or clinically detected and/or presence of any number of matted nodes	Yes

Distant Metastasis (M)

M Category	M Criteria	
	Anatomic site	LDH level
M0	No evidence of distant metastasis	Not applicable
M1	Evidence of distant metastasis	See below
M1a	Distant metastasis to skin, soft tissue including muscle, and/or nonregional lymph node	Not recorded or specified
M1a(0)		Not elevated
M1a(1)		Elevated
M1b	Distant metastasis to lung with or without M1a sites of disease	Not recorded or unspecified
M1b(0)		Not elevated
M1b(1)		Elevated
M1c	Distant metastasis to non-CNS visceral sites with or without M1a or m1b sites of disease	Not recorded or unspecified
M1c(0)		Not elevated
M1c(1)		Elevated
M1d	Distant metastasis to CNS with or without M1a, M1b, or M1c sites of disease	Not recorded or unspecified
M1d(0)		Normal
M1d(1)		Elevated

SELECTION OF TREATMENT MODALITY

Basal Cell and Squamous Cell Carcinomas

The likelihood of cure is similar after surgery or RT for early-stage BCCs and SCCs.[24] Therefore, selection of one modality over another is based on other parameters such as function, cosmesis, age of the patient, convenience, cost, availability of appropriate RT equipment, and the wishes of the patient. Patients with advanced cancers are often best treated with surgery and adjuvant RT if the cancer is resectable and the functional and cosmetic outcomes are acceptable to the patient.

Radiation Therapy Alone

Small skin cancers located on “free skin,” such as the cheek or forehead, may be easily excised and reconstructed with a good cosmetic result and minimal inconvenience; therefore, surgery is usually the treatment of choice for such lesions. It is also desirable to avoid RT in young patients because the late effects of irradiation progress gradually with time and, with very long-term follow-up, may be associated with a suboptimal cosmetic result compared with resection and reconstruction. In contrast, resection of an early-stage skin cancer of the eyelid, external ear, or nose may result in a significant cosmetic deformity and necessitate complex reconstruction that compares unfavorably with RT. This is

particularly relevant in the case of older patients who have a limited life expectancy and who are at higher risk for a perioperative complication if the lesion is large and general anesthesia is required. In contrast, small cancers suitable for Mohs excision with local anesthesia are well treated with this technique.

Patients with locally advanced skin cancers present a difficult problem because, although the likelihood of cure may be better with combined RT and surgery in some situations, the cosmetic result is sometimes unacceptable. Patients receive postoperative RT if surgery is indicated and feasible. If surgery is not feasible, the patient is managed with RT alone. Although it might seem that the risk of bone and/or cartilage necrosis would be high after RT for a skin cancer invading these structures, the observed risk of complications is relatively low.[25,26] Exceptions are advanced cancers of the scalp and those overlying the anterior aspect of the tibia where there is little tissue between the skin surface and the bone. Following definitive RT, bone exposure is likely and may progress to an osteoradionecrosis (ORN) requiring surgical intervention.

Patients with SCC and BCC with incidental PNI have better outcomes after Mohs surgery and postoperative RT compared with RT following a non-Mohs resection.[27] Patients with lesions associated with clinical PNI with gross tumor extending to sites that render complete resection unlikely or unfeasible, such as the cavernous sinus, are treated with RT alone. Subtotal resection does not enhance the likelihood of cure and only increases the morbidity of treatment.

Adjuvant Radiation Therapy

Postoperative RT is added after surgery if pathologic examination of the surgical specimen reveals findings indicative of a high risk for local recurrence, such as close or positive margins and/or invasion of nerve, cartilage, or bone. A significant proportion of patients with positive margins after resection of an early-stage skin cancer may never develop a local recurrence. Postoperative RT may be withheld if the lesion is a BCC, the primary site is located on the free skin, the patient is reliable and will return for close follow-up, and if salvage treatment would have a high likelihood of eradicating recurrent tumor with a good cosmetic result. BCCs of the nose, eyelid, or ear and lesions that would have immediate access to major nerve trunks are usually retreated immediately when resection margins are positive. The risk of recurrence is probably greater than for lesions of the free skin, and the consequences of recurrence may be significant. Observation is particularly attractive for the elderly patient in poor

medical condition who may not live to experience a local recurrence. Metatypical BCCs behave more aggressively than BCCs, and those with positive margins after surgery should be re-excised and/or treated with postoperative RT.

Patients with BCC or SCC and focal incidental PNI involving a small nerve trunk (<0.1 mm) and widely negative margins may be safely observed.[28,29] Otherwise, patients with incidental PNI should be considered for postoperative RT, particularly if the lesion is SCC.

The usual policy for patients with positive margins from SCC is immediate retreatment by either re-excision, RT, or both, depending on the situation. There is evidence that this approach leads to a reduced risk of metastasis and reduced likelihood of death from cancer.

Management of Regional Lymph Node Metastases

Carcinoma of the skin metastatic to the parotid lymph nodes is managed as a high-grade parotid neoplasm, usually with superficial or total parotidectomy followed by postoperative RT.[24,30–32] If only one node is involved and there is no extracapsular extension, it may be safe to withhold RT. However, if the tumor recurs in the parotid area after parotidectomy, the likelihood of salvage is remote.[30] Therefore, it has been our practice to use combined treatment in all patients. If the parotid lymph node metastasis is fixed and thought to be incompletely resectable, the patient is treated with high-dose preoperative RT (6,000 to 7,000 cGy) followed by parotidectomy. RT alone is used only in patients who are inoperable because of tumor extent or poor medical condition. Patients who have positive parotid nodes and clinically negative cervical nodes may undergo a parotidectomy withholding the neck dissection followed by postoperative RT to the parotid and the neck with a high likelihood of local–regional control.[33]

Cervical lymph node metastases are managed just as they would be for other carcinomas of the head and neck. Neck dissection alone is adequate treatment if only one node is involved and there is no extracapsular extension. If two or more nodes contain tumor or if extracapsular extension is noted, neck dissection is followed by postoperative RT.

Merkel Cell Carcinoma

The preferred treatment for MCC is resection of the primary tumor with wide surgical margins (2 to 3 cm minimum) and sentinel node biopsy with completion lymph node dissection or primary dissection of any clinically positive regional

nodes. Our bias is to treat both the primary site and regional lymphatics with postoperative RT. The dose fractionation schedule is the same as that employed for SCC. The role of adjuvant chemotherapy is ill defined. Patients who should be considered for adjuvant chemotherapy are those with positive nodes and/or satellite lesions. Drugs employed are often those used for small cell carcinomas and include etoposide and cisplatin.

Melanoma

The preferred treatment for melanoma is resection of the primary lesion with or without sentinel node biopsy. Patients who have lesions with a depth of invasion exceeding 1 mm and clinically negative nodes should be considered for SLNB. We also perform SLNB for lesions with depth of invasion 0.75 to 1 mm if there are high-risk features including ulceration, regression, invasion into Clark level IV or V, deep margin positive, or young age. Completion lymph node dissection for positive sentinel nodes is controversial but remains standard of care. Fine needle aspiration should be performed on any grossly positive regional nodes, followed by lymph node dissection. Patients with desmoplastic melanoma are usually suitable for surgery alone unless there is extensive PNI associated with a lesion near a named nerve, in which case postoperative RT is considered. Postoperative RT is also employed to treat the primary site when there are in-transit metastases and the margins are equivocal. Adjuvant postoperative RT is often employed for positive regional nodes. Patients who are at high risk for regional lymph node metastases and are unable to undergo SLNB and/or elective node dissection should be considered for elective nodal irradiation of the first-echelon lymphatics. The dose fractionation schedule is usually the MD Anderson Cancer Center hypofractionation technique consisting of 3,000 cGy in five fractions over 2.5 weeks with a reduction off of the spinal cord and/or central nervous system (CNS) at 2,400 cGy.[34] Alternatively, conventional fractionation (5,000 to 6,000 cGy in 200 cGy fractions) may be employed if late effects and suboptimal cosmesis are a concern.[35]

Definitive RT using orthovoltage RT or electrons may be employed for elderly patients with lentigo maligna or lentigo malignant melanoma where excision is not feasible because of cosmesis function and/or medical comorbidities.[36–38] The dose fractionation schedules are the same as those described for postoperative RT.

TREATMENT TECHNIQUES

Treatment techniques vary for primary lesions and for regional lymph node metastases.

Primary Lesion

RT of the primary lesion is usually accomplished using one of three basic external beam techniques (orthovoltage RT, electron beam, and high-energy x-rays or photons) or with an interstitial implant either alone or in combination with external beam techniques (addressed on the next page). Most early skin cancers are managed with orthovoltage RT with beam energies of 100 to 250 kVp. The advantages of this technique, compared with electron beam, are that the maximum dose is at the skin surface; bolus is not required; there is less beam constriction both at the surface and at depth so that smaller fields can be used (Fig. 37.1); shielding of the eye is easier and more effectively accomplished, particularly if electron energies ≥10 MeV are used (Table 37.4)[39]; it is less expensive; and the likelihood of tumor control may be higher, possibly as a result of increased radiobiologic effectiveness (RBE) but more likely because of technical problems that are difficult to overcome when using electrons alone. The disadvantages of orthovoltage x-rays, compared with electron beam, are that there is a higher dose to deeper tissues and to underlying bone and cartilage. The latter problem can be largely eliminated by using heavily filtered orthovoltage beams for tumors involving or overlying cartilage or bone. Another significant problem associated with orthovoltage RT is that most radiation oncology departments do not have an orthovoltage machine, and thus it is unavailable. Electron beam is usually used for lesions of the scalp to reduce the dose to the underlying brain; orthovoltage x-rays are used to treat most other skin cancers. Orthovoltage RT is particularly useful for lesions of the head and neck.

Before treatment with either electron beam or orthovoltage x-rays, a customized lead mask is constructed to collimate the beam directly on the skin surface. A 1.0- to 1.5-cm margin is adequate for a well-defined T1 lesion treated with orthovoltage RT. An additional 1 cm is added to the margin when the electron beam is used to account for beam constriction. For larger and/or ill-defined tumors, a 2-cm margin is usually necessary. If the tumor is located near the eye, a gold-plated lead eye shield is placed directly on the anesthetized cornea to minimize the irradiation dose to underlying structures (Fig. 37.2). The dose beneath the eye shield is depicted for orthovoltage x-rays and electron beams of various energies in Table 37.4. Isodose distributions for the two techniques are shown in Figure 37.1; note that the dose distribution is better for

orthovoltage RT than for electron beam, particularly if a lead mask is not used with the electron beam.

Advanced skin cancers that are deeply invasive are often treated with high-energy photons to adequately cover the deep extent of the tumor. Bolus is used to ensure an adequate surface dose. Field arrangement varies with primary site. For example, a wedge-pair technique may be used for lesions involving the external ear, whereas a three-field technique (similar to that used for paranasal sinus cancer) is frequently used for skin cancers with extension proximally along the second division of the fifth cranial nerve. The target volume includes the entire course of the involved nerve, which would include the gasserian ganglion in this case, to the brain stem. Intensity-modulated radiotherapy (IMRT) may be used in some patients to produce a more conformal dose distribution to reduce the dose to surrounding normal structures. Proton beam radiotherapy may also be used to produce a very conformal dose distribution with steep dose gradients to limit the dose to the visual apparatus and the CNS.[40,41]

Source of collimator distance (SCD) = 95 cm; SSD = 100 cm; isodose %: 95, 90, 80, 70, and 50. **C:** 6-MeV electron beam with tertiary collimation on the phantom surface. SSD = 100 cm; SCD = 100 cm; isodose %: 95, 90, 80, 70, and 50.

The extent of RT fields for patients with PNI varies with histology and the extent of PNI. Patients with BCC or SCC and focal incidental PNI are treated with a wide local field. Those with extensive incidental PNI are treated with fields that include the at-risk nerves to the skull base, particularly if margins are positive or equivocal. The at-risk nerves receive 50 to 70 Gy depending on the extent of PNI and margin status. Patients with clinical PNI receive definitive RT to fields that include the primary site and involved nerves to the skull base.

TABLE 37.4 OCULAR PROTECTION: DOSE BENEATH THE EYE SHIELD

Structure (Depth)	250 kVp X-ray (HVL mm 1.4 Cu)	Electron Beam Energy (MeV)						
		6	8	10	12	14	17	20
Cornea (1 mm)	10%	18%	37%	64%	75%	93%	98%	102%
Lens (8 mm)	9%	9%	19%	36%	46%	61%	70%	87%
Retina (23 mm)	10%	19%	22%	22%	21%	23%	25%	29%

Dose is expressed as a percentage of the dose to D_{max} (depth of maximum dose deposition).
HVL, half-value layer.

The regional lymph nodes are electively irradiated if the suspected risk of subclinical disease exceeds 10% to 15%.[42,43] Patients with SCC and PNI should be considered for elective nodal RT, particularly if the lesion is located on the head or neck.

Dose fractionation schedules used for irradiation of skin cancers are outlined in Table 37.5. We have recently used twice-daily RT with megavoltage photons or protons at 1.2 Gy per fraction to doses of 74.4 Gy in a continuous course with a minimum 6-hour interfraction interval for advanced lesions near radiosensitive structures. The suggested maximum doses for short-course orthovoltage RT are listed in Table 37.6.

Parotid Area Lymph Node Metastases

The parotid gland and upper neck are treated with an *en face* mixed beam of 6-MV x-rays and high-energy electrons (usually 20 MeV), weighted 1.0:0.67 in favor of the electron beam. The electron beam field is 1 cm larger than the x-ray field to account for the beam constriction of the electrons, except where the field abuts the low-neck field (Fig. 37.3). This field arrangement is treated to 4,600 cGy in 23 fractions, specified at a depth of 4 to 5 cm from the skin surface. An anterior field is matched to the lateral mixed beam field to treat the ipsilateral low neck and is irradiated to 5,000 cGy in 25 fractions, specified at D_{max}.

TABLE 37.5 GUIDELINES FOR SELECTION OF EXTERNAL BEAM DOSE

Orthovoltage Dose (cGy)[a]	Examples
6,500 over 7 wk	Large untreated lesion with bone/cartilage invasion or large recurrent tumor.[b]
6,000 over 7 wk	Large untreated lesion with minimal or suspected bone/cartilage invasion.[b]
5,500 over 6 wk	Moderate to large inner canthus, eyelid, nasal, or pinna lesions (20–30 cm^2 area).
5,000 over 4 wk	Small, thin lesion (<1.5 cm) around eye, nose, or ear (10 cm^2 area).
4,500 over 3 wk	Moderate-sized lesion on free[c] skin or postoperative treatment of moderate-sized cancer on free skin with positive margins.
4,000 over 2 wk or 3,000 over 1 wk	Small lesions (1 cm) free on skin.
The following schemes are used when the late cosmetic result is not important and travel for the patient is difficult:	
4,000 in 10 fractions or 3,000 in 5 fractions or 2,000 in 1 fraction	Rapid fractionation schemes produce a high cure rate for small lesions, although the cosmetic result may be less than optimal after 5 y.

[a]Add 10% to dose for supervoltage therapy.
[b]All or a portion of the therapy given with supervoltage photons and/or electrons.
[c]"Free" refers to not involving the ear, nose, eye, or eyelid.
From Mendenhall WM, Million RR, Mancuso AA, et al. Carcinoma of the skin. In: Million RR, Cassisi NJ, eds. *Management head of and neck cancer: a multidisciplinary approach*. 2nd ed. Philadelphia, PA: JB Lippincott, 1994:643–691. With permission.

At 4,600 cGy tumor dose, the primary field is reduced off of the spinal cord, and the dose to the tumor bed is boosted with an anteriorly angled 20-MeV electron beam field or an appositional mixed beam field with an abutting posterior electron strip. The final dose for patients treated at 200 cGy per

fraction with negative margins is 6,000 cGy; with positive margins, 6,600 cGy; and with gross residual disease, 7,000 cGy. If the dose per fraction is reduced to 180 cGy, the total dose is increased by 500 cGy. An alternative to the mixed electron–photon beam is a wedge-pair technique using 4- to 6-MV photon beams. IMRT may also be considered to reduce the dose to the temporal lobe and cerebellum, particularly if the margins are positive and/or tumor involves the deep lobe of the parotid.

Axillary Metastases

Axillary lymph node metastases are irradiated with opposed anterior and posterior portals that include the supraclavicular fossa. The dose fractionation schedule is 4,500 cGy in 25 fractions with a reduction and boost depending on margin status.

Ilioinguinal Lymph Node Metastases

Ilioinguinal lymph nodes are usually irradiated with IMRT to reduce the volume of tissue irradiated, particularly small bowel. The femoral and external iliac vessels are contoured on the treatment planning CT and a 1.5- to 2-cm margin is added to obtain the clinical target volume (CTV).

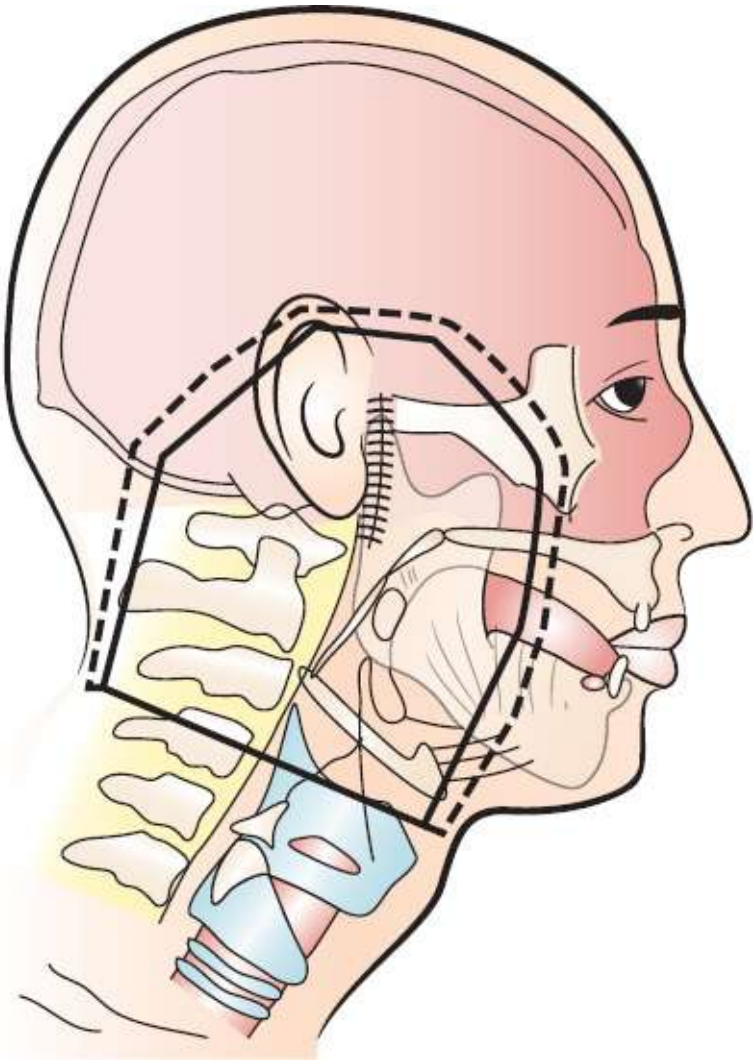

FIGURE 37.3. Typical *en face* mixed beam field used in the treatment of parotid node metastases to encompass the entire parotid bed and surgical scar. Patients are treated supine with a face mask made of low-temperature thermal plastic (polycaprolactone) for immobilization and a lead lollipop to decrease the dose to the contralateral salivary gland. A bolus of petrolatum-coated gauze is applied to all scars.

FOLLOW-UP AND MANAGEMENT OF RECURRENCE

After RT, patients are evaluated every 2 to 3 months for the first and second years, every 4 months for the 3rd year, every 6 months for the 4th and 5th years, and annually thereafter. Chest roentgenograms are obtained annually, and a follow-up CT, MRI, and/or PET-CT is obtained as needed for patients irradiated for advanced lesions.

Treatment of local–regional recurrences after RT alone or combined with surgery is usually resection. If a local recurrence is amenable to *en bloc* surgical resection with frozen section control of the margins, this may be preferable for

selected cases. Local recurrences after RT may be significantly more extensive than is clinically apparent; thus, wide margins are preferred. Retreatment with RT is rarely indicated because of the high likelihood of complications. The most common scenario for recurrence in the neck nodes is failure in a solitary submandibular location; the success rate of salvage neck dissection is high in this circumstance.

RESULTS

Basal Cell and Squamous Cell Carcinomas

Most series reporting the results of treatment for skin cancer contain a preponderance of early lesions and do not employ a staging system, making it difficult to compare various series and the relative efficacy of different treatment modalities.

Primary Lesion

The likelihood of local control after irradiation for skin carcinomas of various sizes managed at the Mallinckrodt Institute of Radiology is outlined in Table 37.7.[44] The probability of local control is higher for smaller lesions, for BCC compared with SCC, and for previously untreated lesions compared with recurrent cancers. The results of RT using various beam energies are listed in Table 37.8; treatment with orthovoltage irradiation yields local control rates that are as good as, or better than, local control rates yielded by other treatment modalities.[44]

Schulte et al.[45] reported on 1,113 patients treated with orthovoltage RT for 1,267 skin cancers and followed for a median of 82 months (Table 37.9). Patients were usually treated at 5 Gy per fraction. The incidence of soft tissue necrosis was 6.3%; 83% healed with conservative treatment.[45]

Al-Othman et al.[46] reported on 85 patients with 88 clinical T4 SCCs (37), BCCs (41), and metatypical BCCs (10) treated with definitive RT at the University of Florida (Gainesville, FL) between 1964 and 1997. Forty-three lesions were previously untreated, and 45 cancers were recurrent after prior surgery. The 5-year outcomes were as follows: local control, 53%; ultimate local control, 90%; regional control, 93%; ultimate regional control, 100%; distant metastasis-free survival, 95%; cause-specific survival, 76%; and overall survival, 56%. Thirteen (15%) of 85 patients developed a severe treatment-related complication.

TABLE 37.7 LOCAL TUMOR CONTROL WITH RADIOTHERAPY ACCORDING TO SIZE, CELL TYPE, AND PRESENTATION (FROM MALLINCKRODT INSTITUTE OF RADIOLOGY—339 PATIENTS)

Size	Basal Cell, Previously Untreated	Basal Cell, Recurrent	Squamous Previously Cell, Untreated	Squamous Cell, Recurrent
≤1 cm	64/66 (97%)	22/23 (96%)	11/11 (100%)	10/12 (83%)

TABLE 37.10 OUTCOMES AFTER TREATMENT FOR SKIN CARCINOMA WITH INCIDENTAL PERINEURAL INVASION (107 PATIENTS)

Parameter	5-Year Outcome
Local control	80%
Ultimate local control	82%
Local–regional control	70%

Ultimate local–regional control	74%
Cause-specific survival	73%
Overall survival	55%

Reprinted from Balamucki CJ, Mancuso AA, Amdur RJ, et al. Skin carcinoma of the head and neck with perineural invasion. *Am J Otolaryngol* 2012;33(4):447–454. Copyright © 2012 Elsevier. With permission.

Balamucki et al.[47] reported on 216 patients treated at the University of Florida for skin carcinomas with incidental (107 patients) or clinical (109 patients) PNI; median follow-up for living patients was 6 years (range, 0.6 to 2.3 years). One hundred eighty-five patients (86%) had SCCs, and the remainder had BCCs or metatypical BCCs. Patients with incidental PNI were treated with surgery and postoperative RT (99 patients), preoperative RT and surgery (4 patients), and RT alone (4 patients). Eight patients received adjuvant chemotherapy. Twenty-six of 107 patients (24%) presented with clinically positive nodes. The outcomes for patients treated with incidental PNI are depicted in Table 37.10. Seventeen of 107 patients (16%) developed treatment complications. Patients with clinical PNI were treated with surgery and postoperative RT (58 patients), preoperative RT and surgery (2 patients), or RT alone (49 patients). Fifteen of 109 patients (14%) presented with clinically positive nodes. The outcomes for patients treated for clinical PNI are depicted in Table 37.11. Fourteen of 62 patients (23%) who had achieved continuous local control experienced symptomatic improvement in clinical neuropathic symptoms after treatment. Thirty-nine of 109 patients (36%) developed treatment complications.

Balamucki et al.[48] reported on a subset of these patients and compared their outcomes with radiographic extent of PNI and found that the extent of PNI was inversely related to the likelihood of local control and survival (Table 37.12).

Regional Nodes

Veness et al.[30] reported on 167 patients treated at Westmead Hospital (Sydney, Australia) between 1980 and 2000 for cutaneous SCCs metastatic to the parotid and/or cervical nodes. Twenty-one patients (13%) were treated with surgery alone, and the remainder received surgery and adjuvant RT. The median time to recurrence after treatment was 8 months. The 5-year local–regional recurrence and disease-free survival rates were as follows: surgery and RT, 20% and 73%, and surgery alone, 43% and 54%, respectively. Multivariate analysis revealed that multiple positive nodes and treatment with surgery alone were significantly

associated with decreased survival.

TABLE 37.11 OUTCOMES AFTER TREATMENT FOR SKIN CARCINOMA WITH CLINICAL PERINEURAL INVASION (109 PATIENTS)

Parameter	5-Year Outcome
Local control	54%
Ultimate local control	57%
Local–regional control	51%
Ultimate local–regional control	56%
Cause-specific survival	64%
Overall survival	54%

Hinerman et al.[31] reported on 117 patients with 121 clinically positive parotids treated at the University of Florida between 1969 and 2005. Patients were treated with preoperative RT and surgery (17 parotids), surgery and postoperative RT (87 parotids), and RT alone (17 parotids). The 5-year outcomes were as follows: local (parotid) control, 78%; local–regional control, 74%;

distant metastasis-free survival, 92%; disease-free survival, 70%; and overall survival, 54%. The 5-year local–regional control rate was 83% after surgery and postoperative RT versus 47% after preoperative RT and surgery or RT alone. Three (3%) patients developed severe complications.

Merkel Cell Carcinoma

Mendenhall et al.[19] reported on 40 patients treated with RT alone (3 patients) or combined with surgery (37 patients) at the University of Florida between 1984 and 2009. Eleven patients received adjuvant chemotherapy. Twenty-four patients had stage I disease, and 16 patients had stage II MCC. Median follow-up on survivors was 4.2 years (range, 2.2 to 14.2 years). No patient was lost to follow-up. The 5-year outcomes are depicted in Table 37.13. No severe late complications were observed.

TABLE 37.13 MERKEL CELL CARCINOMA 5-YEAR OUTCOMES VERSUS STAGE

Outcomes	Stage 1 (*n* = 24)	Stage II (*n* = 16)	All Patients	*P* value
Local control	96%	87%	92%	.3240
Regional control	87%	65%	78%	.1587
Local–regional control	87%	67%	79%	.1607
Distant metastasis-free survival	71%	37%	57%	.0073
Cause-specific survival	58%	27%	45%	.0090
Overall survival	48%	18%	36%	.0037

Melanoma

One of the largest experiences with adjuvant RT for melanoma has been reported by investigators from the MD Anderson Cancer Center (Houston, TX; Table 37.14). Although RT may be used to treat gross disease, this would only occur by default and in mostly palliative situations.

Mendenhall et al.[35] recently reported on 82 patients treated with surgery and postoperative RT with either conventional fractionation (40 patients) or hypofractionation (42 patients) and observed the following 5-year in-field local–regional control rates: conventional fractionation, 78% and hypofractionation, 87%. Most of those treated with hypofractionated RT received the MD Anderson schedule of 30 Gy in 5 fractions over 2.5 weeks.

Tsang et al.[36] reported on 36 patients treated between 1968 and 1988 with definitive RT for lentigo maligna at the Princess Margaret Hospital (Toronto, Canada) and followed for a median 6 years. The 5-year local control rate was 86%. Farshad et al.[38] reported on 150 patients treated at the University of Zurich with definitive RT for lentigo maligna (93 patients), lentigo maligna melanoma (54 patients), or both (3 patients). One hundred one patients were followed for at least 2 years (mean, 8 years); the local control rate was 93%.

CONCLUSIONS

RT is an effective modality for the primary treatment of skin cancer as well as in the adjuvant setting. It is used to treat the primary skin lesion when resection would result in an unacceptable functional and/or cosmetic outcome as well as in the patient who is medically unsuitable for, or who declines, surgery. Adjuvant RT is usually indicated after surgery for close or positive margins, PNI, bone and/or cartilage involvement, metastatic parotid area lymph nodes, multiple lymph node metastases, and extracapsular extension.

PART B

Central Nervous System

CHAPTER 38

Primary Intracranial Neoplasms

Vinai Gondi, Michael A. Vogelbaum, Sean Grimm, and Minesh P. Mehta

ANATOMY

The central nervous system (CNS) is enveloped by three meningeal layers: the *dura mater* (also known as the pachymeninges), the *arachnoid mater*, and the *pia mater*. The pia and arachnoid layers are also referred to as the leptomeninges, and within them is the subarachnoid space, which is filled with cerebrospinal fluid (CSF). Dural folds separate the two hemispheres of the cerebrum (falx cerebri) and the cerebrum from the cerebellum and brainstem (tentorium or falx cerebelli). The frontal and parietal lobes are separated by a well-defined sulcus ("central sulcus"). The frontal and temporal lobes are separated by the sylvian fissure, whereas the parietal and occipital lobes are separated by the calcarine sulcus (Figs. 38.1–38.3).

The diencephalon consists of the thalamus and the pineal region and is situated between the cerebrum and the mesencephalon, adjacent to the third ventricle. Lateral to the thalamus is the internal capsule, which carries the motor fibers (upper motor neurons) from the cortex en route to the brainstem and spinal cord.

At the tentorial notch, the mesencephalon rides on the upper part of the clivus. Its interior, the tectum, is partially occupied by cranial nerve nuclei (for the oculomotor, trochlear, and proprioceptive portions of the trigeminal nerves). The dorsal plate houses the superior and inferior colliculi, which regulate eye movements and hearing impulses, respectively. The trochlear nerve is the only cranial nerve that exits from this dorsal location.

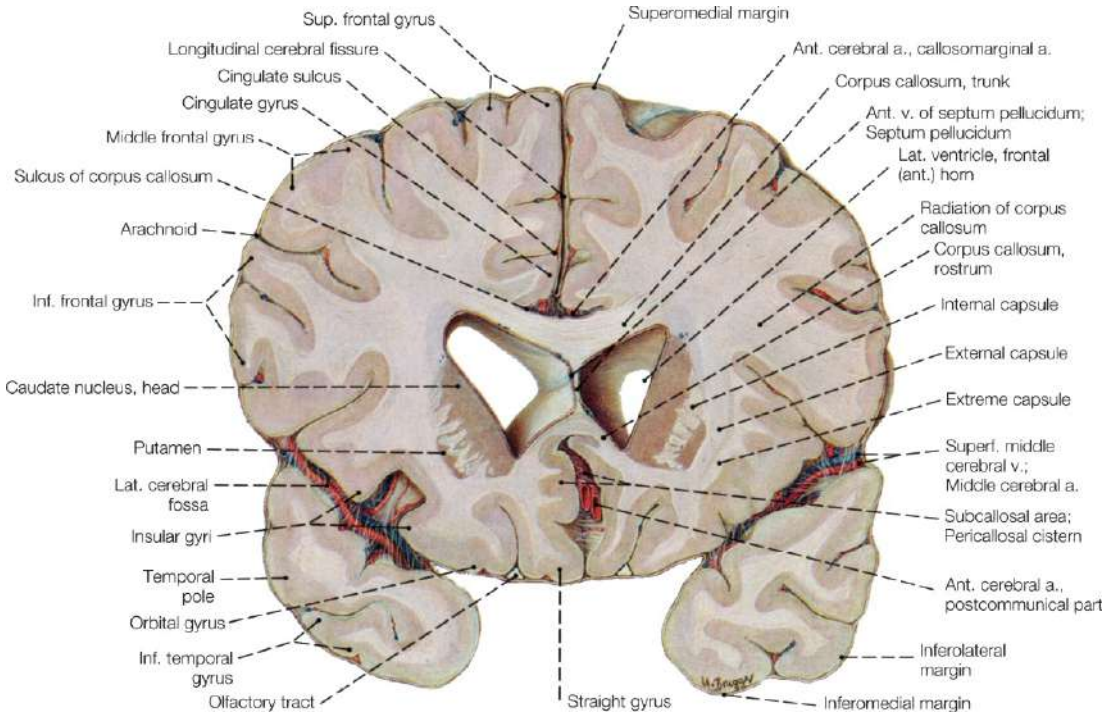

FIGURE 38.1. Coronal section through the telencephalon at the plane of the frontal horn of the lateral ventricle. (Reprinted from Paulsen F, Waschke J, Sobotta J. *Sobotta Atlas of Human Anatomy*. 15th ed. Munich: Urban & Fischer, 2011. Copyright © 2011 Elsevier GmbH. With permission.)

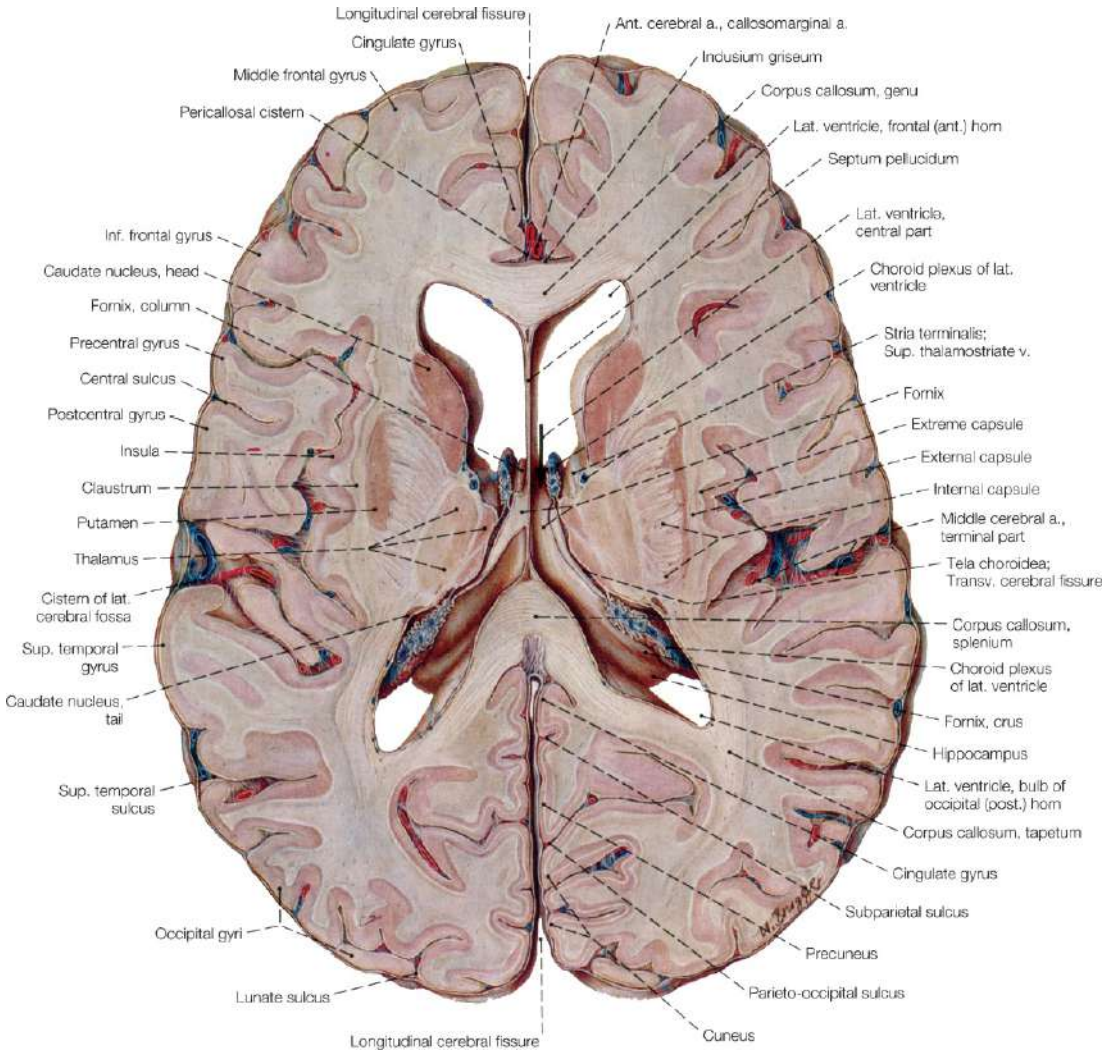

FIGURE 38.2. Transverse section at the level of the floor of the central part of the lateral ventricle. View of the superior surface of the plane of sectioning. (Reprinted from Paulsen F, Waschke J, Sobotta J. *Sobotta Atlas of Human Anatomy*. 15th ed. Munich: Urban & Fischer, 2011. Copyright © 2011 Elsevier GmbH. With permission.)

The pons relays information between the two cerebellar hemispheres and from the spinal cord to the cerebellum, carries the major ascending and descending pathways between the mesencephalon and the medulla oblongata, and contains the major motor and tactile sensory nuclei for the trigeminal nerve, which emerges from its lateral surface. The border between the pons and the medulla oblongata is noteworthy for the emergence of the abducens, facial, and vestibulocochlear (acoustic) cranial nerves.

The cerebellum develops laterally and posteriorly from the pons and differentiates into the median vermis and the bilateral hemispheres, which are flattened by the sloping tentorium on both sides. Anteriorly, the cerebellum faces

the dorsal aspects of the pons and the medulla oblongata (the floor of the fourth ventricle).

The medulla oblongata forms the link between the pons, the spinal cord, and the cerebellum. It houses the majority of the cranial nerve nuclei (abducens, facial, vestibulocochlear, glossopharyngeal, vagal, accessory, and hypoglossal).

CSF is produced by the choroid plexus, which lies in the roofs of the fourth and third ventricles as well as in the medial walls of the central body and inferior horns of the lateral ventricles. The foramina of Monro transmit CSF between the third and lateral ventricles at the superolateral corners of the third ventricle. The aqueduct of Sylvius in the midbrain transmits CSF from the third to the fourth ventricles. It is the narrowest canal of the intracranial nervous system and is therefore the most common location of obstruction of flow by compression or tumor deposits, resulting in noncommunicating (obstructive) hydrocephalus. CSF in the fourth ventricle flows out of the ventricular system through the midline foramen of Magendie and the two lateral foramina of Luschka to the subarachnoid space.

CSF resorption back into the venous system occurs at arachnoid (or pacchionian) granulations, special outpouching structures from the arachnoid membrane that enhance fluid movement from the CSF space into the venous sinus system. Scarring from infection or inflammation or clogging of the arachnoid granulations causes increased pressure in the CSF space and communicating hydrocephalus.

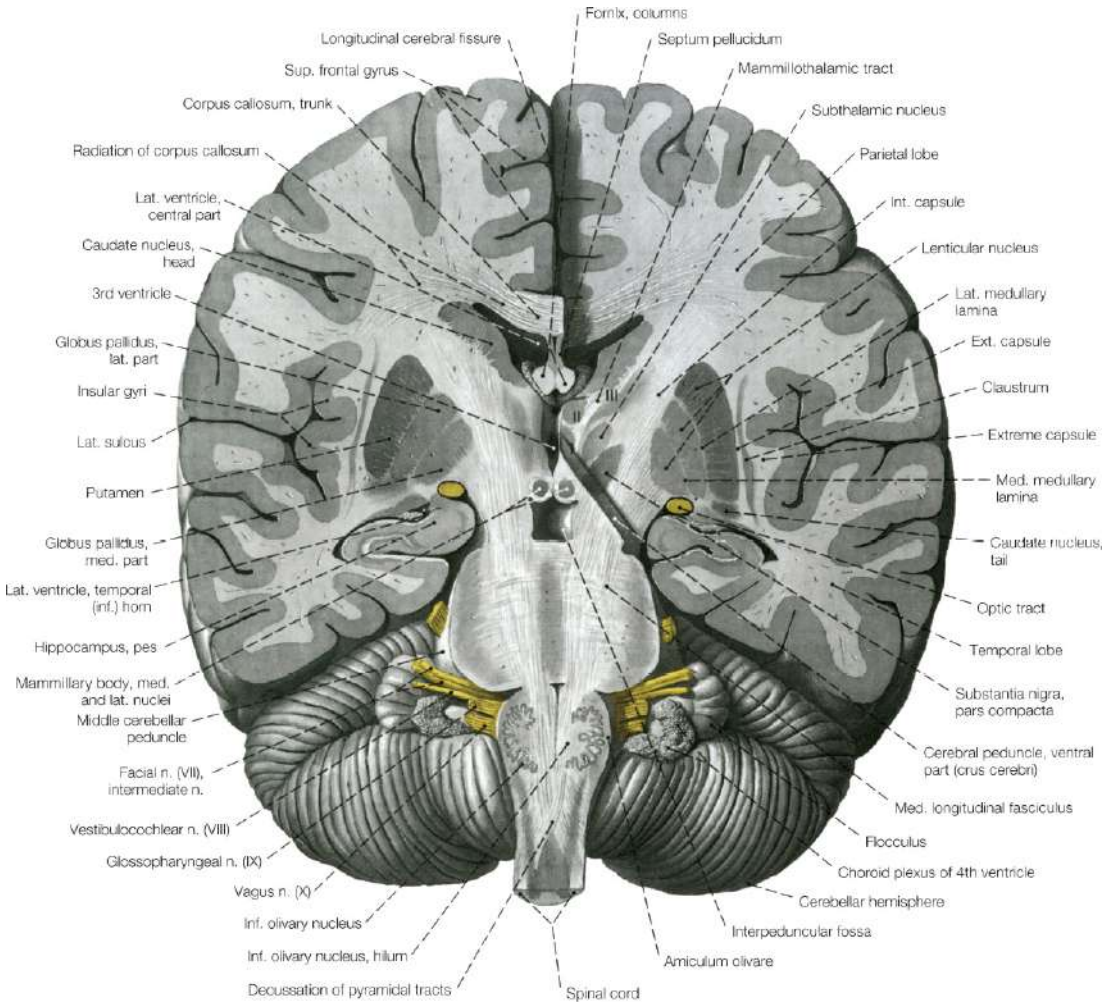

FIGURE 38.3. Section through the telencephalon and brainstem parallel with the cerebral peduncles. View of the posterior surface of the plane of sectioning. On the right side of the figure, the section reaches back to approximately the middle of the cerebral peduncle (oblique section). I to III indicate thalamic nuclei: I, medial nucleus; II, anterior nucleus; III, lateral nucleus. (Reprinted from Paulsen F, Waschke J, Sobotta J. *Sobotta Atlas of Human Anatomy*. 15th ed. Munich: Urban & Fischer, 2011. Copyright © 2011 Elsevier GmbH. With permission.)

EPIDEMIOLOGY

In 2016, there were an estimated 26,070 new cases of primary CNS tumors in the United States and 16,947 deaths, for an incidence of approximately 7.18 per 100,000 persons. The incidence of brain tumors increases with age.[1]

Occupational and environmental exposures have been associated with the development of CNS tumors. Farmers and petrochemical workers have been shown to have a higher incidence of primary brain tumors. A variety of chemical exposures have been linked, as reviewed by Ohgaki and Kleihues.[2] The use of cellular phones has been questioned as a contributing factor to the development

of brain tumors. The World Health Organization (WHO) classified radiofrequency electromagnetic fields, such as those emitted by wireless phones, as “possibly carcinogenic to humans” (Group 2B) based on limited clinical evidence.[3] Although prior cohort, case–control, and time-trend analyses have shown no association between cell phone use and brain tumor risk,[4] more recent case–control studies have suggested a potential increased risk of glioma among individuals with the greatest cumulative lifetime cell phone use (>1,620 hours in one study).[5–9] However, significant concerns with respect to recall and selection biases in both studies prevent a causal association from being concluded.

Prior exposure to ionizing radiation is a known risk factor for development of primary CNS tumors, particularly meningiomas, but also gliomas, sarcomas, and other tumor types.[10,11] There is a 2.3% incidence of primary brain tumors in children treated with prophylactic cranial irradiation for acute leukemia, a 22-fold increase over expected.[12]

Development of intracranial malignancy is also associated with several hereditary diseases such as neurofibromatosis types 1 and 2, von Hippel-Lindau disease, and tuberous sclerosis. Other hereditary associations are with retinoblastoma and Li-Fraumeni syndrome.

NATURAL HISTORY

The natural history of a primary brain neoplasm is determined by its histology, grade, and location. The majority of adult gliomas spread invasively without forming a natural capsule. They frequently cause edema in surrounding tissue. This edema is usually vasogenic but may be cytotoxic. It is seen best on T2-weighted MRI and is responsible for at least some of the clinical symptoms and signs. The edema is a consequence of altered blood–brain barrier (BBB) permeability. Different tumors cause varying amounts of edema (in descending order, metastases, astrocytomas, meningiomas, and oligodendrogliomas).

Some high-grade neoplasms metastasize by “seeding” the subarachnoid and ventricular spaces. Because of gravity or flow, these metastatic deposits are often present in the caudal portion of the spinal canal. Tumors that have a propensity for CSF spread include medulloblastomas, germ cell tumors, and CNS lymphoma. The exact frequency of CSF spread among other histologies (e.g., germ cell tumors, ependymomas) is debated in the literature. Extracranial metastases from primary brain tumors are rare but can occur with medulloblastomas, germinomas, and high-grade astrocytomas.

CLINICAL PRESENTATION

The presenting symptoms of a primary brain tumor are classified as generalized or focal. Headache is more prevalent in patients with fast-growing, high-grade tumors. Seizures are a more common presenting feature in low-grade tumors. Focal neurologic deficits such as weakness, language dysfunction, or sensory loss are more frequent presentations of high-grade tumors. Acute events such as hemorrhage markedly alter the tempo of symptom onset regardless of tumor grade. Table 38.1 summarizes common clinical presentations of the more common CNS tumors.

Because brain parenchyma is anesthetic, headaches associated with brain tumors are due to increased intracranial pressure or to local pressure on sensitive intracranial structures (mainly dura and vessels). Headaches associated with increased intracranial pressure classically occur in the morning. Associated findings may include focal neurologic deficits, behavioral changes, and papilledema. Cushing triad is classically associated with increased intracranial pressure, but the full triad (hypertension, bradycardia, respiratory irregularity) is seen in only one-third of the cases of increased intracranial pressure. Long-standing increases in intracranial pressure may lead to optic atrophy and blindness because of transmission of the pressure to the optic nerves.

DIAGNOSTIC WORKUP

The initial workup of patients with brain tumors must include a complete history and physical examination. Information obtained from relatives and friends is helpful because many tumors cause changes in mentation not appreciated by the patient. In patients with symptoms, signs, or imaging suggestive of systemic dissemination, biopsy confirmation of the primary tumor or at least one of the extracranial metastatic sites is recommended. Solitary brain lesions in adult patients with certain types of known systemic cancer (e.g., lung, breast, or colon cancers or melanoma) are far more likely to be a cerebral metastasis than a primary CNS tumor, although this is not always the case.

Imaging Studies

MRI with a gadolinium (Gd)-containing contrast agent is the imaging modality of choice for most CNS tumors. Computed tomography (CT) is generally reserved for those situations in which MRI is contraindicated, such as implanted pacemaker, metal fragment, or paramagnetic surgical clips, or where there is a

need to image the extent of calcification or hemorrhage.

TABLE 38.1 SYMPTOMS, SIGNS, AND DIAGNOSTIC CHARACTERISTICS OF VARIOUS INTRACRANIAL TUMORS

Tumor	Common Symptoms	Common Signs	Imaging Characteristics
Glioblastoma multiforme	Headache, seizure, unilateral weakness, mental changes	Focal presentation related to tumor location	Enhancing MRI or CT lesion, hypodense interior, often with associated edema
Meningioma	Localized headache	Focal presentation related to tumor location	Enhancing MRI or CT lesion associated with dura
Astrocytoma	Headache, seizure, unilateral weakness, mental changes	Focal presentation related to tumor location	May not enhance on CT or MRI
Cerebral	Headache, seizure, unilateral weakness, mental changes	Focal presentation related to tumor location	
Cerebellar	Occipital headache	Increased intracranial pressure (i.e., papilledema), abducens and oculomotor nerve deficits; coordination	
Brainstem or thalamus	Nausea, vomiting, ataxia	Increased intracranial pressure (i.e., papilledema), abducens and oculomotor nerve deficits; ataxia	May be seen only on MRI
Optic nerve	Ocular changes	Ocular changes	Uniform enhancement on MRI or CT scan
Medulloblastoma	Morning headaches, nausea, vomiting	Coordination, increased intracranial pressure (i.e., papilledema), abducens and oculomotor nerve	Heterogeneously enhancing on MRI or CT, typical lateral location in adults

		deficits	
Ependymoma	Morning headaches, nausea, vomiting	Coordination, increased intracranial pressure (i.e., papilledema), abducens and oculomotor nerve deficits	Heterogeneous enhancement on MRI or CT with or without calcification
Neurilemoma, schwannoma, neurinomas	Unilateral deafness, vertigo	Ipsilateral acoustic and facial or trigeminal nerve deficits	Homogenous enhancing mass on MRI or CT, arising from cranial nerve
Oligodendroglioma	Insidious headache, mental changes	Focal presentation related to tumor location	Heterogeneous lesion that may or may not enhance on MRI or CT, frequently with calcification, cystic regions, or hemorrhage
Lymphoma	Focal presentation related to tumor location	Focal presentation related to tumor location	Homogeneous, intense enhancement on MRI, may have a diffuse or “cotton wool” appearance
Craniopharyngioma	Headache, mental changes, hemiplegia, seizure, vomiting, visual impairment	Cranial nerve deficits (II–VII)	Mixed cystic, calcified lesion on MRI and CT, arising from suprasellar region

CT, computed tomography; MRI, magnetic resonance imaging.

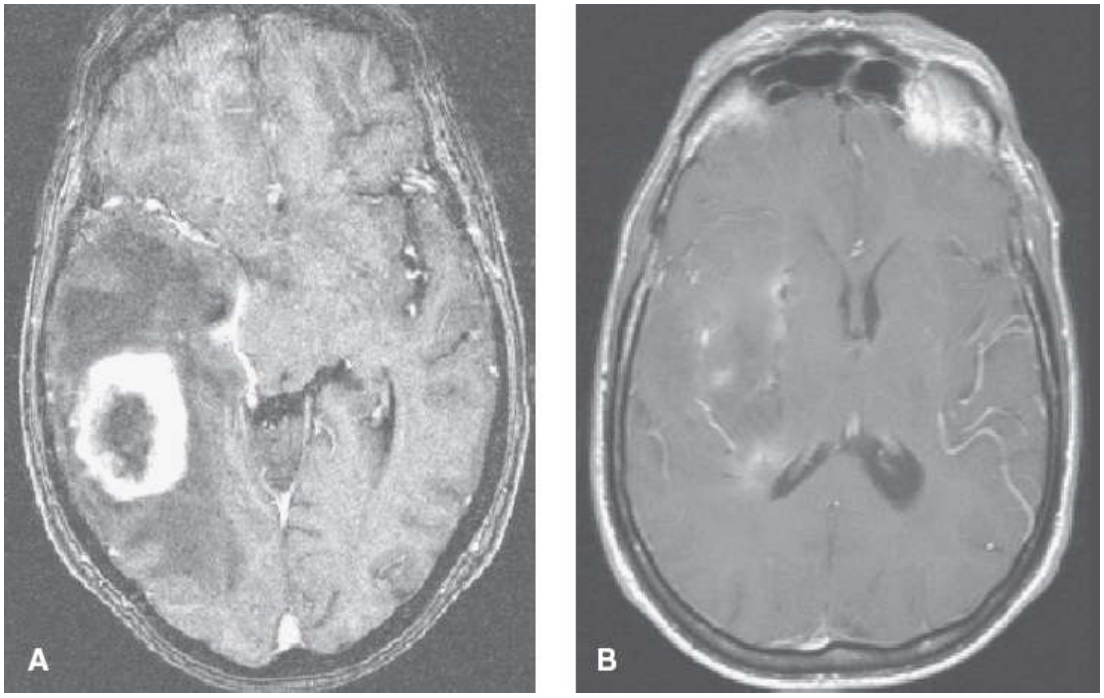

FIGURE 38.4. Magnetic resonance image of brain showing **(A)** glioblastoma, demonstrating a contrast-enhancing lesion with central necrosis and vasogenic edema; and **(B)** low-grade glioma, illustrating a nonenhancing lesion difficult to delineate from normal parenchyma.

Magnetic Resonance Imaging

The most useful imaging studies are T1-weighted sagittal images, Gd-enhanced (usually obtained in high-resolution modes such as SPGR or MP-RAGE) and non-enhanced T1 axial images, T2-weighted axial images, and FLAIR (fluid-attenuated inversion recovery) sequences.[13,14] As is the case with CT contrast agents, Gd-based contrast leaks into parenchyma in areas with BBB breakdown, and the paramagnetic properties of Gd generate hyperintense signal on T1 scans. T1 images usually are better at demonstrating anatomy and areas of contrast enhancement. T2 and FLAIR images are more sensitive for detecting edema and infiltrative tumor. Tumor appearance on T1-weighted MRI is similar to that on CT, although tumor volumes are better delineated on MRI, particularly with low-grade neoplasms that do not demonstrate contrast enhancement (Fig. 38.4). With the increasing incidence of posttreatment “pseudoprogression,” additional specialized diffusion, perfusion, and spectroscopic sequences are being increasingly utilized to distinguish tumor from necrosis or pseudoprogression, and PET imaging may also have some role in this; in the United States, only FDG-PET is approved, but amino acid, FLT, and F-DOPA PET imaging is being evaluated (Fig. 38.5). Diffusion-weighted and functional MR also has utility in

guiding resection.

Neuraxis Imaging

For neoplasms with high risk of CSF spread, staging of the neuraxis is essential. Gd-enhanced MRI of the spine is the imaging modality of choice. Ideally, neuraxis imaging should be performed before surgery. In the immediate postoperative period, spinal MRI scans may be difficult to interpret because arachnoiditis and blood products in the CSF can mimic leptomeningeal metastasis. Delayed spinal MRI (>3 weeks after surgery), combined with an increased dose of intravenous Gd, is a sensitive imaging study to detect leptomeningeal disease.

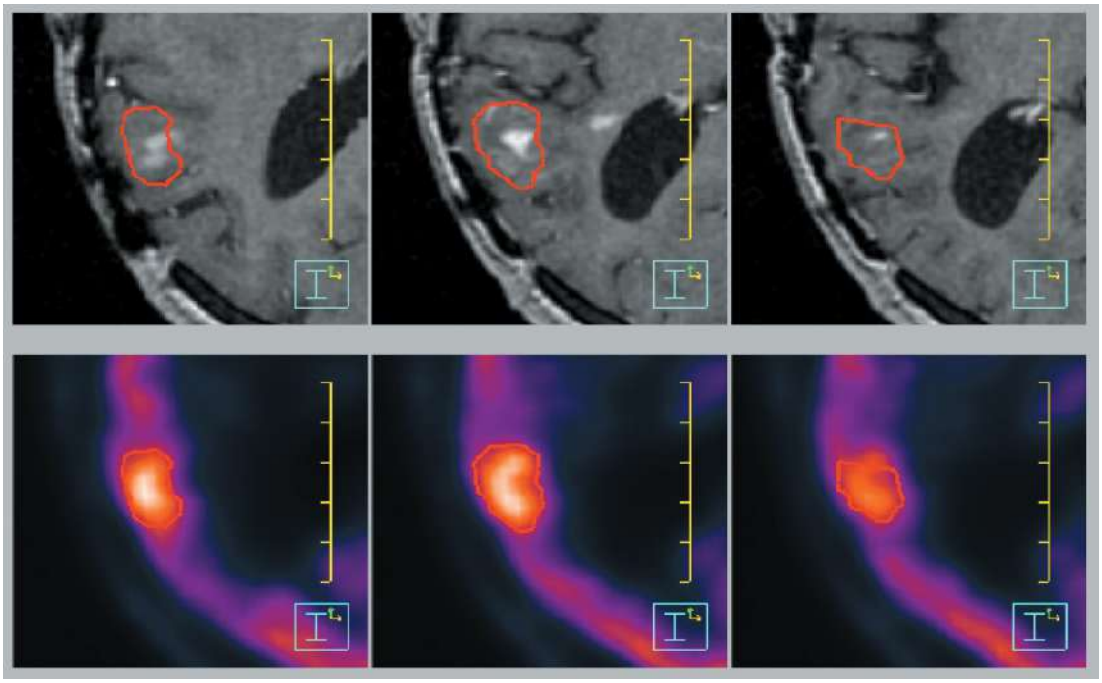

FIGURE 38.5. Oligodendroglioma imaged using an anatomic imaging technique, contrast-enhanced 3D-SPGR T1-w MRI (*top image panel*), and a functional imaging technique, FDG-PET (*bottom image panel*). The red contour delineates the extent of increased metabolic activity seen using functional imaging. Looking at the top panel, one can appreciate the fact that if the anatomic image set alone would be used for target definition it would yield a gross underestimation of the target volume as compared with the functional imaging technique.

Histologic Confirmation of Diagnosis

The morbidity of biopsy has decreased significantly with improvements in operative technique and anesthesia, as well as the availability of stereotactic biopsy techniques. Exception might be made in selected patients, such as those

patients with known active systemic cancer and multiple lesions that are radiographically consistent with brain metastases, patients with typical clinical and MRI findings of a brainstem glioma or optic nerve meningioma, HIV-positive patients with CT or MRI findings consistent with primary CNS lymphoma (PCNSL) and positive Epstein-Barr virus PCR in the CSF, or patients with secretory germ cell tumors.

Cerebrospinal Fluid Cytology

CSF cytology is essential for staging tumors with a propensity for CSF spread (e.g., medulloblastoma, germ cell tumors, and CNS lymphoma). Sampling of the CSF in the immediate postoperative period may lead to false-positive results, however, and is best done before surgery or more than 3 weeks after surgery, as long as intracranial pressure is not elevated. CSF spread of tumor may be associated with several abnormal CSF findings. These include CSF pressure above 150 mm H_2O at the lumbar level in a laterally positioned patient, elevated protein level (>40 mg/dL in the lumbar cistern), a reduced glucose level (below 50 mg/mL), and the finding of tumor cells by cytologic examination. Tumor markers in the CSF may help in making the diagnosis.

Differential Diagnosis

Most adults with new or persistent neurologic findings (focal deficit, increased intracranial pressure, seizures, altered mentation) are investigated using CT or MRI. There are a number of classical imaging features that help refine the differential diagnosis (Table 38.2).

TABLE 38.2 DIFFERENTIAL DIAGNOSIS OF SPACE-OCCUPYING LESIONS ON COMPUTED TOMOGRAPHY OR MAGNETIC RESONANCE IMAGING

Pathology	Features on CT or MRI
Neoplasm	
Primary	Solitary, no prior cancer, thick nodular CE
Metastatic	Multiple, prior cancer, ++edema, located at gray/white junction
Infectious	
Abscess	Fever, acutely ill, ±systemic infection, cyst cavity with smooth thin walls, CE, and restricted diffusion within cavity
Cerebritis	Fever, acutely ill, ±systemic infection, diffuse T2 change, no CE mass
Meningitis	Diffuse enhancement of meninges on T1-weighted imaging (may simulate leptomeningeal metastases)

Vascular	
Infarct	Gray and white matter involvement, wedgelike vascular distribution associated with restricted diffusion and low ADC signal
Bleeding	Homogenous, clears quickly, residual hemosiderin ring
Treatment-related necrosis	Central hypodensity, ring CE, edema, >6 mo after radiation therapy or chemotherapy, metabolic scan shows low activity

ADC, apparent diffusion coefficient; CE, contrast enhancement; CT, computed tomography; MRI, magnetic resonance imaging.

PATHOLOGY

Primary intracranial tumors are of ecto- and mesodermal origin and arise from the brain, cranial nerves, meninges, pituitary, pineal, and vascular elements. In 2016, the WHO revised its classification system for pathologic subtypes of CNS tumors to combine histology with molecular parameters such as IDH1 mutation, 1p19q codeletion, and H3 K27M mutation for gliomas; RELA fusion for ependymoma; and WNT and SHH activation for medulloblastoma (Table 38.3).[15] Guidelines for assigning grade of malignancy are provided, where applicable.

GENERAL MANAGEMENT

The medical management of patients with brain tumors includes management of increased intracranial pressure, seizures, and venous thromboembolic disease.

Cerebral Edema

Glucocorticoids are used to control neurologic signs and symptoms caused by cerebral edema. Lower doses of steroids (e.g., 2 to 4 mg dexamethasone) twice daily have been shown to be as effective as higher doses, and in fact, based on pharmacokinetic properties, even once-daily dosing should be effective. Prolonged steroid use is associated with multiple medical problems, and therefore steroids should be discontinued or tapered to the lowest dose necessary, as soon as possible. Dexamethasone is the most common corticosteroid used for historical reasons and because of minimal mineral–corticoid effects. As with all corticosteroids, a taper is necessary to prevent rebound in cerebral edema and also to allow the pituitary–adrenal axis to recover.

Seizures

Patients with seizures require anticonvulsants. Because anticonvulsants such as carbamazepine, phenobarbital, and phenytoin induce hepatic cytochrome P-450 isoenzymes, which increase the metabolism and clearance of several cancer chemotherapy agents such as paclitaxel and irinotecan,[16] non–enzyme-inducing anticonvulsants, such as levetiracetam, lacosamide, lamotrigine, and pregabalin, are preferred.

Prophylactic anticonvulsant use (in patients who have never experienced a seizure) remains controversial, although practice guidelines from the American Academy of Neurology recommend against their use because of lack of data.[17,18]

SURGERY

Surgical procedures can be summarized as biopsy for diagnosis only, resection for cure, surgical debulking for management of mass effect-related symptoms, CSF diversion procedures to relieve acute symptoms caused by increased intracranial pressure or hydrocephalus, and increasingly re-resection to distinguish and manage the effects of progressive tumor from symptomatic necrosis or pseudoprogression. Other roles of surgery include the placement of chemotherapy wafers, brachytherapy devices, and catheters for interstitial drug delivery and for monitoring tumor drug concentrations and/or biologic effects. Complete resection of tumor is associated with a survival advantage for some tumor types.[19] However, for some radio- and/or chemosensitive malignancies such as PCNSL, aggressive resection is unnecessary, and the surgeon's role is limited to providing diagnostic material.

Operative Technique

Ultrasound and CT- and MRI-guidance systems provide surgeons with intraoperative navigation based upon preoperative and/or intraoperative data. In general, these consist of a workstation into which the relevant imaging studies have been loaded, together with infrared or ultrasound detectors that recognize the 3D orientation and position in space of various tools. Once the patient is registered, the tumor's margins are "visualized" below the scalp so that the surgeon can plan the smallest and safest approach. Resection is assisted by use of the intraoperative microscope and guided by the appearance and consistency of tumor tissue compared with surrounding normal brain. Intraoperative CT, MRI, or ultrasonography can be used to evaluate the completeness of tumor resection. In the case of lesions that are in or near suspected functional cortex,

cortical mapping under awake conditions can be performed to localize areas that are critical for motor or speech function. Endoscopy can be used to minimize access for resection of intraventricular lesions or pituitary tumors, as well as for reestablishing pathways of CSF flow, for example, in cases of tumors that have obstructed the cerebral aqueduct, thereby avoiding the need for a CSF shunt. In addition to intraoperative image guidance, the use of fluorescent tumor-localizing dyes such as 5-aminolevulinec acid has gained acceptance in Europe to enhance the completeness of resection and is being investigated in the United States.

TABLE 38.3 HISTOLOGIC CLASSIFICATION OF TUMORS OF THE CENTRAL NERVOUS SYSTEM

Diffuse astrocytic and oligodendroglial tumors
- Diffuse astrocytoma, IDH mutant
  - Gemistocytic astrocytoma, IDH mutant
- *Diffuse astrocytoma, IDH wild type*
- Diffuse astrocytoma, NOS
- Anaplastic astrocytoma, IDH mutant
- *Anaplastic astrocytoma, IDH wild type*
- Anaplastic astrocytoma, NOS
- Glioblastoma, IDH wild type
  - Giant cell glioblastoma
  - Gliosarcoma
  - *Epithelioid glioblastoma*
- Glioblastoma, IDH mutant
- Glioblastoma, NOS
- Diffuse midline glioma, H3 K27M mutant
- Oligodendroglioma, IDH mutant and 1p/19q codeleted
- *Anaplastic oligodendroglioma, NOS*
- *Oligoastryctoma, NOS*
- *Anaplastic oligoastrocytoma, NOS*

Other astrocytic tumors
- Pilocytic astrocytoma
  - Pilomyxoid astrocytoma
- Subependymal giant cell astrocytoma
- Pleomorphic xanthoastrocytoma
- Anaplastic pleomorphic xanthoastrocytoma

Ependymal tumors
- Subependymoma
- Myxopapillary ependymoma
- Ependymoma
  - Papillary ependymoma
  - Clear cell ependymoma
  - Tancystic ependymoma
- Ependymoma, RELA fusion-positive

- Anaplastic ependymoma
- Choroid plexus tumors
  - Choroid plexus papilloma
  - Angiocentric glioma
  - Astroblastoma
- Neuronal and mixed neuronal-glial tumors
  - Dysembryoplastic neuroepithelial tumor
  - Gangliocytoma
  - Ganglioglioma
  - Anaplastic ganglioglioma
  - Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease)
  - Desmoplastic infantile astrocytoma and ganglioma
  - Papillary glioneuronal tumor
  - Rosette-forming glioneuronal tumor
  - *Diffuse leptomeningeal glioneuronal tumor*
  - Central neurocytoma

Metastatic tumors

The italicized entries are provisional, i.e., the WHO Working Group felt there was insufficient evidence to recognize these as distinct entities at this time.
Reprinted from Louis DN, Ohgaki H, Wieslter OD, et al. *World Health Organization histologic classificaiton of tumours of the central nervous system*. Lyon: International Agency for Research on Cancer, 2016, with permission from the WHO.

Stereotactic biopsy is performed with either a stereotactic frame or scalp fiducials; a CT or MRI is performed and the data are loaded into an image-guidance system. A target and entry points are selected, and the trajectory is visualized on a workstation. The entry point is located on the patient's scalp, and a small burr hole or twist drill hole is made. The biopsy needle is oriented using the image-guidance system and passed to the appropriate depth, and tissue samples are obtained. Multiple tissue samples may be obtained along the needle tract, until the pathologist can provide an intraoperative diagnosis. The volume of tissue removed is insufficient to relieve mass effect, and patients who are symptomatic are better treated by open resection.

A more recently developed stereotactic technique for treating the mass component of brain tumors involves the use of laser interstitial thermal therapy (LITT). Briefly, this approach involves the temporary stereotactic implantation of a cooled laser probe, which can be activated and manipulated within the MRI environment. The laser is used to heat, but not coagulate, adjacent tissue, and it is progressively advanced through the target tissue as the treatment progresses. This approach takes advantage of a previously described relationship between temperature and time, which can be used to predict the likelihood of permanent injury even with relatively small (<10°C) increases in local tissue temperature. A specialized MRI technique, called MR thermometry, is used to monitor tissue temperature, and the combination of temperature data with duration of heating is used by specialized LITT software to create a visual indication on each MRI slice of the probability of tissue death as a result of treatment. LITT for brain tumors was developed initially for the treatment of malignant tumors that would be difficult to access via conventional surgery, and its practice has expanded to include resectable and even benign pathologies. Although the LITT procedure has shown an encouraging safety profile, there have not been any randomized studies to date that have directly compared this approach to conventional surgical treatment.[20]

RADIOTHERAPY

Radiobiologic Considerations Underlying Tissue Injury

The process of radiation injury in the brain is highly complex and dependent on a variety of technical factors including dose, volume, fraction size, and the specific target cell population, as well as secondary mechanisms of expression of injury such as vascular leak causing edema, vascular endothelial loss resulting in hypoxic injury, reactive gliosis, and to-date inadequately studied host factors. Some structures (e.g., optic chiasm, hypothalamus, lacrimal gland, lenses, etc.) appear to be substantially more sensitive to radiation than others. Even focal lesions may result in widespread radiographic and/or functional perturbations. The time course for the manifestation of injury can be highly variable and the clinical picture easily confounded with tumor progression. The effect on endothelial cells often becomes manifest as an early T2 signal abnormality on MRI, possibly due to disruption of the BBB and edema formation. Metabolic perturbations observed with PET may reflect oligodendroglial demyelination. Further vascular perturbation and regeneration in response to injury results in an enhancing lesion on imaging. Delayed effects include white matter necrosis and vascular obliteration. The time course can be shortened from several months to a few weeks by increasing the volume of brain irradiated or increasing the fraction size or total dose.

Historically, late injury from radiotherapy has been reported as the "tolerance" dose at either the 5% or 50`% risk level at 5 years (TD 5/5 or TD 50/5, respectively). The values for whole-brain fractionated radiotherapy at 2 Gy/fraction are 60 and 70 Gy, respectively. With partial-brain irradiation, the corresponding values are 70 and 80 Gy, respectively. In the setting of fractionated radiotherapy with a fraction size <2.5 Gy, quantitative analyses of normal tissues effect in the clinic (QUANTEC) have estimated 5% and 10% rates of symptomatic necrosis at 72 and 90 Gy maximum equivalent doses in 2-Gy fractions, respectively.[21,22]

General Concepts

Pertinent Anatomic Landmarks

With conventional simulation, radiographic and surface topographic reference points for appreciation of beam-to-head projection geometry are necessary. The external auditory meatus define anatomic reference planes such as Reid base line and the Frankfort horizontal plane, connecting points in the two external auditory meatus and one anterior infraorbital edge. Unless marked at simulation, the external auditory meatus may be difficult to see on lateral projections

because of the overlying temporal bone. The two lateral parts of the anterior cranial fossa, the two anterior parts of the middle cranial fossa floors, and the two mandibular angle points, with their lateral locations, represent appropriate reference points. With CT-based planning, the need for identifying these is obviated.

In a lateral radiograph, the sella turcica is centrally located and marks the lower border of the medial telencephalon and diencephalon. The hypothalamic structures are located an additional 1 cm superior to the sellar floor, and the optic canal runs at most 1 cm superior and 1 cm anterior to that point. The pineal body (or the tentorial notch) usually sits approximately 1 cm posterior and 3 cm superior to the external auditory meatus. The cribriform plate is the most inferior part of the anterior cranial fossa; it is an important reference point for the inferior border of whole-brain irradiation fields. In most patients, little distance is found between the lateral projections of the lens and the most inferior part of the cribriform plate. The temporal lobes are situated in the middle cranial fossae, the floor of which is easily identified on lateral radiographs. Individualized blocks should always be used to delineate the field inferior border for WBRT.

On an anteroposterior radiograph with a Frankfort horizontal plane (ear markers and one inferior orbital edge in a horizontal plane), the temporal bones (pyramids) project in the orbits. This implies that the ethmoid sinuses and the sphenoid sinus will project between the orbits, the sella just above these air cavities, and the foramen magnum just below the connection line between the inferior orbital edges. The frontal and occipital lobes therefore project above the orbits, and the temporal lobes and cerebellum project in and somewhat below the orbits.

Treatment Setup

The head should be positioned so that its major axes are parallel with and perpendicular to the central axis incident beam and the treatment table. It may be preferable to fully flex or extend the neck in some patients depending on tumor location and choice of beams, although the use of noncoplanar fields and IMRT techniques makes this less necessary (Fig. 38.6).

Reproducibility of head positioning is achieved by using a fixation device. Many devices are available for this with reproducibility precision ranging from 1 to 5 mm. With the advent of image-guided radiation therapy (IGRT) and intrafraction motion detection, unprecedented accuracy can be achieved in delivering radiotherapy. This permits substantial reduction in margins for setup

variability.[23]

Target Volume Definition

Two major factors drive margin selection: the inaccuracy of estimating the clinical target volume (CTV) and the specific dosimetric and setup variability components that are institution specific and determine the planning target volume (PTV).

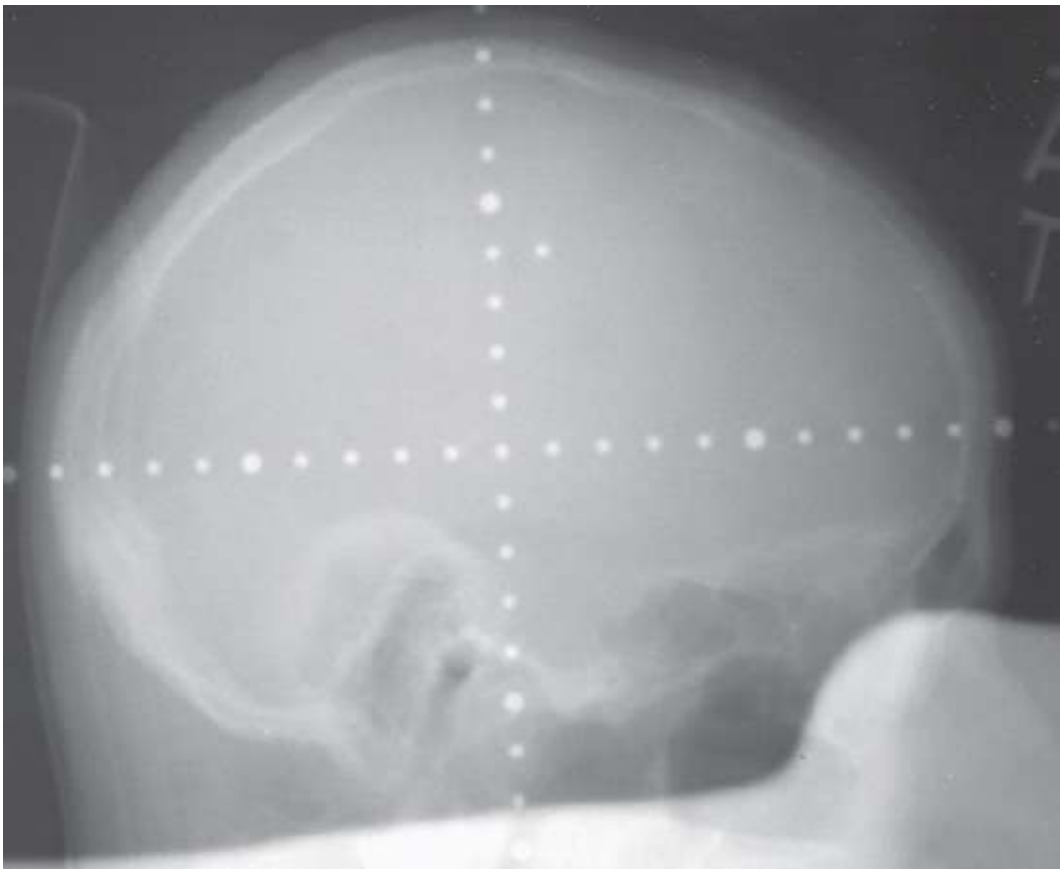

FIGURE 38.6. Lateral portal localization film of whole brain illustrating adequate inclusion of the cribriform plate and the anterior and middle cranial fossae.

Common sense and practice dictates that these CTV expansion margins should not traverse anatomically discontiguous structures or include areas unlikely to be infiltrated by tumor. Inclusion of the bony skull is unnecessary unless direct tumor extension is suspected. With some exceptions, “compartmental crossing” to the contralateral hemisphere or, for example, into the posterior fossa or the brainstem for a supratentorial cortical tumor, is not necessary, but because many infiltrating gliomas “cross” through the anterior and/or posterior corpus callosal tracts, these should be adequately included in

CTV margin selection.

Radiotherapy Techniques

The most commonly employed radiotherapy techniques in the management of CNS tumors are partial-brain irradiation, whole-brain radiotherapy (WBRT), craniospinal irradiation (CSI), stereotactic radiosurgery (SRS), fractionated stereotactic radiotherapy (FSRT), less commonly brachytherapy, and, recently, emerging utilization of proton therapy. The indications for each of these techniques are discussed under the sections on the individual tumor types. CSI is more frequently used in management of pediatric CNS tumors and is discussed in detail in Chapter 82.

Whole-Brain Radiotherapy

WBRT is used most often for patients with brain metastases but also for patients with PCNSLs and as a component of CSI.

Whole-brain irradiation is administered through parallel-opposed lateral portals. The inferior field border should be inferior to the cribriform plate, the middle cranial fossa, and the foramen magnum, all of which should be distinguishable on simulation or portal localization radiographs (Fig. 38.7). The safety margin depends on penumbra width, head fixation, and anatomic factors, but should be at least 1 cm, even under optimal conditions. A special problem arises anteriorly because sparing of the ocular lenses and lacrimal glands may require blocking with <5-mm margins at the cribriform plate.

The anterior border of the field should be approximately 3 cm posterior to the ipsilateral eyelid for the diverging beam to exclude the contralateral lens. However, this results in only approximately 40% of the prescribed dose to the posterior eye. A better alternative is to angle the beam approximately 3 degrees or more (100- or 80-cm source-to-axis distance midline but also field size dependent) against the frontal plane so that the anterior beam border traverses posterior to the lenses (approximately 2 cm posterior to eyelid markers). Placing a radiopaque marker on both lateral canthi and aligning the markers permits individualization in terms of the couch angle. This arrangement provides full dose to the posterior eyes. However, the eyelid-to-lens and -retina topography is individually more constant than the canthus, and lateral beam eye shielding is better individualized with the aid of CT or MRI scans.[24] When in doubt about tumor coverage or lens sparing for tumors in a subfrontal or middle cranial fossa location, CT-based contouring and planning should be considered.

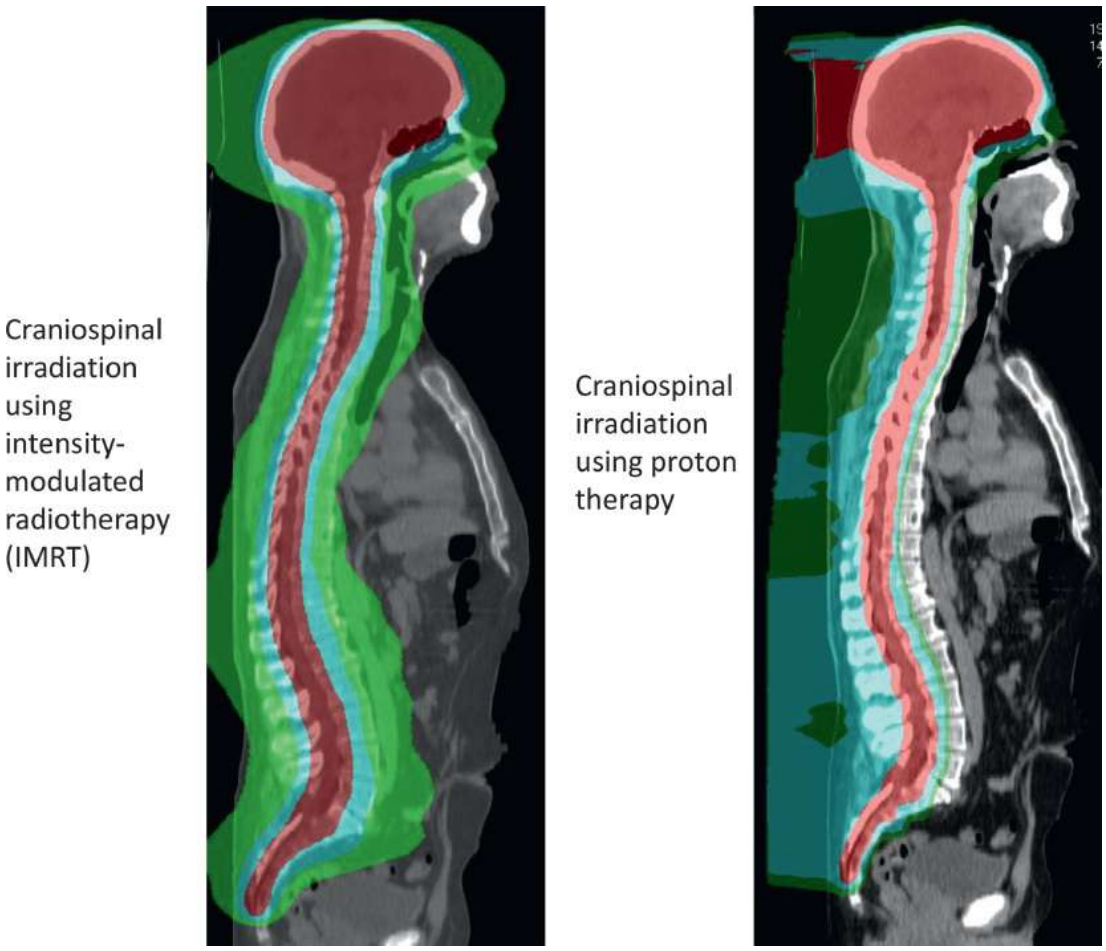

FIGURE 38.7. Comparison of proton therapy to intensity-modulated radiotherapy for craniospinal irradiation demonstrates negligent "exit" dose in visceral structures anterior to the spine and maximal sparing of vertebral body-based marrow achieved with proton therapy.

Craniospinal Irradiation

Traditional CSI techniques utilize opposed lateral cranial fields and one or more posterior spinal fields depending on patient size. The junctioning of noncoplanar fields in the cervical region is potentially hazardous because of the risk of overlap resulting in radiation myelitis. Consequently, great attention needs to be paid to precise immobilization, and a variety of immobilization devices are available for this purpose. Image guidance during radiotherapy can help in ensuring day-to-day reproducibility. The prone position permits direct visualization of the light field from the linear accelerator on the patient thereby allowing daily adjustments of the junctions. However, if anesthesia or sedation is required as may be the case with young children, a supine setup may be considered safer.[25] To avoid the risk of dose overlap, at least two techniques (with numerous variations) are commonly used, and several variations of these

have also been reported. In the first, a gap is employed between abutting fields such that the beam edges intersect deep to the spinal cord. This gap could result in a cold spot in a small segment of the spinal cord. If the beam intersection point were raised dorsally, a hot spot would result.

The second technique attempts to avoid this problem by using a half-beam technique in which the caudal edge of the brain is matched precisely with the cephalad edge of the abutting spine field without cold or hot spots. This requires collimator angulation and sometimes a couch rotation as well. For both techniques, the use of moving junctions (known as "feathering") smoothens out any dose inhomogeneity.[26] Several studies have demonstrated that adequate coverage of the subfrontal region and posterior fossa and depth assessment of the cord require CT-based planning. Given the complexity of CSI, we recommend that it be delivered at centers with adequate staff, experience, and expertise.

With sophisticated techniques such as image-guided intensity-modulated helical tomotherapy and volumetric arc-modulated radiotherapy (VMAT), it is possible to treat the entire neuraxis in a single setup.[27] Increasingly, proton therapy has been used for CSI with placement of the finite distal range in the vertebral body leading to negligent "exit" dose in visceral structures anterior to the spine and maximal sparing of vertebral body-based marrow (Fig. 38.8).

Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS) requires a team composed at a minimum of a radiation oncologist, neurosurgeon, and radiation oncology physicist, in addition to appropriate support staff. SRS can be delivered using a conventional or modified linear accelerator (LINAC) system, a Gamma Knife (Elekta Corp., Stockholm, Sweden) or a robotically controlled miniaturized linear accelerator (CyberKnife). In LINAC radiosurgery, circular or oval collimators ranging from 4 to 40 mm have historically been used to collimate the treatment beam into a circular pencil beam, and treatment is delivered using multiple noncoplanar arcs that intersect at a single point to treat an approximately spherical target of <4 cm in diameter. Newer miniaturized multileaf collimators allow beam shaping. Techniques incorporate multiple noncoplanar arcs with couch and jaw rotations, which permits a greater portion of the three-dimensional space subtended over the skull to be utilized for beam entry. This approach, sometimes referred to as the "hyperarc technique," allows for better dose conformality and rapid treatment of multiple intracranial lesions, without the need for selecting individual isocenters for each lesion. The legacy Gamma Knife is a fixed beam

multisource radiation unit containing 201 cobalt-60 (^{60}Co) sources that are collimated using a helmet with circular apertures ranging from 4 to 18 mm that are focused onto a single target point. The newer Gamma Knife technology obviates the need for “helmet changes” and can effectively allow IMRT-like dose distributions to be created. For irregularly shaped lesions, treatments delivered using either noncoplanar arcs delivered through a single circular collimator or a single collimator helmet lead to the inclusion of a large amount of normal brain and yield inferior conformality. In these cases, it is advantageous to use multiple circular collimators or collimator helmets placed on different target points (and in the newer version of the Gamma Knife [Perfexion], different segments can be treated with different collimator diameters, and differential weighting is also possible) or to consider the use of multileaf collimated beams. The “hyperarc technique” referred above also achieves improved dose conformality because of the combination of multiple noncoplanar arcs, use of a sophisticated multileaf collimator, varying collimator rotations, and multiple couch angles. The newest version of the Gamma Knife (Icon) incorporates an on-board kV imaging tube capable of generating volumetric CT images that permit noninvasive and repetitive positioning for fractionated treatments.

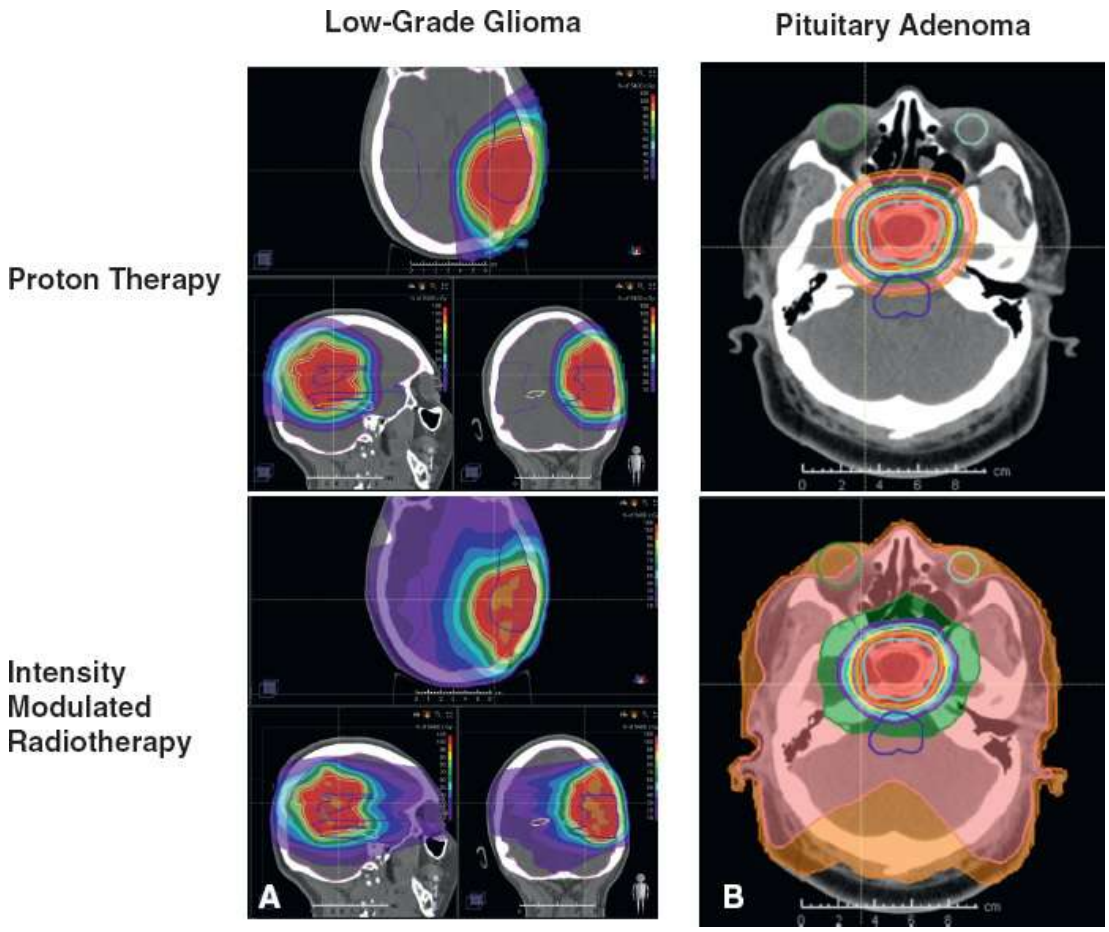

FIGURE 38.8. Comparison of proton therapy to intensity-modulated radiotherapy (IMRT) treatment plans for **(A)** left temporal oligodendroglioma and **(B)** nonfunctional pituitary adenoma, demonstrating tight target coverage and significant sparing of low-dose radiation exposure to normal tissues throughout the brain in tumor types with favorable prognosis.

Radiation Therapy Oncology Group (RTOG) study 90-05 established the maximum tolerated dose of single faction SRS to be 24, 18, and 15 Gy for tumors ≤20, 21 to 30, and 31 to 40 mm in maximum diameter, respectively, and these and other parameters are frequently used to guide prescription doses.[28] In modern practice, because the number of intracranial lesions treated in one SRS session has increased significantly, there has been a tendency toward decreasing the SRS dose; for example, in a large Japanese study of multiple brain metastases, the SRS dose was decreased to 15 Gy.[29]

Fractionated Stereotactic Radiotherapy

For lesions larger than 4 cm and/or located in critical regions, the delivery of a single large fraction treatment as in SRS is not desirable because of a high risk of CNS toxicity. FSRT is a hybrid between conventionally fractionated

radiotherapy and SRS that combines fractionation with stereotactic localization and targeting techniques. Various systems for FSRT have been developed, with a reported accuracy of 1 to 3 mm.[30] As for SRS, the use of multiple arcs and circular collimators for irregularly shaped lesions leads to the inclusion of a large amount of normal tissue. The use of multiple noncoplanar fixed fields each having a unique entrance and exit pathway will be preferable because of better conformality, as multileaf collimators are almost always used.[31–33] With the Perfexion device, the use of the "Extend" frame permits FSRT as well as targeting of lower cranial lesions. With the incorporation of on-board volumetric imaging, modern LINACS and the most recent version of the Gamma Knife (Icon) also permit fractionation, using noninvasive mask-fixation systems. The CyberKnife also permits this option using repetitive 2D radiographic imaging incorporated into a sophisticated skull-anatomy based visualization software. There is increasing use of a 9 Gy x 3 fractions schedule of FSRT for larger (>3 cm) brain metastases.

Heavy Charged Particles

Heavy charged particle beams deposit their dose at a depth that depends on their energy over a distance of few millimeters when the heavy charged particles come to rest, the so-called Bragg peak. In order to cover a larger volume, the particle beam can be modulated, in effect adding up multiple Bragg peaks. The very sharp dose gradient at the distal edge permits the use of high-dose radiotherapy for tumors in critical locations, such as at the clivus and base of the skull, and provides better normal tissue sparing in other situations, especially, for example, in CSI.[24,34] Currently, a small number of European and Japanese centers are treating CNS tumors with carbon ions, which putatively have higher linear energy of transfer (LET) and presumed superior biologic effect, but no substantial clinical data are available to back these claims. There are currently no US centers utilizing these technologies, although neutron-beam irradiation, with or without coadministration of boronated agents to increase the cross-sectional area of interaction, continues to be used in some US centers.

Brachytherapy and Radiocolloid Solutions

Selection criteria for brachytherapy include tumor confined to one hemisphere, no transcallosal or subependymal spread, small size (<5 to 6 cm), well circumscribed on CT or MRI, and accessible location for the implant. A balloon-based system, GliaSite, placed into the cavity at the time of surgery has been

employed in the treatment of recurrent malignant gliomas whose largest spatial dimension is <4 cm and are roughly spherical.[35] After treatment planning, the balloon is filled with a liquid that contains organically bound iodine-125 (^{125}I) and treatment is completed within 3 to 7 days. Direct infusion of radioimmunoglobulins has been used in primary and recurrent brain gliomas.[36]

CHEMOTHERAPY AND TARGETED AGENTS

Conventional Chemotherapy

Many conventional chemotherapy agents do not adequately penetrate normal or nonenhancing tumor-infiltrated brain, while some drugs, despite having a molecular weight and chemical structure that make them appear capable of crossing the BBB, are actively effluxed out of the brain parenchyma by p-glycoprotein and other active transporter substrates. Even when drug delivery is adequate, most CNS tumors are resistant to most conventional chemotherapeutic agents. Alkylating agents such as BCNU (carmustine) and CCNU (lomustine) have been the most widely studied drugs in CNS tumors. These agents cross the BBB, but prolonged use is difficult because of cumulative myelotoxicity and the dose-related risk of pulmonary fibrosis. Despite radiographic responses in 15% to 40% of patients, the impact on survival has been modest at best. Procarbazine has similar efficacy but is better tolerated. Cisplatin and carboplatin have been used as either single agents or in combination regimens. Response rates have been modest, and their impact on survival is unclear. Topoisomerase I (CPT-11, irinotecan) and topoisomerase II inhibitors (etoposide) have shown only modest activity. Taxanes, such as paclitaxel, have not demonstrated activity as single agents. Temozolomide (TMZ), an oral agent with excellent bioavailability, has a good toxicity profile and is the only agent to demonstrate a survival benefit for glioblastoma and anaplastic astrocytoma patients in randomized clinical trials.

The use of combination regimens plays a role in the management of specific CNS tumors. Radiation therapy with immediate chemotherapy utilizing the combination of procarbazine, CCNU, and vincristine (PCV) prolongs survival in patients with anaplastic oligodendroglioma and high-risk low-grade gliomas.[37] Other CNS tumors in which combination regimens are standard of care include PCNSL (high-dose methotrexate with procarbazine/vincristine, or high-dose cytarabine, or TMZ) and medulloblastoma (CCNU, cisplatin, and vincristine or cisplatin and cyclophosphamide and vincristine).

Direct Delivery of Therapeutic Agents

Methods for circumventing the BBB include implantation of slow-release chemotherapy wafers into a tumor resection cavity,[38,39] pharmacologic or osmotic BBB disruption,[40,41] and convection-enhanced drug delivery (CED). CED involves the use of intracerebrally implanted catheters to deliver a drug into the brain parenchyma or tumor, at a slow but continuous rate of flow. Unlike diffusion, in which a drug distributes along an exponentially decaying concentration gradient depending on the size of the molecule, drug distribution by CED is less size-dependent, occurs over a larger volume of brain tissue, and results in a more uniform drug concentration within the volume of distribution.[42,43] Large and/or hydrophilic agents that do not cross the BBB are ideal candidates for delivery via CED. Examples of agents used in CED studies include viruses,[44] paclitaxel,[45] topotecan,[46] and a variety of engineered, targeted protein toxins. These toxins are engineered to include a targeting ligand (e.g., interleukin-4 [IL-4], IL-13, tumor growth factor-α [TGF-α], transferrin) and a genetically altered bacterial toxin that is effective only when internalized by a cell that expresses the target of the ligand.[47] Two phase III clinical trials have evaluated the use of CED. The PRECISE trial[48–51] studied CED of IL-13 linked to *Pseudomonas* exotoxin (cintredekin besudotox), as compared to Gliadel wafers in glioblastoma patients at first recurrence. No difference in overall survival was observed, but cintredekin besudotox was associated a higher rate of complications. The TransMID trial evaluated the efficacy of transferrin-CRM107 delivered by CED to patients with inoperable recurrent or progressive glioblastoma. The trial was terminated early in 2007 because it was deemed unlikely to meet the prespecified criteria for efficacy. Post hoc analysis of the PRECISE trial indicated that the nonspecialized delivery technology that was used in all of the prior CED studies (“off the shelf” single lumen catheters) could not be placed sufficiently close to target tissue because of concerns about backflow of infusate, or leakage into CSF spaces that would prevent effective intraparenchymal delivery. These concerns were magnified by the lack of imaging data to verify extent of delivery in real time. Recently, several specialized, backflow-resistant delivery devices have been introduced into clinical trial, and coinfusion of Gd conjugates, which are visible on MRI, has verified the ability of these devices to produce clinically relevant volumes of distribution. These devices are currently incorporated into new, early-stage therapeutic trials involving CED, and more trials are expected to open over the next few years.

BCNU impregnated in a polymer and made into a wafer has been used for local delivery, placed on the walls of the resection cavity at the time of surgery. The wafer slowly undergoes biodegradation, releasing the active drug. This local delivery system has the advantages of minimal systemic toxicity, no limitation posed by the BBB, and delivery of very high local concentrations of chemotherapy. Studies in glioblastoma (GBM) have shown only marginal benefit.[52]

Targeted Agents

Although no single defining genetic mutation has been identified for gliomas, several key proliferation and survival signaling pathways appear to be important in GBM. The vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), and insulin-like growth factor (IGH) pathways are thought to be particularly relevant in the growth and proliferation of GBM. These pathways are characterized by receptors associated with tyrosine kinase activities and share common mechanisms of pathway activation and intracellular signaling. Overexpression or mutations of receptors and intracellular downstream effectors have been identified in GBM, leading to constitutive activation of signaling pathways, resulting in uncontrolled cellular proliferation, survival, and invasion. The Cancer Genome Atlas Research Network demonstrated that 88% of primary GBM tumors have deregulation in the receptor tyrosine kinases and downstream RAS or PI3K pathways.[41,53] Laboratory and clinical trials have focused on targeting these pathways with a variety of agents including monoclonal antibodies, low-molecular weight tyrosine kinase inhibitors, and ligand-toxin conjugates. At the present time, the VEGF pathway inhibitor bevacizumab is the only targeted agent approved for GBM. The efficacy of others has been overwhelmingly disappointing in GBM.

The only other targeted strategy that has been successful in gliomas is the use of inhibitors of mTor for treatment of subependymal giant cell astrocytomas (SEGA), seen in association with tuberose sclerosis. Franz et al. prospectively treated 23 patients with a definite diagnosis of tuberous sclerosis and increasing SEGA lesion size with daily everolimus. Twelve (52.2%) of patients experienced SEGA volume reductions of ≥50% relative to baseline after 60 months of treatment. The proportion of patients experiencing daily seizures was reduced from 26.9% to 11.1% at 60 months.[54]

Two large randomized trials utilizing the antiangiogenic agent bevacizumab

for the treatment of newly diagnosed GBM improved progression-free survival but failed to improve overall survival.[55] Because approximately a third of GBMs express an aberrant EGFR surface receptor, small molecule inhibitors, antibodies, and vaccine-mediated approaches to this have been undertaken. A phase III study of rindopepimut, an EGFRviii peptide conjugated to keyhole limpet hemocyanin failed to improve survival in newly diagnosed glioblastoma in a prospective, randomized, phase III study.[56,57] Depatuximab mafodotin is an antibody-drug conjugate that preferentially binds cells with EGFR amplification. It is internalized by targeted cells and releases a potent antimicrotubule agent, monomethylauristatin F. A non-placebo controlled Phase II clinical trial in recurrent glioblastoma with EGFR amplification demonstrated six-month progression free survival of 28.8%.[57a] A Phase III, prospective, randomized, placebo control trial of depatuximab mafodotin in newly diagnosed glioblastoma with EGFR amplification has been completed, although the results have not been reported. Investigators have studied various adoptive and active immunotherapies in the treatment of GBM. Despite limited success, there has been renewed interest recently with the development of tumor-specific vaccines and the approval of new agents for other solid tumors. The use of an active, tumor-specific immunotherapy is appealing as it could potentially maintain long-term antitumor response while limiting toxicity. In addition to Rindopepimut (EGFRvIII-targeted peptide vaccine), other vaccine strategies in clinical trials include DC Vax (autologous tumor lysate-pulsed dendritic cell vaccine), ICT-107 (dendritic cells prepared from autologous mononuclear cells that are pulsed with six synthetic peptides), and HSPPC-96 (autologous tumor-derived heat shock protein [glycoprotein 96]). The most recent investigational focus has shifted to the evaluation of immune checkpoint inhibitors, but the data are too preliminary to be considered outside the clinical trial context.

Alternating Electrical Field Therapy

Tumor-treating fields (TTFields) are a novel treatment modality approved for the treatment of either newly diagnosed or recurrent GBM. TTFields therapy involves a medical device and transducer arrays to provide targeted delivery of low-intensity, intermediate-frequency, alternating electric fields to produce antimitotic effects selective for rapidly dividing tumor cells with limited toxicity. In the phase 3 EF-14 trial, TTFields plus TMZ provided significantly longer PFS and OS compared with TMZ alone in patients with newly diagnosed GBM after initial chemoradiotherapy.[58] In the phase 3 EF-11 trial, for recurrent GBM,

TTFields provided comparable efficacy as investigator's choice systemic therapy, with improved patient-reported quality of life and a lower incidence of serious adverse events.[59] Primary toxicity associated with TTFields is skin irritation generally managed with array relocation and topical treatments including antibiotics and steroids.

FOLLOW-UP

The follow-up schedule for a brain tumor patient must be frequent enough to check on side effects and to taper steroids shortly after completion of radiation therapy. Periodic MRIs are used to detect tumor recurrence at a stage when further therapy may be contemplated. Assessment of cognitive functioning and quality of life is important, and patients must be monitored for neuroendocrine and ophthalmologic side effects.

SEQUELAE OF TREATMENT

Surgery

With appropriate patient selection, diligent surgical technique and use of surgical adjuncts such as speech and/or motor mapping, the rate of complications can be minimized. Even in the best of hands, new temporary neurologic deficits can be seen in 15% or more of patients, although the rate of permanent new deficits is typically now <5%.[60] The incidence and types of deficits seen following surgery depend upon the location of the tumor and the deficits present preoperatively. The most common complications associated with surgery are bleeding and infection, particularly in the case of reoperation in a patient who has received prior radiotherapy and/or chemotherapy or when chemotherapy wafers are placed into a resection cavity.[61] It has been suggested that the use of linear incisions (as opposed to U-shaped flaps) can help reduce the incidence of incision-related complications, such as infection.[62] Posterior fossa resections, particularly in children with medulloblastoma, may be associated with posterior fossa syndrome (mutism plus bulbar symptoms). Transient perioperative edema, within about 48 hours of surgery, may be responsible for early postoperative neurologic worsening and can often be mitigated with the use of a short course of high-dose steroid therapy.

Patients with postoperative neurologic deterioration require careful clinical assessment, and in most cases, a CT or MRI is required to determine the cause of

the deterioration. MRI diffusion-weighted sequences can be used to detect the presence of a new infarct. A high index of suspicion should be maintained for postoperative infection because symptoms may be masked by perioperative steroid use, and the headache and fever associated with craniotomy may obscure the classic signs of meningitis.

Radiotherapy

The response of intracranial tissues to radiation has been classically divided into three phases based on the timing of onset of symptoms: acute, subacute, and late.

Acute Toxicity

Transient worsening of pretreatment deficits may develop during the course of treatment, and further acute toxicities may manifest up to 6 weeks following completion of irradiation. These symptoms are believed to be the consequence of a transient peritumoral edema and usually respond to a short-term increase or the institution of corticosteroids. Persistent or refractory symptoms may be caused by tumor progression, and repeat imaging while under treatment may be indicated if the clinical condition worsens despite steroids.

General symptoms such as fatigue, headache, and drowsiness may be seen, especially in individuals treated with large brain fields or with CSI. A mild dermatitis that develops in irradiated areas may be treated with topical agents if necessary. Alopecia within the irradiated areas is common and may be permanent with higher total doses. Nausea and vomiting independent of changes in intracranial pressure may occur, particularly with posterior fossa or brainstem irradiation. Otitis externa can be seen if the ear is included in the irradiation fields, and serous otitis media also may occur. Patients treated with CSI with photons are at risk for mucositis and esophagitis because of the exit dose from the spinal fields through the oropharynx and mediastinum. Hematologic toxicity may also be seen in these patients because of irradiation of the vertebral bodies, a major depot of bone marrow in adults. These GI and hematologic effects are less severe and less frequent with the use of proton therapy for CSI.[63]

Subacute Toxicity

Subacute or “early-delayed” toxicity that develops during the 6-week to 6-month period following irradiation is attributed to changes in capillary permeability as well as transient demyelination due to damage to oligodendroglial cells. Symptoms, which include headache, somnolence, fatigability, and deterioration of pre-existing deficits, usually respond to steroids. The main challenge is to

distinguish the clinical and imaging findings from tumor recurrence. The phenomenon of “pseudoprogression” temporally fits within the subacute toxicity time frame.

Late Sequelae

Late sequelae of radiotherapy appear from 6 months to many years following treatment and are usually irreversible and progressive. They are thought to be due to white matter damage from vascular injury, demyelination, and necrosis. The pathophysiology of radiation-induced neurocognitive damage is complex and involves inter- and intracellular interactions between vasculature and parenchymal cells, particularly oligodendrocytes, which are important for myelination. Oligodendrocyte death occurs either because of direct p53-dependent radiation apoptosis or because of exposure to radiation-induced TNF-α.[63] Postradiation injury to the vasculature involves damage to the endothelium leading to platelet aggregation and thrombus formation, followed by abnormal endothelial proliferation and intraluminal collagen deposition.[64,65]

The most serious late reaction to radiotherapy is radiation necrosis, which has a peak incidence at 3 years. Radiation necrosis can mimic recurrent tumor clinically by the reappearance and worsening of initial symptoms and neurologic deficits and radiographically with the development of a progressive, irreversible, enhancing mass with associated edema on imaging. PET, MR spectroscopy, and nuclear and dynamic CT scanning procedures may aid in the differentiation of radiation necrosis from recurrent tumor. The best treatment for symptomatic necrosis is control of symptoms with steroids followed by surgical debulking, although even after resection necrosis may progress. Given the central role of capillary leakage to radiation necrosis, bevacizumab, an antibody against VEGF, has been tested clinically as treatment for radiation necrosis and has shown encouraging results.[66] Other measures include use of corticosteroids with anticoagulation or hyperbaric oxygen, although randomized trials have not shown these to be useful. In limited clinical series, LITT has shown utility in treating focal radiation necrosis.[67] Although focal necrosis is usually due to radiotherapy alone, diffuse leukoencephalopathy is more commonly associated with the combination of radiotherapy and chemotherapy, particularly methotrexate.

Inclusion of the middle ear may result in high-tone hearing loss and vestibular damage, especially in patients who receive cisplatin. Retinopathy or cataract formation may be seen if the eye is in the radiation field. Optic chiasm and nerve

injury may manifest as a decrease in visual acuity, visual field changes, or blindness at doses >54 to 60 Gy. Onset of hormone insufficiency from irradiation of the hypothalamic–pituitary axis is variable but may be seen with doses as low as 20 Gy.

Cranial irradiation can produce neuropsychological changes and neurocognitive impairment; other factors such as tumor-related morbidity, as well as the effects of surgery and chemotherapy, may also contribute.[68] Decline in list-learning recall has been observed in prospective clinical trials of therapeutic and prophylactic cranial irradiation.[66,69] These changes are thought to be due in part to interactions between the vasculature and parenchymal cells. Hippocampal-dependent functions of new learning, memory, and spatial information processing appear to be most affected.[70–72] Doses as low as 2 Gy can induce apoptosis in the proliferating cells in the hippocampus.[73] Agents such as methylphenidate and memantine or radiotherapeutic strategies such as hippocampal avoidance may improve neurocognitive function.[74–76]

MANAGEMENT OF INDIVIDUAL TUMORS

Malignant Glioma

Malignant or high-grade gliomas account for approximately half of all primary brain tumors in adults. They are rapidly growing tumors that directly invade the brain parenchyma but almost never metastasize outside the CNS. They present in any age group, although most occur in late adulthood. Malignant gliomas correspond to anaplastic gliomas (WHO grade III) and GBM (WHO grade IV). Molecular genetics and results from clinical series have shown these to be two distinct diseases with unique behavior, response to treatment, and prognosis. Historical trials that included grade III and IV gliomas are described in the section on GBM, as patients with GBM constituted the majority of subjects, whereas anaplastic gliomas are discussed in further detail in the following section.

Glioblastoma

GBM accounts for approximately 75% of all high-grade gliomas. The histopathologic features of GBM include nuclear atypia, mitotic activity, vascular proliferation, and necrosis; any three of these suffice to make the diagnosis. GBM is diffusely infiltrative, involving large portions of the brain. MRI characteristically shows vasogenic edema and ring enhancement around

central necrotic regions.

The prognosis for patients with GBM is poor with median survival time of approximately 14 months in highly selected patients receiving contemporary treatment. Pretreatment patient and tumor characteristics such as age at diagnosis, tumor histology, and Karnofsky performance status (KPS) are the best predictors of outcome. Extent of resection, duration of neurologic symptoms, and radiographic response to treatment have also been suggested as predictors of survival.

Curran et al.[79] used nonparametric recursive partitioning analysis (RPA) (a statistical tool that allows for the identification of significant prognostic factors and subsequent classification of patients into groups with similar outcomes) to analyze data from three RTOG trials that included 1,578 patients with malignant gliomas. Age was the most important predictor of survival, with patients <50 years faring best; KPS ≥ 70 was the next most significant prognostic factor. Taking into account these and other variables, patients could be divided into groups with similar outcomes with 2-year overall survival ranging from 4% to 76% and median survival ranging from 2.7 to 58.6 months (Table 38.4). Though developed in patients receiving radiotherapy alone, the RPA classification retains prognostic significance in patients treated with radiotherapy plus TMZ.[79] More recent studies have integrated molecular data from O^6–methylguanine-DNA methyltransferase (MGMT) promoter methylation status and other novel biomarkers to develop novel risk-stratification models.[80]

Molecular Genetics

Glioblastoma may arise *de novo* (primary) or from a low-grade glioma that has transformed into a higher-grade tumor (secondary). Secondary GBM arise in younger patients and are associated with a more favorable prognosis than those with primary GBM. The more favorable prognosis may be related to the impact of younger age and better performance status of this group. Emerging data suggest that promoter methylation of the PTEN gene in low-grade gliomas may be causally linked to secondary malignant transformation to GBM. Secondary GBM usually have a mutation in the isocitrate dehydrogenase (IDH1) gene and often have p53 mutations.

TABLE 38.4 RADIATION THERAPY ONCOLOGY GROUP RECURSIVE PARTITIONING ANALYSIS OF MALIGNANT GLIOMA

	Median Survival

Class	Patient Characteristics	(mo)
I, II	Anaplastic astrocytoma	40–60
	Age ≤50 y, normal mental status or age >50 y, KPS >70, symptoms >3 mo	
III, IV	Anaplastic astrocytoma	11–18
	Age ≤50 y, abnormal mental status	
	Age >50 y, symptoms <3 mo	
	Glioblastoma	
	Age <50	
	Age >50 y, KPS ≥70	
V, VI	Glioblastoma	5–9
	Age >50 y, KPS <70 or abnormal mental status	

KPS, Karnofsky performance status.

Treatment

Standard treatment consists of maximal safe surgical resection followed by radiotherapy with concurrent TMZ chemotherapy and subsequent adjuvant TMZ chemotherapy and consideration for application of TTFields. Other approaches including alterations in the delivery of radiotherapy, newer chemotherapeutic agents, immunotherapy, and other agents are the subject of ongoing research.

Radiotherapy Target Volume

Randomized trials have demonstrated a clear survival benefit to the use of radiotherapy after surgery.[81,82] Localized irradiation volumes are recommended despite the fact that GBM is usually more widely disseminated. Dandy et al.,[83] for example, identified recurrences in the contralateral hemisphere even after hemispherectomy, showing the phenomenal capability of malignant gliomas to spread along white matter tracts. Such findings as well as autopsy studies[84–86] led to recommendations that the entire intracranial contents should be irradiated. However, Hochberg and Pruitt[87] reported that in 35 patients who had a CT scan within 2 months prior to autopsy, 78% of recurrences of GBM were within 2 cm of the margin of the initial tumor bed and 56% were within 1 cm or less of the volume outlined by the CT scan. These findings were confirmed by Wallner et al.[88] who showed that 78% of unifocal tumors (25/32) recurred within 2 cm of the initial tumor volume, defined as the enhancing edge of the tumor on CT scan, and 56% of tumors (18/32) recurred within 1 cm of the initial tumor margin. No unifocal tumor recurred as a multifocal lesion, and large tumors were not more likely to recur farther from the initial tumor margin than smaller tumors.

In a correlative study, Halperin et al.[89] reviewed CT scans and pathologic

sections of 15 brains of patients with GBM who received minimal or no radiotherapy. If radiation treatment portals had been designed to cover the contrast-enhancing volume and peritumoral edema with a 1-cm margin, the portals would have covered histologically identified tumor in only 6/11 cases. However, treatment of the contrast-enhancing area and all surrounding edema with a 3-cm margin around the edema would have covered histologically identified tumor in all cases.

Kelly et al.[90] reported on 40 patients with intracranial glial neoplasms who underwent CT- and MRI-guided stereotactic serial biopsies. Histologic analysis of 195 biopsy specimens showed that contrast enhancement most often corresponded to tumor tissue without intervening parenchyma and hypodensity most often corresponded to parenchyma infiltrated by isolated tumor cells, tumor in low-grade gliomas, or edema. Isolated tumor cell infiltration extended at least as far as T2 changes on MRI. T2-weighted MRI revealed much larger volumes of infiltrated parenchyma than shown by low attenuation on CT scans.

Therefore, inclusion of all radiographic evidence of tumor and associated edema with generous margins is common practice in the design of treatment portals. The extent of margin expansion remains a relatively poorly studied and controversial area, with considerable variance.[91] With advances in MRI technology, the definition of tumor margins continues to change. For example, Pirzkall et al.[92] showed metabolically active tumor extending outside the region defined on T2-weighted MRI in 88% of patients. PET imaging with methionine and/or thymidine may also prove useful.

Radiotherapy Dose

The current “standard approach” delivers a total dose of 59.4 to 60 Gy in 30 to 33 fractions of 1.8 to 2 Gy/fraction, using a “shrinking field” technique. Walker et al.[93] performed a dose–response analysis using data from 420 patients treated on Brain Tumor Cooperative Group protocols. Doses ranged from <45 to 60 Gy using daily fractions of 1.7 to 2 Gy; only one-third of the patients received <60 Gy. A significant improvement in median survival from 28 to 42 weeks in the groups treated with doses of 50 to 60 Gy was found. A Medical Research Council study of 443 patients also showed a significant survival advantage in patients who received 60 Gy compared to those who received 45 Gy (12 vs. 9 months; $P = .007$).[94]

For patients with poor pretreatment prognostic factors and a limited expected survival who are not able to tolerate conventional treatment, a shorter course of

treatment may provide good palliation. Older patients (>65 years), especially those with poor performance status, have been shown to experience limited posttreatment improvement or rapid neurologic deterioration following conventional radiotherapy. Short-course radiotherapy, utilizing hypofractionated techniques, some as short as only 1 week, has been tested in older patients, and results are described below. In Europe and Canada, such hypofractionated schedules are considered “standard” for “elderly” or “poor performance” status patients, and such techniques are also being increasingly utilized in the United States.

Dose Escalation and Altered Fractionation

With the vast majority of tumor recurrences occurring within the previous irradiation field and the poor outcomes associated with standard therapy, regimens designed to deliver a larger dose have been attempted to improve local control and enhance survival.

A benefit for doses >60 Gy either without chemotherapy or with nitrosurea-based chemotherapy has not been demonstrated. The RTOG and Eastern Cooperative Oncology Group (ECOG) randomized 253 patients to either whole-brain irradiation to 60 Gy given in 6 to 7 weeks or 60 Gy plus a 10-Gy boost to a limited volume given in 7 to 8 weeks.[95] There was no benefit for the higher irradiation dose. Chan et al.[96] published the results of 34 patients with high-grade gliomas treated using 3D conformal IMRT to a dose of 90 Gy. At median follow-up of 11.7 months, median survival was found to be 11.7 months and 1- and 2-year survivals of 47.1% and 12.9%, respectively, comparable to historical controls.

Several groups have used hyperfractionated or accelerated regimens as a means to escalate dose, using twice daily, three times daily, and even four times daily fractionation.[97] Only the study of Shin et al.[98–100] showed an improvement in survival using daily fractionation. In this study, 81 patients were randomized to 61.4 Gy in 69 fractions of 0.89 Gy given three times daily over 4.5 weeks or conventional fractionation to 58 Gy in 30 fractions given once daily over 6 weeks. Median survival in the two groups was 39 and 27 weeks, respectively, and the 1-year survival rates were 41% and 20%, respectively ($P < .001$). Others have failed to confirm these results. In a prospective, randomized phase I/II trial, RTOG 83-02 examined dose escalation using twice-daily fractionation in patients with malignant gliomas. Hyperfractionated regimens studied were 64.8, 72.0, 76.8, and 81.6 Gy given in 1.2 Gy fractions twice daily, and accelerated

hyperfractionated regimens were 48 and 54.4 Gy given in 1.6 Gy twice-daily fractions. Patients also received chemotherapy with BCNU. In the final report on all 747 patients, there were no significant differences between the treatment arms with regard to median survival time.[100] A phase III trial compared conventional radiotherapy to 60 Gy in 30 daily fractions to hyperfractionated radiotherapy to 72 Gy in 60 fractions of 1.2 Gy given twice daily.[101] No difference in survival was found. Several other accelerated hyperfractionation regimens to doses over 70 Gy have been investigated, also without significant improvement in survival.[102]

In the contemporary era of concurrent and adjuvant TMZ, escalation of both dose and dose per fraction using IMRT was tested in a prospective phase I/II study. The maximum tolerated dose with temozolomide was 75 Gy in 30 fractions (2.5 Gy/fraction). Median survival was 20.1 months, suggesting improved efficacy compared to other contemporary studies. The probability of in-field failure decreased in with increasing dose escalation. Prospective randomized trial of this dose-fractionation regimen using either IMRT or proton therapy remains ongoing.

Dose Escalation Using Radiosurgery and FSRT

A radiosurgical boost was reported as effective in patients with newly diagnosed malignant glioma in a retrospective analysis of 115 patients treated at three institutions with a combination of surgery, external beam radiotherapy, and LINAC-based radiosurgery on similar institutional protocols.[103,104] In a prospective randomized trial, Souhami et al.[105] compared conventional radiotherapy (60 Gy) plus adjuvant BCNU with and without radiosurgery in 203 patients with GBM. At a median follow-up of 61 months, no significant improvement in median survival was observed (13.5 vs. 13.6 months).

The use of a boost using FSRT was tested prospectively in RTOG 0023.[106] 76 patients with GBM with postoperative residual tumor plus tumor cavity diameter <60 mm were treated with 50 Gy standard radiotherapy in daily 2 Gy fractions, plus four FSRT treatments given once weekly during weeks 3 to 6 of radiotherapy. The FSRT dose was either 5 Gy or 7 Gy/fraction for a cumulative dose of 70 or 78 Gy in 29 treatments over 6 weeks. Overall, no survival advantage was seen when compared to the RTOG historical database.

Dose Escalation Using Brachytherapy

Laperriere et al.[107] used brachytherapy as a boost to conventional radiotherapy in

patients with malignant gliomas. Patients were randomized to external beam radiotherapy (50 Gy in 25 fractions) alone (n = 69) or external beam radiotherapy plus a temporary stereotactic ^{125}I implant delivering a minimum peripheral tumor dose of 60 Gy (n = 71). Median survival was not significantly different between the two arms (13.8 vs. 13.2 months; P = .49).

The results of the Brain Tumor Cooperative Group National Institutes of Health Trial 8701 reported by Selker et al.[108] support these findings. In this randomized, prospective trial, 299 patients with newly diagnosed malignant glioma received surgery, external beam radiotherapy, and BCNU with or without an interstitial radiotherapy boost with ^{125}I. Treatment with an interstitial boost did not prolong survival as compared to conventional treatment.

Radiotherapy delivered by an inflatable balloon brachytherapy catheter has also been tested. Tatter et al.[109] evaluated the safety and performance of one such device (GliaSite Radiation Therapy System, Cytyc, Marlborough, MA). Twenty-one patients with recurrent malignant gliomas underwent surgical resection and implantation of a subcutaneous port. At 1 to 2 weeks following implantation, the catheter was filled with an aqueous solution of organically bound ^{125}I for delivery of a minimum of 40 to 60 Gy over 3 to 6 days, with subsequent removal of the device. Median survival was 12.7 months. Subsequent dose-finding prospective studies failed to determine a maximum tolerated dose as early imaging changes, presumed to be progression, occurred in 7 of 12 patients and interfered with the assessment of treatment-related toxicity.[36]

Dose Escalation Using Proton Therapy

Dose escalation up to 90 cobalt gray equivalent (CGE) with mixed photon and proton-beam irradiation has been tested in two prospective trials.

Fitzek et al.[110] reported on a phase II study of 23 patients with newly diagnosed GBM. Two-year overall survival was 34% and median overall survival was 20 months, which compared favorably to historical data. Recurrence was observed in regions treated to 60 to 70 CGE, but only one recurrence was observed in regions treated to 90 CGE. More recently, Mizumoto et al.[111] reported on a phase I/II study of 20 patients with supratentorial GBM treated with mixed photon and proton-beam irradiation to 96.6 Gy in 56 twice-daily fractions with concomitant nimustine chemotherapy. MRI-defined T2 enhancing region was treated to 50.4 CGE in 28 daily morning fractions. In daily evening fractions, patients were treated to 23.1 CGE for the first 14 fractions to

the T1-enhancing region plus 1 cm and then 23.1 CGE for the subsequent 14 fractions to the T1-enhancing region only. Median survival was 22 months and 2-year overall survival was 45%. Late radiation necrosis was noted in one patient, and late leukoencephalopathy was observed in a second patient. As part of a prospective randomized trial, dose escalation to 75 Gy in 30 fractions using proton therapy is currently under investigation.

Radiosensitizers

Studies using radiation modifiers in conjunction with radiotherapy to overcome the hypoxia present in malignant gliomas have shown disappointing results. Chang[112] reported on 38 patients treated with hyperbaric oxygen and irradiation using fractionation schedules ranging from 36 Gy given in 3 weeks to 60 Gy given in 6 to 7 weeks and compared them with 42 patients treated with radiotherapy alone. An improvement in 18-month survival rate from 10% to 28% and an increase of median survival from 31 to 38 weeks was noted. Perfluorocarbon emulsions, such as Fluosol, which have enormous oxygen carrying capacity, have been tested as hypoxic sensitizers without significant benefit.[113] Randomized studies failed to show significant improvement with the addition of the hypoxic cell sensitizer misonidazole.[114]

Miralbell et al.[98,115] reported the results of a European Organisation for Research and Treatment of Cancer (EORTC) trial examining the addition of carbogen and nicotinamide to overcome the effects of proliferation and hypoxia presumed responsible for radioresistance in GBM. Overall survival was similar in all arms and did not differ from results of series using radiotherapy alone.

The redox-modulating radiosensitizer motexafin gadolinium (MGd) showed encouraging results in a phase I clinical trial[74]; however, results from a single-arm phase II trial, RTOG 0513, of MGd and conventional therapy in newly diagnosed GBM showed no survival improvement.

Chemotherapy

The use of cytotoxic chemotherapeutic agents for glioblastoma dates back to the 1960s when the Brain Tumor Study Group conducted a controlled study using carmustine.[116] After surgery, patients were assigned to one of four treatment groups: (1) no further therapy, (2) carmustine alone, (3) radiation therapy, and (4) radiation therapy followed by carmustine. At 18 months, 23% of patients who received radiation therapy plus carmustine were still alive as compared to 5% with carmustine or radiotherapy alone. The Food and Drug Administration

(FDA) approved carmustine and lomustine for the treatment of brain tumors (including glioblastoma) in the 1970s. Subsequent prospective studies failed to demonstrate a survival advantage to carmustine or other cytotoxic chemotherapy for glioblastoma, although two meta-analyses demonstrated a small survival benefit from chemotherapy.[117]

The only chemotherapeutic agent that has demonstrated efficacy for glioblastoma and anaplastic astrocytoma in randomized trials is TMZ, an oral imidazotetrazine derivative of dacarbazine that is metabolized *in vivo* to an active agent. Like the nitrosureas, it akylates the O^6 position on guanine, producing single-strand DNA breaks. It is well tolerated by patients; fatigue, constipation, and nausea are the most common toxicities. The drug is myelosuppressive in a minority of patients. Approval for the treatment of recurrent anaplastic astrocytoma was obtained from the Food and Drug Administration (FDA) in 1999.[118,119] Its approval for use as adjuvant therapy for glioblastoma was based on a large phase III clinical trial conducted by the EORTC and National Cancer Institute of Canada (NCIC).[120] This phase III trial randomized 573 patients with newly diagnosed glioblastoma (between the ages of 18 to 70 and KPS > 70) to either radiation therapy alone (total 60 Gy in 30 fractions; control arm) or TMZ chemotherapy in combination with radiation therapy (total 60 Gy in 30 fractions; experimental arm). Patients on the experimental arm received TMZ daily during radiation therapy (because of its radiosensitization effect in preclinical studies) at a dose of 75 mg/m^2, followed by monthly TMZ at a dose of 150 to 200 mg/m^2 on a 5 out of every 28 days schedule for six cycles.

Patients randomized to the experimental arm had a median survival of 14.6 months as compared to 12.1 months for the control arm. The 2-year survival of patients treated with radiation therapy plus chemotherapy was 26%, compared to 6% for radiation alone. Toxicity with chemoradiotherapy was acceptable with 7% grade 3 or 4 hematologic toxicities, compared to none in the group treated with radiotherapy alone. Long-term survival benefit from the addition of TMZ has been demonstrated.[121,122] Five-year overall survival was 9.8% for patients who received combined TMZ and radiotherapy as compared to 1.9% for those who received radiotherapy alone.[122] The benefit of adding TMZ to radiotherapy has also been demonstrated for elderly patients (age ≥ 65) with GBM. A recently reported randomized phase III trial demonstrated that adding TMZ chemotherapy during short-course radiation therapy, followed by monthly adjuvant TMZ improved survival of elderly glioblastoma patients from 7.6

month with radiation therapy alone to 9.3 months with combination therapy.[123] Progression-free survival was 5.3 months versus 3.9 months 1-year survival rate was 37.8% versus 22.2%, and 2-year survival rate was 10.4% versus 2.8% with radiation plus TMZ versus radiation alone.

Because only a subgroup of patients benefit from TMZ, their identification is desirable to avoid exposing patients unlikely to benefit to the toxicity of a potentially ineffective therapy. Recent work has focused on identifying potential predictive laboratory markers. Epigenetic silencing of the MGMT DNA repair gene by promoter methylation has been associated with longer survival for malignant glioma patients treated with alkylating agents.[124] A retrospective analysis of assessable cases from the EORTC/NCIC TMZ study demonstrated a survival benefit for patients treated with TMZ and radiotherapy if their tumor contained a methylated MGMT promoter (median 21.7 months) as compared to patients with nonmethylated MGMT promoters (median 12.7 months).[125] In the NCIC-EORTC trial of elderly GBM patients,[123] the MGMT nonmethylated group did not achieve a statistically significant benefit in survival, and consequently, a number of new clinical trials are attempting to enroll the MGMT-unmethylated GBM patients to trials that do not mandate TMZ in the experimental, and sometimes, even in the control arm.

The RTOG completed an 1,100 patient, randomized, phase III trial comparing standard adjuvant TMZ with a dose-dense schedule in newly diagnosed glioblastoma.[126] Eight hundred and thirty-three patients were randomized to receive either standard therapy (TMZ + radiotherapy followed by 6 to 12 cycles of TMZ at a dose of 150 to 200 mg/m^2 on a 5/28 day schedule) or dose-intense TMZ (TMZ + radiotherapy followed by 6 to 12 cycles of TMZ at a dose of 150 mg/m^2 on a 21/28 day schedule). There was no statistical difference between the experimental and standard arm for overall survival (16.6 vs.14.9 months, $P = .63$) or progression-free survival (5.5 vs. 6.7 months, $P = .06$), indicating no additional benefit from dose-intense TMZ. The trial prospectively stratified for MGMT methylation status, and no survival benefit with dose-intense therapy was identified in any subgroup. Overall, MGMT methylation was associated with improved median overall survival (21.2 vs. 14 months, $P < .0001$), median progression-free survival (8.7 vs. 5.7 months, $P < .001$), and response ($P = .012$). As expected, the dose-intense arm resulted in increased toxicity. Thus, at the present time, there is no role for dose-intense TMZ for newly diagnosed glioblastoma patients.

In addition, though the standard for postsurgical care includes radiotherapy

with concurrent TMZ followed by adjuvant TMZ for six cycles, this regimen has been adopted with variations including extending adjuvant TMZ beyond six cycles. A recent pooled analysis of patient-level data from four randomized trials of newly diagnosed glioblastoma demonstrated a slight improvement in progression-free survival (hazard ratio [HR] 0.80, $P = .03$), particularly in MGMT-methylated patients (HR 0.65, $P < .01$), with continuation of adjuvant TMZ beyond six cycles.[127] However, continuation of temozolomide beyond six cycles demonstrated no difference in overall survival in the overall population and specifically in the MGMT-methylated subgroup and, given the potential for increased toxicity, is not considered standard postsurgical care.

Other chemotherapeutic regimens, such as the combination of CPT-11 and TMZ, have shown promising results in a phase II trial with an objective response rate of 25% and 6-month progression-free rate of 38%. When tested prospectively in a single-arm RTOG trial, the regimen did not show improved survival.[128] Buckner et al.[129] reported on a phase III trial of carmustine with or without cisplatin before and concurrently with radiotherapy and observed increased toxicity but no survival benefit with the addition of cisplatin.

Tumor-Treating Fields

Tumor-treating fields (TTFields) involve the placement of noninvasive transducer arrays on the scalp and the delivery of low intensity (1 to 3 V/cm), intermediate frequency (100 to 300 kHz), alternating electric fields to the tumor. TTFields lead to tumor cell kill through their action during two phases of mitosis: (1) during metaphase, by disrupting the formation of the mitotic spindle, and (2) during cytokinesis, by dielectrophoretic dislocation of intracellular constituents resulting in apoptosis. TTFields are most effective when applied in the direction of the division axis of the dividing cell, and therefore, two sequential field directions are applied to tumors by using two perpendicular pairs of transducer arrays in order to increase the efficacy of TTFields.[130] Following preclinical studies demonstrating *in vitro* and *in vivo* activity in glioma, a prospective randomized trial of TTFields versus conventional chemotherapy for recurrent glioblastoma demonstrated no difference in overall survival, but higher patient-reported quality of life and cognitive and emotional function and less toxicity with TTFields.[130,132] This study also demonstrated improved overall with use of TTFields for 18 hours/day or longer.

Interim analysis of another prospective randomized trial demonstrated improvement in overall and progression-free survival but no difference in

serious adverse events or quality of life with the addition of TTFields to conventional treatment involving maximally safe resection and adjuvant chemoradiotherapy for newly diagnosed glioblastoma.[59] Final results of this trial confirm the existence of a survival benefit with a prolongation of median overall survival from 16.0 months to 20.9 months.[132a] Additionally, tumor-treating fields was not associated with any negative influence on quality of life, except for more itchy skin.[132b] Based on these results, TTFields has been approved for the treatment of recurrent and newly diagnosed glioblastoma by the Food and Drug Administration (FDA) in the United States and have obtained a CE mark in Europe for the same indications.

Investigational Approaches

Immunotherapy

Modulation of the immune system is being explored in the setting of GBM through such therapeutic interventions as blocking naturally occurring inhibitory immune checkpoint molecules, adoptive T-cell therapeutics, or vaccine therapy against tumor-specific antigens. Nivolumab, a human IgG4 monoclonal antibody targeting PD-1, demonstrated no improvement in overall survival relative to bevacizumab for recurrent GBM in preliminary results from a phase III trial.[133] Rindopepimut, a peptide vaccine targeting EGF receptor variant III (EGFR vIII), has been tested in multicenter trials of newly diagnosed EGFvIII-expressing GBM following gross total resection and conventional radiotherapy with concurrent TMZ. Although phase II results demonstrated promising outcomes, a double-blind randomized phase III trial failed to demonstrate an improvement in overall survival with the use of rindopepimut.[134] Heat shock protein-peptide complex-96 (HSPPC-96) vaccine is an autologous treatment derived from dendritic cells extracted from the patient's tumor to induce antitumor antibodies, demonstrated no survival benefit when added to bevacizumab for recurrent GBM in preliminary results from a randomized trial.

Radioimmunotherapy

Radioimmunotherapy using monoclonal antibodies against EGFR tagged with ^{125}I has been evaluated in the treatment of high-grade gliomas. In a phase II trial by Brady et al., 25 patients with malignant gliomas (10 with anaplastic astrocytoma and 15 with GBM) were treated with surgical resection or biopsy followed by definitive external beam radiotherapy and one or multiple doses (35 to 90 mCi per intravenous or intra-arterial infusion) of ^{125}I-labeled monoclonal

antibody-425. The total cumulative dose ranged from 40 to 224 mCi. At 1 year, 60% of patients were alive, and the median survival was 15.6 months. In an updated report of this study that included a total of 180 patients with a minimum follow-up of 5 years, median survival was 13.4 months for those with GBM.[135]

Another potential target is tenascin, an extracellular protein overexpressed in malignant gliomas but not found in normal tissue. Radiolabeled monoclonal antibodies to tenascin have been evaluated in phase I or II trials showing activity against newly diagnosed and recurrent malignant gliomas.[136] In a phase II trial by Reardon et al.,[137,138] ^{131}I-labeled murine antitenascin monoclonal antibody was injected directly into the surgical resection cavity in 33 patients with untreated malignant glioma. Patients were subsequently treated with external beam radiotherapy and 1 year of alkylator-based chemotherapy. Even after accounting for prognostic factors, median survival (86.7 weeks) was longer than that of historical controls. Treatment-related toxicities were mild; only one patient required reoperation for radionecrosis.

Targeted Therapies

EGFR gene amplification is seen in approximately 40% to 50% of patients with GBM. EGFR is associated with control of cell growth through autocrine and peregrine effects of growth factors. Inhibitors of EGFR tyrosine kinase such as gefitinib and erlotinib and EGFR antibodies have not been successful to date likely because of mutational resistance mechanisms, limited brain penetration of tyrosine kinase inhibitors, as well as the presence of multiple signaling bypass opportunities. Clinical trials of vaccine therapy directed against EGFRvIII are discussed above. A randomized trial of ABT-414, an antibody-drug conjugate targeting EGFR, added to conventional radiotherapy and TMZ for newly diagnosed GBM with EGFR amplification is ongoing.

Mutations and loss of the PTEN gene are encountered in approximately 70% of patients with GBM. PTEN inhibits signaling through the PI3-kinase and AKT signaling pathway. Loss of PTEN results in loss of effectiveness of EGFR inhibitors, probably because of constitutive signaling through PI3-kinase, which bypasses any upstream EGFR inhibitor effect. Specific inhibitors such as CCI-779 and everolimus are ineffective as single agents. Although preclinical experiments suggest that these agents are potential radiosensitizers,[139–141] a prospective trial of everolimus added to conventional radiotherapy and TMZ demonstrated no survival improvement compared to historical controls in newly diagnosed GBM.[142]

Cilengitide, a selective integrin inhibitor that acts on tumor cell motility and impacts tumor interaction with brain microenvironment, demonstrated no improvement in overall survival when added to conventional radiotherapy and TMZ for newly diagnosed MGMT promoter-methylated glioblastoma in a large phase III trial.[143]

Neovascularization is a major feature of GBM, and many studies demonstrate that GBM secrete VEGF in abundance. The supporting endothelium strongly expresses receptors for VEGF. Bevacizumab, anti-VEGF antibody, has demonstrated impressive radiographic response rate and reduction in peritumoral edema in multiple phase II trials and is FDA approved for the treatment of recurrent glioblastoma (see below). However, two large phase III randomized clinical trials investigating the addition of bevacizumab to the EORTC/NCIC regimen demonstrated no improvement in overall survival.[56,57]

Treatment of Elderly Patients

Approximately one-third of patients with GBM are 65 years or older. Older age has been demonstrated to be an important adverse prognostic factor in GBM. In a population-based survey of 3,298 patients with GBM in Ontario,[144] each decade increase in age has been associated with a reduction in overall survival, with patients older than 70 years having a median survival of 4 to 5 months. In the updated results from the EORTC/NCIC trial, Stupp et al.[122] observed a survival advantage to radiotherapy with concomitant and adjuvant TMZ compared to radiotherapy alone in all age subgroups, including patients >60 years old.

However, because of concerns over the tolerance of conventional chemoradiotherapy for older patients, particularly those with poor performance status, nonconventional approaches to adjuvant therapy have been tested. A phase III ANOCEF group trial observed improved median survival (6.7 vs. 3.9 months) and progression-free survival, but equivalent toxicity, with adjuvant radiotherapy to 50 Gy compared to best supportive care in patients 70 years and older with KPS $\geq$ 70.[145]

Short-course radiotherapy and single-agent TMZ have also been investigated. As described previously, Roa et al. observed no difference between standard radiotherapy of 60 Gy in 30 fractions or a shorter course of 40 Gy in 15 fractions in GBM patients older than 50 years.[146] A more recent European trial compared overall survival between standard radiotherapy (60 Gy in 30 fractions), short-course radiotherapy (34 Gy in 10 fractions), and single-agent TMZ in patients

≥60 years old.[147] This trial demonstrated inferior median survival with 60 Gy radiotherapy versus TMZ in the overall population and inferior median survival with 60 Gy radiotherapy versus short-course radiotherapy in patients >70 years old. TMZ was associated with more grade 3 to 4 toxicity. The NOA-08 phase III trial demonstrated noninferior survival but higher grade 3 to 4 toxicity with 1-week-on/1-week-off TMZ compared to radiotherapy to 54 to 60 Gy in patients ≥65 years old with anaplastic astrocytoma or GBM.[148] These trials also demonstrated that when single modality therapy is being considered because of poor performance status, tolerability concerns, etc., TMZ alone is superior to radiotherapy for the MGMT-methylated patients, but the converse is true for the unmethylated patients.

A Canadian-led phase III trial demonstrated improvement in progression-free and overall survival with the addition of TMZ during and as monthly maintenance doses following short-course radiotherapy (40 Gy in 15 fractions) in elderly (65 years or older) patients with newly diagnosed glioblastoma.[123] Median age of patients was 73 years, and two-thirds were older than 70 years. TMZ prolonged median overall survival from 7.6 months to 9.3 months and increased 1-year survival rate from 22.2% to 37.8%. This survival benefit was most marked in patients with MGMT promoter methylation where median survival was extended from 7.7 to 13.5 months, and for the MGMT-unmethylated patients, the survival difference did not reach statistical significance. Quality of life analyses demonstrated no difference in functional domains but noted more nausea, vomiting, and constipation in patients receiving TMZ. Therefore, in the elderly, and poor performance status, in the absence of statistically significant survival improvement, and the increase in toxicity, the use of TMZ for the unmethylated patient needs to be questioned.

Treatment at Recurrence

Although several therapeutic options have been considered for patients with recurrent GBM, none are curative, and therefore, the management goals should be palliative. Hospice referral for palliative care is reasonable for many patients. Palliative debulking may help selected patients by relieving mass effect and probably extends survival by about 4 to 6 months on average. Based on an impressive radiographic response rate in two nonrandomized, phase II clinical trials,[149,150] single-agent bevacizumab was approved by the FDA in 2009 for the treatment of recurrent glioblastoma. In a study of 49 glioblastoma patients, Kreisl et al.[150] reported objective response rate of 35%, 6-month progression-

free survival of 29%, 3.7 month median progression-free survival, and 7.2 month median overall survival. Similarly, Friedman et al.[149] reported an objective response rate of 28%, 6-month progression-free survival of 43%, median progression-free survival of 4.2 months and median overall survival of 9.2 months in a total of 85 patients. Although approved as a single agent, controversy remains on whether bevacizumab should be combined with a cytotoxic agent as with other solid tumors.

Polymer-based local chemotherapy (carmustine wafers) has been tested in a randomized trial that included 222 patients with recurrent glioma (mostly GBM); survival increased from 44% to 64% at 6 months (P = .02) for patients with GBM, and median survival from 23 to 31 weeks.[53] Systemic chemotherapeutic agents have been tested mostly in the context of clinical trials and have been uniformly disappointing, as have targeted agents with the notable exception of EGFR tyrosine kinase inhibitors in patients with recurrent GBM expressing wild-type PTEN and mutant EGFR.[151] Of 37 patients with recurrent GBM treated with EGFR tyrosine kinase inhibitors at UCLA, there were seven responders, while19 had early progression.[152] Coexpression of mutant EGFR and wild-type PTEN had 86% sensitivity, 89% specificity, and a positive predictive value of 75% for response. The BELOB trial was an open-label phase II trial that randomized patients to single-agent bevacizumab or lomustine versus combination of bevacizumab plus lomustine in recurrent bevacizumab-naïve GBM.[153] This trial demonstrated promising 9-month overall survival of 59% with combination bevacizumab plus lomustine 90 mg/m^2 relative to single-agent bevacizumab (38%) or lomustine (43%). During this trial, lomustine administered in combination with bevacizumab required dose reduction from 110 to 90 mg/m^2 because of severe thrombocytopenia. However, subsequent phase III trial of single-agent lomustine 110 mg/m^2 versus combination bevacizumab and lomustine 90 mg/m^2 for recurrent GBM at time of first progression prolonged PFS but did not confer a survival advantage.[154]

Repeat radiotherapy using one of several different methods (including radiosurgery, brachytherapy, GliaSite balloon brachytherapy, and even repeat external beam radiotherapy) may be considered for carefully selected patients. Hypofractionated re-irradiation with bevacizumab has shown promising results in small single institutional reports, with surprisingly limited toxicity, attributed to “vascular stabilization and protection” resulting from bevacizumab, and more investigations of this approach are being considered.[155] The hypofractionated approach with TMZ and bevacizumab has been extended to the newly diagnosed

setting, and at the Society of Neuro-oncology 2011 meeting, investigators from MSKCC reported median survival in excess of 21 months in a small cohort of unmethylated MGMT GBM patients.[156] A prospective randomized trial of hypofractionated re-irradiation with bevacizumab has completed accrual, and results are pending.

Evidence-Based Treatment Summary

- Maximal surgical resection, although not tested in a prospective trial, is generally recommended to establish pathologic diagnosis, provide tissue for molecular studies, and achieve cytroreduction that may improve neurologic deficits.
- Postoperative radiotherapy has been shown to provide a survival advantage in several clinical trials. The typical radiotherapy dose is 60 Gy in 6 weeks for younger and prognostically favorable patients. Dose escalation beyond 60 Gy has not proven to be effective.
- Temozolomide, given during and after radiotherapy for six cycles, provides a significant survival advantage that is greatest in patients with methylation of the promoter region of the MGMT gene. The benefit in the unmethylated population is questionable. Even elderly patients benefit from this approach.
- Tumor-treating fields administered after radiotherapy and concomitant with high-dose TMZ also prolongs survival.
- Bevacizumab confers no survival benefit for newly diagnosed glioblastoma, but can be an effective salvage therapy at time of progression, although there are no categorical data demonstrating that it prolongs survival in patients with recurrent GBM. It can also be useful in large tumors with significant cerebral edema by improving neurologic disability and sparing prolonged steroids.
- Short-course radiotherapy is a reasonable option for elderly patients or those with poor performance status or transportation limitations.
- If unimodality therapy is being contemplated (especially in sicker patients, less likely to tolerate combination therapy), TMZ alone for the MGMT-methylated and radiotherapy alone for the MGMT unmethylated are reasonable considerations.

Anaplastic Glioma

Anaplastic gliomas (WHO grade III gliomas: anaplastic astrocytoma and anaplastic oligoastrocytoma, Table 38.3) constitute approximately 25% of high-grade gliomas in adults, generally occurring during young to middle adulthood. Histologically, these tumors have increased cellularity, nuclear atypia and

marked mitotic activity, without necrosis or neovascularization. On imaging, anaplastic gliomas may show enhancement and necrosis similar to GBM, although up to one-third of tumors may not enhance.[157]

The prognosis for patients with anaplastic glioma is heavily influenced by a number of molecular genetic factors. Patients with histologically defined anaplastic oligodendroglioma, in general, have a better prognosis. Other prognostic factors include age at diagnosis, mental status, and performance status (see Table 38.4). However, the prognosis of these patients is best defined by molecular factors, such as allelic loss of 1p and 19q and presence of IDH1 mutation (see below). The previously described mixed glioma (anaplastic oligoastrocytoma) is no longer recognized in the 2016 revised WHO criteria.

Anaplastic Oligodendroglioma

Anaplastic oligodendroglioma represents 3.5% of all malignant gliomas and 30% of oligodendroglial tumors. They occur predominantly in adults, with median age at diagnosis of 45 to 50 years, approximately 7 to 9 years older than grade II oligodendroglioma; this age difference reasonably corresponds to the average time of tumor "evolution" from grade II to grade III.

Molecular Genetics

Allelic loss of 1p and 19q is thought to be an early genetic alteration in the transformation and progression of oligodendrogliomas. Combined 1p and 19q deletions have been found in 63% of patients with anaplastic oligodendroglioma and 52% of patients with mixed anaplastic oligoastrocytoma, whereas astrocytic tumors have a lower incidence (8% to 11%) of combined 1p and 19q deletions.[158] Deletions in 1p and 19q have been associated with longer progression-free survival, overall survival, and chemo- and radiosensitivity.[158–160]

The impact of 1p19q codeletion status on outcome has been confirmed in two phase III trials. RTOG 94-02 retrospectively assessed 1p and 19q status in 263/291 enrolled patients (71%) with anaplastic oligodendroglioma/oligoastrocytoma randomized to receive chemotherapy with PCV followed by radiotherapy or radiotherapy alone.[38] Combined loss of 1p and 19q was present in 44% of patients in the PCV plus radiotherapy arm and 52% in the radiotherapy alone arm and was more frequent in anaplastic oligodendroglial tumors (76%) than in anaplastic oligoastrocytoma (24%). Combined loss of 1p and 19q resulted in a longer median survival time (14.7 vs. 2.6 years [$P < .001$]

in patients receiving PCV plus radiotherapy; 7.3 vs. 2.7 years [$P < .001$] in patients radiotherapy alone). In EORTC 26951, 368 patients with anaplastic oligodendroglioma/oligoastrocytoma were randomized to receive radiotherapy followed by PCV or radiotherapy alone.[39] Presence of 1p or 19q loss was found to be the most important predictor of outcome, with a median survival of 10.3 versus 1.9 years for tumors with or without combined allelic loss of 1p and 19q, respectively.

Others molecular factors with clinical implications include somatic mutations in the isocitrate dehydrogenase 1 (IDH1) gene and MGMT promoter methylation. IDH1 mutations have been observed in 55% to 80% of grade II and III gliomas.[161] Though rarely present in primary grade IV gliomas, IDH1 mutations are frequently present in secondary grade IV gliomas that develop from lower-grade tumors, providing a biologic explanation for this clinical categorization.[162] IDH mutations generate an oncometabolite that is believed to be contributory to malignant transformation for precursor cells to gliomas and therefore is an early event. Intriguingly, in spite of the fact that the mutation generates the causative oncometabolite, prospective trials of anaplastic gliomas have demonstrated IDH1 mutations to be a strong positive prognostic factor. In EORTC 26951, IDH1 mutations were observed in 46% of patients and demonstrated prognostic significance, independent of 1p/19q codeletion, in both arms of the trial for both progression-free survival and overall survival.[163] In RTOG 9402, IDH1 mutations were observed in 74% of patients, were associated with longer overall survival (9.4 vs. 5.7 years), and identified patients without 1p19q codeletion who derived an overall survival benefit from the addition of PCV chemotherapy to radiotherapy (5.5 vs. 3.3 years).[164] This suggests that both subgroups, 1p19q codeleted (which almost always harbor IDH mutations), as well as the 1p19q noncodeleted, but with IDH mutations, should be treated with combination chemoradiotherapy, and the third subset, 1p19q noncodeleted without IDH mutations, has the worst prognosis (similar to GBM) and appears unlikely to derive benefit from the addition of chemotherapy. In both the EORTC and RTOG trials, the longest overall survival after PCV chemotherapy plus radiotherapy was observed in patients whose anaplastic oligodendroglial tumors contained both allelic loss of 1p and 19q and IDH1 mutation (overall survival 12.8 years on EORTIC trial, 14.7 years on RTOG 9402). MGMT promoter methylation has also demonstrated prognostic significance for anaplastic oligodendroglial tumors. However, unlike grade IV astrocytoma tumors, in which MGMT promoter methylation predicts survival benefit from TMZ added

to radiotherapy, MGMT promoter methylation has not shown similar predictive significance for outcome to PCV chemotherapy in anaplastic oligodendroglial tumors.[165] This is to be expected because MGMT methylation provides a mechanistic opportunity for TMZ to exert its specific cytotoxicity, and the PCV regimen does not contain TMZ or a drug that creates an identical cytotoxic DNA lesion. A German multicenter phase III trial of up-front radiotherapy versus up-front chemotherapy for newly diagnosed anaplastic gliomas observed IDH1 mutations to be a stronger prognostic factor than either 1p19q codeletion or MGMT promoter hypermethylation.[162] The caveat of course is that both MGMT promoter hypermethylation and IDH1 mutations are strongly correlated with 1p19q chromosomal loss.

Treatment

The current standard of care for patients with anaplastic oligodendrogliomas is maximal surgical resection followed by postoperative radiotherapy and chemotherapy. The radiotherapy target volume includes both the postoperative cavity and any residual enhancing disease, but also the FLAIR or T2 abnormality; unlike the situation with GBM, the postoperative FLAIR abnormality from anaplastic oligodendroglioma (and for that matter low-grade, grade 2 gliomas) most likely represents predominantly residual tumor with minimal contribution from tumor-associated edema and therefore has to be included in the target volume. Indirect support for this comes from the small, but growing body of data regarding supraradical resection of lower grade gliomas, where complete resection of all MR abnormality is associated with longer survival.[166] Although the commonly used radiotherapy dose on prospective trials of anaplastic oligodendroglioma is 59.4 Gy, this never took into account molecular variability, and some have proposed that consideration could be made to lower the RT dose to 54 Gy for tumors with favorable prognostic features as outlined above, to minimize long-term toxicity (e.g., 1p19q codeleted).

Anaplastic oligodendrogliomas are generally thought of as chemosensitive primarily based on high response rates to PCV in several studies. Two large randomized trials, described above, have investigated the use of sequential chemoradiotherapy compared to radiotherapy alone with chemotherapy reserved for salvage in patients with anaplastic oligodendroglioma and oligoastrocytoma.[38,39] With 11-year follow-up on RTOG 9402, the addition of PCV chemotherapy for four cycles prior to radiotherapy did not impact overall survival for the overall cohort, but did prolong overall survival for patients with

allelic loss of both 1p and 19q from 7.7 years to 14.7 years.[38] Among patients without combined allelic loss of 1p and 19q, the addition of PCV chemotherapy prior to radiotherapy prolonged survival for patients with IDH1-mutated tumors from 3.3 to 5.5 years.[164] With 11-year follow-up, the EORTC trial did observe an overall survival prolongation with the addition of PCV for six cycles after radiotherapy in the overall cohort from 2.6 to 3.5 years, with more benefit observed in tumors with combined allelic loss of 1p and 19q.[39] Therefore, currently, it would be prudent to conclude that in practice, both the 1p19q codeleted and any IDH-mutated (with or without 1p19q codeletion) patients should receive chemoradiotherapy, but the role of combinatorial therapy for the 1p19q noncodeleted and IDH wild-type tumors is questionable.

Because of the significant toxicity associated with PCV, many clinicians now use TMZ, which is much better tolerated. TMZ has produced high response rates in patients with anaplastic oligodendroglioma. Chinot et al.[167] administered TMZ to 48 patients with anaplastic oligodendroglioma/oligoastrocytoma who had previously failed PCV chemotherapy. The objective response rate was 43.8% (complete response 16.7%, partial response 27.1%). Vogelbaum et al.[168] reported the results of RTOG 01-31, a phase II trial in which TMZ was given preradiotherapy to newly diagnosed patients with anaplastic oligodendroglioma/oligoastrocytoma. In the 27 patients available for review, the objective response rate was 33.3% (complete response 3.7%, partial response 29.6%). The 6-month-progression rate was 10.3%. Toxicity was acceptable. In a retrospective series from Ducray et al.,[169] up-front temozolomide for patients older than 70 with anaplastic oligodendroglioma or anaplastic oligoastrocytoma demonstrated a median progression-free survival of 6.9 months and median survival of 12.1 months, with improved outcomes in patients with MGMT methylation. Response to temozolomide has also been shown to be significantly associated with loss of 1p in a small retrospective study.[170]

In addition, a recent international retrospective study of over 1,000 adults with anaplastic oligodendroglial tumors observed that combination chemotherapy and radiotherapy was associated with longer time to progression and overall survival than either modality alone.[171] In cases without 1p19q codeletion, Lassman et al. observed that combination chemotherapy and radiotherapy was associated with longer time to progression and overall survival than either modality alone. In cases with 1p19q codeletion, combination chemotherapy and radiotherapy was associated with longer median time to progression compared to either modality alone, but this difference was not

associated with a survival advantage. In addition, longer time to progression was observed with PCV, compared to temozolomide, in codeleted cases. Therefore, although temozolomide is widely used in lieu of PCV, the data supporting this practice are weak at best, and, based on Lassman's retrospective review, possibly deleterious.

Anaplastic Astrocytoma

Molecular Genetics

Anaplastic astrocytomas can be separated into molecular subgroups based on 1p19q codeletion status and IDH mutation status. Anaplastic astrocytoma with 1p19q codeletion and IDH mutation carries the most favorable prognosis, whereas anaplastic astrocytoma without 1p19q codeletion but with IDH mutation carries an intermediate prognosis. IDH wild-type anaplastic astrocytoma carries the worst prognosis, comparable biologically to GBM.[172]

Treatment

The current standard of care for patients with anaplastic oligodendrogliomas is maximal surgical resection followed by postoperative radiotherapy and chemotherapy. The radiotherapy target volume and dose are similar to those for anaplastic oligodendroglioma.

Levin et al. randomized patients with anaplastic gliomas or GBM to receive radiotherapy with adjuvant BCNU or PCV.[173] The use of PCV was found to be associated with an improved outcome in patients with anaplastic glioma. In contrast, a retrospective review of 432 patients with newly diagnosed anaplastic astrocytoma treated with BCNU or PCV on RTOG studies showed no improvement in survival with chemotherapy.[174]

A prospective phase III trial by the United Kingdom Medical Research Council randomized 674 patients of whom 117 (17%) had anaplastic astrocytoma after surgery to radiotherapy alone or radiotherapy followed by PCV.[175] There was no advantage for adjuvant PCV in any subgroup. The median survival of patients with anaplastic astrocytoma, 13 to 15 months, was substantially lower than the median survival of 2 to 3 years reported in previous trials, which has led to debate over the applicability of these results.

Temozolomide has shown activity in patients with recurrent anaplastic astrocytoma. In a phase II trial by Yung et al.[120] 162 patients with anaplastic astrocytoma were treated with temozolomide (150 to 200 mg/m^2/d on days 1 to 5 every 28 days) at first relapse. The 6-month progression-free survival was 46%

and overall survival was 13.6 months. The objective response rate was 35% (complete response 8%, partial response 27%).

The effectiveness of temozolomide was further tested in a phase III trial of non–1p19q-codeleted anaplastic glioma patients (the CATNON Intergroup trial). This trial randomized patients with newly diagnosed anaplastic glioma without 1p19q codeletion to radiotherapy alone versus radiotherapy followed by adjuvant temozolomide for 12 cycles versus radiotherapy concomitant with daily temozolomide and followed by 12 cycles of adjuvant temozolomide. Preliminary results from a planned interim analysis by an independent Data Monitoring Committee demonstrated a prolongation of overall survival with the addition of adjuvant temozolomide with an increase in 5-year survival from 44.1% to 55.9%.[176] MGMT methylation was observed in 42% of patients and was prognostic for overall survival. However, MGMT methylation did not predict for prolonged survival with the addition of adjuvant temozolomide. The impact of concurrent temozolomide and IDH1 mutational status requires further follow-up.

RTOG 9813 was a phase III trial of radiotherapy plus temozolomide versus radiotherapy plus nitrosourea.[172] This study closed early because of inability to meet target accrual rate. However, with median follow-up of 10.1 years, no difference in progression-free or overall survival was observed. However, the radiotherapy plus nitrosurea arm experienced more grade 3 or higher toxicity (76% vs. 48%) primarily because of myelosuppression, which led to discontinuation of therapy in 27.6% in the nitrosurea arm versus none in the temozlomide arm. The trial demonstrated the prognostic benefit of the IDH1 mutation in AA with IDH wild type (7.9 vs. 2.8 years).

The NOA-04 trial compared radiation with two chemotherapy regimens for anaplastic gliomas, the majority of whom carried a diagnosis of anaplastic astrocytoma.[177] In a 2:1:1 randomization, 318 patients were assigned to partial-brain irradiation alone versus PCV versus temozolomide with time to treatment failure as the primary endpoint. Chemotherapy failures were salvaged with radiotherapy, and vice versa, and further, temozolomide failures were salvaged with PCV and vice versa, almost ensuring that every patient received every therapy at some point. Time to treatment failure was similar between each of the arms, as was overall survival, imputing that the sequence of radiotherapy, temozolomide or PCV might not actually matter. This study also helped to establish *IDH1* mutation as an important prognostic factor for anaplastic astrocytoma.

A North American Intergroup trial is currently enrolling patients in order to

compare chemoradiotherapy with either temozolomide or PCV for both grade 3 and grade 2 gliomas.

Evidence-Based Treatment Summary

- Maximal resection, although not tested in a prospective trial, is generally associated with more favorable outcome and is recommended whenever feasible.
- Molecular characterization of the tumor in terms of combined allelic loss of 1p and 19q and IDH mutational analysis carries important prognostic information.
- Postoperative radiotherapy has been shown to provide a survival advantage in several clinical trials. These trials included patients with WHO grade III and IV tumors; no trial for only grade III tumors, evaluating RT versus no RT, has been conducted. The radiotherapy dose is typically 59.4% to 60 Gy in 6 to 6.5 weeks. Although some have proposed that tumors with prognostically favorable molecular features could be treated to a slightly lower dose of 54 Gy in 6 weeks given the potential for extended survival with the addition of chemotherapy and the desire to minimize long-term neurotoxicity.
- In patients with anaplastic oligodendroglioma, the addition of PCV chemotherapy to radiotherapy prolongs overall survival, most notably in patients with combined allelic loss of 1p and 19q, but also in those with IDH mutation. Although temozolomide is frequently used for these patients, there has been no direct comparison between PCV and temozolomide, and limited evidence supports its use.
- In patients with anaplastic astrocytoma, (most without combined allelic loss of 1p and 19q), the addition of adjuvant temozolomide after radiotherapy provides a survival advantage, and IDH retains prognostic significance. The exact role of concurrent temozolomide and the impact of IDH mutational status have not been fully defined. Based on the NOA-04 trial, if all three approaches, i.e., radiation, temozolomide, and PCV are to be used, sequencing may not matter.

Low-Grade Glioma

Low-grade gliomas are generally slower-growing tumors that are divided into pilocytic and nonpilocyitc subtypes. They account for 20% of gliomas and 10% of primary intracranial tumors in adults.

Pilocytic Astrocytoma

Pilocytic astrocytoma, also known as juvenile pilocytic astrocytoma,

corresponds to WHO grade I. They are more common in children. On imaging, they are well circumscribed enhancing lesions, often with a cystic component. Tandem duplication of chromosome 7q34 resulting in fusion of the BRAF and KIAA1549 genes is observed in 60% to 80% of sporadic pilocytic astrocytomas.[178]

Treatment

Pilocytic astrocytomas are more amenable to total resection than other low-grade gliomas. Fenestration of the cyst and resection of the mural nodule are usually curative. In tumors in which the wall of the cyst enhances, cystic degeneration of a larger tumor is more likely, and resection of the entire cyst is necessary. Complete resection of pilocytic astrocytomas is associated with excellent survival, with the majority (>90%) of patients cured of the tumor; no adjuvant therapy is necessary. Incomplete resection is associated with long-term survival rates of 70% to 80% at 10 years.

The benefit of postoperative radiotherapy is unclear. The usual recommendation is for close follow-up following gross or subtotal resection, and utilizing radiotherapy for tumors that have recurred more than once, or for those with considerable residual disease in a critical location, where even slight progression could result in significant morbidity. NCCTG 867251 enrolled 20 patients with supratentorial pilocytic astrocytoma on a prospective trial of radiotherapy after biopsy (3 patients) or observation after gross (11 patients) or subtotal (6 patients) resection.[179] With 20-year follow-up, progression-free survival was 95% and overall survival was 90% with the cause of death in both patients being unrelated to tumor. If radiotherapy is indicated, the dose is typically 50 to 54 Gy (1.8 to 2 Gy fractions). However, there is evidence of improved progression-free survival with RT, and immediate postoperative irradiation may be appropriate in some relatively uncommon cases, depending on the location of the tumor, the extent of residual disease, the feasibility of repeated surgical excision, and availability for follow-up.

The presence of the tandem duplication of chromosome 7q34 resulting in fusion of the BRAF and KIAA1549 genes, observed in 60% to 80% of sporadic pilocytic astrocytomas, has prompted the use of BRAF inhibitors in some of these patients, especially at recurrence, and when other options have been exhausted. Occasional tumor responses have been reported.

Evidence-Based Treatment Summary

- Maximal surgical resection, although not tested in a prospective trial, is associated with more favorable outcome and is recommended whenever feasible. Molecular testing, especially for BRAF should be conducted, if feasible.
- Postoperative radiotherapy may be considered in patients with incompletely resected tumors, based on risk factors for progression and consequences of progression.
- Chemotherapy does not have an established role in pilocytic astrocytoma in adults, but BRAF inhibitors are being used in situations where other options have been exhausted.

Nonpilocytic/Diffusely Infiltrating Gliomas

Nonpilocytic or diffusely infiltrating low-grade gliomas are classified as WHO grade II tumors. They may arise from astrocytic, oligodendrocytic, or mixed lineage. Presentation usually occurs in the third or fourth decade of life and only a small percentage of patients are younger than 19 or older than 65. Approximately 80% of patients present with seizures.[180] CT typically demonstrates an ill-defined, diffuse, nonenhancing low-density region, often in the frontal or temporal lobes. Calcifications are commonly seen with oligodendrogliomas. MRI is more sensitive in detecting and defining these lesions, which are hypointense and nonenhancing on T1-weighted images and hyperintense on T2-weighted images. Because these tumors are highly infiltrative, tumor always extends beyond the abnormality observed on imaging. MR imaging analysis reveals an average growth rate of 5 mm/year.[181]

Histologically, there is increased cellularity compared to normal brain tissue with mild to moderate nuclear pleomorphism and no evidence of mitotic activity, vascular proliferative changes or necrosis. Differentiation from reactive gliosis can be difficult. Histologic subtypes are often identified in low-grade astrocytomas. Fibrillary and protoplasmic subtypes convey no specific prognostic information. Gemistocytic subtypes behave in a fashion more consistent with a malignant glioma.

Several clinical variables have been found to be of prognostic importance. Pignatti et al.[182] performed the most comprehensive of these analyses and constructed a scoring system to identify patients at low and high risk. This trial was based on data from two large European phase III trials for low-grade glioma designed to examine the dose and timing of postoperative radiotherapy, EORTC 22844 and 22845. Cox regression analysis was used to identify prognostic variables from 322 patients from EORTC 22844 and then validated on 288

patients from EORTC 22845. Multivariate analysis showed that age 40 or older, astrocytoma histology, maximum diameter 6 cm or greater, tumor crossing the midline, and presence of neurologic deficits negatively impacted survival. A prognostic scoring system was derived: patients with up to two of these factors were considered low risk (median survival 7.7 years) and patients with three or more, high risk (median survival 3.2 years). However, the data used to identify these prognostic factors predated modern clinical trials evaluating molecular genetics.

Molecular Diagnosis and Prognosis

The 2007 WHO criteria classified tumor subtype based on subjective measures that led to significant interobserver variability and suboptimal diagnostic reproducibility. Recent retrospective molecular analyses of tumors from patients enrolled on randomized clinical trials have identified important molecular alterations with prognostic implications. As described above, this has led to a fundamental shift in tumor classification using a combined histologic-genotype model, as outlined in the 2016 WHO CNS tumor grading system (Table 38.3), which gives priority to genotypic alterations over histologic appearance in order to reduce subjectivity and increase reliability.

The distinction between astrocytoma and oligodenroglioma rests on the detection of combined allelic loss of 1p and 19q, which is characteristic of oligodendroglioma, as well as additional genetic aberrations such as ATRX, TP53, and TERT mutations. 1p19q codeletion is present only with an IDH1 mutation and is the molecular signature with the most favorable overall prognosis. The prior tumor subtype of mixed oligoastrocytoma is no longer considered a distinct entity on the 2016 WHO CNS tumor grading system, as the 1p19q-codeleted and IDH-mutant grade II oligodendroglioma and the IDH-mutant grade II astrocytoma are considered mutually exclusive subtypes. 1p19q-codeleted and IDH-mutant grade II oligodendroglioma, when associated with a TERT mutation, carries a median overall survival of 11 years, whereas IDH-mutant grade II astrocytoma associated with TP53 mutation and ATRX loss carries a median survival of only 6 to 8 years. Low-grade gliomas identified as IDH wild type show clinical behavior similar to high-grade tumors with poor overall survival.[183]

Smith et al.[158] found loss of 1p and 19q in 44% of 52 patients with oligodendrogliomas, of which 34 (65%) were low grade. Combined loss of 1p and 19q was associated with an improved probability of survival, independent of

other factors such as age. Fallon et al.[184] examined 139 tumor samples from 80 patients with primary and recurrent oligodendrogliomas of which 74% were grade II at initial diagnosis. Combined loss of 1p and 19q occurred in 71% of patients, more commonly in pure oligodendrogliomas (75%) than in mixed oligoastrocytomas (39%). Patients with combined loss of 1p and 19q had an overall median survival of 14.9 years compared to 4.7 years for those without 1p and 19q deletions.

Okamota et al.[185] found a similar frequency of loss of 1p and 19q of 70% in patients with low-grade oligodendrogliomas in a population-based study. In a review of 44 cases of low-grade oligodendrocytic tumors, Sasaki et al.[186] considered half of the cases classical oligodendroglioma and the remainder nonclassical oligodendroglioma with more astrocytic features on histopathology. Deletion of 1p was detected in 86% and 27% of these groups, respectively. Response to chemotherapy was assessed at time of recurrence in 13 patients. Of the 11 who responded to chemotherapy, 10 had loss of 1p. Both of the nonresponders were found not to have loss of 1p. A small prospective trial by Hoang-Xuan et al.[187] found a similar trend. Loss of 1p with or without loss of 19q, which was detected in 12/26 patients with low-grade oligodendrocytic tumors treated with temozolomide, was found to have a significant association with response to chemotherapy ($P < .004$).

IDH1 mutations may be predictive of a better prognosis in patients with low-grade gliomas, but this marker does not categorically appear to predict response to chemotherapy, with the caveat that the data testing this are dated and sparse.[188] In one prospective trial of radiotherapy with or without chemotherapy, presence of IDH1 mutation was associated with prolonged median survival from 5.1 years among patients without the mutation to 13.1 years among those with the mutation, when receiving the combined modalities.[189] Promoter methylation of the PTEN gene has been associated with poorer prognosis and a higher likelihood of malignant transformation.[190] Other smaller studies have not shown an association between other molecular findings and chemosensitivity.[191,192]

Unplanned molecular analyses of EORTC 22033-26033 demonstrated prognostic significance associated with molecular characterization.[193] Median PFS was 62 months for IDH-mutated/1p19q-codeleted tumors, 48 months for IDH-mutated/1p19q noncodeleted tumors, and 20 months for IDH wild-type tumors. MGMT promoter was methylated in all patients with IDH-mutated/1p19-codeleted tumors, in 86% of IDH-mutated/1p19q noncodeleted tumors, and 56% of IDH wild-type tumors.

Treatment

The clinical course for patients with diffusely infiltrative low-grade tumors is variable with some patients having long survival even with treatment and others suffering from progressive deterioration despite treatment. In general, early intervention is indicated for almost all patients. Adequate tissue sampling is critical to ensure accurate diagnosis, and maximal surgical resection in this context may be advisable in appropriately selected patients. In younger patients (<40 years) who have undergone complete resection, observation with serial imaging is an option. In those who have undergone a subtotal resection or those with high-risk features, postoperative radiotherapy and chemotherapy is recommended, typically 50 to 54 Gy in 1.8 Gy fractions.

Surgery

Although surgery is considered an integral part of treatment, the goal of surgery and its timing are still debated. In practice, most patients undergo surgery at presentation in order to establish the diagnosis and to determine histology, grade, and molecular characteristics that affect treatment. However, even under the best circumstances, total resection with an adequate margin is rarely achieved because of the diffusely infiltrative nature of these tumors and involvement of eloquent regions. Although controversial, most studies have found total or subtotal (>90%) resection to be associated with improved outcome.[194] Moreover, with the advent of modern MR imaging and intraoperative electrostimulation in the awake craniotomy setting to assist in identifying critical areas of the brain, resection may be achieved with less morbidity and mortality than in the past.[194–196] Proponents of aggressive resection are also supported by studies that suggest that radical surgery results in more accurate histopathologic diagnosis.[197] In RTOG 98-02, 5-year progression-free survival in 111 good risk patients, defined as patient age <40 and gross total tumor resection, was 48%.[198] Review of postoperative MR imaging demonstrated crude recurrence rates of 26%, 68%, and 89% for <1, 1 to 2 and >2 cm residual disease, respectively.

Radiotherapy

Three recent phase III trials provide the best evidence with respect to the indications for radiotherapy as well as the dose (Table 38.5).

Patients considered favorable by the scoring system introduced by Pignatti et al.[182] are typically observed postoperatively and given radiotherapy at disease progression or recurrence. This practice is based on the results of a phase III trial

by van den Bent et al. in EORTC 22845.[199] In this multi-institutional trial, 314 patients with low-grade gliomas were randomized to receive postoperative radiotherapy to 54 Gy in fractions of 1.8 Gy (n = 157) or radiotherapy at progression (n = 157). A significant improvement in median progression-free survival was found with early radiotherapy, 5.3 versus 3.4 years (P < .0001), but there was no difference in median survival, 7.4 versus 7.2 years (P = .872). It is of note that only 65% the patients in the delayed radiotherapy group received radiotherapy at progression. Malignant transformation occurred in 65% to 72% of patients with no difference between the two groups. Although seizure control was superior in the early radiotherapy group, adequate data on quality of life were not obtained. The authors concluded that although early radiotherapy may be appropriate in some situations, for example, patients with symptomatic lesions, withholding radiotherapy until tumor progression does not jeopardize survival.

TABLE 38.5 PHASE III TRIALS OF PATIENTS WITH LOW-GRADE GLIOMA TREATED WITH RADIOTHERAPY

Study (Reference)	Treatment Arm	*N*	5-Year Survival (%)
EORTC 22845	Observation[a]	157	66
	54 Gy (30 fractions)	157	68
EORTC 22844	45 Gy (25 fractions)	171	58
	59.4 Gy (33 fractions)	172	59
NCCTG	50.4 (28 fractions)	101	72
RTOG 9802 (age ≥40 or STR)	64.8 (36 fractions)	102	64
	54 Gy (30 fractions)	128	63
	54 Gy plus PCV	126	72

[a]Treatment with radiotherapy at progression.
CCNU, vincristine; EORTC, European Organization for Research and Treatment of Cancer; *N*, number of patients; NCCTG, North Central Cancer Treatment Group; PCV, procarbazine; RTOG, Radiation Therapy Oncology Group; TMZ, temozolomide.

For patients given radiotherapy postoperatively, the dose has been established by 2 phase III trials. In EORTC 22844 379, patients were randomized to receive 45 Gy in 5 weeks or 59.4 Gy in 6.6 weeks postoperatively.[200] With a median follow-up of 74 months, overall survival (58% vs. 59%) and progression-free survival (47% vs. 50%) were similar in both arms.

In a joint North Central Cancer Treatment Group (NCCTG), RTOG, and ECOG study, 203 patients were randomized to low-dose radiotherapy to 50.4 Gy

in 28 fractions (n = 101) or high-dose radiotherapy to 64.8 Gy in 36 fractions.[201] There was no significant difference in progression-free survival or overall survival. Survival at 2 and 5 years was 94% and 72%, respectively, with low-dose radiotherapy and 85% and 64% with high-dose radiotherapy. Grade 3 to 5 neurotoxicity occurred in 5% of patients in the high-dose cohort and 2.5% of patients in the low-dose cohort.

Consequently low-dose radiotherapy, 50 to 54 Gy in 1.8 Gy fractions, is the standard of care for patients with low-grade gliomas. The target volume is local, with a margin of 2 cm beyond changes demonstrated on traditional MRI sequences. Using FLAIR images, which usually show abnormality beyond any enhancing or nonenhancing tumor, a smaller margin of 0.8 to 1 cm may be used.

However, this concept of dose will likely need to be revisited in light of the fact that it might be possible to decrease dose (to say 45 Gy) in the most favorable subset (1p19q codeleted, IDH mutated), but increase it (to say 59.4 Gy) in the most unfavorable subset (IDH wild type).

Chemotherapy

Multiagent chemotherapy, in particular PCV, appears promising with response rates ranging from 50 to 80% in recurrent and newly diagnosed tumors.[191,192] The publication of mature results from RTOG 9802 has significantly altered the standard of care, as the addition of PCV to radiotherapy provided a significant overall survival advantage.[189] In this phase III trial, 254 unfavorable patients (age 40 or greater with subtotal resection or biopsy) were randomized to receive radiotherapy alone to 54 Gy in 30 fractions or radiotherapy followed by six cycles of standard-dose PCV. With a median follow-up of 11.9 years, median overall survival was extended from 7.8 years following radiotherapy alone to 13.3 years following radiotherapy plus chemotherapy, and 10-year overall survival was increased from 40% with radiotherapy alone to 60% following radiotherapy plus chemotherapy. The superiority of radiotherapy plus chemotherapy over radiotherapy alone was observed with all histologic subtypes, although the difference did not reach statistical significance among patients with astrocytoma. Patients with IDH1-mutated tumors had longer survival with the addition of chemotherapy to radiotherapy. The number of events in patients with IDH1 wild-type tumors was too small to evaluate treatment effect in this subgroup. Acute grade 3 or 4 toxicity occurred in 67% of patients who received radiotherapy plus PCV as compared with 9% of patients who received radiotherapy alone.

Temozolomide has been shown to have activity in phase II trials in newly diagnosed and recurrent low-grade gliomas.[187,202–204] RTOG 0424[205] was a phase II study of patients diagnosed with low-grade glioma with three or more risk factors for recurrence as established by the aforementioned EORTC Cog regression analysis, reported by Pignatti and colleagues[182]: (1) age ≥ 40, (2) astrocytoma histology, (3) bihemispherical tumor, (4) preoperative tumor diameter ≥6 cm, and (5) preoperative neurologic function status >1. In this study, patients were treated with radiotherapy to 54 Gy in 30 fractions with concurrent and adjuvant temozolomide for 12 cycles. With median follow-up of 4.1 years, 3-year overall survival was 73%, which was significantly improved relative to the 54% rate derived from the prespecified historical control. Median survival time had not yet been reached. Three-year PFS was 59%. Grade 3 or higher toxicities were increased from 10% to 43% with the addition of temozolomide.

Prior to the publication of the mature results of RTOG 9802, a number of efforts to exclude or delay radiotherapy in the management of low-grade glioma, based on the expectation of equivalent results from the use of temozolomide were undertaken.

EORTC 22033-26033 was a phase III intergroup trial that randomized 477 patients to either dose-dense temozolomide (75 mg/m^2 once daily for 21 days, repeated every 28 days (one cycle) for maximum of 12 cycles) or radiotherapy (50.4 Gy in 28 fractions) with low-grade glioma and at least one of the following high-risk features: (1) age ≥40, (2) progressive disease, (3) tumor size >5 cm, tumor crossing midline, or neurologic symptoms.[193] The primary endpoint was PFS, with the study powered to demonstrate a prolongation in PFS with the use of dose-dense temozolomide as opposed to radiotherapy. The study observed no difference in PFS with median PFS of 46 months following radiotherapy and 39 months following temozolomide. Unplanned analyses demonstrated improved PFS with radiotherapy relative to temozolomide for IDH-mutated, 1p19q noncodeleted tumors (55 vs. 36 months). Other molecular subgroups did not show treatment-related differences, although patient numbers in this unplanned analysis were small. Temozolomide was associated with higher grade 3 to 4 hematologic toxicity (9% vs. <1%) and more grade 3 to 4 infections (3% vs. 1%). With median follow-up of 3 years, no difference between health-related quality of life, assessed using the EORTC patient-reported questionnaires, and cognitive function, as assessed by the Mini-Mental Status Examination, was observed.[206] This trial, at least based on the results available to date, does not support the use of up-front temozolomide and deferral of radiotherapy for WHO

grade II gliomas. Similarly, a prospective single-institution trial of 120 patients with WHO grade II gliomas proactively treated with up-front temozolomide, and deferral of radiotherapy demonstrated median survival of 9.7 years, considerably inferior to the 13.3 years noted on the chemoradiotherapy arm of RTOG 9802.[207] These data therefore should suffice to detract from the practice of radiotherapy deferral for these patients, outside the clinical trial context.[193,206]

Evidence-Based Treatment Summary

- Maximal surgical resection, although not tested in a prospective trial, is generally associated with more favorable outcome and is recommended whenever feasible.
- Molecular analysis of resected tumors for 1p19q codeletion, IDH1 mutation, and MGMT promoter methylation, as well as other genetic aberrations such as TP53, TERT, and ATRX, provides important prognostic information that complements known clinical risk factors and may aid in treatment decision-making; these should be obtained whenever feasible.
- Postoperative radiotherapy has not been shown to provide a survival advantage in the only clinical trial testing this question, although progression-free survival and seizure control were superior. The typical radiotherapy dose is 45 to 54 Gy; randomized trials do not show a survival advantage with higher doses, but dose-tailoring based on molecular features has not been tested and could be considered in future trials. In fact, based on the longevity of patients with favorable features, other attempts to reduce radiotherapy-related toxicity should also be considered, and in that vein, NRG Oncology has launched a randomized trial testing protons versus photons for grade 2 gliomas.
- In a practice-changing phase III trial, the addition of PCV chemotherapy to radiotherapy significantly lengthened overall survival in patients with subtotally resected tumors or whose age was 40 or higher. The addition of temozolomide to radiotherapy has also improved survival in high-risk tumors relative to historical control data, but these data do not approach level 1. A randomized trial comparing temozolomide radiotherapy to PCV with radiotherapy is underway.
- The substitution of radiotherapy with dose-dense temozolomide in high-risk tumors does not provide a PFS benefit, significantly augments hematologic toxicities, and does not impact long-term cognitive functioning or patient-reported quality of life. In IDH-mutated/1p19q noncodeleted tumors, radiotherapy is associated with improved PFS relative to dose-dense temozolomide. Retrospective comparison to a large multi-institutional

experience raises concern about possible survival degradation when radiotherapy is deferred.

Gliomatosis Cerebri

Gliomatosis cerebri is a rare condition with diffuse involvement of multiple parts of the brain (greater than two lobes), frequent bilateral growth and regular infratentorial extension. This entity has been removed from the 2016 revision of the WHO classification of CNS tumors but is instead considered a special pattern of spread of diffuse glioma subtypes, and therefore, obtaining tissue and performing molecular analysis is strongly recommended.[16] On MRI, there is typically diffuse increased signal on T2-weighted and FLAIR images and low or absent signal in the affected areas on T1-weighted images.

Treatment choices remain limited. Perkins et al.[208] reviewed the treatment outcomes of 30 patients with gliomatosis cerebri treated with radiotherapy. Transient radiographic improvement or disease stabilization was achieved in 87% of patients with clinical improvement observed in 70%. Patients younger than 40 and those with nonglioblastoma histology had significantly improved overall survival.

In a French study, 63 patients with gliomatosis cerebri were treated initially with PCV or temozolomide.[209] Objective responses were observed in 33% of patients and radiologic responses in 26% with no significant difference between the two regimens. Median progression-free survival and overall survival were 16 and 29 months, respectively. Regardless of regimen, patients with an oligodendroglial component had significantly better outcomes in terms of progression-free and overall survival.

A recent German phase II trial treated 35 gliomatosis cerebri patients with procarbazine and lomustine.[210] Median progression-free survival was 14 months, and median overall survival was 30 months. Twelve patients received salvage radiotherapy at progression. IDH1 mutation was a strong independent prognostic factor.

A retrospective review of 296 patients with gliomatosis cerebri from the literature (n = 206) and the Association des Neuro-Oncologues d'Expression Francaise (ANOCEF) network (n = 90) demonstrated median survival of 14.5 months.[211] Patients younger than 42, with better KPS, low-grade histology, or oligodendroglial subtype, had better outcomes. The impact of radiotherapy on survival remained unclear.

Evidence-Based Treatment Summary

- Maximal surgical resection is not an achievable goal.
- Radiotherapy is considered the standard, but no trials have validated its role. Dose remains ill defined.
- The role of chemotherapy remains ill defined.
- In the absence of definitive data, our recommendation is therefore to treat based on histopathologic and molecular features; one such strategy includes the following:
    a. Non-GBM, IDH mutated, (grade 2 or 3): treat all visible tumor to 45 Gy with concurrent and adjuvant temozolomide.
    b. Non-GBM, IDH wild type, (grade 2 or 3): evaluate for MGMT status; if methylated, treat all visible tumor to at least 45 Gy (and consider possible focal boosting to 54 to 59.4 Gy), with concurrent and adjuvant temozolomide; if unmethylated, substitute PCV for temozolomide.
    c. GBM: if MGMT unmethylated, RT alone, and if methylated, temozolomide alone; consider adding RT for methylated patients if performance status is high, or there is significant tumor response to temozolomide.

Adult Brainstem Glioma

Brainstem gliomas account for 15% of all pediatric brain tumors but can occur in adults.[212] They can be divided into several distinct types. Diffuse midline glioma is a narrowly defined but phenotypically and molecularly distinct tumor that is characterized by K27M mutations in the histone H3 gene *HeF3A*, or less commonly in the related *HIST1H3B* gene, occurring primarily in children (but sometimes in adults), with a diffuse growth pattern and midline location (e.g., thalamus, brainstem, and spinal cord).[213,214] This entity was newly defined in the 2016 revision to the WHO classification system and includes tumors previously referred to as diffuse intrinsic pontine glioma (DIPG).[16] Although these tumors are associated with poor prognosis, their distinct molecular characteristic provides rationale for future targeted therapies.

Diffuse midline gliomas can have diverse imaging appearances, ranging from expansile masses without enhancement or necrosis to peripherally enhancing masses with central necrosis but little surrounding T2/FLAIR abnormality.[215] In contrast, focal, dorsally exophytic or cervicomedullary tumors can be low grade and have a much better prognosis, especially when found in the context of neurofibromatosis. In addition, enhancement, particularly in a focal lesion, may

suggest a juvenile pilocytic astrocytoma rather than a high-grade glioma. Although rare, other aggressive tumors such as PNETs and atypical teratoid-rhabdoid tumors can occur in the brainstem.[216,217] Nonneoplastic processes that may be confused with a primary brainstem tumor include neurofibromatosis, demyelinating diseases, arteriovenous malformations, abscess, and encephalitis.

Treatment

Corticosteroids may be necessary to manage neurologic symptoms until treatment is instituted. Patients with hydrocephalus may require placement of a ventriculoperitoneal shunt. The approach to treatment should be based on the type of brainstem glioma as determined by both the clinical presentation and radiographic findings. Surgery is the treatment of choice for operable lesions (i.e., accessible focal tumors, dorsally exophytic and cervicomedullary tumors). For low-grade tumors amenable to surgical resection, as in other low-grade gliomas, the role of postoperative radiotherapy is controversial and many would advocate close observation. For unresectable low-grade tumors radiotherapy should be delivered using volumes and doses as for low-grade gliomas in other locations.

Involved field radiotherapy is the primary treatment for infiltrating pontine gliomas. The GTV is usually best defined using T2-weighted or FLAIR MRI. A margin of 1 to 1.5 cm is added to create a CTV and further expanded by 0.3 to 0.5 cm to create a PTV. Margins may not need to be uniform in all directions, particularly where bone limits tumor extension. These lesions should be treated with doses on the order of 55.8 to 60 Gy using daily fractions of 1.8 to 2.0 Gy/day. Although radiotherapy provides short-term benefits, long-term results have remained dismal. There is no benefit from radiotherapy dose-escalation. Chemotherapy has no established role. Chapter 82 provides more details as most data on intrinsic pontine gliomas come from pediatric trials.

Fewer data exist with respect to brainstem glioma in adults, but there is some evidence that these tumors may be less aggressive in adults, with overall survival that ranges from 45% to 66% at 2 to 5 years, perhaps because of a greater frequency of more favorable tumor types.[218] Kesari et al.[219] published a series of 101 adults with brainstem gliomas and observed 5- and 10-year overall survival rates of 58% and 41%, respectively. Of 24 candidate factors, they observed prognostic significance associated with ethnicity, tumor location, age of diagnosis and tumor grade. In the series from ANOCEF, 48 adult patients with brainstem gliomas were grouped on the basis of their clinical, radiologic, and

histologic features.[220] Nearly half had nonenhancing diffusely infiltrative tumors and had symptoms that were present for more than 3 months. Eleven of these 22 patients underwent biopsy, and nine had low-grade histology. Nearly all underwent radiotherapy and had a median survival of 7.3 years. A second group of 15 patients who had presented with rapid progression of symptoms and had contrast enhancement on MRI were described. Fourteen of these patients underwent biopsy and anaplasia was identified in all 14 specimens. Despite radiotherapy, the median survival in this group was 11.2 months, which approximates the survival in pediatric series.

Evidence-Based Treatment Summary

- Surgical resection is indicated for patients with favorable tumor types (based mostly on location) but is not an achievable goal in patients with intrinsic pontine gliomas; however, obtaining tissue is strongly recommended, and molecular testing should be considered.
- The H3 K27M mutation defines a phenotypically and molecularly distinct tumor, called diffuse midline glioma, occurring in midline location and associated with an especially poor prognosis; however, this maybe a targetable driver mutation. Gliomas with diffuse growth pattern and midline location should be tested for H3 K27M mutation.
- For diffuse midline gliomas, radiotherapy is considered the standard. The addition of chemotherapy remains undefined.

Ependymoma

Ependymoma accounts for only 1.8% of all adult brain tumors.[2] Rosette formation is a hallmark of ependymoma on pathologic specimens. WHO grade I ependymomas, including myxopapillary ependymoma, typically occur in the spine, and subependymoma.[16] In adults, the subependymomas, which are mostly intracranial, have favorable clinical outcomes. Ependymomas are otherwise divided between WHO grade II and III (anaplastic), with the latter showing increased mitotic activity, tumor necrosis, and microvascular proliferation suggests a diagnosis of anaplastic ependymoma. Unlike pediatric ependymomas, which largely arise intracranially, 75% of ependymomas in the adult population arise in the spinal canal. Spinal ependymomas typically present with sensory deficits. Ependymomas may expand locally, extend along ependymal spaces, and occasionally disseminate through the CSF. However, the predominant pattern of relapse is local, even when anaplasia is present.[221–226]

Posterior fossa and supratentorial ependymoma are biologically different tumors but are both treated with surgery and radiotherapy. In a recent international collaborative study,[227] nine molecular subgroups of ependymoma were identified, three in each anatomic compartment: spine (SP), posterior fossa (PF), and supratentorial (ST) region. In each compartment, one molecular subgroup of WHO grade I subependymoma (ST-SE, PF-SE, and SP-SE) was observed, occurring in adults only. In the spine, the two other molecular subgroups matched the histopathologic diagnoses of myxopapillary ependymoma (SP-MPE) and WHO grade II and III ependymoma (SP-EPN). In the posterior fossa, the remaining two molecular subtypes were classified as PF-EPN-A and PF-EPN-B. PF-EPN-A occurs primarily in infants and young children (but is observed in 11% of adult patients) and because of its predominately lateral location can be difficult to completely resect and thus is associated with high relapse rates.[228] PF-EPN-B occurs primarily in older children and adults and is associated with more favorable prognosis. More than 70% of supratentorial ependymomas are characterized by fusions between *C11ORF95* and *RELA* genes.[229] Termed ST-EPN-RELA tumors, these ependymomas are can occur in both adults and children and are recognized as a distinct molecular entity by the 2016 revision of the WHO classification system. The remaining supratentorial tumors harbor fusions to the oncogene *YAP1* and have a highly favorable prognosis.

Treatment

Maximal surgical resection, including second surgery if necessary, is the initial treatment for ependymoma. Surgery alone may be sufficient in selected patients based on the results of pediatric series described in Chapter 82. However, the standard of care for most adults is postoperative irradiation. There appears to be a radiation dose response with improved tumor control with doses >50 Gy and doses of 54 to 59.4 Gy are typically prescribed. Radiation dose for spinal ependymomas can be limited by spinal cord tolerance. At 1.8 to 2 Gy/fraction, the estimated risk of radiation myelopathy is <1% at 54 Gy and <10% at 61 Gy.[230]

Historically, for posterior fossa tumors, the entire posterior fossa has been irradiated. However, Paulino[231] has shown that the pattern of failure to be “local,” i.e., within the tumor bed itself. In nine patients who received radiation therapy to the tumor bed plus a 2 cm margin, the two failures in this group were within the tumor bed (i.e., there were no failures within the posterior fossa

outside the tumor bed). For most patients, a more usual volume now consists of the tumor bed and any residual disease (GTV) plus an anatomically defined margin of 1 to 1.5 cm to create a CTV. Larger margins may be required in areas of infiltration, and special attention must be paid to areas of spread along the cervical spine because 10% to 30% of fourth ventricular tumors extend down through the foramen magnum to the upper cervical spine.[225,232] Radiotherapy field size for spinal ependymomas commonly includes two cranial and two caudal vertebral bodies. Lumbosacral or sacral ependymomas should include coverage of nerve roots with the caudal border extending to S4/S5 and lateral borders extending to the sacroiliac joints.

In the past, CSI was recommended for patients with high-grade and infratentorial tumors who were believed to be at an increased risk of CSF spread.[223] Modern series document that local recurrence is the primary pattern of failure and that the incidence of isolated spinal relapses is low even among the highest-risk patients, with the majority of spinal failures associated with local recurrences.[221,224] As a result, the current recommendation for patients with ependymomas is limited-field radiation if the spinal MRI scan and CSF cytology are negative. Patients with neuraxis spread (positive MRI or positive CSF cytology) should receive CSI (36 Gy) with boosts to the areas of gross disease and to the primary tumor to total doses of 50 to 59.4 Gy. One exception is spinal myxopapillary ependymomas (WHO grade I), where MR evidence of neuraxis spread can be treated with focal radiotherapy, rather than CSI.

Chemotherapy has not been proven useful in ependymoma. Randomized trials of chemotherapy in the pediatric population have failed to identify a clinically useful benefit relative to radiotherapy,[233] although a study of neoadjuvant chemotherapy to permit second-look surgery for subtotally resected tumors remains ongoing.

Results of Treatment

In modern series that utilized mostly local fields for patients with nondisseminated disease 5-year survival is on the order of 70%.[223,232,234–237]

Several authors have attempted to identify variables associated with improved outcome in adults. Ferrante et al.[235] analyzed 20 patients with fourth ventricle ependymomas. The 5-year survival rate in patients older than 16 years was 60%. The use of postoperative irradiation was associated with a markedly improved 5-year survival of 68% versus 18% without radiotherapy ($P = .011$).

Reni et al.[238] reported on a series of 70 adult intracranial ependymomas and

observed 5-year overall and progression-free survival rates of 67% and 43%, respectively. Older age and supratentorial location were poor prognostic factors, and the use of postoperative radiotherapy was associated with improved progression-free survival and a trend toward improved overall survival.

Metellus et al.[239] evaluated 114 adult patients with intracranial ependymoma and observed incomplete resection and supratentorial location to be significant predictors of recurrence and poor survival. For incompletely resetected tumors, postoperative radiotherapy improved both overall and progression-free survival. In a study of spinal myxopapillary ependymomas from the Rare Cancer Network,[240] use of postoperative radiotherapy was an independent predictor of progression-free survival.

A retrospective study of 23 adult patients with supratentorial ependymomas treated at Columbia-Presbyterian Medical Center with a variety of radiotherapy field sizes and doses (including SRS) showed a 5-year survival rate of 100% for hemispheric tumors and 73% for third ventricular tumors.[237] Of interest, six patients with low-grade tumors did not receive postoperative irradiation. Five remained free of recurrence during a mean follow-up period of 69 months.

Five-year survival was 62% for a French series of 34 adult patients with ependymoma, 17 of whom had anaplastic histology.[241] Gross total resection was performed in 27 patients. Half of the 34 patients were irradiated; 13 of these received local fields to a mean dose of 56 Gy. Univariate analysis showed that anaplasia and location in the brain parenchyma predicted for poor outcome.

Evidence-Based Treatment Summary

- Maximal surgical resection should be performed when feasible.
- Postoperative radiotherapy is considered the standard, but no prospective trials have validated its role. CSI is used only in patients with disseminated disease.
- The role of chemotherapy remains to be defined.

Medulloblastoma

Medulloblastoma is a relatively rare tumor in adults with an incidence of 0.5 per 100,000.[2,242] The majority arise in the 20- to 40-year age group. Adult medulloblastomas are more frequently located laterally than those in childhood (50% vs. 10%), and are more frequently desmoplastic.[243] In addition, the incidence of severe anaplasia is lower than in the pediatric population.[244] Medulloblastoma is a densely cellular tumor with small, darkly staining ovoid cells with hyperchromatic nuclei and frequent mitoses. Homer Wright rosettes

(clustered cells surrounding a central eosinophilic core) are characteristic. CSF dissemination may manifest as positive cytology or macroscopic seeding of the subarachnoid space and is not uncommon. Systemic spread is seen in approximately 5% of patients, mostly to bone and bone marrow. Shunt procedures have been suggested as a cause, although modern series dispute this.[245]

In children, adverse prognostic factors include male gender and age <3 years.[246] Patients with total or near-total resections fare better than those with subtotal resection or biopsy only, and residual tumor >1.5 cm^2 on postoperative scans is an adverse prognostic factor. Patients with CSF spread have a worse prognosis. Patients are classified as "average risk" if there is <1.5 cm^2 residual tumor and no dissemination; patients with >1.5 cm^2 residual and/or dissemination are considered "high risk."

Molecular analyses have identified four distinct subgroups that have now been defined in the 2016 revision to the WHO classification system.[16,247] WNT tumors most frequently occur in late childhood and adolescence, are rarely metastatic, and have a favorable prognosis regardless of metastatic status. Most WNT tumors display classic medulloblastoma histology and nuclear localization of CTNNB1 (β-catenin), as detected by immunohistochemical staining.[248] Ongoing research has focused on therapeutic de-escalation for this favorable subtype, although prognosis of WNT tumors is worse in adults, relative to pediatric patients.[249] SHH tumors account for most of the infant and adult medulloblastomas and are rare in children. SHH tumors are typically found within the cerebellar hemispheres and have an intermediate prognosis. All nodular desmoplastic medulloblastomas can be characterized as SHH subgroup.[250] Non-WNT and non-SHH tumors are classified as group 3 or 4. Although there can be considerable overlap between these groups, group 3 tumors have characteristically poor prognosis. Group 3 tumors affect mostly infants and children, are rare in adults, commonly present with metastases, and are characterized by MYC amplification. Group 4 tumors can affect patients of all ages.

Treatment

All patients with nondisseminated medulloblastoma should undergo complete resection if feasible. In cases where extension into the brainstem precludes complete resection without significant morbidity, there is no benefit to complete surgical resection as compared to near-total resection.[251]

In general, the treatment guidelines for pediatric medulloblastoma detailed in Chapter 82 should probably be followed. Postoperative radiotherapy should begin within 28 to 31 days following surgical resection whenever possible. Radiotherapy is delivered to the entire craniospinal axis followed by a boost to the tumor bed for average-risk patients and to the posterior fossa and gross metastatic disease for high-risk patients. Although there may be less concern over long-term toxicity of full-dose CSI in adults as compared with children, adults treated for medulloblastoma with a mean dose to the whole brain of 35 Gy have been shown to have long-term cognitive deficits.[252] It may be reasonable to extrapolate from the pediatric experience and to treat healthy young adults with average-risk disease with reduced-dose CSI (23.4 Gy) as long as appropriate multiagent chemotherapy is administered. For average-risk patients, boost to the tumor bed plus a 1.5 cm margin as opposed to whole posterior fossa) to 54 Gy is associated with equivalent event-free survival outcomes, although reduction in CSI to 18 Gy (as opposed to 23.4 Gy) leads to inferior event-free survival.[253] Full-dose CSI (36 Gy) should be delivered in the setting of high-risk disease. This is then followed by a boost to the posterior fossa. Intracranial and spinal metastases should be boosted as well to total doses on the order of 45 to 50 Gy for spinal metastases and 50 to 54 Gy for intracranial metastases. Treatment is usually delivered at 1.8 Gy/day.

The role of adjuvant chemotherapy in children with medulloblastoma is well established but remains unclear in adults. A series of 32 adults with medulloblastoma from Germany has shown a nonsignificant trend to prolonged survival with adjuvant chemotherapy.[254] However, preliminary results from NOA-07 a prospective trial of chemoradiotherapy for adult medulloblastoma demonstrated favorable event-free survival rate of 67%.[255] Ability to complete at least four cycles of adjuvant chemotherapy was dependent on age, with leukopenia being the most common toxicity. The use of proton therapy has been associated with a meaningful reduction in hematologic and gastrointestinal toxicity and should be considered when feasible for adult medulloblastoma.[63]

Evidence-Based Treatment Summary

- Molecular classification has identified four distinct subtypes: WNT, SHH, group 3 and group 4.
- Maximal surgical resection should be performed, where feasible.
- Standard treatment consists of postoperative radiotherapy to the craniospinal axis followed by a boost to the tumor bed for average-risk disease and to the

posterior fossa and any intracranial/spinal metastases for high-risk disease.

- The use of chemotherapy generally follows the pediatric indications and guidelines.

Primary Central Nervous System Lymphoma

Primary central nervous system lymphoma (PCNSL) is a non-Hodgkin lymphoma that is restricted to the central nervous system (brain, spinal cord, meninges, and eye) and accounts for <3% of primary intracranial malignancies. It occurs in two distinct patient populations: immunocompromised (HIV, posttransplant, etc.) and immunocompetent. Immunodeficiency is the only known risk factor. Immunocompetent patients present typically in the sixth and seventh decades of life, whereas immunosuppressed individuals more commonly present in the third and fourth decades of life.

The majority of PCNSLs are B-cell lymphomas of intermediate or high grade that are indistinguishable from high-grade non-Hodgkin lymphomas occurring elsewhere in the body. In immunocompetent patients, PCNSL typically presents with one or multifocal (in 30%) mass lesions primarily located in the frontal lobes, corpus callosum, and deep periventricular brain structures. Although the lesions appear focal, diffuse involvement of the parenchyma is invariably present. As a consequence of this deep localization, patients usually present with cognitive dysfunction or personality change. Other symptoms include headache or focal neurologic dysfunction such as hemiparesis or hemisensory loss; seizures are rare. Symptoms often progress over weeks to months before a diagnosis is made.

On MRI, PCNSL is hypointense on T1 and hypointense to isointense on T2/FLAIR sequences with variable surrounding edema. There is usually homogenous enhancement with IV contrast. Ring enhancement is uncommon, except in immunocompromised patients. The appearance on T2 sequences and lack of central necrosis help differentiate PCNSL from glioma.

Even with the “classic” imaging appearance, histology is essential for diagnosis. If PCNSL is suspected, stereotactic biopsy is the best approach; extensive resection does not improve survival. Corticosteroids should be held at presentation unless absolutely necessary (e.g., impending brain herniation) because their “lytic” effect on lymphoma may lead to a false-negative biopsy. Once a diagnosis of PCNSL is established, an extent of disease workup is required. At diagnosis of PCNSL, ocular disease is present in 20% (often misdiagnosed as idiopathic uveitis) and demonstrable leptomeningeal disease is

present in 25% (usually asymptomatic until late). A complete staging workup consists of contrast-enhanced brain MR, lumbar puncture (for CSF cytology, flow cytometry, and Epstein-Barr virus PCR), slit-lamp ocular exam (to look for intraocular lymphoma), HIV serology, and contrast-enhanced spine MRI. Systemic staging (body CT, bone marrow biopsy) is rarely positive in patients with typical findings of CNS lymphoma but should be performed if systemic symptoms are present (weight loss, night sweats, fever).

Age and performance status are the most important prognostic factors. A RPA analysis of 338 patients at Memorial Sloan-Kettering Cancer Center led to the identification of three RPA classes: class I (age <50) was associated with median survival of 8.5 years; class II (age >50 and KPS ≥ 70) 3.2 years; and, class III (age >50 and KPS < 70) 1.1 years.[256] The International Extranodal Lymphoma Study Group evaluated 378 patients and observed age >60, ECOG >1, elevated LDH, high CSF protein and deep regions of the brain as prognostic.[257]

Molecular analyses have identified activating mutations in MYD88 and CD79B in PCNSL, which are important in the Bruton tyrosine kinase (BTK) pathway.[258] BTK integrates B-cell antigen receptor (BCR) and Toll-like receptor (TLR) signaling. Diffuse large B-cell lymphomas (DLBCL), which includes PCNSL, frequently harbor mutations in genes encoding members of the BTK pathway. These include the BCR-associated protein CD79B and myeloid differentiation primary response 88 (MYD88), a cytosolic adapter protein that links interleukin-1 and TLRs with the Nuclear factor kappa B (NF-κB).

Treatment

The role of surgery is limited to establishing the tissue diagnosis. This is best achieved by stereotactic biopsy; extensive tumor resection offers no survival benefit. Because PCNSL often responds dramatically to corticosteroid therapy, corticosteroids should be avoided unless absolutely necessary until after tissue is obtained.

PCNSL is exquisitely sensitive to radiotherapy and chemotherapy. Although never studied in a prospective fashion, WBRT is thought to be more effective than focal radiotherapy because of the extensive infiltration of lymphoma throughout the brain. The optimal dose is 45 to 50 Gy, and there is no benefit of adding a boost to the tumor site. With WBRT alone, median survival is 12 to 18 months and the five-year survival rate is only 4%.

The standard systemic lymphoma chemotherapy regimens are ineffective for PCNSL, as demonstrated in prospective clinical trials.[259–261] High-dose systemic

methotrexate, administered at a high dose (1 to 8 g/m^2) and at a rapid rate of infusion to overcome the blood–brain barrier, is the only agent that has demonstrated improved survival over WBRT alone. A recent randomized phase II study suggests that combination chemotherapy with methotrexate results in superior disease control and survival as compared to single-agent methotrexate.[262] High-dose methotrexate regimens produce adequate levels of drug in the CSF so that direct instillation of chemotherapy (e.g., using an Ommaya reservoir) into the CSF is not necessary, unless CSF cytology is positive.[263]

Whole-brain radiotherapy is typically used as postchemotherapy consolidation in patients younger than 60, as a salvage strategy for recurrence, or as up-front therapy alone for patients with poor performance status (KPS < 40) or renal failure. Patients ≥60 years are at high risk of developing treatment-relate neurotoxicity following treatment with methotrexate and WBRT; WBRT is often deferred in this subgroup except for recurrence.

Neurotoxicity after PCNSL treatment is characterized by dementia, ataxia, and urinary incontinence, occurring a mean of 7 months from treatment. Both methotrexate and radiotherapy can cause this syndrome, and the combination is synergistic. The risk is greatest in patients ≥60 years of age at diagnosis and when methotrexate is administered concurrently or following radiotherapy. In one phase II trial, patients ≥60 years had a 100% incidence of neurotoxicity at 24 months, whereas those <60 had a 30% incidence at 96 months.[264]

The commonly used radiotherapy schedule for PCNSL in immunocompetent patients is 40 to 45 Gy to the whole brain. The posterior orbits should be included in the whole-brain fields. In patients with ocular involvement, the whole eye can be treated to 30 to 40 Gy, with shielding of the anterior chamber and lacrimal apparatus after this dose. However, most treating physicians reserve the use of ocular radiotherapy for failure of intravitreal methotrexate and rituximab. CSI has been advocated for patients with documented CSF involvement. However, intrathecal chemotherapy is preferred because it may be equally efficacious but less toxic with less impact on bone marrow reserve.

For immunosuppressed patients with PCNSL, modification of the irradiation dose and schedule may be necessary. Patients with poor prognostic features (low KPS, CD4 counts <200, advanced AIDS) may be treated with an abbreviated course of radiotherapy (e.g., 36 to 40 Gy).

Results of Treatment

Unlike non-CNS lymphoma, there appears to be a radiotherapy dose response with a threshold between 30 and 50 Gy, with a median of 40 Gy. A study by Bessell et al.[265] showed a higher relapse rate and reduced survival rate in patients who received 30.6 Gy WBRT as compared to 45 Gy in patients who had complete response to chemotherapy. This was significant for patients younger than 60. However, radiation doses beyond 45 to 50 Gy are associated with a plateau in radiation response. The RTOG conducted a phase II study (RTOG 83-15) to evaluate WBRT as first-line treatment. Median survival was 12 months and recurrence in the brain occurred in 61% of patients, with more relapses in the 60 Gy region, suggesting no clear dose–response over 40 Gy.

The most widely used treatment regimen is based on a phase II study (RTOG 93-10) that treated 102 newly diagnosed PCNSL patients with five cycles of high-dose methotrexate (2.5 g/m^2), vincristine, and procarbazine followed by 45 Gy WBRT and high-dose cytarabine (3.0 g/m^2) postradiotherapy.[266] Approximately halfway through the study, the dose of WBRT was decreased to 36 Gy delivered by hyperfractionation to those that achieved a complete response after preradiotherapy chemotherapy. 58% of patients achieved a complete response and 36% had a partial response after preradiotherapy chemotherapy. Median progression-free and overall survival was 24 and 37 months, respectively.

Long-term results with various combination chemotherapy regimens that include intravenous and intrathecal methotrexate, cranial radiotherapy, and intravenous cytarabine have been encouraging, especially in patients younger than 50 years (5-year survival rate of 60%). In older patients (>50 years), results are poor (5-year survival of rate of <10%) and toxicity is greater with dementia and ataxia in a substantial proportion of patients.[267]

Chemotherapy has also been used without radiotherapy or as a means of delaying radiotherapy particularly in patients over age 60 because of their substantial risk to develop treatment-related neurotoxicity.[268] Complete responses occur in >50% of patients. Single-agent methotrexate using a dose of 8 g/m^2 had a high response rate, but responses were of a relatively short duration with a median progression-free survival of approximately 1 year.[269]

Eliminating WBRT from treatment regimens results in higher recurrence incidence, but this does not appear to translate into an overall survival detriment. The German PCNSL phase III trial randomized 524 patients to high-dose methotrexate-based chemotherapy with or without whole-brain radiotherapy to 45 Gy in 1.5-Gy fractions.[270] The addition of upfront WBRT significantly

prolonged PFS, most prominently in patients who did not achieve a complete response following chemotherapy, but this benefit did not translate into an overall survival difference. In patients with disease less sensitive or insensitive to high-dose methotrexate, WBRT was observed to be more effective than high-dose Ara-C. The addition of upfront WBRT led to greater impact in patient-reported cognitive functioning and global health status, as well as lower values on Mini-Mental Status Examination.[271]

Current work is focusing on methods to eliminate or reduce the risk of neurotoxicity without compromising long-term disease control. Shah et al.[272] reported a phase II study that evaluated the effectiveness and toxicity of reduced-dose WBRT (23.4 Gy) in patients who achieved a complete response following methotrexate-based chemotherapy. The estimated 2-year overall survival and progression-free survival in these 19 patients was 89% and 79%, respectively. At a follow-up of 12 months, none of the patients treated with reduced-dose RT developed treatment-related dementia on neurocognitive studies. This approach was further evaluated in a multicenter phase II study of rituximab, methotrexate, procarbazine, and vincristine (R-MVP) followed by consolidative WBRT to 23.4 Gy in patients who achieve a postchemotherapy complete response.[273] Consolidative cytarabine was given after radiotherapy. Among 52 patients enrolled, 60% achieved a complete response after R-MVP with a 2-year PFS of 77% and a 3-year OS of 87%. Cognitive assessments demonstrated improvement in executive function and verbal memory after R-MVP with stability of follow-up scores.

The use of high-dose chemotherapy with autologous stem transplant (HDC/ASCT) in newly diagnosed PCNSL patients is another strategy that has been explored as an alternative to WBRT. Available data are limited to a few small, nonrandomized phase 2 studies.[274] In a single-institution study, patients who developed a complete or partial response to R-MVP proceed with HDC with thiotepa, cyclophosphamide, and busulfan, followed by ASCT.[275] In transplanted patients, two-year PFS and OS were 81%. Two ongoing clinical trials (NCT01011920; NCT00863460) randomizing patients to consolidative WBRT versus HDC/ASCT will help establish the highest tolerated and most effective consolidation strategy. Until more data are available, HDC/ASCT consolidation to primary chemotherapy can only be recommended as an experimental approach.

Ibrutinib is a first-in-class, oral inhibitor of BTK. Ibrutinib induces death of DLBCL cells with deregulated BCR signaling and has showed promising

activity in a variety of B-cell malignancies, with 70% to 90% response rates in patients with Chronic Lymphocytic Leukemia, Small Lymphocytic Lymphoma, Mantle-Cell Lymphoma, and Waldenström Macroglobulinemia, but only about 25% response rates in relapsed/refractory DLBCL.[276] In a phase 1–2 study, ibrutinib was administered to 20 patients with relapsed or refractory PCNSL or secondary CNS involvement (SCNSL). Patients received ibrutinib at 560 or 840 mg once daily in the dose-escalation portion of the study and 840 mg once daily in the expansion portion. Responses were observed in 15 of 20 patients (75%); 10 of these had a complete response. For PCNSL, the response rate was 77%. Ibrutinib CSF concentrations two hours post dose were 0.77 ng/mL (1.7 nM) and 1.95 ng/mL (4.4 nM) in the 560 and 840 mg groups, respectively, demonstrating a dose-dependent increase in CSF penetration, and levels sufficient to induce cell death in CNS lymphoma cells in culture. Upon mutational analysis, many tumors harbored mutations in the BTK pathway, but tumors without such mutations also responded. Ibrutinib therefore has substantial activity in patients with relapsed or refractory B-cell lymphoma of the CNS and is being further developed for front-line testing.[277]

In patients with immunosuppression and PCNSL, results are discouraging, although selected patients (non-HIV immunosuppression, favorable-prognosis patients with AIDS) may have survival comparable with that of nonimmunosuppressed populations when treated in a standard fashion.[278]

Evidence-Based Treatment Summary

- Surgical resection is not necessary.
- Avoiding or deferring WBRT results in inferior PFS but without significantly impacting OS. Lower-dose WBRT is being investigated to improve the therapeutic window.
- High-dose systemic methotrexate is the only agent that has demonstrated improved survival over WBRT alone. High-dose methotrexate-based chemotherapy followed by whole-brain radiotherapy is the standard treatment for patients <60 years of age with a good performance status. Patients who achieve complete response with high-dose methotrexate–based chemotherapy should be treated with WBRT to reduced dose of 23.4 Gy in 1.8-Gy fractions.
- High-dose methotrexate–based chemotherapy alone with deferred radiotherapy may be preferred in elderly patients because of substantial risk of neurotoxicity associated with combined chemotherapy–radiotherapy regimens.
- WBRT alone should be pursued for patients who are not candidates for

chemotherapy.

Meningioma

Meningiomas account for approximately 30% of primary intracranial neoplasms and are the most common benign intracranial tumor in adults.[2] The peak age of incidence is in the sixth and seventh decades, although they may occur at any age. They are more common in women. Typical locations for meningiomas include the cerebral convexities, falx cerebri, tentorium cerebelli, cerebellopontine angle, and sphenoid ridge. Malignant varieties with invasive growth and aggressive behavior occasionally occur.

Grossly, meningiomas are well-circumscribed firm, tan, or grayish lesions arising from the meninges. Hyperostosis of adjacent bone may be present. Microscopically benign meningiomas usually have a bland whorled appearance with little anaplasia or mitotic activity. Psammoma bodies may be present. Histologic variants (e.g., fibrous, transitional, angiomatous) can be identified but are of little prognostic significance. Malignant varieties are identified on the basis of clinical behavior (rapid growth or recurrence, invasiveness) or pathologic features such as microscopic features of malignancy (cellular or nuclear anaplasia, mitotic figures) or specific histologic type (rhabdoid, papillary, anaplastic). The 2007 updated WHO grading criteria incorporate mitotic activity, nuclear to cytoplasmic ratio, spontaneous necrosis, brain invasion, and certain meningioma variants to assign a grade I through III (Table 38.6).[279] Benign meningiomas (~78% to 80%) are classified as WHO grade I and associated with slower growth and lower risk of recurrence, atypical meningiomas (20%) WHO grade II with an increased likelihood of aggressive behavior, and anaplastic or malignant gliomas (3% to 5%) WHO grade III and associated with high invasiveness and the worst prognosis. The 2016 update to the WHO classification system introduced brain invasion as a criterion that, similar to mitotic count of 4 or more, can alone suffice for diagnosis of an atypical WHO grade II meningioma.[16]

TABLE 38.6 WHO 2016 TUMOR GRADE

Grade I (Benign)	Grade II (Atypical)	Grade III (Anaplastic/Malignant)
Any major variant other than clear cell, chordoid, papillary, or rhabdoid **OR** Does not fulfill criteria for	Frequent mitoses (>4 per 10 hpf) **OR** 3 or more of the following:	Excessive mitotic index (>20 per 10 hpf) **OR** Frank anaplasia defined as focal or diffuse loss of meningothelial differentiation resembling:

grades II or III	Sheeting architecture Hypercellularity (focal or diffuse) Prominent nucleoli Small cells with high nuclear–cytoplasmic ratio Foci of spontaneous necrosis **OR** Additional subtypes/features Chordoid meningioma Clear cell meningioma Brain invasion	Sarcoma Carcinoma or Melanoma **OR** Additional subtypes/features Papillary meningioma Rhabdoid meningioma

b.i.d., twice daily; RT, radiotherapy.

Meningiomas are known to be induced by ionizing radiation, with an average interval to diagnosis of 19 to 35 years, depending on the dose of radiation. They may be multiple particularly in patients with neurofibromatosis type 2 (NF2) and in non-NF2 families with a hereditary predisposition to meningioma.

The most common cytogenetic alteration in meningiomas involves a deletion of chromosome 22. Molecular genetics findings indicate that approximately 50% of meningiomas have allelic losses that involve band q12 on chromosome 22. Allelic losses of chromosomal arms 6q, 9p, 10q, and 14q are seen in both atypical and anaplastic meningiomas. Genetic and cytogenetic alterations accumulate with progression from WHO grade I to WHO grade III lesions. Mutations in the NF2 gene have been detected in 60% of sporadic meningiomas. The cumulative effect of NF2 mutations or copy number alterations affecting chromosome 22 is the loss of activity/function of a tumor suppressor protein, Merlin (Moesin-ezrin-radixin-like protein) encoded by the gene *NF2*. More recent genomic analysis of meningiomas reveals that in the 40+% of tumors without chromosome 22 loss or NF2 mutation, other somewhat uncommon, but potentially targetable mutations can be identified. In a whole-genome or whole-exome sequencing on 17 meningiomas and focused sequencing on an additional 48 tumors, most meningiomas were found to have “simple genomes,” with fewer mutations, rearrangements, and copy number alterations than reported in other CNS tumors in adults. This study confirmed focal *NF2* inactivation in 43% of tumors and found alterations in epigenetic modifiers of NF2 in an additional 8%

of tumors. A subset of meningiomas lacking *NF2* alterations harbored recurrent oncogenic mutations in *AKT1* and *SMO* with immunohistochemical evidence of activation of these pathways. These mutations are linked to the potential for identifying targeted therapeutics for some meningiomas.[280] A recent analysis of 274 high-grade meningiomas compared to 456 low-grade meningiomas concluded that high-grade meningiomas actually have a higher mutation burden, but no statistically significant mutated genes other than NF2 could be identified.[281]

In a recent analysis of the histologically aggressive variant, rhabdoid meningiomas, designated in the WHO classification as high grade, sequencing of cancer-related genes in 27 meningiomas from 18 patients with rhabdoid features was performed, findings from which led to specifically evaluating the breast cancer (BRCA)1–associated protein 1 (BAP1) expression by immunohistochemistry in 336 meningiomas. The tumor suppressor gene *BAP1*, a ubiquitin carboxy-terminal hydrolase, was found to be inactivated in a subset of high-grade rhabdoid meningiomas. Patients with BAP1-negative rhabdoid meningiomas had reduced time to recurrence compared with patients with BAP1-retained rhabdoid meningiomas, and a subset of patients with BAP1-deficient rhabdoid meningiomas harbored germline BAP1 mutations, indicating that rhabdoid meningiomas could be a harbinger of the BAP1 cancer predisposition syndrome.[282] These findings are beginning to provide clues toward the goal of identifying actionable mutations in meningioma.

The incidental finding of a meningioma on CT or MRI is not uncommon, particularly in the elderly. Many meningioma patients are asymptomatic and may remain so for a long time.[283,284] Lesions in the cerebellopontine angle commonly present with symptoms of cranial neuropathy. Cerebral convexity meningioma may present with symptoms of headache or a seizure. Meningiomas of the sphenoid wing or optic nerve may be associated with visual loss. The differential diagnosis of meningioma in the base of the skull or spine includes bone metastasis or primary bone tumors (chondrosarcoma, chordoma, osteosarcoma). In the cerebellopontine angle, acoustic neuromas may resemble meningiomas on imaging.

Meningiomas typically grow slowly. In 47 asymptomatic patients with meningioma diagnosed incidentally by MRI, Nakamura et al.[285] reported a mean annual growth measured using serial MRI of 14.6% and a mean tumor doubling time of 21.6 years. Higher annual growth rates were seen in young patients and lower annual growth rates in patients with calcification and hypointense or

isointense T2 signals on MRI. The location of the lesion, extent of surgical resection, and histopathologic features of the tumor (benign or malignant) are the most important determinants of prognosis.[286]

After surgery, the average time to recurrence is approximately 4 years. In a review of 38 patients who underwent subtotal resection, the mean diameter increase was 0.37 cm/year and mean tumor doubling time was 8 years.[287]

Treatment

Grade I Meningioma

Patients with asymptomatic lesions may be observed and followed with serial imaging. The treatment of choice for symptomatic or progressive benign meningiomas is complete surgical resection if it can be accomplished with acceptable morbidity. Resection of these typically vascular tumors may be facilitated by preoperative angiography with or without embolization. Even after complete resection, 7% to 12% of these tumors recur at 5 years and 20% to 25% recur at 10 years[288,289] so that follow-up with serial imaging is necessary.

Complete resection of skull-based, cerebellopontine angle, or cavernous sinus meningiomas may be difficult without significant morbidity. Subtotal resections are associated with higher relapse rates of 39% to 47% at 5 years and 60% to 61% at 10 years without adjuvant therapy.[288,289] For these patients, conservative subtotal resection followed by postoperative irradiation may give good local control with less morbidity than an aggressive base of skull resection. An alternative approach for patients who have undergone subtotal resection is follow-up with further surgery, if feasible, and radiotherapy delayed to time of recurrence.

In patients with subtotally excised unresectable or recurrent meningiomas, the typical radiotherapy dose is 50 to 54 Gy in 25 to 30 fractions over 5 to 6 weeks. The target volume for radiotherapy is defined by CT or MRI scan and modified according to the neurosurgeon’s description of the location of residual tumor. The margin expansion for meningiomas is based on the knowledge of direction of spread, especially through neural foramina, bony invasion, dural tails, and so forth. The GTV is the enhancing abnormality on contrast-enhanced MRI. Margin expansions then incorporate setup errors and block margins; these can vary from 0.5 to 1 cm in total depending on the precision of the immobilization and delivery systems. Multiple fields with wedges or rotational fields and 3-D conformal techniques are used for maximal sparing of normal brain tissue. IMRT or proton therapy may be helpful in avoiding adjacent surrounding structures.

Postoperative irradiation after less than complete resection improves local control, prolongs the interval to recurrence, and improves survival. In series by Condra et al.,[288] subtotal resection with postoperative irradiation had a local control rate of 87% at 15 years compared to 76% following total excision and 30% after subtotal excision (P = .0001). In modern series using MRI and CT localization, 5-year local control is reported to be >90%.[290]

Radiosurgery as the sole modality or as postoperative adjuvant therapy may be of interest for selected patients, generally those with smaller tumors. In recent series, 5-year progression-free survival rates are >80%.[291–295] In a recent single institutional study, 85 patients eligible for a potential Simpson grade 1 or 2 resection were treated with SRS (usually because of preference). These patients received SRS either because of radiographic evidence of growth (72%) or postoperative recurrence (28%). With a mean follow-up of 69 months, the estimated 2-, 5-, and 10-year local control rates were 99%, 93%, and 93%, results that compare well with surgical series.[296]

Chemotherapy has not been useful in the treatment of benign meningiomas. Given the high estrogen and progesterone receptor expression on meningiomas, progesterone receptor antagonists have been tested but have not been found beneficial.

Grade II and III Meningioma

For atypical or malignant meningiomas, the recurrence rate after surgery alone is high (41% to 100% at 5 years), even after complete surgical resection,[297] and postoperative irradiation after maximal resection is recommended for all patients. The target volume is more generous than that used for benign meningiomas. The GTV and/or resection bed is typically expanded by 0.5 to 1.0 cm along the dural margin and into brain parenchyma in cases of brain invasion, The recommended dose is on the order of 54 to 59.4 Gy in 30 to 33 fractions for atypical meningioma and 59.4 Gy in 33 fractions for malignant meningioma, although some have reported improved local control with higher doses.[298]

RTOG 0539 enrolled 52 patients into an intermediate-risk cohort comprising WHO grade II tumors with gross total resection (70%) and recurrent WHO grade I tumors (30%) and treated with fractionated radiotherapy to 54 Gy[299]. 3-year and 5-year PFS were 92% and 84%, comparable to PFS estimates following observation of resected WHO grade I meningioma observed in the same trial. In a National Cancer Database analysis, the use of adjuvant radiotherapy for subtotally resected WHO grade II meningioma improved overall survival.[300] In

the setting of gross totally resected WHO grade II meningioma, two randomized trials seek to address whether adjuvant radiotherapy prolongs PFS and OS.

In a review of 38 patients with malignant meningiomas by Dziuk et al.,[297] use of postoperative radiotherapy resulted in superior local control. At 5 years, irradiation following initial resection improved 5-year disease-free survival from 15% to 80% (P = .002). Progression-free survival was 57% in patients treated with total resection and radiotherapy compared to 28% in patients treated with total resection alone.

Systemic therapy has no defined role. Combined chemotherapy with vincristine, adriamycin, and cyclophosphamide has shown some efficacy in patients with malignant meningiomas.[301]

Unresectable or Recurrent Meningioma

In patients in whom aggressive surgery is not an option, radiotherapy may relieve symptoms and decrease the rate of tumor progression.

Radiotherapy may be useful in the treatment of recurrent meningioma. In a review by Miralbell et al.,[302] progression-free survival at 8 years for patients treated with subtotal resection and radiotherapy at first recurrence was 78% compared to 11% in patients treated with resection alone (P = .001).

Various chemotherapy treatments that have been used in patients with recurrent meningiomas include combined doxorubicin and dacarbazine or ifosfamide and mesna.[303] Long-term low-dose daily hydroxyurea may have some activity.[304]

Hormonal manipulation, including tamoxifen and the antiprogesterone drug RU486, showed some activity in a SWOG phase II evaluation of tamoxifen in unresectable or refractory meningiomas.[305] However, a subsequent SWOG phase III study of mifepristone for unresectable meningioma was negative.[306]

The EORTC has completed accrual to a randomized open-label multicenter comparative phase II trial investigating whether trabectedin demonstrates sufficient antitumor activity against recurrent grade II or III meningioma to justify further investigation in phase III or as adjuvant therapy for newly diagnosed disease after resection and radiotherapy. Trabectedin blocks DNA binding of the oncogenic transcription factor FUS-CHOP and reverses the transcriptional program in myxoid liposarcoma. By reversing the genetic program created by this transcription factor, trabectedin promotes differentiation and reverses the oncogenic phenotype in these cells. Other than transcriptional interference, the mechanism of action of trabectedin is poorly understood. It is

approved for use in sarcomas and has demonstrated anectodal responses in meningioma; results of this trial are awaited. The Alliance for Clinical Trials in Oncology is currently conducting a trial of targeted agents selected by the presence of specific mutations in recurrent/progressive meningioma. In this three-arm phase II trial, patients with NF2 would be treated with vismodegib, those with SMO mutations with the focal adhesion kinase (FAK) inhibitor GSK2256098, and those with AKT mutations with a PI3Kinase pathway inhibitor.

Evidence-Based Treatment Summary

- Small asymptomatic meningiomas in noncritical locations, especially in the elderly or in patients with other comorbidities, can be observed.
- The goal of surgery is to completely resect the meningioma, with negative margins as patients with WHO grade I completely resected meningiomas have low rates of relapse and can be observed postoperatively.
- For subtotally resected or unresectable progressive meningioma, radiotherapy is frequently used but has not been tested in a prospective clinical trial. Local control appears to be improved with postoperative radiotherapy. Both radiosurgery and radiotherapy have been used in this context, but have not been directly compared.
- For grades II and III meningioma, postoperative radiotherapy is routinely recommended.
- Primary radiotherapy or radiosurgery could be used for unresectable, progressive meningiomas.
- Systemic therapy does not have a defined role in meningioma.

Craniopharyngioma

Craniopharyngiomas arise from epithelial remnants of the Rathke pouch and are typically found in the suprasellar region in children or adolescents. They account for <5% of all CNS neoplasms in adults. They are slowly growing tumors that often have solid and cystic components, the latter filled with lipoid, cholesterol-laden (“crankcase oil”) fluid. Although appearing well encapsulated, craniopharyngiomas typically demonstrate invaginations into adjacent brain and may provoke a vigorous glial reaction.

The cystic nature of craniopharyngiomas is usually evident on CT and MRI and helps distinguish these tumors from other base of skull lesions and pituitary adenomas. The solid portion is often calcified and enhancing, whereas the cystic portion typically demonstrates a thin rim of enhancement. The finding of

multiple cysts of varying intensity on T1- and T2-weighted MRI is characteristic of craniopharyngioma.

Intrasellar lesions may compress the pituitary gland and hypothalamus, producing hormonal abnormalities, especially antidiuretic and growth hormone deficits. Prechiasmal lesions may compress the optic pathway leading to visual field cuts or decreased central visual acuity. Retrochiasmal lesions may grow into the third ventricle and cause hydrocephalus or compress the optic tracts. Craniopharyngiomas can occasionally reach enormous size and produce neurologic impairment by direct impingement on brain parenchyma. Surgical decompression is the optimal treatment for rapid symptom relief. However, the location, proximity, and adhesiveness of the tumor to adjacent structures often preclude complete resection.

Treatment

A discussion of craniopharyngioma in the pediatric context is provided in Chapter 82. Management options include complete resection, subtotal resection alone, or subtotal resection or biopsy followed by postoperative radiotherapy.

Complete surgical resection, which is applicable only to a minority of patients, is associated with local control and long-term survival in 70% to 90% of patients.[307] However, aggressive resection may be associated with significant morbidity, with up to a 10% incidence of perioperative mortality and up to 30% severe morbidity, especially diabetes insipidus or other endocrine deficits, visual impairment, obesity, and memory impairment.

Partial resection or cyst aspiration and biopsy rapidly relieve local compressive symptoms and have less operative morbidity but are associated with eventual tumor progression in most cases. Long-term survival and local control are achieved only in approximately 30% of patients. In contrast to aggressive resections, subtotal resections carry a mortality of about 1%.

With a limited surgical procedure (partial resection or cyst aspiration plus biopsy) followed by radiotherapy, local control and survival rates are nearly equivalent to those achieved with complete resection, with survival rates of 89% and 77% at 5 and 10 years, respectively, as compared with 53% to 37% for patients who have had subtotal resection alone. Typically, doses of 50.4 to 54 Gy in 28 to 30 fractions (1.8 Gy) are delivered to the postoperative residual tumor and the borders of preoperative tumor extent with a 1- to 1.5-cm margin depending on the accuracy of the imaging used for planning and the reproducibility of the treatment setup. Reduction of margins to 0.5cm can be

considered when weekly MR imaging during treatment is used to monitor intratumoral cystic changes. In patients with compressive symptoms, surgical decompression before irradiation is essential because the tumor typically responds slowly to radiotherapy, and radiation-induced edema may worsen compressive symptoms.

With these dose recommendations (i.e., 1.8-Gy fractions to 50 to 54 Gy), the risk of visual impairment is very low (1% and 1.5%). In a retrospective analysis of patients treated with 51.3 to 70 Gy, a higher incidence of radiation-related complications was seen in those who received more than 60 Gy (with an actuarial incidence of optic neuropathy of 30% and brain necrosis of 12.5%), without any concomitant improvement in tumor control.[308]

Radiotherapy may be given as salvage rather than immediately after subtotal resection. In a series of 76 patients treated at the University of Pennsylvania, long-term survival rates were equivalent.[309] In another series, radiotherapy given at recurrence yielded a 10-year progression-free survival rate of >70%.[310] Recurrences occur from 3 to 192 months (median 12 months) after subtotal resection so that close surveillance is necessary during the first years following incomplete resection.

Other modalities used in the treatment of craniopharyngioma have included intralesional bleomycin and radioactive colloid instillations for cystic tumors. Radiosurgery may be useful in ablating small residual or recurrent tumors.[311] With radiosurgery, dose to the optic chiasm and nerves must be kept below 8 Gy, estimated to be radiobiologic tolerance for optic neuropathy with single-fraction radiosurgical doses. As a result, radiosurgery use should be restricted to tumors <3 cm in size and located >3 to 5 mm from the optic apparatus.

Evidence-Based Treatment Summary

- Surgical resection is recommended, when feasible.
- The use of postoperative radiotherapy has not been tested in prospective trials but reduces the risk of recurrence and improves survival in incompletely resected tumors. Cyst decompression and biopsy followed by radiotherapy may be an acceptable treatment for patients for whom resection is not considered feasible.
- Intracavitary bleomycin or radiocolloids may be useful in cystic tumors.

Vestibular Schwannoma and Neurofibroma

Neurilemomas, also known as schwannomas and neurinomas, arise from the

Schwann cells of the myelin sheath of the peripheral nerves. When occurring close to the eighth cranial nerve, they are also called vestibular schwannomas or acoustic neuromas. These tumors account for approximately 6% of CNS neoplasms in adults. They may be sporadic or associated with NF2, with bilateral vestibular schwannomas being pathognomonic of this disease. Most sporadic vestibular schwannomas are unilateral and occur in the fourth and fifth decades of life. Those arising in patients with NF2 tend to occur in the second or third decades. These tumors grow slowly in a well-circumscribed, expansile fashion, displacing adjacent nerves rather than invading them. Most arise from cranial nerve VIII in the medial internal auditory canal. Less commonly, they may arise from other cranial nerves, the trigeminal nerve being the most common alternate site.

Growth in the internal auditory canal gives rise to vestibular and hearing abnormalities in up to 95% of patients. A progressive unilateral sensorineural hearing loss is characteristic. Expansion into the cerebellopontine angle may lead to trigeminal symptoms, and a unilateral absent corneal reflex is an early sign of trigeminal involvement. Large tumors may impinge on the cerebellum and brainstem, leading to ataxia and long tract signs as well as involvement of cranial nerves IX, X, XI, and XII.

Pure tone and speech audiometry are the most useful screening tests. Selective loss of speech discrimination in excess of pure tone loss is particularly suggestive of vestibular schwannoma. Brainstem auditory evoked responses typically demonstrate a slowing of conduction, and electronystagmography may detect a decrease in caloric response on the ipsilateral side. Thin-slice Gd-enhanced MRI through the cerebellopontine angle is the imaging modality of choice for suspected vestibular schwannoma. Thin-slice, contrast-enhanced, high-resolution CT scan is an acceptable alternative when MRI is not obtainable. An intensely enhancing lesion close to the internal auditory canal is highly suggestive of this diagnosis. Patients with suspected neurofibromatosis should have complete imaging of the craniospinal axis to document other neurilemomas, neurofibromas, and meningiomas that may be present.

Neurofibromas differ from neurilemomas in their cellular composition and growth pattern. Although neurofibromas also arise from peripheral nerves, they are most commonly multiple and associated with NF1. Neurofibromas expand rather than displace the nerve of origin. Histologically, neurofibromas are composed of a hypertrophied mass of fibroblasts and Schwann cells through which run normal neurons. Symptoms are caused primarily through compression

of the involved or adjacent nerves.

Treatment

Treatment should offer a high chance of local control as well as preservation of cranial nerve function. Observation alone may be appropriate in patients willing to undergo regular clinical and imaging follow-up and may allow treatment to be deferred for some time. The mainstay of treatment has been microsurgical resection. Retrosigmoid (suboccipital) middle fossa and translabyrinthine approaches offer the possibility of hearing preservation but are associated with higher incidences of seventh nerve damage and postoperative complications. The translabyrinthine approach is associated with low operative morbidity and mortality but sacrifices hearing. At centers with expertise in microsurgical resection, total or near-total resection rates of 90% are routinely obtained with a surgical mortality rate of <2%. Anatomic preservation of the facial nerve may be achieved in 90% of patients and functional preservation in more than two-thirds. Preservation of useful hearing is reported in 30% to 50%. In patients in whom a near-total or total resection is achieved, the tumor recurrence rate is <10%. In patients in whom a subtotal resection is achieved, tumor recurrence may occur in one-third to one-half. Adjuvant radiotherapy may reduce the rate of recurrence to that of complete resection.

In patients with a medical contraindication to surgery, treatment with external beam irradiation alone is an option. A dose of 50 to 55 Gy in 25 to 30 fractions over 5 to 6 weeks is recommended. Maire et al.[312] evaluated 24 patients with stage III and IV cerebellopontine angle schwannomas treated with external irradiation. With median follow-up of 60 months, there was an 88% tumor control rate with no injuries to the cranial nerve V or VIII.

Radiosurgery may be an alternative to microsurgical resection. The well-circumscribed nature of these tumors, coupled with their typical intense enhancement on MRI, facilitates their localization and treatment using stereotactic techniques. The progression-free survival rate with radiosurgery is nearly 90% at 20 years. Radiosurgical treatment with higher doses yielded high rates of tumor growth arrest (>80%) and tumor shrinkage in up to two-thirds of patients, although facial or trigeminal neuropathy develops in nearly one-third of patients as long as 2 years after therapy. The volume of the lesion is a significant risk factor for complications involving cranial nerve V, VII, or VIII. Temporary enlargement may occur up to 2 years following radiosurgery.[313]

Noren[314] reviewed the results of 669 patients with vestibular schwannoma

treated with Gamma Knife radiosurgery between 1969 and 1997. Long-term growth control was achieved in 95%. Facial weakness and/or numbness occurred in approximately one-third of patients during the 1970s but <2% in the 1990s. Hearing was preserved in 65% to 70% of patients, although tinnitus was rarely changed by treatment. With dose reduction to 12 to 13 Gy, high rates of tumor control and cranial nerve preservation may be achieved. Flickinger et al.[315] reported the results of 313 patients treated with radiosurgery to median dose of 13 Gy. The actuarial 6-year tumor control rate was 98.6%. The actuarial 6-year rates for preservation of seventh nerve function, normal fifth nerve function, unchanged hearing level, and useful hearing were 100%, 95.6%, 70.3%, and 78.6%, respectively. Hayhurst et al.[316] reported on their clinical series of 200 patients treated with radiosurgery to 12 Gy and observed 5 cm^3 to be the target volume threshold above which adverse treatment effects were more likely. In addition, they observed a maximum dose threshold of 9 Gy to cranial nerve V as significantly associated with trigeminal neuropathy.

Radiosurgery provides similar local control with less morbidity than surgery for small (<3 cm) unilateral tumors. In a series from the University of Pittsburgh, radiosurgery was found to have improved preservation of facial function ($P < .05$) and hearing ($P < .03$) with decreased associated morbidity ($P < .01$) when compared to surgical resection.[317]

FSRT has been shown to give local control rates of 91% to 97% with similar effects on cranial nerves V and VII.[318–321] However, in one series, FSRT resulted in 2.5-fold greater preservation of hearing compared to radiosurgery.[318] FSRT may be an option for tumors too large to receive radiosurgery.

Bevacizumab has been used in patients with progressive bilateral vestibular schwannomas associated with NF2, usually in the context of bilateral hearing loss, producing both tumor regression and restoration of hearing in some patients. This has led to this approach being actively investigated at present. Sporadic and NF2-related vestibular schwannomas express VEGF, and bevacizumab binds VEGF with high affinity. In the initial experience reported by Plotkin et al., 10 NF2 patients at risk for complete hearing loss or brainstem compression were treated with bevacizumab on a compassionate-care basis and demonstrated promising results with 6 of 10 patients experiencing ≥20% tumor volume reduction and 4 of 7 patients experiencing significantly improved hearing.[322]

Evidence-Based Treatment Summary

- Small nonprogressive tumors can be observed.
- Surgical resection is generally considered the standard of care for symptomatic lesions.
- Radiosurgery produces outcomes equivalent to surgery, although these modalities have not been prospectively compared.
- Fractionated stereotactic radiotherapy is being increasingly employed, with institutional reports suggesting a lower incidence of cranial neuropathies than radiosurgery, but this has not been prospectively validated.
- The role of bevacizumab in NF-2-associated progressive bilateral vestibular schwannomas is being explored.

Hemangioblastoma and Hemangiopericytoma

Hemangioblastomas are benign vascular tumors that present during the third and fourth decades of life. They account for 1% to 2% of primary CNS tumors in adults. Most arise in the cerebellum, constituting the most common primary cerebellar tumors in adults. An association with von Hippel-Lindau disease is noted in 10% of patients. Histologically, the tumor consists of closely packed, thin-walled blood vessels in a stroma of large, oval foamy cells. The lesions are intensely enhancing on CT and MRI, and angiography confirms the vascular nature of the lesion. Imaging of the craniospinal axis often documents multiple lesions in patients with von Hippel-Lindau disease. Treatment is surgical and complete resection is curative. Radiosurgery has also been shown to be useful in patients with unresectable disease but is associated with higher rates of recurrence.[323–325] In von Hippel-Lindau, treatment of symptomatic hemangioblastoma is warranted, but observation of asymptomatic tumors can be considered.[326]

Hemangiopericytoma is a sarcomatous lesion developing from smooth muscle in blood vessels usually along the base of the skull, although intraparenchymal lesions may be seen. In contrast to other primary CNS tumors, hemangiopericytomas commonly develop systemic metastases. There is a 90% 9-year actuarial risk for local failure following surgical resection only. Postoperative radiotherapy to total doses of 50 to 60 Gy reduces the risk of recurrence rate and improves overall survival. Tumor control is dose dependent, with doses >50 Gy associated with superior outcomes. Radiographic response is slow. Radiosurgery has been used for recurrent hemangiopericytomas, with reported local control rates of approximately 80% following treatment.[327]

Evidence-Based Treatment Summary

- Surgical resection is recommended, when feasible, for both of these diseases.
- Radiotherapy is generally reserved for subtotally resected progressive hemangioblastoma, but there are no prospective data.
- Postoperative radiotherapy is recommended for subtotally resected hemangiopericytoma, but there are no prospective data.
- Radiotherapy or radiosurgery may be considered for unresectable tumors.

CHAPTER 39

Pituitary Gland Cancer

Theodore E. Yaeger

ANATOMIC CONSIDERATIONS

The pituitary gland, also known as the hypophysis cerebri, is an important endocrine organ. It appears as an ovoid body, the main portion of which is situated in the hypophysial fossa of the sphenoid bone (Fig. 39.1). That main portion is physically connected to the brain by the infundibulum. The diaphragma sellae forms a dural roof for the greater part of the hypophysis and is pierced by the infundibulum. In front of the infundibulum, the superior aspect of the gland is related directly to the arachnoid and pia[1] and the subarachnoid space then extends below the diaphragma.[2] The gland is completely surrounded in the fossa by a fibrous capsule that fuses with the endosteum.[3]

The hypophysis is related above to the optic chiasma and below to the intercavernous venous sinus and the sphenoid air sinus. This location conveniently allows an endonasal approach for surgical purposes[4] with laterally to the cavernous sinuses. By causing pressure on the chiasma, hypophysial tumors commonly result in visual defects such as superior temporal anopsia or bilateral temporal hemianopsia. Clinically, this is described as a profound loss of peripheral vision of varying degrees depending on achieved tumor size and chiasm affects.

The hypophysis is best divided on the embryologic basis into two main parts[5]: the adenohypophysis and the neurohypophysis. The former comprises the pars infundibularis (or pars tuberalis), the pars intermedia, and the pars distalis. The latter comprises the median eminence, the infundibular stem, and the infundibular process or neural lobe. The median eminence is frequently also classified as part of the tuber cinereum. The terms infundibulum or neural stalk is used for the median eminence and the infundibular stem. The term hypophysial stalk usually refers to the pars infundibularis and the infundibulum.

The adenohypophysis constitutes about 80% of the total volume of the

pituitary gland[6] and is an embryologic diverticulum from the buccopharyngeal region. The pars distalis area secretes a number of hormones. The neurohypophysis develops as a diverticulum from the floor of the third ventricle. Specifically, it is not an actual endocrine-producing gland but more appropriately should be considered a storage gland for neurosecretions produced by the hypothalamus, which are then carried down via the axona of the supraoptico-hypophysial neural tracts.

Blood Supply and Innervations

The hypophysis is supplied by a series of hypophysial arteries from the internal carotids. The maintenance and regulation of the activity of the adenohypophysis are dependent on the blood supply by way of the hypophysial portal system.[7–11] Nerve fibers from the hypothalamus liberate releasing factors into the capillary beds in the infundibulum, and these substances are then carried by the portal vessels to the distal parts of the gland, causing the effects relevant to the specific secretions. The neurohypophysis receives its main nerve supply from the hypothalamus by way of fibers known collectively as the hypothalamohypophysial tract. This tract contains two main sets of fibers: the supraopticohypophysial tract and the tuberohypophysial tract.

Gross Appearance

Upon gross examination, the pituitary gland is a small, gray, rounded gland. It is developed from ingrown oral epithelium known as Rathke pouch as an extension of the developing oral cavity. As development matures, the gland is eventually cut off from its origins by the growth of the sphenoid bone and settles into what is described as a saddle-shaped, base-of-brain, bone depression formally called the sella turcica. The anterior pituitary has a portal vascular system that is the conduit for the transport of hypothalamic-releasing hormones from the hypothalamus to the anterior pituitary. Hypothalamic neurons have terminals in the median eminence where the hormones are released into the portal systems. This vascular supply traverses the pituitary stalk and then enters the anterior pituitary lobe. Most pituitary hormones are controlled predominately by releasing factors from the hypothalamus, with the exception of prolactin, which is controlled by the dopamine system via an inhibitory mechanism. It is attached to the lower surface of the hypothalamus by the infundibular stalk. The Rathke pouch portion forms the anterior lobe and the intermediate area. The posterior pituitary is embryologically derived from an outpouching from the floor of the

third ventricle and grows inferiorly along the stalk of the anterior lobe. In contrast to the anterior lobe, this posterior lobe is supplied by the inferior hypophyseal artery. This will then drain into the venous sinus system for direct product release into the systemic circulation. As such, the pituitary gland has a dual circulation; one is composed of arteries and veins and the other a portal venous system that links the hypothalamus and the anterior lobe. Lastly, the neural tissue of the infundibular stalk essentially forms the posterior lobe. In general, the pituitary gland averages 1.3 × 1.0 × 0.5 cm in size and weighs 0.55 to 0.6 g. It temporarily enlarges during pregnancy.[12] Overall, it is about the smallest functioning gland in the human body, but it has a critically important role in systemic physiologic regulation as demonstrated next.[6]

Physiology

There are five cell types that are revealed using specific antibody staining:

- *Somatotrophs*. Growth hormone–producing acidophilic cells constituting about 50% of the anterior lobe
- *Lactotrophs*. Prolactin-producing acidophilic cells (also known as mammotrophs)
- *Corticotrophs*. Basophilic-appearing cells that produce adrenocorticotrophic hormone, pro-opiomelanocortin, melanocytic-stimulating hormone, endorphins, and lipotropin
- *Thyrotrophs*. Very pale-appearing cells that produce thyroid-stimulating hormone
- *Gonadotrophs*. Basophilic cells that produce follicle-stimulating hormone and luteinizing hormone

MORPHOLOGY

The most common pituitary adenoma is a small, soft, well-circumscribed lesion that may be confined to the sella turcica. Larger lesions typically extend superiorly through the diaphragm sella into the suprasellar region. This can cause compression of the optic chiasm and adjacent structures, including cranial nerves. Continued expansion eventually erodes the sella turcica, the anterior clinoid process, and can project into the cavernous and sphenoid sinuses. As many as 30% of cases adenomas can be nonencapsulated and infiltrate adjacent bones, dura, and rarely into the brain proper.[13] Foci of hemorrhage and necrosis are hallmarks of these invasive larger adenomas and are easily identified by

imaging. Pituitary apoplexy occurs when an acute hemorrhage causes a rapidly enlarging mass. Clinically, this presents with dramatic symptomatic issues that are the result of the sudden onset of mass effects in a relatively confined space.

CLINICAL COURSE

The signs and symptoms of active pituitary adenomas can include endocrine abnormalities, mass effects, or both. Abnormalities associated with excessive secretions of anterior pituitary hormones are specific to the particular aberrant cell line, as described below. Local mass effect can be associated with any type

of pituitary tumor, including a rare metastatic tumor from another site. The earliest changes in local anatomy result in radiographic changes with local deformation of the sella, the diaphragm, and bone erosions. Ultimately, compression of surrounding normal soft tissues results in visual field abnormalities with headache, nausea, and vomiting; eventually compressing the nonneoplastic pituitary and resulting in hypopituitarism. This can occur rapidly if there is hemorrhage resulting in pituitary apoplexy with excruciating headache, diplopia from pressure on the oculomotor nerves, visual defects, and eventually hypopituitarism.

The posterior pituitary or neurohypophysis consists of pituicytes—modified glial cells—and axonal processes extending from nerve cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus. These cells transit through the pituitary stalk to the posterior lobe where the two posterior lobe hormones, oxytocin and vasopressin, are stored.

Hormones are secreted from the following lobes:

- *Intermediate lobe:* no effects are known in warm-blooded mammals.
- *Anterior lobe: Growth hormone*–regulating cell division and protein synthesis; *adrenocorticotrophic hormone*, which regulates the functional activity of the adrenal cortex; *thyroid-stimulating hormone*, which regulates the functional activity of the thyroid gland; *follicle-stimulating hormone*, which regulates ovarian follicles and spermatogenesis; *luteinizing hormone* (in women), which stimulates ovulation, formation of the corpus luteum, and secretion of estrogen and progesterone. In men, it can be called *interstitial cell–stimulating hormone*, which stimulates testosterone secretion. Also in women, there is *prolactin*, which induces secretion of breast milk.
- *Posterior lobe:* Hormones are secreted by the neurosecretory cells of the hypothalamus and pass through the fibers of the supraopticohypophyseal tracts in the infundibular stalk to the neurohypophysis where they are stored. These stored secretions are *oxytocin*, which acts on smooth muscles of the female uterus to increase contractility. There is also *antidiuretic hormone*, which increases water reabsorption of the renal system via the kidney tubules, and a derivative known as *vasopressin* to regulate blood pressure.

DISORDERS

Diseases of the pituitary are divided into those that affect the anterior lobe and those that affect the posterior lobe. The former are either hypersecretory or

hyposecretory in nature. In most cases, hypersecretion is caused by a functioning adenoma within the anterior lobe. Hypopituitarism may be caused by a variety of destructive processes, including ischemic injury, radiation exposure (including therapeutic radiation), inflammatory responses, and nonfunctioning tumors such as a squamous “pearl” from cell rests that occurs during the embryo stage of development. Other than endocrine abnormalities, diseases of the anterior pituitary may manifest by a local mass effect. Radiographically, this can usually be seen by enlargement of the sella turcica. Clinical signs are visual field defects or vision cuts, evidence of increased intracranial pressure by optic examination or a patient’s complaint of double vision, headache, and nausea. The posterior pituitary may also provide clinical evidence of antidiuretic hormone abnormalities. This can present as the symptoms of inappropriate antidiuretic hormone (SIADH) resulting in hypervolemia and hyponatremia if the gland is still in a functioning state.

Hyperpituitarism and Pituitary Anterior Adenomas

Excess production of hormones related to the anterior pituitary is often caused by a benign adenoma arising from cells in the anterior lobe. Less commonly, there can be hyperplasia or, rarely, actual carcinoma of glandular elements. Conversely, nonfunctioning adenomas may cause hypopituitarism as they grow and displace the normal functioning gland. Functional pituitary adenomas are usually composed of a single aberrant cell *type*, thus producing a single dominant hormone. Less common are adenomas that may have a single cell *line* but produce more than one hormone product; these are called plurihormal. Rarely are functional adenomas with multiple cell lines. Regardless, the vast majority of pituitary adenomas are monoclonal in origin, suggesting a single somatic cell, even when a plurihormonal diagnosis is made.[14] Some plurihormonal adenomas may arise from a primitive stem cell. This type may subsequently differentiate to develop multiple productive cell lines simultaneously. Molecular studies have identified specific mutations (such as a single base-pair missense mutations) that would stabilize one protein into an active formation while inhibiting a controlling protein, thus mimicking an active hormone. This has been identified in about 40% of growth hormone–secreting tumors. Other molecular aberrations seem more sporadic, and the pathogenesis of most pituitary tumors is still largely unknown.

PHYSIOLOGY

Hyperpituitarism of the Pituitary Lobes

Hypersecretion of the anterior lobe causes gigantism, acromegaly, and Cushing disease (pituitary basophilism). Hyposecretion of the anterior lobe causes dwarfism, Simond disease (pituitary cachexia), Sheehan syndrome (postpartum pituitary necrosis), acromicria, eunuchoidism, and hypogonadism. A posterior lobe deficiency results in a hypothalamic lesion that causes diabetes insipidus. Anterior *and* posterior lobe deficiencies *plus* a hypothalamic lesion causes Frohlich syndrome (adiposogenital dystrophy) and pituitary obesity.

Anterior Lobe

In the anterior lobe, the most common tumor, accounting for about 30% of all adenomas, is a prolactinoma (lactotroph adenoma).[15] These range from small or microadenomas (Fig. 39.2) to very large and expanded tumors associated with clinical presentations of mass effects. Microscopically, they are chromophobic or weakly acidophilic by staining.

Immunohistochemistry can identify prolactin within the cells as secretory granules. Prolactin is a very efficient hormone, and even microadenomas can produce enough excess prolactin to cause hyperprolactin syndrome. Serum concentrations of prolactin tend to be proportional with the size of the tumor. Patients between 20 and 40 years of age presenting with amenorrhea, galactorrhea, loss of libido, and infertility should be checked for serum prolactin.[16] Almost 25% of cases of female amenorrhea are related to increased prolactin. At an older age, the clinical manifestations could be very subtle and unfortunately leading to patients presenting with mass effects as the primary symptoms. Hyperprolactinemia also occurs normally during pregnancy and reaches a peak at delivery. It can continue postpartum by suckling stimulation in lactating women. Interference with a dopamine feedback mechanism by damage to the dopaminergic neurons within the pituitary stalk (via head trauma) in the hypothalamic region or the use of drugs (reserpine, haloperidol, phenothiazines, estrogens) that block the lactotroph cell receptors can result in lactotroph hyperplasia. Moreover, any mass within the stalk can disturb this inhibition influence, causing a mild elevation in serum prolactin. As such, a mild elevation does not necessarily indicate a prolactin-secreting adenoma. Finally, renal failure and hypothyroidism can also elevate prolactin.

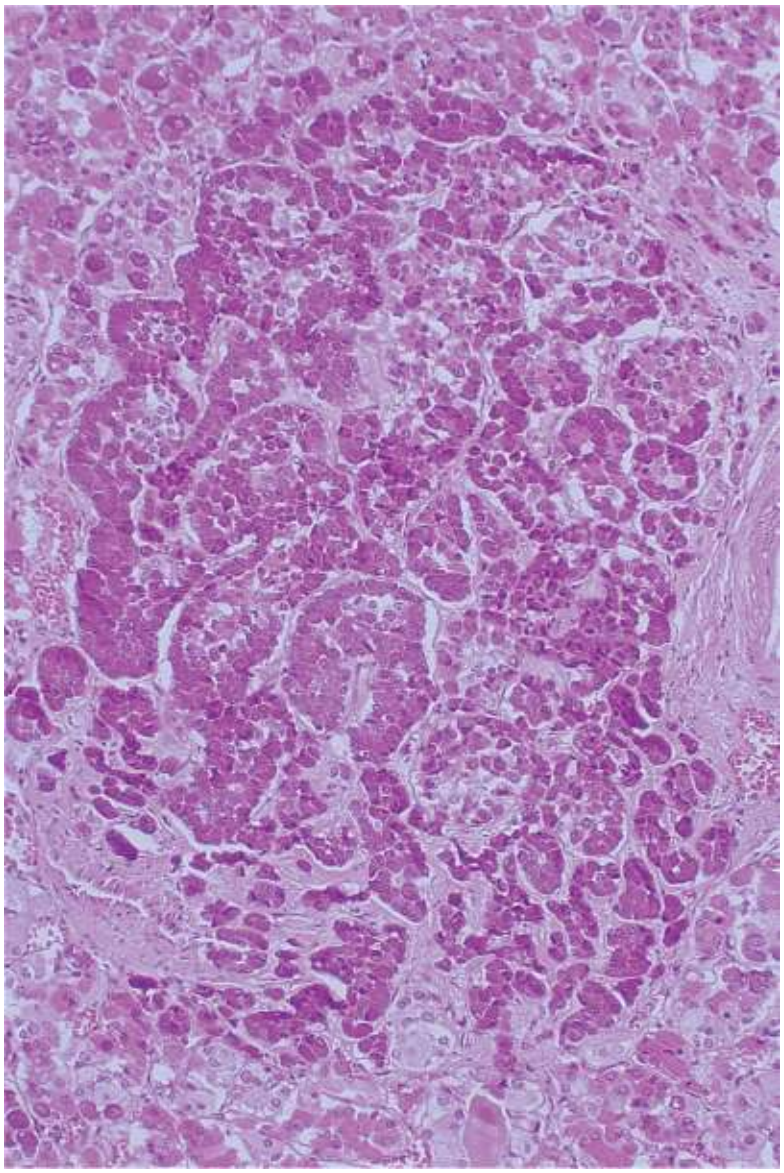

FIGURE 39.2. Photomicrograph of microadenoma. (From Damjanov I. *Histopathology: a color atlas and textbook*. Baltimore: Williams & Wilkins, 1996. With permission.)

Prolactinomas are typically treated with bromocriptine (Box 39.1) that is a dopamine receptor agonist causing the lesions to diminish in size and function. Growth hormone (somatotroph cell)–secreting tumors are the second most common functional tumors. Approximately 40% of somatotroph tumors express an oncogene (*GSP*), which is a mutant GTPase-deficient alpha subunit of the G protein designated Gs.[17] Histologically, these tumors are composed of acidophilic to chromophobic granulated cells. Immunohistochemistry can also demonstrate growth hormone associated with small amounts of prolactin.[18]

Children who develop hypersecretion adenomas before the epiphyses are closed develop clinical gigantism. If the epiphyseal plates have fused, such as in young adults, then acromegaly can occur. This is usually manifested clinically with enlarged hands and feet, increased bone density, enlarged thyroid, heart, liver, adrenals, and broadening of the lower face with jaw protrusion that can develop into prognathism. Patients often have associated prolactinemia, with gonadal dysfunction, hypertension, congestive heart failure, and a risk of gastrointestinal cancer. The goals of treatment are to control serum growth hormone and decrease mass effects of the primary adenoma while preventing deficiencies. Most commonly, the tumors are removed surgically via a transsphenoid approach in younger patients, treatment with external-beam radiotherapy (see the Radiation Techniques section), or drug therapy. Eventually, good growth hormone control over a long period allows the characteristic tissue overgrowth and related symptoms to recede, with improvement in metabolic abnormalities. It is important to remember that because clinical manifestations of growth hormone are subtle, these adenomas can usually present with mass effects from large tumor sizes. Corticotrophin cell adenomas usually present as microadenomas. Histologically, these tumors are basophilic, but they can be chromophobic and stain for the periodic acid stain (Schiff stain) because of presence of carbohydrate in the precursor adrenocorticotrophic hormone (ACTH). Excess ACTH eventually leads to Cushing *syndrome*, with a chronic hypersecretion of cortisol from adrenal stimulation. However, when the hypercortisolism comes directly from the pituitary adenoma, the process is Cushing *disease*. Nelson syndrome (hyperpigmentation, hyporeflexia, vision loss, headache, and menstrual irregularities) occurs in most cases by a loss of inhibitory feedback of adrenal cortisol of the pituitary when hyperfunctioning adrenals are surgically excised and a subclinical pituitary corticotroph microadenoma exists. The microadenoma is stimulated, but hypercortisolism does not occur due to the absence of the adrenals. However, mass effects can still occur, and ACTH precursor molecules can also stimulate melanocytes, thus producing hyperpigmentation. It is more common in women and younger patients.

Box 39.1

Pituitary Adenoma Management Overview

Symptomatic adenomas present for medical attention as a result of hormone secretions,

compression of nearby normal structures with neurologic symptoms, or compression of the pituitary stalk causing hypopituitarism. An initial therapy for most prolactinomas is with a dopamine agonist such as bromocriptine, lysuride, or pergolide. Medical intervention usually decreases adenoma function and size. Initial therapy for other pituitary adenomas is transsphenoidal surgical resection. Surgery is generally safe and reverses neurologic symptoms, with most patients normalizing hormone levels. It is mostly useful to cure microadenomas. Radiation therapy is often reserved for patients with residual disease after surgery, such as after a debulking surgery. It is also considered for recurrence after definitive surgery or for medically inoperable patients. Typically, conventional radiation delivers a dose of 45 Gy at 1.8 Gy daily fractions. At this dose, good control can usually be achieved with a very low risk of optic neuropathy. Normalization of hormone levels, however, can take months to years to achieve.

TABLE 39.1 PITUITARY ADENOMA DISTRIBUTIONS

Type	Frequency (%)
Prolactinoma	20–30
Growth hormone adenoma	5
Mixed growth/prolactin adenoma	5
Adrenocorticotrophic hormone adenoma	10–15
Gonadotroph adenoma	10–15
Null cell adenoma	20
Thyroid-stimulating hormone adenoma	1
Plurihormonal adenoma	15

Mixed adenomas, gonadotroph, and thyrotroph adenomas can occur, but these are less frequent than nonsecreting or null-cell adenomas (Table 39.1). Mostly gonadotroph adenomas are luteinizing or follicle-stimulating producing tumors of middle-age men and women with complaints of chronic fatigue or menorrhea.[19] Like null-cell adenomas, these tumors can become substantial in size with mass effects (Table 39.2). Thyrotrophs are rare, found in about 1% of patients, and are a rare source of hyperthyroidism.[20] Primary pituitary carcinomas are quite rare, typically not functional, and have variable polymorphisms. A clinical diagnosis of an actual carcinoma requires the demonstration of metastases, usually to lymph nodes, brain, bone, or liver, and rarely elsewhere. Radiation therapy to the primary pituitary site can be palliative.

Hypopituitarism

Decreased secretions of pituitary hormones can result from diseases of the

hypothalamus or the pituitary proper, which cause syndromes of hypopituitarism. Most cases of a hypofunctioning pituitary result from the destruction of more than 75% of the anterior gland. Metastatic tumors, involuted primary tumors, ischemic necrosis, or surgical or radio-ablated pituitary can produce empty sella syndrome. A Rathke cleft cyst can accumulate proteinaceous fluids, expanding and destroying the normal pituitary. Primary necrosis can be caused by postpartum Sheehan syndrome[21] or by disseminated intravascular coagulopathy (DIC) and, more rarely, sickle cell crisis. Also causative is elevated intracranial pressure from hydrocephalus, head trauma, or severe shock. Destroying all or part of the functioning pituitary can result in a clinical diagnosis of empty sella syndrome.[22]

TABLE 39.2 ENDOCRINE SECRETIONS AND CLINICAL PRESENTATIONS

Type of Secretion	Frequency (%)	Symptoms	Size at Diagnosis
Prolactinoma	43	Women: amenorrhea, galactorrhea Men: impotence, hypopituitarism	Microadenoma Microadenoma
Nonsecreting	30	Hypopituitarism	Microadenoma
Gonadotrophin Growth hormone	17	Children: gigantism Adults: acromegaly	Microadenoma Microadenoma
Adrenocorticotrophic hormone	7	Cushing disease Nelson disease	Microadenoma
Thyroid-stimulating hormone	1	Hyperthyroidism	Microadenoma or macroadenoma

Box 39.2

Craniopharyngiomas

Craniopharyngiomas are frequently calcified and can be visualized radiographically. They are usually about 3.5 cm in diameter, encapsulated, and solid but can be cystic or multilobulated. They can displace cranial nerves and the optic chiasm and protrude into the floor of the third ventricle. They are thought to be vestigial remnants of the Rathke pouch, representing about 2% of intracranial tumors, occurring about half the time in children and young adults. In children, they can cause growth retardation. Adults usually present with visual disturbances. Both can demonstrate hormonal disturbances and diabetes insipidus. Histologically, there can

be two forms. The adamantinomatous form has nests or cords of squamous to columnar epithelium in a background of spongy-like reticulum. Because keratin formation occurs, these tumors are frequently calcified. A brisk glial reaction can occur if in direct contact with brain tissue. The second type is a papillary craniopharyngioma. These are usually solid sections of squamous cells typically lacking a cystic component and calcification.

Histologically the empty syndrome presents as a small fibrotic nidus of tissue in a radiographically expanded sella turcica. Two distinct types are identified: primary empty syndrome, which occurs in obese women with multiple pregnancies, and a defect of the diaphragma sella, which allows arachnoid matter and cerebrospinal fluid to herniate into an expanded sella, thus compressing the pituitary gland. Hyperprolactinemia can occur due to the loss of dopamine inhibition. Only rarely does actual complete hypopituitarism occur because enough functioning residual tissue usually remains. Secondary syndromes can occur from surgical removal, radiation ablation, or spontaneous infarction. These patients express hypopituitarism syndromes. Rare congenital defects are known,[23] such as a gene that encodes Pit-1, a transcription factor related to important pituitary-specific genes such as growth hormone, prolactin, and thyroid-stimulating hormones. The genetically altered protein will bind to the appropriate cell receptors but can de-activate the expression of the gene, thus causing the patient to fail to produce the appropriate hormone(s). Less frequently, diseases of the hypothalamus or hypothalamic stalk can cause the pituitary to become dysfunctional. These can include craniopharyngiomas (Box 39.2),[24] metastases, sarcoidosis, or tuberculous meningitis and infiltrative diseases such as opportunistic infections. Radiotherapy to nearby structures such as the brain, base of brain, optic chiasm, and nasopharynx can also cause hypothalamic disorders at higher doses. Dysfunction of the adrenal cortex, thyroid, and gonads, the loss of melanocyte-stimulating hormone, atrophy of the genitalia, amenorrhea, impotency, loss of libido, and pubic and axillary hair are changes related to the cause and type(s) of deficiencies in pituitary hypofunction.

Posterior Lobe

The posterior pituitary is composed of pituicytes—modified glial cells—with associated axonal processes extending from nerve origins in the supraoptic and paraventricular nuclei within the hypothalamus. Two proteins are produced: antidiuretic hormone (ADH) and oxytocin. These hormones are stored in the posterior pituitary and released with the appropriate stimuli. Oxytocin functions to stimulate the smooth muscle contractions of the uterus during birth as well as stimulating smooth muscle of the lactiferous mammary gland ducts within the

gravid breasts. No known clinical abnormalities are known for inappropriate secretions. ADH is a nonpeptide produced primarily in the supraoptic nucleus (see anatomy). ADH is released from axon terminals from the neurohypophysis directly into the general circulation secondary to appropriate stimulation(s). ADH is causative for two distinct clinical syndromes: diabetes insipidus and the syndrome of inappropriate ADH secretion (SIADH). Diabetes insipidus can result from head trauma, surgical or radiation damage, tumors, and inflammatory conditions. It causes the inappropriate oversecretion of urine and can lead to life-threatening dehydration. SIADH is causative in the absorption of excessive water, thus causing hematologic dilution (hypervolemia) and hyponatremia. The most frequent cause of SIADH is from ectopic ADH produced by malignant neoplasms such as lung carcinoma (commonly small cell) and by nonneoplastic lung disease producing a paraneoplastic syndrome. However, direct or compression injury to the hypothalamus or posterior pituitary is known in the presence of glial tumors such as primary central nervous system (CNS) neoplasms or craniopharyngiomas. These can cause direct mechanical or stimulatory effects. SIADH causes hyponatremia, cerebral edema, and neurologic dysfunction, and patients are typically initially evaluated because of sudden clinical changes in cognition.[25] Peripheral edema does not usually develop because although the blood is diluted, it retains a normal total volume except when hypervolemia occurs.

RADIATION THERAPY

Radiation therapy can be a highly effective form of intervention to control pituitary adenomas. In current practice, it is rarely the sole means of treatment and is usually reserved for patients with residual surgical disease or the medically inoperable patient. The overall 10-year control rates are consistently reported in the range of 85% or higher,[26–29] including two recent reports from the University of Florida[28,30] that report a 93% control rate at 9.2 years and the absence of “late recurrences” with long-term follow-up using doses of 45 Gy or higher. In the former report,[27] patients were analyzed as to whether they experienced surgery followed by radiation versus radiotherapy alone. Combined approaches achieved a 95% control rate, whereas radiotherapy alone achieved 90% at 10 years of follow-up. Importantly, an 80% control rate was achieved for patients treated by initial surgery who then developed a recurrence after application of delayed radiotherapy. This result is consistent with an older report

from Princess Margaret Hospital analyzing 166 patients with similar treatment and results.[26]

Pediatric pituitary adenomas have similar results when comparing surgery and radiation with radiotherapy alone. In the study by Grigsby et al.,[31] 19 patients were treated who were younger than 19 years of age, and at 15 years of follow-up, only two had failed. It is a small study but that is likely due to the relative rarity of these tumors. A sentinel paper was published in 1971 that arguably solidified the use of about 45 Gy as the threshold dose for acceptable local control and tolerance.[32] This has been confirmed many times by both American and European authors.[33]

Although there can a lack of tumor progression, clinically and radiographically, many patients who have elevated hormone levels at the outset of definitive therapy do not achieve complete normalization following radiotherapy alone. The University of Heidelberg reported on 68 patients with hormone active adenomas. The complete response rate for normalization occurred in only 38%.[28] Again, Princess Margaret Hospital reported on 145 patients receiving radiation alone for hormonally active adenomas. Although the progress-free rate was 96%, the long-term biochemical remission rate (if >2 years) was only 40%.[34] Therefore, radiation alone is demonstrated to be highly effective for controlling pituitary adenoma growth and progression. However, radiotherapy alone is less effective in normalizing hormone activity when patients present with a hormone active tumors. Biochemical suppression or persistence then requires ongoing medical management as needed for symptoms and/or function. Common suppressive medications are bromocriptine or cabergoline. Insufficiencies are supplemented appropriately.

A newer technique has rapidly become available when using radiotherapy intervention for pituitary adenomas: stereotactic radiosurgery (SRS). A number of institutions have reports using SRS either as a single fraction or with a fractionated schedule, called fractionated stereotactic radiotherapy (FSRT).[35] In FSRT, conventional doses of 45 to 50 Gy are delivered using a relocatable head-frame technique over about 5 weeks. With SRS, a single fraction is delivered in doses from 10 to 27 Gy (lower for nonfunctioning, higher for functioning) and often using cranial hard-fixation techniques.[35–37] The local control rates using these advanced techniques have been reported as >90%, and the prevalent hypothesis is that the hormone response rates would be higher than with conventional doses. In an encouraging article, Yoon et al.[37] reported that 11 of 13 patients had normalization of prolactin-secreting adenomas within 1 year.

Unfortunately, Mitsumori et al.[36] reported that the 3-year actuarial rate for an adverse CNS event was 38% for a single fraction versus 0% (in that study) for the FSRT technique. Presently, many radiation oncologists are using modified fraction schemes via various technologies, being acutely aware of the nearby critical anatomic structures—especially the radiosensitive optic chiasm, and the likely potential that patients will live long enough to develop late sequelae particularly for the younger population. There is an excellent and deeply referenced review in Neurosurgery Focus about early stereotactic pituitary radiotherapy.[38]

Radiation Techniques

Radiation therapy planning and delivery has evolved from a two-dimensional calculated, parallel-opposed small open or minimally blocked bitemporal fields (Fig. 39.3) to three-dimensional, computer tomographic–assisted planning (Fig. 39.4) that uses a multiple field approach with custom blocks or multileaf collimation (MLC) blocked portals designed to concentrate therapeutic doses and minimize risks to surrounding normal tissues. Intensity-modulated radiotherapy can be accomplished via several approaches using megavoltage photons with MLC or three-dimensional constructed beam modulators. Either technique essentially produces dose distributions consistent with desired treatment plans to cover the region of interest and protect surrounding normal critical structures with highly conformal energy clouds and lowered hot spots (Fig. 39.5). Radiosurgery also employs megavoltage x-rays, but typically, the beams are delivered through small tubular collimators or sources from many angles and multiple planes of approach. Two machines—Gamma Knife (Elekta Corp, Stockholm; Fig. 39.6) and CyberKnife (Accuray Inc., Sunnyvale, CA; Fig. 39.7)—usually deliver the desired doses through dozens to hundreds of “pencil beams.” There are many newer machines available today to deliver stereotactic body radiotherapy.

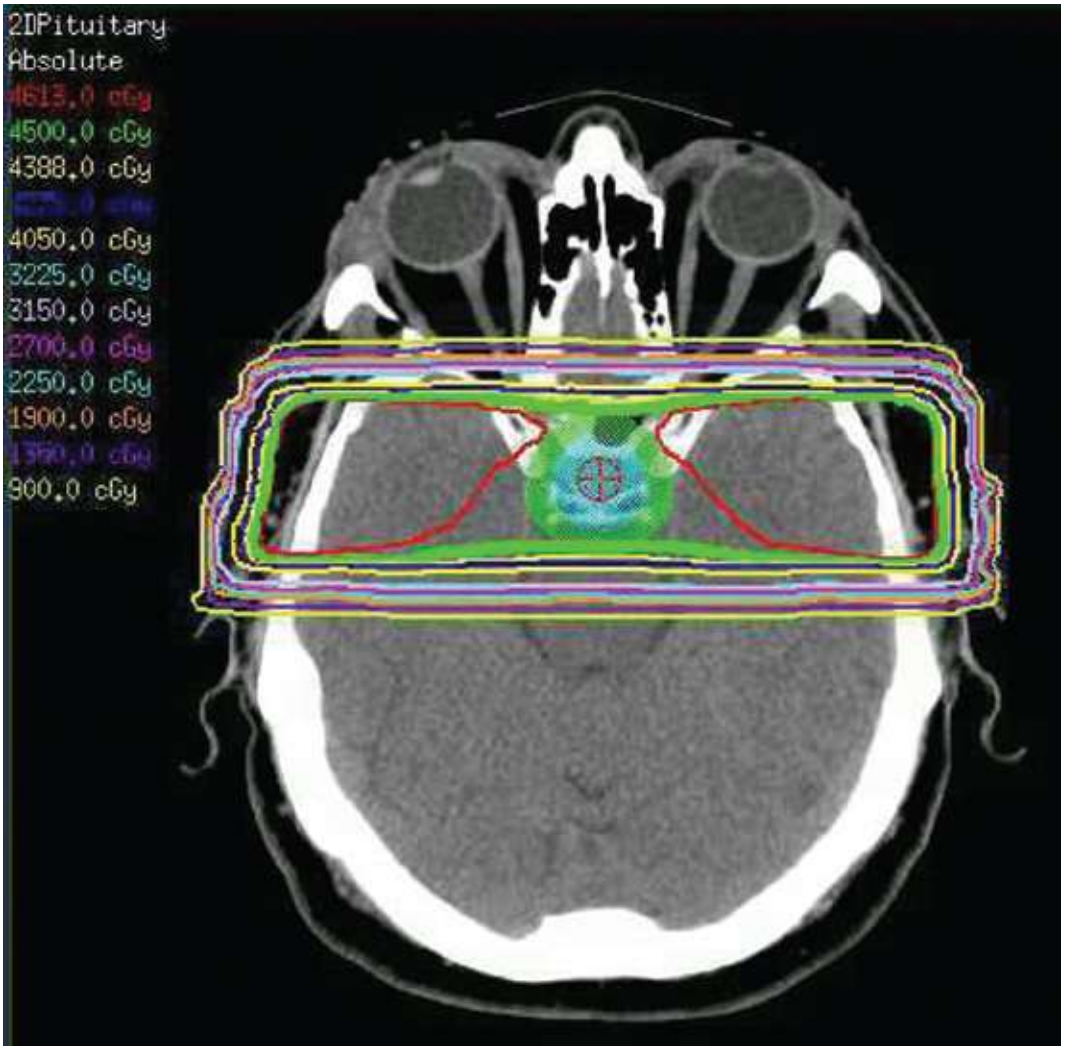

FIGURE 39.3. Two-dimensional parallel opposed pair radiotherapy planning.

At present, there are an increasing number of facilities that are investigating treatments with protons.[39] Proton therapy, while still exceedingly expensive, utilizes the unique advantage of the Bragg-Peak phenomenon to deliver doses mostly confined to the region of interest (Fig. 39.8).

Late Effects

A common worrisome potential when using higher doses to a pituitary adenoma is the possibility of developing late radiation-induced optic neuropathies. Although it has been reported that the incidence of optic nerve damage is low, ranging from 0.7% to 2%, the risk of optic nerve or chiasm injury is dependent on the proximity of the chiasm, the total delivered dose and dose per fraction.[27,28,34] Even with conventional doses of 45 to 50 Gy, the risk is very low, but it is not zero. Additionally, doses ranging from 45 to 50 Gy to the whole pituitary gland carry substantial risk of causing hypopituitarism. This is reported in the range of 10% to 30% in some series,[26–29,35] and potentially half of all patients treated to 45 Gy will develop a deficiency of at least one pituitary hormone within 2 to 5+ years after definitive radiotherapy. Therefore, the patient must be followed indefinitely for this complication risk. Second malignant neoplasms are always a concern for long-term survivors who have received therapeutic doses of radiation. The Royal Marsden Hospital looked at 334 patients irradiated for pituitary adenomas to a media dose of 45 Gy. Five patients developed a secondary brain tumor, for an actuarial risk of 1.3% at 10 years and 1.9% at 20 years.[40] Thus, the relative risk of developing a second tumor compared with the normal, unexposed, population was 9.3%. Princess Margaret Hospital reported similarly with four gliomas from 306 treated patients over a latency period of 8 to 15 years. The actuarial risk was 1.7% at 10 years and 2.7% at 15 years for a relative risk of 16%.[41]

CONCLUSION

The hypophysis cerebri or pituitary gland may be the smallest functioning gland in humans, but it represents one of the most critical functioning endocrine glands for normal development, growth, organ regulation, reproductive regulation, and birthing functions as well as regulation of other hormone glands in the total body system. The physical gland may be small, but its capabilities are great. Dysfunction of any part of this hormone gland has wide-reaching implications for endocrine abnormalities and for local mass effects. The latter especially affects the optic nerves and proliferates a cascade of additional and potentially devastating hormonal dysfunctions. The former influences cellular division, protein synthesis, regulation of the adrenal cortex and the thyroid, follicle and

sperm production, formation and function of the gravid uterus, testosterone secretion, and milk production. Lasting effects from chronic hypopituitarism also increased mortality from cardiac and cardiovascular events.[42,43] To summarize, adequate medical knowledge and understanding of the pituitary gland include understanding multiple feedback mechanisms required for the hormone normal-regulatory processes of the human body. Knowledge of therapy mechanisms for abnormalities plays an essential role for medical intervention, especially for the appropriate use of radiotherapy.

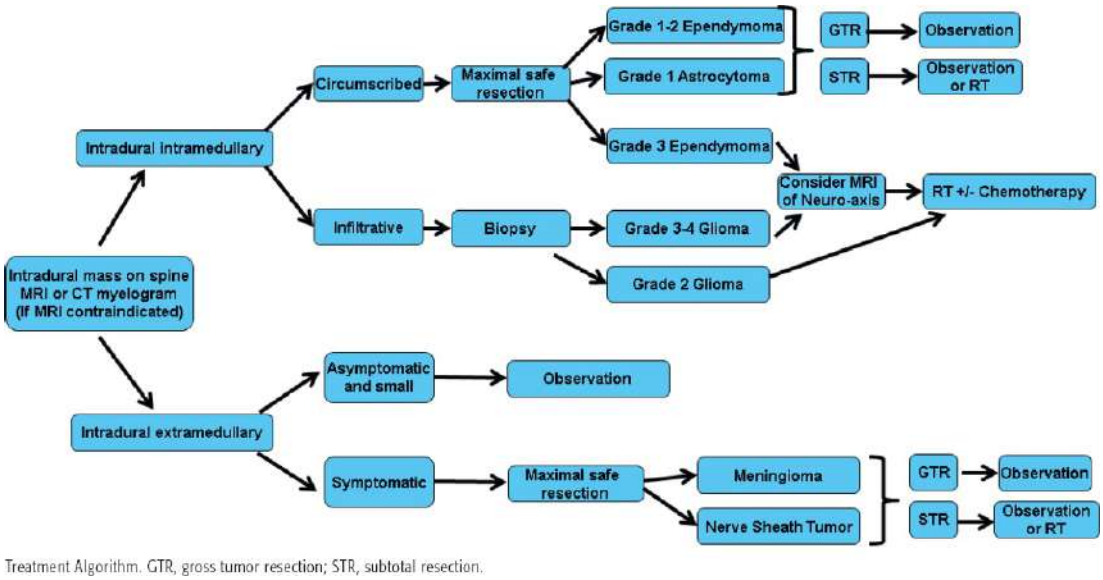
CHAPTER 40

Spinal Canal

Jiayi Huang, Clifford G. Robinson, and Jeff M. Michalski



Treatment Algorithm. GTR, gross tumor resection; STR, subtotal resection.

Treatment Algorithm. GTR, gross tumor resection; STR, subtotal resection.

INTRODUCTION

Tumors of the spinal cord and cauda equina account for approximately 3% of primary central nervous system (CNS) tumors overall and 4% in children.[1] Spinal canal tumors are classified by the World Health Organization (WHO) according to histologic types. Clinically, they are also characterized by their location relative to the protective layers of the spinal cord as extradural, intradural–extramedullary, or intramedullary (Fig. 40.1). Intramedullary lesions arise from the intrinsic substance of the spinal cord. Histologically, intramedullary spinal cord neoplasms include gliomas such as astrocytoma, ependymoma, and oligodendroglioma. Intradural–extramedullary tumors arise from the connective tissues, blood vessels, or coverings adjacent to the cord or cauda equina. Common histologies include nerve sheath tumor, meningioma, and ependymoma. Extradural tumors are most commonly metastatic, although

primary tumors in this compartment may occur as well. Primary extradural tumors arising from the vertebral bodies may include benign tumors such as osteoid osteoma, osteoblastoma, or aneurysmal bone cysts, or as malignant tumors such as plasmacytoma or myeloma, chordoma or chondrosarcoma, osteosarcoma, and Ewing sarcoma. Other primary extradural tumors arising outside of the vertebral body include epidural hemangiomas, lipomas, extradural meningiomas, nerve sheath tumors, and lymphomas.

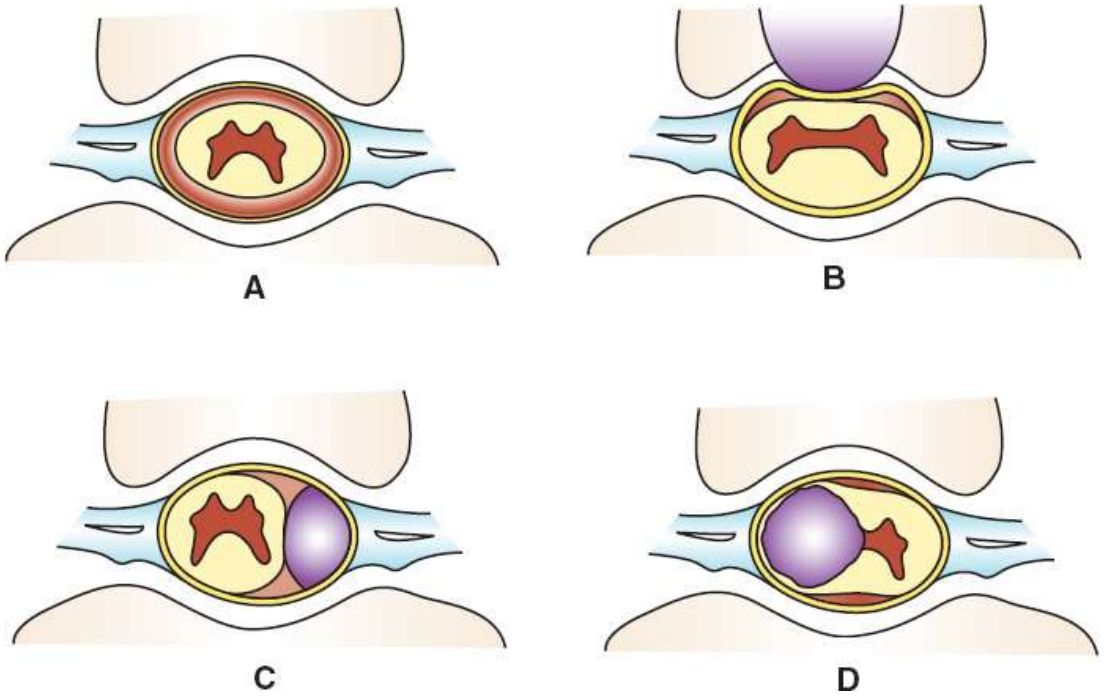


FIGURE 40.1. Neoplasms affecting the spinal cord. **A:** Normal transverse spine. The spinal cord is enveloped by the pia, arachnoid, and dura mater, which are housed in the spinal canal and surrounded by ligaments supporting the vertebral bony structures. The subarachnoid space contains cerebrospinal fluid (*brown*). **B:** Transverse spine with extradural mass. An extradural mass (e.g., metastasis) from the vertebral body is compressing the dural sac and the spinal cord from the anterior direction. The subarachnoid space becomes obliterated at that level, causing a myelographic block. **C:** Transverse spine with an intradural–extramedullary mass. The mass, typically a meningioma or nerve sheath tumor, is compressing the spinal cord and roots in the dural sac, causing a myelographic block with a laterally displaced cord and, at times, producing a capping contour of contrast border. **D:** Transverse spine with intramedullary mass. An intramedullary mass (astrocytoma or ependymoma) is infiltrating and expanding the spinal cord within the dural sac, causing a myelographic block.

Radiation therapy is an important modality in the management of both primary and metastatic tumors involving the spinal canal. This chapter focuses primarily on the management of primary spinal cord tumors. Primary extradural

tumors are usually managed in a manner similar to histopathologically identical tumors arising at other locations and will not be discussed here in detail. The management of metastatic tumors involving the spinal canal is discussed in Chapter 96.

ANATOMY

Spinal Cord

The spinal cord is a slender cylinder composed of functional segments corresponding to 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. In contrast to the brain, the white matter of the spinal cord is located in the periphery and surrounds the central gray matter. The gray matter contains the cell bodies of sensory, motor, and autonomic neurons. On cross section, the gray matter is a butterfly-shaped region with anterior horns controlling motor function, lateral horns (in the thoracic and upper lumbar region) controlling autonomic functions, and posterior horns involved in sensation. The white matter contains the axonal elements of neurons that transmit impulses to and from the brain. As in the brain, the axons of the spinal cord white matter possess a myelin sheath formed by the cytoplasmic extension of glial cells. Schwann cells sheath the spinal nerves that enter and exit the spinal cord. The spinal cord is organized into somatotopically distinct regions (Fig. 40.2). The lateral and anterior spinal cord white matter contains the nerve tracts that are involved with fine motor control and tone, including the corticospinal tracts. The spinocerebellar tracts transmit muscle stretch and tone sensation from the extremities to the cerebellum. The lateral spinal thalamic tract is located laterally near the spinal cord surface and carries ascending crossed pain fibers to the thalamus. The dorsal columns transmit fine touch and positional sensation from the extremities to the brain. Because of its serial organization, injury to the spinal cord results in characteristic neurologic findings that depend on the location of the insult.

The spinal cord is surrounded by the meninges, which is composed (from outer to inner) of the dura mater, arachnoid, and pia mater. The pia mater covers the spinal cord and its blood vessels. This layer condenses laterally into approximately 20 pair of dentate ligaments, which suspend the cord to the dura mater. The dura mater forms a dense, fibrous barrier between the bony spinal canal and the spinal cord. The dural sac ends inferiorly at S2-3, but the dura continues with the filum terminale down to the coccyx. The arachnoid mater

resides between the dura mater and the pia mater. The arachnoid encloses the subarachnoid space filled with cerebrospinal fluid (CSF). The subarachnoid space follows the arachnoid down to the end of the dural sac.

The growth of the vertebral column during childhood takes place at a rate and extent greater than that of the spinal cord itself. By adulthood, the spinal cord is nearly 25 cm shorter than the vertebral column and ends near the level of the L1 vertebral body. Because of this differential growth, the exit level of each pair of spinal nerves in the spinal cord is usually higher than the corresponding vertebral body level. For example, in adults, the C8 nerve root leaves the cord at the C6 vertebral body, the T6 nerve at the T3 vertebral level, and the T12 nerve at the T9 vertebral level. All of the lumbar nerves exit the spinal cord from vertebral levels T10 through T12, and all of the sacral nerves exit the spinal cord near the L1 vertebral level. The lower lumbar, sacral, and coccygeal nerves form the cauda equina, the collection of nerves that fills the thecal sac below L1. At its most caudal extent, the cord tapers to a thin segment, the conus medullaris. It is tethered to the coccyx by the filum terminale, a dense thread of pia mater.

Spinal Canal

The posterior body surfaces and neural arches of the vertebrae form the vertebral foramina, which in continuity form the spinal canal. Vertebral foramina are triangular in the lumbar and cervical regions, where the cord is mostly mobile, and round in the thoracic region. The spinal canal is lined with ligaments, including the posterior longitudinal ligament on its anterior wall, the flaval ligaments between adjacent arches, and the interspinous ligaments between the spinous processes. At each vertebral level, a spinous process protrudes from the posterior aspect of the neural arch, and transverse processes extend from the lateral edges of each arch. The laminae are those portions of the neural arch between the spinous and transverse processes, and the pedicles lie between the transverse processes and the body. At the intersection between the laminae and pedicles are superior and inferior paired articular facets. The superior articular facets are synovial joints that articulate with the inferior articular facets of the vertebra immediately above. The paired pedicles of each vertebra are notched at their superior and inferior edges such that the notches from two contiguous vertebra form an intervertebral foramen, through which the spinal nerve courses.

EPIDEMIOLOGY

Based on population data in the National Program of Cancer Registries (NPCR) and Surveillance, Epidemiology, and End Results (SEER) programs from 2004 to 2007, 22% of primary spinal tumors are malignant and 78% nonmalignant (62% benign and 16% with borderline behavior).[2] The most common sites are the spinal cord (60%), followed by the spinal meninges (36%), and the cauda equina (4%). Incidence appears to increase with advancing age, peaking at the seventh decade of life. Age-adjusted incidence rates are 0.76 per 100,000 persons for nonmalignant tumors and 0.22 per 100,000 persons for malignant tumors. The frequency of nonmalignant cases is higher for females (60%), whereas malignant cases are equally distributed by sex. Age-adjusted rates appear to be higher in Caucasian race and non-Hispanic ethnicity.[2] In adults, the most common histology types are meningioma (37.6%), nerve sheath tumor (23.1%), ependymoma (20.5%), and astrocytoma (4.2%). In children, the most common histology types are astrocytoma (31.4%), ependymoma (21.6%), oligodendroglioma (16.8%), nerve sheath tumor (13.3%), and meningioma (7.4%) (Table 40.1).[1]

NATURAL HISTORY

Primary spinal tumors have the capacity to cause significant neurologic morbidity. Intramedullary tumors produce neurologic damage by local invasion

or cystic compression of the cord, whereas extramedullary lesions compress, stretch, or distort the cord or the spinal nerves. Primary spinal cord tumors may be focal or relatively localized in some patients but may involve nearly the entire length of the cord in others. Local tumor progression is the dominant form of treatment failure of spinal cord tumors, though leptomeningeal dissemination may occur rarely.[3,4] Spread to lymph nodes is not typically seen with spinal canal tumors. Extraneural spread is rare, occurring with an overall incidence of approximately 1%, though this risk appears to be higher than cerebral tumors.[5] The major causes of death in patients with spinal canal tumors are complications of paraplegia or quadriplegia such as infection or respiratory compromise.

CLINICAL PRESENTATION

Pain is the most common presenting symptom, affecting approximately 72% of patients.[6] Often the pain is localized to the region of involvement and may be present well before the patient manifests localizing neurologic signs. Radicular pain, a result of pressure on nerve roots, reflects the distribution of the involved root and indicates that conduction is intact. Numbness replacing pain is a more advanced sign that indicates compromise of spinal nerve or nerve tract conduction. Extramedullary tumors can cause distention of the dura with severe pain in the region of the tumor that is characteristically aggravated by recumbency because of venous congestion. Thus, pain is often worse at night. Movement or the Valsalva maneuver also may worsen pain.

TABLE 40.1 Primary Spinal Canal Tumors of Adults and Children: Types, Locations, and Frequencies[a]

	Type	Location	Frequency (%)
Adults	Meningioma	Intradural–extramedullary	37.6
	Nerve sheath tumor	Intradural–extramedullary	23.1
	Ependymoma	Intramedullary or intradural–extramedullary	20.5
	Astrocytoma	Intramedullary	4.2
	Hemangioma	Intramedullary	3.8
	Oligodendroglioma	Intramedullary	2.5
	Others	—	8.4
Children	Astrocytoma	Intramedullary	31.4
	Ependymoma	Intramedullary or intradural–extramedullary	21.6
	Oligodendroglioma	Intramedullary	16.8
	Nerve sheath tumor	Intradural–extramedullary	13.3

Meningioma	Intradural–extramedullary	7.4
Hemangioma	Intramedullary	1.8
Others	—	7.7

[a]Based on Central Brain Tumor Registry of the United States (CBTRUS) statistical Report from 2008–2012.

Other symptoms of CNS involvement include weakness (55% of patients), sensory deficits (39%), and sphincter dysfunction (15%).[6] Low-grade tumors generally have a more prolonged duration of symptoms than high-grade tumors. Bladder and bowel dysfunction as presenting symptoms are relatively uncommon except for tumors that involve the conus medullaris and filum terminale.

Tumors involving the lumbosacral spine present with a cauda equina nerve root compression syndrome. Patients may have radicular pain in the anterior (L4), lateral (L5), or posterior (S1) thigh with corresponding paresthesias followed by muscle wasting of the glutei, hamstrings, or tibialis anterior muscles. Saddle anesthesia, absent ankle reflexes (S1), or plantar (S2) responses may be present. Impotence and loss of anal or bulbar cavernous reflexes also may occur.

DIAGNOSTIC WORKUP

History and Physical Findings

Table 40.2 shows the diagnostic workup for primary tumors of the spinal cord. A meticulous and accurate patient history and physical examination are critical aspects of the initial assessment and can often localize suspected spinal tumors. The neurologic examination should concentrate on testing motor and sensory functions and reflexes. The differential diagnosis of a patient with a spinal cord tumor may include syringomyelia, multiple sclerosis, amyotrophic lateral sclerosis, diabetic neuropathy, viral myelitis, or paraneoplastic syndromes.

A cutaneous sensory level may be definable, although the level of cord injury will be a few segments higher than the superior level of sensory loss because of pathway crossing characteristics. Loss of pain and heat and cold sensation below a specific dermatomal level indicates compromise of the spinothalamic pathway in the lateral columns. Impaired posture, gait, and coordination and loss of vibration sense indicate compromise of the posterior spinocerebellar pathways or the posterior columns.

At the level of the lesion, flaccid weakness and loss of tendon reflexes may

occur. Below the lesion, the same signs are noticed in acute stages, but spastic paralysis and hyperactive tendon reflexes plus an upward Babinski toe sign ensue in subacute and chronic stages. These findings are consistent with lower and upper motor neuron involvement, respectively. The signs and symptoms of neurologic dysfunction may be asymmetric. In some cases, a classic Brown-Séquard syndrome may be present with ipsilateral loss of motor function and fine touch sensation and contralateral loss of pain and temperature sensation below the level of the lesion.

TABLE 40.2 DIAGNOSTIC WORKUP FOR PRIMARY SPINAL CORD TUMORS

General
History
Physical examination
Complete neurologic examination
Diagnostic Imaging Studies
Plain radiography
Magnetic resonance imaging of the entire spine
Magnetic resonance imaging of the brain (Consider for high-grade ependymomas or astrocytomas)
Myelography with computed tomography (if MRI is contraindicated)
Laboratory Studies
Cerebrospinal (CSF) cytology (consider if clinical or radiological suspicion of leptomeningeal disease)

Autonomic reflexes (e.g., sweating) frequently are increased below the level of the lesion and may encompass the whole body if the lesion is cervical. Sweating disappears at the level of the compressed cord. Disruption of urinary and bowel function usually occurs later than sensory and motor dysfunction. Early loss of bladder function, saddle anesthesia, and later pain characterize neoplasms of the conus medullaris and filum terminale.[7]

Radiographic Studies

Although plain films are not typically used as the principal imaging modality for the evaluation of suspected spinal canal tumors, abnormalities can be detected from increased intracanal pressure including erosion of vertebral pedicles, enlargement of the anteroposterior diameter of the bony canal, or scalloping of the posterior wall of the vertebral bodies. Calcification may be seen in extramedullary tumors, especially meningiomas, and less frequently in nerve sheath tumors. Changes are more likely to be detected on plain radiographs in

children than in adults, such as kyphoscoliosis or scalloping of the vertebral bodies.[8,9]

Myelography, once considered the standard examination in evaluation of the spinal cord and canal, is now used principally in patients who are unable to undergo magnetic resonance imaging (MRI) because of the presence of implanted ferromagnetic materials or for whom images at the level of concern are distorted by the presence of surgical hardware. In this situation, computed tomography (CT) scanning combined with myelography will give better spatial resolution. CT myelography may be particularly beneficial as part of radiotherapy treatment planning in the postoperative setting, where the spinal cord may be obscured by artifact on the MRI.[10]

Computed Tomography

CT is most helpful in evaluating the spine for extradural pathologic processes. Bone tumors or paraspinal soft tissue masses that secondarily involve the spinal cord (e.g., dumbbell tumors) can be imaged with contrast-enhanced CT scans. Nerve sheath tumors can enlarge the intervertebral foramina or spinal canal and cause smooth erosion of bone. Meningiomas are occasionally calcified. Both of these neoplasms are partially outlined by CSF and produce extramedullary deformity by displacement of the spinal cord.[11]

Magnetic Resonance Imaging

MRI has replaced myelography and CT as the imaging study of choice in evaluation of tumors of the spinal canal. Sagittal and axial images give a three-dimensional appreciation of the patient's anatomy and help plan therapy. The various signal characteristics of the CSF—white and gray matter, bone and bone marrow, fat, and flowing blood—all facilitate the interpretation of the study. Some cystic tumors, vascular lesions, or lipomas can be diagnosed based on their characteristic signals on T1- and T2-weighted images without contrast injection. Intravenous gadolinium-diethylenetriamine pentaacetic acid (Gd-DTPA) administration improves the sensitivity of MRI by enhancing the solid component of intramedullary tumors and differentiating them from surrounding edema or syrinx cavities (Figs. 40.3 and 40.4). Unlike low-grade gliomas in the brain, nearly all spinal cord gliomas, regardless of grade, enhance with Gd-DTPA. Sagittal T1-weighted images usually localize intramedullary mass neoplasms along with adjacent cysts. Intradural–extramedullary lesions also show enhancement on T1-weighted images after administration of Gd-DTPA.

The use of Gd-DTPA also increases the sensitivity of detecting leptomeningeal metastases.[12]

MRI of the brain should be performed in patients with high-grade ependymomas or astrocytomas to exclude the possibility of neuraxis seeding or the presence of an intracranial primary tumor.

Cerebrospinal Fluid

A patient suspected of having a spinal canal neoplasm should not be subjected to a lumbar puncture before MRI. Symptoms may be exacerbated after a spinal tap because of shifting of the spinal cord and incarceration before the tumor can be localized adequately. The CSF usually has increased protein levels and may exhibit xanthochromia, especially with extradural compression conditions, but lower values can be found in cases of intramedullary disease and with compression in the cervical region.[7] The incidence of leptomeningeal spread in patients with primary spinal cord glioma is low overall but is substantially more common with malignant tumors. Of note, two recently recognized entities have significantly higher risk of leptomeningeal dissemination: glioblastoma with primitive neuronal component and diffuse leptomeningeal glioneuronal tumors (DLGT).[13,14] Cytologic examination of the CSF is not done routinely but may be considered in the presence of clinical or radiologic suspicion.

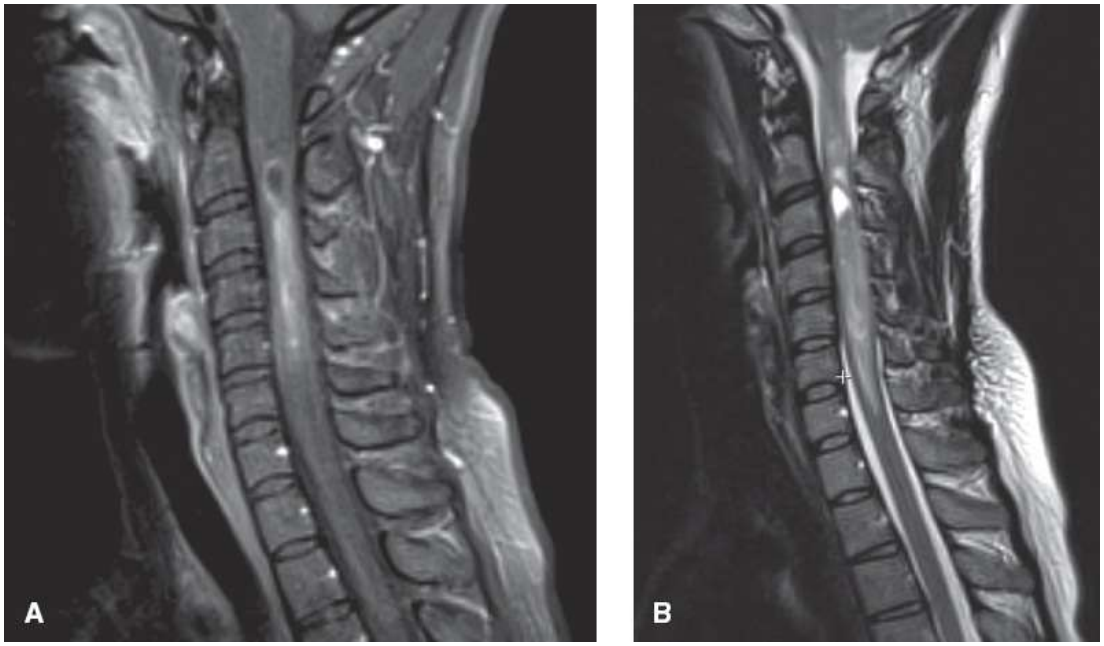

FIGURE 40.3. Sagittal magnetic resonance imaging scans of a 30-year-old female with a low-grade astrocytoma involving the cervical spine. **A:** T1-weighted image demonstrates an intramedullary lesion that expands the cord from the level of the

craniocervical junction to the level of C7. The enhancing component extends from mid C2 to C5, and there is an associated cystic component at the cranial aspect of the lesion. **B:** T2-weighted image demonstrates T2 hyperintensity within the lesion suggestive of edema and hypointensity suggestive of blood products.

FIGURE 40.4. Sagittal magnetic resonance imaging scans of a 12-year-old male with a myxopapillary ependymoma involving the lumbar spine. **A:** T1-weighed image demonstrates a homogenously enhancing intradural extramedullary mass at the level of L1. **B:** T2-weighted image demonstrates hyperintensity of the mass. (Courtesy Aseem Sharma, MD, Mallinckrodt Institute of Radiology.)

Tissue Diagnosis

Suspected primary tumors of the spinal cord and spinal canal should be pathologically confirmed whenever possible. Strong consideration should also be given to biopsy of any presumed metastatic tumors if they are the first site of disease recurrence after successful management of a previous malignant primary tumor. In rare circumstances in which emergency radiation therapy is indicated to relieve spinal cord compression in the absence of a confirmed cancer diagnosis, a patient should be made aware of the consequences of treatment in

the absence of a definitive diagnosis, including the inability to tailor therapy based on histology and possible delay of appropriate treatment for nonmalignant etiologies.

PATHOLOGIC CLASSIFICATION

The current comprehensive classification system of spinal tumors was published by the WHO in 2007 and recently updated in 2016 to incorporate many molecular markers to establish histology types. The WHO classification groups CNS neoplasms by the tumor histology and provides a grading system to predict prognosis and guide therapy.[15,16] Tumor types include neuroepithelial (i.e., astrocytoma, ependymoma, ganglioglioma), nerve sheath (i.e., schwannoma, neurofibroma), meningioma, lymphoma, germ cell, and metastatic tumors. Clinically, spinal tumors are also characterized by their location as extradural, intradural–extramedullary, or intramedullary.

Intramedullary Tumors

Intramedullary spinal tumors constitute approximately 20% to 30% of all primary spinal tumors, and approximately 80% are glial in origin of which ependymoma is the most common histology (60% to 70%) followed by astrocytoma (30% to 40%).[17] Ependymomas are derived from glial cells similar to those lining the ventricular system and can be either intramedullary or intradural extramedullary. Histologic subtypes can be classified into three grades based on histologic appearance and biologic behavior. Grade I tumors include myxopapillary ependymoma and subependymoma. Myxopapillary ependymomas typically occur around the conus medullaris and often involve the cauda equina or filum terminale. Grade II tumors include cellular (classic), papillary, clear cell, and tanycytic subtypes. Grade III tumors are defined as anaplastic ependymomas.[16,18]

In contrast to intracranial astrocytoma, the majority of spinal cord astrocytomas are low grade (WHO grade I or II), including 75% in adults and 85% to 90% in children.[6,19,20] Juvenile pilocytic astrocytomas (grade I) in particular, as in other locations in the CNS, are not infiltrative in nature. Recognition of this feature, along with advances in surgical techniques and intraoperative monitoring, has led neurosurgeons to manage these tumors with more radical resections. However, many fibrillary astrocytomas (grade II) as well as anaplastic astrocytomas (grade III) and glioblastoma multiforme (grade

IV) are infiltrative, and complete resection carries a significant risk of neurologic disability. In these cases, a subtotal resection or biopsy may be the only safe surgical option.[21–23]

A discriminating feature of intramedullary spinal cord tumors is the presence or absence of a syrinx. Syringes associated with spinal cord astrocytoma occur in 20% to 40% of patients. Syringes can span the entire length of the cord, although they tend to favor more rostrally located tumors, as well as favoring the more rostral portion of the tumor itself.[24] In certain instances, a syrinx may even extend into the medulla, producing an obstructive hydrocephalus.[25] The syrinx itself can be responsible for significant neurologic deficit.

A variety of vascular neoplasms can arise from within the spinal cord, including arteriovenous malformations, hemangiomas, and hemangioblastomas. Approximately one-third of hemangioblastomas are associated with von Hippel-Lindau disease. These are benign neoplasms that are usually well circumscribed and amenable to surgery.[26] Unresectable or recurrent hemangioblastomas may be treated with stereotactic radiosurgery (SRS).[27]

Intradural–Extramedullary Tumors

Most intradural–extramedullary neoplasms are meningiomas, nerve sheath tumors, or extramedullary ependymomas such as myxopapillary ependymomas. They usually are amenable to complete surgical excision.

Meningiomas are usually benign, slow-growing, well-encapsulated neoplasms that are easily separated from the spinal cord; most can be completely excised, and they rarely recur. They may arise anywhere within the intradural space but are most commonly found in the cervicothoracic region and are uncommon in the lumbar region and rare in the sacrum. Spinal meningioma occurs more frequently in females. The peak incidence is between the sixth and eighth decades of life. The duration of symptoms before diagnosis is typically between 12 and 24 months, with longer duration as an independent predictor for a lack of improvement after surgery.[28]

Nerve sheath tumors arise from the Schwann cell, the cell responsible for insulating peripheral nerves and contributing to impulse conduction. Nerve sheath tumors have been called neurofibroma, schwannoma, neuroma, and neurilemoma in the past. More recently, a distinction between neurofibroma and schwannoma has been made. Although both tumors arise from Schwann cells, certain gross, microscopic, and clinical features help distinguish the two. Growing evidence also suggest that they arise via distinct pathogenic

mechanisms.[29,30] Neurofibromas typically encase involved nerve roots, whereas schwannomas commonly displace the nerve roots because of their asymmetric growth. The plexiform neurofibroma is associated with type 1 neurofibromatosis, and the presence of multiple tumors helps establish the diagnosis of this genetic condition. In contrast, schwannoma is associated with type 2 neurofibromatosis. Patients with type 1 neurofibromatosis may be at risk for malignant tumor transformation following radiotherapy.[31,32] Nerve sheath tumors usually are solitary and may occur in any section of the spinal canal. They are evenly distributed in the cervical, thoracic, and lumbar regions; they are least common in the sacrum. They occur in men and women with equal frequency and are most commonly diagnosed in the fourth through sixth decades of life. Most of these tumors are completely intradural, although 10% to 15% may have an extradural component as well (so-called dumbbell tumors). Most nerve sheath tumors are benign, well-encapsulated lesions that are amenable to total surgical excision. The rare malignant nerve sheath tumors have a natural history similar to soft tissue sarcomas, and they should be treated as such.[33,34]

Miscellaneous Neoplasms

Unusual intradural–extramedullary tumors include lipomas, dermoids, and epidermoid tumors. They are typically benign and amenable to complete resection. Even if incompletely excised, recurrences are usually slow.

Extradural Tumors

Most extradural tumors are metastatic, and the presentation and management of these is discussed in Chapter 94. A variety of primary bone and soft tissue tumors may arise from an extradural location and involve the spinal canal. Bone tumors include osteosarcoma, chordomas, chondrosarcoma, and Ewing sarcoma. Soft tissue tumors include soft tissue sarcomas, including malignant nerve sheath tumors, lymphomas, and neuroblastomas. These tumors and their management are discussed in Chapters 82 (lymphoma), 86 (osteosarcoma/chordoma), 87 (soft tissue sarcoma), 90 (neuroblastoma), and 92 (Ewing tumor), respectively.

PROGNOSTIC FACTORS

The major prognostic factors in patients with primary spinal canal tumors are tumor type and grade, tumor extent and location, patient age, and presenting neurologic function. Treatment-related factors that influence the outcome include tumor resectability and the use of radiation therapy for certain tumor

types. Many of these factors are interdependent. For example, ependymomas occur most frequently in the distal spinal canal and are more often resectable than astrocytic tumors.

Recently, Milano et al. analyzed 664 patients with spinal cord astrocytomas and 1,057 patients with spinal cord ependymomas using the SEER database. In this largest study to date on prognostic factors for long-term outcome, lower grade, younger age, and surgical resection were associated with significantly better overall survival and cause-specific survival for both astrocytomas and ependymomas. Radiotherapy was associated with worse cause-specific survival, but this is likely because of adverse selection bias. The 5-year overall survival of grades 1, 2, 3, and 4 astrocytomas was 82%, 70%, 28%, and 14% and the 5-year cause-specific survival was 89%, 77%, 36%, and 20%, respectively. The 5-year overall survival of grades 1, 2, and 3 ependymomas was 92%, 97%, and 58% and the 5-year cause-specific survival was 100%, 98%, and 64%, respectively.[35] Weber et al. analyzed the long-term outcomes of 183 patients with spinal myxopapillary ependymomas from a pooled database of the Rare Cancer Network and the MD Anderson Cancer Center and reported 10-year overall survival of 92% and 10-year progression-free survival of 61%. Tumor recurrence occurred in 32% of patients, and 85% of the recurrences were local. On multivariate analysis, older age (≥36), adjuvant radiation therapy, and gross-total resection were associated with improved local control and progression-free survival.[36]

Several investigators have reported that patients with cervical spinal tumors have a worse survival and neurologic outcome than patients with more caudal tumors.[37–40] Guidetti et al. stated that patients with cervical lesions had a higher surgical risk and complication rate, which made thorough resection of tumors in this location difficult and sometimes inadvisable.[40] In a series of 62 patients with exclusively intramedullary ependymomas, patients with high cervical presentations (above C5) accounted for 4 of 6 postoperative deaths because of apneic respiratory complications.[38] In the Mallinckrodt Institute of Radiology experience, Garcia reported that the primary tumor location was the most important prognostic feature. It was suggested that a greater concentration of function per unit volume of the upper spinal cord compared with that of the cauda equina accounted for the worst neurologic outcome and survival in patients with rostral tumors.[39] In these studies, tumors affecting the cervical spinal cord were more likely to be astrocytomas, and tumors in the caudal spinal cord, filum terminale, or cauda equina were more likely to be ependymomas.

The anatomic dependence of various tumor types may also contribute to the better prognosis seen in patients with tumors of the lower spinal canal.

Extensive involvement of the spinal cord with an ependymoma is associated with a worse outcome. Linstadt et al. reported a 93% 10-year disease-specific survival rate with localized ependymoma compared with 50% for patients with diffuse tumors.[41] Extensive tumors have a 50% local failure rate after surgery and radiation therapy, compared with only 20% for limited disease (one to three vertebral body segments).[42] However, extent of disease has not been a prognostic factor in other series.[43]

Neurologic function at diagnosis is an important clinical prognostic factor. In general, the fewer the symptoms and the better the neurologic function at presentation, the greater the likelihood the tumor will be controlled with fewer long-term adverse neurologic sequelae. Poor neurologic function in patients with spinal cord tumors is often attributable to the disease process and a prolonged delay in diagnosis rather than the effect of surgery or radiation therapy.[38,40,44]

SURGICAL MANAGEMENT

Intramedullary Tumors

Intramedullary tumors, most of which are astrocytomas and ependymomas, present a surgical challenge. Complete surgical excision is the treatment of choice if it can be achieved without compromising neurologic function. Ependymomas are more frequently amenable to gross total excision than are astrocytomas.[21,40] Myxopapillary ependymomas most commonly involve the cauda equina and are less aggressive than other ependymomas, though they have been reported to seed the CSF.[45–49] Encapsulated myxopapillary tumors of the cauda equina are frequently amenable to complete en bloc excision, and the recurrence rate is very low. Unencapsulated or adherent tumors often are removed piecemeal and are associated with a high local recurrence rate after surgery alone, and adjuvant radiation therapy should be considered.[42,49–51]

Complete resection of intramedullary tumors with preservation of neurologic function was not possible until 1940, when Greenwood introduced the bipolar coagulation forceps. Since then, other technologic advancements have emerged, including the dissecting microscope, intraoperative ultrasound, ultrasonic aspirator, contact laser scalpel, and intraoperative neurophysiologic monitoring. These modern surgical techniques have increased the complete resectability of intramedullary tumors while minimizing neurologic injury.[52–55]

Intraoperative ultrasonography is used to localize the lesion, define its extent, and assess the progress of tumor resection.[56] The ultrasonic aspirator allows removal of tissue fragments from within 1 mm of the vibrating tip, permitting dissection immediately adjacent to vital neural tissue.[57] The contact laser scalpel only delivers thermal energy to tissue upon direct contact, and the laser beam resides entirely within a coated sapphire crystal probe tip. It provides precise dissection of tumor with little mechanical or thermal injury to normal spinal cord parenchyma.[58]

Intraoperative neurophysiologic monitoring is considered standard of care for resection of intramedullary tumors. It is dependent on two key components: somatosensory-evoked potentials (SEPs) and motor-evoked potentials (MEPs). SEPs are monitored continuously during the incision of the dorsal midline of the spinal cord to avoid injuring the dorsal column, as the cord anatomy is often distorted by the tumor. MEPs are monitored once the surgeon starts to dissect the tumor to avoid irreversible damage to the corticospinal tract. MEPs should be monitored using a combination of epidural electrodes (D waves) and signals from limb muscle (mMEPs). Typically, a decrement of 50% or more of D-wave amplitude is considered a major indication to stop surgery.[59] Sala et al. reported that the use of intraoperative neurophysiologic monitoring during resection of intramedullary tumors significantly improved long-term ambulatory status as compared to historical controls.[60]

The risk of paralysis after surgery is <1% of patients with minimal or no preoperative neurologic deficits but may be much higher for those who present with more substantial deficits. Approximately one-third of patients will develop temporary motor deficits after surgery and most will have at least some postoperative deterioration in neurologic status.[61,62] If complete excision of low-grade spinal cord tumors is achieved, the local recurrence rate is low and prognosis is excellent without additional adjuvant therapy. In patients who recur, tumor regrowth is often slow and second resection may be possible.[22,63–65]

Intradural–Extramedullary Tumors

The treatment of choice for most tumors in this location is maximal surgical excision with preservation of neurologic function. Most benign nerve sheath tumors can be completely resected with low risk of recurrence. In contrast, complete resection of malignant peripheral nerve sheath tumor is difficult, and local recurrence is high and typically occurs between 7 and 15 months after surgery. For spinal meningioma, local recurrence is low after Simpson grade I

resection but can be as high as 30% after Simpson grade II resection with an average time of 12 years after surgery. Thus, Simpson grade I resection is preferred for spinal meningioma if attainable.[66–68]

CHEMOTHERAPY

The reported use of chemotherapy for primary spinal canal tumors is limited. Outside of a clinical trial, chemotherapy is often reserved for patients with progression of disease following surgery and radiotherapy with no other treatment options. Combined with the low incidence of the disease, most studies are retrospective with very few patients, which limits any definitive conclusion regarding their efficacy. The use of chemotherapy for spinal canal tumors is often extrapolated based on the experience for intracranial tumors. However, such assumption requires further validation as the underlying oncogenesis and biologic pathways may be different between the two entities.[69]

Platinum and etoposide are generally considered the most active agents for ependymomas. In the setting of recurrent ependymoma, platinum-based chemotherapy has been shown to produce higher response rates than nitrosourea-based chemotherapy, but most patients in the studies had intracranial ependymomas.[70,71] In a prospective phase II study, 10 consecutive patients with recurrent cellular spinal cord ependymomas were treated with oral etoposide. Two patients had partial responses, and five patients had stable disease. The median overall survival was 17.5 months.[72]

Temozolomide is an attractive agent for primary spinal cord glioma given its success in treating intracranial astrocytoma.[73] Kim et al. reported their experience of treating two patients with primary spinal cord glioblastoma multiforme with concurrent radiotherapy and temozolomide followed by adjuvant temozolomide. The two patients survived 12 and 16 months, respectively, in contrast with a median survival time of 9 months in other reports.[74] Chamberlain reported a series of 22 patients with recurrent WHO grade II glioma treated with temozolomide. Overall, there were 18% partial response and 55% with stable disease. The median survival was 23 months, and progression-free survival at 2 years was 27%.[75]

For young children, especially those <3 years of age, there is an even greater interest in identifying effective and minimally toxic chemotherapy to delay or eliminate radiation therapy. There are two prospective cooperative group trials that have included children with primary spinal cord astrocytomas. In one

clinical trial conducted by the French Society of Pediatric Oncology, eight children with unresectable or recurrent intramedullary low-grade gliomas were treated with a planned 16-month course of carboplatin, procarbazine, vincristine, cyclophosphamide, etoposide, and cisplatin. Seven of the patients had a clinical or radiographic response to the chemotherapy. Five of the patients remained progression free, with follow-up ranging from 16 to 59 months.[76] In the Children's Cancer Group 945 trial, 13 children with high-grade astrocytic spinal cord neoplasms were assigned to receive two cycles of "8-drugs-in-1-day" chemotherapy before radiation therapy, then eight additional cycles thereafter. At 5 years, 46% of the children had no progression and 54% were alive. The authors argued that more intensive therapy was necessary.[77] Mora et al. reported a small but thought-provoking study of three infants with spinal cord astrocytomas (WHO grade II or III) treated with irinotecan and cisplatin. All three infants had subtotal resection and progressed on conventional carboplatin-based chemotherapy. After switching to irinotecan and cisplatin, all three patients had remarkable radiologic and clinical response. At the time of the last follow-up, they had remained in remission at 12, 20, and 48 months after diagnosis. The authors hypothesized that irinotecan and cisplatin may provide synergistic effect without overlapping toxicities.[78] A recent phase II Children's Oncology Group clinical trial (COG-ACNS0423) treated pediatric patients with high-grade glioma with adjuvant radiation and concurrent temozolomide followed by additional temozolomide and lomustine chemotherapy, which included 5% of spinal high-grade astrocytomas. The study demonstrated improved event-free survival and overall survival as compared to historical controls of similar regimen without lomustine.[79]

RADIATION THERAPY

There are currently no randomized controlled trials to guide the role of radiation therapy for primary spinal canal tumors. Clinical use of postoperative radiation therapy is generally guided by patterns of failure and the prevailing attitude of many radiation centers.[80] Patients with completely resected low-grade astrocytomas and ependymomas typically have an excellent prognosis, with local failure rates of <10% without additional therapy.[68,81–83] Most centers do not advocate routine use of adjuvant radiation therapy in this setting, but long-term follow-up is indicated as late failures can occur.

In contrast, adjuvant radiation therapy after incomplete resection or piecemeal

excision of low-grade ependymomas and astrocytomas is supported by retrospective analyses. Guidetti et al. first reported a beneficial outcome in patients receiving radiation therapy after an incomplete excision of an ependymoma.[40] Piecemeal removal of ependymoma in the region of the conus medullaris, cauda equina, and filum terminale (most commonly myxopapillary ependymoma) has high local failure rate ranging from 20% to 43%. Adjuvant radiation therapy in these patients after piecemeal excision produces similar local recurrence rate equal to that of patients undergoing gross total resection.[42,49,51,84] The long-term outcome of 183 spinal myxopapillary ependymomas from Weber et al. showed adjuvant radiation therapy improved 10-year progression-free survival from <40% to 70%. The authors advocated more liberal use of adjuvant radiation therapy for myxopapillary ependymoma patients with subtotal resection, piecemeal resection, or questionable gross–total resection.[36] In a multi-institutional series, adjuvant radiation therapy significantly improved progression-free survival in the 40 patients with low- and intermediate-grade astrocytomas.[21] After adjuvant radiotherapy, the cumulative incidence of local failure ranges from approximately 20% for low-grade ependymoma to 40% for low-grade astrocytoma.[80]

Nonetheless, there are clinical circumstances in which careful follow-up after incomplete resection is appropriate, with a second surgery or radiation therapy considered at the time of progression or recurrence. Radiation therapy of the spine in a child may produce a spinal deformity (i.e., scoliosis or kyphosis) because of retardation of bone growth from damage to epiphyseal plates of the vertebral bodies as well as soft tissue fibrosis and contracture.[85] Most spinal cord tumors in young children are either low-grade astrocytomas or well-differentiated ependymomas that have a very low growth rate. Delaying radiation therapy until recurrence or tumor progression may allow the child to grow at a normal rate for several years before receiving radiation therapy. Constantini et al. reported a series of 164 patients younger than 21 years of age treated with radical surgery alone without adjuvant radiotherapy. Gross total resection or subtotal resection was achieved in 77% and 20% of patients, respectively. The 3-month neurologic function was 60% stable, 16% improved, and 24% deteriorated compared with preoperative function. The 5-year progression-free survival rate for low-grade and high-grade tumors was 78% and 30%, respectively.[86]

The prognosis of high-grade astrocytomas and ependymomas is dismal, and multimodality treatment is recommended, ideally on a clinical trial. Adjuvant

radiation therapy is routinely recommended regardless of the extent of resection. The role of concurrent and adjuvant chemotherapy for high-grade intramedullary astrocytoma remains inconclusive as discussed earlier. Despite aggressive treatments, few patients with high-grade astrocytomas survive beyond 2 years.[80,87] As with intracranial high-grade glioma, novel therapies beyond traditional radiotherapy and cytotoxic chemotherapy are desperately needed.

Relapse can occur years after treatment and is predominantly local. In a series of 37 spinal ependymomas treated with adjuvant radiotherapy, more than 50% of failures developed 5 years after diagnosis, and the extent of surgical resection correlated with time to progression.[88] These findings were confirmed in another series of patients with spinal myxopapillary ependymoma, where Chao et al. reported a median time to recurrence of 7.7 years.[89]

The prognosis is excellent for most patients with intradural–extramedullary tumors, which rarely recur after total excision. However, subtotally resected meningiomas may recur late after surgery.[90] Some investigators have advocated postoperative radiation therapy using either conventional fractionated external-beam radiotherapy or SRS.[91,92] Data supporting the routine use of radiation therapy in the management of patients with nerve sheath tumors, vascular malformations, lipomas, hemangiomas, teratomas, and dermoids are limited.

RADIATION THERAPY TECHNIQUES

Target Volume

Historically, it had been recommended that superior and inferior field borders encompass two vertebral bodies above and below a tumor defined by myelography, with the width of the field approximated between the tips of the lateral processes of the vertebral bodies. With the advancement of CT simulation and MRI fusion, the gross tumor volume (GTV) can be more accurately defined and smaller margins may be used. For low-grade astrocytomas or ependymomas, a clinical target volume (CTV) margin of 0.5 to 1 cm is appropriate. The CTV should encompass the preoperative GTV plus any associated intratumoral cysts. It is not necessary to include an intramedullary syrinx that extends above or below the primary tumor unless there is radiographic or surgical evidence of tumor extension to these regions. Planning treatment volume (PTV) margins of 0.5 cm or less may be used to account for setup error, with smaller PTV margins necessitating adequate patient immobilization and optimal daily localization techniques (orthogonal kilovoltage imaging, cone-beam CT, etc.).

High-grade astrocytomas and ependymomas can be more infiltrative, and a larger CTV margin of at least 1.5 cm craniocaudally should be used. Merchant et al. described a diffuse failure pattern in children with high-grade gliomas shortly after completing radiation therapy, suggesting that the tumor was not adequately covered in the irradiated volume and the need for larger CTV margins of 1.5 cm.[93] The intervertebral foramina should be included within the CTV if tumor extension is suspected.

For myxopapillary ependymomas involving the conus, a 1.5-cm CTV margin cephalad and caudad to the GTV is used, but not beyond the thecal sac, which is typically at the level of S2-3. If the cauda equina is involved, the CTV should extend inferiorly to encompass the entire thecal sac, with the volume widened at the sacroiliac joints to ensure adequate coverage of the meningeal sleeves in the intervertebral foramina. Failure to adequately encompass the thecal sac has been associated with an increased rate of treatment failure.[84]

Craniospinal or spinal axis irradiation usually is not indicated in the treatment of most spinal cord tumors; local failure accounts for most tumor recurrences.[21,39,41,42,82] However, neuraxis dissemination may be seen in patients with anaplastic ependymomas,[94] malignant astrocytomas,[95,96] and myxopapillary ependymomas.[46,47] Craniospinal irradiation may be considered if there is evidence of leptomeningeal dissemination.

Radiation Technique

For conventional external-beam field arrangements, cervical cord tumors are typically treated with parallel opposed lateral fields to reduce dose to the oral cavity, larynx, and pharynx. Thoracic cord tumors are commonly treated with direct posterior or posterior wedge fields to limit dose to the anterior structures such as the lungs, esophagus, and heart. Lumbar and cauda equina tumors are mostly treated with opposed anteroposterior–posteroanterior portals because of the lumbar lordosis and the deep location of the vertebral canal. Three-dimensional (3D) conformal or intensity-modulated radiation therapy (IMRT) methods may reduce normal tissue toxicity and should be considered when exit dose to the anterior midline structures of the trunk would otherwise be excessive (Fig. 40.5).[47] However, IMRT may increase the volume of normal tissue receiving low doses (integral dose) and is theoretically associated with a higher risk of secondary malignancy.[97]

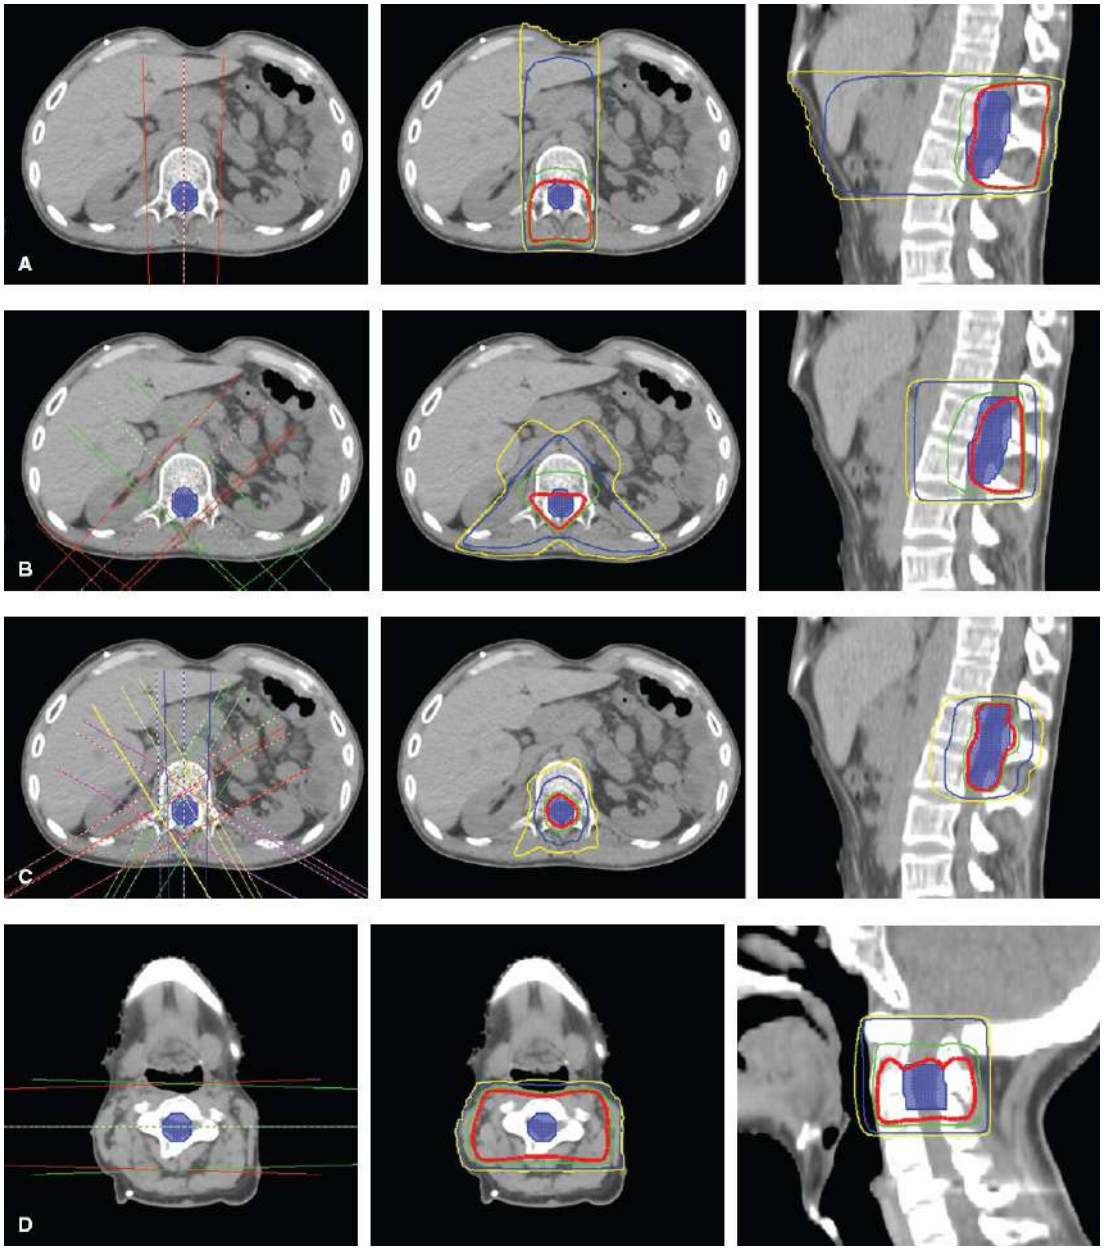

FIGURE 40.5. Treatment planning for spinal cord tumors. Planning treatment volume (PTV) in *solid blue. Red line,* prescription dose of 50.4 Gy; *green line,* 95% of prescription dose of 47.88 Gy; *blue line,* 30 Gy; *yellow line,* 20 Gy. **A:** A single posteroanterior field. The advantages of this beam arrangement include simplicity and near-universal applicability in most spinal cord radiation therapy treatments. One disadvantage of this field arrangement is the large volume of tissue that receives a significant exit dose. The axial and sagittal isodose displays reflect a 6-MV x-ray beam treated to a point just anterior to the PTV. **B:** Paired posterior oblique wedge fields. The advantage of this technique is a decrease in high exit-dose irradiation to anterior tissues with a more conformal irradiation dose distribution near the target volume. Disadvantages include more complicated treatment setup and verification. The axial and sagittal isodose displays reflect a 45-degree wedged pair of 6-MV x-ray beams treated to the same point with a 90-degree hinge angle. **C:** Intensity-modulated radiation therapy (IMRT). An advantage is a highly conformal dose

distribution with excellent sparing of adjacent critical structures. Disadvantage are complexity and high integral dose. The axial and sagittal isodose displays reflect a five-field static IMRT plan with 6-MV x-rays. **D:** Opposed lateral fields. An advantage is a homogeneous dose distribution in the target volume with sparing of anterior structures from significant irradiation dose. A disadvantage is limited applicability in cervical and lower lumbosacral sites. Exclusive use of this field arrangement in the thorax and upper abdomen is inappropriate because of limited lung and kidney tolerance. The axial isodose display reflects a pair of laterally directed 6-MV x-ray fields treated to the midplane of the cervical spine. (**C**, Courtesy Andrew Lindsey, Washington University Department of Radiation Oncology, St. Louis, MO.)

In female patients requiring treatment to the lumbosacral spine for cauda equina tumors, a lateral technique may be used to avoid exit irradiation to the ovaries and uterus. This technique prevents the anterior pelvic structures from receiving significant irradiation dose, which is desirable in young women and girls to minimize incidental irradiation of the ovaries. The superior aspect of this field can be matched to the divergence of a superior posteroanterior field in a fashion similar to the junction of a cranial portal to a spinal portal in craniospinal irradiation. Beam modifiers such as wedges or tissue compensators may be required with this lateral beam arrangement. Care should be taken to avoid irradiating the kidneys at the L1 through L3 levels with this technique. Arms should be positioned appropriately to avoid entrance or exit irradiation from the lateral beams.

The depth of the vertebral surface of the cord beneath the skin surface is determined from CT or MRI, and for short field lengths this depth is used for dose prescription. The treatment plan should provide a homogeneous dose distribution. For small lesions of the cervical spinal cord, where lateral fields will be used, radiation beam energies of 4 to 6 MV photons achieve a homogeneous dose distribution. Lesions involving the thoracic and lumbar spine often require combinations of low-energy (4 to 6 MV) and high-energy (18 to 25 MV) photons to achieve a homogeneous dose distribution when posterior fields are used. Attention to the exit dose delivered to anterior anatomical structures needs to be considered against dose heterogeneity in the target volume. Parallel-opposed posterior and anterior fields or paired oblique wedge fields can give homogeneous dose distributions with x-ray energies as low as 4 or 6 MV.

Radiation Dose

Low-grade astrocytomas and ependymomas should be irradiated to a total dose of 50.4 Gy, given in 1.8 Gy daily fractions. High-grade astrocytomas can be treated to a dose of 54 Gy with 1.8 Gy daily fractions. High-grade ependymomas

and multifocal low-grade astrocytoma should be treated to a dose of 50.4 to 54 Gy.[80] Limited dose response data exist for spinal cord tumors. In the Mallinckrodt series of 37 patients with primary spinal cord tumors, local control and survival were significantly better for those received 40 Gy or higher.[39] Shaw et al. reported that the local failure rate of ependymomas was 35% in patients receiving 50 Gy or less compared with only 20% in patients receiving more than 50 Gy.[42] However, doses beyond 50.4 Gy have not been shown to improve local control or survival.[41,96,98] In patients with high-grade ependymomas or other spinal cord gliomas with evidence of CSF dissemination, craniospinal irradiation should be considered. Typical doses to the craniospinal axis range from 36 to 45 Gy, with a boost to sites of gross tumor to 50.4 to 54 Gy.

Stereotactic Radiosurgery

Stereotactic radiosurgery provides the ability to deliver highly conformal, high-dose radiation in such a manner as to mitigate normal tissue injury while escalating dose to the target volume. Most spine SRS reports to date have focused on its use in the management of metastatic disease to the spine. In a recent review, Hsu et al. found local control rates in excess of 80% in most series, with significant pain improvement in 43% to 97%.[99]

A few reports have also detailed spine SRS in the management of patients with intradural tumors. In the largest series reported to date, Gerszten et al. treated 73 patients with benign intradural spinal tumors (meningioma, schwannoma, neurofibroma) using CyberKnife (Accuray Inc, Sunnyvale, CA) spine SRS to doses ranging from 16 to 30 Gy in 1 to 5 fractions. At a median of 37 months follow-up, the local control rate was 98% and pain improved in 70% of meningiomas, 50% of schwannomas, and 0% of neurofibromas. Three patients developed radiotherapy-related spinal cord toxicity 5 to 13 months after treatment.[91] Overall radiographic response rates for benign intradural tumors in the series reported to date range from 28% to 39%.[99]

Investigators from Stanford University have reported their experience treating spinal cord ependymomas and hemangioblastomas using spine SRS delivered with the CyberKnife system (Fig. 40.6). In the earliest report, 7 patients with 10 intramedullary spinal tumors (7 hemangioblastomas, 3 ependymomas) received spine SRS to a dose of 18 to 25 Gy in 1 to 3 fractions.[27] At a mean follow-up of 12 months, one ependymoma and two hemangioblastomas were smaller on follow-up imaging, with the remainder stable. No significant treatment-related complications were reported. In a follow-up study, Daly et al. reported a 3-year

actuarial control rate for 27 spinal hemangioblastomas treated with spine SRS to 18 to 25 Gy in 2 to 3 sessions. One patient developed a grade 2 foot drop 4 months after SRS, and two patients developed grade 1 sensory deficits.[100]

Early results of spine SRS for intradural–extramedullary or intramedullary lesions are promising, and with the rapidly increasing availability of extracranial radiosurgery devices, SRS for these patients will no doubt increase in utilization. However, with such few reports and limited follow-up to date, caution certainly seems warranted given the potential for late toxicity in these patients with high rates of long-term survival. Issues related to spinal cord tolerance after spine SRS are discussed below.

Proton Therapy

Proton therapy is a form of particle radiation that provides very conformal radiation therapy with a lower integral dose than other forms of photon radiation therapy.[101] Due to its unique physical property, it can spare low dose exposure to the normal tissues distal to the proton beam, which theoretically should translate to reduction of late-toxicities such as secondary malignancy and cardiac disease, especially for young adults or pediatric patients.[102–104] Amsbaugh et al. reported a prospective case series of 7 pediatric patients with spinal ependymomas treated with proton therapy (ranging from 45 to 54 cobalt gray equivalents). They showed proton therapy was well tolerated and dramatically reduced dose to all normal tissues anterior to the vertebral bodies as compared to photon therapy. After relatively short median follow-up of 26 months, local control, event-free survival and overall survival were all 100%, and there were no grade 3 toxicity.[105] However, due to the relative rarity of the primary spinal tumors and the required long-term follow-up for endpoints such as secondary malignancy and cardiac disease, sufficient clinical data to support or refute the benefit of proton therapy for spinal tumors will unlikely to emerge in the near future. Individualized decision based on tumor location, patient age, and access to proton therapy will be required to consider treatment for proton therapy.

SPINAL CORD TOLERANCE

A reversible myelopathy can occur within 2 to 6 months after radiation therapy. L’Hermitte’s sign, characterized by shocklike sensations radiating to the hands and feet when the neck is flexed, is the classic finding. It is believed that this phenomenon is related to transient demyelination of the treated length of the

spinal cord.[106,107] This syndrome usually lasts a few weeks, and no therapy is required. It is not associated with chronic progressive myelitis.

Chronic, progressive, or delayed myelopathy can occur months to years after radiation therapy. The latency period of chronic myelopathy has been reported to be bimodal with peaks of incidence occurring at 13 and 29 months. The early peak may correspond to white matter injury with subsequent demyelination, and the latter peak may correspond to microvascular injury. Permanent myelopathy is characterized by progressive motor weakness, paresthesias, and loss of pain or temperature sensation. Patients ultimately lose bowel and bladder control and experience complete sensory and motor function loss.[108] Diagnosis of radiation myelopathy requires that the dominant neurologic abnormality be localized to a segment irradiated and other causes have been ruled out. MRI may assist in the diagnosis, with cord edema frequently being present in the early delayed phase. Within 8 months of the onset of symptoms, the T1-weighted images may show low intensity in the region of spinal cord injury, whereas the T2 image shows high intensity. The lesion may enhance with Gd-DTPA. Late changes in patients with permanent delayed myelopathy may include atrophy.[109] Even with modern imaging, it may be difficult to determine whether neurologic deficits after radiotherapy are related to tumor progression or treatment-induced myelopathy.

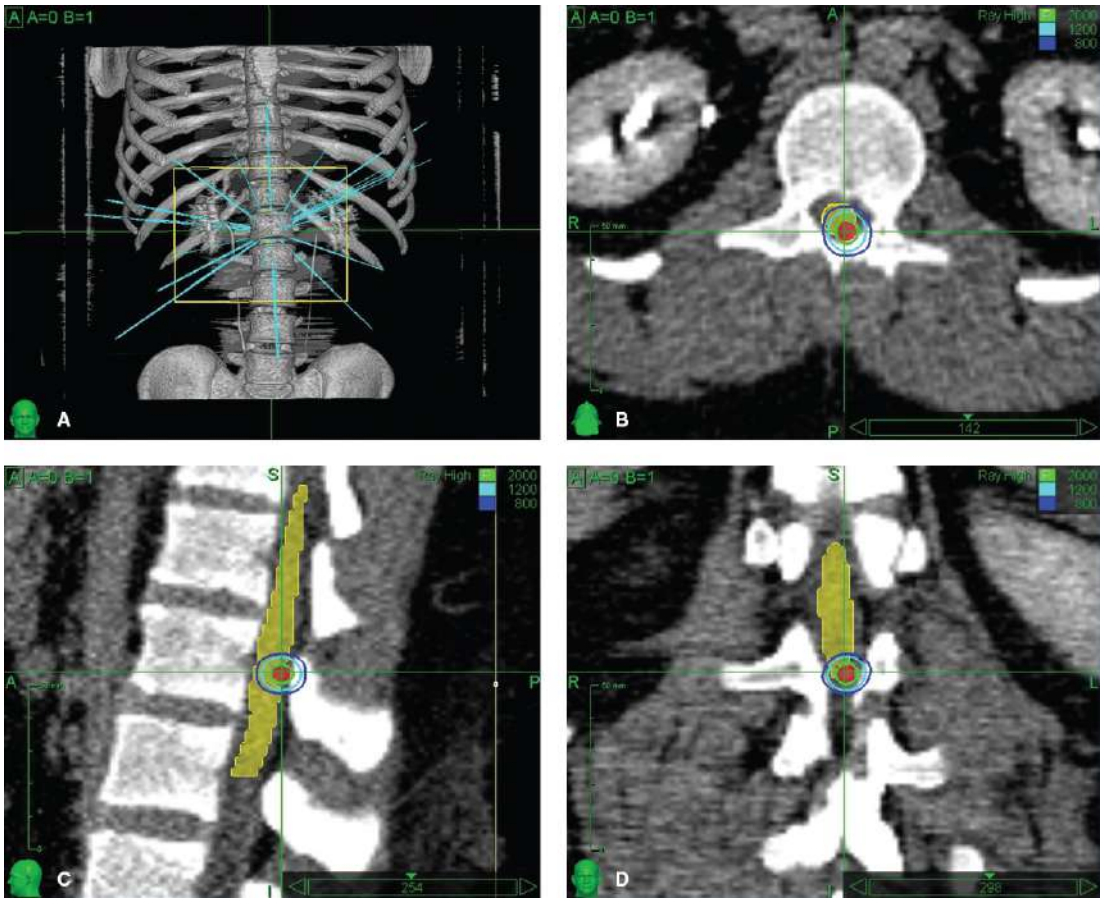

FIGURE 40.6. Stereotactic radiosurgery for an L1 hemangioblastoma. A single dose of 20 Gy was delivered with CyberKnife using 87 noncoplanar beams as shown in *blue*. As is typical of treatment delivery with this unit, the plan is nonisocentric. Gross tumor volume is shown in *solid red*, spinal cord in *solid yellow*. *Green line*, prescription dose of 20 Gy; *light blue line*, 12 Gy; *dark blue line*, 8 Gy. **A:** Three-dimensional representation of select noncoplanar beam paths. **B:** Axial isodose display reveals a sharp dose gradient between the prescription dose and the 12 and 8 Gy isodose lines. **C:** Sagittal isodose display. **D:** Coronal isodose display. (Courtesy Scott Soltys, MD, and Megan Daly, MD, Stanford University Department of Radiation Oncology, Stanford, CA.)

The occurrence of chronic progressive myelopathy depends on total dose, fraction size, volume, and region irradiated. Historically, the spinal cord has been limited to maximum doses of 45 to 50 Gy with fractionation schedules of 1.8 to 2 Gy per day. These estimates came from an era of inexact dose estimation with a bias toward reporting injury in highly selected populations.[110,111] More recently, data have been published from institutions that have treated large groups of patients in systematic and reliable fashion. The Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) initiative comprehensively reviewed modern radiotherapy toxicity data and published guidelines on spinal

cord tolerance.[112] For conventional external-beam radiation therapy at 1.8 to 2 Gy per day, a dose of 50 Gy, 60 Gy, and 69 Gy is associated with a 0.2%, 6%, and 50% rates of myelopathy, respectively. However, pediatric patients and patients receiving potentially neurotoxic chemotherapy may have decreased spinal cord tolerance, with reports of myelopathy at doses 50 Gy or less.[113–115]

Dose–volume data for myelopathy after spine SRS is evolving. In a multi-institutional review of 1,075 patients treated with spine SRS principally for metastatic disease, the rate of spinal cord toxicity was 0.6%.[116] Data from the QUANTEC initiative indicate that the rate of myelopathy will be <1% with the maximum dose to the spinal cord limited to the equivalent of 13 Gy in a single fraction or 20 Gy in 3 fractions.[112] The most commonly employed dose constraint for single fraction SRS is to keep <10% of the spinal cord (defined as 3 to 6 mm above and below the target volume) to <10 Gy.[99] Intriguing data from investigators at Stanford University utilizing SRS for spinal hemangioblastoma suggest that spinal cord tolerance may be higher than predicted by conventional modeling.[100,117] Maximum cord dose delivered in 2 to 3 sessions in their series was an average of 22.7 Gy (range, 17.8 to 30.9 Gy) to small volumes, with only 1 of 24 treatments resulting in myelopathy. Such a phenomenon may at least in part be explained by preclinical experiments suggesting a dramatic length and partial volume effect to spinal cord tolerance after radiation. For example, in one animal study, the ED50 (dose at which 50% of animals developed limb paralysis) for single fraction full thickness radiation to the spinal cord was 20.4 Gy for a 20 mm cord length, compared with 53.7 Gy for 4 mm and 87.8 Gy for 2 mm cord lengths.[118]

Both animal and human studies have demonstrated that irradiated spinal cord may recover at least partially over time. Animal experiments of reirradiation using Rhesus monkeys estimated cord recovery of 76%, 85%, and 100% at 1, 2, and 3 years, respectively.[119,120] In human studies, where reirradiation is at least 6 months after the initial radiation course, essentially no cases of myelopathy were observed when the cumulative 2-Gy equivalent doses are 60 Gy or less.[112,121]

CONCLUSIONS

Spinal canal tumors are relatively rare and consist of diverse histological entities. Surgery remains the primary treatment modality, aided by gradual advances in neurosurgical techniques. Adjuvant radiotherapy is generally considered for incomplete resection, recurrent tumors, or high-grade tumors. New radiotherapy

techniques such as intensity modulated radiotherapy or SRS have shown promising potential to improve the therapeutic ratio. The role of chemotherapy is not clearly defined and is often extrapolated from intracranial counterparts. Continued long-term follow-up of clinical outcomes and innovation of novel approaches are essential for improving the management of spinal canal tumors.

PART C

Head and Neck

CHAPTER 41

Tumors of the Eye and Orbit

Nicholas J. Sanfilippo and Silvia C. Formenti

Primary tumors of the eye and orbit are rare. The American Cancer Society estimates that in 2017, there will be 3,130 new cases with 330 deaths from primary eye cancers.[1] Male to female incidence is similar. In adults, melanoma is the most common primary intraocular cancer, followed by lymphoma, whereas in children, retinoblastoma is the most common tumor, followed by medulloepithelioma. Metastases, or secondary intraocular tumors, are more common than primary tumors and typically come from breast or lung cancers.[2] Numerous other tumors such as rhabdomyosarcoma, optic nerve glioma, conjunctival tumors, and eyelid carcinomas also occur in the orbit. Radiation therapy (RT) has been effective in the treatment of many of these tumors, can be delivered externally or by brachytherapy depending on the clinical situation, and can been used exclusively or in concert with other treatments such as surgery or chemotherapy. Technologic advances such as intensity-modulated radiation therapy (IMRT), proton beam therapy, and stereotactic radiotherapy (SRT) have a key role in management of these tumors given the anatomy proximity of structures in this location. This chapter will outline the most relevant malignant and benign conditions of the eye and orbit with emphasis on radiotherapeutic management. Because cancers originating in the eye require significant radiation dose for their control, exposure of normal tissue is often inevitable, with possible late toxicities that warrant therapeutic interventions. Consequently, the management of eye tumors is an exquisitely interdisciplinary field that requires successful collaboration with ophthalmologists.

ANATOMY

The eye is not an exact sphere but rather a fused two-piece unit. The smaller, more curved frontal unit is the cornea and is linked to the larger unit called the sclera. The corneal segment is typically about 8 mm in radius. The sclera

constitutes the remainder of the eyeball with radius of approximately 12 mm. The cornea and sclera are connected by the limbus. The iris and the pupil are seen instead of the cornea because of the cornea's transparency. The area opposite the pupil, the fundus, shows the characteristic pale optic disc or papilla, where vessels enter the eye and optic nerve fibers depart the globe. Dimensions of the globe differ among adults by only 1 or 2 mm. The vertical measure, generally less than the horizontal distance, is about 24 mm in adults. The eye is made up of three coats or tunics, enclosing three transparent structures (Fig. 41.1). The outermost layer is composed of the cornea and sclera. The middle layer consists of the choroid, ciliary body, and iris. The innermost is the retina, which whose blood supply is from the vessels of the choroid as well as the retinal vessels. The lens is suspended to the ciliary body by the suspensory ligament, made up of fine transparent fibers.

RADIATION TOLERANCE OF OCULAR STRUCTURES

Eyelid

Acute radiosensitivity of eyelid skin is comparable to the skin at other sites, and loss of eyelashes may occur at doses as low as 20 Gy using standard fractionation.[3] Late effects can include telangiectasia and atrophy. Xerophthalmia can result from doses as low as 24 to 26 Gy and may be the result of dysfunction of the meibomian glands, lacrimal acinar cells, or both.[4] Significant xerophthalmia can cause corneal desiccation and pain. It is generally believed that smaller fraction sizes, longer treatment schedules, and smaller volumes will reduce late effects, but this must be weighed against the potential for ocular trauma when using shielding on a daily basis.[5] Optimum management of eyelid toxicity includes cleanliness, dressings for moist desquamation, healing time, and artificial tears to mitigate meibomian gland dysfunction.

Conjunctiva

Acute conjunctivitis is common with doses ≥30 Gy, and superimposed occasional bacterial or rarely viral infections may occur.[6] Conjunctivitis can be reduced by treating with an open eye with megavoltage equipment if the clinical situation permits. Treatment of acute conjunctivitis involves artificial tears to relieve symptoms and treatment of an underlying infection when indicated.

Lacrimal System

The lacrimal gland system includes the main lacrimal glands, accessory lacrimal glands, and lacrimal duct system, and symptoms of dryness can occur if any of these structures receive radiation. The most concerning late effect is “dry eye syndrome,” where patients can experience tearing, redness, discharge, foreign body sensation, blurred vision, and photophobia. Moderate-dose orbital RT (30 to 45 Gy) can cause dry eye syndrome 4 to 11 years after treatment, whereas higher doses (>57 Gy) can produce it in 9 to 10 months.[7] Lacrimal shielding should be used if it does not compromise tumor control. Similarly, if clinically feasible, shielding the accessory lacrimal glands may reduce toxicity if the main gland is irradiated. IMRT can help minimize risks of RT-induced xerophthalmia, and prophylactic nasolacrimal duct intubation with silicone tubing may be considered in high-risk patients.[8,9] Treatments available for RT-induced xerophthalmia include topical lubricants, moist chamber goggles, punctual occlusion with plugs, or tarsorrhaphy.

Cornea

Although RT can directly injure the cornea, most acute corneal toxicity results from loss of the tear film with secondary keratitis sicca. Punctate epithelial erosions are common after conventionally fractionated RT doses of 30 to 50 Gy.[10] They typically subside within several weeks but can persist for years. At higher doses, corneal edema (40 to 50 Gy) or perforation (60 Gy) may occur, causing pain, tearing, foreign body sensation, or reduced vision. Corneal toxicity can be reduced by using megavoltage equipment and reduce the surface dose or by using careful RT planning to minimize corneal irradiation so long as tumor dose is not compromised. Commercially available eye shields may also be used, particularly for electron beam RT.[11] There are little published data on management of corneal toxicity from RT. Close ophthalmologic follow-up is recommended, so topical treatment with steroids or antibiotics can be administered when indicated.

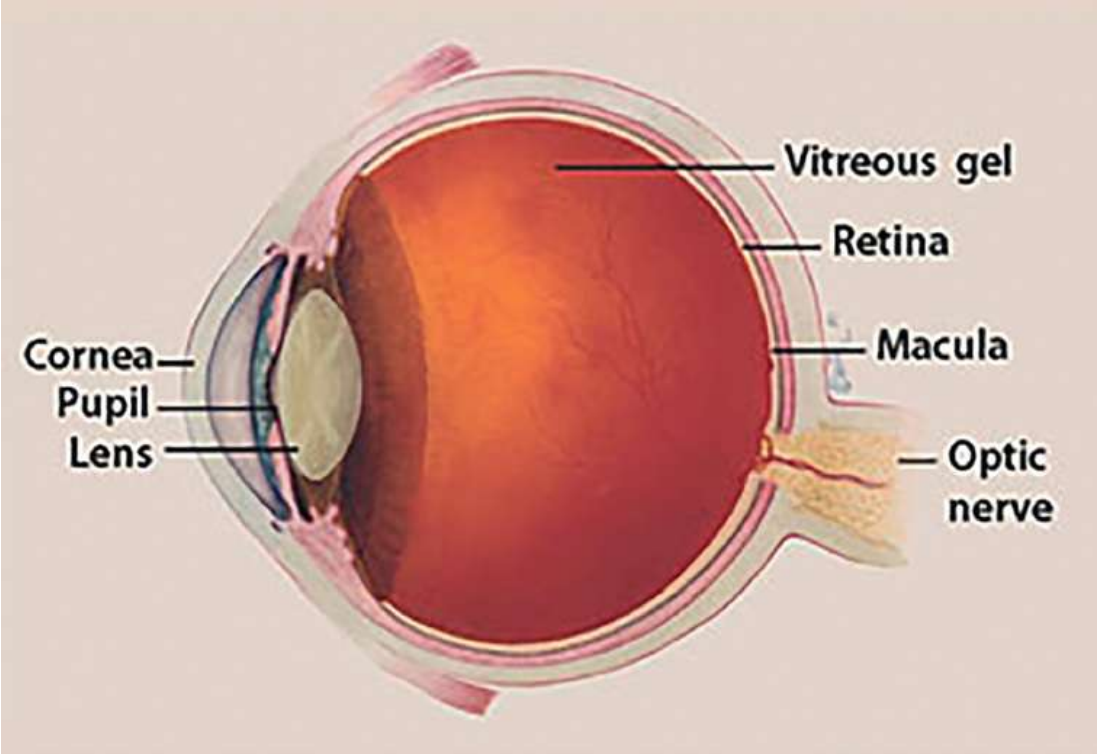

FIGURE 41.1. Normal eye anatomy. (Courtesy of National Eye Institute, National Institutes of Health.)

Iris

The iris is relatively radioresistant, and thus, acute iritis is rare. However, persistent iritis, with symptoms such as pain, red eye, and blurred vision, has been observed after hypofractionated RT doses of 30 to 40 Gy and after doses ≥70 Gy given with conventional fractionation.[12] A problematic late effect of the iris is neovascular glaucoma, where patients may present with ocular pain, headache, photophobia, decreased vision, and redness.[13] Risk factors include higher radiation dose, diabetes, vitreous hemorrhage, and retinal detachment. Whenever possible, techniques that spare the anterior chamber should be adopted. The primary treatments for iritis and neovascular glaucoma are topical steroids and cycloplegic drops, respectively. Laser panretinal photocoagulation (PRP) or peripheral cryotherapy may prevent or delay the progression of glaucoma if performed early in the course of glaucoma development. However, in many cases, more aggressive intervention such as trabeculectomy may be required. Occasionally, progression to a blind, painful eye may necessitate enucleation. Therapies such as intravitreal bevacizumab as an adjunctive treatment to retinal ablative procedure appear to be promising for the management of iris neovascularization associated with neovascular glaucoma.[14]

Lens

The lens is exquisitely radiosensitive. Age at time of treatment, total dose, and fractionation contribute to cataract formation.[15,16] Hall estimated 50% risk of cataract for 1-Gy exposure to the lens during childhood.[15] In adults, higher doses are associated with radiation-induced cataract: After 2.5 to 6.5 Gy, there is a 33% of progressive cataract with latent period of 8 years, whereas after 6.51 to 11.5 Gy, there is a 66% risk with a latent period of 4 years.[16] Cataract risk can be reduced by using customized lens shields and lens-sparing techniques or by using more fractionated RT schedules. IMRT may be used to reduce cataract risk by reducing overall lens dose. The corrective treatment for RT-induced cataract is surgery, which yields excellent results.

Retina

Radiation retinopathy is a late effect of RT that typically presents 6 months to 3 years after treatment, although cases have been reported as far as 15 years after therapy.[17] Patients may be asymptomatic or may complain of floaters or reduced visual acuity. Clinical signs include microaneurysms, telangiectasia, hard exudates, cotton wool spots, and neovascularization. The threshold dose for retinal damage is 30 to 35 Gy: In a Cochrane database review of RT for macular degeneration, no retinopathy or optic nerve damage was reported in 1,154 patients treated with doses up to 24 Gy.[18] The risk of retinopathy increases dramatically when doses exceed 50 Gy using standard fractionation.[19] Incidence as well as severity is also increased by coexistent diabetic retinopathy, hypertension, collagen vascular disease, simultaneous chemotherapy, and pregnancy.[20] No proven therapy exists for radiation retinopathy. Local photocoagulation may improve symptoms, and there is interest in intravitreal bevacizumab, albeit with marginal results: In a recent study from the Dunedin Hospital where patients with choroidal melanoma were treated with stereotactic RT, prophylactic treatment with intravitreal bevacizumab did not lower the rate of retinopathy.[21]

Optic Nerve

Like the retina, the optic nerve manifests toxicity months or years after RT, with a peak incidence at 18 months.[22] Radiation-induced optic neuropathy (RION) has a variable presentation and is related to the nerve fibers most affected, usually causing visual field defects. In a review by investigators from the Mayo Clinic, the risk of RION was almost zero with conventionally fractionated doses

≤50 Gy and still rare with maximum dose <55 Gy. The risk of RION increases from 3% to 7% at 55 to 60 Gy and is substantial (>7% to 20%) at doses >60 Gy.[23] Parsons, in a series of 131 patients (215 optic nerves) treated with RT for extracranial head and neck tumors, found no RION in nerves that received <59 Gy.[24] Fraction size was of primary importance: In cases where >60 Gy was received, fraction size was more important than total dose in producing RION. The 15-year actuarial risk was 11% when fraction size was <1.9 Gy compared with 47% when fraction size was >1.9 Gy. A significant exception in development of RION appears to exist for patients treated for pituitary tumors, where toxicity has been reported at doses as low as 46 Gy in 1.8-Gy fractions.[23] Because there is no known effective therapy for RION, to minimize optic nerve, dose-sophisticated treatment planning must be implemented to minimize treatment volume, total dose, and especially dose per fraction.

MANAGEMENT OF BENIGN OCULAR DISEASES

Pterygium

Pterygium is a benign growth of fibrovascular tissue on the conjunctiva that can cause irritation, erythema of the cornea, and, in advanced cases, obstruct vision. The exact cause of pterygium is unknown, but it is associated with excessive exposure to wind, sunlight, or sand. It has also been postulated that ultraviolet light exposure may increase the risk of pterygium development.[25] At present, no reliable medical treatment exists to reduce or even prevent pterygium progression. If symptoms are severe, the only definitive treatment is surgical removal, which requires removal of the head, neck, and body of the pterygium. Without adjuvant treatment, surgical resection alone carries recurrence rates of 20% to 80%.[25] Therefore, adjunctive measures are recommended, which can be broadly classified as medical methods, beta-irradiation, and surgical methods. Intraoperative and postoperative mitomycin C are the most commonly used medical adjuncts, reducing recurrence rates to 3% to 37%.[26] However, topical chemotherapy is not commonly used out of concern for late complications including scleral sclerosis, infectious scleritis, perforation, or endophthalmitis, all with consequences that can impair vision.[27] Beta-irradiation has a historical role in management of pterygium. In a prospective randomized study, 96 eyes with primary pterygium received beta-irradiation with a strontium 90 after resection or sham radiation.[25] Local control was 93.2% for the irradiated group versus 33.3% for the sham radiation group. Like topical chemotherapy, however,

beta-irradiation has generally been abandoned due to the risk of sight-threatening complications such as scleral necrosis, infectious scleritis, corneal perforation, and endophthalmitis.[28] Thus, this therapy is of historic interest. Surgical adjuvant therapy is the mainstay of management for primary and recurrent pterygium. Currently, conjunctival autografting is generally regarded as the procedure of choice because of its efficacy and long-term safety, with recurrence rates of 2% to 39% without the attendant sight-threatening complications of topical chemotherapy or beta-irradiation.[29]

Choroidal Hemangiomas

Choroidal hemangiomas are benign vascular tumors of the choroid. Although probably congenital in all cases, they are frequently undetected until after the second decade of life and can have a wide range of clinical features and treatment options.[30] These tumors are characterized as either circumscribed or diffuse. Most circumscribed choroidal hemangiomas are noted first when they produce visual symptoms caused by accumulation of serous subretinal fluid, degenerative changes in the macular retina, or both. In contrast to circumscribed choroidal hemangiomas, the diffuse variety is larger and associated with Sturge-Weber syndrome, a neurologic disorder marked by a distinctive port-wine stain on the forehead, scalp, or around the eye. This stain is a birthmark caused by an overabundance of capillaries near the surface of the skin. Blood vessels on the same side of the brain as the stain may also be affected. Diffuse tumors are usually diagnosed in young patients either because of the examination of the fundus prompted by a facial hemangioma (port-wine stain) or because of the visual impairment secondary to serous retinal detachment or hyperopic amblyopia (Fig. 41.2). The clinical course of either form of choroidal hemangioma is highly variable, with visual impairment ranging from none to total blindness. Neither variety of choroidal hemangioma metastasizes or transforms to malignancy. Therefore, the primary indication for treatment is to prevent loss of visual acuity.

Treatment alternatives include laser photocoagulation, thermotherapy, photodynamic therapy, and radiotherapy. Photocoagulation is beneficial for circumscribed lesions, but diffuse lesions have high recurrence rate and retinal damage is possible.[30] Low- to moderate-dose radiation using lens-sparing external beam photon irradiation, episcleral plaque therapy, proton beam therapy, and SRT have all been used in the treatment of choroidal hemangioma.[31] Total doses of 18 to 30 Gy delivered in 10 to 18 fractions of external beam photon RT

can result in partial flattening of the hemangioma, resorption of subretinal fluid, and reattachment of the retina within 6 to 12 months.[32] Heimann reported no recurrence of subretinal fluid with a mean follow-up of 3.6 years.[32] In another series with follow-up of 66 months, Kivela found that subretinal fluid had reaccumulated in only 1 of 12 patients treated, thus demonstrating response durability.[33] In very advanced cases with retinal detachment, a higher dose of 36 Gy in fractions of 1.8 Gy appear to be efficacious, but larger series with longer follow-up are needed to reliably assess response durability and delayed side effects, including retinopathy and cataract formation.[32,33] Lens-sparing techniques, including three-dimensional conformal RT with computed tomography (CT) planning, should be considered to reduce the incidence of cataract formation.[34] Brachytherapy has also been used for choroidal hemangioma treatment, particularly for circumscribed. This treatment usually achieves resolution of subretinal fluid and reattachment of the retina with preservation of pretreatment visual acuity.[35] Radiation dose varies with the isotope, but in a study using iodine 125 with target dose of 48 Gy to the apex of the lesion, tumor regression was noted in all 8 of 8 cases treated.[35] Long-term results of proton beam therapy have been reported from investigators at the Institut Curie: In a series of 71 cases with circumscribed choroidal hemangioma treated with 20 Cobalt Gray Equivalent, retinal reattachment occurred in all cases, and a completely flat scar was obtained in 91.5%.[36] The main complications during the surveillance period were cataract (28%) and radiation-induced maculopathy (8%). No cases of eyelid complications or neurovascular glaucoma were observed.

Capillary Hemangioma

Capillary hemangiomas are benign endothelial cell neoplasms that rarely occur on the eyelids or skin of the orbit. Retinal capillary hemangiomas may represent component of the von Hippel-Lindau syndrome (VHL), and lesions of the face that occupy the distribution of the trigeminal nerve can be a component of Sturge-Weber syndrome. The natural history of these lesions is usually spontaneous regression over 3 to 4 years, making conservative management the treatment of choice.[37] Occasionally, however, lesions may be large enough to obstruct vision and amblyopia may occur. Treatment options then include corticosteroids, interferon alfa-2a, laser therapy, embolization, immunomodulators, surgery, and systemic propranolol.[38] Because of these many alternatives, RT in the management of capillary hemangiomas is primarily of historical interest, with original studies showing that doses in the 16 to 20 Gy

range provide effective local control.[39]

Orbital Pseudotumor

Orbital pseudotumor is a rare inflammatory process that affects the soft tissue components of the orbit. Clinically, it presents in the fourth and fifth decade of life with signs and symptoms including proptosis, swelling, increased orbital pressure, and restricted ocular motion.[40] The diagnosis is based on history, imaging of the orbit, and pathologic examination of tissue in accessible lesions. Characteristic imaging features include extraocular muscle enlargement, optic nerve thickening, and inflammation of retrobulbar adipose tissue. Treatment options for orbital pseudotumor include corticosteroids, external beam radiation therapy (EBRT), immunotherapy, chemotherapy, and surgery; corticosteroids are typically used as primary treatment.[41] Radiotherapy is usually reserved for cases that are refractory to corticosteroid treatment. Mathiesen recently described 20 orbits treated with a median dose of 20 Gy and at follow-up of 16.5 months found improved symptoms and/or reduction of corticosteroid dose in 87.5% with 56% able to discontinue steroid treatment completely.[42] Based on these observations, radiation appears to achieve durable control in orbital pseudotumor and is an effective strategy in patients who respond poorly to medical treatment.

Thyroid-Associated Orbitopathy

Thyroid-associated orbitopathy (TAO), frequently termed Graves ophthalmopathy, is part of an autoimmune process that can affect the orbital and periorbital tissue, the thyroid gland, and, rarely, the pretibial skin or digits (thyroid acropathy).[43] Although the use of the term thyroid ophthalmopathy is more general, the disease process is specifically an orbitopathy in which the orbital and periocular soft tissues are primarily affected with secondary effects on the eye. TAO may compromise a patient’s vision by causing diplopia, decreased ocular motion, exposure keratitis, or optic neuropathy. A variety of treatments exist, starting with thyroid hormone regulation to the use of corticosteroids, external beam radiotherapy, or surgical decompression.[44] Radiation therapy with moderate doses has historically been used in cases refractory to medical therapy. Abboud reported symptom improvement in 87% of cases with doses of 20 Gy using standard fractionation.[45] However, prospective studies examining RT for TAO suggest that its role is unclear. Numerous randomized controlled trials have tested orbital RT for TAO, although studies differed with respect to severity of TAO on trial entry, radiation dose and

fractionation, and inconsistent use of concurrent corticosteroids.[46–54] In controlled randomized trials, RT resulted in only a small benefit. Mourits randomized 59 patients to either 20 Gy in 10 fractions to both orbits or sham RT and found improved globe motility and elevation, but no difference in change in lid fissure, soft tissue swelling, proptosis, or clinical activity score (a measure of disease activity and propensity to progress).[50] The authors concluded that RT should be used only for motility impairment. Gorman randomized 42 subjects to orbit RT to one orbit and sham RT to the other followed by the reverse therapy 6 months later.[54] No clinically or statistically significant differences were observed at 6 months. At 12 months, muscle volume and proptosis were slightly improved in the orbit that was first irradiated. Prummel conducted a trial where 88 patients with mild TAO were randomly assigned to bilateral RT or sham RT.[53] Radiation was effective in improving motility and decreasing severe diplopia, but no differences in health-related quality of life were detected, although lack of complete quality of life data on 58% of subjects resulted in low power to detect a difference. Complications of orbital RT are rare but not insignificant. Even in the absence of known diabetes mellitus, the risk of definite retinopathy is 1% to 2% in the first 10 years after treatment.[55] Thus, based on randomized data, the role of RT for TAO remains controversial. A 2008 report on orbital RT for TAO by the American Academy of Opthalmology concluded that although extraocular motility may improve with RT, the evidence of treatment effect is controversial and more studies are needed to determine if improved motility translates into improved quality of life.[56] Part of difficulty in evaluating RT for TAO is that moderate to severe TAO is rare.[57] Therefore, from a practical management standpoint, a reasonable indication for RT, in combination with steroid therapy, is for patients that are refractory to steroid treatment alone.[58] Radiation technique for TAO usually involves treatment of both orbits with parallel-opposed lateral portals with low-energy (6-MV) photons. A downward 5-degree tilt or use of half-beam block should be used to avoid direct radiation of the contralateral lens.

OCULAR AND ORBITAL MALIGNANT TUMORS

Metastatic Carcinoma to the Uvea

Tumor metastases to the eye are more common than primary ocular cancers, with the uvea representing the most common site affected.[59] Shields and colleagues described a comprehensive series of usual metastases and found that

within the uvea, 88% of metastases are to the choroid (Fig. 41.3), followed by metastases to the iris (9%) and ciliary body (2%).[2] This large difference is thought to reflect blood supply, which heavily favors the choroid as compared to the iris or ciliary body. The most common primary cancer sites for uveal metastasis in males were lung (40%), gastrointestinal (9%), and kidney (8%). The primary site was unknown at the time of presentation in 29% of males. In females, the most common sites included breast (68%), lung (12%), and other (4%). Metastases can be either unilateral or bilateral. In a study of 264 patients with uveal metastases from breast cancer reported by Demirci, 62% of patients had unilateral metastasis at presentation. Patients with breast cancer metastatic to the uvea show survival rates of 65% at 1 year, 35% at 3 years, and 24% at 5 years.[60]

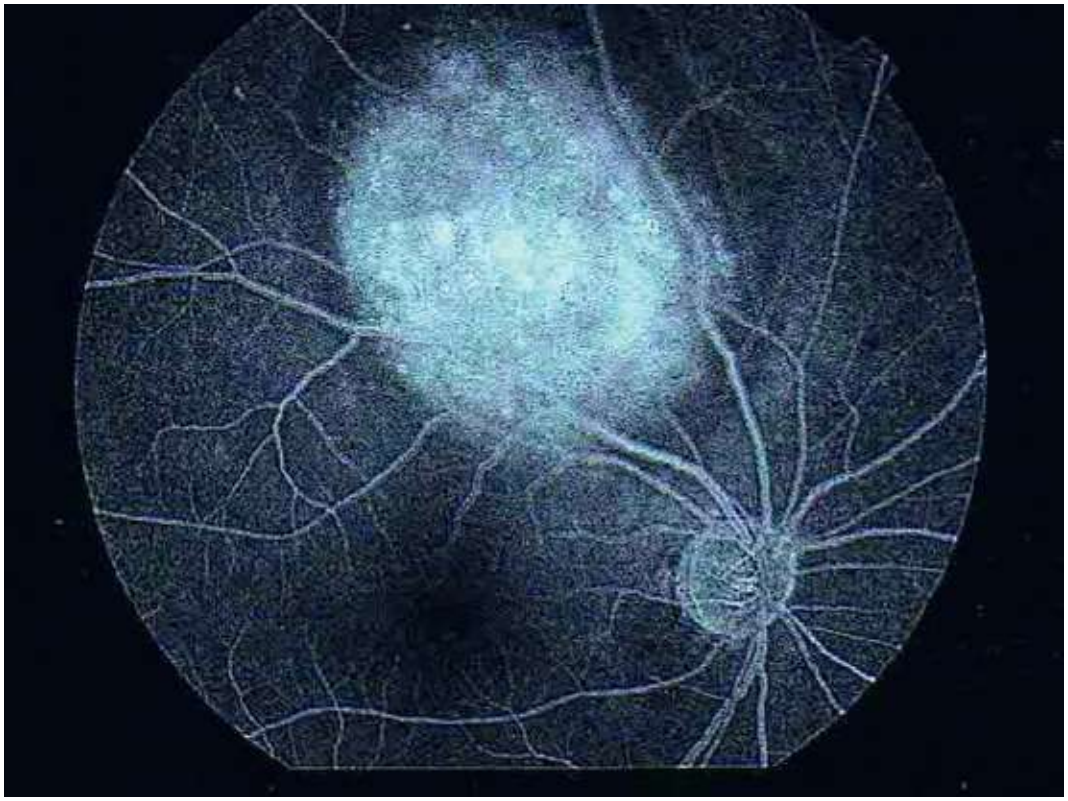

FIGURE 41.3. Fundus fluorescein angiography of choroidal metastasis from non–small cell lung cancer showing hyperfluorescence from the surface of the choroidal tumor in its late phase with the accumulation of subretinal fluid. (From Singh A, Singh P, Sahni K, et al. Non-small cell lung cancer presenting with choroidal metastasis as first sign and showing good response to chemotherapy alone: a case report. *J Med Case Rep* 2010;4:185.)

Numerous treatment options exist for choroidal metastases, including

systemic chemotherapy, hormonal therapy, EBRT, brachytherapy, or photodynamic therapy. Individualized treatment should be considered, taking into account disease extent and life expectancy with the primary goal of maintaining visual acuity. As systemic treatments for metastatic cancers improve, clinicians may be more frequently faced with treatment of symptomatic choroidal metastases. For cases with multifocal or diffuse presentations, external beam radiation has been effective with doses in the range of 20 to 40 Gy. Rosset described 58 patients (88 eyes) treated with external beam radiation with a median dose of 35.5 Gy (range 20 to 53 Gy) in 10 to 30 fractions.[61] Various techniques were used and lens sparing was achieved whenever possible. Visual acuity improved in 62% of patients, with significantly better results when doses >35.5 Gy were used. Complications include three cataracts, retinopathy in a single patient who underwent a biopsy, and one case of glaucoma from subretinal hemorrhage. In cases of unilateral disease undergoing bilateral radiation, the authors noted no cases of new contralateral lesions but did describe new contralateral lesions in 3 of 26 patients when unilateral technique was used. Although they recommended bilateral irradiation even for unilateral disease (Fig. 41.4), a case can be made for unilateral treatment, especially as modern techniques can more easily avoid the contralateral side and make retreatment feasible if necessary.

Plaque brachytherapy is usually reserved for solitary metastases. This modality offers precise, controlled radiation delivery to the eye and requires only 3 to 4 days of treatment, an important consideration in uveal metastases because many patients have limited survival expectancy. Clinical factors to consider for plaque therapy include the size and thickness of the lesion and the distance of the lesion from the optic nerve and foveola. Investigators from the Wills Eye Hospital studied 36 patients who received plaque radiotherapy either as primary or salvage treatment (after external radiation) for uveal metastases.[62] The mean duration of treatment was 86 hours and mean doses to the apex and base of the tumor were 68.8 and 235.6 Gy, respectively. Tumor regression was documented in 94% of cases with median follow-up of 11 months. Five of six cases where plaque therapy was used after suboptimal response to external irradiation were successfully salvaged. Complications from plaque radiotherapy are similar to those of external beam therapy, including dryness, radiation retinopathy, papillopathy, and cataract. The investigators concluded that plaque radiation is an effective, time-efficient method for treatment of selected solitary uveal metastases. Thus, both EBRT and plaque therapy are effective therapies for

uveal metastases with the optimal treatment depending on the extent of intraocular disease, symptoms, and overall condition and prognosis of the patient. Close collaboration of ophthalmologists, radiation oncologists, and medical oncologists is imperative to tailor an appropriate treatment strategy for each patient.

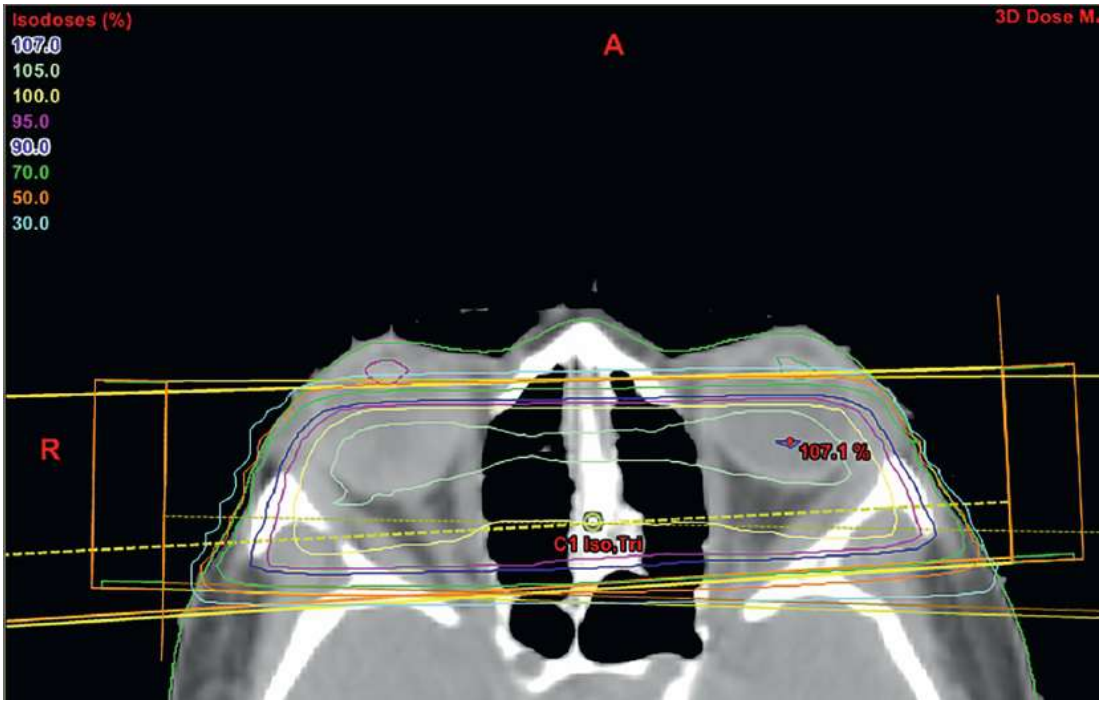

FIGURE 41.4. Bilateral radiation therapy for uveal metastases in a patient with widely metastatic lung cancer.

Malignant Melanoma of the Uvea

Uveal melanomas represent <5% of all malignant melanomas with approximately 2,580 new cases and 270 deaths per year in the United States.[63] These tumors may arise from any of the three parts of the uvea and are sometimes referred to by their location, such as iris melanoma (Fig. 41.5), ciliary body melanoma, or choroidal melanoma (Fig. 41.6). True iris melanomas, originating from within the iris as opposed to originating elsewhere and invading the iris, are distinct in their etiology and prognosis, such that the other tumors are often referred to collectively as “posterior uveal melanomas.” Although uveal melanoma is rare among nonwhites, the role of sunlight and other environmental factors is unknown.[64] Detection of uveal melanoma is often by routine examination with or without symptoms; a study from the United Kingdom showed that 45% of patients were asymptomatic when their tumor was

detected.[65] Advances in diagnostic techniques such as binocular indirect ophthalmoscopy, angiography, and B-scan ultrasonography have aided ocular oncologists in the evaluation and management of patients with uveal melanoma.[66]

Several treatment options exist for uveal melanoma. Most patients are treated with the goal of eradication of disease and long-term survival. There is evidence that local tumor recurrence is associated with increased mortality.[67] Factors predictive of local recurrence include epithelioid cell type, large tumor size, and posterior tumor extension.[68] When possible, curative treatment should be sought with the goal of preserving vision with acceptable cosmesis. In patients with known metastatic disease, the main objective is to preserve vision and remove any threat of the eye becoming painful within the patient's life expectancy. Many factors influence treatment selection, including tumor size, location, and extent; secondary effects, such as cataract; concurrent ocular disease, such as diabetic retinopathy; the patient's general health and life expectancy; and the cost and duration of the treatment.[69] In cases where maintaining useful vision is feasible, organ preservation therapy should be considered, and thus, RT delivered either externally or by brachytherapy has been instrumental in the primary management of uveal melanoma.

Observation

It is not uncommon for indeterminate pigmented uveal tumors to be observed without treatment until growth is documented. The probability of malignancy can be estimated according to tumor thickness, serous retinal detachment, orange pigment, and symptoms.[70] Patients and clinicians can then make a combined decision on when to commence therapy after discussion of risks and benefits.

Enucleation

Enucleation was traditionally the standard of care for choroidal melanoma since the late 19th century, but its effectiveness in improving survival has never been clearly demonstrated.[71] A study from the Helsinki University Hospital looked at the long-term prognosis of patients treated by enucleation between 1962 and 1981 and found death was attributable to melanoma in 61% of cases.[72] They also reported that cause-specific mortality (CSM) increased with longer follow-up. The 5-, 15-, 25-, and 35-year CSM was 31%, 45%, 49%, and 52%, respectively, thus illustrating that a substantial number of patients die of metastatic disease more than 5 years after enucleation. The desire to improve survival and preserve vision stimulated the development of alternative, organ-preserving therapies for uveal melanoma. Still, enucleation is required in a subset of patients, either because tumor is too extensive at presentation or if vision loss were likely to occur with conservative treatment. General guidelines for enucleation include tumor diameter >17 mm; thickness >6 to 7 mm; involvement of the optic disc; invasion of more than 30% of the iris, ciliary body, or angle; retinal perforation;

or poor general health of the patient.[69]

Endoresection

Transretinal endoresection is controversial, mainly because of fears of seeding tumor cells, but has been advocated for juxtopapillary tumors up to 10 mm in diameter.[70] The operation involves vitrectomy; tumor removal with a vitrector either via a retinotomy or after lifting a retinal flap, fluid–air exchange to drain any subretinal fluid, endolaser photocoagulation to destroy any residual tumor in the sclera and to achieve retinopexy, air–silicone exchange, and, if possible, adjunctive brachytherapy.[73] Given the seemingly heightened risk of tumor seeding with endoresection, some investigators have recommended preoperative stereotactic radiation, but this practice is similarly controversial.[74] Endoresection carries approximately 10% risk of local recurrence, which can arise from microscopic disease in the scleral bed or at the margins of resection.[73]

Transscleral Resection

Transscleral local resection has been promoted for tumors >6 mm thick in patients highly motivated to retain vision and in patients with severe exudative retinal detachment after radiotherapy.[69] The procedure carries substantial operative risk. Choroidectomy and cyclochoroidectomy, for example, require hypotensive anesthesia with systolic blood pressure lowered to approximately 40 mm Hg.[75] The operation involves the preparation of a lamellar scleral flap, ocular decompression by limited pars plana vitrectomy, resection of the tumor together with the deep scleral lamella, suturing of the scleral flap, intraocular injection of balanced salt solution, and adjunctive brachytherapy either at the end of the operation or a several weeks later. This procedure has approximately 30% incidence of local relapse when performed exclusively, but this probability declines to approximately 10% when perioperative brachytherapy is delivered.[76]

Transpupillary Thermotherapy

Transpupillary thermotherapy (TTT) is a procedure in which 1-minute applications of 3-mm spots of low-energy diode laser are administered to the tumor and the surrounding choroid.[77] The objective is not immediate thermoablation but rather heating the tumor by only a few degrees so that following treatment, tumor regression occurs slowly, often resulting in a white scar. This technique may be used for indeterminate choroidal tumors. Some advocates of TTT recommend combined brachytherapy with TTT: Yaravoy and colleagues reported improved tumor regression and recurrence free survival with

similar complication rates when TTT was used with brachytherapy compared with brachytherapy alone.[78]

Plaque Brachytherapy

Plaque brachytherapy is the mainstay of treatment in many centers, with iodine 125 and ruthenium-106 being the most common isotopes, although palladium 103 has also been used effectively.[79] Iodine emits gamma rays, which have a range sufficient for tumors up to 8 to 10 mm thick, whereas ruthenium delivers beta particles that have a more limited range, which is suitable for tumors <5 mm thick. Historically, the general objective with all plaques is to deliver approximately 80 Gy to the tumor apex by fixing the plaque in the exact location of the tumor (Figs. 41.7 and 41.8). However, recent data suggest lower doses may be sufficient for tumor control with less toxicity: Perez and colleagues examined 190 cases treated between 1988 and 2010 and analyzed outcome with respect to apical dose.[80] Local control and overall survival did not differ according to dose quartile (<69 Gy, 69 to 81 Gy, 81 to 89 Gy, >89 Gy). However, visual acuity and radiation complications increased with increasing dose and the authors concluded that doses as low as 69 Gy may be appropriate for uveal melanoma. Dedicated computer modeling has been developed for radiotherapy planning to create a three-dimensional model of the eye and determine the appropriate treatment time and estimated dose to the optic nerve, macula, and lens.[81] Tumors in approximating or overhanging the optic disc present a dosimetric challenge but may be treated with brachytherapy. Sagoo and associates reported on 141 such patients treated with plaque brachytherapy.[82] In 126 eyes, the plaque utilized a notched design, which created an elliptical dose distribution with median dose of 85 Gy. Local control was 90% and metastases developed in 13%. Visual acuity was generally poor, with 77% having final acuity of 20/200 or worse. However, given the alternative of enucleation, this technique represents a reasonable alternative.

The largest prospective experience of patients treated by plaque brachytherapy was conducted by the Collaborative Ocular Melanoma Study (COMS) group. From 1986 to 2003, COMS conducted two multicenter trials of brachytherapy with iodine 125 versus enucleation in selected patients with choroidal melanoma. Long-term results were subsequently published in COMS Report 28 in 2006, which evaluated 1,317 patients.[83] Eligible patients had unilateral choroidal melanoma with an apical height of 2.5 to 10 mm and a maximum basal tumor diameter (MBTD) of 16 mm. Patients whose tumors were contiguous with the optic disc were ineligible, as were patients with metastases from melanoma or another malignancy. Patients were followed for 5 to 15 years and within 12 years after enrollment and 471 of 1,317 (36%) died. Overall, CSM at 5 and 10 years for both treatment arms were 19% and 35%, respectively. Cumulative all-cause mortality was 43% in the iodine 125 arm and 41% in the enucleation, indicating that with long-term follow-up, no survival difference

existed between plaque brachytherapy and enucleation. Age >60 years and MBTD >11 mm were the primary predictors of time to death. Local control was excellent in the COMS series with only 12.5% of patients requiring salvage enucleation.[84] Visual acuity after plaque brachytherapy depends on a number of features. Shields reported the outcome of 1,106 patients with baseline visual acuity of 20/100 or better who underwent brachytherapy for uveal melanoma and found 34% of patients had poor visual acuity at 5 years and 68% at 10 years, defined as 20/200 to no light perception.[85] Factors adversely affecting visual acuity were age >60 years, poor vision at baseline, increasing tumor thickness (>8 mm), proximity to the foveola of <5 mm, recurrent tumor, subretinal fluid, and history of diabetes or hypertension. Best results were obtained in eyes with small tumors outside a radius of 5 mm from the optic disc and foveola. The American Brachytherapy Society updated their consensus guidelines on plaque therapy for uveal melanoma in 2014 and determined that brachytherapy is appropriate for the majority of uveal melanomas.[86] Exceptions include tumors with >5 mm of extraocular extension, basal diameters that exceed the limits of brachytherapy applicators, patients with blind and painful eyes, and patients with no light perception.

Proton Beam Therapy

Proton beam therapy may be used to treat uveal melanoma and is usually indicated for tumors that extend close to or are contiguous with the optic disc, referred to as parapapillary and peripapillary tumors, respectively.[87] Because of the dosimetric properties of protons, which deliver a homogeneous dose to tumor with a sharp field edge, a high tumor dose can be delivered with relative sparing of the optic nerve. The decision to use proton therapy over other forms of external beam radiation, such as helium ions or SRT, often depends on the availability of treatment facilities. One of the largest experiences in proton beam therapy for uveal melanoma is from the Harvard Medical School.[88] Treatment planning involves intraoperative examination by transillumination or indirect ophthalmoscopy, and the edges of the tumor are delineated by four tantalum rings sutured to the sclera. For tumors of the ciliary body and peripheral choroid, surgery is not performed; transillumination is instead used to define tumor margins in relation to the iris and cornea. Radiation planning is done with an interactive three-dimensional computer system to define the beam aperture and range modulation needed to adequately encompass the tumor with a 1.5 mm to allow for motion during treatment, setup error, and possible microscopic

extension.[89] Patients receive a total dose of 70 Cobalt Gray Equivalents (CGE), which is delivered in five equal fractions over 7 to 10 days (63.6 proton Gy × 1.1 relative biologic effectiveness = 70 CGE).[86] The Harvard group recently reported long-term follow-up in a series of 573 patients with peripapillary and parapapillary melanomas with median surveillance of 96.3 months.[85] Local recurrence was rare, with 5- and 10-year local recurrence of 3.3% and 6%, respectively, and similarly high rates of local control have been observed in a larger series from the same institution.[90] Enucleation rates were 13.3% and 17.1% at 5 and 10 years after treatment, respectively. Of 450 patients with baseline visual acuity of 20/200 or better, two-thirds had visual acuity <20/200 years after treatment, although 56% could count fingers. The most common complications were radiation maculopathy and/or papillopathy. By 3 years, the cumulative rate of both complications was 49%, and by 10 years, it increased to 61% for papillopathy and 68% for maculopathy. The visual outcome after proton therapy depends on the height of the tumor and its location relative to the fovea and optic nerve.[88] Anterior segment severe complications, such as rubeosis iridis and neovascular glaucoma, occur less frequently, with each occurring in approximately 15% of cases at 5 years postradiation.[91] These results indicate that although visual acuity is compromised with proton beam therapy, particularly in patients with juxtapapillary lesions, some preservation is possible and eye conservation is likely with low rates of local recurrence.

Stereotactic Radiotherapy

Stereotactic radiation can be delivered by linear accelerator (LINAC) or by specialized devices for focused radiation such as the Leksell gamma knife. Because gamma knife treatment is usually done in a single fraction, the term radiosurgery is applied, whereas for LINAC-based treatment, single-fraction or multifraction treatment are possible. Gamma knife radiosurgery (GKR) for uveal melanoma was introduced in 1998 by investigators at the Indiana University School of Medicine.[92] Nineteen patients with uveal melanoma were treated to a dose of 40 Gy prescribed to the 50% isodose line. With median follow-up of 40 months, 3- and 5-year overall survival rates were 86% and 55%, respectively. The 3- and 5-year tumor control rates were both 94%. Six of the 19 treated patients (32%) developed distant metastasis 31 to 75 months after GKR. Out of the 19 patients treated, 2 had improved, 4 had stable, and 13 had worse vision in the treated eye. Similar results were reported in a larger series of 78 patients from investigators in Milan.[93] The dose was adjusted over the treatment period:

7 patients received 50 Gy at the 50% isodose line (1994–1995), 21 patients received 40 Gy to the 50% isodose line (1995–1999), and 47 patients received 35 Gy to the 50% isodose line (2000 through 2006). Local tumor control was achieved in 91.0% of patients, and the eye retention rate was 89.7%. A significant relative reduction of visual acuity was observed during follow-up most commonly because of the exudative retinopathy (33.3%), neovascular glaucoma (18.7%), radiogenic retinopathy (13.5%), and vitreous hemorrhage (10.4%).

One theoretical disadvantage of single-dose stereotactic radiosurgery is the potential for complications. In particular, severe radiation retinopathy is dose dependent with respect to both total dose (>25 Gy) and dose per fraction (>2 Gy).[94,95] Muller and colleagues conducted a prospective study on 102 patients with uveal melanoma treated with fractionated SRT between 1999 and 2007.[96] Patients had uveal melanoma of the choroid or ciliary body with a tumor thickness smaller than 12 mm and diameter <16 mm with no metastases. The SRT technique, like GKR, utilized a fixed immobilization system, and a dose of 50 Gy was delivered in five equal fractions on 5 consecutive days using 6-MV photons with stereotactic arcs. With median follow-up of 32 months, local control was achieved in 96% of patients. Fifteen enucleations were performed 2 to 85 months after radiation, and best corrected visual acuity (defined as 20/x while using glasses if needed) decreased from a mean of 0.26 at diagnosis to 0.16 at 3 months postradiation and declined to 0.03 at 4 years after therapy. Deterioration of visual acuity was in part related to complications. Grade 3 to 4 neurovascular glaucoma occurred in 9 patients, 8 of which required enucleation. In these 9 patients, tumors were not anteriorly located, nor did they receive a high dose to the ciliary body, as one might expect, but were associated with grade 3 retinopathy. The authors hypothesized that the physical reaction of ischemic retinopathy might also affect vessels in the ciliary body. Thirteen patients (13%) developed grade 3 or 4 optic neuropathy, which was associated with posterior tumors and optic nerve dose, which was limited to 4 Gy/fraction. Grade 3 cataracts occurred in 10 patients (10%) and were managed by extraction and lens implantation. Cataract formation was dose related, with a median dose of 5 Gy/fraction to the lens causing cataract in 50% of cases. The authors concluded that although local control was excellent, the number of secondary enucleations was substantial, particularly from neurovascular glaucoma.

Retinoblastoma

Retinoblastoma (Rb), the most common ocular malignancy in childhood, affects approximately 300 children per year in the United States.[94] The incidence is higher in developing countries, and although the reason for this is not clear, lower socioeconomic status and the presence of certain human papillomavirus sequences have been implicated.[95] Rb has a heritable form and nonheritable form, with approximately 55% of children having the nonheritable form. If there is no family history, the disease is labeled "sporadic," but this does not necessarily indicate that it is the nonheritable form, because bilateral cases, most of which are heritable, also have no family history. Rb can present with unilateral disease (two-thirds of cases), with bilateral disease, or rarely with tumor in both eyes and the pineal gland, which is called trilateral disease.[97] Approximately 80% of children in Rb are diagnosed before the age of 3, with unilateral cases diagnosed at an earlier age (14 to 16 months) than those with bilateral presentations (29 to 30 months).[98] Histologically, Rb develops from immature retinal cells and replaces the retina and other intraocular tissues. Macroscopically, viable tumor cells are found near blood vessels, whereas zones of necrosis are found in relatively avascular areas. Microscopically, both undifferentiated and differentiated elements may be present. Undifferentiated elements appear as collections of small, round cells with hyperchromatic nuclei; differentiated elements include Flexner-Wintersteiner rosettes, Homer-Wright rosettes, and fleurettes from photoreceptor differentiation.[99]

The study of Rb has provided insights into the genetic basis of cancer. The Rb gene (*RB1*) is located on the long arm of chromosome 13 (13q14). In order for Rb to develop, both copies of the gene at the 13q14 locus must be lost, deleted, mutated, or inactivated. If either the maternal or paternal copy of the gene that is inherited by an individual is defective, then that individual is heterozygous for the mutant allele. Tumor formation requires both alleles of the gene to be mutant or inactive. These two mutations correlate to the two "hits" theorized by Knudson, which was based on the finding that children with bilateral Rb developed multifocal, bilateral tumors at an earlier age than those with unifocal, unilateral tumors.[100,101] The first "hit" can be inherited and would be present in all cells in the body, and the second "hit" results in loss of the remaining normal allele and occurs within a particular retinal cell or cells with dysregulation of the cell cycle.[102] In sporadic, nonheritable Rb, both hits occur within a single retinal cell after fertilization (somatic events), thus resulting in unilateral Rb. Identifying the *RB1* mutation can have management implications both in the affected child as well as siblings and future offspring. For example, if *RB1*

mutation is detected, then siblings, children, and other relatives can be tested for the mutation. If they carry the mutation, they need to undergo rigorous examinations under anesthesia to rule out Rb.[103]

The most common and obvious sign of Rb is leukocoria, a discoloration of the pupil (Fig. 41.9). Less common and less specific signs and symptoms are deterioration of vision, a red or irritated eye, faltering growth, or developmental delay. Children with retinoblastoma can develop a squint, commonly referred to as "cross-eyed" or "wall-eyed," indicating strabismus.[104] In developing countries, eye enlargement is a common finding of advanced disease. Funduscopy typically reveals a white-colored main tumor (Fig. 41.10), frequently with satellite lesions in the retina, subretinal space, and/or vitreous referred to as "seeds." Secondary serous retinal detachment may be associated with large lesions. To confirm these findings, a detailed examination under anesthesia through dilated pupils is performed.

Ultrasonography of the eyes is often performed to evaluate the intraocular mass with attention to heterogeneity and calcifications, which support a diagnosis of Rb. Ultrasonography is not as sensitive as CT, which is the ideal imaging choice to detect intraocular calcifications. Although CT raises the concern of exposure to radiation in children <1 year of age with germ line mutations,[105] it is still frequently used to confirm the diagnosis, particularly in developing countries. Magnetic resonance imaging (MRI) of the brain and orbits is the most sensitive means of evaluating for extraocular extension and also provides better delineation of the optic nerve and the pineal area.[106] MRI of the brain and spinal cord and cerebral spinal fluid examination are indicated when there is gross invasion of the optic nerve by imaging studies or evidence of microscopic involvement beyond the lamina cribrosa on histopathologic examination of the enucleated eye. A bone marrow examination and a bone scan are indicated only in cases of an abnormal blood count or clinical symptoms suggesting osseous metastases. The diagnosis of retinoblastoma is based on

examination by an ophthalmologist and imaging studies. Biopsy is generally not performed due to the theoretical risk for extraocular dissemination, which could convert an intraocular, curable tumor into extraocular, metastatic disease.

Rb can spread in a variety of ways, including direct invasion of the optic nerve into the chiasm or dissemination through the subarachnoid space to the brain and spinal cord. Tumors can also invade the choroid and the vascular layer and spread via blood to the bone and bone marrow.[107,108] Anterior spread can occur and involve the aqueous venous channels, conjunctiva, and lymphatics or invade the sclera into the orbit with eventual spread to regional lymph nodes.

Treatment

Management of Rb requires close cooperation of a multidisciplinary team of ophthalmologists, pediatric oncologists, pediatric radiation oncologists, pathologists, genetic counselors, nurses, and social workers. Most unilateral cases present with advanced intraocular disease and require enucleation, which is also indicated for eyes with recurrent disease and no useful vision. Children with bilateral presentations typically require multimodality therapy with chemotherapy and local therapy. Staging and classification schemes have been developed to assess outcomes, particularly for intraocular Rb. The Reese-Ellsworth (R-E) classification, developed in the 1960s, was the first of these (Table 41.1).[109] Specifically, the R-E classification, which has five groups, was devised to predict prognosis in eyes that were treated with EBRT. Eyes with disease consistent with the lower groups have a lower risk for enucleation following EBRT, whereas group V eyes have the highest risk for enucleation. In recent years, chemotherapy has diminished the role EBRT for intraocular disease and thus the R-E classification is less useful. Alternative grouping systems have been proposed by Shields and Murphree, among others.[110,111] The International Retinoblastoma Classification, developed by a consensus panel in Paris in 2003, is used by many cooperative study groups (Table 41.2). An additional system has been proposed by Chantada designed to address extraocular disease and microscopic disease following enucleation.[112]

Enucleation

Most children with unilateral Rb present with advanced disease and require enucleation. Other indications for enucleation are cases of bilateral disease where the eye with more advanced disease does not respond to chemotherapy or other treatments, when active tumor is present in an eye with no vision, when

glaucoma is present as a result of neovascularization of the iris or tumor invasion into the anterior chamber, and when direct visualization of an active tumor is obstructed by conditions including hemorrhage, corneal opacity, or cataract.[113] Enucleation is curative in >95% of patients with unilateral disease. Orbital implants are often used and connected to orbital muscles, and excellent cosmesis can be achieved.

External Beam Radiation Therapy

Rb is a highly radiosensitive tumor as first shown by Hilgartner in 1903.[114] By virtue of its radiosensitive nature, Rb was historically treated with first-line EBRT in a majority of cases, with doses of 42 to 50 Gy given in 1.5 to 2 Gy/fraction resulting in 87% eye preservation in R-E groups I to IV versus 29% in group V eyes.[115] In recent decades, however, the trend has been to avoid RT when possible out of concern of growth deformities of the bony orbit and mortality related to osteosarcoma development.[116,117] However, EBRT still has a viable role in the management of Rb, particularly as salvage treatment in tumors that are refractory to chemotherapy and other local therapies. Other indications include lesions that are too large, numerous or close to the optic disc or fovea for focal therapy to preserve central vision. EBRT also has a special role in treating eyes with vitreous seeds.[118] Chan reported on 36 eyes that received EBRT after incomplete response to primary chemotherapy and focal therapies in 22 patients with bilateral Rb.[119] Thirty-two received lens-sparing EBRT, and the remainder received whole eye EBRT to a dose of 40 to 44 Gy in 20 to 22 fractions. The rate of eye preservation was 83%, and 67% required no further treatment. Visual acuity was recorded for 19 eyes, of which 10 read 6/9-6/5, 3 read 6-18-6/36, and 6 read 6/60 or worse. Side effects were limited to cataracts and dry eyes although follow-up (median 40 months) was insufficient to assess second malignancies. The investigators concluded that EBRT was highly effective in preserving eyes with useful vision in bilateral Rb in cases refractory to chemotherapy and focal therapies. In a more advanced population, Kingston evaluated consolidative EBRT (40 to 44 Gy) in 14 patients with R-E group V eyes after induction chemotherapy with carboplatin, etoposide, and vincristine.[120] Four eyes were enucleated primarily for severe disease at presentation, and of the remaining 20, 6 required enucleation (4 for recurrence, 2 for neovascular glaucoma). Of the 12 surviving children, 5 have visual acuity of better than 1/60 in at least one eye. Thus, although most group V eyes could be salvaged, the resultant visual acuity was often poor.

TABLE 41.1 REESE-ELLSWORTH CLASSIFICATION OF RETINOBLASTOMA

Group 1: Very favorable for maintenance of sight
A. Solitary tumor, smaller than 4 disc diameters (DD), at or behind the equator
B. Multiple tumors, none larger than 4 DD, all at or behind the equator

Group 2: Favorable for maintenance of sight
A. Solitary tumor, 4 to 10 DD at or behind the equator
B. Multiple tumors, 4 to 10 DD behind the equator

Group 3: Possible maintenance of sight
A. Any lesion anterior to the equator
B. Solitary tumor, larger than 10 DD behind the equator

Group 4: Unfavorable for maintenance of sight
A. Multiple tumors, some larger than 10 DD
B. Any lesion extending anteriorly to the ora serrata

Group 5: Very unfavorable for maintenance of sight
A. Massive tumors involving more than one half of the retina
B. Vitreous seeding

TABLE 41.2 INTERNATIONAL CLASSIFICATION OF RETINOBLASTOMA

Group	Subgroup	Quick Reference	Features
A	A	Small tumor	Retinoblastoma ≤3 mm in size[a]
B	B	Larger tumor	Retinoblastoma >3 mm in size[a] or
		Macula	Macular retinoblastoma location (<3 mm to foveola)
		Juxtapapillary	Juxtapapillary retinoblastoma location (≤1.5 mm to disc)
		Subretinal fluid	Clear subretinal fluid ≤3 mm from margin
C		Focal seeds	Retinoblastoma with
	C1		Subretinal seeds ≤3 mm from retinoblastoma
	C2		Vitreous seeds ≤3 mm from retinoblastoma
	C3		Both subretinal and vitreous seeds ≤3 mm from retinoblastoma
D		Diffuse seeds	Retinoblastoma with
	D1		Subretinal seeds >3 mm from retinoblastoma
	D2		Vitreous seeds >3 mm from retinoblastoma
	D3		Both retinal and vitreous seeds >3 mm from retinoblastoma
E		Extensive	Extensive retinoblastoma occupying >50% globe or
			Neovascular glaucoma
			Opaque media from hemorrhage in anterior chamber,

	vitreous, or subretinal space
	Invasion of postlaminar optic nerve, choroid (>2 mm), sclera, orbit, anterior chamber

[a]Refers to 3 mm in basal dimension or thickness.

Radiation techniques in Rb should provide uniform coverage of the entire retina approaching the ora serrata and coverage of up to 10 mm of the optic nerve while sparing the lens and bony anatomy to the extent possible.[116] In practice, the dual goals of irradiating the entire retina and protecting the lens present a difficult challenge. Historically, a single lateral field was used for the management of one eye and parallel-opposed fields for the management of both eyes. The traditional border for these “D-shaped” fields was the lateral rim of the bony orbit, which could result in underdosing of the anterior retina with associated local failure. McCormick reported local failure in two-thirds of cases when a lens-sparing lateral technique was used.[121] Based on these concerns, more sophisticated techniques were developed, such as the anterior lens-sparing technique, modified lateral field techniques using oblique angles, anterior treatment techniques using electrons, and multiple noncoplanar arcs.[122–125]

Intensity-modulated radiation therapy (IMRT) is well suited for the treatment of small tumors such as Rb. Krasin performed a planning study that favored the use of IMRT over conformal, anterior–lateral photon and anterior electron plans for the treatment of the entire globe.[126] IMRT resulted in the greatest sparing of the surrounding bony orbit and other normal tissues. As acute and late toxicity is related to volume and dose of normal tissue irradiated, proton therapy has been considered for the treatment of Rb, with the added advantage of reducing low-dose exposure of normal tissue. Lee compared protons with three-dimensional conformal RT, IMRT, and electron therapy when treating the entire retina and vitreous cavity.[127] Protons provided superior coverage with greater sparing of normal tissue, with potential for a superior therapeutic ratio. Krengli reached similar conclusions looking at target coverage and lens sparing using protons for various intraocular tumor locations and beam arrangements.[128] Mouw and colleagues from the Massachusetts General reported clinical outcomes on 49 Rb patients (66 eyes) treated with proton beam therapy between 1986 and 2012.[129] At a median follow-up of 8 years, no patients died of retinoblastoma or developed metastases. The posttreatment enucleation rate was 18% and only 11% in patients with stage A to B disease (International Classification for Intraocular Retinoblastoma). Twelve eyes (20%) required intervention for a complication (mainly cataract) and no in-field second malignancies were

reported. Based on these dosimetric and clinical data, proton beam irradiation should be favored in the management of Rb. Historically, patients with hereditary disease who received EBRT have a cumulative incidence of second cancers of 35%, compared with 6% among nonirradiated patients. This risk is even higher if treatment takes place before 1 year of age.[130] Cataracts, optic nerve damage, total retinal vascular occlusion, vitreous hemorrhage, and facial and temporal bone hypoplasia are other complications associated with EBRT therapy.[131]

Brachytherapy

Brachytherapy with iodine 125, gold, and more recently ruthenium have been used in selected cases of Rb.[132] The intention is to deliver a dose of 40 to 45 Gy transsclerally to the apex of the tumor over a period of 2 to 4 days. This treatment is limited to tumors that are <16 mm in base and 8 mm in thickness and can be used as the primary treatment or, more frequently, in patients who had failed initial therapy including previous EBRT.[133] Shields described 79% local control at 5 years using this method.[134] Side effects are generally less common than with EBRT and include optic neuropathy, radiation retinopathy, and cataract formation. Second malignancies do not appear to be associated with this type of local therapy. Relative contraindications include larger tumors and those that involve the macula.

Thermotherapy

Thermotherapy involves the application of heat directly to the tumor with infrared radiation. A temperature between 45°C and 60°C is reached, which is below the coagulative threshold and therefore spares the retinal vessels from coagulation.[135] Thermotherapy alone can be used for small lesions that are ≤3 mm in diameter without vitreous or subretinal seeds. In a study of 91 tumors, 92% of the tumors that were <1.5 mm in diameter were controlled with thermotherapy alone.[133]

Chemothermotherapy and Laser Photocoagulation

Larger tumors or tumors with subretinal seeds are usually treated with a combination of thermotherapy and chemotherapy (chemothermotherapy), usually delivered within hours of each other. In one study of 188 retinoblastomas, tumor control was achieved in 86% of cases.[136] Complications included focal iris atrophy, paraxial lens opacity, sector optic disk atrophy, retinal traction, optic disk edema, retinal vascular occlusion, retinal detachment,

and corneal edema. Chemothermotherapy may be especially useful for patients with small tumors adjacent to the fovea and optic nerve, where RT or laser photocoagulation may result in significant visual loss. Laser photocoagulation is recommended only for small posterior tumors with the goal of coagulating the tumor's blood supply.[137] Effective therapy usually requires 2 to 3 sessions at monthly intervals. Complications of this treatment include retinal detachment, retinal vascular occlusion, retinal traction, and preretinal fibrosis.

Cryotherapy

Cryotherapy induces tumor tissue to freeze rapidly, resulting in damage to the vascular endothelium with secondary thrombosis and infarction of the tumor tissue. It may be used as primary therapy for small peripheral tumors or for small recurrent tumors previously treated with other modalities. Tumors are typically treated three times per session, with one or two sessions at monthly intervals. Ninety percent of tumors <3 mm in diameter are cured permanently, and complications are few and rarely serious.[138] Transient conjunctival edema and transient localized serous retinal detachments can occur. Vitreous hemorrhage can be observed in large or previously irradiated tumors.

Chemotherapy

Chemotherapy has been used to treat intraocular retinoblastoma since the early 1990s. It is used to reduce the size of the tumor to allow local ophthalmologic therapies, including cryotherapy, laser photocoagulation, or thermotherapy to eradicate the remaining disease. This combination of therapies has been promoted to avoid EBRT and/or enucleation and thereby decrease the potential for long-term side effects while salvaging useful vision. The common indications for chemotherapy for intraocular Rb include tumors that cannot be effectively treated with local therapies alone, usually because of the size. Chemotherapy may be indicated in children with unilateral or bilateral disease, but many patients with unilateral disease are diagnosed with advanced disease and require enucleation. Numerous studies have been published that show that chemotherapy is effective in eliminating the need for EBRT or enucleation in R-E group I to III eyes while proving to be significantly less successful in eyes with group IV or V disease.[139–142] Carboplatin, vincristine, and etoposide are generally used, and cyclosporine has been added to the regimen in some institutions in order to reduce drug resistance.[143] Chemotherapy regimens from different investigators vary in the number and frequency of cycles, but they are generally well

tolerated, with the expected side effects of myelosuppression and associated risk of infection. A risk of second malignancy also exists, especially when using etoposide.[144] Chemotherapy alone is not very effective in avoiding EBRT or enucleation in patients with R-E group V eyes, especially those with vitreous seeds. Friedman showed that only 53% of 30 group V eyes could be controlled with chemotherapy alone.[145] Based on these data, modern regimens incorporate carboplatin, vincristine, and etoposide along with sub-tenon (the virtual space between the capsule and the sclera) carboplatin for more advanced patients.[146] Eyes with diffuse vitreous seeding rarely respond to chemotherapy alone, and although EBRT is modestly successful, other approaches are needed. Therapies for patient with vitreous or subretinal seeding include intra-arterial chemotherapy (IAC) with selective catheterization of the ophthalmic artery. In a landmark study, Gobin described 78 patients (95 eyes) treated with IAC with melphalan with or without topotecan and evaluated procedure success, event-free (RT or enucleation) ocular survival, and ocular and extraocular complications.[147] The procedure succeeded in 98.5% of cases, and the ocular event-free survival rates at 2 years were 70% for all eyes, 82% for eyes that received IAC as primary treatment, and 58% for eyes that had prior treatment with chemotherapy or EBRT, and there were no permanent complications. Abramson reported similarly encouraging results in 67 patients (76 eyes) treated with IAC.[148] Among previously untreated patients, the ocular salvage rate was 83% for eyes with subretinal seeding only, 64% for eyes with vitreous seeding only, and 80% for eyes with both. Patients with persistent or recurrent vitreous seeding after primary treatment require more novel approaches. Gohssemi and colleagues tested combined intravitreal melphalan and topotecan in 9 such eyes followed by cryotherapy and control was achieved in 6 eyes (66%) using 1 to 3 injections, with 33% requiring enucleation because of the disease persistence.[149]

Management of Extraocular Disease

Patients with extraocular disease historically have had a poor prognosis, but studies using combinations of chemotherapy and EBRT have been encouraging. Chantada reported a 5-year EFS rate of 84% in 15 patients with orbital or preauricular disease treated with chemotherapy that included vincristine, doxorubicin, and cyclophosphamide or vincristine, idarubicin, cyclophosphamide, carboplatin, and etoposide.[150] These patients also received EBRT of 45 Gy administered to the optic chiasm for patients with orbital disease and to the involved nodes for those with preauricular lymphadenopathy. More

recently, Chawla reported a prospective comparison of 2 neoadjuvant chemotherapy regimens followed by enucleation, EBRT, and adjuvant chemotherapy.[151] Fifty-four patients were randomized into two chemotherapy groups: Group A patients received vincristine, etoposide, and carboplatin (VEC) and group B patients received carboplatin and etoposide, alternating with cyclophosphamide, idarubicin, and vincristine. EBRT was delivered 4 to 6 weeks after enucleation and consisted of 40 Gy in 20 fractions over 4 weeks to the involved orbit. At 4 years, the survival probability for group A was higher (63% vs. 25%, $P = .05$) and the authors suggested that neoadjuvant chemotherapy with high-dose VEC be considered in these cases.

Primary Intraocular Lymphoma

Primary intraocular lymphoma (PIOL), formally known as ocular reticulum cell sarcoma, is an uncommon clinical manifestation of non-Hodgkin lymphoma, which arises in the retina or the vitreous humor.[152] It usually develops in patients in the fifth and sixth decade of life as a chronic, relapsing and steroid-resistant uveitis and vitritis. Patients often complain of blurred vision, a painless loss of vision, and floaters. Intraocular lymphoma may occur independently, prior or subsequent to a primary central nervous system lymphoma (PCNSL). PIOL progresses to intracranial involvement in 60% to 85% of cases.[153] Patients often complain of blurred vision, a painless loss of vision, and floaters. Historically, PIOL has been difficult to diagnose, often taking several years from the onset of symptoms to establishing a diagnosis, which likely contributed to suboptimal outcome in many cases.[154] Given the tumor's rarity, the optimal treatment of PIOL is unclear. Radiation therapy has been used with durable control after 35 to 45 Gy given exclusively to both eyes in the absence of CNS disease.[151] However, concerns of CNS relapse have led investigators to use chemotherapy as initial treatment and radiation as a consolidative therapy.[155,156] Methotrexate and cytosine arabinoside are most commonly used given their ability to cross the blood–ocular barrier.

Optic Pathway Glioma

Optic pathway gliomas, with or without contiguous involvement of the hypothalamus, have an incidence of approximately 1 in 100,000, with 90% presenting in the first two decades of life.[157] Most of these neoplasms are pilocytic or low-grade astrocytomas.[158] Untreated, the clinical course is that of deterioration of visual acuity, progressive visual field deficits, endocrine or

intellectual impairment, and death in up to 30% because of the local tumor progression.[159] Multiple treatment strategies exist, including surveillance, chemotherapy, RT, and surgery, of some combination of therapies. Advances in management have resulted in cause-specific survival rates of 90% to 100% except in cases associated with neurofibromatosis, which carry a worse prognosis.[160,161] Therefore, multidisciplinary management of optic pathway gliomas is critical with an emphasis on reducing treatment-related sequelae. The role of surgery is limited but may be a reasonable treatment option in patients where tumor is confined to a single optic nerve with no useful vision. Local failure rates of approximately 5% can be achieved after complete resection.[155] Radiation therapy has resulted in 10-year survival rates ranging from 40% to 93%, but with potentially severe long-term sequelae, including endocrine problems, neurodevelopmental disorders, and second malignancy.[162] Concerns of these toxicities are significant enough such that at most centers, children of any age are initially treated with chemotherapy in order to delay irradiation until progression. Investigators have found that a 2.5- to 3-year delay in RT can be achieved with this approach.[158]

The main indication of RT is for progressive disease, and radiation doses in the range from 45 to 60 Gy in 1.8- to 2.0-Gy fractions have been effective. Erkal reported on 33 cases of OPG treated between 1973 and 1994.[159] Twenty-four children had optic pathway gliomas and nine had chiasmatic–hypothalamic gliomas. Evidence of neurofibromatosis was present in six children. Subtotal resection was performed in 22 and biopsy in seven. Median total dose was 50 Gy in 25 fractions and mean follow-up was 13.6 years. Ten-year overall, progression-free, and cause-specific survival rates were 79%, 77%, and 88%, respectively. Differences in any of the survival endpoints between optic pathway and chiasmatic–hypothalamic gliomas were not statistically significant, but absence of neurofibromatosis correlated with significantly better progression-free and cause-specific survival. Grabenbauer reported a series of OPG with assessed visual outcomes.[163] Twenty-five patients received RT following surgery or biopsy. Treatment volume included a 0.5- to 1-cm margin around the tumor as depicted on CT or MRI. Age-adjusted radiation doses ranged from 45 to 60 Gy with a fraction size of 1.6 to 2 Gy. Overall survival and progression-free survival rates were 94% and 69% at 10 years, respectively. Age >10 years at time of treatment and total radiation dose >45 Gy were associated with significantly improved progression-free survival. Hypothalamic deficiency also correlated with age, with an incidence of 69% in patients <10 years old compared with

25% in patients >10 years old. As for visual acuity, 36% had an improvement, 52% remained stable, and 12% had measurable deterioration. The authors concluded that postoperative RT with a total dose above 45 Gy should be considered for patients with progressive OPG. Lifelong yearly evaluations for levels of growth hormone, thyroid and adrenal, are warranted because there is frequent need for replacement therapy, particularly in children under 10 years of age.

As in all pediatric malignancies, radiation technique should be approached with an emphasis on normal tissue sparing. Comb reported on 15 patients treated with fractionated stereotactic RT (FSRT) to a median total dose of 50.2 Gy at 1.8 Gy/fraction.[164] The progression-free survival rate at 3 and 5 years was 92% and 72%, respectively. Functional results were encouraging with only two patients having worsening of vision after RT. Seven had preexisting endocrinopathy, but only one additional patient had endocrine dysfunction after treatment, suggesting FSRT is an effective option for OPG. Still, conformal RT, intensity-modulated radiation, and FSRT carry concerns of second malignancy due the large volume of intracranial tissue receiving a low, potentially mutagenic dose of radiation. For this reason, proton beam therapy has been advocated: Fuss and colleagues evaluated dosimetry plans for proton versus conformal plans in seven cases of OPG and found proton therapy offered substantial normal tissue sparing both at high- and low-dose areas.[165] The difference was more apparent in tumors >80 cm^3, but even in tumors <20 cm^3, conformal RT resulted in a larger amount of normal tissue receiving low to moderate doses of radiation.

Orbital Tumors

Primary Orbital Lymphoma

Orbital non-Hodgkin lymphomas (NHL) account for only 0.01% of NHL and are typically B-cell lymphomas.[166] Depending on the stage and grade of disease, observation, first-line chemotherapy, and chemotherapy followed by RT are treatment options. RT is generally the treatment of choice for NHL localized to the orbital cavity.[167] Local control in the rates of 90% to 100% can be achieved using doses of 30 to 36 Gy.[168] Historically, radiation was delivered with an anterior portal prescribed to the orbital apex or by wedged anterior and lateral fields. Late effects from these techniques include cataract formation, lens ulceration, glaucoma, and lacrimal impairment.[166] More recently, investigators have described the use of intensity-modulated radiation therapy (IMRT) in orbital lymphoma to reduce dose to the contralateral orbit, lacrimal gland, and

lens (Fig. 41.11).[169]

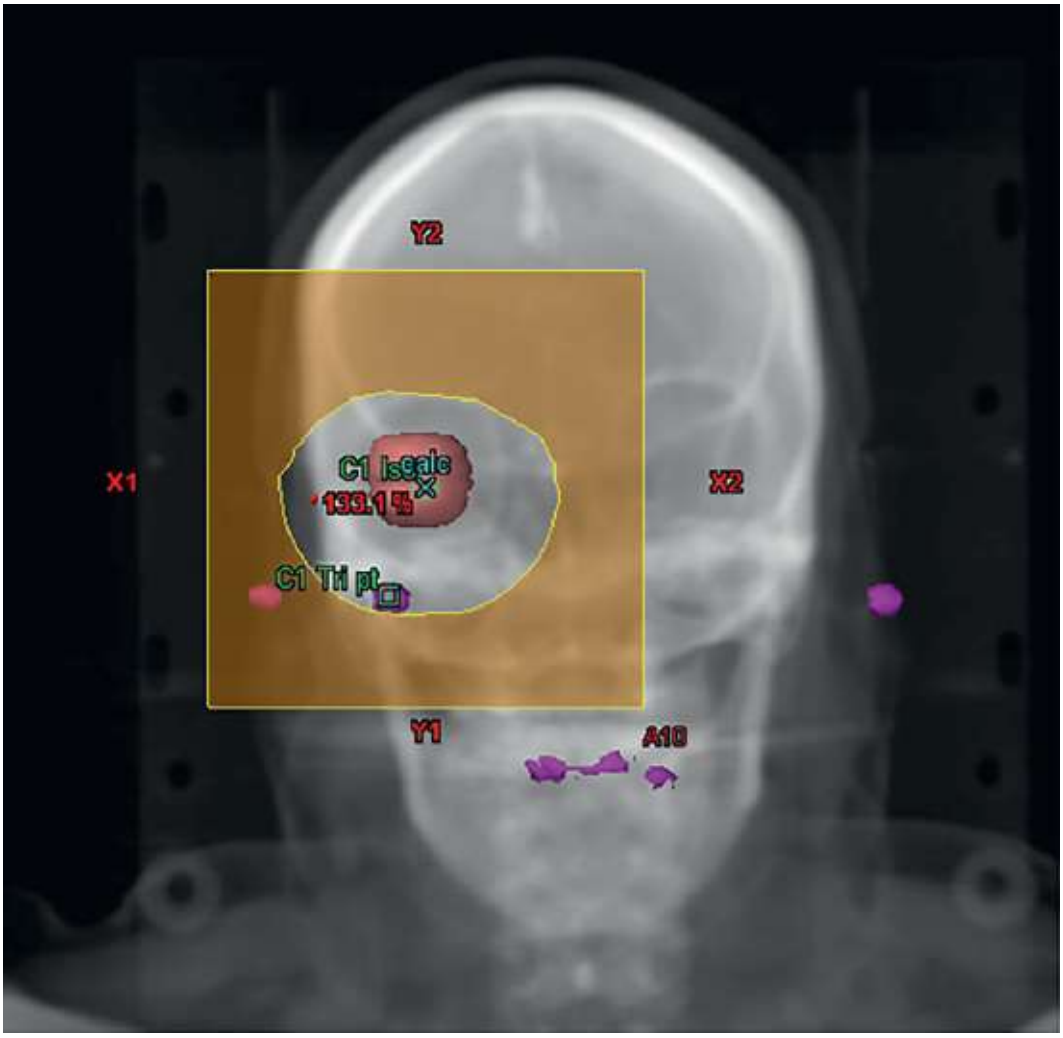

FIGURE 41.12. Electron beam therapy for mucosa-associated lymphoid tissue lymphoma of the conjunctiva. The patient received 30.6 Gy using 9-MeV electrons. Lens shielding was not used because of the extent of disease at presentation.

Conjunctival Tumors

Conjunctival tumors comprise a variety of conditions, from benign papilloma to malignant lesions such as squamous cell carcinoma (SCC). Radiotherapeutic management of these tumors is related to the histologic type, as is the case in tumors found elsewhere. MALT lymphoma, for example, has been effectively managed with exclusive RT with local control rates approaching 100%.[170] In a series of patients with MALT lymphoma of the ocular adnexa that included 37 patients with conjunctival disease, Hashimoto reported local control rates of 100% with a median dose of 30.6 Gy.[171] Electron beam therapy was frequently used with eye lens shielding when possible depending on the extent of disease (Fig. 41.12). Treatment options for SCC include excision with or without

adjuvant cryotherapy or topical chemotherapy, whereas advanced cases may require orbital exenteration.[172] RT has been used in the primary, adjuvant, and salvage setting with a variety of methods including photon, proton, and electron beam therapy.[173,174] Most frequently, however, radiation is used in patients with relapsed disease. The treatment volume typically includes gross tumor with margins of approximately 1 cm and doses of approximately 60 Gy, as in cases of SCC from other sites.[175]

Sebaceous Carcinoma of the Eyelid

Sebaceous gland adenocarcinoma occurs in the periorbital area, usually in the eyelid.[176] It can exhibit aggressive local behavior and can metastasize to regional lymph nodes and distant organs. Older individuals tend to be affected, but it occurs with greater frequency and at an earlier age in patients with hereditary retinoblastoma treated with radiation.[177] The main systemic association is Muir-Torre syndrome, an autosomal dominant condition characterized by greater frequency of sebaceous adenoma, sebaceous carcinoma, keratoacanthoma, and gastrointestinal malignancies.[178] The most common pattern of metastasis of eyelid sebaceous carcinoma is through the lymphatic channels to regional lymph nodes. Historically, regional node metastasis occurred in about 30% of cases, but metastases have become less frequent in recent years.[179] Tumors that originate in the upper eyelid tend to metastasize to preauricular and parotid nodes. Tumors of the lower eyelid region can metastasize to submandibular and cervical nodes. Until recently, orbital exenteration was believed to be the only reasonable option in the management of sebaceous carcinoma that involved most of the conjunctiva and invaded the orbit. However, local excision with adjuvant therapies, such as topical chemotherapy or cryotherapy, is becoming more common.[180,181] EBRT, with doses of approximately 60 Gy, is rarely used for primary treatment but should be considered for patients with adverse features such as regional lymph node involvement or recurrent disease.[182]

Orbital Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) affects 250 to 300 children per year in the United States.[183] In 1950, Stobbe demonstrated improvement in the outcome in head and neck sites when RT was added after incompletely resected RMS.[184] In 1961, Pinkel and Pinkren advocated adjuvant chemotherapy after complete surgical excision and postoperative RT, which was the beginning of the multimodal approach to solid tumors.[185] Recognizing the value of this multimodal approach

as well as the relative rarity of these tumors, in 1972, the leadership of three US cooperative pediatric cancer research groups formed the Intergroup Rhabdomyosarcoma Study Group (IRS) to investigate the biology and treatment of RMS. Since then, five successive clinical protocols involving almost 5,000 patients have been completed: IRS-I, 1972–1978; IRS-II, 1978–1984; IRS-III, 1984–1991; IRS-IV Pilot (for patients with advanced disease only), 1987–1991; and IRS-IV, 1991–1997.[186–191] The head and neck region is the most common site of presentation and accounts for about 35% of the patients in the IRS studies.[192] These tumors are most commonly of the embryonal subtype and rarely spread to regional lymph nodes. Orbital tumors produce proptosis and, occasionally, ophthalmoplegia (Figs. 41.13 and 41.14). Modern management of RMS is multiagent chemotherapy followed by RT. Consideration of prechemotherapy as well as postchemotherapy tumor volume must be considered when planning RT. McDonald reported on 20 patients with head and neck RMS (2 orbit) treated with IMRT to total dose of 50 Gy, in accordance with cooperative group protocols.[193] The initial targeting of the prechemotherapy tumor volume with 1- to 2-cm margin to 30.6 to 36 Gy followed by a cone-down boost to the postchemotherapy tumor volume with a 0.5- to 1-cm margin allowed for significant sparing of normal tissues. Only 1 patient (5%) developed an in-field recurrence after 50 months. The 3-year event-free survival, overall survival, and risk of central nervous system failure were 74%, 76%, and 7%, respectively.

Periorbital Skin Cancers

Skin cancers of the eyelid and periorbital skin include most frequently basal cell carcinoma (BCC), SCC, but also rare histologies such as Merkel cell carcinoma (MCC).[194] For small BCC and SCC, single modality treatment with surgery or RT results in good local control, but RT is frequently used due to cosmetic concerns. For more advanced tumors or more aggressive histologies, such as MCC, combined surgery and RT are typically recommended. Low-energy electron beam therapy or orthovoltage irradiation is useful in this setting and can be delivered with an eye shield. RT for skin tumors requires doses of 60 Gy or more for definitive treatment using standard fractionation, but altered fraction can be employed to shorten treatment duration and minimize ocular trauma of shield placement.
