# *Preface*

The *Clinical Trials Handbook* represents a collective attempt to present the entire range of approaches to the clinical development process for potential new therapeutic moieties, assembled in the context of this Wiley series on the entire process of pharmaceutical discovery and development. This volume, in fact, is the seventh in this series, which is intended to be comprehensive in its coverage.

The volume is unique in that it seeks to cover the entire range of general topics in the field of clinical trials while also presenting chapters that focus on a specific therapeutic usage over a wide range of disease claims. The 52 chapters cover introductory, regulatory and logistical issues, data management, general study design issues, types of clinical trials, and ethical and oversight issues.

This book would not have occurred without the dedicated efforts of Wiley's managing editors, Zabrina Mok and Gladys Mok. Their persistence in the recruitment of contributors and ensuring follow through was essential.

While like all textbooks this one presents the state of the practice and field at a specific period in time, I hope that it will become a frequently consulted friend.

SHAYNE COX GAD

### **1.1 GOALS OF CHAPTER**

The purpose of this chapter is to consider the overall goals and requirements of conducting clinical trials. It is an opportunity to avoid pitfalls by viewing the larger picture. This chapter seeks to provoke consideration of key issues without duplicating the more detailed work of later chapters.

## 1.2 GOALS OF CLINICAL TRIALS AND WHAT IS AT STAKE

The ultimate goal of drug development is the creation of new, safe, and effective compounds for treating human disease. Clinical trials comprise the portion of this endeavor involving human subjects. While the basic tenants of scientific inquiry do not differ from preclinical research, the stakes are higher and the regulations more stringent.

The cost of conducting clinical trials can be measured in two ways: the human cost and the resource cost. The human cost is the cost from the patient's perspective. The patient suffers from a condition dire enough that experimental therapy is a consideration. He or she holds out hope for this therapy and trusts to the scientific skill and integrity of those conducting the trial. The patients expose themselves to an incompletely understood therapy and usually suffer some degree of toxicity in order to gain uncertain benefit. Prior to a drug being declared useful or not, hundreds or thousands of patients may be involved in trials related to the drug.

On another balance sheet, there is the impressive economic burden of drug development. The cost of successfully bringing a new drug to market is now in the range of \$800 million [1]. The interval between the start of clinical testing and the submission of an application for regulatory approval of a new drug is estimated at 6 years [1]. Even so, fields such as oncology are seeing an increase in drugs under study [2]. Yet there are limits to the number of clinical centers able to conduct trials. More importantly, there is a limit to the number of patients that are eligible to participate in a given trial, either by reason of demographic factors, comorbidity, incompatible disease parameters, or willingness. These limitations suggest that investigators must be selective about which drugs they study in clinical trials.

While drug discovery still involves an element of happenstance, contemporary drug development is ever more focused on mechanisms specific to a given disease. Frequently, therefore, a disease population will have been targeted during preclinical development. It is up to the clinical trials process to assess whether the new agent is both safe and effective in this or other populations. Generally, the first concern is assessing drug toxicity and the related dosing and pharmacokinetics. Following this, some evidence of efficacy is sought. If it is found, efficacy must be confirmed in larger, randomized trials. Finally, postmarketing surveillance studies may be performed. These successive clinical trials are usually categorized by phase, and these phases will be introduced below.

## 1.3 INTRODUCTION TO PHASE I-IV CLINICAL TRIALS

### 1.3.1 Introduction to Phase I Trials

**Purpose** New drugs are first introduced into human subjects in phase I trials. The primary goal of these first studies is to assess the safety of the agent and to determine an acceptable dose for further study. Related goals include the assessment of pharmacokinetics as well as pharmacodynamics. To study pharmacokinetics is to study how the body affects the drug: How is the drug absorbed? How is the drug distributed between body compartments? How is the drug metabolized and excreted? Pharmacodynamics is the relationship between drug exposure and drug effect. Here

we ask what normal physiological or disease processes are altered when a drug is administered at varying doses.

**Methods** The method used is to some extent dictated by the drug and disease under consideration. In fields other than oncology, phase I trials are typically undertaken in healthy volunteers. Typically, increasing doses of a drug are employed in small successive cohorts of patients. Each cohort is assessed, and subsequent dose levels are only used if excessive toxicity (often termed dose-limiting toxicity) is not encountered. At each dose level, blood or other body fluid is taken for pharmacokinetic studies.

In oncology studies, the first and lowest dose level may be based upon animal toxicities (e.g., 10% of the dose that is lethal in 10% of mice ( $LD_{10}$ )) and dose increments are often based upon a modified Fibonacci sequence (1, 2, 3, 5, 8, 13, ...), a scheme that decreases the dose increment with each subsequent level. The notion is to limit patient exposure to dose-limiting toxicity through more cautious later stage dose increases. Alternative dosing schemes employ one patient per dose level or a continuously modified dosing increment based upon observed toxicities; the goal of such alternative methods is to increase phase I efficiency and limit the number of patients who receive too little or too much drug [3]. At some point, toxicity is deemed to be excessive, and the appropriate dose level is then established, typically at the dose just below this point of excessive toxicity.

Pharmacokinetics is the study of the drug absorption, transport, distribution, metabolism, and elimination; the goal is to improve drug delivery and efficacy. An understanding of the molecular target may have implications for drug exposure. For example, antimetabolites used against cancer are considered to be most effective in the DNA (deoxyribonucleic acid) synthesis phase (S-phase) of the cell cycle. To best inhibit tumor growth, it is considered optimal to maintain a constant or prolonged exposure of the cancer to drug such that most cells are caught as they transit through S-phase. Pharmacokinetic analysis can tell the investigator if such an exposure is occurring and may prompt alternative dose schedules in subsequent studies.

Pharmacodynamic assays—assays that assess the effect of the drug on normal physiology or disease—may be useful in assessing whether a drug is likely to have a clinical effect. In cardiology, for example, the effects of a new agent on subjects' blood pressure or electrocardiogram may be relevant [4]. In studies of new antibodies or other targeted therapies, a therapeutic effect may be seen without the dose-dependent toxicities expected with other agents (e.g., the antimetabolite methotrexate used in rheumatoid arthritis or cancer). Conducting assays that demonstrate molecular changes in the relevant target could serve as a proof of concept for the agent; this, in turn, could prevent the need for higher dose levels, levels that could induce toxicity and would increase the duration of the study.

**Results** At the end of a phase I study, acute toxicities should be understood. Toxicities related to more long-term exposure may not be apparent until future studies are undertaken. In conjunction with the pharmacokinetic assays and any pharmacodynamic work, an assessment must be made as to whether further studies should be conducted, and, if so, at what dose. Pharmacokinetic analysis may suggest that changes in dose or dosing frequency are required. In instances where toxicity may be excessive at doses not expected or observed to have a useful biological

effect, further phase I studies may be designed to circumvent the toxicity. While preliminary activity against disease may be observed in phase I studies, the initial assessment of positive clinical outcomes is primarily the arena of phase II studies.

### 1.3.2 Introduction to Phase II Trials

**Purpose** Phase II studies are conducted to assess the initial activity of an agent against disease. Further information is gathered about an agent's adverse effects, and additional pharmacokinetic or pharmacodynamic studies may be conducted.

**Methods** Unlike phase I studies, which may employ many different doses of an agent, phase II trials typically employ one or occasionally a few dose levels. Larger cohorts of patients are exposed to the drug in order to observe one or more clinical endpoints. The measured endpoints will vary depending upon the drug and field of study. In trials of heart failure, for example, physiological parameters (e.g., ventricular remodeling) may be assessed in addition to clinical measures such as exercise tolerance [5, 6]. Vaccine studies typically assess safety and immune responses and may involve both treatment and control groups [7]. In oncology, tumor response (shrinkage) rates have traditionally been used as a measure of response, but newer targeted drugs have led to greater reliance upon endpoints such as stable disease rates. Prior to conducting the study, investigators should specify what minimal level of drug activity will be accepted as evidence to warrant subsequent investigation. Phase II studies should be designed as precursors to phase III studies.

Phase II studies may be single-arm assessments of drug activity; such studies have an implied comparator of prior trials or clinical experience. Alternatively, randomized studies may be conducted, comparing the experimental arm with either a placebo, a standard therapy control arm, another experimental arm, or different doses of the experimental arm itself. The randomized study, while of limited power, may improve drug development by increasing the likelihood of selecting the best drug or dose for further development [8]. When a standard treatment arm is used as a comparator, that arm may serve as a barometer for the severity or nature of the disease in the overall study cohort. Excellent or poor results in the experimental arm are interpreted in light of the control arm.

A more recent study type, the randomized discontinuation study, begins with a lead-in period in which all subjects receive the experimental arm. After a predetermined period, subjects are randomized between continuing the study drug and receiving a placebo or no therapy. The lead-in period eliminates noncompliant subjects and unresponsive disease, increasing the likelihood of differences being observed in the randomized portion of the study. The cost is in the greater number of patients required for the study due to drop-out in the initial nonrandomized period [9].

**Results** As noted, the clinical endpoints vary widely based upon disease and agent type. If a drug effect was seen, it must be considered whether the effect was sufficiently interesting in light of existing therapies or other study arms. If a clinical effect was not seen, one must assess whether this could be explained by any biological surrogates or pharmacokinetic studies also undertaken. The clinical efficacy must

be assessed in the face of observed toxicities. More severe toxicities might be acceptable for lifesaving therapies but not for agents directed at minor ailments. At the end of the phase II study, the investigator should have an initial assessment of a new agent's impact on a disease as well as a better understanding of the toxicity profile.

Two important and frequently used statistical concepts should be introduced here. The first is power. In clinical terms, power is the probability that a study will find that a drug is effective when the drug truly *is* effective. Statistically, it may be described as  $\text{Power} = 1 - \beta$ , where  $\beta$  is the probability of a study finding a drug ineffective despite the truth being that the drug *is* effective— $\beta$  is therefore also called the  $\beta$  error. A related term, the  $\alpha$  error, represents the opposite mistake; it is the chance that a study will find a drug effective when in truth the drug is ineffective. By general agreement, the value of  $\alpha$  is usually set at 0.05. Power increases with larger studies (i.e., more patients) and when more prespecified clinical events occur. Phases I and II trials typically employ small numbers of patients, which tends to increase error rates and limit statistical options. Nevertheless, statistics can inform us of the limitations of our knowledge. For example, if we observed 3 of 25 patients with cancer to have tumor responses, we could determine that—with 95% likelihood—the true response rate was from about 3–30% [10]. If we had hoped for better, we would need to carefully consider any next trial. Phases III and IV studies, described below, rely heavily on thoughtful consideration of  $\alpha$  and  $\beta$  errors.

### 1.3.3 Introduction to Phase III Trials

**Purpose** Phase III studies are typically large randomized studies designed to demonstrate useful clinical activity in a specific disease setting. The process of randomizing patients between different treatment arms is fundamental to avoiding biased interpretations of outcomes.

**Methods** The design of phase III studies is critical both in addressing a specific hypothesis and in the pragmatic sense of making a drug useful in clinical practice. Fundamentally, this means that an appropriate patient population must be selected, all treatments must be clinically relevant, and the expected improvement in outcome must be both clinically meaningful and statistically measurable. Eligibility criteria—those criteria that determine which patients may join the study—must define a population that is both adequately generalizable to include patients representative of the diseased cohort but also homogeneous enough to retain statistical power and to be applicable to a usefully recognizable disease group. For example, studies may be difficult to interpret when they include both early- and late-stage patients. If a study is positive, to which population is it best applied? If negative, might it be positive in one of the disease subpopulations if a study were done only in that group.

Treatment arms cannot ignore previously existing therapies. With respect to heart failure, a new drug must take into account that many patients will also be on ACE (angiotensin-converting enzyme) inhibitors,  $\beta$ -blockers, diuretics, antiplatelet agents, and possibly other medications. Excluding these medications may make the study uninterpretable in the real-world clinical context and, more importantly, it may be unethical.

The endpoint of a phase III study should be an accepted and clinically relevant one that is specified before the trial is conducted. For example, in many cancers, an improvement in response rate is not considered an adequate phase III endpoint, whereas improvements in survival or disease-free survival may be accepted. Secondary endpoints—quality of life, for example—may be employed but must be recognized as such at study completion.

A common difficulty with phase III studies is inadequate power. This is often due to an overly optimistic estimate of improvement in a clinical outcome, an estimate that may be a product of resource limitations. A lesser and potentially meaningful improvement may be missed if too few patients are accrued to the study or follow-up is too short.

**Results** The primary and any secondary clinical outcomes must be assessed and interpreted as planned. In circumstances where the primary outcome is of borderline significance or where the primary and secondary clinical outcomes are disparate, explanations may be considered and used as hypotheses for future study. Post hoc analyses are frequently conducted but can only be hypothesis generating.

### 1.3.4 Introduction to Phase IV Trials

**Purpose** Phase IV studies, sometimes called pharmacoepidemiologic studies, are those that are conducted after a drug has been approved for marketing. Such studies, often large, may assess a drug for uncommon toxicities that may be undetectable in smaller phases I–III studies, or they may establish the activity or tolerability of a drug in a particular population or practice setting.

Studies conducted to assess new methods of drug administration, combinations with other agents, or activity in other diseases—that is, studies seeking a new marketing indication—are better described and conducted as the phases I–III studies they represent. Similarly, a distinction can be made between trials seeking to answer a specific postmarketing question and those conducted solely to increase market share, so-called seeding trials. In the latter, there may be an incentive for the involved physicians to prescribe the drug in question and there may be no intent to publish the results [11, 12].

**Methods** Phase IV studies may be conducted in several ways.

1. Descriptive studies, sometimes collections of drug toxicities captured over time, may identify new problems. These may range from case studies to series of patients collected by companies or regulatory bodies. Although resource intensive, large prospective cohort studies may also be conducted to capture infrequent adverse events.
2. Randomized studies may be used to compare an agent to other similar agents or to confirm earlier results.
3. Case-control studies or retrospective cohort studies can be conducted after data on a drug has accumulated. This would typically be done to assess for unusual side effects or associations of a drug with the development of a subsequent disease, such as malignancies or autoimmune sequelae.

4. Cross-sectional studies, although perhaps less useful, assess drug exposure and outcomes in a population at a specific time. Causality may be more difficult to assess if a sequential temporal relationship cannot be determined [12].

**Results** The results of phase IV studies may be required to fulfill regulatory requirements after accelerated approval of a new drug. The additional numbers and prolonged follow-up provided by postmarketing studies may also be crucial in revealing important but infrequent toxicities. On occasion, these findings may lead to the withdrawal of a drug from the market, as, for example, after cardiovascular complications were associated with the anti-inflammatory drug rofecoxib [13, 14].

## 1.4 PRINCIPLES OF TRIALS DEVELOPMENT

### 1.4.1 Big Picture, Small Picture

**Overall Goal: Improved Patient Care** The details involved in protocol design and regulatory requirements can be overwhelming. Remembering the fundamental goal of clinical research—improved patient care—can be an aid; study design and decision making should be influenced by the consideration of what is best for patients.

Patients seek relief from suffering. The investigator should therefore choose the most relevant endpoint for a given trial. Studies of rhinitis may reasonably examine patient reporting of nasal discharge and congestion [15], while studies of pancreatic cancer must consider an agent's impact on survival or more relevant measures of symptoms or quality of life. Research protocols must be designed with these parameters in mind. The outcome of interest must be described in sufficient detail that it may be easily replicated, a matter as important in assessing a study's value in support of regulatory approval as it is to an understanding of what benefit a drug may be to future patients. Any clinical trial must assess the toxicities associated with treatment. Known adverse effects must be clearly described and provisions made for the adjustment of treatment to mitigate such toxicities should they occur. Of course, for sufficiently severe toxicities, a warning system must be in place to inform patients, investigators, and the companies and agencies overseeing the study. The details of such reporting requirement may vary, but the act of sharing such information is sensible.

**Quality** After careful protocol development comes the messy process of administering a protocol. Invariably, aspects of the protocol appear to be open to interpretation, and at some point there will be lapses in study conduct or paperwork. The maintenance of quality in a study means always trying to adhere to the letter and spirit of the protocol. It means that the responsible investigator must be available to arbitrate whether patients are actually eligible and whether protocol violations have occurred. It means that study coordinators must vigorously pursue the complete assessment of patients and the related documentation. Every effort must be made to follow patients to the completion of study. A poorly followed or documented study may be difficult to interpret and may not be acceptable to regulatory agencies or other entities overseeing the trial.

**Nothing in Isolation—The Bench and the Bedside** The present era is one of exciting new agents, many directed at specific targets in the disease process. Even while such agents must undertake the staged clinical trials process, they may evoke interesting biological questions with implications for ongoing or future studies. The prospective collection, banking, and analysis of biological specimens may reveal subsets of patients for whom a new agent may have particular benefit.

For example, small-molecule tyrosine kinase inhibitors directed at the endothelial growth factor receptor (EGFR) have been investigated in patients with non-small cell lung cancer. Despite good preclinical data [16], clinical studies demonstrated more limited benefit, ultimately resulting in limitations of access to one such drug, gefitinib, previously approved by the Food and Drug Administration (FDA) under accelerated approval [17]. The investigation of tumor samples, however, revealed that some tumors had mutations in the tyrosine kinase domain of the *EGFR* gene, with corresponding protein changes and apparent improvements in clinical responses [18, 19]. Unfortunately, this finding was made posthumously for gefitinib, but the implications for future development of this class of drug are clear. When feasible, biological investigations and specimen preservation should continue during the clinical period of study.

#### 1.4.2 Human Element

**Differences between Mice and Humans** Despite the fact that 99% of mouse genes have human counterparts [20], several important issues separate the species. First, important differences in biology can mean significantly different drug metabolism and elimination, such that pharmacokinetics can only be generally predicted [21]. Second, human xenografts planted in mice may respond to drug therapy, but such responses are not consistently predictive of response phase II clinical studies [22]. This supports the necessity of clinical studies. Third, ethics dictates that both the goals and conduct of preclinical and clinical studies must differ. In animals, while the suffering and distress of animals is to be minimized [23], it is accepted that toxicities must be observed in other species to understand new agents and protect the humans that are subsequently exposed. By contrast, the very structure of trials in humans is one of careful staging to avoid excessive toxicity or any death. Earlier studies establish safety while later studies assess for useful clinical activity of a drug.

**Relevance of Ethics** There are more and less obvious aspects of ethics involved in clinical drug development. We have fortunately recognized and codified the obvious, so, for example, it is universally recognized that withholding effective treatment for the sole purpose of observing natural disease history is unethical [24]. But there are less flagrant examples that affect study design.

The phase I study by its nature poses ethical conundrums. It is a study designed to assess toxicity and an acceptable dose for a drug, with clinical benefit being a secondary consideration. Thus, subjects put themselves at risk for uncertain benefit, and healthy volunteers stand no chance of clinical benefit. But the phase I trial is accepted for several reasons. First and foremost, if one accepts that our society wishes to continue to make progress against disease, it becomes an unavoidable necessity. A new drug must at some point be introduced into the human population.

This must be done in a careful and systematic fashion, but risk can only be minimized, not eliminated.

Second, patients who face the option of a phase I study are often those who have a disease without further standard therapeutic options. Although the chance of benefit for a given patient is likely to be very low, a chance for therapeutic success may be motivation enough [25], and altruism may play a smaller role in patient decision making than frequently thought [26]. Yet even when informed consent may be forthcoming, phase I studies are at greater risk than later phase studies for violating the principle of beneficence (i.e., offering insufficient benefit to justify risk) and for abusing the desperation of a vulnerable patient population at the expense of the ethical principle of justice [27].

Another challenging aspect of phase I studies is drug dosing. In oncology, it has been observed that benefit derived from new cytotoxic drugs occurs more frequently when doses are near the limit of acceptable toleration of side effects [28]. This means that patients who receive lower drug doses earlier in the study are less likely to have benefit, although they may also have less toxicity. Phase I dosing is therefore a balance between minimizing toxicity and maximizing any possible benefit for the greatest number of patients [25]. It is thus incumbent on investigators to carefully plan dosing increments during protocol development and assess side effects as the trial progresses.

Phase III studies, though more likely to confer benefit than phase I studies, still pose ethical challenges. One such difficulty is the decision about whether to stop a trial during interim analysis. A trial of hormone therapy (letrozole) after curative surgery for breast cancer was stopped at an interim analysis when the treated patients demonstrated lower rates of disease recurrence [29]. It may reasonably be asked whether such a study might better be continued blinded until longer follow-up was available or a survival difference was or was not found. While unquestionably it is better to avoid recurrence of breast cancer, the cost of adopting such therapy must be balanced against an incomplete study, other potentially better therapies, or trials that might be aborted by early adoption of the considered drug [30]. We are also accepting the financial cost of a new drug by its adoption. A society may reasonably consider for any therapy whether the gains so achieved are incurred at a reasonable cost in terms of other societal concerns. Such issues make it apparent that ethics is not a matter of nebulous constructs but an integral consideration for clinical trials.

**Quality of Life** Another aspect of research that separates the clinical from the preclinical phase is the human interpretation of ailments. From pain to dyspnea, humans demonstrate a range of subjective degrees of discomfort from the insults of disease [31, 32].

Although less concrete and more difficult to assess than endpoints such as survival or hospital admissions, quality of life or symptom control data can be meaningful to patients and clinicians. In circumstances where endpoints such as survival are not readily demonstrated, such as in rheumatoid arthritis, measurements of quality of life, symptoms, and function are useful to assess drug efficacy [33]. Investigators should endeavor to use validated scales so that the results are less open to question. Still, quality of life measures have provided challenges. How often does one conduct measurements? How does one account for the inevitably missing data points [34]?

In the field of oncology, quality of life scales alone have yet to prove sufficient for drug approval by the FDA. In contrast, other simple and easily comprehensible measures of pain or composite endpoints that include pain have been accepted as a basis for drug marketing [35].

1.4.3 Multidisciplinary Nature of Clinical Trials

**Actors** The manifold tasks and varied expertise required to conduct contemporary clinic trials necessitate the input and assistance of several groups. Prior to initiating a clinical trial, it must be assured that all the players are properly cued. Table 1 lists the persons and groups that typically must be available to conduct a trial, listed roughly in order of appearance but not importance.

Due to the diverse resources required to conduct clinical trials, it is not always practical for an organization to maintain capacity for every aspect of study conduct.

TABLE 1 Entities Involved in Clinical Trials

| Entity                                                | Role                                                                                                                                                                                                                                                                 |
|-------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Principle investigator                                | While not all trials are conceived by the principle investigator, the principle investigator is responsible for the overall conduct of the trial.                                                                                                                    |
| Funding agency/<br>company                            | This may be a corporate, government, or charitable agency. In addition to funding, companies may supply drug. These bodies are frequently involved in receiving and disseminating reports of adverse events.                                                         |
| Statistician                                          | Statisticians are involved in study design, interim analyses, and the final analysis.                                                                                                                                                                                |
| Study coordinators                                    | Study coordinators are involved in all aspects of trials: protocol and form creation, submission of the protocol to various review boards and government regulatory agencies, patient consent and registration, as well as data collection, cleaning, and summation. |
| Contract and financial<br>administrators              | These persons negotiate agreements between funding agencies and centers conducting the trial, aid in the creation of budgets, and distribute funds necessary to conduct the trial.                                                                                   |
| Scientific review<br>committee                        | This body reviews the scientific merit of a clinical trial and may suggest improvements.                                                                                                                                                                             |
| Health/safety<br>committee                            | Although not involved in all studies, this group is responsible for ensuring that investigators adhere to regulations regarding infectious and hazardous substances.                                                                                                 |
| Institutional review<br>board/ethics<br>committee     | This body assesses whether the study meets the standards of respect for persons, beneficence, and justice and will prohibit substandard studies.                                                                                                                     |
| Data safety<br>monitoring board                       | Created before the initiation of the trial, this body provides objective oversight of the study and may recommend early closure of a study for reasons of either significant early benefit or excessive toxicity.                                                    |
| Pharmacists                                           | Pharmacists are responsible for research drug control and accounting.                                                                                                                                                                                                |
| Nursing staff                                         | Drug administration and sample collection requires both nursing staff and physical space, sometimes including facilities for overnight visits.                                                                                                                       |
| Pharmacokinetics<br>specialists                       | Pharmacokineticists are usually involved in phase I drug design and sample collection and analysis but may also be involved in later phase studies.                                                                                                                  |
| Outcomes<br>assessments staff<br>(e.g., radiologists) | Depending upon the outcomes being assessed, radiologists or other specialists may be required to interpret study data. In some instances, independent and blinded individuals or groups may be used to assess study data in a more objective fashion.                |

For this reason, an industry of contract research organizations has arisen to provide research services not available from in-house sources. These organizations can provide services such as research ethics review, protocol preparation, study administration, regulatory consultation, and radiologic imaging support. They can offer the advantages of expertise and efficiency in trial conduct, with offsetting disadvantages of decreased control over details, the need to rely on the contract agency for quality, and the need for careful communication with respect to the hired agency's responsibilities and goals [36].

**Statisticians** The early inclusion of an experienced statistician is advisable for most studies. In order to obtain a useful study result, a hypothesis must be generated and a statistical test must be chosen prior to study conduct. *Post hoc* statistical analyses can lead to new hypotheses for future research but cannot generate definitive answers [37].

A statistician can help to clarify the question under consideration. For example, when conducting a phase II study in heart failure, one may wish to assess the difference in exercise duration between two treatment arms [6]. Using the expected or minimally acceptable difference and the desired error rates, a statistician can advise on the number of patients that need to be recruited to the trial. Failure to determine this need may result in a futile, underpowered study or one which unnecessarily exposes excess patients to an experimental therapy.

In larger, phase III studies, the patient exposure and resource stakes are typically greater. As with our phase II example, realistic expected differences between endpoints must be considered. It must be decided whether the new therapy is likely to be superior, or whether the investigator wishes only to demonstrate that it is noninferior (although either less toxic, more convenient, or substantially cheaper), as the sample size will be larger in the latter case and the hypothesis test different. The ethical challenges of the interim analyses were previously mentioned, but the statistical challenges can also be substantial. One must estimate how many events are required in a population to sufficiently conduct the analysis, then employ a test that will assess the difference while accounting for repeated statistical testing. The goal is to avoid both false-positive studies and prolongation of a futile trial [38].

**Setting** During study development, investigators must decide where the trial will be conducted: primarily among academic centers and cooperative organizations or in community centers, usually under the auspices of a pharmaceutical company and frequently organized by contract research organizations. In addition, a study will be domestic or international.

Traditionally, academic centers and organizations have conducted clinical trials, although this has been changing [39]. While the clinical trials infrastructure is more commonly in place in academic centers, community centers have demonstrated the ability to conduct clinical trials as effectively as academic centers [40–43], and organizations have formed that may efficiently recruit patients within such centers [39]. Community-center-based trials may have the advantage of a more generalizable patient population than that seen in academic centers [44, 45]. Limitations of community trials may include limited recruitment despite declared interest, a need for financial incentives, a need for easy documentation, and a lack

of perceived benefit to the physician [46] or managed care organization [47], although these characteristics are by no means exclusive to community trials [48]. The corporate control of data, use of for-hire ethics boards, and the greater dependence on financial incentives can leave some community trials more open to question [39]. Indeed, possibly as a result of publication bias and data control, publications of industry-sponsored work tend more often to report in favor of the experimental therapy [49]. For this reason, studies conducted by academic centers may offer superior credibility.

While the logistical and regulatory convenience of domestically conducted clinical trials is undisputed, there may be advantages to studies conducted on an international basis. Most evidently, the recruitment pool may be vastly increased, particularly when countries are included where nonexperimental options are relatively limited—a source also of some ethical debate [50]. Dollar costs may also be reduced when developing countries are involved [51]. The result of international studies may be more generalizable and more readily accepted by clinicians debating the applicability of a trial to their setting. While the international adoption of standards such as the Guideline for Good Clinical Practice aims to facilitate drug development by improving the acceptance of trial results by the regulatory bodies of differing countries [52], the actual conduct of such studies can still be challenging. Differing bureaucracies and approval methods for experimental studies can mean expensive or prolonged approval processes. In developing countries, the conduct of trials may require increased support for centers with little experience conducting clinical trials, and simplified and minimized information collection. Despite the sometimes difficult logistics, it is recommended that randomization remain centralized [53].

#### 1.4.4 Know Your Audience, Know Your Market

**Who Is the Audience?** When developing a clinical trial, one must take into consideration the interested parties. First and foremost, there is the patient, who must deem the trial safe and attractive. There is the clinical investigator (and institutional review board), who must find the trial to be of sufficient scientific and ethical merit to allow accrual. There are the regulators, who may need to approve the trial for it to proceed and who will eventually need to approve an agent for nonexperimental use. And finally, there is the market, really an amalgam of the wills of patients and clinicians as influenced by competing therapies. While the term market connotes a mercenary purpose, the consideration of a drug's market is both worthy of time and compatible with the goal of optimal patient care.

**Considering Current and Evolving Practice** Clinical trials are not conducted in isolation. Rather, they become available to patients as an option alongside existing standard therapies. This imposes limitations on the experimental and control arms for a trial. For example, in many instances a patient commencing treatment for more than very mild rheumatoid arthritis (RA) would be a candidate for methotrexate [54]. Starting a patient purely on an experimental therapy could thus be deemed inadequate, and the experimental arm may need to employ both methotrexate and the experimental agent in combination. Similarly, it is considered unethical to unnecessarily delay treatment through the use of a placebo in the control arm of

a patient with RA [55]. Obviously, a trial that fails to consider these points is unlikely to be allowed to proceed, and even if approved may be unable to accrue.

Recognizing variations in clinical practice, a flexible treatment scheme has sometimes been adopted by trialists. In lieu of defining a specific control arm in a clinical trial, investigators may be allowed to choose the particular control or treatment arm that will be employed at their center [56, 57]. Such a trial is more likely to be attractive to a wider range of clinicians, as they may adopt local practices to the trial in question. This has obvious benefits for accrual and may enhance the generalizability of the study. On the other hand, such an open model may make it less clear what is being compared. For example, if the experimental arm contains several forms of therapy, a local investigator may not know if his or her standard regimen has been adequately compared to the experimental arm based on the primary analysis. While subset analyses may be performed, they are typically exploratory.

In addition to present practice, other concurrently operating clinical trials may impact on future practice and the ability to conduct a trial under development. First, a trial in the same population may compete for the finite pool of potential participants. Second, if a competing study is finished and found to be positive before the developing or ongoing study is complete, study completion may become impossible. The competing study may change the standard treatment landscape, alter investigator equipoise over the developing or ongoing study, and inhibit patient accrual. Patients will need to be informed of the evolving standard, and they may choose to avoid or withdraw from the trial.

Just as standards exist in clinical practice, methods of conducting clinical trials are largely standardized. While trial methodology is evolving, investigators and review boards may be uncomfortable with new methods. For example, in phase I studies in oncology, the common method of accrual is to admit cohorts of three to six patients at successive drug doses. Alternative methods, such as the accrual of one patient per dose level, or the continuous reassessment of the maximum tolerated dose using Bayesian methods have been advocated as potentially more efficient [3]. However, there is evidence that the implementation of new study methods is delayed, suggesting the discomfort of physicians or reviewing committees [58].

**Considering Endpoints** The choice of endpoint depends upon both the disease under consideration and the phase of clinical development of the drug. In congestive heart failure (CHF), for example, past successes in improving clinical outcomes have made it difficult to further improve results and to detect such improvements in phase III trials [59]. For drug development, this means that having an early, phase II assessment of activity is important to determine whether a drug should go on to phase III study. Given that phase II trials are intended to be shorter and smaller than phase III trials, using longer term endpoints such as hospitalization or mortality is unlikely to be practical. Surrogate endpoints are therefore considered for these phase II trials. While clinical endpoints represent measures of disease important to patient well-being or survival, surrogate endpoints are alternative endpoints that represent disease biology or a secondary clinical outcome and are intended to shorten the investigative timeline. To be valid, surrogates must correlate well with improvements in important clinical endpoints. One example of such a surrogate is brain natriuretic peptide, a neurohormone that predicts left ventricular function and prognosis and that has also become a diagnostic test [60]. While there is disagree-

ment about which surrogates are useful in CHF [61], the patient exposure to experimental therapy and the cost required by phase III studies dictate that an effort be made to use phase II studies, and surrogate markers can serve a useful role. Phase III endpoints must be more clinically relevant, in part because surrogate endpoints are not entirely reliable. In CHF, therefore, mortality is still a preferred measure of efficacy, although hospitalization rates and other secondary measures may be considered [62].

Endpoints once deemed of limited clinical value may gain importance through greater experience. Improvements in disease-free survival, an endpoint less concrete than overall survival, have historically not been regarded as sufficient to merit a change in clinical practice in many areas of oncology. More recently, analysis of accumulated studies has suggested that 3-year disease-free survival is an accurate surrogate of 5-year survival when administering adjuvant chemotherapy to patients who have had curative surgery for colon cancer [63]. The use of oxaliplatin in the adjuvant colon cancer setting was approved by the FDA on the basis of a disease-free survival benefit, and there is the potential to use such surrogates to shorten drug development time [64].

## 1.5 EXAMPLE IN DRUG DEVELOPMENT

To further understand the clinical trial process, it is useful to consider an example. The field of oncology has seen an increase in the number of experimental agents directed at specific disease mechanisms. These targeted drugs are sometimes considered to have the ability to prevent tumor growth while not actually causing tumor shrinkage (tumor response), and may be termed cytostatic agents. Typically, new drugs are first studied in patients with advanced, metastatic disease, and tumor response has been employed as a surrogate for clinically important endpoints such as survival. The challenge in studying cytostatic drugs is that they may not induce tumor response and may be less effective in patients with greater burdens of disease. Hence, useful drugs may be missed if tumor response is relied upon to demonstrate activity [65].

Such were the considerations during the development of marimastat, a matrix metalloproteinase inhibitor. Matrix metalloproteinases are a family of proteins that degrade extracellular matrix and thus facilitate the migration and metastasis of tumor cells and facilitate vascular growth. Preclinical work suggested marimastat inhibited this process [66]. Except for the first study, performed in healthy volunteers [67], phase I studies suggested a dose-limiting arthritis [68, 69]. These studies indicated doses for further work and suggested that achievable plasma levels were likely sufficient to achieve target inhibition.

Few single-agent phase II studies were performed, and tumor responses were rare [70–72]. With the understanding that marimastat might not show typical responses in tumors, a large study was performed with various tumor types to assess a surrogate endpoint, a change in tumor markers [73]. With the exception of prostate-specific antigen, the tumor markers that were used are not sufficiently associated with clinical endpoints that they are usually accepted as surrogates [65]. While an impact on tumor markers was suggested by this and another study [74], there was no clear evidence of improvement in any clinical endpoint.

Acknowledging the difficulty in detecting activity in metastatic disease, Miller et al. conducted a randomized phase II study in the adjuvant breast cancer setting [75]. This trial encountered musculoskeletal toxicity that prevented drug administration from being sufficiently sustained to warrant further adjuvant study.

Phase II data could thus be regarded as tenuous, but optimism was such that phase III drug development proceeded. In fact, for both the lung cancer and gastric cancer trials, there was no phase II data to support phase III efforts [76, 77]; the study in gastric cancer was based in part on pathological changes noted in a phase I trial [78]. The results of phase III studies were almost universally disappointing [77, 79–81], although minimal activity was seen in gastric cancer [76]. Development of the drug ceased.

It is unfair to be overly critical of the participants in such a story, but certain issues may be usefully considered. First, phase I studies may demonstrate some aspects of a drug's toxicity, but only with more patients and longer term follow-up will toxicity become clear. This became more evident in the phase II study in the adjuvant breast cancer setting, and flushing out the toxicity profile is another argument for phase II studies beyond looking for initial clinical activity. A resource-intensive phase III study would likely have been aborted in the same adjuvant situation. Second, surrogate markers can be misleading [60, 82, 83]. To be considered true surrogate markers, they must be biologically relevant, show a consistent and proportional relationship between a change in the marker and a clinically meaningful endpoint, and this relationship should be demonstrable in repeated studies [60]. Most tumor markers do not satisfy these requirements, and thus their use was probably not justified. That said, even markers directly in the biological pathway of a drug are not a guarantee of adequate surrogacy, as redundant and alternative molecular pathways may dilute or eliminate the relationship of the surrogate to a clinical endpoint. Unfortunately, an adequate biological surrogate test had not been established for *marimastat*. Proceeding to phase III studies based on uncertain surrogate markers was thus a gamble.

How does one decide when to carry out phase III studies in oncology for cytostatic drugs? This is still an evolving field. In terms of using clinical outcomes, the use of stable disease is being used by default, although there is modest evidence of a relationship between this and the more concrete endpoint of survival [84–88]. As response and even stable disease may be difficult to demonstrate in advanced malignancy, biomarkers are likely to remain relevant. Measuring direct effects on tumor is likely ideal, but many tumors are not readily accessible for repeat biopsy after treatment. In this instance, one might pursue changes in biomarkers in accessible tissue such as skin. There is still the hazard, however, that skin changes may not be representative of tumor changes. In either case, unless a similar drug has established a true surrogate relationship for the biomarker in question, investigators are left to establish the relationship, a very difficult task during the limited number of trials undertaken with a developing drug. In the absence of a validated surrogate or true clinical evidence of activity, the preclinical or clinical biological data must be compelling to proceed with large randomized studies. If it is, investigators might consider whether it is better to study the drug in the setting of earlier disease, perhaps in the adjuvant setting. While the benefit of a cytostatic agent may be more evident in this setting, larger treatment groups and longer follow-up are typically required to detect the small improvements in outcome often seen in early disease.

## 2.1 INTRODUCTION

Investigational new drug (IND) is a key phase within the drug development life cycle that requires considerable interactions between pharmaceutical companies and the Food and Drug Administration (FDA), the federal agency with principal responsibility to license new medical products for human use. As the IND approval authority it is the FDA's responsibility to protect public health by ensuring the safety, efficacy, and security of human and veterinary drugs and biological products. At the same time, the FDA's mission is to enable rapid advancement of pharmacological therapeutics development through technological innovations that make medicines more effective, safer, and affordable.

In the context of the IND process, these dual missions may seem contradictory and require a carefully balanced consideration of the risk–benefit of new medical products. For on the one hand, IND is the mechanism for new innovations in pharmacological therapeutics to meet the public health challenges; it is also the venue for introducing new risks with potentially devastating impact on public health and general environment. With the increasing number of new product development projects involving genetic engineering and recombinant DNA (deoxyribonucleic acid) technology in biological product development, the scope and volume of cell-based new biologics product development have expanded dramatically in the past two decades. For example, a new class of cell-based recombinant technology products generally known as the human cells, tissues, and cellular and tissue-based products (HCT/Ps) have created an entire array of investigational biologics. Similarly, new biodefense-oriented medical countermeasures such as vaccines, immunoglobulins, and monoclonal antibodies to protect and counter bioterrorism-related threats have potentials to introduce long-term human health and ecological risks.

Therefore, IND review and approval process will have to take into consideration not only the inherent benefits of introducing novel technological solutions for medical countermeasures during clinical trial, but consider the potential adverse impact to clinical trial subjects and the long-term public health and environmental consequences.

Nevertheless, medical product development is never complete without safety and efficacy data collected directly from studies on human subjects, which is why every drug or biologics product developer is bound to submit an IND application. This application process requires considerable forethought and preparation to ensure that the product under development is suitable for studies with human subjects.

Clinical investigators participating in the clinical studies and the study sponsors must document every facet of the study planning, data generation, and data management as long as the IND is in effect.

Regulatory affairs covering new medical product development are influenced by external factors driven by industry interests and new legislations promulgated by Congress aimed at improving the quality and safety of pharmaceuticals to protect and promote public health. Proactive efforts of the FDA in international forums and multilateral engagements with entities such as the International Conference on Harmonisation (ICH) and the Organization for Economic Cooperation and Development (OECD) brings scientific and technical discussions and harmonization of quality systems and safety guidelines for medical products registration.

In the past three decades a couple of major external events posed unique challenges to the drug development policies in general and IND-related regulatory affairs in particular.

First, the advent of AIDS (acquired immunodeficiency syndrome) in the 1980s drew unprecedented attention to the entire drug development and approval process. Changes in the new drug approval process was aimed at broadening involvement of patient community during the early phase of drug development activities and an overall pressure on the government agency to expedite the new drug approval process. Enormous efforts were made by those affected by the epidemic to gain “expanded access” to investigational drugs even before FDA granted a formal approval.

There simply was no mechanism in place within the regulatory affairs environment to circumvent the key milestones required in the new drug approval process and hesitation in the scientific circles to provide expanded access to highly toxic investigational drugs with potentially dangerous adverse effects. Combined efforts from the regulatory affairs and scientific community created the new National Institutes for Allergy and Infectious Diseases (NIAID) and funded the AIDS treatment research initiative known as Community Programs for Clinical Research on AIDS (CPCRA). A network of clinical study centers were created under the CPCRA to provide HIV-infected community access to IND products through participation in clinical trials. Expanded access to AIDS-related investigational drugs were made possible through IND treatment and parallel track protocols.

The complex nature of the HIV epidemic and highly toxic properties of some IND hindered broader access to possible pharmacological interventions for the affected community. However, the FDA finally issued regulations that broadly interpret use of IND for therapeutic purposes, which provided access to thousands of critically ill patients drugs not yet formally licensed for commercial use. NIAID created a “parallel track” program where selected INDs were made available to HIV-infected patients who could not participate in the clinical trial and have no other clinical alternatives. The parallel track policy was invoked to access IND for broader therapeutic uses, when available clinical evidence is less than adequate to apply the treatment IND clause to broaden access to investigational drugs for therapeutic uses.

Second, post-9/11 challenges to develop medical countermeasures to manage the threat of bioterrorism introduced unexpected demands on the new drug development regulations. The global threat environment called for expedited development of medical countermeasures such as vaccines, antidotes, and diagnostics to prevent

and protect the public against biological warfare agents. With very limited production capacity for vaccine products in the biotechnology industry community, and an assortment of experimental candidate products at very early stages in development, challenges were daunting at the starting point of this major national undertaking. Next, federal regulators and the biodefense product development community were faced with a major technological hurdle by way of potency testing for protective effects of experimental vaccines requiring live-agent tests, which completely eliminated the option of clinical trials for product efficacy determination. With clinical data only on the safety of the product, for most part regulatory decision to grant new biological licensure application would be based on efficacy data from experimental animal studies.

In 2002, the FDA published, a landmark “animal efficacy rule” amending the drug and biologics product regulations to allow appropriate studies in animals in cases where excessive toxicity would make human efficacy studies not ethical or feasible [1]. For example, the FDA approved ciprofloxacin for postexposure management of inhalational anthrax based on serum concentrations of the drug in human studies as a surrogate measure to serum concentrations associated with survival of animals exposed to aerosolized *Bacillus anthracis* spores. This data together with related data on the efficacy of ciprofloxacin in humans on other infections was the basis for the approval.

Use of the anthrax vaccine as an investigational new drug by the U.S. Department of Defense is yet another area where regulatory affairs relating to IND came head on with the national priority to rapidly develop and deploy medical countermeasures to protect military personnel and civilians from biological warfare agents. Controversies surrounding the military management of the unprecedented waiver to the FDA requirements of informed consent process and the role of institutional review board (IRB), the institutional level oversight authority over the conduct of the anthrax clinical trial, are yet to be resolved. As there are no published clinical studies on the efficacy or long-term safety of the anthrax vaccine, the protective value of the vaccine in humans is unknown.

With the best of intentions to protect the military and the public from the real threat of biological weapons, the wrenching decision by the military authorities to vaccinate uniformed personnel with an IND vaccine product through an unprecedented waiver of informed consent put the government in uncharted territory on the regulatory policy relating to IND development.

The following sections in this chapter will examine in detail the investigational new drug application process; the prevailing regulations relating to various aspects of IND investigation; latest requirements under good tissue practice for highly sophisticated biotechnology-derived products; various mechanisms, tools, and performance matrix to monitor IND clinical investigations; and emerging biosafety and biosecurity considerations in IND clinical investigations.

## 2.2 INVESTIGATIONAL NEW DRUG APPLICATION PROCESS

The IND is an embedded phase within the long drug development life cycle that could run anywhere from 10 to 13 years depending on the candidate product and study requirements. During the preclinical experimental investigations, a candidate

drug product with promising pharmacological potentials against a target disease or a physiological condition, and did not cause unacceptable damage to healthy tissue, is eligible to move into the IND phase. Through the IND process, the study sponsor requests permission from the FDA to begin clinical trials.

The IND is also a mechanism through which the pharmaceutical industry sponsor will obtain exemption to transport the IND product across state lines. Under the current federal law only licensed drugs are permitted for broader distribution and transportation across state lines. Thus, IND allows transport of investigational drug products for expanded clinical trials involving geographically dispersed multiple study locations.

The FDA grants three types of INDs: (a) investigator-initiated IND, (b) emergency use of IND, and (c) treatment IND. These INDs are granted either for commercial uses or for research use categories. A commercial uses category basically refers to an application from a pharmaceutical industry sponsor involved in medical product development for commerce. Whereas the research use category covers clinical investigations performed with the academic objective to better understand the clinical pathologies and effectiveness of medical countermeasure strategies. Research-oriented clinical investigations may involve either experimental products or an approved drug for new medical interventions.

*Investigator-Initiated IND* The application is submitted by a clinical investigator who is the study sponsor as well as the principal clinical investigator. An investigator-initiated IND may not have a commercial intent and primarily to investigate an unapproved medical countermeasure, or an approved product for a new indication not covered under the approved label. Investigators are required to file an IND application if the planned study with an approved drug involves a new patient population, which was not the basis in the clinical studies used in the earlier new drug licensure application.

*Emergency Use of IND* During a public health emergency the need for an experimental product may arise, but without sufficient time to complete the formal IND application process. Under such extraordinary circumstances the regulatory agency may authorize shipment of an investigational product for a specified use in advance of an IND. A public health official should make a request to the FDA under emergency situations to obtain the authorization for emergency uses.

*Treatment IND* The FDA issues a treatment IND for interim broader clinical uses if the experimental product shows promise in clinical trials for serious public health problems or immediately life-threatening conditions while the final clinical work is still under progress and the FDA review underway. For example, the 1980s AIDS epidemic introduced treatment INDs as part of a long-term effort to incorporate the concept of expanded access into the IND regulations. With very limited therapeutic options available to control and manage an expanding epidemic, use of investigational products for therapeutic purposes was made possible through this regulatory mechanism. In 2006, the FDA proposed new rules allowing seriously ill patients, and those with HIV/AIDS with limited or no treatment options, easier access to unapproved investigational products.

**EXHIBIT 1** Key development milestones in the investigational new drug development life cycle. Phase IV generally refers to a postmarketing surveillance of a newly approved medical product.

Exhibit 1 illustrates the key milestones in the IND phase of the drug development life cycle. At the conclusion of pharmacological and toxicological investigations on candidate experimental products during pre-IND phase, the drug sponsor makes a key decision to proceed with the IND application for those candidates with promising pharmacological data on the efficacy and acceptable toxicological data on safety. Hence, the IND application must have a sound rationale and supportive experimental data covering the following three broad areas:

**Pharmacology and Toxicological Data** Data from studies on experimental animals or similar model systems allow an assessment on the safety of the product to begin testing in human subjects and promising pharmacological effectiveness together with the underlying biochemical and molecular mechanism of action. This set of experimental data is collectively known as the pharmacokinetics and pharmacodynamics (PK/PD) and serves as a key benchmark on the bioavailability and mode of action.

**Clinical Protocol and Investigator Information** IND application must have a detailed protocol of the proposed clinical studies and risks to human subjects, if any, during the course of the clinical investigation. This section should also include sufficient information on the educational background and technical qualifications of the clinical investigators, who are generally practicing clinicians, and other medical and scientific professional with oversight responsibility. Also, included under this section is a certified undertaking by the principal investigator to obtain informed consent from all human subjects participating in the clinical trial and approved by the institutional review board (IRB) specially created to oversee the conduct of a proposed clinical trial.

**Product Manufacture Information** This section will provide a summary of the product composition, chemistry, formulation information, product stability

data, and manufacturer-related information, controls used for manufacture, and product quality assurance.

Phase I clinical studies focus on clinical pharmacology and short-term tolerance tests involving only a small number (not more than 50) healthy volunteers. The primary goal of phase I is the safety of the IND and a determination of dose ranges and appropriate routes of administration. Depending on the study design, phase I may involve limited pharmacokinetic analysis. Although in most cases phase I studies are performed on healthy individuals, there are instances patients are enrolled as human subjects during this phase when clinical investigation involves highly toxic products or targeted against life-threatening diseases such as AIDS or cancer.

Phase II clinical trials are designed to examine efficacy and refine the dose range from previous investigation [2]. These trials are longer in duration, taking 2 or more years, compared to phase I and involve a larger pool of human subjects and may involve more than one study location. Most phase II study designs are randomized, case-controlled investigations, where a group of patients receiving the IND drug, the “treatment group,” is compared with a matched group of patients with comparable clinical profiles, case history, and factors such as age, sex, and other demographic background, the “control group,” receives a placebo or standard therapy. Most phase II studies are double blinded by design in that both the patients and clinical investigators administering the study do not know the composition of the treatment and control groups and who is getting the IND product under study. The randomized, case-controlled study design greatly improves the validity of the clinical outcome data, and the double-blind design reduces errors in the study interpretation or other forms of bias.

Phase III trials are expanded investigations involving an even larger pool of human subjects running into thousands and involving multiple study locations and clinical investigators to address differences in responses due to demographic and geographic factors. Phase III trials are designed to further substantiate observations on safety and efficacy from previous clinical investigations, and a larger pool of human subjects allow the appearance of potentially less frequent adverse events not captured in smaller study populations.

At the conclusion of the phase III trial phase, the study sponsor would file applications with the FDA to obtain commercial licensure for the IND. A new drug application (NDA) is filed for a drug candidate, and for a biologics product this application is called biological licensure application (BLA). A product with an NDA/BLA is no longer an IND and is now commercially available for the public. According to industry reports, about 20% of the IND candidates make it through all phases of the research and are finally approved.

Phase IV could be either a postmarketing study to obtain additional information on the new drug in terms of rare adverse events, additional benefits, and optimal usage not captured during the clinical trials. Given a much broader population now exposed to the new medical product, early phase monitoring in the postmarketing period is generally considered phase IV. This phase is unique in that clinical investigation up until this point is a controlled study with a “treatment” group compared with a matched “control” group. Phase IV has no control group but merely tracks reports for adverse events or other product-related performance data. A phase IV data collection requirement is not mandatory for every approved medical product.

Depending on the potentials for adverse events from controlled clinical studies, the FDA may direct a sponsor to perform postmarketing surveillance for known and unexpected adverse events. Alternatively, a sponsor may proactively implement a phase IV plan to collect data on the potential benefits from the new drug to capture or increase market share for the new medical product.

Phase IV is sometimes differentiated from postmarketing surveillance when this phase actually involves a more structured design and clinical intervention within the terms of the product license. This differs from a postmarketing surveillance, which is mostly noninterventional and observational of the general population using a newly approved medical product. An interventional phase IV is carried out at hospitals or clinics to further consolidate the efficacy database of the newly approved product. This could be part of a risk management plan by the sponsor to obtain additional efficacy and safety data before general release of a new product.

The totality of findings from a well-designed, multiple clinical studies using targeted patient population with a demographic makeup similar to the general population forms the scientific rationale and data analytics to support submission of an NDA or a BLA to the FDA. It could take as many as 3 years for the FDA to review the nonclinical and clinical trials of data submitted in support of an NDA/BLA package before making a final decision on approval.

As part of this protracted engagement between the study sponsors and the FDA during the IND phase, several meetings are held as milestones for key decision points.

Exhibit 2 illustrates a work flow diagram for the industry meetings with the FDA during the IND phase and description of the meeting objectives and outcomes.

**EXHIBIT 2** Flow diagram of industry meeting with the Food and Drug Administration during various phases of the IND process.

Product sponsor with plans to begin the IND phase must first submit a request for a pre-IND meeting with the FDA and include in that request a brief description of the experimental product, description of the clinical indication, and clinical study approach. Once the meeting date is established, the product sponsor must submit a pre-IND package (as required under 21 CFR 312.82) providing more detailed information on the preclinical experimental data, product manufacturing information, preliminary information on physiochemical characterization of the product and manufacturing specifications, and the outline of the proposed clinical protocol(s).

Exhibit 3 summarizes the general focus of the key IND meetings and the nature of information requirements for discussions. For example, during the pre-IND meeting, the general focus of the information requirements are chemistry and formulation-centric data, whereas the end of phase II (EOP-II) meeting covers study progress review, manufacturing, product stability, safety issues, process validation, and quality systems related information unique to drugs, biologics, and rDNA protein biotechnology drugs. The EOP-II meeting will review the efficacy study results, data gaps and deficiencies, and phase III study plans. Sponsors may update the FDA on potential problems identified and resolved, and information necessary in support of the marketing application.

The IND submissions are a complicated undertaking that should not only meet the technical content requirements, but also strictly comply with the content and format specifications (21 CFR 312.23).

Exhibit 4 is an example of the content requirements in a typical IND submission compliant with the regulatory requirements.

An investigator brochure must be included in the IND submission if the candidate product is supplied to clinical investigators who are not part of the study sponsor's organization. An investigator brochure together with the clinical trial protocol are the fundamental documents required in the IND submission. The investigator brochure must provide a description of the candidate product, a summary of the pharmacology and toxicology, summary information on safety and effectiveness, and a description of the risks of adverse events and recommended precautions or special monitoring.

Once the IND package is received from the sponsor-investigator, the FDA will assign an IND number. A regulatory project manager (RPM) for each submission handles all administrative matters related to processing the IND and serves as the regulatory point of contact for the study sponsor and/or investigator.

Exhibit 5 is a work flow diagram of the IND review and approval process. IND submissions could be made either as hardcopy document or electronic submission. An alternate mechanism to submitting IND is through the master file submission (21 CFR 314.420). A master file will contain product and manufacturing information but does not include clinical protocol. Permit holder for the master file could at a later period add the clinical protocol information when filing the IND. The master file submission format protects proprietary product and manufacturing information from other outside organizations participating in the clinical trial. Using a cross-reference filing format, authorized persons would then file relevant clinical information without access to other proprietary information. The FDA will access both IND and master file information to begin the review. The review process begins only when the IND files are populated in the master file.

Essentially, the IND review team for a drug or biologics product candidate consists of the (a) RPM, (b) product reviewer, (c) pharmacology/toxicology reviewer,

| IND Meetings                            | General Objectives                                                                                                                                                                                                                                                                                                                      | Drugs/Biotechnology Products/Conventional Biologics                                                                                                                                                                                                                                                                                     |                                                                                                                                                                                                                                                                                                                                                      |                                                                                                                                                                                                                                                                     |

| Additional Information                                 |

**EXHIBIT 4** Illustrative example of the information content requirements in a typical IND submission by sponsor of the medical product development.

**EXHIBIT 5** Flow diagram of the IND review and approval process.

Usually within 30 days after submission, the IND goes into effect and the decision is communicated via a letter as long as there are no holds placed on the IND.

During the IND review, regulators may decide to place a clinical hold. A clinical hold is an order issued by the FDA to delay a proposed clinical investigation or to suspend an ongoing investigation. When a complete clinical hold is placed on an IND, all clinical work comes to a halt. The FDA may place a partial clinical hold to delay or suspend part of the proposed clinical investigation, meaning that holds may be placed on some clinical protocols within the study while others are allowed to proceed without delay. The regulatory criteria guiding the FDA's decision to place a clinical hold may be one or a combination of risk factors such as: (a) human subjects would be exposed to unreasonable and significant risk; (b) the investigator brochure was misleading, or erroneous, or incomplete; (c) the clinical investigators are not qualified; or (d) IND does not contain sufficient information to assess the risks to subjects of the proposed study (21 CFR 312.42). A hold is placed on more advanced phase II/III trials if a proposed study design is deficient to meet the study objectives.

It is up to the study sponsor to provide the deficient information and clarifications to release the clinical hold placed on the trial. If the sponsor response addresses all the issues detailed in the clinical hold letter, the response is considered complete and the FDA is required to respond within 30 days of receipt of the submission. However, the 30-day clock does not apply to partial or incomplete responses to the clinical hold.

Clinical hold is a risk management mechanism available to the regulators to address potential deficiencies and safety-related issues during the IND phase of the product development. For example, the new generation of tissue-derived biologics products and vaccines pose considerable challenge in the areas of safety, quality, and product potency determination. To a large measure, clinical trials are designed to collecting data to addressing these sorts of issues during the product licensure application. As stated above, one of the more common reasons a clinical hold may be placed is when the FDA cannot determine from an IND clinical protocol the risks to human subjects during clinical investigations.

One of the alternative options to circumvent clinical trial requirements and facilitate product development in areas related to national security such as bioterrorism threat, or a major public health emergency such as pandemic influenza, is to approve medical treatment based on efficacy data from experimental animals. The regulation, known as "animal rule," provides a mechanism for the FDA to expedite the approval process as long as the efficacy data from preclinical investigations on experimental animals are well-designed and data from the studies considered sufficient and adequate by the expert review committee. Only safety data from a phase I clinical trial is required as supportive evidence in making the final determination.

### **2.2.1 Roadmap for Future IND Product Development**

There is a growing concern in the pharmaceutical industry, scientific community, and among regulators on the decrease in the number of IND applications submitted over the past several years. Regulatory burden is cited as a major concern by the industry, although other factors related to extremely expensive up-front investments

required in new drug/biological development projects and the unpredictability of the product development activities. The product development community is beginning to employ the power of computational tools through bioinformatics to develop predicative tools on safety, effectiveness, and scale-up and manufacture of candidate therapeutics products.

Recognizing the importance of technology and regulatory compliance alignment in the development of novel therapies, the FDA unveiled a strategic document in 2004, the Critical Path Initiatives [3], which was aimed at identifying existing challenges in pharmaceuticals-oriented technology domains having a direct impact on the discovery and development of novel medicinal products. As part of this effort the Critical Path Opportunities List was compiled grouping program areas of emphasis under six categories covering mostly new product development strategies and technologies, development of new product development, testing and evaluation methods, and application of best business practices in product development. A brief summary of the six grouped critical path opportunities aimed at IND development activities are:

1. *Better evaluation tools such as biomarkers* for pregnancy, cardiovascular diseases, infectious diseases, cancer, neuropsychiatric diseases, and the like.
2. *Streamline clinical trials* in terms of innovative trial designs, application of best business practices in clinical data management, trial protocol development, and data analytics.
3. *Harnessing the power of bioinformatics* to identify new drugs and biologics candidates for development, identify safety biomarkers, adverse effects data mining, modeling and analysis, and failure analysis.
4. *Moving manufacturing toward twenty-first century* covering biotechnology-derived products, new generation vaccines, detection of contaminants in biologics during product development, scale-up and manufacturing, tissue engineering, product potency evaluation, and application of nanotechnology for therapeutics development.
5. *Development of products to meet public health needs* such as antimicrobial testing strategies, safety of blood and blood-derived products, and novel animal models in biodefense product development.
6. *Product development for at-risk population* with a specific focus on pediatrics. This would include better extrapolation of dose–response regimen in pediatric clinical trials, drug metabolism and therapeutic response, and new therapies for juvenile diabetes.

The Critical Path Initiative is unclear on market-driven factors critical to successful new drug development. First, biotechnology companies are involved in highly sophisticated genomic and proteomics-based product development and clinical gene therapy work in a domain with unclear regulatory implications and product liability issues due to potentials for long-term risks to public health. Commercially oriented research organizations are afraid of long-term liability lawsuits and have fewer incentives to take an active role in government-funded product development projects. This has to a large extent adversely reduced the available capacity to undertake a broad range of new product development projects.

Second, insurance coverage reform requires an equally forward leaning regulatory policy environment to encourage present shortage of providers of insurance to cover clinical trials. Whereas funded by the National Institutes of Health product development programs provide a modest coverage of the insurance cost incurred as part of the clinical trials, most of the cost is borne by the industry, hospitals, and academic institutions involved in medical product development related projects. At present, there are no defined mechanisms available within the existing regulations to the industry to directly address these issues with the regulatory agencies.

Finally, a roadmap for the future is incomplete if channeling of the R&D investment fails to reflect the requirements identified in the Critical Path Initiative. These industry investments in the R&D may not be consistent with the goals identified in the Critical Path Opportunities List. Industry investment in R&D priorities are defined and driven by market consideration. For example, considerable R&D resources are invested in protecting existing market shares, or to develop what are called “me too” drugs, with focus mostly in the formulary redesign and testing and not in breakthrough research in novel therapeutics development. Likewise, considerable product R&D and development is invested in derivative drugs taking the resources away from targets identified in the Critical Path Opportunities List.

Regulatory analysts are of the opinion that the national policy toward advanced therapeutics development requires a broader engagement of the R&D community, academia, and the industry, together with increased funding for processes development and assessments. Similarly, additional policy-level initiatives are required to simplify legal and financial barriers to clinical trials and additional resources to emerging genomics and proteomics-based product development.

## 2.3 GLP REGULATIONS IN NONCLINICAL INVESTIGATIONS

In the drug development process, preclinical investigation is a critical step during which drug molecules discovered from early phases of toxicological screening are subjected to a comprehensive animal testing before an IND can be filed. The regulatory requirements governing this process have imposed strict rules as to how a newly discovered chemical or biochemical molecule will be tested and evaluated prior to approval for testing in humans. The existing good laboratory practice (GLP) guidelines clearly lay out how preclinical experimentations is done in order to ensure the safety of the drug molecules, which then forms the basis for filing an IND application for approval to begin clinical trials (21 CFR 58).

Fundamentally, GLP is a quality system concerned with the organizational process and conditions under which nonclinical health and environmental safety studies are conducted. The organizational, personnel, and facility related GLP compliance requirements are written to ensure quality of data produced by nonclinical and clinical laboratories meet the best business practices and provide international acceptance to the quality of data generated in support of a new medical product licensure application.

The GLP regulations are part of the broad good laboratory practices for conducting preclinical experimental investigations in pharmaceutical product development for research or marketing permits. The scope of GLP regulations includes food and color additives, animal food additives, human and animal drugs, medical devices for

human use, biological products, and electronic products (biomedical devices). Compliance with GLP regulations is part of the requirements under the IND application for drugs and biologics (21 CFR312).

Existing GLP guidelines clearly define the parameters of preclinical experimental investigation to include *in vivo* and *in vitro* experiments in which test articles are studied prospectively in test systems under laboratory conditions to determine their safety. However, these tests do not include studies utilizing human subjects or clinical studies or field trials in animals. Also, preclinical experiments covered under this guideline does not include basic exploratory studies carried out to determine whether a test article has any potential utility or to determine physical or chemical characteristics of a test article (21 CFR58.3).

When product development companies outsource nonclinical studies to contract research facilities or academic research and development establishments, the GLP regulations require every entity participating in the nonclinical study included as part of the IND application and must comply with the provisions set forth under this regulation. As part of the enforcement mechanism the FDA may conduct facility inspection or authorize a designated third party with credentials to perform facility visit to ensure all laboratory records and study specimens related to the study are maintained and remain within the scope of the IND application under investigation.

Exhibit 6 schematically represents the key GLP requirements as part of pre-clinical investigations of an IND product, comprised of facility infrastructure components, business process, and personnel experience.

The GLP guidelines related to infrastructure cover experimental animal facility performing clinical research sites. Facility floor plans and material and process flows to attain operational isolation and prevent cross-contamination is one of the key criteria in the GLP compliance. Facility floor design and process flow plans are assisted by standard operating procedures to all study methods, operational-related

**EXHIBIT 6** Key Good Laboratory Practices requirements during the IND product development phase.

issues such as cleaning and maintenance, equipment calibration and certifications, and routine inspections.

The GLP guidelines require that experimental product-related nonclinical studies and clinical investigations on the IND should have approved written protocols. These protocols should clearly outline the objectives of the study, proposed study methodology and details related to the test materials, procedures, analytical plans, and maintain supportive documentation.

The organization and personnel aspects relating to GLP cover strict reporting requirements for laboratory personnel and testing facility management in nonclinical laboratory studies. For example, individuals found at any time to have an illness that might adversely affect the quality of work and pose risk of infection to others in the facility must be reported immediately. The quality assurance unit within the facility has the responsibility to monitor studies and assure management that the facilities, equipment, personnel, methods, practice, records, and controls are in compliance with the GLP regulations. During an FDA inspection, the written procedures and internal quality assurance (QA) logs and records must be available for inspection.

A key international initiative aimed at instituting and harmonizing GLP is the Organization for Economic Cooperation and Development (OECD) guidelines, a multilateral organization with 30 member states and 70 other participating nations. The goal of OECD GLP guidelines is to ensure “data generated in the testing of chemicals in an OECD member country in accordance with OECD Test Guidelines and OECD principles of GLP are accepted in other member countries for purposes of assessment and other uses relating to the protection of man and the environment” [4].

The OECD GLP guidelines provide a framework for laboratories to plan, perform, monitor, record, report, and archive experimental laboratory studies. These guidelines would assist regulatory agencies within the member state, where the GLP-certified laboratory facility exists, inspect, and ensure compliance with the national GLP guidelines set in compliance with OECD. At the same time, data generated from a GLP-certified facility assures other international regulatory agencies within the OECD that the study results on pharmaceutical compounds could be relied upon as to the hazard and potential risks to users, consumers, and the general environment.

## **2.4 INVESTIGATIONAL NEW DRUG cGMP COMPLIANCE REQUIREMENTS**

Although the U.S. federal government efforts to mandate the safety and purity of drugs goes as far back as 1902, when Congress decided to have biological products manufacturing facility licensed individually to protect the public from dangerously contaminated sera and vaccines, it was only in 1962 that the concept of “manufacturing controls” was introduced in the legislative statute, which was promulgated as “current good manufacturing practices” or simply cGMP.

cGMPs are essentially a family of systems consisting of policy procedures and written analytical documentation to guide a facility at the process levels on medical product manufacturing related activities. The goal of the cGMP is to ensure reli-

ability of a product manufactured at the facility through an established set of standards and processes for quality, purity, potency, composition, and identity claimed by the product sponsor. As a result, cGMP covers the entire gamut of the production systems, which includes plant and grounds, equipment and utensils, sanitation of building and facilities, quality assurance and quality control, production and process controls, warehousing, distribution and postdistribution process, and records access and archival system.

Compliance with cGMP is a fundamental requirement for a medical product development company whether involved in IND or routine manufacturing of licensed products. During the early years after cGMP promulgation, pharmaceutical industries experienced problems relating to potency, cross-contamination, sterility, and labeling related issues. As a result, the FDA initiated the Intensified Drug Inspection Program (IDIP) as an inspection mechanism to regulate the industry. If violations are found during an inspection, product(s) in the entire production line cannot be distributed until the industry demonstrates full compliance. For example, if during a routine GMP audit, some unknown particles were discovered in a production process, the plant will be ordered to temporarily shut down until the contaminants can be identified and removed from the production system. The facility management will perform a full-blown analysis involving sampling from the entire production lines, complete a battery of tests to identify the contaminants, and take measures to eliminate the problem. Only after a clear demonstration of these efforts would a resumption of normal production activity be allowed at the facility.

#### **2.4.1 cGMP for IND During Phase I Clinical Trials**

The 2006 FDA Guideline on the Preparation of IND Products (for human and animal uses) primarily addresses the regulatory compliance to cGMP regulations required under the Federal Food, Drug and Cosmetic Act (FD&C Act). These guidelines have no legally enforceable authority but are viewed as recommendations to address cGMP requirements in the production of INDs for phase I studies.

The earlier 1991 guideline addressed primarily the large-scale industrial manufacturing environment and not others such as small- or laboratory-level production of investigational new drugs. Also, the 1991 guideline did not clarify fully the FDA's programmatic expectation to adopt an incremental approach to institute manufacturing controls for the INDs. While addressing these issues, the 2006 guidelines represent the FDA's efforts to formally establish an approach guiding implementation of manufacturing controls in relation to IND products for phase I clinical trials. IND production settings covered in these guidelines include small-scale manufacturing at laboratory, batch productions for exploratory studies, and multiproduct and multibatch testing of IND products manufactured for phase I clinical investigations.

The 2006 FDA guidelines apply to all IND drug and biological products (including finished dosage forms used as placebos) for phase I clinical studies, which includes investigational recombinant and nonrecombinant therapeutic products, vaccines, allergenic products, *in vivo* diagnostics, plasma derivatives, blood and blood components, gene therapy products, and somatic cellular therapy products that are subject to cGMP requirements. However, these FDA guidelines do not apply

to (a) human cell or tissue products, (b) clinical trial of products subject to the device approval or clearance provisions within the existing regulations, (c) INDs manufactured for phase II/III clinical studies, and (d) approved products that are being used during phase I studies for other study endpoints such as route of exposure and new indications not covered in the approved label.

Exhibit 7 illustrates the key elements of a cGMP program for a facility involved in the manufacture of IND for clinical studies. The system components to establish

**EXHIBIT 7** FDA recommended approaches to complying with current good manufacturing practices during IND phase I investigations. (Based on FDA [5].)

manufacturing controls for an IND are similar to routine cGMP programs at pharmaceutical facilities covering process elements, facility and personnel, production and laboratory controls, quality assurance, and control. In the case of investigational biological products requiring special precautions, biosafety and biosecurity-related issues are part of the overall facility and process-level compliance requirements.

With safety and quality of product as the primary focus, the guidelines for the production of IND for use in phase I clinical studies are centered on the establishment of cGMP-driven quality control process. The nature and extent of manufacturing controls needed to achieve the desired quality criteria differ not only between the IND products and commercial manufacture but also among the IND products manufactured for various phases of clinical studies. However, regulatory guidelines are yet to delineate cGMP requirements to these product development phases.

### 2.4.2 cGMP for IND

In its efforts intended to streamline the IND process, while at the same time ensure the safety and quality of drugs at the earliest stages in the development pipeline, the FDA excluded most of the phase I INDs from the cGMP regulations for human drugs, including biological products [5]. The FDA maintains regulatory oversight on the production of INDs under the general statutory cGMP authority and the requirements set forth under the IND application authority. The amendment of the cGMP regulation was considered as part of the FDA's overall efforts to guide the industry with a consistent framework to manage and establish controls on the manufacturing at the early product development stages. However, the FDA withdrew the final rule published in the 2006 *Federal Register* to evaluate comments received from the industry and published a modified rule in 2008. The final rule specifies that 21 CFR Part 211 no longer applies for IND, including those under the exploratory products category manufactured for use in phase I clinical trials.

The regulatory implications invoking the general statutory cGMP authority for IND means that overarching goals to ensure quality, purity, potency, and composition of the investigational product under clinical trial meet the general standards set forth under the cGMP. Hence, facilities manufacturing the IND for clinical studies must comply with all requirements that include the facility, equipment and utensils, sanitation of building and facilities, quality assurance and quality control, production and process controls, warehousing, distribution and postdistribution process, and records access and archival system.

### 2.4.3 From cGMP to Quality Systems

The concept of quality systems and its relevance to cGMP requirements were first identified under the FDA guidelines for finished medical devices intended for human use (21 CFR 820).

Exhibit 8 is a comparative summary of the quality systems applicable to cGMP requirements under the FDA guidelines and the International Organization for Standardization (ISO) 9001 requirements for medical devices intended for human use. The quality systems components under these guidelines cover organizational structure and control, management systems, quality audits, and personnel and training. The requirements for subcontractors involved in the product manufacturing

| cGMP Quality Systems Requirements <sup>a</sup>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  | ISO 9001 Requirements <sup>b</sup>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

**EXHIBIT 8** Comparative summary of the quality systems applicable to current good manufacturing practices within the FDA and ISO 9001 guidelines.

activities are required to adhere to the quality assurance and quality control standards established by the sponsoring entity.

In 2004, the FDA introduced a transformational paradigm to cGMP through a quality systems-based approach for drugs and biologics products. The quality systems approach is based on the policy to encourage the pharmaceutical and biotechnology industries to adopt risk management principles. Regulatory shift to quality-systems-driven cGMP is in response to consistent problems with quality assurance and quality assurance operations in the medical products manufacturing sector. The FDA has declared quality systems approach as the mechanism to improve the predictability, consistency, integration, and overall effectiveness of its regulatory operation [3].

A risk-based approach to management controls, inspection, and oversight is one of the key pillars of the quality systems. Need for a risk-based regulatory approach was considered critical in the context of rapid advances in the process development and complex manufacturing processes for biotechnology-derived products. Process elements in these complex operations are at best ill defined, with limited manage-

ment controls and potentials for failures to meet quality assurance/quality control (QA/QC) targets. Other product-related quality systems considerations relate to safety issues such as contamination in the production systems, potentials for adverse human health, and environmental impact due to the biological agents and systems involved in the manufacture of specialized medical countermeasures such as vaccines against bioterrorism.

The risk-based approach essentially involves a scheme to prioritize the pharmaceutical facility inspection decision-making process. Through this prioritization scheme, the FDA will determine inspection of those facilities posing the greatest public health impact. The nature and extent of inspections at these facilities remains flexible and change with risk reduction strategies implemented at these facilities. A similar risk-based approach is used to assess product safety review as well. This includes product quality of INDs, preapproval chemistry, manufacturing controls, and postapproval supplement processes. The performance matrix to measure effectiveness of risk-based quality system implementation are (a) continuous improvement in product manufacturing, (b) increased product quality and process efficiency, and (c) availability of new medical products.

As part of the risk-based management initiative, the FDA established the Office of New Drug Chemistry (ONDC) within CDER, to establish a risk-based pharmaceutical quality assessment system with a focus on critical product quality attributes as it relates to safety and efficacy. Quality attributes such as product chemistry, formulation, manufacturing processes, and performance are targeted for process optimization and continued improvements.

Management controls are critical to addressing GMP issues such as the establishment of institutional-level policy and governance structures that communicate management intentions and priorities. Such a framework includes establishment of a systematic review of quality data trends on a regularly scheduled basis, resourcing plans and prioritization, and setting performance matrix and incentive systems. A risk-based decision framework is ideally suited to develop up front a decision scheme to prioritize these activities, set an internal monitoring to track status, and adjust the oversight requirement based on quality-systems-based performance matrix and internal audits. In particular, internal audits are a proactive mechanism to discover deviations from quality systems and correct deficiencies before a minor error escalates to a crisis level. Thus, management systems consistent with the risk-based framework for quality systems offers a win-win solution in terms of protecting the core business interests of the industry and the regulatory goals for cGMP compliance.

## **2.5 ROLE OF ORPHAN DRUG ACT IN INVESTIGATIONAL NEW DRUG**

Orphan drugs belong to a FDA category designation for medical countermeasures intended for use in a rare disease or condition defined under Section 526 of the Food and Drug Act. Designation of an IND under the exclusive approval provisions of the orphan drug provides the manufacturer with treatment use of investigational orphan drugs. Orphan drug status also guarantees a 7-year period of exclusive marketing of the licensed drug. As of December 2008, the FDA has listed a total of 1951 pharmaceutical products under the orphan drug designation [6]. Orphan

drug products are expected to be used in treatment of over 6 million people annually in the United States.

In order for an IND product sponsor to avail the orphan drug status for the candidate product under development, sufficient documentary evidence should be prepared for submission demonstrating that:

1. The IND candidate is developed to treat a disease or condition for which the drug is intended to affect fewer than 200,000 people in the United States or, if the drug is a vaccine, diagnostic drug, or preventive drug, fewer than 200,000 dose-units are administered annually.
2. There is no reasonable expectation that the costs in research and development for the IND candidate will be recovered from sales of the IND drug even to more than 200,000 people, or dose-units, within the United States.

IND applicants seeking orphan drug provisions at the early investigational phase of the product development must write and obtain written recommendations from the FDA clarifying the nonclinical and clinical investigational data requirements to satisfy the regulatory provisions. In particular, the IND application must provide considerable details with authoritative references to description of the disease or condition for which the drug is proposed to be investigated and the proposed indication or indications for use for such disease conditions, and the basis for conclusion that the drug is for the disease or condition that is rare in the United States (21CFR 316.10).

As part of this application requirements, IND applicants must provide sufficient data backed up with analysis of available nonclinical and clinical data pertinent to the drug and the disease to be studied with supportive publications. This requirement is considered particularly advantageous for an IND product intended to treat a life-threatening or severely debilitating illness, especially when there are no other satisfactory alternative therapy available. IND orphan drug applicants meeting these requirements are expected to go through an expedited FDA review.

On the basis of background information submitted by the IND applicant seeking orphan drug status as part of the preclinical and clinical investigations, the FDA will determine (a) whether the disease or condition for which the drug is intended is rare, or not so, in the United States, and (b) whether there exists sufficient evidence and supportive rationale for permitting investigational use of the drug for the rare disease condition.

A product manufacturer could avail the orphan drug designation for a previously unapproved drug, as long as the supportive documents specify a rare disease or condition. Alternatively, a new orphan drug designation could be requested for a drug already in the market, as long as the new indications based on new research and development suggests its use in the treatment of a rare disease or condition. The current regulation allows even an approved drug, which does not have an orphan drug designation, to apply and receive such a status as long as the drug has indicated use like the orphan drug for the same rare disease or condition, but is shown to have superior clinical response or demonstrated safety by way of adverse drug reactions. More than one sponsor may receive orphan drug designation of the same drug for the same disease or condition, as long as each applicant files an independent request with the FDA seeking such a designation.

| IND Orphan “Same Drug” Category                                                                                                                                                                                                                                                                                                                                                                                                                | “Same Drug” Regulatory Definition                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

| <b>Large Drug Molecule (Macromolecule)</b><br>An IND candidate that contains the same principal molecular structural features (but not necessarily all of the same structural features) and is intended for the same use as a previously approved drug, except that, if the subsequent drug can be shown to be clinically superior, it will not be considered to be the same drug. Criterion applied for various categories of macromolecules. | <p>Two protein drugs would be considered the same if the only differences in structure between them were due to posttranslational events or infidelity of translation or transcription or were minor differences in amino acid sequence; other potentially important differences, such as different glycosylation patterns or different tertiary structures, would not cause the drugs to be considered different unless the differences were shown to be clinically superior.</p>                                                    |
|                                                                                                                                                                                                                                                                                                                                                                                                                                                | <p>Two polysaccharide drugs would be considered the same if they had identical saccharide repeating units, even if the number of units were to vary and even if there were postpolymerization modifications, unless the subsequent drug could be shown to be clinically superior.</p>                                                                                                                                                                                                                                                 |
|                                                                                                                                                                                                                                                                                                                                                                                                                                                | <p>Two polynucleotide drugs consisting of two or more distinct nucleotides would be considered the same if they had an identical sequence of purine and pyrimidine bases (or their derivatives) bound to an identical sugar backbone (ribose, deoxyribose, or modifications of these sugars), unless the subsequent drug were shown to be clinically superior.</p>                                                                                                                                                                    |
|                                                                                                                                                                                                                                                                                                                                                                                                                                                | <p>Closely related, complex partly definable drugs with similar therapeutic intent, such as two live viral vaccines for the same indication, would be considered the same unless the subsequent drug was shown to be clinically superior.</p>                                                                                                                                                                                                                                                                                         |

**EXHIBIT 9** Summary of the definitions for IND orphan “same drug” categories for small and large drug molecules.

Exhibit 9 summarizes the definitions for IND orphan “same drug” categories for small and large drug molecules. The decision criteria as to when an IND can be considered an orphan drug are driven by the inherent differences in the chemical composition of the moiety. For example, covalent or noncovalently modified derivatives of previously approved small drug molecules, which are mostly synthetic organic compounds, could be classified as an orphan drug as long as it is indicated for a rare disease or condition, or is shown to have a superior clinical response compared to the original compound.

The definition for what constitutes “same drug” is more complex for biologics, which are macromolecules such as proteins, complex polysaccharide drugs, and polynucleotide drugs. Here the differences are based not on the primary polymer sequence but on differences in the higher structure due to posttranslational modifications as in the case of proteins, or postpolymerization modification as in the case of polysaccharide- or polynucleotide-based drugs.

The provisions within the orphan drug approval process provide a market protection of 7 years during which time the FDA will not approve another sponsor’s marketing application for the same drug. Once approved, the updated list of products with orphan drug status is published periodically in a report titled “Approved Drug Products with Therapeutic Equivalence Evaluations.” The FDA also publishes a cumulative list of pharmaceutical products that have received orphan drug designation and a separate list of those that have received marketing approval. As of December 2008, there are a total of 1951 pharmaceutical products with orphan drug designation and 325 products with marketing approval.

## 2.6 REGULATORY REQUIREMENTS TO PROTECT HUMAN SUBJECTS

Protection of human subjects in a clinical trial is a critical requirement under existing regulations with the aim that participants in an investigational research are familiar with the study and are provided with a minimum amount of information to provide informed consent. Therefore, the scope of regulations covering protection of human subjects (21 CFR, Part 50) pertains mostly to compliance with the overarching regulatory goals protecting the rights and safety of subjects involved in clinical research investigations. The roles and responsibilities of the IRB (discussed in the following sections) covers additional specific obligations and commitments at the institutional levels to the standards of conduct by the investigators, sponsoring agencies, and the institutional authority to the overall safety and protection of clinical research subjects.

Exhibit 10 is a flowchart illustrating a general guideline for a clinical investigator to determine if a waiver or alteration of an informed consent requirement is practical or feasible to their proposed IND clinical investigations. The principal investigator leading the clinical study must first establish whether the proposed clinical study poses greater than minimal risk to the human subjects. If it is determined that the study poses more than minimal risk, then a waiver/alteration of the informed consent requirement is not allowed. However, if it is determined that the proposed study poses only a minimal risk, the principal investigator must establish the rationale that (a) the proposed waiver will not affect the rights and welfare of the human subjects, and (b) it is appropriate to provide patient information to the study subject later. The IRB should review these request waivers as displayed in the flowchart and communicate to the principal investigator the decision on waiver request.

Hence, informed consent constitutes a fundamental requirement in clinical research planning and management. Under the prevailing regulations, no clinical investigation involving human subjects could proceed without the investigator having first obtained the legally effective informed consent of the subject or the subject’s legally authorized representative. In order for the human subject or his or

**EXHIBIT 10** Flowchart illustrating a general guideline for clinical investigator to determine if a waiver or alteration of an informed consent requirement is practical or feasible to their proposed IND clinical investigations.

her authorized representative to make an informed decision, it is contingent upon the clinical investigating team to provide the information in a format easy to understand and disclose all relevant scientific, technical, and legally binding issues pertaining to the proposed study. The informed consent paperwork should not have any legal language that might waive any of the subjects' legal rights and release the investigator, sponsoring agency, and the performing institution from liability due to negligence.

Although informed consent is a fundamental prerequisite, there may be instances when a investigator working on an IND may not be able to obtain consent, such as (a) when the human subject is in a life-threatening situation and requires immediate administration of the investigational product, or (b) when the human subject is unable to communicate with, or could not obtain a legally effective consent form, and insufficient time to obtain consent from subject's legal representative, or (c) when no alternative methods or approved, or generally recognized therapy is available that has an equal or greater likelihood of saving the subject's life. Under a combination of circumstances listed here, the investigator and the physician conducting the clinical trial must certify in writing citing the reason(s) and substantiate with additional records as needed and submit to the IRB within 5 working days after the use of the IND test article.

The president of the United States may waive the informed consent requirement for the administration of an IND (including an antibiotic or a biological product) to the members of the U.S. armed forces in connection with a particular military

operation, in support of a specific protocol under an IND application by a Department of Defense sponsored clinical investigation (10 U.S.C. 1107[f]). Under this statute the president must first establish, at the request of the secretary of defense, that obtaining consent is not feasible, despite the best interests of the military member, and apply the standards and criteria set forth under the FDA regulations. A key consideration in the presidential request for waiver is the determination that the military operation presents substantial risk of exposure to chemical, biological, nuclear, or other form of exposure from the deployment that are likely to produce serious life-threatening injury or illness, or even death, and that there are no known or acceptable biodefense-related medical countermeasures currently available that could meet the potential health threat posed by the military operation.

As required under this statute, the Department of Defense will constitute an IRB with at least three members not affiliated to the Defense Department or the federal government to review and approve the proposed IND protocol without informed consent.

The flowchart in Exhibit 10 illustrates a general guideline for a clinical investigator to determine if a waiver or alteration of an informed consent requirement is practical or feasible to their proposed IND research. It is incumbent upon the investigator and the study sponsor to determine response to each of these questions in the decision tree and provide supportive documentation to the IRB as required under the regulations.

Clinical investigators must provide a clear statement of objective and explain the purpose of the research, expected duration of subject participation, description of the study protocol and actual procedures, and clearly identify procedures that are experimental in nature. The informed consent disclosures must provide sufficient information on the potential risks to health and well-being of the subject, while describing the anticipated benefits from participation in the study. The subjects must be aware of their rights and confidentiality of health information such as disease condition, medical treatments, and so forth.

The patient information and consent forms (PICF) must be approved by the IRB prior to use. A fully executed informed consent should be dated and signed by the subject or the subjects legally authorized representative at the time of the consent. All signed consent forms should be retained by the clinical investigator throughout the study period and a copy of the consent form provided to the subject.

A recent study by Beardsley et al. [7] investigated the patient knowledge and satisfaction regarding the informed consent process for cancer clinical trials and found that the lengths of PICFs, submitted to the IRB over the past few years, have increased with time.

Exhibit 11 illustrates the number of pages in the PICFs of 102 patients participating in 27 therapeutics clinical trials across 4 hospitals over the past 6 years on approved cancer clinical trials. A notable observation from this study was that although the number of pages in the PICF has grown dramatically from a mean of 7 pages (range 3–9) in 2000 compared to 11 pages (range 7–21) in 2005, important information for the patient was missing in several cases and that the patient understanding was inversely proportional to the page count of the PICFs. Evidently, the number of pages in the PICF does not correspond to the effectiveness in communicating the complex details of a clinical trial protocol.

**EXHIBIT 11** Number of pages in the participant information and consent form in a sample of clinical studies performed during the past 5 years. (Source: Beardsley et al. [7].)

## 2.7 REQUIREMENTS FOR OVERSIGHT: IRB

At the institutional level clinical trials require a thoroughly objective and unbiased oversight and review of proposed investigations by a duly appointed IRB. It is the responsibility of the IRB to conduct a technical review upfront of a proposed clinical investigation that supports applications for research involving INDs or marketing permits for products regulated by the FDA. The goal of an IRB review process is to ensure protection of the rights and welfare of human subjects proposed under a clinical investigation (21 CFR, Part 56).

No clinical investigation could begin without proper review and approval of an IRB, unless the FDA provides a formal waiver of any of the IRB requirements, including the requirement for review for specific research activities otherwise covered under these regulations. All clinical investigations involving INDs must meet the IRB requirements and obtain proper approvals prior to submission to the FDA for a formal review of the application. IND product applications with data generated from a clinical research activity conducted without proper review and documentation of an initial and continuing IRB review process may be rejected by the FDA from further consideration.

Under the existing regulations, some categories of clinical investigations may be exempt from a formal IRB review process. A couple of these exemptions apply to IND candidates; for example, investigational new products of test articles for emergency use, provided that such emergency use is reported to the IRB within 5 working days. However, subsequent use of the test article must proceed only after completion of a proper IRB review. There are other likely scenarios under which an investigational new product may be used during an emergency such as biological countermeasures products such as vaccines and therapeutics against bioterrorism-related biological agents. With much of the product development activity in the preclinical experimental research for new generation biodefense products, an emergency use of promising candidates may become necessary.

As another example, a waiver to current requirements under the formal IRB review process may be obtained if a clinical investigation for an investigational new drug for research purposes has commenced before July 27, 1981, and was subject to the requirements of IRB review under the then prevailing regulations, and provided that the investigation remained under the review of an IRB, and compliant with requirements in effect before July 27, 1981.

The IRB represents an institutional-level mechanism to approve, monitor, and report on regulatory aspects relating to clinical research set forth under FDA regulations and guidelines. As part of this effort IRB has:

1. Authority to review and approve or reject all clinical research activities.
2. Authority to seek additional information given to subject as part of informed consent to ensure that sufficient information is provided to protect the rights and welfare of subjects in the clinical research.
3. Verify all documentation relating to informed consent as required under the FDA regulations. Furthermore, IRB will determine whether a waiver is required to allow a legally authorized representative to sign a written consent form under certain conditions as long as it does not present more than minimal risk of harm to subjects.
4. Authority to ask and obtain from the principal investigator of an IND clinical research relevant information to clarify, supplement, or modify the research plan to meet the institutional and regulatory requirements.
5. Responsibility to notify clinical investigator and the institution in writing on the decision to approve or reject a proposed research activity or modification required to obtain the IRB approval.
6. Responsibility to perform reviews of research at appropriate intervals to ensure the clinical investigations are in accordance with the IRB approved protocols and plans.
7. Responsibility to inform study sponsor any exceptions to informed consent and duly document that the disclosure has occurred.
8. Responsibility to ensure that if children are some or all the subjects for a clinical study, the study plans are in compliance with appropriate regulations (under 21 CFR, Part 50).

Exhibit 12 illustrates key criteria for approval of a clinical research by the IRB. As the core of the approval process, IRB must establish that the clinical research proposal poses potentially minimal risk to human subjects, and the anticipated benefits associated outweigh potential risks associated with the clinical study.

### **2.7.1 Composition of IRB**

The IRB consists of at least five members drawn from a multidisciplinary background in order to facilitate a proper review of the clinical research activities undertaken by the institution. From the standpoint of a review of a proposed clinical research activity involving an IND product, it is crucial that the IRB members be thoroughly familiar with the technical requirements, potential vulnerability of the

**EXHIBIT 12** Key criteria considered by the institutional review board as part of review and approval of a clinical research proposal.

clinical subjects under the proposed investigation, the nature and extent of institutional commitments, other considerations including cultural background, sensitivity to such issues as community attitudes toward race and gender issues, and the safeguard of rights and welfare of human subjects. Vulnerability of clinical subjects to a clinical trial involving an IND would have to consider cases when children, pregnant women, prisoners, elderly subjects, or mentally and/or physically disabled persons are part of a clinical investigation.

Under existing regulations an IRB should be comprised of (a) qualified men and women drawn not entirely from one profession to minimize bias; (b) members representing both scientific and nonscientific disciplines relevant to bringing a balanced consideration of the overall institutional review process; (c) members from external community drawn either from professional societies and community organizations not affiliated with the institution; and (d) members without a conflict of interest, either as participants in the proposed study or as study sponsors.

The IRB is required to follow a systematic review process, follow written procedures, and document the review process (a) prior to the commencement of a clinical research activity, (b) continuing review of the research and reporting its findings and actions, and (c) document IRB review findings, approvals, and reporting to regulatory agencies as required.

Upon submission of all relevant documents of a proposed clinical study, an IRB is established to approve and oversee on a continuing basis to determine the nature, frequency, and extent of reviews required and the need for verifications from sources other than investigators that no material changes have occurred since previous IRB review. The IRB will establish written procedures for reporting changes in research protocols and ensure that changes in approved protocols were reviewed and approved prior to actual changes made to the study. A formal approval by the IRB requires that the review include at least one IRB member whose primary area of focus is in the nonscientific area, and that a majority on the IRB committee approves the proposed clinical research.

It is the responsibility of the IRB to provide formal reports to the appropriate institutional officials and the FDA of any untoward findings in the course of ongoing clinical investigations such as unanticipated problems involving risks to human

subjects, breaches in compliance to approved study protocols, noncompliance with regulations or requirements, or determinations of the IRB. If a study is suspended or terminated for any of these reasons, the decision must be communicated by the IRB immediately to the appropriate institutional authorities and the FDA.

## **2.8 REQUIREMENTS OF FINANCIAL DISCLOSURE**

As part of the overall review of all clinical studies submitted in marketing applications, existing regulations require the study outcomes not tainted by potential sources of bias in clinical studies due to financial interests of clinical investigators. This review must ensure disclosure, if any, of the potential financial interest for clinical investigators participating in the clinical studies in the form of payment arrangements such as royalties, or proprietary interest in the product such as a patent, or equity interest with the study sponsor submitting the new product application.

The FDA is required to review financial disclosure information for all new human drugs and biological products and marketing applications and reclassification petitions for medical devices. IND applications may have certain exemptions to these requirements, depending on the nature of the clinical investigation, study design, and the type of data collected during these investigations.

This requirement applies to all sponsors submitting marketing applications to the FDA for approval of a drug, device, or biological product. It is the responsibility of the sponsor to ensure all financial disclosures in the form of disclosure statements and certifications are submitted for each clinical investigator involved in the clinical studies. Financial disclosure statements are required for even submissions of clinical study results from other investigations directly relevant to the application but obtained from investigators who are not part of the sponsor-funded clinical studies. As required under the law, regulators will use the clinical study technical information submitted by the sponsor together with disclosure statements and information collected during on-site inspections to determine the reliability of data and ensure no biases are introduced in the interpretation of the study results from clinical investigations toward a new product development, including INDs.

### **2.8.1 Covered Clinical Studies**

As part of the financial disclosure requirements, the FDA defines what constitutes covered clinical studies (20 CFR, Part 54.2). A covered clinical study could be the complete study or parts of the study protocol dealing with the efficacy of a drug or device in humans submitted in a marketing application or reclassification petition. The key to this requirement is the determination that the study, either in total or parts, deals with the efficacy of a product and/or a study outcome making a singular but significant demonstration of safety. This would not include the phase I clinical investigation of INDs, which would generally involve dose-thresholds determination, clinical tolerance, pharmacokinetics, and general pharmacological studies except those involved in the determination of product efficacy.

Financial disclosures include clinical investigators directly involved in the study and those under subcontract to the principal clinical investigator working on a large

study at multiple locations. These disclosures also include spouses and children of clinical investigators so as to eliminate potential sources of bias in clinical studies.

## **2.8.2 Certification and Disclosure Requirements**

Regulations require the sponsors of clinical studies to submit to the FDA a list of all clinical investigators who were involved in the clinical studies evaluating the efficacy and safety of the product, including the exemptions afforded to certain INDs. These submissions must provide complete and accurate details of financial emoluments in any form accrued by the investigators either directly or indirectly (through a subcontract) from the study sponsors. Clinical investigators with IND exemptions must provide the sponsors with sufficient accurate information to allow subsequent disclosure or certification.

In order to certify that a clinical investigator has no financial interest, the study sponsor should obtain from each clinical investigator directly or indirectly (through a subcontract) a copy of FDA Form 3454 declaring absence of any financial interests or arrangements, duly signed by the chief financial officer or other responsible corporate official of the sponsor. If the certification covers only parts of the clinical data in the application, those parts should be clearly identified as such and appended with a list of studies covered under the certification. It is the responsibility of the clinical investigator to update relevant changes to the financial relationship with the sponsor or its affiliated contractor during the course of the study.

## **2.8.3 Disclosure Statement Evaluation**

Existing regulations provide a combination of evaluation strategies on the potential impact of any disclosed financial interest on the reliability of the study through (a) financial disclosure information and certifications furnished by the sponsor, (b) information collected from on-site inspection, and (c) effect of study design.

As part of the financial disclosure evaluation, regulations will consider potential for impact on study reliability based on the nature and extent of a disclosed financial interest, extent of downside financial benefits from an approved product, and steps taken by the sponsors to mitigate the potential biases on the study outcome. A key to this evaluation is the assessment of the overall study design, particularly large studies with multiple investigators scattered at different geographic locations and investigating on different study endpoints. Single and double-blind clinical trial designs, quantitatively verifiable endpoints at multiple locations involving different investigators, study design development, and actual study administration and data collection by unconnected investigating team working at different locations are some of the mitigating measures to minimize, or possibly eliminate, potentials for bias, should there be a financial interest among some investigators participating in the clinical study.

A key goal of the regulatory evaluation is to ensure reliability of clinical data submitted as part of a marketing application of human drug, biological product or device, and applicable INDs. If during the evaluation process it was revealed that financial interests on the part of a clinical investigator may have influenced the study outcome, regulators could respond by (a) initiating audits of data derived from the clinical investigation in question, (b) request submission of additional analysis of

data to reassess the interpretation of study results, (c) request the sponsor to conduct additional investigation through an independent third party, and (d) refuse to consider the study results as part of overall consideration for an agency action (21 CFR 54.5).

Study sponsors must retain all relevant financial records of clinical investigators involved in the study. These records must have all the changes in financial status submitted by the clinical investigator to the sponsor during the course of the investigation.

## 2.9 REQUIREMENTS FOR GOOD TISSUE PRACTICE COMPLIANCE

With the advent of recombinant technologies in biological product development, the scope and volume of cell-based new biologics product development have expanded dramatically in the past decade. This group of therapeutic products, generally known as the human cells, tissues, and cellular and tissue-based products (HCT/Ps) has opened a vast range of therapeutic products development using cell-based recombinant technologies. Although the first-generation cell-based therapeutic products were mostly blood and tissue transplantation, the scope of cell-based therapeutics has now expanded into other areas such as tissue repair and regeneration, modification of immune functions, facilitate tissue/organ regeneration, and gene replacement therapies. The potential for adverse effects and health and environmental risks associated with HCT/Ps presents a unique regulatory challenge.

Recognizing the need for an entirely new regulatory framework, the FDA proposed current good tissue practices (cGTP) rule together with the cGMP to prevent introduction, transmission, and spread of communicable diseases and mitigate potential environmental contamination from HCT/Ps infectious agents. This together with the requirements under cGMP for production of safe, pure, and efficacious products addresses both process controls at the manufacturing phases as well as the potential impact of releases into the general environment. As a result, the cGTP guidelines outline the methods used in the manufacture of HCT/Ps as well as recordkeeping and establishment of a quality program (21 CFR, Parts 16, 1270, and 1271).

All HCT/Ps are required to comply with the cGTP guidelines, and those candidate products, considered from initial assessment as having potentials for inducing adverse environmental impact, are required to comply with both the cGTP and cGMP requirements and are required to obtain premarket approval through the IND application process for biologics products.

The cGTP guidelines introduce additional regulatory compliance requirements in the IND clinical research investigations. Both sponsors and clinical study investigators are expected to comply with additional cGTP-driven requirements in terms of facility-level process controls, recordkeeping, and establishment of quality programs. Additional requirements of labeling, reporting, inspection, and enforcement apply under the cGTP to all HCT/Ps IND product development related activities. It is relevant to note that the cGTP requirements for HCT/Ps are regulated under the authority of the Public Health Services Act (PHS Act) and not as drugs, devices, and/or biological products. The regulatory community acknowledges the overall intent of cGTP is to improve protection of public health through good clinical care

and application of sound scientific principles to improve quality and reliability of IND product related data [8].

Facilities working on HCT/Ps are required to investigate any adverse reaction with the potential for communicable disease related to a HCT/P under development and report immediately for broader distribution. Under the cGTP guidelines, adverse reaction are defined as a noxious and unintended response to any HCT/P for which there is a reasonable possibility that the response may have been caused by the product or a causal relationship cannot be ruled out [3]. As set forth in the cGTP guidelines, it is the responsibility of the facility handling the HCT/Ps and sponsors to investigate any noxious or unintended adverse reaction and report. Regulatory agencies receiving these reports from multiple sources will look for a general pattern in the adverse events reporting to determine the nature of the emerging trend and seriousness in terms of public health impact. For example, several hospitals reporting an outbreak of methicillin-resistant *Staphylococcus aureus* (MRSA) following a procedure involving a therapeutic product from a human tissue may trace its origin to a single establishment with contamination with MRSA.

Facilities handling HCT/Ps are required to report to the FDA of any serious adverse reactions involving a communicable disease. The cGTP regulatory guidelines define reporting requirements for adverse reactions involving a communicable disease as those that are (a) fatal, (b) life-threatening, (c) result in permanent impairment of body function or permanent damage to body structure, or (d) necessitate medical or surgical intervention including hospitalization. This report must be filed with the FDA within 15 days of initial receipt of information. According to published records, this will be the first federal requirements for reporting of adverse reactions from transplanted HCT/Ps.

Perhaps, adverse event surveillance linked to facilities and operations involving HCT/P is the most critical element in the cGTP guidelines for it requires a mechanism to detect and identify adverse events by physicians and infection control practitioners in a clinical setting, and a reporting mechanism to risk managers at the facility level and onward to the regulatory agencies. The FDA has established the MedWatch program, the safety information and adverse event reporting program, to encourage and enable voluntary reporting, which is crucial for the overall program success. Although MedWatch handles issues involving commercially available pharmaceutical products, facilities performing HCT/P-related IND clinical investigational activities are required to use the same systems for reporting adverse events.

## 2.10 REQUIREMENTS FOR IND LABELING

The drug label, also known as the package insert, is intended to provide an accurate and concise summary of all relevant information necessary for the user to determine the safety and efficacy for approved indications. Current regulations outline the overall requirements on content and format of labeling for human prescription drugs (21 CFR, Part 201.56). As required under this regulation, the label must provide information that is accurate and should not be written in a promotional tone, and most of all misleading in terms of the effectiveness, approved indications, and contraindications. As far as possible the label claims must be based on data

(Limited by Federal Law to Investigational Use.)

**EXHIBIT 13** Sample investigational drug label for exclusive use during the clinical trial.

derived from clinical studies and not based on experimental data from nonclinical studies.

The labeling requirements set forth under the current regulations for all drugs and biological products apply to the IND as well.

Exhibit 13 illustrates a sample investigational drug label for exclusive use during the clinical trials. The label format and content should be in strict compliance with the regulatory requirements for package inserts with the exception that the label for the IND must clearly mention that under federal law the product is meant only for investigational uses and a note of caution that the content is a new drug. The name of the physician on the label must be a participating clinician in the IND clinical trial.

The IND labeling issue is particularly relevant in the “off-label” and investigational use of marketed drugs, biologics, and medical devices. Off-label use of an approved drug refers to a use, by a practicing physician, of a drug that is not included in the approved label for human prescription drugs.

A general topic of discussion in the clinical research and regulatory affairs community is whether an off-label use of an approved drug constitutes experimental investigation that normally requires formal review and approval by an IRB and strictly follows the informed consent process. Likewise, there is some confusion as to whether an off-label use of an approved drug requires formal submission of an IND application to FDA.

The requirements under good medical practice and the references within the existing drug approval process address these issues.

Good medical practices establish the principles and values that guide medical professionals in clinical care and service delivery. Although the good medical practices are essentially addressed to clinical practitioners, its broader goal is to let the public know what they can expect from medical services rendered at a clinical setting. This is particularly relevant in the context of off-label use of an approved drug for an indication not included in the approved label.

If a physician uses a product for an indication not on the approved label based on his or her clinical knowledge and patient history, it is extremely important that the use be based on sound scientific rationale and a thorough understanding of the product indications and potentials for adverse effects and maintain complete records

of all treatment procedures and therapeutic regime for off-label uses. However, under the current regulations there is no requirement of off-label uses for a formal submission of an IND application, investigational device exemption, or an IRB review. Instead, the clinical knowledge and expert judgment of the physician based on a detailed knowledge of the product and the patient clinical condition guide the off-label use of an approved drug or medical devices. Off-label uses within an institutional medical practice may require an IRB review or other existing institutional oversight and governance process.

It is important to note that the off-label use of an approved drug is not the same as the investigational use of an approved pharmaceutical product since investigational use indicates the use of an approved product in a clinical study protocol must comply with the FDA requirement under the IND application procedures (21 CFR 312). This compliance requirement is essential when the objective of the investigation is to develop additional information relating to product safety or efficacy, in which case an IND application and due process is required. However, this requirement is not considered essential if the proposed investigation meets all the following six conditions: (a) Proposed investigation will not lead to a new NDA application in support of a new indication for use or support any significant change in the approved labeling for the pharmaceutical product; (b) proposed investigation is not intended to support a significant change in advertising of the product; (c) proposed investigation does not involve a route of administration, or dosage level, or use in a subject population, or any other factor that could significantly increase the risks associated with the use of the pharmaceutical product; (d) proposed investigation requires a formal IRB review or any other related IND application filing requirements; (e) proposed investigation is an attempt to comply with a requirement concerning promotion and sale of a pharmaceutical product; and (f) proposed investigation does not invoke the exemption from informed consent requirements for emergency research (21 CFR 50.24).

Hence, the off-label use of an approved drug is guided by the good medical practice and is the practitioner's responsibility for prescribing a drug for uses not indicated in the approved label. The off-label uses in a clinical setting should be based on a sound scientific rationale and a thorough understanding of the pharmacological data determining the label content. Although the IND application requirements do not apply under these conditions, legal actions are more important in the off-label use of an approved drug. Physicians are at the risk of facing a malpractice lawsuit for negligent use of any drug whether or not the FDA has approved the use of that drug (both label and off-label). Therefore, labeling does not preclude a physician from applying his or her accumulated clinical knowledge and expert judgment in the determination of off-label uses.

In contrast to off-label use, most investigational use of an approved pharmaceutical product in a clinical study protocol must comply with the existing requirement under the IND application procedures.

## **2.11 MONITORING OF INVESTIGATIONAL NEW DRUG RESEARCH**

From a regulatory compliance standpoint, monitoring IND research revolves around nonclinical and clinical research facilities and data generated from these

investigations. Apart from the core requirements of quality and integrity of investigational data submitted in support of an IND application, monitoring ought to protect the rights and welfare of the human subjects involved in clinical research. Recognizing the need for a comprehensive monitoring program, the FDA has instituted the Bioresearch Monitoring (BIMO) program to fundamentally ensure the quality and integrity of the data submitted to support IND applications, and simultaneously ensure protection of the rights and welfare of human subjects during this process.

The BIMO program covers both on-site inspections and data audits to monitor all aspects of the experimental and clinical research conducted in support of the FDA regulatory approval process. According to published reports, the BIMO program on average conducts over 1000 inspections annually and covering GLP audits of nonclinical testing labs, clinical investigators, sponsors/monitors, and the IRBs [6]. Implemented through four multicenter compliance programs, BIMO covers facilities and clinical research activities at both domestic and international locations.

Large medical institutions, both private clinical research facilities and academic teaching institutions with significant clinical research related activities, have established a detailed institutional-level monitoring of the IND-related clinical research studies, including standard operating procedures and GCP both at the institutional and study levels.

Exhibit 14 illustrates institutional-level GCP compliance monitoring elements during an IND clinical research activity. The goal of institutional-level monitoring is to oversee clinical research activities and ensure that these activities are conducted, recorded, and reported in compliance with the established protocol and standard operating procedures and good clinical procedures.

Monitoring is a continuous activity requiring reporting and regularly scheduled reviews by the IRB, which has the oversight responsibility. Depending on the clinical study design, a medical review committee may be established to specially monitor a clinical protocol. On the contrary, audit is a systematic and independent investigation conducted by an external team of all aspects of a clinical study and its overall compliance with the standard operating procedures, GCP, and applicable regulations.

Most often the goal of monitoring review is to improve performance, establish data integrity, protect human subjects, and establish compliance with internal procedures and regulatory requirements. Exhibit 14 lists typical monitoring elements related to GCP compliance in IND clinical research relating to process improvements, data integrity, protection of human subject, and compliance with GCP and applicable regulations. The responsibility for most of the GCP compliance rests with the principal investigator and the monitoring responsibility with the IRB.

### **2.11.1 Clinical Risk Assessment**

A key element of the institutional-level monitoring of the IND research activity is the establishment of a risk assessment and risk management program. As part of the risk assessment process, it is important to distinguish between hazard and risk. Whereas hazard may be defined as any factor—internal or external to the clinical investigation—that could cause harm, risk is the measure of the probability that

| Compliance Element                          | Description                                                                                                                                              | Lead Responsibility                      | Monitoring Responsibility                |

| Clinical research management system (CRMIS) | CIO establishes a customized CRMIS to track work flow and link database.                                                                                 | CIO/principal investigator               | IRB                                      |
| Patient outreach program                    | Oversee clinical subject recruitment process; resources for outreach and enrollment and retention; cost-effectiveness analysis.                          | Principal investigator                   | IRB/study operations support office      |
| Informed consent                            | Electronic documentation to track all paperwork; quality assurance; educational resources to assist patient education on the study and informed consent. | Principal investigator                   | IRB                                      |
| Inclusion/exclusion criteria documentation  | Case report forms, detailed checklists; supportive documentation; links to database.                                                                     | Principal investigator                   | IRB/medical review committee             |
| Adverse effects reporting system            | Serious adverse event (SAE), unexpected adverse event (UAE) reports in real time; and periodic; links to database.                                       | Principal investigator                   | IRB/medical review committee/<br>FDA     |
| Drug/biologics accountability               | IND/IDE application templates; SOPs; sponsor IND documentation.                                                                                          | Principal investigator/<br>study sponsor | IRB/pharmacy department                  |

**EXHIBIT 14** Institutional level monitoring of IND of good clinical practice compliance during IND clinical investigations.

harm will be caused by the hazard. Therefore, presence of hazard alone does not constitute establishment of risk to a research study. What is needed is a structured risk assessment process that takes into account all technical, operational, and information systems and processes related to an IND clinical investigation and a clearly worked out risk mitigation strategy.

Exhibit 15 is a notional illustration of various elements of a clinical risk assessment and risk mitigation process. It is important to note that the clinical team should identify potential hazards inherent in a trial and their associated risks, potential consequences, and a reasonable approach mitigating the risks.

Hazard identification and assessment should identify and sort hazard by its origin and potential impact such as:

**EXHIBIT 15** Notional illustration of various clinical trial risk assessment and risk mitigation process as part of an institutional monitoring of IND research activities.

1. Hazard for the participants arising due to failure to properly complete the informed consent process or information systems failure to protect the privacy of participants.
2. Hazard for participants due to the nature of intervention mechanism set up as part of the study design such as unexpected and/or expected adverse effects, assessment methods such as biopsy, radiation, and pharmaceutical adjuvants used in the IND formulation.
3. Hazard for the trial such as potentials for an incomplete study due to failures in human subjects recruitment and follow-up, violation of the inclusion/exclusion criteria, reliability of the study results, procedural errors, improper information assurance, quality systems failure, failure in adherence to study protocol, general fraud, and misrepresentation.

Risk management approaches must carefully weigh the consequences of the hazard, either to the study participant or the clinical trial, or both, before developing options for mitigating the risks. For example, establishment of a training program for informed consent process, privacy protection, and information assurance and quality systems would address several participant- and study-specific hazards. Similarly, establishment of systems to monitor and report adverse effects and systems to maintain awareness and ability to report adverse events, systematic review of the study design and clinical trial protocol to assess the statistical power and reliability, and a well-designed monitoring and reporting program to track and report study violations are some of the more commonly employed options to mitigate risks associated with IND clinical investigations.

### 2.11.2 Computerized Systems in Clinical Trials

Clinical research management systems are the indispensable platform to seamlessly integrate clinical research, IND activities and regulatory management. Clinical

research systems employ clinical-rules-based decision systems to help guide clinical practices that are key to clinical trials and establish a collaborative environment for information exchange, storage, retrieval, and analysis. Recognizing the importance of clinical information systems to IND, the BIMO program inspections and audits are centered on the data resident in the clinical research management systems to ensure highest standards of quality, reliability, and conformity with the regulations.

Information gathered during clinical studies should meet the established criteria of quality to remain compliant with requirements for electronic data and a mechanism to audit the system for data attribution, accuracy, and originality. Guidance is available to the industry on how these data quality requirements might be satisfied where computerized clinical research management systems are employed to generate, analyze, modify, archive, and transmit clinical data [2]. This guidance also addresses requirements of the Electronic Records/Electronic Signatures rule (21 CFR Part 11). The guidance may be applicable to source documents created in hardcopy and later entered into a computerized clinical research management system, or directly entered into a computerized system, or automatically captured by a computerized system.

The guidance to industry identifies standard operating procedures relevant to use of computerized systems such as:

1. *Data Entry*: To ensure data attributability through identification of individuals entering the data, passwords protection to limit and track access control, electronic signatures, audit trails, and date and time stamps.
2. *System Features*: Features that will facilitate collection of quality data such as consistent use of terminologies, data tags to facilitate inspection and review, ability to retrieve data, maintain collateral information relevant to data integrity, and system capability to reconstruct a study to backtrack how data were obtained and managed in support of an audit.
3. *Security*: To include physical and logical security. Physical security refers to internal safeguards built into the system and external safeguards to restrict access to authorized users. The system must have a robust feature to prevent unauthorized access. Logical security refers more to maintaining data integrity and to ensure that the information resident in the system is not altered, browsed, or transferred using external software applications.
4. *System Dependability*: To ensure that the system is in conformity with the study sponsors' established requirements for completeness, accuracy, and reliability. System documentation should be readily available for inspection during site visits. Sufficient documentation on software systems validation such as written design specifications, test plan, and test results and demonstration validating the system design specifications.
5. *System Controls*: To include software version controls, contingency plans in the event of a system failure, and a backup and recovery plan to retrieve electronic records.
6. *Training Records*: To include documentation on qualification of individuals managing the database systems and data entry activities, and training records for verification that suitable training was provided to individuals performing these functions.

7. *Records Inspection:* During a facility inspection all records submitted to the Agency may be audited for track changes, no matter how they were created or maintained.
8. *Electronic Signatures:* Electronic signatures are intended to be the legally binding equivalent of conventional handwritten signatures.

### 2.11.3 Quality Assurance

As part of an IND product development activity, it is the responsibility of the sponsor to ensure compliance with all pertinent regulations and quality standards. For example, product development methodologies will be compliant with section 505(b) of the Food, Drug, and Cosmetic Act, 21 U.S.C. § 355(b), methodology used for preparation of the drug substance, and the control testing used to monitor its identity, strength, quality, and purity, as required for IND submission.

Exhibit 16 illustrates the dramatic shift in the regulatory landscape of QA before and now, propelled due to an increasing emphasis on quality systems and the establishment of a robust QA/QC as part of the entire product development life cycle. In the last decade, the regulatory affairs related to QA during IND have shifted to a more activist role with explicit requirements for audits and greater contacts between the industry and the regulators on QA-related matters. The reporting requirements have increased transparency of the IND information collection processes and improved access to QA data.

From the industry standpoint, the IND product development and clinical trials landscape has changed significantly in the past two decades, propelling the need for a reform in regulatory compliance requirements in quality control and quality assurance. More and more clinical investigations now involve extended studies, involving multiple sites and having a large volume of clinical trial subjects at each site. Added

| Regulatory Landscape Before                                                                                                       | Regulatory Landscape Now                                                                                                                                                                                                                                                                      |
|-----------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| No explicit requirement for QA audits                                                                                             | Audit required under the FDA International Conference on Harmonisation (ICH) GCP Consolidated Guidelines. Section 5.19 (Audit).                                                                                                                                                               |
| Mostly left to the sponsors to implement QA as an in-house program and considered a cornerstone of program management success.    | Explicit requirement under the FDA International Conference on Harmonisation (ICH) GCP Consolidated Guidelines. Section 6.11 (Quality Control and Quality Assurance—Documents). Other QA guidelines are: European Union (EU) The Engage Guidelines; World Health Organization GCP Guidelines. |
| No explicit QA related reporting requirements                                                                                     | Greater contact with the industry on QA.                                                                                                                                                                                                                                                      |
| QA was a “black box” as far as FDA was considered and interpreted as a tool for success for sponsor’s product development program | Increased transparency and reporting requirements on misconduct and activities leading to compromise on the safety and security of human subjects.                                                                                                                                            |

**EXHIBIT 16** Comparison of the regulatory affairs role in the quality assurance and quality control during the IND phase of product development.

to this is the new and expanded role now played by clinical research organizations and a vastly expanded pool of clinical investigators now taking part in IND-related clinical studies. Large pharmaceutical companies have reached out to global destinations for IND-related clinical trials bring in countries and medical research institutions that were traditionally not part of the product development pipelines. Access to highly sophisticated clinical research information systems and electronic connectivity have made possible information collection, sharing, and analysis in a widely distributed global environment. Finally, an increasing number of IND clinical studies are now designed that allow participation of sensitive human subjects based on age group and pre-existing clinical conditions. These are compelling enough reasons for the regulators to recognize the need for a compliance framework addressing quality control and assurance as an overall requirement throughout the product development process.

The quality assurance and product technical support departments of the sponsors are responsible for assuring that IND study participants meet the quality objectives and comply with the established guidelines. Participating institutions (hospitals, academic medical institutions, and clinical research organizations) are required to implement and follow written approved procedures to ensure all operations are performed in accordance with quality systems guidelines under the GCP and cGMP regulations and in-house policies.

All personnel supporting or engaged in the IND-related manufacture, testing, or quality assurance are required to comply with the established written approved procedures. In addition, these institutions must have a comprehensive quality program that controls all manufacturing including a complete document control system, documentation review and approval, auditing, and training.

As part of the overall document control process related to QA, study sponsors and participating institutions must maintain an approved document entry and tracking system that includes specifications, standard operating procedures, testing protocols, batch records, and test reports. Study sponsors may establish management oversight of the entire process with real-time oversight of critical production and testing activities, as well as audits.

Exhibit 17 illustrates a typical list of areas covered during QA audits of a biologics facility. The audit area covers floor areas for proposed activities, equipment identified for the projects, documentation, employee training, and facility audit/biosafety inspection records. Facilities used for the IND product development may be inspected to verify the availability of appropriate space, compliance with biosafety requirements, equipment and personnel to operate the following functional areas: (a) fermentation suite, including downstream processing, (b) purification suite separated into upstream and downstream purification rooms, (c) production support areas, (d) process and facility utility area, (e) waste treatment area, (f) warehousing, (g) QA/QC, (h) cell banking, (i) finished and in-process material storage, and (j) offices.

## 2.12 EMERGING BIOSAFETY AND BIOSECURITY REQUIREMENTS

Biotechnology and pharmaceutical companies with an array of biologics product development portfolios and clinical research organizations are beginning to place

| Facilities and Equipment                                                                                                                                                                                                                                                 | Qualification and Calibration                                                                                                                                                                                                                                                                     |

**EXHIBIT 17** Typical list of areas of compliance investigated during audits of IND product development programs.

considerable importance on laboratory biosecurity with a focus on improving security at microbiological research facilities, clinical laboratories, and ancillary laboratory services such as biological material storage and distribution facilities. A key element of this growing awareness requires a clear delineation of the concepts of biosafety and biosecurity in IND product development activities in the context of new regulations. Whereas biosafety refers to institutional-level measures to prevent and mitigate the accidental release of biologic agents and toxins, biosecurity refers to instructional measures that guard against the deliberate release of pathogens for malicious purposes (including bioterrorism). Thus far, existing U.S. and international regulations and guidelines have focused on biosafety rather than biosecurity.

In the aftermath of the 9/11 terrorist attacks, followed in the same year by a string of anthrax attacks in the United States, the Congress passed two significant pieces of legislation. First, the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism (USA PATRIOT) Act of

2001 established criminal penalties for possession, shipping, and receiving of certain biological agents, known as select agents (SA) and toxins, if used as a weapon or for any reason not plausibly justified for prophylactic, protective, bona fide research, or other peaceful purposes.

Second, the Public Health Security and Bioterrorism Preparedness and Response Act (PHSBPRA) of 2002 greatly expanded controls over dangerous pathogens and toxins stored, used, and transferred between laboratory and ancillary facilities within the United States. These legislations establish the regulatory premise to introduce biosecurity practices at research laboratories handling dangerous etiologic agents and toxins as part of an overall national security program.

For the most part, biosafety and biosecurity practices are guided by institutional policy and governance set up for this purpose. The environmental health and safety (EH&S) division is most often charged with addressing all biosafety and environmental regulatory affairs as they apply to development, production, and testing of IND products. It is up to the management leadership in an organization to recognize and prioritize the importance of biosafety and biosecurity as fundamental requirements at all phases of product development activities. This requires a careful integration of EH&S-related guidelines and regulations throughout the product life-cycle development. For an effective EH&S program it is important that staff be highly qualified in the areas biosafety, environmental health, and risk assessment and having working knowledge of the regulations covering product development.

Exhibit 17 is a summary of typical areas of compliance investigated during an audit of an IND product development facility. Evidently, the audit areas are cGMP and quality systems related areas but with a focus on the safety and security of the product and processes with a goal of protecting the workers in the occupational setting and the general environment. As part of the safety and security-related audits, the EH&S team may review floor plans as they relate to potential for cross-contamination and release of potentially infectious materials in the working environment. Production process and laboratory equipment, air and water distribution systems, and sanitary systems inspected to ensure built-in engineering protection segregate and contain hazardous chemicals and biological materials from drinking water systems, heating, ventilating, and air-conditioning (HVAC) systems. Warehouse and receiving facility for nonclinical experimental facilities are where animal housing is maintained and bulk raw chemicals are stored. Finally, biocontainment facilities involving biosafety levels 2 or 3 (BSL-2 or BSL-3) are required for handling potentially dangerous etiologic agents and infectious materials for experimental purposes.

As required, the EH&S will perform a biosafety-related risk analysis, known as the maximum credible event (MCE) analysis to determine the potential for accidental release of dangerous biological agents into the occupational environment within the facility and general environment outside, and assess the facility-level crisis and consequence management capability and resources for effective containment of an accidental release during manufacturing, processing, storage, or animal testing operations.

EH&S staff perform preaward audits of subcontractor facilities to ensure compliance with all applicable and current federal, state, and local laws, codes, ordinances, and regulations, as well as all public health services safety and health provisions. These activities would include:

- Review of subcontractor's facility safety plan and complete site visit to verify floor plan details on the ground and review safety records, biosafety oversight committee meeting minutes, and standard operating procedures (SOPs).
- Review the type of hazardous chemicals regulated under the Resource Conservation and Recovery Act (RCRA, 1976) and perform hazard assessment as required.
- Conduct detailed site visits and proposed testing of production areas and associated support areas. All areas are assessed for the appropriateness of the biological safety level employed and compliance with the biosafety standard including general housekeeping, security, and general safety (fire, chemical, radiation, and electrical).
- Review all documentation required by federal, state, and local regulations and related in-house documentation. Documents that are reviewed may include, but not limited to, chemical hygiene plans, safety SOPs, biosafety/safety committee meeting minutes, HAZCOM plan, biological safety plan, training records, engineering control equipment maintenance and certification records, written respirator program, and medical surveillance program.
- Written recommendations are provided as part of the facility biosafety visit and a corrective action plan is requested.
- Monitor facility compliance with biosafety and environmental practices through annual inspections and frequent communications with the facility EH&S staff.

The EH&S staff from the sponsoring organization may be required to provide support and additional oversight over the entire spectrum of facility biosafety, environmental regulatory affairs, workers protection requirements for hazard analysis, and risk assessment for IND product-related development activities.

Requirements for biosafety practices and compliance with environmental and worker protection are unique for each project and could change as the nature of activities change. For example, the volume of a potentially infectious material stored at a facility could determine the biosafety requirement. Thus, a lower biosafety level for a storage operation (with no volume changes) may not apply for a production/testing-related operation where volume changes are likely. Likewise, a higher volume of a hazardous chemical stored at the facility could warrant application of RCRA regulations, whereas a lower volume would be excluded from the regulation.

Both sponsoring organization and participants in the product development activities can make no compromise on biosafety and environmental regulations compliance, designed to be used as screens upfront in facility selection process and monitored by designated staff from both organizations to ensure that the facility remains fully compliant with regulatory requirements throughout the IND activities.

## **2.13 CONCLUSIONS**

The IND is a key phase within the drug development life cycle. The regulatory affairs relating to IND requires a balancing consideration of the inherent benefits

of introducing novel medical products for human use, while at the same time protect clinical trial subjects from potentially harmful test candidates during the preclinical product development phase.

The FDA regulations are the principal drivers of the regulatory affairs related to IND development. Existing FDA regulations relating to IND clinical trials such as cGMP, GLP, and GCP guide IND development for drugs and biologics, and new initiatives such as the GTP attempt to incorporate the expanded scope and volume of recombinant technology-based HCT/Ps and genomic therapies. The FDA has reinvigorated the scope of regulatory affairs related to clinical risk assessment, quality assurance, quality control, and use of computerized systems in clinical trials. Electronic IND submissions have eliminated the need for voluminous hardcopy submission, which require the entire study planning, preparation, execution, and management within the information systems domain.

Biotechnology companies are involved in highly sophisticated biologics products development based on genomics and functional proteomics with unclear regulatory implications, risks to clinical subjects, product liability, and potentials for long-term public health risks. Recognizing the importance of technology and regulatory compliance in the development of novel therapies, the FDA launched the Critical Path Initiatives covering product development strategies and technologies in these IND development areas.

Recently, the FDA initiated the BIMO to proactively ensure the quality and integrity of data submitted in support of IND applications and to protect the rights and welfare of clinical trial subjects. Through a combination of on-site inspections and data audits BIMO attempts to monitor all aspects of the experimental and clinical research conducted in support of the regulatory approval process.

In the aftermath of 9/11, research laboratories are beginning to place considerable importance to improving biosecurity at microbiological research facilities, clinical laboratories, and ancillary laboratory facilities to guard against misuse of pathogenic materials and select agents used in IND research and medical countermeasure products development activities. At the institutional level, integration of a robust EH&S program for biosafety and biosecurity as part of the product development life cycle is an essential regulatory requirement.

## **APPENDIX: APPLICABLE AND RELEVANT REGULATIONS COVERING IND**

### **Key IND-Related Regulations**

|                    |                                                                                      |

### **3.1 PREPARING HUMAN STUDIES IN LIGHT OF PRECLINICAL STUDIES**

The first study to assess for safety in human subjects begins with the initial development of the drug. The particular physiological target for the drug should be known (e.g., whether it is designed to bind to serotonin receptors or specific tumor receptors). This target is determined by the group or company designing the pharmaceuti-

cal, which develops a molecule that is based upon existing ones or based upon known physiological molecules. Thus, the initial safety assessment targets the most likely pharmacological effects of similar molecules. For example, a drug that is intended to bind to the serotonin reuptake sites would be expected to have a safety profile similar to that of other drugs that bind the serotonin reuptake sites. With this knowledge in mind, the initial approach toward evaluating the safety of the new drug would include an evaluation of all pharmacological effects of known related drugs.

In addition to the presumed effects of a new drug based on related drugs, extensive animal studies (as described elsewhere in this book) also provide important information regarding how to assess for safety in human subjects [1]. The Food and Drug Administration (FDA) guidelines for nonclinical safety studies required for the conduct of human trials was published in 1997 [2]. Initial data in mouse and rat models provides preliminary information regarding the physiological changes to blood counts, electrolytes, liver function, immune function, and cholesterol levels. The initial small-animal data also provides clues of potential clinical adverse effects such as disturbances in behavior, appetite, sleep, and activity levels. If such effects are observed, then special care must be taken to observe similar effects in human subjects, and the study must be designed accordingly to evaluate these effects and also to reduce the risk of adverse effects. Initial toxicology studies in animals typically require a small and large animal in addition to nonhuman primates. However, there may be reasons to forego such studies in the case of a drug that targets a process for which there is no appropriate animal model. For example, recent studies of radiopharmaceuticals designed to bind to amyloid plaque in patients with Alzheimer's disease did not require study in nonhuman primates since there is no good model. Therefore, the results are not very meaningful in evaluating the potential effect in human subjects.

Toxicology studies typically require the administration of several different doses, often at substantially higher doses than will eventually be given to human subjects. The drug is then given to the animals for a time period similar to that in which the drug will actually be given. The test article is then given with measurements made of the concentration in the serum of the animals throughout the study. At the end of the dosing regimen, animals are typically sacrificed in order to assess for drug-related changes. Of course, if any results of the animal toxicology studies suggest that the drug might, in fact, pose a substantial danger to human subjects, this might prevent its even being tested in human subjects.

Observations for mortality, morbidity, and the availability of food and water are conducted at regular intervals for all animals. Observations for clinical signs are usually conducted daily on main study animals. In addition, some type of functional observational battery (FOB) is conducted on surviving main study animals prior to initiation of dosing, throughout the trial, and then at completion. Body weights are measured and recorded daily for all animals. Food consumption is measured and recorded daily for main study animals. Ophthalmoscopic examinations are conducted on animals pretest and on main study animals at termination. Blood and urine samples for clinical pathology evaluations are collected from all main study animals at termination. Blood samples for determination of the plasma concentrations of the test article are collected at designated time points throughout the study.

Upon completion of the study, complete necropsy examinations are performed on all main study animals, organ weights are measured, and selected tissues are microscopically examined. A similar analysis is performed in a large-animal model such as dogs with similar evaluations of clinical and laboratory assessments in addition to necropsy evaluations. At the conclusion of these studies, if there are any alterations observed in the animals, reporting of these findings in the investigational new drug (IND) are required and also necessitates careful evaluation in human subjects. Animal studies provide valuable information to assist in the assessment of safety during the development of a test article for human studies. Thus, if there was a significant change observed in platelet function in dogs, then platelet function should be closely evaluated in humans. Often this requires evaluation for at least the duration of the effect observed in animals, and sometimes longer. Thus, if platelet effects were noticed to last up to 2 days in animals, this should be evaluated for at least 2 days and most likely longer in human subjects.

### **3.2 ESTIMATED BIODISTRIBUTION AND PHARMACOKINETICS IN HUMANS**

Similar to toxicology studies, pharmacological evaluation also follows from animal studies and estimates of drug effects. Serum and tissue evaluation of drug concentrations and metabolism is necessary for determining the overall pharmacological effects and to evaluate potential adverse effects of the test article. Biodistribution evaluation in mice and rats and nonhuman primates can be very valuable in predicting the distribution in humans.

Some drugs are easier to have their biodistribution and pharmacology quantified. For example, many radiopharmaceutical products, which combine a radioactive atom with a molecule that follows some aspect of body physiology, can have their biodistribution evaluated through a series of imaging studies in which the radioactivity emitted from the product is detected with scans performed at a number of time points after administration of the drug. This allows for an evaluation of the distribution of the drug as well as the dosimetry that refers to the radioactive exposure an individual receives from the product. Nonradioactive drugs typically require an evaluation of serum concentration of the drug at various time points after administration. It may also be necessary to evaluate urine and fecal samples to determine drug concentrations and help evaluate the mechanism of excretion from the body.

The distribution and concentration of the drug in the body also helps with dose determination. If it is found that a drug is excreted more rapidly in human subjects than in animals, it might be appropriate to increase the dose administered. Drug escalation trials are frequently performed with chemotherapy agents and psychiatric drugs to evaluate both safety and efficacy. The dose of the drug is increased at regular intervals, usually after at least three subjects have had no significant adverse reactions or toxicity. If the drug is determined to be relatively safe, or has minor safety concerns, then the next step is to appropriately design the phase I safety evaluation in human subjects to evaluate the metabolic and pharmacologic actions of the study drug, side effects, and possible early evidence of the drug's effectiveness in humans as described in 21 CFR part 312.21. Preclinical studies to evaluate safety in humans are an essential step in the drug development process and will provide

valuable information for the investigational new drug application and the investigational drug brochure.

### 3.3 INITIAL IND PROCESS

In order to begin any clinical investigation in one or more humans that involves a test article, the study sponsor or sponsor-investigator is required to file an IND application with the FDA. For clarification the “sponsor” means the person who initiates the clinical investigation but who does not conduct the investigation; the “sponsor-investigator” is an individual who both initiates and conducts a clinical investigation either alone or with others. This distinction is important since there are legally binding responsibilities associated with each role. Guidance from the Center for Drug Evaluation and Research (CDER) and the Center for Biologics Evaluation and Research (CBER) at the FDA describes a number of important regulations and provides guidance regarding the IND process. This information must be consulted for the development of any new pharmaceutical products and the submission of an IND application in accordance with 21 CFR part 312.

Under current regulations, any use in the United States of a drug product not previously authorized for marketing in the United States requires submission of an IND to the FDA. The Code of Federal Regulations sections 21 CFR 312.22 and 312.23 contain the general principles underlying the IND submission and the general requirements for an IND’s content and format.

The IND process has a number of components that are summarized below. These sections are also important due to the need for the FDA to determine what safety data is most important to evaluate in human subjects. Most pharmaceutical companies are very aware of the requirements for the IND process. For investigators in the academic or clinical setting, the IND is more formidable and more comprehensive than investigative protocols. However, it is generally recommended that investigators request a telephone conference with the appropriate FDA office prior to submitting an IND so that the process can run as smoothly as possible. In this conference call, specific issues regarding the evaluation of safety in humans can be discussed so that the final IND and study protocols are more likely to be acceptable to the FDA and also the institutional review board. Ultimately, the IND application is designed to assist and guide investigators (either private or public) to study the safety and pharmacology of new drugs.

Once an IND is filed with the FDA, there is a 30-day period in which the FDA is able to review the IND information, request additional information, and provide a nonobjection letter to enable the investigators to begin human studies, or put the study on hold. If additional information is required, this can sometimes be in the form of additional toxicology studies in animals including genotoxicity. The FDA might also require additions to be made to the study protocol for more extensive safety evaluation. This review might include additional types of measures or adding more time points for evaluation. Once these issues are resolved, and the protocol and IND application has been amended accordingly, the FDA may issue a nonobjection letter to begin a phase I human study. Timely and open communication with the FDA is encouraged to facilitate the IND process. If an investigator does not respond, an IND application may be put on hold. This is generally an unfavorable

outcome since the FDA is no longer under any time restriction to process the application, which can often substantially prolong the initiation of a study. However, the Institutional Review Board (IRB) approval of the amended protocol must always be obtained prior to the initiation of the study.

### 3.4 OVERVIEW OF SECTIONS OF IND

There are a number of sections required for an IND submission as described below and summarized from 21 CFR 312.23 for studies with a new drug or for a new indication of an approved drug:

1. Section 1 is the cover sheet (Form FDA-1571) containing the name, address, and telephone number of the sponsor, the date of the application, and the name of the investigational new drug. The phase or phases of the clinical investigation to be conducted is identified. By signing this form, the sponsor (or sponsor-investigator) makes a commitment not to begin clinical investigations until an IND covering the investigations is in effect. There is also a commitment that an Institutional Review Board that complies with the federal requirements will be responsible for the initial and continuing review and approval of each of the protocols in the proposed clinical investigation. The investigator also states a commitment to conduct the investigation in accordance with all other applicable regulatory requirements. The name and title of the person responsible for monitoring safety evaluation and also the conduct and progress of the clinical investigation is provided. The sponsor (or the sponsor-investigator) or the sponsor's authorized representative then signs the cover letter form.

#### 2. *Table of Contents*

3.i. *Introductory Statement and General Investigational Plan* This section usually includes a brief summary of the pharmaceutical agent to be tested, its presumed pharmacological and clinical effects, and how this will be tested through this IND.

3.ii. *Summary of Previous Human Experience* This section includes currently performed human studies. For completely new pharmaceutical products, this will be very brief and simply state that no human studies have been performed. However, for pharmaceuticals that are now being tested for other indications, there may be a substantial amount of information regarding the safety of physiological effects of the drug. It is important to provide a history of the drug development that includes a comprehensive summary from the literature that includes study populations, sample size, adverse events, and a summary of study outcomes.

3.iii. *Withdrawal of Drug* This section reports any reasons why the drug, or comparable drugs that have been developed, has been withdrawn for medical or other reasons.

#### 3.iv. *Overall Plan for Investigational Year*

a. *Rationale for this study:* The reason for the study design, including reasons for specific safety testing, and evaluation of the pharmacology profile and initial efficacy are described here.

b. *Indications for this study:* This section typically establishes why this study is needed and describes the overall goals for developing the investigational product.

c. General approach for evaluating this drug: This section describes whether the proposed study is for safety, biodistribution, pharmacology, dose escalation, or some other study design.

d. Clinical trials to be conducted during the first year: a comprehensive description of the anticipated activity of the first year of the study.

e. Estimated number of patients to be given the drug.

f. Risks: This section identifies the risks and severity and seriousness of the drug risks based upon the toxicological data found in animal studies and in prior studies conducted with humans with the drug or related drugs.

4. This section is reserved for the FDA.

5. *Investigator's Brochure* The investigator's brochure is required for clinical trials involving sites other than the one of the primary sponsor of the IND. Thus, a single site study of a new drug may not require an investigator's brochure. However, if multiple sites are involved, then an investigator's brochure is required to provide information about the drug and to ensure consistency in the conduct of the study at each site. The investigational brochure is developed in accordance with 21 CFR 312.55.

5.i. This section includes the drug substance and the structural formula of the drug.

5.ii. This section provides a summary of the toxicological and pharmacological effects of the drugs in animals and to humans if known.

5.iii. This section describes the pharmacokinetics and toxicological effects of the drug in animals and humans if known.

5.iv. This section provides a summary of known information related to safety and effectiveness in humans from prior clinical studies.

5.v. This section includes risks and side effects on the basis of prior experience with the drug or with similar drugs and provides precautions for drug monitoring and safety requirements in the use of the investigational drug.

#### 6.1. *Protocols*

6.1.a. *Objectives and Purpose* Describes an overview of the reasons and goals for the study—that is, to evaluate safety, biodistribution, pharmacology, efficacy, and the like.

6.1.b. *Personnel and Qualifications* This section lists and describes the individuals and the sites/organizations involved in executing the study providing evidence of their individual qualifications.

6.1.c. *Patient Selection and Number* A basis for the number and type of subjects to be recruited for the study are described. The source of recruitment must be mentioned particularly if it involves patient populations rather than controls. Justification of the number of subjects is also essential for ensuring that the appropriate numbers of subjects are studied without putting too many individuals at risk.

6.1.d. *Study Design* This section details the overall study design and is similar to what would be included in a full IRB submission including evaluative measures, “the type of control group that will be used and the methods to be used to minimize bias on the parts of the subjects, investigators and analysis” (21 CFR 312.23), and standardized procedures that will be used for data collection, data analysis, and

statistical analysis. It is important to state that safety is a primary component of the study and to design the protocol and standardized measures accordingly. Human studies must include safety as a critical evaluation measure.

6.1.e. *Determination of Dose, Maximum Dose, and Duration* The dose, route of administration, and maximum dose and individual dose exposure are described, usually based on animal data or prior human studies.

6.1.f. *Observations and Measures* In this section, the specific types of measures, both physiological and clinical (i.e., safety) are described. It is also important to describe what measures will be regarded as safe and which as adverse effects giving clear ranges for various measures.

6.1.g. *Clinical Procedures and Minimization of Risk* All clinical procedures are to be described with a focus on monitoring how risk will be minimized during the study. This might refer to existing animal or prior human experience and might also describe how adverse events will be managed.

## 7. *Chemistry, Manufacturing, and Control Information*

7.i. *Chemistry* This section describes the actual chemical composition of the drug including both active and inactive ingredients “to assure the proper identification, quality, purity and strength of the investigational drug.” The molecular weight and structure is also typically provided. In IND phase I studies, the emphasis in this section is on the identification of the raw materials that comprise the new drug.

### 7.ii. *Manufacturing and Control*

a. *Drug Substance* This is usually an extensive section that details where and how the drug is to be produced. Drug production should be according to good manufacturing practices and includes a description of the facilities and chemical reactions required to produce the material. The standard operating procedures for production do not have to specifically be included, but this section essentially follows them, and they can be included in the IND appendices to clarify the production process of the drug. A comprehensive description of the facilities and the personnel trained to oversee the drug production processes are included. If the drug is manufactured off-site, additional drug standard operating procedures and accountability measures are documented. The scope of the investigation will guide the amount of information to be submitted with the initial IND application. However, as the drug development proceeds and the study moves from a limited clinical investigation to a larger drug production and subject enrollment, the manufacturing and control procedures will be reported accordingly.

b. *Drug Product* This lists all the components of the drug product including active and inactive components, possible alternatives, and materials that do not appear in the final product but are used during manufacturing. Acceptable limits and analytical methods for assuring product stability, purity, and sterility are also included.

c. *Placebo Product* In studies that use a placebo in a controlled clinical investigation, a brief description of the manufacture and control is provided.

d. *Labeling* This section provides copies of all labels and labeling to be provided to each investigational site.

e. *Environmental Analysis Requirements* Describes whether an analysis of environmental issues is required.

## 8. *Pharmacology and Toxicology Information*

8.i. *Pharmacology and Drug Disposition* This section describes in detail the pharmacological properties of the investigational product as currently understood. This might be based primarily on animal studies but can also include previous human experience. This section is divided into each of these sections for clarification of the information provided to the FDA. In particular, data on nonprimate and primate species can be included under separate subheadings. Information provided should include the known pharmacology and biodistribution in animals and the presumed pharmacology in human subjects.

8.ii. *Toxicology* Similar to the pharmacology studies, this section can be expanded into subsections relating data from nonprimate and primate species with regard to toxicology studies.

a. Results on laboratory and clinical data as well as postmortem organ analysis are usually provided. It is often preferable to have two nonprimate species and one nonhuman primate species included in the analysis.

b. Each toxicology study that supports the safety of the investigator and data will be reviewed.

8.iii. *Statements of Compliance or Noncompliance* These statements of compliance indicate that the studies were conducted in compliance with good laboratory practice or provide a statement that provides the reasons or explanation for non-compliance with good laboratory practice (part 58).

9. *Previous Human Experience with Investigational Drug* In human studies, this section can be extremely brief. For drugs that have been used in humans for other purposes and are now being used for new indications, there may be substantial human experience. This information can be extremely valuable in establishing safety, pharmacology, and toxicology profiles of the study drug or test article.

9.i. This section provides detailed information that is relevant if the drug has been studied or marketed in the United States or in other countries. Comprehensive descriptive information must be provided about any clinical studies that have been conducted with the drug. This information may include published studies. Other information that may be relevant to the proposed investigation can be referenced in a bibliography or literature review.

9.ii. This section is needed if the test article is a combination of drugs previously investigated or marketed.

9.iii. If the drug has been marketed outside of the United States, this information should be described here, including whether the drug has been withdrawn from marketing for potential safety reasons.

10. *Additional Information* This section can include miscellaneous aspects of drugs including those that might have drug dependence and abuse potential or drugs that have radioactive elements. In pediatric studies, plans to assess safety and effectiveness in this population are described. Additional information that would aid in the evaluation of the drug safety can be included.

## 3.5 IND EXEMPTION STATUS

With these requirements in mind, it is also important to evaluate whether an IND is actually necessary. Many times in the clinical setting a particular pharmaceutical

product is used in an off-label manner. However, such a use in a research study may potentially require an IND. For example, if a drug with the specific indication for hypertension is used to help heart failure and an investigator wishes to test the use of the drug for heart failure, an IND might be required. However, the FDA and CFR regulations allow for an investigator to use a pharmaceutical product without an IND if the following conditions are met.

To begin with, the drug which is to be used must already be lawfully marketed in the United States. The investigational study must not be intended to support a new indication for use or to support a significant change in the advertising of the product. Importantly, the study should not involve the use of a different route of administration or dosage level or use in a patient population that significantly increases the risks associated with the use of the drug product. As with all studies, the study must be submitted, reviewed, and approved by the IRB and be conducted in accordance with standard regulations.

If these conditions are met, then an IND may not be required and the study can be performed under an exempt status. The advantage of an IND exemption is that it allows academic researchers who do not have an interest in altering the indications or marketing of a particular pharmaceutical to conduct a clinical investigation. Frequently, an investigator or clinician is interested in the pharmaceutical for a clinical or purely research perspective. In such cases, they may not need to utilize the full IND process.

It should also be clearly stated that there is no such thing as an “IND exemption” in the sense that there is no letter or form that can be obtained from the FDA. The FDA can always be contacted if there is a question as to whether an IND is required. Some institutions have initiated programs through their research offices or IRBs to help investigators determine whether an IND is required for a specific study product and may even provide a letter attesting that an IND is not required. However, for any investigator working in conjunction with a sponsor or a pharmaceutical company, or for all completely new materials, an IND is required.

### **3.6 INSTITUTIONAL REVIEW BOARD ISSUES**

IRB review is not substantially different for initial prospective studies of drugs in human subjects than in other nonsafety studies. However, the use of a new pharmaceutical agent typically requires more careful consideration due to the potential for a higher level of risk to patient safety and the additional institutional risk. It is important that the IRB can determine exactly how safety will be evaluated and how adverse effects will be managed. The specific descriptive language in consent forms can be difficult to develop since the drug has never been used in human subjects. Care must be taken to explain this lack of human experience, and it must be clear to the IRB and to the subject who gives consent to participate in the study that the principal aim of the study is to test the drug’s overall safety. It is important to state that this is the first time this drug has been administered to human subjects.

The timing of IRB approval and submission of the IND to the FDA can sometimes be challenging. The FDA requires a 30-day period to review an IND. During that period, the FDA can request additional information regarding the preclinical

physiology, pharmacology, and toxicology status of the pharmaceutical. In addition, the FDA may also request changes to the study design and protocol that has been submitted to the IRB for review. Thus, while IRB approval can be obtained concurrently with FDA evaluation of the IND, sometimes there is a substantial amount of interaction with the regulatory entities that require changes to protocols depending on the recommendations of both the IRB and FDA. In other words, if the original study design will evaluate safety data such as serum electrolytes at time 0 and 4 hours after drug administration, the FDA may request an additional blood draw at 24 hours. Approval to add this additional blood draw would have to be obtained as an amendment to the IRB protocol and may also require an additional revision to the consent form. Sometimes the IRB will not provide approval of the study until the FDA provides its “nonobjection” letter. Thus, it is sometimes helpful to know the FDA response prior to full submission to the IRB.

Any revisions that an IRB requires in the protocol or consent must also be submitted to the FDA as amendments. The amendment process is much different, though. For an amendment to be considered active, all that is required is IRB approval and submission to the FDA. Once these two requirements are met, the amendment can be considered to be in effect and future subjects can be studied according to the amended protocol.

However, if the investigator is conducting the study with a sponsor, the sponsor will act as the liaison between the investigator and the FDA. In clinical trials, the study cannot be initiated until the FDA, the IRB, and the sponsor have granted approval in writing for the study to begin.

### 3.7 STUDY DESIGN

All clinical studies must be performed under the current good manufacturing practices and good clinical practices guidelines (these practices are described by the guidelines produced through the International Conference on Harmonisation [3]). Further, they must be conducted with the requirements of appropriate ethical conduct as set by the Nuremberg Code [4], the Declaration of Helsinki [5], the 1962 Kefauver–Harris Amendments to the Food and Drug Act, and the Belmont Report [6]. Many of these guidelines are formalized in the Code of Federal Regulations [7].

The focus of safety studies is primarily to assess for all possible adverse physiological and clinical effects of the drug over the time period that the individual is exposed to the drug. The time period of exposure depends on the dose, dosing regimen, and half-life of the drug. For radiopharmaceuticals that require administration only on a single day, subjects are usually evaluated for only 1 or 2 days. Prolonged follow-up is not usually necessary since it is unlikely for the drug to have some effect days after it is in the subject’s body. On the other hand, drugs that are administered over many days require evaluation over a similarly long time period. It may even be necessary to evaluate subjects months or even a year later. Some of the issues related to study design are described below in more detail.

### 3.8 SUBJECT SELECTION

The subjects usually recruited for phase I studies of safety are healthy controls. This provides the best evaluation of safety in the human body. Rigorous prescreening consisting of serum and urinalysis along with comprehensive medical histories can assist in recruiting a healthy control group that is not being treated for chronic medical or psychiatric conditions. In phase I studies conducted with an IND, healthy controls should have normal physiological measures and clinical status, thus making abnormal changes related to the new drug easier to detect. It is also ideal that subjects are not taking any medications, including over-the-counter drugs, since these could potentially interfere with the evaluation of physiological effects of the new drug or may interfere with its pharmacology. Such drug interaction assessments are usually made after the initial safety assessment in controls.

There are a number of circumstances in which healthy controls are not appropriate in the initial safety assessment of a drug. When a drug is specific for a target population, measuring safety in healthy individuals may not accurately reflect the safety of the drug in the manner in which it will be used. For example, a drug that targets Alzheimer's disease (AD) pathophysiology (i.e., the development of amyloid plaque) may not make sense to study in healthy individuals since they do not have the plaque formation in the first place. Thus, the drug will bind very differently in healthy controls compared to AD patients. If the physiological half-life of the drug in controls is 12 hours, but in AD patients is 1 week, then the safety profiles in the different populations may also be vastly different.

Another reason that controls might not be appropriate would be if the drug is expected to have substantial risks but is developed for a population in which such risks may be warranted. The classic example here is of chemotherapy agents. These drugs, which often have substantial effects on blood counts or electrolytes, cannot be tested in healthy individuals since the drugs are too dangerous with no benefit either to them or to healthy controls. In these cases, the target population is studied, usually with a dose escalation design in which the first small group of three to five subjects is studied with a relatively low dose. If the lower dose does not result in substantial adverse effects, then the next group of subjects is studied at an incremental increase in dose. The drug dose continues to increase until specific safety criteria thresholds are reached. Thus, if hematological toxicity reaches level 3, then the drug is not given in any higher doses. After the initial safety assessment, then an efficacy trial can be performed at the highest, safe, dose.

One problem with studying safety in disease populations is that many of these individuals are regularly taking one or more drugs that may affect safety and pharmacology of the new drug. It is not always feasible or safe to withdraw all medication to wash out existing drugs prior to the initiation of a new drug regimen. For example, many patients with cancer take a variety of medications designed to help with their cancer, their overall health and mental well-being, or other related problems. Care must be taken to exclude patients with specific medications that are expected to interfere with the test drug. This may be determined by the evaluation of other related drugs or simply based on knowledge of the physiological processes associated with the different drugs.

**TABLE 1    Laboratory Values Assessed for Safety Studies**

---

|                                                                       |
|-----------------------------------------------------------------------|
| Cell blood count with differential (CBC)                              |
| Coagulation values (prothrombin time and partial thromboplastin time) |
| Prolactin and cortisol levels                                         |
| Electrolyte panel, including Blood Urea Nitrogen (BUN) and creatinine |
| Thyroid function tests, including Thyroid Stimulating Hormone (TSH)   |
| Follicle Stimulating Hormone (FSH) and Leutinizing Hormone (LH)       |
| Urinalysis, routine                                                   |
| Liver function tests                                                  |
| Cholesterol                                                           |
| Urine toxicology screen                                               |
| Autoimmune screening panel                                            |
| Pregnancy test                                                        |

---

**3.9    SAFETY MEASURES**

Safety measures usually include both laboratory as well as clinical assessment. Laboratory values are typically evaluated at baseline and then at regular intervals spanning the subject’s exposure to the test drug. For single-dose drugs, the evaluation may last only a couple of days while for drugs given over many days, the laboratory values must range over a similar time period. Table 1 shows typical laboratory values that are assessed in such studies. The most commonly used values include complete blood count, electrolytes, and liver function, but additional studies should be evaluated as determined through the results of preclinical animal studies. Values are compared to determine if substantial changes are associated with the administration of the test drug. If abnormalities are observed, then changes should be followed until they resolve. Usually, clear guidelines are established prior to the study that indicate what will be considered a drug-related change. In many cases, this requires an assessment of change rather than absolute values since a patient may experience a 10% drop in platelet count but still be in the normal range. This may ultimately lead to the need for evaluation of platelet counts prior to receiving the drug and if the counts are already low, limiting the use of the drug may be necessary.

In addition to laboratory values, physiological measures of heart rate, blood pressure, respiratory rate, and oxygen saturation may be useful in evaluating the safety of the test drug. Electrocardiography (EEG) is also important, especially when the drug may have specific cardiac effects. As with laboratory values, such measures might be made across the period during which the drug is administered. For a single-use drug such as a radiopharmaceutical imaging agent, physiological measures might be performed from a period immediately prior to drug administration up to one hour after administration. Subsequent measures might be made several hours later, 1 day, or even 2 days later. As with laboratory values, specific ranges of change might be described to clearly delineate what will and will not be considered a safety issue with the test drug.

A clinical evaluation including physical exam and report from the patient are also necessary at predefined intervals. The physical exam often includes evaluation of the skin (especially for an allergic reaction), hair, eyes, mucosa, heart, lungs, abdomen, and extremities. In addition, a neurological exam of strength and sensa-

tion may be useful. In addition to the psychological measures and laboratory values, the subjective experience of a study participant is also valuable. An ongoing dialog or direct questioning with the study participant should include whether they have the onset of any specific symptoms such as headache, dizziness, lightheadedness, gastrointestinal discomfort, nausea, chest or abdominal pain, weakness, and shortness of breath, sleep disturbance, or changes in appetite or mood.

It should also be noted that these extensive safety evaluations might be lessened after the initial experience with the test drug. Thus, after the initial safety evaluation, a more streamlined approach to safety measurement might be needed. In the example above of a single-dose radiopharmaceutical, eventual monitoring might only be required up to the first 10 or 20 min after administration.

### 3.10 MONITORING FOR ADVERSE EVENTS

Adverse events and serious adverse events have a very specific definition. Such events must be carefully evaluated and assessed to determine if the test drug is, in fact, related to the event. *Unexpected adverse drug experiences* are defined as any adverse drug experience, the specificity or severity of which is not consistent with the current investigator brochure; or, if an investigator brochure is not required or available, the specificity or severity of which is not consistent with the risk information described in the general investigational plan or elsewhere in the current application. Such adverse events may be minor unexpected laboratory changes or other clinical responses that are not anticipated. It is important that these adverse events be regarded and documented very specifically. For example, hepatic necrosis would be unexpected (by virtue of greater severity) if the investigator brochure only referred to elevated hepatic enzymes or hepatitis. It should also be clear that the term “unexpected” refers to an adverse drug experience that has not been previously observed rather than from the perspective of such experience not being anticipated from the pharmacological properties of the drug.

*Serious adverse drug experiences* are defined as any adverse drug experience occurring at any dose that results in any one of the following outcomes: Death, a life-threatening adverse drug experience, inpatient hospitalization or prolongation of existing hospitalization, a persistent or significant disability/incapacity, or a congenital anomaly/birth defect. A serious adverse drug experience may also be defined based upon appropriate medical judgment, as an event that may jeopardize the patient or subject and require medical or surgical intervention to prevent one of the outcomes listed above. Examples of such medical events include allergic bronchospasm requiring intensive treatment in an emergency room or at home. It is extremely important for the investigator to anticipate which effects are associated with a patient’s clinical condition and which effects can be associated with the study drug or the rigors of the study procedures.

Reporting of adverse events is critical to any preclinical safety study. The requirements include that the sponsor (investigator) notify the FDA and all participating investigators in a written safety report of: (a) any adverse experience associated with the use of the drug that is both serious and unexpected or (b) any finding from tests in laboratory animals that suggests a significant risk for human subjects including reports of mutagenicity, teratogenicity, or carcinogenicity. Each notification

should be made as soon as possible and in no event later than 15 calendar days after the sponsor's initial receipt of the information and should be prominently identified as an "IND safety report."

The sponsor must also notify the FDA by telephone or by facsimile transmission of any unexpected fatal or life-threatening experience associated with the use of the drug as soon as possible but no later than 7 calendar days after the sponsor's initial receipt of the information. Each telephone call or facsimile transmission to the FDA should be transmitted to the FDA new drug review division in the Center for Drug Evaluation and Research or the product review division in the Center for Biologics Evaluation and Research that has responsibility for review of the IND.

### **3.11 PREPARING FOR PHASE II STUDIES AND ADDITIONAL SAFETY EVALUATION**

Once the safety, pharmacology, and toxicology data is available from the initial human studies, this information is reported to the FDA as part of the next step to begin phase II studies. The phase II study protocols can be submitted under the same IND as amendments. The data from the phase I studies is typically included as new information that helps support the protocol to study the use of the drug in more specific patient populations and also in an expanded sample size.

The phase II trials will typically continue to evaluate safety, but on a lesser scale, and with more specific evaluations. Thus, if in the phase I study, electrolytes, liver function, cholesterol, and complete blood counts were evaluated with only the liver function studies showing any change, the phase II study may only include evaluation of liver function tests. If no laboratory abnormalities are observed in the phase I study, then no additional laboratory values may be necessary. Whatever changes to the safety evaluation of the drug in the phase II studies, these will ultimately have to be acceptable to the FDA and the IRB review committees.

### **3.12 CONCLUSIONS**

Overall, the process of moving studies from the animal preclinical studies to human use studies is complex, but following the regulatory guidelines for the FDA IND process, the IRB, good manufacturing practices, and good clinical practices is imperative and relatively straightforward. The Code of Federal Regulations specifies the requirements for these studies and can be obtained in book or online formats. By following these requirements, the ability to propose and execute phase I studies can be readily performed by both industry and academic sponsors and investigators.

## 4.1 BACKGROUND

### 4.1.1 Reasons for Drug Attrition

The reasons for drug attrition have evolved over the years; over the last decade, however, lack of safety (combining both nonclinical and clinical) remains the major cause of attrition during clinical development, accounting for approximately 35–40% of all drug discontinuation (see Table 1) [1–3]. More worrying is the fact that over the last few years despite a widened/increased testing battery there is no clear trend toward a reduction of the attrition due to safety reasons.

In this section, a brief summary of the nature, frequency, and consequences of adverse drug reactions (ADRs) in two clinical situations is presented. They are ADRs experienced by healthy volunteers and patients participating in clinical studies with potential new medical entities (NMEs) and those experienced by patients prescribed licensed medicines. A review of these two situations points to areas of success with the current practices for nonclinical safety testing but also identifies areas where further research might lead to new or better nonclinical safety testing.

Prior to reviewing the literature, it is worth considering some frequently used definitions. Differences can be found in the literature in how the concepts are defined. We have decided here to use the definitions published by the International Conference on Harmonisation (ICH) [4, 5], as those concepts are used (direct or with some adaptations) by many pharmaceutical companies and are recognized by regulatory agencies.

**TABLE 1 Evolution of Reasons for Drug Discontinuation in Clinical Development**

| Reasons                  | Percentage [2] | Percentage [3] | Percentage [1] |
|--------------------------|----------------|----------------|----------------|
| Portfolio considerations | 23             | 22             | 20             |
| Clinical efficacy        | 22             | 23             | 26             |
| Clinical safety          | 12             | 20             | 14             |
| Toxicology <sup>a</sup>  | 23             | 19             | 21             |
| Other <sup>b</sup>       | 20             | 16             | 19             |

<sup>a</sup>Includes general/safety pharmacology.

<sup>b</sup>Includes reasons such as clinical pharmacokinetics/bioavailability, nonclinical efficacy, nonclinical pharmacokinetics/bioavailability, formulation, patent, legal, or commercial, regulatory. Overall, safety reasons accounted for up to ~40% of all drug discontinuation.

#### 4.1.2 Frequently Used Definitions

An *adverse event* (AE) can be defined as any unfavorable and unintended sign (including an abnormal laboratory finding), symptom, or disease temporally associated with the use of a medicinal product, whether or not considered related to the medicinal product.

An *adverse drug reaction* (ADR) is an adverse event where a causal relationship between the AE and the medicinal product is at least a reasonable possibility.

*Serious adverse events/adverse drug reactions* are defined as those that might be significant enough that if related to the medicinal product lead to important changes in the way the medicinal product is developed or used. This is particularly true for reactions that in their most severe forms threaten life or function.

The *severity*, which is the quantification of the reactions/symptoms (mild, moderate, severe), is used to describe grades of discomfort. One often used definition has been suggested by Tangrea et al. [6]: (i) mild, slightly bothersome, relieved with symptomatic treatment; (ii) moderate, bothersome, interferes with daily activities, only partially relieved with symptomatic treatment; and (iii) severe, prevents regular activities, not relieved with symptomatic treatment. A single serious ADR is always significant and very often has a high impact, its impact depending on when in the development process it occurs, and on the perceived benefit–risk profile of the NME. It can lead to the discontinuation of a drug in development, a significant limitation in the use of a drug (precaution, contraindication), or even to the withdrawal of the drug from the marketplace. A nonserious ADR can be more or less severe in its intensity, and its impact will depend upon its frequency and intensity. Nonserious ADRs can lead to a high degree of noncompliance, if they are perceived as annoying even if the symptoms they cause are not medically serious.

Pharmacological classification can divide ADRs in humans into five types (Table 2). Type A reactions (approx. 75% of all ADRs belong to this category) result from an exaggeration of the drug's normal pharmacological action when given in the usual therapeutic dose; they are normally dose dependent. Conventional pharmacology studies, combining primary, secondary, and safety pharmacology studies, can therefore reasonably be expected to predict type A ADRs. Functional toxicological measurements may predict type C ADRs. Conventional toxicology studies address type D ADRs, whereas prediction of type B responses (traditionally deemed as not predictable) occurring only in “susceptible” individuals require a more extensive

**TABLE 2 Classification of Adverse Drug Reactions (ADRs) in Humans**

|        |                                                                              |                                                           |
|--------|------------------------------------------------------------------------------|-----------------------------------------------------------|
| Type A | Dose-dependent; predictable from primary, secondary, and safety pharmacology | Main cause of ADRs (~75%), rarely lethal                  |
| Type B | Idiosyncratic response, not predictable, not dose related, usually serious   | Responsible for ~25% of ADRs, but majority of lethal ones |
| Type C | Long-term adaptive changes                                                   | Commonly occurs with some classes of drug                 |
| Type D | Delayed effects, e.g., carcinogenicity, teratogenicity                       | Low incidence                                             |
| Type E | Rebound effects following discontinuation of therapy                         | Commonly occurs with some classes of drug                 |

Source: Adapted from Redfern et al. [7].

nonclinical and clinical evaluation to identify individuals at risk. The increased possibility to identify genetic risk factors will hopefully lead to a better understanding of this type of reactions [8]. The type E ADRs are rarely investigated nonclinically using functional measurements unless there is cause for concern.

#### 4.1.3 Data Availability

The first human studies (phase I and early phase II) are generally very safe as a carefully selected population limit the potential for adverse effects (Table 3). In fact, molecules with a significant potential to generate serious ADRs are probably never given to healthy volunteers and are only given to patients where a significant benefit might be expected (e.g., refractory cancer patients) only with great care. These studies are to be conducted under frequent and extensive surveillance for the emergence of potentially worrisome ADRs. While AEs occur in phase I/healthy volunteer studies, they are generally more related to the required changes in lifestyle (e.g., caffeine deprivation) and the experimental procedures (e.g., needle puncture) than to the drugs [9, 10]. Nonclinical safety testing probably contributes significantly to the maintenance of this good track record; this is supported by published reports showing that single-dose nonclinical safety studies could overall accurately predict the clinical outcome [11–13]. The common ADRs observed with a high incidence (10–30%) during this early phase is linked to the gastrointestinal (nausea) and central nervous (headache) systems. In addition, an ADR specific to the NME under investigation that is pharmacologically mediated can be detected at this stage.

Early phase II studies are usually so-called dose-finding studies in selected patients and give the first indication of what type A reactions are to be expected in the targeted patient population. During continued clinical development as the population of exposed patients increase both in numbers and diversity, an increasing number of patients report AEs, with a wide variation in the type, frequency, and severity. Nonserious ADRs are often mechanism, drug class, or disease related (Table 4). Such ADRs limit the utility of an NME by restricting its use to those patients who either do not experience or can tolerate the ADRs, and they do not usually pose a “safety” issue. Serious ADRs tend to be present only at low frequencies. Pharmacological mechanism related to serious ADRs can occur in sensitive individuals, those with unusual kinetics, and in the presence of kinetic or occasion-

**TABLE 3 Risks to Healthy Volunteers in Phase I Clinical Research Trials**

| Year    | Number of Volunteers | Moderately Severe AE | Potentially Life-threatening AE | Deaths | References |

**TABLE 4 Major Causes of Acute Functional Adverse Drug Reactions**

| Acute Adverse Drug Reaction                                                            | Example                                                                                                                             |
|----------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------|
| Augmented (“supratherapeutic”) effect of interaction with the primary molecular target | Pronounced bradycardia with a $\beta$ blocker; pronounced hypotension with an angiotensin II receptor antagonist                    |
| Interaction with the primary molecular target present in nontarget tissues             | Sedation caused by anti-histamines                                                                                                  |
| Interactions with secondary molecular targets                                          | Interactions with the hERG cardiac channel leading to QT interval prolongation (e.g., some antipsychotics and antihistamines drugs) |
| Nonspecific effects                                                                    |                                                                                                                                     |
| Pharmacologically active metabolites                                                   | Inhibition of the hERG channel transcription by desmethyamiodarone, metabolite of amiodarone                                        |

Source: Adapted from Redfern et al. [7].

ally dynamic drug interactions. In principle, such ADRs might be predictable from safety pharmacology testing, although it should be acknowledged that safety pharmacology testing is usually conducted in young adult healthy animals under conditions that may be suboptimal to detect such effects. Occasional nonpharmacological (type B) serious ADRs occur; these can be induced by direct chemical toxicity, hypersensitivity or immunological mechanisms. Serious ADRs always limit the use of an NME by requiring warnings, precautions, and contraindications or preclude regulatory approval (depending on the frequency, seriousness, and perceived benefit–risk balance of the NME). In addition to preventing the development of NMEs likely to induce certain types of serious ADRs, a key contribution that can be made by nonclinical safety testing is in the elucidation of the mechanisms responsible for these ADRs. Once the mechanism responsible for the ADR is known, it becomes possible to prepare soundly argued precautions and contraindications.

When medicines are on the market, the actual incidence of serious ADRs is difficult to judge. The main source today for judging the safety profile of a drug on the market comes from spontaneous reports (from health professionals and in some countries patients) to health authorities. Numerous publications discuss the limitations of spontaneous reporting systems because of, for example, the underreporting of serious ADRs and the difficulty to assess the frequency of a certain ADR due to lack of exposure data in such systems [21–23]. However, based on these data and on studies looking at ADRs in a defined population such as hospitalized patients it is clear that serious ADRs occur with sufficient frequency to be a serious concern [24]. One authoritative review concludes that between 1 in 30 and 1 in 60 physician consultations are caused by ADRs (representing 1 in 30–40 patients [25]). The same review concludes that 4–6% of hospital admissions could be the result of ADRs. Although there is debate about the number of deaths caused by ADRs, the figure of around 100,000 deaths per year in the United States is often quoted [7, 24]. The majority of the above references are about serious ADRs that could be predicted or avoided, only a subset are idiosyncratic [26, 27].

The frequency of a serious ADR can be very low (e.g., 0.25–1.0 cases of rhabdomyolysis per 10,000 patients treated with a statin [28]; however, when millions of patients are under treatment, this can generate substantial morbidity. Serious ADRs may also be due to clinical error (e.g., misprescribing contraindicated drugs) or to

patient self-medication error—especially in the era of mass media communication and information. Independent of the cause of a certain serious ADR, it is important to investigate the pharmacological mechanisms driving these events. For example, the elucidation of the connection between drug-induced Torsades de Pointes, QT interval prolongation, and hERG potassium channel blockade has been considered as a major advance in this area, leading to avoidance of NMEs that have the potential to cause QT interval prolongation due to cardiac arrhythmias and sudden death by the rapid development of nonclinical in vitro screening assays of medium to high throughput capabilities [29].

To better understand the main causes for ADR-related drug withdrawals, medicines withdrawn from either the United States or worldwide markets were reviewed [25, 30]. The principal reasons, presented in Table 5, highlighted the fact that several of these toxicities fall into the remit of nonclinical safety testing, with the usual suspects ranking top of the list such as toxicities related to the cardiovascular, hepatic, and nervous systems. The prominence of arrhythmias in Stephens' review [25] probably reflects the recent interest in Torsades de Pointes type of arrhythmias.

Limitations of the data set are now considered. In most cases, hard evidence regarding the predictive value of nonclinical testing is not readily available in the public domain [12, 31–38]. When an NME has a serious negative effect in a nonclinical test, there may be limited information in the public domain, as the result may have precluded clinical development, and therefore the information was never published. If there has been no effect in a nonclinical test, and likewise no effect on the corresponding variable in humans, these negative data may have been deemed not to be of general interest. Thus there is a huge amount of unpublished information that might be of value for better understanding certain types of adverse effects. In addition, the scientific and medical community is left with examples of side effects in humans that were not identified during nonclinical assessment.

One publication attempted to explore the predictive value of safety/general pharmacology assays to humans [12]. Some significant correlations were reported. For example, decreased locomotor activity in rodents was positively correlated with dizziness and sleepiness in humans; decreased intestinal transit in rodents was correlated with constipation and anorexia in humans; decreased urinary and sodium excretions in the rat were correlated with edema in humans; decreased blood pressure in dogs was positively correlated to flushes, dizziness, headache, and malaise in humans; increased heart rate in dogs was correlated to palpitation; and increased blood flow in dogs was correlated to flushes and headache. Rather more bizarrely,

**TABLE 5 Evolution of Main Safety Reasons for Drug Withdrawal over Last 40 Years**

| Worldwide Withdrawal<br>(121 medicines) [30] | Percentage | U.S. Withdrawal (95 medicines) [25]                     | Percentage |
|----------------------------------------------|------------|---------------------------------------------------------|------------|
| Hepatic toxicity                             | 26         | Cardiovascular toxicity incl. arrhythmias               | 19 (12)    |
| Hematological toxicity                       | 10         | Neuropsychiatric effects/abuse liability/<br>dependency | 12         |
| Cardiovascular toxicity                      | 9          | Hepatic toxicity                                        | 9          |
| Dermatological effects                       | 6          | Bone marrow toxicity                                    | 7          |
| Carcinogenicity issues                       | 6          | Allergic reactions                                      | 6          |

the findings of analgesia, decreased body temperature, and anticonvulsive activity in rodents were each correlated with thirst in humans; the finding of pressure reflex to vagal stimulation was correlated with sleepiness, malaise, and thirst in humans. This indicates the limitations of such methods and the fact that correlations between events do not necessarily imply causal relationships.

There are, however, numerous examples of drugs that cause AEs in humans, which would be detectable in nonclinical safety evaluation assays. Some notable examples of individual drugs showing untoward effects in nonclinical studies that are correlated in a quantitative sense with AEs in humans have been reported [7]. For example, (a) the sedative effects of clonidine in various animal species and humans; (b) the propensity of cisapride to prolong ventricular repolarization; (c) the respiratory depressant effects of morphine; (d) the nephrotoxic effect of cyclosporine; and (e) the gastrointestinal effects of erythromycin. These examples illustrated the very good agreement of effects across all species tested and across a narrow range of doses, concentrations, or exposures.

However, there are areas that should be carefully considered to ensure optimization of the assays and ultimately increase the predictive value of nonclinical testing. These include, but are not limited to: (a) species differences in the expression or functionality of the molecular target mediating the adverse effects; (b) differences in pharmacokinetic properties between test species and humans; (c) sensitivity of the test system; (d) optimization of the test conditions; (e) appropriately statistically powered study designs; (f) appropriate timing of functional measurements in relation to the time of maximal effect, maximal exposure, and/or maximal tissue concentration; (g) delayed/chronic effects of parent drug and/or metabolites; (h) difficulty of detection in animals in standard nonclinical safety studies (e.g., arrhythmia, headache); and (i) assessment of a suboptimal surrogate endpoint that predict with some degree of confidence the clinical outcome (e.g., QT/QTc interval prolongation as a surrogate of TdP). Overall careful consideration should be paid to the sensitivity, specificity, and overall predictivity of nonclinical assays prior to using them for building an integrated risk assessment.

## **4.2 ASSESSMENT OF PREDICTIVE VALUE OF NONCLINICAL SAFETY TESTING TO HUMANS BY ORGAN SYSTEMS**

### **4.2.1 Cardiovascular System**

Over the last few years, data have been generated to assess the value of nonclinical tests to predict the potential of NMEs to prolong the duration of the QT interval of the electrocardiogram and ultimately the proarrhythmic potential of these drugs. The published data converged in that an integrated risk assessment based upon data on the potency against hERG, an *in vivo* repolarization assay, and if necessary an *in vitro* action potential assay are in a qualitative sense predictive of the clinical outcome [39–42]. These data have been further supported by publications suggesting that a 30-fold margin between the highest free plasma concentration of a drug in clinical use ( $C_{\max}$ ) and the concentration inhibiting by 50% the hERG current ( $IC_{50}$ ) could be adequate to ensure an acceptable degree of safety from arrhythmogenesis with a low risk of obtaining false positives [43–45]. Most recently, Wallis et

al. [46] have reported that, based on a data set of 19 compounds, combining data from the hERG assay and the in vivo QT repolarization assay predicted in 90% of cases the clinical outcome of the “thorough QT/QTc study.” In addition, the author suggested that a robust electrocardiographic monitoring during the phase I clinical trials combined with the preclinical data predicted in all cases the outcome of the thorough QT/QTc study. These data support the view that a dedicated thorough QT/QTc study as required per ICH E14 [47] does not add any additional value to the integrated QT risk assessment. These preliminary data would require to be strengthened with a larger data set. Such initiative is ongoing under the auspice of the ILSI-Health and Environmental Sciences Institute (HESI). Along the same lines, in a review of 25 anticancer drugs, Schein et al. [48] showed that based on general clinical assessment and pathology rather than on functional changes both primates and dogs predicted cardiovascular toxicities in 90% of cases in which the toxicities were observed in humans (Table 6). The authors suggested that physiological measurement monitoring could have further improved the overall predictivity to the clinical outcome. Furthermore, Olson et al. [13] showed good concordance between cardiovascular findings in dogs and humans. The translation was less robust between humans and rodents possibly due to the technical challenges associated with monitoring of cardiovascular function in rodents. Furthermore, based on a data set of 88 drugs, Igarashi et al. [12] showed good concordance between some pharmacological findings in animal models and their associated clinical adverse drug reactions (e.g., blood pressure reduction versus flushes, dizziness, headache, malaise; increase in heart rate versus palpitation and increase in blood flow versus flushes and headache) [12].

**TABLE 6 Species and Assays Predictive Value of Humans' Safety Endpoints**

| Safety Endpoint | Specie and/or Assay | Number of Compound | Sensitivity (%) | Specificity (%) | Predictivity (%) | References |

<sup>a</sup>Within twofold the free therapeutic plasma concentration. (Values in parentheses indicate) number of compounds showing toxicity in humans. The sensitivity was determined as the ratio of true positive (true positive/false negative). A high sensitivity reflects a low level of false positives. The specificity was determined as the ratio of true negative/true negative plus false positive. A high specificity reflects a low level of false negatives. The predictivity was determined as the ratio of true positive plus true negative/the total number of compounds evaluated.

#### 4.2.2 Nervous System

Most of the adverse drug effects relating to the nervous system impact on the quality of life rather than the risk to life (e.g., lethargy, anorexia, insomnia, personality changes, nausea). There are, however, some serious life-threatening adverse effects involving the nervous system (e.g., loss of consciousness and convulsions). Some of them reflect the fact that the central nervous system (CNS) controls the other two vital organ systems for that CNS impairment could be fatal (e.g., decreased respira-

tory drive leading to respiratory arrest; decreased sympathetic outflow leading to cardiovascular collapse). The nervous system adjusts the function of the other acutely vital organ systems according to current and long-term requirements of the organism. Therefore, drug effects on cardiovascular and respiratory functions can be mediated via a direct action within the CNS or via sensory nerve endings located in the cardiovascular and pulmonary systems. Some CNS adverse effects can be indirectly life threatening. For example, drowsiness, cognitive impairment, motor coordination, dizziness, involuntary movement, and visual or auditory disturbances can all affect driving performance; moreover, depression or personality changes can lead to suicidal tendencies. As an illustration, the number of deaths in the United States between 1984 and 1996 in patients receiving terfenadine was 396, a small proportion of which were attributed to sudden death resulting from Torsades de Pointes. This overall low incidence of fatalities is nevertheless a significant improvement over the first generation of antihistamine drugs that have been suspected to be responsible for significant fatalities in car accidents resulting from their sedative effects [49, 50]. General pharmacological tests for effects on the nervous system are usually observational studies of rodent general activity or multidimensional functional assays of motor activity [51–53]. For a series of 84 new drugs (excluding anticancer agents) studied in Japan, an evaluation of their capacity to predict adverse reactions in humans showed a general nonspecific correlation. For example, decreased locomotor activity in rodents was positively correlated with dizziness and sleepiness in humans [12]. A degree of overprediction was reported, particularly from studies that used high doses. Similarly, in the study of 45 miscellaneous drugs by Fletcher [54], high-dose effects such as ataxia and convulsions in animals did not occur in humans, and subjective effects such as dizziness, headache, dry mouth and sweating in humans were not predicted by animal studies. The correlation was stronger for other effects on the central nervous system.

Where effects on the central nervous system have been assessed in conventional toxicity studies using both clinical monitoring and histopathological examination of the brain and nervous tissue, a reasonable degree of concordance has been shown. Evaluation of the effects of up to 25 diverse anticancer drugs in dogs, monkeys, and humans showed a reasonable degree of concordance (nearly 40%) in neurological and neuromuscular toxic effects ([48]; Table 6). Dogs and monkeys had similar predictive values and high doses were needed to achieve the best correlation, whereas specific symptoms correlated poorly. The earlier study of 21 anticancer drugs by Owens indicated only a moderate correlation between neurotoxic effects in humans and animals [55]. The correlation was strong for alkylating agents but less so for other classes of drugs studied. Interestingly, the study of 150 miscellaneous drugs by Olson and colleagues [13, 56] showed that, overall, the nonrodent data were better correlated with adverse neurological effects in humans than the rodent data. A key neurological safety liability is the potential for drug-induced seizure (see Table 7); in this regard it is encouraging to note that the proconvulsive potential of marketed drugs was detected in a zebrafish larvae assay with a significant level of sensitivity, specificity, and overall predictivity [58] (Table 6).

So, while the data indicate poor prediction of subjective neurological effects, the information on the significant toxicities of anticancer drugs indicates that the conventional approach using histopathological examination detects potentially serious neurotoxic effects.

**TABLE 7 Incidence of Adverse Drug Reactions Related to Each of the Major Physiological Functions**

| Physiological System                | Percentage of Compounds Reporting ADR with Incidence >3% (%) |
|-------------------------------------|--------------------------------------------------------------|
| Cardiovascular                      | 35                                                           |
| Arrhythmias                         | 3                                                            |
| Central & peripheral nervous system | 56                                                           |
| Seizure                             | 3                                                            |
| Gastrointestinal                    | 67                                                           |
| Motility                            | 44                                                           |
| Hepatic                             | 11                                                           |
| Immune                              | 0                                                            |
| Renal & urinary                     | 17                                                           |
| Respiratory                         | 32                                                           |

*Note:* Data extracted from BioPrint [57]. Based on a set of 1138 drugs annotated for human ADRs. Not all compound-ADR annotations include incidence data; figures have been corrected to account for missing incidence data.

Certain types of side effects to the CNS (e.g., agitation, hallucinations, headache) are reported with some medicines. Such effects are not easily identifiable in animal studies.

**Special Senses** Relatively few instances of visual, auditory, or vestibular disturbances are reported in early clinical studies with new drugs. As such, there is a paucity of data comparing effects on these functions between laboratory animals and humans. However, ophthalmoscopic examination is usually performed in toxicity studies and is routinely accompanied by histopathological examination of the eye, prior to dosing of humans with a new drug. Consequently, it is probable that any agent that provokes severe ocular damage in animals after relatively short periods of dosing would not progress to clinical studies. Moreover, agents that have potent cataractogenic properties or that are severely toxic to the retina would be identified in relatively short, repeat-dose studies. Emerging data suggest that performing an optomotor assay in either the zebrafish [59] or in rodents [60] could detect drug-induced impairment of visual function with a reasonable sensitivity and specificity toward the clinical outcome. Specific tests of auditory function are seldom done routinely. But careful clinical observation of animal comportment probably eliminates agents that produce acute and severe auditory or vestibular damage.

#### 4.2.3 Respiratory System

A large body of data has accumulated on experimental methodology for examination of the effects of environmental and occupational chemicals on the respiratory tract. This is because inhalation is a primary mode of human exposure to foreign materials [61]. However, for inhaled drugs, there is limited information available in the public domain; part of the difficulty is that any significant respiratory side effects would be considered as unacceptable and consequently not progressed into humans. So we are probably left only with the circumstance of having taken a compound into humans, seeing an adverse effect, and then attempting to find suitable animal

models that could have predicted it in order to screen against it in the future. Some companies working in this area have expressed concerns over the ability to predict potential for “cough” reactions or bronchospasm. The effects of drugs are evaluated preclinically in dedicated safety pharmacology studies [62]; until the implementation of the ICHS7A [62], this was usually done alongside cardiovascular assessment in anesthetized dogs. In the comparison of 104 investigational new drugs by Igarashi and colleagues [12] in which this approach was used, respiratory disturbance was not frequently reported in humans. However, when respiratory related ADRs were reported in humans, these were not predicted by safety pharmacology testing.

In toxicity studies, effects on respiration are usually evaluated by clinical observation and histopathology of lungs and air passages, although it is usually recognized that clinical observation are “inappropriate to assess drug effects on respiratory function” [62]. In the study of 45 drugs by Fletcher [54], both toxicology and pharmacology animal studies overpredicted respiratory effects in humans. Similarly, Schein and colleagues [48] noted that this form of screening in nonrodents predicted respiratory signs or respiratory pathology in four out of five cases, but with a high percentage of false positives (Table 6).

Nowadays respiratory function is usually assessed in rodents using whole-body plethysmography, which provides an indication of drug effect on ventilatory parameters. Dennis Murphy [63] has argued that drug effect on both ventilatory parameters and lung mechanics should be assessed prior to first administration to humans since changes in lung mechanic (e.g., bronchoconstriction) may remain undetected/unpredicted using whole-body plethysmography methods.

#### 4.2.4 Gastrointestinal System

Clinical gastrointestinal adverse reactions account for ~18% of total ADRs, and 20–40% in hospitalised patients. There is a high degree of underreporting [64]. Diarrhea alone accounts for about 7% of all drug ADRs. For example, more than 700 drugs are implicated in causing diarrhea [65]. The majority are functional in nature (nausea, vomiting, dyspepsia, abdominal cramps, and diarrhea or constipation) and fewer are pathological (e.g., ulceration) or enhanced susceptibility to infection (e.g., pseudomembranous colitis) [66]. Overall, ~80% of gastrointestinal (GI) ADRs are predictable type A pharmacological reactions [67], that is, predictable from the primary and/or secondary pharmacological targets. From 1960 to 1999 two drugs withdrawn due to GI toxicity—Indoprofen and Pirprofen nonsteroidal anti-inflammatory drugs (NSAIDs) [30]. NSAID use in the United States alone is estimated to be responsible for over 100,000 hospitalisations and 17,000 deaths per year [68]. More recently, a prospective analysis of 18,820 United Kingdom patients; 17 deaths attributed to GI ADRs; most attributed to NSAID use [69].

The review of safety pharmacology studies performed in Japan on 88 noncancer drugs showed a good correlation between rodent intestinal transport and general adverse effects such as anorexia and constipation in humans [12]. In the review of conventional toxicology studies that included histopathology of the gastrointestinal tract, Olson and colleagues [13] showed good concordance between gastrointestinal effects in animals and humans, particularly for nonsteroidal anti-inflammatory drugs, anti-infective, and anticancer agents. In that review, large animal data were

a better predictor than data obtained from rodents. The data also showed good correlation between animal toxicology studies and humans for a diverse set of 45 drugs [47] and may be a link to the fact that large number of drugs are associated with gastrointestinal ADRs, thus increasing the sensitivity of detection level.

The rodent, dog, monkey, and human GI toxicity data also showed a strong correlation in the study of 21 anticancer drugs by Owens [55]. Surprisingly, in the study of 25 anticancer drugs by Schein [48], the dog was superior to the monkey as a predictor of adverse GI effects in humans (Table 6). For example, monkeys were remarkably resistant to vomiting, an adverse event that was observed in humans with 21 of the 25 compounds. Gastrointestinal tract toxicity was a significant contributor to the remarkably good quantitative correlation of toxicity across species based on dose/body surface area for the 18 anticancer drugs studies by Freireich and colleagues [70]. This is not surprising since oncology drugs tend to be used at maximum tolerated doses at which gastrointestinal side effects are quite common.

It has been suggested that the GI tract of dogs is highly physiologically similar to that of humans in terms of motility patterns, gastric emptying, and pH, particularly in the fasted state [71]. This observation, coupled with the ability to use a formulation similar to that used in humans, makes the canine GI tract a most relevant model.

#### **4.2.5 Hepatic System**

Hepatotoxicity is an important adverse drug effect and a relatively common reason for termination of the development of an NME [13, 73]. At present, drug-induced hepatic injury accounts for more than 50% of cases of acute liver failure in the United States [74]. In conventional nonclinical studies of toxicity, the cornerstone of the assessment of hepatotoxic potential is measurement of circulating liver enzymes and hepatic histopathology [75]. A review of 38 chemicals, 24 of which were drugs that produce hepatic toxicity in humans, showed a concordance of 80% with findings in conventional toxicity studies [76]. Hepatic toxicity was not under-predicted in the study of 25 anticancer drugs in dogs and monkeys that used conventional hepatic enzyme measurements and histopathology ([48]; Table 6). The study of anticancer drugs by Owens [55] showed a similar good correlation.

Conversely, the study of data on 150 drugs exhibiting human toxicities showed that the concordance between hepatotoxicity found in animal studies and that observed in clinical practice was little more than 50% [13]. This larger study undoubtedly included agents that developed idiosyncratic responses, which are not usually detected in early clinical trials because of their rarity. This is a significant problem—in recent years there have been notable examples of hepatic toxicity of a poorly understood, idiosyncratic nature that have caused the withdrawal of marketed drugs despite extensive and essentially negative nonclinical testing and large clinical trials. The thiazolidinedione troglitazone, an antidiabetic drug, was associated with serious hepatic injury in patients despite its lack of hepatic toxicity in preclinical studies [77]. Another example is bromfenac, a nonsteroidal anti-inflammatory drug [74]. Hepatic failure also occurred in clinical trials with the nucleoside analog fialuridine as a result of mitochondrial disturbance and steatosis. Despite long-term treatment of monkeys, dogs, and rats with fialuridine, the only hepatic effects observed were

increases in apoptosis and nuclear atypia in rats [77]. Ximelagatran was found to cause liver enzyme elevations such as alanine aminotransferase (ALT) in 7.9% of patients treated in long-term studies (>35 days). Routine nonclinical animal data did not show any liver enzyme elevations. Ximelagatran and its metabolites were tested in an extensive study program including cell viability, mitochondrial function, formation of reactive metabolites, and reactive oxygen species without finding an explanation to the mechanism behind the ALT elevation [78].

It is probable that most NMEs that produce severe hepatotoxicity in animals are not tested in humans, so that the true level of concordance is likely to remain obscure. However, overall, the data seem sufficiently robust to conclude that overt liver damage observed in animal toxicity studies indicates potential risk of hepatic toxicity in humans. This underlines the prudence of a critical histopathological examination of the liver tissue in nonclinical studies and careful patient monitoring in response to any hepatic alerts from animal studies.

#### **4.2.6 Renal and Urinary System**

Renal toxicity is assessed by conventional histopathology, measurement of blood urea and electrolytes, and examination of urine volume and the sediment it contains. Concordance in the database of 150 drugs reviewed by Olsen and colleagues [13] was fair. A good correlation was noted among the 21 anticancer drugs reviewed by Owens [55], with rodents and dogs performing equally well. However, in a review of 45 drugs, renal toxicity was correctly predicted by animal studies in 3 instances but overpredicted in 22 others [54]. Similarly, the study of 25 anticancer drugs in dogs or primates correctly predicted renal toxicity in 9 cases, underpredicted in 1, and overpredicted in 14 [48].

#### **4.2.7 Endocrine System**

Endocrine changes during nonclinical studies are routinely assessed only by histological examination of endocrine organs, unless there are particular reasons to suspect endocrine effects. Olson and colleagues [13] noted only moderate concordance (60%) between animals and humans. As might be expected from the way in which the endocrine system responds to stimuli, these effects were not common in humans and generally occurred after phase I studies. The review by Fletcher [54] indicated that endocrine findings in nonclinical studies significantly overpredict effects in humans. Endocrine effects, particularly those involving the adrenal gland, are commonly reported in toxicity studies [79]. These findings often represent adaptive alterations to repeated doses of drugs and usually manifest as changes in glandular weight and cellular atrophy or hypertrophy. These changes might not have significant implications for human safety in single-dose studies, but they characterize possible endocrine effects that need to be assessed in clinical trials.

#### **4.2.8 Hemopoietic System**

Hemopoiesis is routinely assessed by examination of peripheral blood, bone marrow smears, and histopathology of the blood-forming and lymphoid organs. Theus and Zbinden [80] reviewed prior industry practice for the assessment of coagulation in

1984 and found substantial deficiencies. The screening practice that they proposed for animal studies is similar to that used in humans and has now been almost universally adopted for pharmaceutical testing.

There is substantial data on the concordance of adverse effects on hemopoietic tissue due to anticancer and antimetabolic drugs between animals and humans. The evidence indicates good correlation for both rodents and humans and dogs and humans for myelotoxicity, although the particular cell series affected sometimes differs [48]. Thrombocytopenias were correctly predicted for 13 of 18 anticancer drugs that produced this toxicity in humans. Moreover, in the series of 18 anticancer drugs studied by Freireich and colleagues, hemopoietic toxicity was one of the most significant contributors to the remarkably good quantitative correlation across species based on dose/body surface area [70].

A reasonable correlation between animals and humans was also noted for decreases in white blood cell counts in the study of 139 drugs by the Japanese Pharmaceutical Manufacturers Association [12]. Anticancer drugs and antibodies did predominate in this series, but the authors also detected a considerable number of false negatives and false positives in their data.

#### **4.2.9 Immunological System**

Specific tests of immune function are not routinely performed for conventional new drugs prior to their use in humans. An international collaborative study showed that examination of peripheral blood white cells, histological examination of thymus and spleen, and, in particular, careful histological examination of lymphoid tissue in the rat is a good primary method of identifying agents that are significant direct-acting immunotoxins [81]. New screens of immune function in animals are sometimes proposed for drug assessment [82, 83], but more sophisticated tests of immune function might be more appropriate and safely conducted in human studies. Coping with the potential impact of biotechnology-derived pharmaceuticals on immune status and immunogenicity is a special challenge for which careful attention to the principles of immunology is needed [84].

#### **4.2.10 Skin**

Of all tissues, skin shows the least concordance between effects in animal studies and human patients. A general lack of predictive reliability for skin reactions in humans has been noted in the reviews of anticancer and other drugs ([48, 54, 55]; Table 6). Adverse skin hypersensitivity effects have caused the development of a relatively large number of potential NMEs to be terminated [13, 73, 85].

### **4.3 SPECIAL CONSIDERATIONS**

#### **4.3.1 Biologic and Biotechnology-Derived Pharmaceutical, Biopharmaceutical, and Biotech Drugs**

The definitions of biology-related therapeutic agents and examples of agents are presented in Table 8; there are a number of important differences between biologics

**TABLE 8 Definitions of Biology-Related Therapeutic Agents**

| Term                                                                               | Definition                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | Examples                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Biologic                                                                           | A therapeutic agent derived from a biological source or produced using a biological process. For the purposes of this chapter, this will include drugs obtained by extraction from human or animal tissues and body fluids or produced by biotechnological means (recombinant or hybridoma technology).<br>It will include cell-, virus-, and bacteria-based products as well as DNA-based therapeutics. It will NOT include certain small-molecule agents produced by fermentation (e.g., antibiotics) or plant-derived products (botanicals). | Plasma-derived proteins (albumin, clotting factors, immunoglobulin preparations)<br>Tissue-derived proteins (animal insulins, human pituitary-derived growth hormone)<br>Vaccines (live, attenuated, or killed whole-cell preparations, recombinant peptide vaccines, DNA, and viral vector vaccines)<br>Recombinant peptides and proteins<br>Monoclonal antibodies<br>Products derived from transgenic animals or plants<br>Gene therapy and related tissue or cell therapy products<br>Antisense drugs |
| Biotechnology-derived pharmaceutical, biopharmaceutical, biotech drug <sup>a</sup> | Any drug produced by biotechnological means, such as recombinant or hybridoma technology, are generally regarded to include recombinant peptides or proteins, antibodies, genetically modified tissue, and cell-based products as well as DNA-based products.                                                                                                                                                                                                                                                                                   | Vaccines (as above)<br>Recombinant proteins or peptides and derivatives (e.g., erythropoietin, clotting factors, insulins, or insulin analogs)<br>Monoclonal antibodies and antibody fragments (e.g., Fabs)<br>Transgenic animal products (e.g., rh albumin)<br>Gene therapy products (as above)                                                                                                                                                                                                         |

<sup>a</sup>These terms are basically interchangeable and broadly refer to the same type of therapeutic agents.

and conventional small molecules that need to be understood to design effective nonclinical and clinical programs for these products. They refer principally to the production process, molecular weight and composition, microheterogeneity, species specificity, pleiotropism, dose-level selection, metabolism, and catabolism [86, 87]. The available regulatory guidance on the nonclinical safety testing of biologics has recently been reviewed [88]. Although there are a number of product-class-specific guidelines that have been published over the years (for review see Ryle [87]), the most relevant general guidance on the nonclinical testing of biologics is the ICH S6 [89]. The guideline emphasizes the need for a flexible, case-by-case approach and appropriate species selection, with special attention paid to immunologically mediated effects in animals and their relevance to human patients. Some of the special considerations that need to be taken into account in the nonclinical testing of biologics include the source and quality of the test material (in particular batch-to-batch variability), species selection, immunogenicity (in particular after repeated dosing), dosing schedule, dose levels and study durations, immunomodulation, and the assessment of local tolerance. The serious adverse events observed with the CD28 agonist antibody TGN-1412 in a phase I study in early 2006 ([20]; Table 3) demonstrate how difficult it is to lay out any general examples of typical nonclinical

programs for biologics. Recent investigations on the mechanisms of the TGN-1412-mediated “cytokine storm” will enable the development of novel procedures to improve nonclinical safety testing of immunomodulatory therapeutics [90]. Meanwhile this serious adverse event has led to evolving regulatory expectations for this type of product [91].

#### 4.3.2 Genotoxicity

There has been much contention about the relevance of genotoxicity assays to the testing of pharmaceutical agents since their introduction more than 30 years ago [92]. However, extensive study has led to a better understanding of the chemical determinants that provoke genotoxic effects through electrophilic attack of biological macromolecules [93]. As a consequence of this understanding, mutagenic activity is often simply avoided in the drug discovery process with the exception of certain classes of drugs aimed at treating cancer (for review see Guzzie-Peck [86]). Nevertheless, prior to first human exposure, *in vitro* tests for mutations and chromosomal damage are routinely carried out according to internationally agreed technical guidelines that are based on a large body of historical data for diverse chemicals. However, it can be difficult to assess human risk when unexpected or unexplained activity in these bacterial or mammalian cell tests occurs. Such activity usually precludes dosing to healthy volunteers at least until further work elucidates the mechanism of activity and characterizes any hazard. Subsequently, *in vivo* assays of bone marrow micronucleus, peripheral blood cytogenetics, and liver unscheduled DNA (deoxyribonucleic acid) synthesis in rodents are usually done. The technical performance of these tests has also been the subject of international collaborative studies. *In silico* approaches are now used routinely and tend to supersede *in vitro* testing of genotoxic potential.

An area of growing regulatory concern is the assessment of potentially genotoxic impurities of pharmaceuticals. The ICH and the European Medicine Agency (EMA) have published guidance documents focusing on the safety evaluation of impurities in pharmaceutical drug substances and drug products [94–100]. The EMA guidance is based on a threshold of toxicological concern (TTC) derived from animal carcinogenicity data using multiple worst-case assumptions to estimate a daily dose associated with a lifetime cancer risk of 1 in 100,000, a risk level considered acceptable for genotoxic impurities in human medicines. Based on these assumptions, presentation of the TTC as a single figure infers an unwarranted level of precision and supports the adoption of a more flexible approach by regulatory authorities when evaluating new drug products; a range within five fold of the TTC limit would be sensible. Furthermore, the limit is based on 70 years continuous daily exposure, a scenario that is uncommon for most medicines and irrelevant to the preregistration clinical development phase. To address this later point a staged TTC has been developed that proposes limits based on shorter durations of treatment (e.g., up to 1-year). Based on recent history, this approach has been acceptable by some authorities but not others, and it is imperative that steps are taken to reach a common agreement between the pharmaceutical industry and regulatory authorities worldwide in order that new medicines can continue to be developed and delivered to benefit patients in a safe and timely manner [101].

### 4.3.3 Genital System and Teratology

Reproductive changes are seldom reported in early clinical trial studies, largely due to the exclusion of women of child-bearing potential from these studies [54]. In a report from the Federal Institute for Occupational Safety and Health, several reviews as well as studies on individual compounds have been analyzed with respect to the suitability of different study designs and endpoints to detect effects on male reproduction in animal species [102]. However, only a few studies were available that characterize the human situation. A considerable inter- and intraindividual variability was noted with respect to key parameters associated with fertility in men (e.g., sperm count, motility, morphology, and volume). Interspecies extrapolation factors were derived from the most sensitive endpoint in laboratory animals. Despite the small database and limitations of the studies that prevented any robust conclusion, it was felt that humans were generally not more susceptible to reproductive toxicants than laboratory animals as was originally assumed. For the purpose of hazard identification a subacute study exploring concentrations that produce significant general toxicity might be sufficient. If effects were found, for the purpose of risk assessment the no-adverse-effect level has to be identified by testing sensitive endpoints. Although a subchronic study was felt preferable, a subacute study may be sufficient. Similar observations emerged from a collaborative study in Japan of 16 drugs, 12 of which were associated with infertility in humans; results showed that histopathological endpoint was the most sensitive method for preclinical detection of drugs with antifertility properties [103]. A recommendation from the Federal Institute for Occupational Safety and Health report was to develop and validate a rabbit model allowing sequential sperm analysis and better observation of behavior [102].

Teratology, the study of abnormal prenatal development and congenital malformations induced by exogenous chemical and physical agents is being primarily assessed using *in vivo* approaches. Although the interspecies concordance and extrapolation to humans is in large part unknown, mainly because teratogenic compounds are either not progressed into humans or progressed under very restricted usage. Although, animal studies in mammals remain the gold standard, other alternative methods/assays are being explored. In this regard, it is worth mentioning three *in vitro* methods endorsed as scientifically validated by the European Centre for In Vitro Alternative Methods (ECVAM) in 2001 [104]: the embryonic stem cell test, the micromass test, and the whole-embryo culture. More recently, the use of the zebrafish opens some promising avenues [105].

### 4.3.4 Safety Biomarkers

The field of safety biomarkers (SBMs) is advancing rapidly. Our improved understanding of the molecular bases of organ toxicity suggests that monitoring specific molecular responses may provide improved prediction of human outcomes and in doing so provide “bridging SBMs” that may eliminate much of the current uncertainty in extrapolating from laboratory models to human outcome. Modern high-throughput technologies for proteins or endogenous metabolites offer a major opportunity to systematically identify sensitive and specific plasma or urine SBMs that could serve as an index of damage specific to each of the important

internal tissues and organs. SBMs can serve many decision-making purposes. Depending on where SBMs are used in the drug discovery/development process they demand different levels of validation and qualification. SBMs can be deployed for (i) target related toxicity, (ii) CD family-related toxicity, (iii) unexpected toxicity during GLP studies, and (iv) unexpected toxicity during clinical development. In accepting an SBM as qualified for regulatory decision-making, FDA has exhibited clearly that it will operate only within a broad scientific consensus. This means that:

- Data on an SBM from different investigative methods should be convergent and support a single hypothesis for its role in a certain organ toxicity.
- There are no or few data that are incompatible with the hypothesis.
- The data available in support of an SBM are persuasive to independent expert peer groups.
- The data should have originated from multiple and independent investigations in several laboratories.

A suitable way to reach this consensus is to share the interest in developing biomarkers in consortia formed by, e.g., pharma and diagnostic companies, academia, and regulators.

## 4.4 SUMMARY AND FUTURE CHALLENGES

### 4.4.1 New Targets and New Approaches to Treat Diseases

Advances in molecular biology and biotechnology allow for the identification of new molecular targets, leading to the discovery and development of newer pharmaceutical agents that act at these novel molecular sites in an attempt to ameliorate the disease condition. Moreover, new therapeutic approaches are being developed (e.g., gene therapy, biotech products) that offer new challenges to assessing their safety in humans. Inherent in the novelty of new targets and new approaches is the risk of unexpected and unwanted effects that may or may not be detected based on current scientific knowledge and with current techniques and assays.

One of the biggest challenges for the biotechnology and pharmaceutical companies in the twenty-first century will be to develop and deliver drugs that fit the individual patient's biology and pathophysiology ("personalized medicine") [106, 107]. In addition, new developments in therapeutic approaches, such as those involving biopharmaceuticals and gene therapy, offer promise in the treatment or prevention of diseases for which current approaches are ineffective.

At the same time health care costs are increasing dramatically in many countries, and aging populations often require treatment with multiple drugs. In addition increased drug development costs and recent high-profile issues relating to drug safety highlight the need for finding new medicines with acceptable safety profiles while minimizing development cost.

There is a need to identify/screen out drug candidates with poor safety profiles as early as possible in the drug discovery process, and nonclinical safety assessment functions have an important role to play in achieving this goal [108].

To increase the overall value of the nonclinical assays would require to better understand their predictive value for humans; to achieve this would require reviewing analysis data available in the public domain as well as proprietary information and sharing the outcome of such effort widely. This could ideally be achieved via consortia involving academic institutions, regulatory agencies, and the pharmaceutical industry. Such approaches have been recently initiated [109, 110].

#### **4.4.2 Science and Technology**

Nonclinical safety evaluation faces significant scientific challenges to keep pace, to adapt, and to incorporate new technologies in the evaluation of NMEs in nonclinical assays/models and identifying the effects that pose a risk to human volunteers and patients. Recent examples have included the use of electrophysiological techniques to evaluate the effects of NMEs on the hERG channel [111] and telemetry techniques to assess the effects of NMEs on the duration of the QT interval in unstressed animals (for review see McMahon et al. [29]), therefore enabling to establish integrating QT risk assessment reliable and predictive of the clinical outcome. The development and utilization of technologies and approaches that have a direct clinical correlate should also be encouraged; for example, the utilization of echocardiography to assess drug effect on ejection fraction can be applied in both a nonclinical and clinical setting. Furthermore, efforts should continue to construct databases relating to the predictive value of nonclinical assays to humans either through retrospective analysis or through purposely designed studies [13, 39–42, 57, 72].

#### **4.4.3 Regulatory Requirements**

Continued benefit–risk assessment is today at the center of drug development and drug life-cycle maintenance together with the requirement to submit risk management plans to regulatory agencies together with licensing applications [112, 113]. These requirements have helped pharmaceutical companies to develop cross disciplinary working to ensure identification, assessment, and better understanding of safety risks and to devise risk minimization activities. Wherever feasible conditional approvals based on fewer patients and with rigorous prospective safety follow-up should be considered. In its March 2004 Critical Path Report [114], the Food and Drug Administration (FDA) suggests that limited exploratory IND investigations in humans (phase 0) can be initiated with less, or different, nonclinical support, that is required for traditional IND studies because exploratory IND (e-IND) studies should present fewer potential risks than do traditional phase I studies that look for dose-limiting toxicities. The nonclinical program should be considered on a case-by-case basis depending on the specific objectives for a given e-IND.

#### **4.4.4 Training and Development**

Disciplines involved in nonclinical safety evaluation of NMEs face significant challenges of attracting, training, and certifying investigators to ensure the future of these disciplines. The paucity of training in certain biomedical scientific disciplines (toxicology, pathology, pharmacology, physiology) has had detrimental long-lasting effects such as (a) an impact on the development of intact animal models of human

function and disease; (b) an impact on skills to conceptualize biomedical hypothesis and experiments at the level of the intact animal; and (c) an impact on the process of nonclinical and clinical drug discovery and development. There is a clear need to ensure all parties involved in the training, education, and development of individuals working in these disciplines work together to ensure continuous supply of these key skills.

Developing organized, planned, and prospective methods for clinical safety data review to interpret and act on this data will require integrated databases, possibilities to search historical data, and possibilities to bring information together from multiple sources in a new way would enable assessing the concordance between preclinical and clinical safety data and ultimately refine the nonclinical safety testing strategies to select the safest candidate drugs.

### **5.1.1 INTRODUCTION**

For over 2000 years medicine was practiced based on lessons passed down from teacher to student drawn from ancient beliefs regarding illness in the human body and the actions that must be taken to restore health. The principles of Hippocrates and the writings of Galen served as a guide for therapy. There is no doubt that observation of what worked and what did not work, and refinement of practice

based on experience, has also shaped medical practice from its earliest days, but for centuries, theory held sway over empiricism.

The situation changed with the systematic application of data collection and observation of outcomes and evolved into the modern practice of evidence-based medicine, driven primarily by the results of clinical trials. The history of clinical trials begins with the recognition of disease as a discrete condition that is similar enough from patient to patient to allow the rational application of the experimental method to determine which therapies work and which do not. It continues with recognition of the need to control for biases that can emerge in clinical experimentation resulting in the establishment of the gold standard of the double-blind randomized controlled trial. In addition, this history involves the recognition of the fact that using human subjects to gain scientific knowledge and help future patients requires regulation and procedures to ensure that the rights of these subjects as individuals are protected. Finally, this history involves the development of government agencies to support and oversee the development of clinical research and the emergence of the pharmaceutical industry as the dominant force in the development of new therapeutic agents. Each of these elements, and other aspects of this history, could be explored in a separate book, and each discipline from oncology to cardiology to psychiatry to surgery has unique stories and features that are beyond the scope of this chapter. We present here an overview of some of the key developments and ongoing issues that should serve as an introduction to the rich history of clinical trials and the rise of the pharmaceutical industry.

### 5.1.2 FROM HEROIC TO EVIDENCE-BASED MEDICINE

Medical practice from the time of Hippocrates (460–361 BC) was based on theory, and chief among these was the humoral theory that held that the human body was composed of four humors: yellow bile, black bile, phlegm, and blood. Disease was understood to arise from an imbalance of humors; the role of the physician was to bring the individual back into balance, by adding or removing substances from the body. In essence, this was the ultimate form of personalized medicine, where detection of a fever did not lead to a search for an underlying disorder but indicated an imbalance unique to the individual that needed to be corrected. Balance could be restored by vomiting, diarrhea, or sweating or taking in substances such as mercury or arsenic. One of the most dramatic means of restoring balance, and of demonstrating the knowledge and power of the clinician, was through bloodletting, or phlebotomy.

This practice, depicted on ancient Greek vases dating to the time of Hippocrates, and described extensively in the writings of Galen (AD 129–200), physician to Roman Emperor Marcus Aurelius, was a dominant form of medical therapy for over 2000 years until the mid-nineteenth century. Galen wrote several books on bloodletting and established the use of bloodletting as a form of heroic medicine, stating “the first and most important indications for phlebotomy are ... the severity of the disease and the strength of the patient” [1]. Patients with severe disease might be bled to the point of syncope in an effort to restore health [2]. Though this may seem counterproductive based on our current understanding of illness, there are conditions such as heart failure or kidney failure where, in the absence of diuresis or

dialysis, phlebotomy may have helped some patients. Further, the impetus to “heroic medicine” where severe disease in an otherwise healthy patient is treated with a dramatic, but unproven therapy, still exists in medicine and society as evidenced by the use of bone marrow transplant for breast cancer as recently as the 1990s [3].

The centrality of phlebotomy to practice in Galen’s time is indicated by his instructions to subject patients to bloodletting, not only when they were sick but also for disease prevention. He wrote in *On Treatment by Venesection*, “the time for phlebotomy is not only when severe disease is established, but also when it is likely to occur” [1]. Galen’s teachings were translated into Arabic and preserved in the Arabic world while Europe was in the Dark Ages. This practice was later adopted by European monks and continued throughout the Renaissance and into the nineteenth century.

One of the chief American proponents of bloodletting, and the practice of heroic medicine, was Benjamin Rush (1745–1813). In the face of the yellow fever epidemic of 1793, when thousands were dying, Rush advocated not just bloodletting but copious bloodletting, regardless of the state of the patient [4]. Rush was a notable physician in Philadelphia (in addition being signatory to the Declaration of Independence and treasurer of the U.S. Mint), and when the epidemic struck he tried a variety of therapies including purging with calomel (mercury), blistering, wrapping patients in vinegar-soaked blankets, and cinchona bark before deciding that more drastic measures were needed [4]. He reportedly saw over 100 patients a day and was both practitioner and promoter of bloodletting, continuing to advocate the practice for widespread use through yellow fever epidemics in 1794 and 1797 [5]. Rush called on his students to “Venerate the Lancet. It is the Magna gratia Coeli, The great gift of Heaven” [4]. Bloodletting was perhaps most famously used in American history in the treatment of President George Washington. Despite four heroic bloodlettings totaling up to 2 liters of blood in less than 24 hours (about 40% of total volume for an average male), performed by colleagues of Benjamin Rush, Washington succumbed to what was likely bacterial epiglottitis and died on December 14, 1799 [6].

Thus, principles and theories established over 2000 years earlier continued to provide the basis of medical practice; while knowledge of biology and human physiology advanced, the rational use of therapy did not. This unfavorable situation would begin to change with the conduct of clinical experiments and, importantly, the distribution of information regarding new therapeutic interventions and methods of validation. Progress toward the age of clinical trials required both the willingness to try new things (i.e., experiment) and the appreciation of the need for systematic observation, recording, and analysis of outcomes.

One of the first documented clinical experiments was the trial of inoculation as a treatment for smallpox performed by Cotton Mather during the epidemic of 1721 (Table 1). Inoculation, the practice of introducing a small amount of infectious material into a healthy subject in order to convey a mild case of disease that would prevent development of a more severe life-threatening form, was practiced in China as early as 1000 bc. However, it was not accepted practice in 1721 when Mather convinced Dr. Zabdiel Boylston to inoculate Bostonians against a smallpox epidemic, and they decided to collect data. Their report of 2% mortality among inoculated patients versus 14.9% among naturally infected patients, represents one of the first known instances of clinical data collection to guide future clinical practice [7].

**TABLE 1** Timeline of Select Events in History of Clinical Research

|      |                                                                                                  |
|------|--------------------------------------------------------------------------------------------------|
| 1721 | Mather smallpox inoculation in one of earliest documented clinical experiments                   |
| 1753 | Lind study of citrus for scurvy compares multiple concurrent treatments                          |
| 1798 | Jenner conducts smallpox vaccination trial                                                       |
| 1834 | Trousseau conducts first blinded placebo-controlled trials                                       |
| 1836 | Louis pioneers systematic evaluation of therapy and numerical method.                            |
| 1846 | Morton publicly demonstrates value of ether for anesthesia                                       |
| 1847 | Semmelweis studies role of hygiene in preventing maternal death with historical controls         |
| 1870 | Lister conducts single-arm study of antiseptics with historical control                          |
| 1896 | Fibiger conducts first randomized control trial, of diphtheria serum for treatment of diphtheria |
| 1938 | U.S. Food Drug and Cosmetics Act requires regulation of claims of new medications                |
| 1946 | Brittish MRC conducts first modern randomized control trial, evaluates streptomycin for TB       |
| 1949 | Nuremberg Code states importance of voluntary informed consent for research                      |
| 1954 | Salk polio vaccine trial, landmark large randomized placebo control trial                        |
| 1964 | Declaration of Helsinki stresses concern for the interests of research subjects                  |
| 1978 | Belmont report produces a practical guide to ethical research conduct                            |

---

In a testament to the slow dissemination of medical knowledge in the eighteenth century, the same study was essentially conducted by Edward Jenner in England in 1796. Jenner found that exposure to small amounts of cowpox could prevent both fulminant cowpox and the more lethal smallpox; he coined the term vaccination, based on *vaccinia*, Latin for cowpox [8].

It is possible to see the origin of clinical trials in these early clinical experiments. Though these efforts lacked the structure and methodology of anything resembling a modern clinical trial, the notion of studying or demonstrating the effectiveness of an intervention, rather than applying it based solely on theory, as was the case with phlebotomy, marked a profound shift in the approach to patient care. Other pioneering examples include the demonstration of the value of citrus (vitamin C) for scurvy by James Lind in 1747 [9], demonstration of ether (anesthesia) by William Morton in 1846 [10], and demonstration of the value of hygiene for prevention of childbed fever by Ignaz Phillip Semmelweis in 1847 [9].

Lind conducted a study among 12 Brittish sailors assigned to different dietary therapies for treatment of scurvy, which is estimated to have killed over 1 million people in the seventeenth and eighteenth centuries, and showed rapid recovery of sailors eating citrus. He published “Treatise on the Scurvy” in 1753 [9]. Morton demonstrated the value of ether to prevent operative pain to a room full of skeptical surgeons in the Massachusetts General Hospital Amphitheatre on October 16, 1846 [10]. His work was publicized by Henry J. Bigelow in the November 1846 *Boston Medical and Surgical Journal* [5]. Semmelweis conducted a natural experiment of sorts, demanding handwashing by physicians and medical students between work with cadavers and work on the delivery wards and demonstrated a drop in the rate of childbed fever and death from sepsis from 10% of mothers to less than 2% after imposition of this change in hygiene [5]. It is notable that widespread adoption of the practice of anesthesia for surgery and handwashing in obstetrics lagged many years behind these clinical demonstrations and publication highlighting the importance of an established method for demonstrating efficacy in medicine and the importance of community reliance on evidence to guide practice [9].

Though case series and public demonstrations are a form of clinical research, the true origin of systematic clinical research dates to the era of the Paris Clinical School

and the work of Pierre Charles Alexandre Louis. As noted above, bloodletting, whether by leech or lancet, was used widely though the nineteenth century based on the inherited wisdom for the time of Galen. The first evidence-based challenge to this practice emerged when Pierre Louis, a young physician at La Charite Hospital in Paris in the 1820s, decided to evaluate the impact of bloodletting compared to other treatments on outcomes in pneumonia. The very concept of such a study represents a shift in the understanding of disease. As historian of science Charles Rosenberg has noted in *The Therapeutic Revolution*, the movement toward recognition of diseases as discrete entities as opposed to personal states of imbalance was a necessary conceptual step for the study of the impact of therapeutic interventions on populations of patients, and the collection of data to guide therapy for future patients [11]. This subtle difference between therapies as means to restore balance versus therapies as targets for specific processes was critical for the development of evidence-based medicine. The development of the randomized clinical trial required both innovation in methodology and a transformation in this concept of disease. However, this step was accompanied by other changes in medicine, perhaps equally important for the development of clinical trials, such as movement of the place of illness from home to hospitals, allowing evaluation of large numbers of like cases, improvements in dissemination of knowledge, and a skepticism toward unproven therapies [11].

Pierre Louis evaluated 77 cases of pneumonia, stratified by whether they were bled on days 1–4 of illness or days 5–9. He found that 44% (18 of 41) of patients undergoing early bleeding died, compared to 25% (9 of 36) undergoing delayed bleeding [12]. That there was no comparison to a “no bleeding” control group speaks to the importance of bleeding as a therapy during this period. Describing what he called the “numerical method,” Louis wrote about the need to compare treatments among comparable numbers of patients to determine which treatment should be used in the future [13]. This was a radical suggestion at the time and contradicted the established practice of medicine based on the physician’s clinical judgment on a case-by-case basis. The move toward standardized evaluation, by no means robust in Louis’ time, now seems obvious, yet echoes of the debates over evidence-based medicine versus clinical judgment remain today.

Louis’ work was published in 1836, entitled *Researches on the Effects of Blood Letting in Some Inflammatory Diseases* [14]. His findings sufficiently challenged the dogma that he conceded: “The results of my researches . . . are so little in accordance with general opinion, that it is not without a degree of hesitation I have decided to publish them.” He published patient-specific data in detailed tables so that his work could be reviewed and analyzed by others. Even in the face of his own empirical evidence, he questioned whether a more aggressive “dosing” might have achieved better results. “Should we obtain more important results if, as is practiced in England, the first bleeding were carried to Syncope? The practice deserves a trial, but great success cannot, I think be anticipated; since many cases, the history of which I have drawn up, and which were fatal, were bled to a sufficient extent” [14]. In the face of this evidence, among the first well-documented clinical evaluations in which we can see the origins of modern clinical research [12], he reluctantly concluded that “bloodletting has had very little influence on the progress of pneumonitis, or erysipelas of the face, and angina tonsillaritis, in the cases under my observation” [14].

Though Pierre Louis relied on large numbers of cases, rather than randomization, he had hit upon both the importance of empirical observation to determine the safety and efficacy of therapy and the need to control for confounding factors among patients undergoing different interventions. Further, he argued not only that such evaluation was valid, but that “therapeutics cannot advance without it” [14]. Louis relied on advances in mathematics and probability theory to develop a basis for clinical science and called for evaluation of a magnitude of harms and benefits of any intervention to determine its worth [15].

Of note, bloodletting declined based on the work of Louis and others but persisted for many decades. A Philadelphia physician reported in 1862 that among over 9500 cases, only one was treated with general bloodletting, 12 with cupping, and 3 with leeching [11].

The work of Pierre Louis inspired the great American clinician Oliver Wendell Holmes who argued in 1843 that clinical evidence must guide practice [16]. Physicians from Great Britain and the United States took up the scientific method of Pierre Louis and began to collect outcome data on common practice, essentially conducting retrospective observational evaluation of common therapeutic practices [13]. In the absence of such evidence for most common medical practices of that day, this dawning awareness of the need for clinical research initially led to therapeutic nihilism [11]. However, it also produced the necessary environment for development of advances in care.

When Joseph Lister pioneered antiseptic surgical techniques in 1865 and studied their impact in subsequent years, he evaluated them based on clinical evidence by comparing outcomes from cases prior to the technique with those after introduction of the technique, essentially conducting a single-arm study and using a historical control [13, 17]. Similar advances in the management of infectious disease were made through testing of new therapies and comparison with historical controls in studies of diphtheria.

The problem with historical controls is that improvements in outcome may be due to the intervention, due to other changes in practice, or due to changes in the patient population that may occur over time. Therefore a pioneering advance in the history of clinical trials was the use of concurrent controls, first conducted in the trial of diphtheria serum by Danish physician Johannes Fibiger in 1896 [18].

Fibiger (1867–1928) alternately assigned new patients with diphtheria to standard therapy versus standard therapy plus diphtheria serum depending on the day of treatment between May 1896 and May 1897 [19]. The primary outcome was mortality, and secondary outcomes included croup and fever. He also evaluated toxicity, primarily development of serum sickness. Among 484 patients, 8/239 (3%) treated with serum died versus 30/245 (12%) controls [19]. Though no formal statistics were used, this trial demonstrated the importance of large numbers, randomization (future studies would improve over alternating days as a means of randomization), and concurrent controls. As Fibiger wrote: “In many cases a trustworthy verdict can only be reached when a large number of randomly selected patients are treated with the new remedy and at the same time, and equally large number of randomly selected patients are treated as usual” [18].

If Fibiger took the first steps toward pioneering the randomized control trial, the final steps in establishing this methodology were taken by the British Medical Research Council (MRC) in 1946 in what is typically termed the first true random-

ized control trial. Interestingly, at this juncture the history of clinical trials merges with the history of the pharmaceutical industry. The MRC conducted a trial of the promising new drug streptomycin for treatment of pulmonary tuberculosis, and one of the ethical rationales for randomization was that the drug, produced by the American pharmaceutical company Merck, was in short supply in Britain [20]. Widespread availability of the drug in America precluded a randomized trial, but in Britain, one of the only ways to obtain the drug was through participation in the MRC trial. The trial randomized 97 patients using random numbers in sealed envelopes to streptomycin versus control in a double-blinded fashion [20]. The trial demonstrated both the value of randomization and the value of streptomycin for tuberculosis. There was “considerable improvement” of chest X rays among 55% in the streptomycin group versus 8% of the controls, and 7% deaths in the streptomycin group versus 27% among controls [20].

Since the 1940s when the methodology of the randomized clinical trial was definitively established and embraced by the medical community, the pace of advancement in medical therapy has been remarkable. A clinical trial system for systematic assessment of novel interventions has been established, and government agencies, academic institutions, and private industry have been organized around the goal of discovering new treatments and testing them in a scientifically rigorous fashion. Other important steps along this pathway included the development of the trial system with phase I trials to test first in human interventions or combinations focused on safety, phase II studies to expand evaluation of safety in a select patient population and to evaluate efficacy, and phase III trials to provide a randomized controlled comparison between an experimental intervention and a standard therapy. There are of course variants of this trial structure, such as phase I/II trials, randomized phase II trials, pilot studies, phase IV trials (typically aftermarket trials to provide real-world safety and efficacy data), and emerging phase 0 trials (very small trials using low doses to study method of action) [21], and a full discussion of trial design is beyond the scope of this chapter. The conceptual steps described above paved the way for our modern system of clinical research.

Two other aspects of modern clinical trials that deserve note in this history, however, are the development of blinding and the placebo-controlled trial. Both of these are related to controlling for bias. When a research subject knows he or she is receiving an intervention that is supposed to work, it may affect subjective and even objective outcomes through psychological factors. Blinding means that the subject does not know what intervention he or she is receiving. Double blinding, used in some trials, means the physicians providing the intervention and assessing the outcome also do not know which intervention the subject is receiving. One common form of blinding involves use of a placebo. A placebo, based on the Latin word for “I shall please,” is an inert substance that is not expected to have any direct therapeutic value but that can be used in a trial to make a subject believe he or she is receiving a therapy and help sort out psychological effects of being treated from true physiologic effects. In modern clinical trials, this is used in randomized studies when there is no appropriate standard of care, or when you want to compare adding a novel intervention to a standard intervention to the standard intervention alone.

The history of using placebo controls, or “blinded assessment,” in clinical research dates to the late eighteenth century when blinded assessment was used to determine

if “mesmerism,” a then popular form of therapy in which the practitioner directed a sort of psychic force (characterized as a form of animal magnetism) at a patient to treat illness [22]. Researching the history of this subject, Kaptchuk relates that the first experiment actually used blindfolds to prevent the subject from knowing if mesmerism was really being applied, and it was conducted in 1784 in the house of Ben Franklin. Later, blind assessment was combined with the use of placebo in trials intended to study the validity of homeopathy, a practice of treating disease with minute amounts of a substance linked to the disease (on the principle of “like cures like”) [22]. These trials conducted in 1834, by the French physician Armand Trousseau (later famous for describing a syndrome of migratory blood clots associated with abdominal cancer), were the first blinded placebo-controlled trials, leading Trousseau to conclude that homeopathic remedies were no more active than placebo [22]. Use of placebo controls did not become a standard part of clinical research until later in the nineteenth century when they were used in a series of German studies examining the health effects of a variety of natural and nutritional remedies [22]. The use of randomization combined with blinding and placebo controls appears to have first emerged in the Michigan tuberculosis trials in 1926 in which a gold-based intravenous therapy was compared to intravenous water [22]. In 1954, this methodology was famously used to establish the safety and efficacy of the Salk polio vaccine, in a placebo-controlled trial involving almost 2 million subjects [23].

The degree to which medical therapy has evolved from reliance on theory, and distrust of empiricism, as recently as the time of Benjamin Rush, to reliance on evidence-based medicine and the randomized clinical trial, is exemplified by debate over whether treatment in a clinical trial itself now represents the standard of medical care in some settings [24, 25]. This view has been widely advocated in oncology, given both the poor outcomes with standard therapy for many diseases, and the clear advances demonstrated in clinical trials, particularly in treating childhood malignancy. The concept of a “trial effect” has been postulated, whereby treatment within a clinical trial conveys therapeutic benefit over and above the benefit of the experimental intervention itself [26]. Though it is not clear that such a trial effect holds up when comparisons of patients treated within clinical trials and patients treated outside of trials are subjected to the type of rigorous standards used to assess any intervention [27], it is notable that the clinical trial has emerged not only as a means to demonstrate the value of novel therapies, but as *the* recommended option for the care of some patients [24].

### 5.1.3 ROLE OF FDA AND RISE OF PHARMACEUTICAL INDUSTRY

No discussion of the history of clinical trials and drug development would be complete without mentioning the role of the Food and Drug Administration (FDA) and its analogous regulatory authorities throughout the world. Prior to the twentieth century, the U.S. government did little to regulate the marketing of therapeutic products; fraudulent claims were commonplace and went unpunished. Over the last 100 years, the FDA’s role has evolved to encompass three fundamental assurances: safety, efficacy, and adequate and accurate labeling [28].

Most observers consider 1906 to be the birth of the modern FDA [29]. In that year, Congress passed the original *Pure Food and Drugs Act*, which was signed into

law by Theodore Roosevelt. The statute prohibited misbranded and adulterated foods, drinks, and drugs in interstate commerce. Specifically, the law required companies to disclose weights and measures of their products and to provide labels disclosing whether their products contained alcohol, morphine, opium, cocaine, heroin, euaine, chloroform, cannabis, chloral hydrate, or acetanilide. Several forces provided the impetus for the law, including an exposé of the harmful preservatives used in the meat-packing industry as well as the realization of an increasing incidence of drug addiction from the use of “patent medicines.” Congress originally designated the Bureau of Chemistry in the Department of Agriculture, founded in 1862, to enforce the law; it would not be until 24 years later, in 1930, that the agency name would be changed to the FDA.

It is important to note that the original Pure Food and Drugs Act focused on ensuring accurate disclosure about product content, but the act did not prohibit firms from making false therapeutic claims as long as the firms provided accurate content labeling. Congress enacted the Sherley Amendment, in 1912, to address this loophole. The amendment specifically prohibited firms from the labeling of medicines with false therapeutic claims if the labels were intended to defraud the purchaser. That this legal standard was difficult to prove weakened the practical impact of the amendment. Radiothor, a radium-containing tonic that could be fatal with chronic ingestion, and Lash-Lure, an eyelash dash that blinded some women, are just two examples of worthless or harmful products widely marketed at the time. Efforts to enhance the laws stalled in Congress for years until the occurrence, in 1937, of the unfortunate Elixir Sulfanilamide disaster.

Sulfanilamide had been shown, by 1937, to have dramatic, curative activity against streptococcal infections. In an attempt to capitalize on a recognized demand for the agent in liquid form, especially among children, Tennessee-based S.E. Massengill Co. sought to manufacture an elixir formulation. Chemists at the company found that sulfanilamide would dissolve in diethylene glycol and that this solvent had an attractive mixture of fragrance and flavor. The company was not required to, nor did it chose to, carry out toxicity testing on the new formulation. Tragically, the highly toxic analog of antifreeze killed more than 100 people, many of whom were children. In the wake of the tragedy, Congress and the president moved quickly to enact the *Food, Drug, and Cosmetic Act*. The new law required, for the first time, that drugs be safe for their intended use. Specifically, the law required premarket approval for all new drugs; firms had to demonstrate proof that their drugs were safe prior to their marketing. Furthermore, the law gave the FDA authority to identify drugs that would require a prescription from a physician.

It was not until 1962, almost 25 years after the original Food, Drug, and Cosmetic Act, that Congress amended the 1938 act by codifying a requirement that drugs demonstrate adequate evidence of efficacy in addition to safety. Congress indicated that the FDA should require “full reports of investigations which have been made to show whether or not such drug is safe for use and whether such drug is effective in use” [30]. The new law was in many ways the result of hearings held by Senator Estes Kefauver. The senator had worked for years to try to reform the agency, but his efforts languished until the thalidomide tragedy, which played out mainly in Europe, provided the catalyst for Congressional action. Congress also gave the FDA control over the regulation of drug development trials, including the requirement

for informed consent, the regulation of drug advertising, and the power to establish and enforce good manufacturing practices. As part of the law Congress required the FDA to assess the efficacy of all drugs introduced since 1938.

Over the next 40 years, Congress enacted several additional laws governing the FDA, including the Orphan Drug Act and the Federal Advisory Committee Act. Multiple sets of drug regulations were also developed during the latter half of the twentieth century to refine and interpret the laws. The 1990s, however, proved to be the next highly consequential period for the FDA's evolution. The AIDS crisis in the late 1980s and early 1990s provided the major impetus for reform. Activists targeted the FDA for failing to approve drugs quickly enough in the face of the crisis. Congress responded over the period of 1992–1997 by enacting two laws, the Prescription Drug User Fee Act of 1992 (PDUFA) and the FDA Modernization Act of 1997. Collectively, these laws have had a profound impact on the FDA's regulation of drugs intended to treat serious or life-threatening illnesses. Programs such as Fast Track Designation, Priority Review, and Accelerated Approval have each worked to expedite the development of drugs intended to treat serious illnesses such as cancer.

Of these three programs, the accelerated approval mechanism has had the largest impact [28]. The provisions under accelerate approval permit the FDA to approve agents to treat serious or life-threatening illnesses before the clinical benefit necessary to meet the standard for regular approval has been demonstrated. Specifically, the FDA can grant initial drug approval on the basis of a surrogate measure of clinical benefit (e.g., CD4 count or tumor shrinkage) if the treatment is intended to treat a serious or life-threatening illness and is reasonably likely to be superior to available therapies [31]. The FDA in turn receives agreement from the drug's sponsor to complete confirmatory trials in the postapproval period. If the postapproval trials fail to show clinical benefit, the FDA has a mechanism to remove the drug from the market in a timely manner. If history is any guide, the regulatory evolution of the FDA will continue into its next 100 years. Recent efforts have focused on enhancing the agency's ability to monitor the safety of drugs and devices in the postapproval period [32]. The agency has also become more active in collaborating with sponsors, academe, and clinical societies in order to improve the return on the nation's public and private investment in research and development. The FDA's Critical Path project is one such promising area of regulatory research. The program includes efforts to provide a structure for the inclusion of response or toxicity biomarkers into the drug development process, an area that is certain to receive additional attention in the coming years [33].

Amidst this regulatory framework, and in concert with the evolution toward evidence-based medicine, the commercial pharmaceutical industry has risen to become the dominant source in the development of new therapeutics. From the development of aspirin in 1897 to today's molecularly targeted cancer therapies, most diseases now have at least some symptomatic or curative medicinal treatments. In addition to development of the basic science that paved the way for rational development of new drugs, and the clinical science that created the foundation to determine their safety and efficacy, two pieces of legislation played a major role in paving the way for the modern pharmaceutical industry. Both pieces of legislation arose from a perceived need to provide a greater economic incentive for the development of new drugs. The Orphan Drug Act, passed in 1983, provided 7 years of

exclusive marketing and large tax credits to cover research and development costs for any drug designed to treat a rare disease. Similarly, the Drug Price Competition and Patent Term Restoration Act, passed in 1984, provided industry with extended patent protection to cover the significant time required for research and development and allowed generic versions of drugs to be produced and marketed without repeated expenditure for clinical trials of the generic formulation. Though other factors likely contributed, the passage of these laws in the early 1980s corresponded with an exponential rise in expenditure on research and development by the pharmaceutical industry.

In 2006, research and development (R&D) spending for the biopharmaceutical industry alone was as high as \$55.2 billion [34]. Member companies of the Pharmaceutical Research and Manufacturers of America (PhRMA) spent approximately \$2 billion on R&D in 1980; over the last quarter century, they have grown their R&D expenditures at an astonishing compound annual growth rate of more than 12%. This growth in private R&D spending has dramatically outstripped the growth in spending by the National Institutes of Health (NIH). In 2006, the NIH budget amounted to \$28.6 billion, a little more than half of the amount spent by biopharmaceutical companies [35]. This growth reflects underlying secular changes in the process of drug development. Once the purview of a few fine chemical companies located in the Upper Rhine Valley in Switzerland and in the greater Philadelphia area, the effort to discover and develop new drugs has transformed into a commercially focused, capital-intensive enterprise fraught with risk and uncertainty and producing many more failures than successes. In fact, fewer than 1 in 10 drugs entering clinical trials will ever gain marketing approval from the FDA [36], and at least 1000 molecules are screened for each that enters clinical testing [34]. For some diseases such as cancer, the ratio of winners to losers is even more unfavorable [37]. Of the thousand of agents in some stage of clinical or preclinical development, as few as 20 new molecular entities will reach the FDA regulatory standard for approval. The high failure rate and demanding regulatory standard together drive the cost of new drug development, which by some estimates exceeds \$800 million for each successful approval [38].

The effort to manage the investment in drug development has led to the formation of another thriving entity—the contract research organization (CRO). With more than 1000 CROs in operation and with industrywide revenue exceeding \$17 billion, for-profit CROs have, in large part, taken over academia's historic role in organizing new drug development. Clinical researchers from the academe remain crucial to some aspects of development, but CROs now often take the lead in identifying study centers, recruiting patients, acquiring and monitoring data, and even performing relevant statistical analyses. As of December 2007, there were more than 11,000 clinical trials actively recruiting patients for a treatment clinical trial according to [clinicaltrials.gov](http://clinicaltrials.gov). The work required to plan and execute all of these trials has overwhelmed the resources in both the academe and in the pharmaceutical industry, especially as the pharmaceutical industry completes substantial downsizing efforts. A series of high-profile incidents involving research subjects sustaining harm along with potential conflicts of interest have drawn criticism over the industry's increasing reliance on CROs. It is possible that at some time in the future, CROs will be subject to additional regulatory scrutiny and action; for now, their role in clinical drug development appears secure.

#### 5.1.4 PROTECTION OF HUMAN RESEARCH SUBJECTS AND BIRTH OF BIOETHICS

The history of clinical trials and the pharmaceutical industry is closely tied to the history of bioethics, the concerns of which now shape the regulation of clinical research and pharmaceutical development. Though medical ethics traces its routes back at least to the teachings of Hippocrates and the dictum “*primum non nocere*” or “first do no harm,” the rise of modern bioethics began in the twentieth century with the reaction to the atrocities of Nazi science. It is important to understand that the origin of modern bioethics as it concerns research ethics (the ethics of clinical research) emerged from a reaction to scandal, rather than an *a priori* guide to how to conduct clinical science. There is a strong and continued emphasis on protection of human subjects from research that at times appears to come into conflict with the need to recruit patients to clinical trials to advance care for future patients. By recognizing the origins of the concerns of human subjects’ protections, and the continued need for emphasis on respect of research subjects as persons, it is possible to conduct clinical research efficiently, while securing the ethical foundation of such science.

Nazi science was characterized by use of human beings as research subjects without their consent, to explore the limits of human endurance, the effects of exposure to extremes and a variety of toxins, and characterized by complete disregard for the well-being of the subject [39]. The crimes of Nazi science were publicly exposed at the Nuremburg Medical Trial of 1946–1947 in which 23 German doctors were tried for experiments performed on victims in concentration camps from 1933 to 1945 [40]. The Nuremburg Code, published in 1949, was developed to not only ensure that such atrocities were never repeated but to advance the ethical conduct of all studies involving human subjects. The first principle established by Nuremburg was the requirement for voluntary informed consent on the part of the research subject [41]. This principle remains at the heart of human subjects protection and is a core component of all further codes of ethical research, though how to define and obtain meaningful informed consent remains a subject of debate. Additional principles related to the need for clinical research to be conducted in the interest of humanity, based on good preclinical science, designed to minimize harm to subjects, with consideration of the welfare of subjects and their right to decline participation ensured throughout the research [41]. The Nuremburg Code was a starting point, but further guidance was needed to establish broadly based guidelines for research ethics.

In the wake of involvement by physicians in Nazi experiments, the World Medical Association (WMA) established the Committee on Medical Ethics in 1952. Based on a series of meetings and debates, the WMA published the Declaration of Helsinki in 1964 [42]. The declaration emphasized the rights of research subjects to be informed of the potential risks involved in research and of the voluntary nature of research participation. This document recognized a distinction between research with therapeutic intent that might benefit the subject and research with scientific goals only, but emphasized that under all circumstances “the interest of science or society could never take precedence over considerations related to the well-being of the subject” [42]. Ethicists have debated the practicality of imposing such a principle on research that by definition involves unknown risks to subjects, but the

principle of respect for the rights and well-being of the subject that the Declaration establishes is clear.

No history of clinical trials would be complete without consideration of the significance of the Tuskegee syphilis trial. This study was initiated in the 1930s by the U.S. Public Health Service to evaluate the impact of untreated syphilis in a cohort of African American men. Though there were few known effective therapies for syphilis at the time of initiation of the study, the deadly natural history of the disease had already been demonstrated in Scandinavian subjects [43]. In the context of that time, this question of the course of untreated syphilis in black patients clearly arose out of racism. Further, the subjects were tricked into participation in an observational study under the false premise that they would be receiving therapy. For example, subjects undergoing a lumbar puncture for research purposes were solicited to receive a “special treatment” from the nurse [43]. Though this study was initiated prior to the Nuremburg Code and Declaration of Helsinki, it was continued by the U.S. Public Health Service and published in major journals until 1972, when the scandal was exposed by the press [43].

Failure to consider the well-being of research subjects was also not exclusive to racist research. In 1966, H. Beecher, a professor of anesthesiology at Harvard Medical School wrote a landmark exposé of 22 clinical studies supported by top academic, government, and industrial institutions, and reported in leading medical journals, that violated the rights of the participants, frequently through failure to obtain informed consent [44]. In response to Beecher’s publication, the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established, and the report of the commission, the Belmont Report was released in 1978 [45]. The first principle, respect for persons, called for respect of subjects’ autonomy and the need for special protections for those with decreased autonomy (e.g., in children, subjects with neuropsychiatric disorders, or imprisonment). The second principle, beneficence, called for proactively taking steps to promote the well-being of research subjects, in addition to seeking to avoid harm and respecting their wishes. Finally, the Belmont Report recognized the principle of justice, which called for research to be conducted among populations who could benefit from the research. The report emphasizes that all clinical research must be clearly distinguished for routine clinical practice, that voluntary informed consent is required, and that research must be carefully designed to maximize potential benefits and minimize potential harms to the research participants [45].

Many guidelines and national and international codes of research ethics have been developed and promoted since the publication of the Nuremburg Code. The core principles in 13 major codes and declarations were evaluated and analyzed recently by Emmanuel and colleagues; they elucidated seven ethical principles that should guide all clinical research [46]. These principles of value, scientific validity, fair subject selection, favorable risk–benefit ratio, independent review, informed consent, and respect for potential and enrolled subjects are proposed as universal requirements of clinical research, grounded in the underlying principle of respect for persons [46].

The need for regulation of clinical research should not obscure the fact that, for many interventions, testing of safety and efficacy within a clinical trial may be the most ethical way to provide a novel intervention to a patient for whom outcomes with standard therapy are inadequate. A prime example was high-dose chemother-

apy and bone marrow transplantation for breast cancer. Early-phase single-arm studies among patients with advanced disease demonstrated results that appeared substantially better than those seen among historical controls treated without transplant [47]. In fact, advocates for breast cancer patients and some clinicians questioned the ethics of conducting randomized trials for a “proven therapy” [48]. In a tawdry portion of the history of clinical research, the story was complicated by the falsification of data by a prominent researcher, Bezwoda, who presented fabricated randomized clinical trial data at major scientific meetings and in publication [49], further promoting the use of this intervention prior to confirmation in ongoing randomized trials, and in fact, likely slowing accrual to those trials [3]. In the end, well-designed randomized control trials demonstrated no improvement of outcomes for women with advanced breast cancer from high-dose chemotherapy and transplant compared to less aggressive and toxic forms of therapy [50].

### 5.1.5 ACADEMIA–INDUSTRY COLLABORATION

In addition to general concerns over human subjects protection in clinical research, there has been recent increased attention to the role of the pharmaceutical industry in clinical research. In brief, this concern stems from the fact that the pharmaceutical industry now plays the dominant role as the sponsor of clinical research and the fact that most elements of the pharmaceutical industry are for-profit. As noted above, in 1992, pharmaceutical industry investment in research exceeded the operating budget of the NIH for the first time. Increased funding appears to have translated into increased sponsorship of published clinical research. An increase in documented pharmaceutical sponsorship of clinical research over time has been noted in stroke trials [51], oncology trials [52, 53] and in randomly selected trials from five medical journals [54]. The majority of studies in many areas of medical research are now supported in some way by the pharmaceutical industry.

One interesting aspect of the association between pharmaceutical sponsorship and clinical research has been the observation that pharmaceutical industry involvement correlates with publication of positive clinical trials. This association was first noted by Davidson et al. in 1986 [55]. Davidson’s initial observation was supported by a systematic review reported in 2003 by Bekelman et al. [56]. Pooled analysis of 37 studies, which collectively included 1140 clinical trials, demonstrated that industry sponsorship correlated with positive study outcomes or “pro-industry” conclusions with an odds ratio of 3.60 (95% confidence interval, 2.63–4.91). The reason for this association is unclear, but potential explanations include biased trial design, or interpretation of results, superior or safer selection of agents to take forward into later phase trials, or failure to publish negative studies [52]. These possibilities support the movement toward clinical trial registries and further evaluation of this association.

Concerns over potential bias in research sponsored by the pharmaceutical industry have heightened the tension over closer academia–industry collaborations. It is not surprising that as the pharmaceutical industry became the dominant funding source for clinical trials and the academic medical centers remain the dominant site for clinical research that academia and industry would by necessity become partners. Several studies have addressed conflicts of interest in academia–industry relationships. In 2000, Boyd and Bero reported that 7.6% of faculty investigators reported

financial ties with industry with the percent of involvement growing over time, likely representing an underestimate based on variable and voluntary reporting requirements [57]. In an effort to manage potential bias and conflicts of interest in academia–industry collaboration, the International Committee of Medical Journal Editors issues guidelines for clinical research, but as of 2002, it was not clear that these guidelines were widely implemented, leaving this an ongoing area of interest and evaluation [58].

Ultimately, well-regulated collaboration between academic centers and the pharmaceutical industry should continue to yield advances in therapy to the betterment of society. In fact, the model of academia–industry collaboration in oncology stands out as an example of what can be achieved when the resources and efficiencies of industry partner with the intellectual resources of the academic world, and increasingly with clinical care in both academic and community-based research centers.

### 5.1.6 CASE STUDY: EARLY-STAGE ONCOLOGY TRIALS

Over the past two decades, the growth of clinical research in oncology has exceeded the growth in all other areas of medicine. A great deal of scrutiny of the cancer-related research infrastructure has accompanied this growth, providing an excellent case study on which to highlight many of the issues raised in this chapter. As of early December 2007, there were 6214 clinical trials actively recruiting patients with cancer that were registered with the National Institutes of Health (NIH; [clinicaltrials.gov](http://clinicaltrials.gov)). Most (80%) of these trials were early-phase, or developmental trials (phases I and II), with 1653 phase I trials and 3323 phase II trials. The number of drugs and biologics in clinical trials for the treatment of cancer is now greater than the combined total of the next two most represented therapeutic classes, anti-infectives and immunologics [36]. Cancer drug development has transformed from a low-budget, government-sponsored enterprise to a high-stakes multi-billion-dollar industry with hundreds of biotech and pharmaceutical companies seeking approval and adoption of their products [59].

The structure regulating clinical trials is complex, with multiple agencies and groups sharing responsibility and oversight. At the federal level, the FDA regulates industry-sponsored research, while the Office of Human Research Protection (OHRP) oversees human research sponsored by the Department of Health and Human Services (HHS). In the wake of highly publicized lapses in the oversight of clinical research and instances of questionable ethics of some investigators, some of which led to tragic outcomes, the OHRP was recently elevated from the NIH to the Office of the HHS Secretary. In addition, individual or centralized institutional review boards (IRBs), ethics committees, clinical investigators, and sponsors all add layers of oversight to clinical cancer trials to ensure that they are performed safely and ethically.

Phase I trials represent the first testing of an experimental agent in humans, acting as a point of translation of years of preclinical work into the clinic [37]. As already outlined, the major objectives during phase I are to characterize the agent's toxicity profile and to determine a schedule and dose appropriate for further testing. Phase I cancer trials differ from phase I trials in other areas of medicine in two important ways. First, phase I trials in other areas of medicine typically enroll

healthy participants, whereas phase I trials in oncology almost always enroll patients who have cancer and who have exhausted standard treatments. Second, investigators and patients seek to realize therapeutic benefit in phase I cancer trials, usually as a secondary endpoint. Unlike phase I trials in other areas of medicine, treating physicians almost always enroll patients in phase I cancer trials with therapeutic intent, and patients often expect to benefit [60, 61].

The ethical basis of phase I cancer trials has been questioned, in part because they involve potentially vulnerable cancer patients near the end of life [62]. Some ethicists have raised concern that patients who chose to participate may experience significant risks with little chance to benefit. Others have pointed out that patients who participate have unrealistic expectations about the probability of benefit or the goals of research, despite having gone through the informed consent process [63]. Still others have been concerned that cancer patients may have judgment that is clouded by their illness and therefore cannot make truly voluntary decisions.

Much of the debate has now evolved to focusing on the estimated risk–benefit ratio in phase I trials. Over the 5-year period from 1986 to 1991, three groups published response rates in meta-analyses of phase I clinical trials [64–66]. Rates of objective response (usually as defined by tumor shrinkage by greater than 50%) ranged from 4 to 6%. Toxic death rates were reported to be around 0.5%. A major limitation to the relevance of these studies is that they are outdated and do not include assessment of the risks and benefits associated with phase I trials of the newer targeted agents. Researchers at Harvard recently reported trends in the risks and benefits to patients participating in phase I clinical trials submitted for presentation at the American Society of Clinical Oncology over the period of 1991–2002 [37]. The overall respective response and toxic death rates of 3.8 and 0.54% were similar to those published in prior meta-analyses. What was striking, however, were the trends over time. The overall toxic death rate for 213 published studies from this sample decreased over time, from 1.1% over the first 4 years of the study (1991–1994) to 0.06% over the most recent 4-year period (1999–2002). After adjusting for characteristics of the investigational agents and the experimental trials, the odds of patients dying from an experimental treatment fell by more than 90% from 1991 to 2002. Interestingly, the odds of a patient dying from a targeted or biologic treatment were four times lower than the odds of dying from a traditional cytotoxic agent. Rates of objective response also declined over time but by proportionally much less.

There has been no explicitly articulated standard about what determines a socially acceptable risk–benefit ratio [67]. Agrawal and Emanuel recommended comparing risk–benefit ratios in phase I cancer trials to socially accepted determinations already used for cancer such as FDA approval standards. By this construct, the risk–benefit ratio of many phase I cancer trials may not be clearly worse than those used by the FDA in its approval of anticancer drugs or by medical oncologists in their treatment decisions. In the Harvard study [37], some phase I trials produced as high or higher rates of response than those used to support FDA approvals. FDA approvals for irinotecan in colon cancer and topotecan in ovarian cancer were based on phase II response rates of 10–15%. In comparison, the response rates among trials in the top decile of phase I trials analyzed by the Harvard group exceeded 13%. Response rates in phase I trials are also comparable to those in the third-line or greater treatment of many solid tumors. Making these considerations more complex is the

understanding that patients confronting death may have higher tolerances for risk than agencies overseeing their clinical research. George Zimmer, an English professor and phase I trial participant, wrote that “the enemy is not pain or even death, which will come for us in any eventuality. The enemy is cancer, and we want it defeated and destroyed. This is how I wanted to die—not a suicide and not passively accepting, but eagerly in the struggle” [68].

### 5.1.7 CONCLUSION

Clinical trials have evolved from a time when empiricism was viewed with derision by those who believed medical therapy should be based on theory and a priori understanding of health and disease to the foundation of evidence-based medical practice. Recognition of diseases as discrete entities, rather than personal states of imbalance, transition of health care from home to institutions such as hospitals, and the development of methods for valid comparisons of therapy and control of bias were all critical factors in development of the modern clinical trial. Clinical trials have been instrumental both in preventing the use of ineffective treatments from bloodletting, to bone marrow transplant, to breast cancer and in providing a platform for development of novel therapeutics that have revolutionized medicine and improved outcomes for patients. The progress in clinical trials has been built on the efforts of many diligent investigators and countless patients who have become research subjects. Along the way, we have learned to design better trials and to take better care of patients participating in these trials. Institutions and industry have emerged to regulate and promote clinical research and the development of complex relationships between government, industry, clinical research organization, academia, and community practices to advance medical knowledge safely and efficiently is ongoing. The optimal design of clinical trials remains contested in many areas, ethical questions regarding the quality and requirements of informed consent abound, and debates regarding the balance of evidence-based practice versus clinical wisdom continue.

We are entering an era of targeted therapy based on understanding of the molecular biology of disease and the ability to rationally design drugs for selected targets. In addition, we are finding that understanding the discrete disease entity alone is not sufficient for optimal treatment, and the specifics of the individual patient, from co-morbidities, physiologic status, and pharmacogenomic differences can play a major role in the outcome of any given therapy. Now more than ever before, clinical trials have the potential to transform medicine and improve health, and the dedication of researchers, and most importantly patients who are willing to participate in clinical research are needed to write the next chapter in the history of medicine.

Adaptive research denotes an approach to clinical trials that incorporates what is learned during the course of a study or development program into how it is completed, without compromising validity or integrity. Adaptive components need

not be confined to the frequently encountered but unduly narrow vision of enabling changes in a study's design, valuable and interesting as such changes are. Rather, adaptive methods may encompass potential changes in all program-related resources and activities, including changes in logistical, monitoring, and recruitment procedures, and sometimes even personnel and travel requirements. The goal of adaptive methods is making better and more timely decisions to allocate all study resources more efficiently, reduce costs and timelines, and better achieve informational goals compared to traditional study and program approaches.

Efficient management is particularly important in activities as complex as clinical research, which involves a range of activities that includes patient recruitment, randomization, supply chain logistics, and flow of information. Additional complexity commonly arises when pharmaceutical studies are conducted at multiple sites, often in different countries, cultures, and languages. Effective management of clinical trials requires continuous monitoring and measurement of numerous activities. The essence of adaptive research is to continuously measure progress in the many aspects of a complex study, learn from such measures, and, based on what is learned, act expeditiously to make changes to improve the remainder of the study and even an entire development program.

On a pragmatic level, adaptive studies not only require the ability to measure outcomes of interest continuously but also to make data and summarized information about those measurements available in a timely manner to different audiences according to study role. This is essential for effective study management. In a clinical context, this means not just continuously tracking trial data collected on case report forms but also generating performance metrics that enable refinements in operations. This learn-as-you-go approach contrasts with the traditional black-box methodology of clinical trials in which data and particularly operational indices are often lacking altogether or available too late to enable study personnel to respond: Clean data are generally not available until after a study is completed, and study performance metrics such as recruitment rate, reasons for screen failures, and the like are often lacking entirely.

Interest in adaptive methods has mounted as a result of the soaring cost of clinical research and numerous trial failures, including particularly costly and well-publicized failures of major late-stage trials. In addition to greater efficiency, adaptive methods provide a number of appealing advantages, such as a more nuanced view of product performance that may enable earlier strategic decisions about appropriate target populations, earlier warnings about ineffective trials, and a broader view of research programs as continuous, integrated activities rather than a staccato, linear series of separate trials with inevitable delays in between.

Adaptive methods seek to bring "gold-standard" trial methodology up to date by taking advantage of the many technological advances during the 60 years since the trials that established comparative clinical trials as a means of assessing a pharmaceutical product's performance in the late 1940s [1]. Particularly salient are markedly more efficient approaches to data capture and validation, the growing power of affordable desktop computers, and the ability of the Internet to move data throughout the world easily, quickly, and cheaply.

Advances in data capture and validation open possibilities for much earlier understanding of study performance and trends. Computational advances stimulated the development of statistical methodology enabling midcourse "looks" at study progress based on data collected to date. The most common example is

sequential analyses, which preserve design integrity but inform decisions that improve the course of the study. The simplest result of such an interim analysis is early stopping for futility. Although statistical methodology is beyond the scope of this chapter, both books and software have become available that focus on adaptive research. See, for example, Chow and Chang [2] and Hu and Rosenberger [3].

An additional benefit of adaptive approaches is enabling a more nuanced perspective into candidate performance, following the realization over time that a simple “yes–no” answer as to a drug’s efficacy is likely an oversimplification. Adaptive trials maintain the same high standards of scientific integrity and reliability as the standard methodology while dramatically improving operational and economic efficiency and informational breadth, depth, and quality.

Adaptive research also allows clinical researchers to employ the same basic management principles as typical modern businesses, using real-time data and analysis to inform decisions that continually optimize operations. Figure 1 contrasts the continuous acquisition of knowledge in adaptive studies with a conventional trial that does not generate clean, meaningful data until much later. Adaptive methods require continuously updated operational performance metrics; the conventional approach often lacks the real-time data essential to make such metrics available to improve trial management.

Preserving study integrity—the ability to perform unbiased clinical evaluations—is paramount with all clinical evaluations, including adaptive ones. While commonplace in other industries, managing in response to changing data is fairly new in clinical research because excluding bias has been achieved primarily by denying access to data, including much of the data that would be useful for trial management. Like conventional trials, adaptive research still relies on techniques to exclude bias, including blinding. However, adaptive trials also employ additional planning and special operational procedures that prevent those performing the study from accessing unblinded results data. Only designated individuals have access to the information required to make decisions about specific adjustments during the trial. Firewalls

**FIGURE 1** With the traditional approach (dashed line), most knowledge is acquired at the end of the trial. An adaptive approach uses newer techniques to capture and analyze data continuously, to support both scientific inferences and performance measures—knowledge that managers can use to support decisions to tightly manage the trial. The difference between the two approaches represents the ignorance handicapping the managers of a traditional trial. (Figure copyright 2006, Health Decisions, Inc. Used by permission.)

must be incorporated from the outset to ensure that decision makers cannot jeopardize, whether knowingly or not, the study's scientific integrity. Fortunately, sophisticated computer access control and data encryption techniques provide useful tools for controlling the dissemination of information and potential sources of bias.

Developing protocols for adaptive trials demands more attention than conventional planning because multiple scenarios must be considered and specific plans included for addressing each. For example, a study that involves midstudy elimination of dosing arms (pruning, a common technique in dose-finding trials) normally includes safeguards to ensure that investigators are blinded as to which dose is being eliminated. Maintaining the blind may require logistic changes such as different packaging of study supplies. Additional examples of measures to exclude bias are included in Section 5.2.4.

### 5.2.1 TYPES OF ADAPTIVE TECHNIQUES: STRATEGIC AND OPERATIONAL

Any study involves both a strategic design and operational plans. Adaptive techniques similarly fall into the two broad categories of strategic adaptations and operational components. Strategic adaptations refer to changes in the study's design, such as the number of subjects to be included or how patients are to be allocated to treatment arms during the study. Operational adaptations focus on how the study is run: recruitment, enrolling patients, improving data quality (measured by number of queries generated), assuring timely responses to data discrepancies, detecting site performance problems early, and efficient means of allocating resources such as field monitors. Although much recent discussion focuses on the strategic components of adaptive research, the operational components can be at least as beneficial to timelines and budgets. Moreover, operational adaptations have the advantage of not requiring regulatory approval. Operational adaptive methods enable far tighter trial management through continuous monitoring and refinement of the many elements involved, resulting in savings in time and expenses of 20% or more compared with traditional management techniques. In the light of ever increasing study budgets, the savings from operational adaptations have strong appeal.

There are several prerequisites for both strategic and operational components of adaptive research: the continuous, timely collection of data and generation of meta-data (data *about* the data, such as performance metrics that might include rates of enrollment, screen failures, queries, and the like); the ability to rapidly turn a stream of raw data into meaningful information; and the ability to present information in different forms to meet the needs of study staff performing different functional roles. All these are essential to enabling specific informed actions to improve trial operations. Indeed, at many points during a trial, the measures of how the study is progressing may demand greater attention than the actual data collected as part of the clinical evaluation; the need for trial data may be intermittent (e.g., at an interim analysis), while the need for metadata to inform management decisions is continuous.

Efficient electronic data collection (EDC) is an absolute requirement for adaptive research. Unfortunately, not all EDC is efficient in practice. EDC for adaptive purposes must be able to capture data in electronic form shortly after it is generated and quickly transfer it to a central database. Many EDC systems currently used in

the pharmaceutical industry rely on hand keyboard entry (“Web-based” EDC systems), which result in unnecessary delays in data acquisition. Such delays typically range from several days to several weeks, reflecting the lack of enthusiasm among clinical personnel for performing the tedious chore of keyboard data entry. A second and more important shortcoming of many EDC systems is their inability to track metadata, or the metrics that enable effective study management. EDC systems that fail to provide an integrated means of addressing important dynamic components of adaptive trials such as supply management and patient randomization can induce as many problems as they solve. The fact that Web-based EDC systems have existed for more than 7 years and yet the majority of clinical trials continue to be done with paper and pen reflects the industry’s experience that Web-based EDC is expensive, difficult to implement and maintain, and often fails to deliver bottom-line benefit. Alternatives to Web-based EDC for adaptive trials are included in Section 5.2.4.

While substantial improvements in efficiency may be gained through strategic adaptive methods, the optimal approach to clinical trials incorporates both strategic and operational elements. Combining both elements promises to go beyond improving the mechanics of individual studies to improve how studies and development programs are managed. Like the navigators of old who planned long voyages based on inaccurate maps and poor or nonexistent navigational equipment, planners of clinical trials today must start out with plans based on guesses. In clinical trials, the guesses are about key trial parameters such as the size of the treatment effect, variability of data, dropout rates, and even the appropriate range of dosages to test. Modern drug companies, like the early explorers, have often learned too late that their best planning efforts have landed them not at the intended destination with rich economic rewards but in unforeseen surroundings with bleak prospects. Adaptive techniques represent a GPS (Global Positioning System) for present-day clinical trials: We must still make initial guesses, but the capacity to make multiple midcourse corrections, on many levels, is an integral part of the study. Rather than relying on a series of discrete decision points, an adaptive approach substitutes a process of continuous assessment and response. As a result, study staff is no longer condemned to making guesses and then sticking with them until the study is done, only then discovering how each guess compares to reality.

Clinical development is evolving from the traditional model of discrete phases punctuated by pauses to a continuous process. The traditional model is one of defining safety and kinetics (phase I), then defining optimal doses (phase II), then pivotal studies required for regulatory approval (phase III). The emerging integrated model is largely made possible by an adaptive approach that renders the process continuous, with faster decision making along the way, the flexibility to shorten (or lengthen) certain components in response to data generated, and minimizing or eliminating the gap between studies. Indeed, this so-called learn–confirm model can extend beyond development to postmarketing, maximizing learning about a product throughout its life cycle, minimizing postmarket problems, and maximizing opportunities.

The following sections that discuss specific adaptive techniques are arranged according to the chronology of development, starting with the earliest clinical studies in a product’s life cycle, efforts to define the safety envelope, and the balance between efficacy and safety. We then progress through larger studies that focus on

better definition, selection of dosing for large-scale confirmatory (pivotal) studies, and finally pivotal studies. An important difference in how study design is approached, especially in regard to adaptive techniques, between earlier studies to define safety and dosing and the pivotal studies that serve as the basis for marketing approval, is that regulatory bodies grant a greater degree of autonomy in the early (learning) evaluations (subject, of course, to the broad constraint of not jeopardizing the safety of subjects involved in evaluations). Thus, the learning phase currently offers greater opportunity to apply adaptive approaches. The use of adaptive methods in the learning phase allows earlier, more accurate determination of promising and less promising products, reduced development time and expense, and reduced wasting of resources on candidates that eventually fail to reach market.

## 5.2.2 STRATEGIC ADAPTATIONS

### 5.2.2.1 Drug Performance and Rising Dose Escalation Studies

The earliest phases of development involve confirmation of pharmacokinetic (PK) and pharmacodynamic (PD) assessments from animal models and determination of approximate dosing ranges for human administration. Such studies are usually performed in “normal” (disease-free) populations and may, to a limited degree, explore these parameters in individuals for whom the product is ultimately targeted. The keys for these early studies are rapid acquisition and assessment of data and timely decision making, minimizing the interval between when a dose is administered and when a decision can be made with respect to the next dosing.

For PK and PD studies as well as early studies that rely on these parameters (e.g., dose escalation), assessments are normally batched to reduce the expense involved in running samples. However, the balance between the reduced costs of batched assessments—always a choke point—and the potential economic gains from earlier availability of assessment results, may warrant a reexamination of traditional reliance on batching samples. Each assay and product under evaluation differs, but researchers should at least consider the alternative of obtaining data from individual tests earlier.

Rising-dose escalation studies illustrate the critical nature of rapid, accurate data in achieving high velocity in clinical studies and programs. The interval between dosing, assessment, and a decision about progressing to the next higher dose often consumes 6 weeks. Adaptive techniques, with their focus on the rapid collection and assessment of data, as well as rapid dissemination of information for appropriate action, may reduce this interval to days or even a single day. This can be accomplished by (1) exploiting the availability of data very quickly after drug administration and collection of safety data, (2) using a system that efficiently collects and summarizes data, and (3) disseminating and displaying the information via a universal mechanism such as the Web.

Figure 2 shows a system that meets these requirements and enables next-dose decisions to be made within 2 days of the last dose; this rate-limiting step is dictated by a 48-hour primary observation period after administration. The requirement for rapid data availability mandates use of a digital pen (Fig. 3) for data collection along with processes and software that enable the data for each individual to be

**FIGURE 2** Immediate, clean data requires the ability to collect, digest, and report a variety of data and performance metrics. While data collection systems are common, these may take extended periods to enter data. Most systems currently in use lack the “middleware” (central box) necessary for rapid data collection and validation as well as the ability to report data rapidly. In addition, few systems routinely generate performance metrics, such as indicators of recruitment progress and issues, essential to running a tight study that minimizes timelines. (Figure copyright 2007, Health Decisions, Inc. Used by permission.)

**FIGURE 3** A digital pen used for data capture. This method electronically reads in data, eliminating the requirement for manual data entry. (Figure copyright 2006, Health Decisions, Inc. Used by permission.)

displayed within minutes of when it is collected. Summaries that show data on all subjects are displayed over the Web, enabling timely access by decision makers regardless of location or time.

The benefits of this system are significant. First, the usual bottleneck the delays getting clean data is eliminated, making each subject and the collective experience of all subjects immediately available to appropriate members of the study team. A stream of raw data is transformed into meaningful information, summarized with drill-down capabilities, and presented in a manner that supports decisions about next steps. Second, decisions are more timely, nuanced and better informed because accumulated information can be tracked and analyzed along the way, rather than

waiting until the end to examine all data. Third, the ability to make this information immediately available to all decision makers regardless of location drives timelier and more efficient study management across all offices and sites associated with a study. Such an approach can easily cut four or more weeks from each decision cycle. With an early-phase study, this can translate to a reduction of 50% or more in study timeline.

### 5.2.2.2 Adaptive Dose Finding

Conventional dose-finding studies typically utilize a modest number of equal-sized treatment arms, generally three to four, often with a comparator arm. Each arm is administered a different dose for a given period, data are examined and, hopefully, justify a decision to proceed with the most promising doses into pivotal testing (the “confirm” part of the learn–confirm model). Planning for this approach involves selecting the most promising doses, then bracketing them; in effect, this builds on earlier dose escalation studies that gave a sense of the same information but with fewer subjects.

Dose-finding studies are conducted with the goal of winnowing dosing choices to a small enough number to allow proceeding to larger, more expensive pivotal trials. Compared to earlier studies, these involve more subjects receiving each dose, yielding more data, enabling greater understanding and greater certainty about efficacy and safety. Such studies are often planned (“powered”) with enough subjects to achieve statistical differentiation between dosing arms for the efficacy outcome. Although reassuring to decision makers, this approach may not be necessary to achieve the objective of rejecting some of the dosing arms. Adaptive techniques make possible earlier decisions to reject less effective or less safe doses, thus conserving resources and time. In addition, the ability to examine data as it accumulates can lead to superior understanding of the data and contribute to better decisions about doses to carry forward.

Under an adaptive scenario, information is made available as data are generated and go/no-go decisions can be made not at some predetermined interval but whenever the information generated yields sufficient knowledge to justify the step. In many instances, less desirable treatment arms (outliers) will be apparent early on. A key benefit of the adaptive approach is the ability to accumulate adequate information early in the trial to justify eliminating less promising arms, allowing the concentration of resources (notably study subject) to arms that show greatest promise. In such early learning-phase trials, regulators generally allow sponsors the latitude to forego a rigidly defined decision point in favor of making decisions on dosing arms when the sponsors are comfortable that sufficient information has accumulated (sponsor’s risk). Adaptive methods provide an opportunity for sponsors to make earlier, better informed judgments without pushing every arm to a sample size that provides statistically significant results. Rather, there is the flexibility to discontinue a treatment arm as soon as it becomes apparent that it is less desirable than others.

The adaptive approach changes the way dose-finding evaluations are performed. Importantly, since some arms can likely be eliminated early, there is the luxury of starting with a larger number of arms than would be possible with the traditional approach. For example, in a study of a neuroprotective agent administered a single time by IV (intravenous) soon after stroke, researchers established a procedure for

selecting 1 of 16 possible doses to be given each patient, with the dose in each instance selected based on data observed to that point in the trial. In the actual conduct of the trial, 15 different doses were tried [4].

The ability to test more arms at this stage means that earlier development often need not be as thorough. And because arms are cut off early, there is little or no extra expense in gathering data on a greater number of dosing arms and then focusing resources where they are most needed—in differentiating the final two or three dosing arms rather than in accumulating additional information about arms that data already show lack promise. Another benefit of earlier termination of less promising arms is that fewer patients are exposed to less efficacious and less safe doses. In addition, the ability to examine data as they are generated—where each new patient, visit, and evaluation adds to an existing storehouse of information, and trends may emerge from the changing data—often provides a far more nuanced perspective on product performance than a single cross-sectional view at the conclusion of an evaluation.

Figure 4 illustrates how an adaptive dose-finding study is conducted. If the informational goal is defined by 80 patients, then we begin with a number of dosing arms, in this case 8. Early on, data will likely make it apparent that many of these arms

| Time (mo)      | 2  | 4    | 6    | 8    | 10   | 12   | 14 | 16               | TOTAL             |

| #/arm/mo       | 10 | 10   | 10   | 10   | 10   | 10   | 10 | 10               |                   |
|                |    |      |      |      |      |      |    |                  | TOTAL \$6,000,000 |

**FIGURE 4** Comparison of adaptive (top) and traditional dose-finding studies. Dropping less promising arms early on (pruning) allowed this study to achieve its informational goals four months sooner, at a cost \$1.5 million less, by monitoring incoming data from the study's outset and focusing resources on the most promising arms. After the first observation period, one arm (T3) is terminated because of poor results for efficacy, safety or both. The remaining arms are continued to the next observation period, at which time an additional arm (T2) is similarly cut. The remaining dose arm and the comparator (P) may under certain circumstances then be rolled into the pivotal evaluation, utilizing data already gathered. (Figure copyright 2006, Health Decisions, Inc. Used by permission.)

are less promising and can be cut off earlier than is customary. Although Figure 3 shows discrete, evenly spaced decision points, these are in practice more likely to be irregular, with the most obvious decisions coming early in the study. The result of this approach in this example shows how the desired number of patients is reached earlier and at a lesser cost than would be the case if we had taken a traditional approach of using, say, four dosing arms that enroll 80 patients each. If each patient costs \$15,000, the adaptive study will be completed 25% faster (saving 4 months) and cheaper (saving \$1.5 million). The cost savings are even greater in the light of the institutional costs of maintaining a company for an extra 4 months, a factor that is particularly compelling for developing companies where such institutional costs can be a key determinant of success and, in some cases, survival.

### 5.2.2.3 Sample Size Reestimation

The progression of a compound into large-scale testing demands major commitments of time and money. A key driver of both study duration and cost is the number of patients required for successful completion of the study. The appropriate sample size is determined based on the magnitude of difference in outcome measure between the product being evaluated and a comparator, acceptable levels of possible error (risk of false-positive or false-negative results), variance of data, and rates of subject compliance and drop-out. With luck, initial estimates of these factors may be off only modestly, but they will still be off. If the estimates err more than modestly, the consequences for sample size requirements can be enormous. For example, reducing the estimate of treatment effect by one-half can quadruple the sample size for a fixed sample test and will require the maximum sample size for a group sequential test [5].

Underestimation of sample size may result in a study that fails to detect a difference between the test drug and the comparator, even if one is present; overestimation of required sample size wastes time, money, and other resources. The severe penalty for underestimation means that, in practice, sample size estimates err on the high side, with the consequence that time and money will often be spent unnecessarily in overcompensating for the possibility of falling short of the sample size necessary for detecting a difference. It is therefore not surprising that much research is devoted to approaches to adjusting sample size during clinical trials and a variety of methods are in use [6].

The benefit of an adaptive approach is that it enables an informational goal to be met precisely, arriving at a defined goal of informational content rather than by surrogate measures, neither undershooting nor overshooting. In this context, reestimation means adjusting each of the initially estimated parameters based on data that has actually been observed in the study rather than continuing to rely on the earlier guesses made without benefit of such observations. Reestimation can be employed multiple times for multiple course corrections, although careful attention must be paid to statistical techniques to ensure that design integrity is preserved. Sample size reestimation can be viewed as an extension of well-accepted group sequential trial designs that have evolved over the past two decades.

The value of sample size reestimation is illustrated by a recent oncology study, where this technique allowed the study to be completed 9 months sooner than originally planned. An interim analysis demonstrated an effect size ( $\delta$ ) considerably

stronger than originally anticipated. The savings from the resulting sample size reduction also extended beyond recruitment itself, eliminating the cost of treatment, supplies, monitoring, and follow-up for each patient that might have been included in excess of the number required to meet the study's informational goals. The oncology study's use of sample size reestimation contributed to a savings of \$16 million in development costs. Even greater financial benefits flowed from a 9-month reduction in time to market.

#### 5.2.2.4 Adaptive Randomization

Adaptive randomization can provide greater efficiency by altering the probability that a new subject entering the study will be allocated to a treatment arm that accumulating trial data shows to be more desirable and by ensuring that the desired statistical power is preserved [3]. Early on, when little is known about patient response to different treatments, a subject will be equally likely to be randomized into any treatment arm; during the course of the study, as outcome information accumulates, the randomization ratio can be continuously changed to favor the more beneficial or safe outcome (response-adaptive randomization), to balance covariates (risk factors that modify the probability of an outcome) across different treatment arms (covariate-adaptive randomization), or to balance an undesired deviation from the intended allocation ratio (treatment-adaptive randomization) [2]. There are also sophisticated combinations, such as covariate-adjusted response-adaptive randomization, a procedure that takes into account previous patient responses to treatments, previous patient covariates, and the covariates of the patient to be randomized [3].

In contrast, normal fixed allocation schedules ensure that each patient entering the study will have the same probability of allocation to each arm throughout the life of the study regardless of whether study data shows some arms to be unpromising by reason of lesser efficacy or safety. Continuing with fixed allocation ratios despite evidence of lesser efficacy or safety raises ethical concerns. When data shows an imbalance in covariates between treatment groups, continuing with a fixed allocation procedure can undermine the ability to draw valid inferences about differences in treatment effect. Moreover, continuing with a fixed allocation in the unfortunate event that an imbalance develops in the size of actual treatment groups can undermine statistical power and thus jeopardize the validity of the trial as a whole.

With response-adaptive randomization, allocation ratios are most commonly changed based on favorable outcome (assuming safety not to be an issue). There are different algorithms for achieving this goal. The most common is the randomized "play-the-winner" scheme, which assumes that the outcome for the previous patient is known before the next patient is assigned a treatment group. If the treatment for the preceding patient has a positive outcome (a success), an additional "ball" representing that patient's treatment group is added to the randomization pool; if the preceding patient has a negative outcome, no "ball" is added to the urn. If randomization were based on a bowl of black and white Ping-Pong balls, the study would begin with the same number of white and black balls. Over time, however, if one treatment is more beneficial than others, the randomization pool would progressively be seeded in favor of that treatment [2].

Response-adaptive randomization offers the additional advantage of collecting more data on patient response to the drug under test in the doses that are likely to reach market. This may result in greater understanding of the drug's behavior in the formulation that physicians will prescribe and patients will receive after approval. Physicians and patients will both benefit from superior prescribing information. When deciding whether to approve the drug, regulators may also benefit from the availability of more and better information on the doses that will be prescribed in the event of approval.

Covariate-adaptive randomization seeks to balance covariates across treatment groups by weighting the randomization procedure to increase the number of patients with certain covariates in the treatment group or groups in which these covariates have turned out to be underrepresented [2, 3]. (In practice, covariates can also be accounted for through mathematical techniques such as multivariable analysis.)

Treatment-adaptive randomization balances the number of patients assigned to each treatment group by using any of several weighting schemes based on adjusting the number of hypothetical balls in an urn in favor of the treatment group with lagging membership or creating the algorithmic equivalent of a coin that is biased in favor of that treatment group [2].

Adaptive randomization can be combined with a Bayesian approach to study design. This allows patients to be randomized to a specific arm in direct proportion to the degree of promise it shows relative to other arms. Thus, as experience accumulates and successful treatments are retained while unsuccessful ones dropped, the allocation ratio is progressively slanted in favor of the successful treatment. When a certain balance has been achieved, the study is declared to be completed. For example, if a study begins with a 1:1 randomization scheme but then adds each successful outcome back to the randomization pool over time and drops the unsuccessful outcomes (failures), the randomization pool becomes successively seeded in favor of the successful arm. A Bayesian approach allows a study to be defined as completed when a predetermined proportion is reached, say, 95% of patients are randomized into a particular arm, reflecting the experience of far greater success with that arm. The Bayesian approach is intuitively appealing in that it incorporates each new piece of information on success or failure of treatment into how the study proceeds from that point onwards. The Bayesian approach is also more broadly appealing in that it provides a way to minimize patient exposure to less successful arms on a continuous basis. In practice, however, Bayesian approaches may be complicated by the complex definitions of success and the requirement to consider safety, which is difficult to measure on a dichotomous scale.

The mechanics of adaptive randomization and a Bayesian approach require a centralized, real-time randomization system in addition to the other prerequisites for conducting adaptive studies, such as efficient data capture and cleaning, previously discussed. Besides supporting adaptive randomization, centralization and the immediacy of the electronic process also provide the ability to stop enrolling patients immediately when the target population size is reached, eliminating unnecessary effort and expense that are inevitable in less centralized systems. Even more important, the ability to stop patient enrollment instantly reduces the exposure of additional patients to less desirable treatments.

### 5.2.2.5 Seamless Designs: Rolling One Phase into Next

With growing appreciation of drug development as a continuous process, the notion of defining best doses and then rolling straight into pivotal studies utilizing the identified best doses becomes compelling. The strongest reasons for doing so are (1) minimizing the delay, often 12 months or more, between dose-finding studies and initiation of pivotal studies; (2) the efficiencies gained from going through the trial startup process a single time rather than twice; (3) a head start recruiting investigators and test subjects for the pivotal study; (4) the potential to adapt the population of the confirmatory phase based on data on responsive subgroups from the learning phase; and (5) the ability to combine data from the learning phase and the confirmatory phase in conducting a final analysis of trial data.

However, it is important to recognize as well that the break between phases can be an important time to analyze data and perfect the final design of a separate pivotal study. Study managers should weigh the possible need for an interval to allow greater analysis and more refined planning against the potentially huge savings in time and expense if phases can be combined. Additionally, managers should weigh the need to take advantage of an interim period for discussions with regulatory authorities to assure their acceptance of the plan as a basis for approval in the event of a successfully executed study.

A large study that is progressively refined from the phase II dose-finding stage and then continues into the phase III confirmatory study is among the most complex adaptive strategies but also the most rewarding. Executing this strategy is demanding because it requires a great deal of advance planning to anticipate and deal with different possible outcomes. In addition, the final statistical analysis may be extraordinarily complex.

The use of adaptive methods to combine phase II and phase III studies begins with establishing a number of dosing arms and pruning those down to the manageable two to three (including a comparator) for a confirmatory stage. Once the final doses have been identified, the study is then quickly expanded and, assuming a second pivotal study is warranted, it is implemented immediately (Fig. 3).

Simulations can be extremely useful in modeling possible outcomes and their ramifications. Adopting the strategy of rolling a phase II study into phase III requires confidence that all the methodologies and infrastructure essential for the adaptive approach are in place and functioning well—quick and accurate data capture, rapid data validation, the prompt generation of meaningful information, readiness for continuous decision making, and the capacity to manage logistics of the study, such as supply chain management, with great efficiency based on timely data. The benefits of rolling a phase II study into phase III are commensurate with the effort: This approach can easily reduce development time by a year or more and save many millions of development dollars.

Eliminating the gap between phases is only one of the benefits of rolling directly from a phase II study into phase III, conducting, in effect, one continuous study instead of two separate ones. This has the added advantage of incorporating in the phase III study the knowledge gained from relevant arms in the early dose-finding portions. There are also benefits for patient recruitment and data collection. Patients already screened in the dose-finding phase can be enrolled in the pivotal portion of the study, and existing patient data collected in the dose-finding phase can contrib-

ute to greater efficiency in the pivotal phase. However, it is important to be mindful that the protocol must not change from that specified at the initiation of the study; this places a premium on the challenging task of anticipating all outcomes when planning the study. Despite the challenges, the risks associated with combining phases II and III are low. The worst-case scenario for such an adaptive study, with no successful adaptations carried out, is the equivalent of conducting the same study conventionally, without the use of adaptive methods.

Combining data from the two phases requires procedures to control the type 1 error rate for the comparison of the test drug with the control. In addition, the final statistical analysis for the combined data from the learning and confirmatory phases will be more complex than usual [2]. It is also important to think through the plan for the seamless trial to ensure that the issues that might be analyzed between two separate studies are adequately analyzed in advance.

One of the greatest advantages of combining phases is that the entire startup process is handled once instead of twice. A single protocol can be developed, reviewed, and approved in a single process for both phases. Recruitment of investigators and patients is simplified because some of the investigators for the pivotal phase will already be familiar with the study. However, combined studies also require that many other investigators be set and ready to go when the final dosing decision is made. This raises a host of other issues such as making appropriate provisions for addressing an investigational review board (IRB) and making consent forms and study materials available in a timely manner. Considerably greater attention than usual is required to ensure that all requisite components mesh.

#### **5.2.2.6 Other Strategic Adaptations**

Another important class of adaptive techniques lays particular emphasis on extending the period of assessment and decision making. For example, it is possible to plan an adaptation that allows changing the test hypothesis from superiority to noninferiority, and to redesign multiple endpoints to update correlations or change the hierarchical order. It is also possible to establish a decision rule with criteria for determining whether to refocus the study on a subpopulation that is specified in advance. Noninferiority studies may be handled quite differently, especially in regard to hierarchical outcomes: These may, for example, declare success for an initial noninferior phase and then continue the study with the hope of generating data to support a superiority claim. The advantage of this approach is the potential for earlier marketing of the product. Obtaining data to support a noninferiority claim requires a more modest sample size and may yield results that allow the product to enter the market with a noninferior approval while the study continues to accumulate information that may support a superiority claim.

The range of techniques for strategic adaptations continues to evolve with the refinement of existing methods as well as the addition of new approaches and tools.

### **5.2.3 OPERATIONAL SIDE OF ADAPTIVE RESEARCH**

The fundamental principles of adaptive research apply not only to the sophisticated and innovative techniques for strategic adaptations but also to many of the activities

common to virtually all clinical studies, whether or not they involve strategic adaptations. Implementing efficient data capture, rapid data cleaning, generation of a range of performance metrics, and readiness for informed decision making based on such information can produce dramatic gains in efficiency. For historical reasons, the pharmaceutical industry makes little use of such capabilities today. Nonetheless, there is no reason why the industry should not take advantage of what amount to the same management techniques already used by most contemporary businesses to bring clinical studies into the modern era.

Since the necessary changes for operational adaptations need not affect study or program design, they do not require regulatory approval. Operational adaptations can therefore be implemented immediately, and their benefits are at least as profound as those flowing from strategic adaptations. One clear illustration is a large, complex phase III evaluation of an Alzheimer's drug candidate, where efficient collection of data and performance metrics enabled the completion of patient enrollment in record time and the closing of the database within 2 weeks of the last patient visit. As a result, this study saved 1.6 years and \$32 million in direct costs measured against the sponsor's internal projections of 5 years and \$100 million [7, 2000; this article can be found online at <http://www.healthdec.com/media/articles/AnAlzheimersDrugGoesonTrial.pdf>].

As previously noted, the same capabilities involved in making such gains in efficiency are required for all types of adaptive studies. In a broader sense, such capabilities represent the application of principles of tight management to the complex realities of clinical studies. Other industries have shown the way. The principle of just-in-time inventory brought new efficiencies to the automobile industry; the same principle, managing operations based on continuous, real-time information about important business processes, has been widely adopted in manufacturing and other highly competitive industries. While pharmaceutical development is considerably more complex and knowledge based than manufacturing, intelligent management can apply the same general principles to clinical studies while preserving study integrity and validity through careful operational controls and information management, preserving blinding, randomization, and other hallmarks of clinical research. The need for specific measures to exclude the possibility of bias does not, in an age of sophisticated access control systems, require near total ignorance for all study personnel of all study operations until the very end, when it is too late to take advantage of data and performance metrics for effective trial management. The need to remedy major shortcomings in the efficiency of current development practices is evident; so is the availability of methods with the potential to solve current problems and make dramatic, rapid improvements in efficiency.

Surprisingly, one critical requirement for tight study management is frequently overlooked: the timely reporting of performance metrics. Effective management is impossible without timely, accurate information about performance; in clinical studies, achieving tight management through operational adaptations requires the same capabilities as strategic adaptations: rapid data collection from the field, rapid data cleaning, timely analysis and summarization, and, importantly, presentation of information in different forms meaningful to staff performing different functional roles. The study manager, for example, may be centrally interested in knowing why certain sites are enrolling faster than others and will therefore want to track frequency of screen failures and the distribution of different reasons for them. The

field monitor may wish to know how to help a site decrease its query rate, allowing her to spend less time in managing minutiae of the study and, thanks to more accurate data collection and the reduced incidence of queries, more time helping sites conduct the study efficiently and achieve database lock faster. The head of R&D may be most interested in the projected dates for completion of enrollment and database lock. In summary, good performance metrics enable greater understanding of study progress, far tighter control, more effective allocation of resources such as monitoring time, faster enrollment, and, in the larger scheme of things, shorter timelines and lower costs.

#### **5.2.3.1 Enrollment**

Closely monitoring the progress of enrollment and the incidence of reasons some patients cannot be enrolled allows continuous tuning of enrollment strategies and criteria. Comparison of site performance, especially in larger studies, generally reveals a wide range of performance. The study manager's job is often to use such information to dig deeper, determine the reasons some sites lag in enrollment while others excel, and intervene as necessary to improve enrollment across the entire study. In some cases, close scrutiny of enrollment performance at different sites may reveal difficulties repeatedly encountered despite best efforts. In that event, case study managers may confront a decision about taking measures to overcome sub-optimal enrollment that is not due to operational inefficiencies, such as adding sites.

Comparison of site performance usually does reveal that certain sites are enrolling more effectively than the rest. The reasons may vary; the ability to track a variety of enrollment metrics in real time enables a manager to determine what the reasons are. Analysis begins with examining the frequency of screen failures and the reasons for them. Real-time access to performance metrics of the individual sites allows early identification of effective and ineffective recruitment activities for the particular study and its population. The lessons, both good and bad, should be shared immediately with all sites to enhance recruitment efforts studywide.

Detailed performance metrics on recruitment can also quickly determine whether any specific inclusion/exclusion criteria are disproportionately hindering recruitment of the desired study population. If this is the case, it is imperative to find out quickly. It may be appropriate to consider different recruitment strategies to obtain access to a more suitable population. Failing that, possible adjustments in inclusion/exclusion criteria may require consideration. Understanding the options depends on having timely, accurate enrollment data from investigative sites. The ability to manage enrollment effectively is impaired in direct proportion to the degree to which the availability of such data is lacking or delayed.

#### **5.2.3.2 Site Performance**

Much higher levels of efficiency are possible when study managers and monitors can track site performance continuously and in sufficient detail to identify and address problems. Most studies currently lack the ability to track such metrics. As a consequence study management becomes a passive affair left to the vagaries of the site monitor. Because monitors often lack training and experience managing

sites, there may be no one at all providing effective management. Furthermore, depending on any individual as an information and management filter invariably introduces subjectivity and uncertainty, no matter how well trained that individual may be.

Query rates and query response times on submitted data are easily measured and provide strong indications of site performance in general. Query metrics are important on several levels. Most importantly, the existence of numerous queries late in a study delays database lock and all downstream events, including analyses, progression, and submissions. In addition, instituting rapid data entry, validation, and return of queries produces faster, more meaningful feedback to sites on their performance, enabling each site to reduce errors, often quite significantly. By contrast, systems that rely on paper and pen, with double key data entry, generally take a month or more—often much more—to return queries to sites about data previously submitted. During the interval, each site, unaware of the problems in the data it collected, will continue to make the same errors, increasing the volume of errors and the time required to correct them and inevitably delaying database lock.

Key site performance metrics that should be continuously tracked include patients screened, screen failures and reasons, good clinical practice compliance issues, query rates, query resolution, the number and age of outstanding queries, and specific case report form (CRF) fields, forms, and validation ranges that are generating the most queries at each site. Number of adverse events, both serious and nonserious, should also be tracked.

Continuous attention to site performance indices has the additional benefit of allowing technology-enabled distributed management with reduced requirements for a monitor to go to each site to determine how things are going. Rather, the generation and tracking of such parameters enables all members of the study team to examine performance metrics. The metrics enable each member of the team to focus attention where it is most needed. The availability of detailed metrics also opens the door to performance-based site management, allowing study management to institute incentives for strong performance and disincentives for poor performance. Performance-based management stands in stark contrast with the present approach, with each site knowing it will be paid the same amount for each patient regardless of performance. Although this is currently the standard approach to “management” of investigational sites, it hardly deserves the name.

### 5.2.3.3 Adaptive Site Monitoring

Monitoring is one of the most expensive components of clinical research, typically accounting for one-third of study costs. Yet the objective of monitoring, while important, is fairly modest: To ensure that the data in the database is accurate. The high costs of monitoring investigational sites are often assumed to be inevitable sacrifices to the cause of ensuring data accuracy. An adaptive approach, however, can use the stream of timely information from the field to allow many functions now performed during site visits to be handled centrally, enabling far more rapid and standardized assessment of site performance based on performance metrics while also reducing costs.

The highest levels of monitoring efficiency are made possible by use of electronic data capture methods, such as the digital pen, that can serve as source documenta-

tion. Source document verification itself accounts for approximately 80% of monitoring time. The digital pen and similar devices, detailed in Section 5.2.4, are used by the clinician to write in a familiar way on a form laid out with a grid that enables software to match data entries to appropriate fields. Captured data is stored in the digital pen and transmitted to a central database, where the pen is inserted in a dock attached to a computer. With this approach, the digital data is not a transcription of the source data; it is the source data itself. It is unnecessary for the monitor to compare electronic data to an original piece of paper. Data first recorded in electronic form, including data values and an image of each completed form (reviewed if necessary to resolve any ambiguities), is checked and corrected promptly through queries to site personnel after both automated and human review. Use of EDC technology capable of serving as source data provides great cost savings in the source data verification process by eliminating the time and expense of comparing electronic data to stacks of printed material.

Much of the work that monitors currently do can be done much better and more accurately by systems that harness technology. Data capture that obviates the need for traditional source data verification is one example. Effective use of such technology in conjunction with adaptive techniques can reduce monitoring costs by two-thirds or more while enabling far faster and more effective verification of data accuracy.

Adaptive approaches to site monitoring reflect a fundamental change in the way studies are conducted. Increasingly, the tedious, repetitive manual tasks such as comparing two values on different pieces of paper will be replaced by electronic tools and automated processes. The evolution to such processes will be further improved with the adoption of electronic medical records, ultimately resulting in a monitoring process requiring no manual steps. As a consequence, the monitoring function will be changed from that of the box checker of today into that of a manager and consultant whose main job will be to assure site performance. The monitor will be able to focus on optimizing each site's performance against trial objectives rather than constantly comparing the content of one database field to the content of the same field on a paper CRF. Monitors can spend less time on minutiae and more time observing, analyzing, and reacting to study trends. The job of the monitor will increasingly shift to anticipating and addressing issues before they can develop into problems that require extensive cleanup.

Performance metrics can help monitors identify problems at a sufficiently specific level to suggest both causes and potential solutions. The number of visits needed at sites can be determined based on each site's performance metrics rather than equal numbers of visits at similar intervals for all sites. Sites with more and bigger problems can receive more site visits; sites with outstanding performance, fewer. For example, with the tracking of the number of unmonitored fields, the accumulation of a sufficient number can trigger a site visit. But while a good monitor might verify between 500 and 1000 fields per day, depending on the study, a less experienced monitor might do half that. The less experienced monitor could schedule a visit when, say 500 fields accumulate, while a more effective monitor could wait longer. Using an arbitrary, uniform schedule, the less experienced monitor might have a difficult time, while a more experienced monitor would waste time at the site and traveling.

## 5.2.4 IMPLEMENTATION ISSUES

An adaptive development program requires a different approach to study design, data capture, job functions, business processes, and planning. When first moving into adaptive research, the simplest approach is to start with baby steps while refining processes and increasing capabilities. Phase II adaptive dose finding and sample size reestimation are generally the most straightforward types of adaptive trials to undertake.

### 5.2.4.1 Data Capture and Validation

Adaptive research is critically dependent on the timely availability of accurate information. Information to effectively manage any given study may include specific decision criteria related to strategic adaptations, but it always involves continuous assessment of operational performance measures. Careful attention to operational issues is a prerequisite for achieving strategic adaptive goals. For example, slow availability of outcome information will delay and possibly cripple efforts at adaptive dose finding, and slow recruitment inevitably undermines any strategic adaptive decisions because a shortage of patients guarantees a shortage of data. Thus, the trial will be inefficient no matter how sophisticated or sound the planned adaptations.

Efficient data capture is a prerequisite for adaptive studies. In contrast to Web-based EDC and its attendant delays for data reentry, two newer forms of data capture have demonstrated superiority for adaptive studies. The first is an electronic pen incorporating an optical sensor that records keystrokes as data are entered on paper CRFs. After completion of CRFs, the pen is docked and the data transmitted to a central location, where keystrokes are converted to numbers and letters and the data recorded in the study database, along with an exact electronic image of each CRF, available for review by data management personnel in the case of ambiguous or missing data. Together with complementary systems that enable automated validation, the electronic pen provides the capability of having information from a patient visit—summarized and interpreted information, as opposed to raw data—on a sponsor's desktop before a patient even leaves the investigational site.

The second new form of data capture consists of fax-back systems. These offer another way to allow the simplicity of pen-and-paper data entry coupled with efficient software to read incoming forms. Fax-back tools, first introduced more than a decade ago, have improved markedly in recent years, adding the ability to read data electronically and store both the data and an image of each completed form in the study database.

In practice, digital pen systems have proven to be the most accurate and timely data-capture method, with query rates of approximately 1% (1 query issued per 100 fields) compared with approximately 5–10% for fax-back systems. Both methods are significant improvements over older pen-and-paper, double-key manual data entry, which often has query rates on the order of 20%. However, the most important determinant of query rates is not the data-capture method itself but the “middleware”—the software and/or systems that bring data into the trial system, validate it, and return queries. The main reason for the superior efficiency of the electronic pen is its linkage with the sophisticated middleware that enables queries to be returned

to investigational sites within minutes of their submitting data. The middleware not only markedly reduces the feedback time but also enables tracking of query rates by interviewer, question, and a multitude of other variables that help identify sources of error so that they can be immediately corrected. This is a boon for adaptive research since the ability to capture data, analyze it, and rapidly respond to performance metrics such as query rates is the essence of an adaptive approach.

A data-capture device such as the digital pen allows the clinician an intuitive, familiar means of recording and transmitting data to the study database, where it can be transformed electronically to information meaningful for individual study roles through “widgets” (Fig. 5) or the Web. And, as previously noted, if the CRF can be used as source data, the work of monitors is greatly diminished, allowing them to focus on management rather than rote tasks.

Advanced data management systems also incorporate sophisticated procedures that automate validation and query generation. These go well beyond the simple checks such as data ranges to incorporate algorithms that consider trends, consistency across visits as well as within a visit, and head off future problems by identifying studywide weaknesses as well as individual site or interviewer problems. These processes similarly help assure rapid availability of clean data as well as providing rapid feedback and management assistance that assure better site performance in the future.

#### 5.2.4.2 Planning

Since potential adaptations and related decision criteria must be specified in advance, the effort required to plan an adaptive study is greater than for a conventional trial.

**FIGURE 5** Desktop “widget” that provides immediate project status, updated in real time. (Figure copyright 2006, Health Decisions, Inc. Used by permission.)

Protocols employing adaptive techniques must specify through predetermined decision rules precisely what will occur in different circumstances and with different values emerging in trial data. This approach is a requisite element to ensure that scientific integrity is not compromised, knowingly or otherwise. Simulation during planning can effectively be used to explore a variety of “what if” scenarios to determine sample size adequate to control variance and other elements affecting statistical power. The simulations are also useful in analyzing decision rules for planned adaptations and operational issues such as ensuring adequate supplies in the event of different adaptive changes.

Planning of adaptive trials must include specific arrangements to exclude bias. This includes measures to eliminate the possibility of unauthorized parties inferring from adaptations actually made in the course of a trial the data that brought about the adaptations, effectively unblinding the study. Such back solving of study data can be prevented by measures such as limiting access to information about the specific rules governing planned adaptations and defining decision criteria in terms of ranges rather than precise values. The latitude allowed by regulatory authorities for blinding and other study elements are, however, substantially greater during early testing than during confirmatory studies.

When unblinded assessments are required (such as sample size reestimations or, in some instances, pruning treatment arms), a firewall must be in place to ensure that those running the study do not gain access to information that may affect how the study is conducted. For example, an adaptive trial protocol may require independent (internal or external, focusing on safety and/or efficacy) analyses that require access to unblinded data. Decisions may also involve a broader range of business issues such as whether to discontinue a study. While such decisions may be delicate, it is critical that safeguards be incorporated to prevent contamination of the ongoing study; this is equally true whether required by regulatory stipulations (confirmatory phase) or not (learning phase), as compromised data creates opacity in a situation that demands clarity. These situations are normally handled by compartmentalized groups who are not involved in the study itself, often by a steering committee that may have other groups (such as safety) reporting to it. The ultimate power to decide, subject to the specified decision criteria, whether to implement adaptive changes often rests with the steering committee.

Simulation can also be used not only to explore the likelihood of different scenarios that affect study design but also for optimizing business processes and defining job functions to support the development program’s objectives. Although the effort required is greater, the thorough analysis of possible future scenarios provides an invaluable opportunity to moderate or eliminate potential choke points. Over time, the longer view and greater flexibility that are hallmarks of adaptive research can substantially improve allocation of a development program’s financial resources and accelerate attainment of the program’s goals.

#### **5.2.4.3 Process Optimization**

Despite the current variability in the conduct of clinical trials, almost all trials require repeatedly performing the same essential processes. These processes can be defined much more clearly and precisely than is customarily done. The analysis required to define a process precisely will often suggest ways to improve the process.

It is process improvement in combination with new technology that brings huge rewards. The gains from inserting expensive new technology into an inefficient process are minimal.

Optimizing processes for adaptive research requires minimizing the individual variations in trial processes, including variations among the approaches taken by different project managers. The organization of the trial should be implemented in a system rather than according to each project manager's idiosyncrasies. The test of whether the project manager's role is defined precisely enough is whether it would be easy to plug in a replacement.

Furthermore, optimizing a study or program based on analysis of data as it is collected is not just a matter of inserting more frequent interim analyses into existing processes. The trial processes must provide a continuous flow of up-to-date, clean data. To the extent that current processes render data unavailable—whether because it has not been entered, validated, passed on from person A to person B, or made accessible in a useful form—study managers may be prevented from making key decisions or deceived by incomplete data into making decisions that turn out to be erroneous.

#### **5.2.4.4 Decision Making**

In adaptive trials, learning and decision making no longer wait until the very end, with the sudden transformation from having no data and knowledge to having a deluge of data and the need to extract knowledge all at once. Progress must be considered weekly, emerging trends identified continuously, and decisions taken as necessary to optimize the trial.

The point of gaining a greater understanding of data at an earlier time is to inform decisions to optimize the course of a trial. Greater efficiency in an adaptive study is the result of active managers making timely decisions directing specific changes. Having information earlier achieves little if managers fail to understand it and, where appropriate, to take action.

#### **5.2.4.5 Adaptive Data Monitoring**

The challenges of adaptive data monitoring require careful attention in implementing strategic adaptations. Besides attention to the exclusion of bias through organizational arrangements such as independent data management committees and independent statistical services, there must also be careful attention to arrangements for timely, accurate analysis of data to facilitate all potential adaptive decisions. Statistical methods must be selected and approved, and analytical procedures and tools created and tested to avoid delay or confusion in the implementation of pre-defined decision rules [8].

#### **5.2.4.6 Regulatory Considerations**

Regulators have been receptive to proposed methods of conducting clinical trials more efficiently while preserving validity and integrity. Understandably, they have not granted blanket approval for clinical researchers to try all new methods for strategic adaptations. However, they have shown a willingness to consider adaptive

techniques. Regulators have also expressed greater receptiveness to certain adaptive techniques and have indicated some general preferences for the use of those techniques. As detailed guidance for conducting adaptive studies is awaited, it is possible to provide a brief summary of regulatory preferences.

1. Two of the easiest adaptive components to apply are sample size reestimation and pruning in dose-finding studies. Regulatory groups allow sponsors a great deal of latitude as to how they conduct early studies, and the issue of defining doses suitable for final (pivotal) testing is basically at the sponsor's own risk. Sample size reestimation can be used in this early stage as well as more powerfully in late (pivotal) testing; the benefits of sample size reestimation in the early phases are sufficiently powerful as to merit serious consideration for all such studies.

2. All possible adaptations in a trial must be specified in advance, as well as the criteria for deciding whether to carry out the adaptations. Adaptive studies should never be thought of as providing license to make any changes that happen to occur to trial managers along the way; it would be a grievous mistake to think that adaptive techniques provide a less stringent substitute for well-planned, carefully executed studies, or that regulators regard adaptive techniques so indulgently.

3. Simulations are often helpful in understanding possible outcomes and are of interest to regulators. Simulations allow assigning probabilities to different potential developments in the trial and analyzing the repercussions of each development. Newer software and powerful computers facilitate exploration of scenarios, often forcing consideration of study variables that might otherwise go unattended. Simulations increase understanding of the effects of specific adaptations on the conduct and results of the trial. Both the results of simulations and the software used to conduct simulations for trial planning should be submitted to regulators. It is advisable to request a special protocol assessment to review an adaptive design and, at that time, to provide simulations demonstrating that the type 1 error is preserved.

4. If decisions on adaptations require considering unblinded data, regulators may prefer that the data is analyzed and reviewed by independent statisticians and an independent data management committee rather than by the sponsor. It is important, however, to recognize and limit the power of outside bodies that may fail to fully appreciate business consequences of managerial decisions. Not surprisingly, academic groups are often less attuned to the business consequences of decisions made about clinical studies.

5. Criteria for decisions on adaptations should be specified and managed in such a way as to minimize the possibility of unauthorized parties inferring important blinded information from the specific adaptations that are carried out. For example, if sample size is to be readjusted based on the magnitude of the treatment effect, knowledge of the sample size chosen might enable unauthorized parties to back solve for the treatment effect. Such concerns can be allayed in at least two ways. First, the specific technique and criteria that will be used for sample size reestimation can be kept confidential. For example, there should be restricted access to knowledge about the type of sample size reestimation that is planned—whether reestimation will be based on the size of the treatment effect alone, or the size of the placebo effect, or the variability observed in trial data, or based on multiple parameters. Second, the decision criteria themselves should be specified in ranges;

thus, when the sample size is readjusted to a specific value, the most that can be inferred by those who learn of the adjustment is that a parameter fell somewhere within a range.

6. Regulators will want detailed information about the measures taken to ensure the exclusion of bias. There must not only be a “firewall” between those who are allowed access to specific information and those who are not, but the firewall must be one that regulators agree is likely to be effective.

## 5.2.5 PROMISE OF ADAPTIVE METHODS

Adaptive techniques represent a major advance in pharmaceutical development made possible by advances in communications and technology. In many aspects, adaptive techniques represent a step into the type of modern management that is the norm in other large industries. Modernizing trial management requires evolutionary changes built on time-honored principles—but also requires greater flexibility in an industry known for its conservatism and “not invented here” attitude. Adaptive methods have been developed over time, based on solid theoretical foundations, specifically to address many of the limitations and inefficiencies of the current approach to clinical research.

The changes required for the shift to adaptive methods are profound and extend beyond technology to encompass work processes and the functioning of individuals performing different study roles. Technological tools and related processes are meant to provide a stream of current information that sheds light on study progress and bottlenecks. The new technologies and processes do not replace managers. Rather, they enable managers truly to manage, by providing a wealth of current status information and communications that drive effective functioning studywide.

Committing to an adaptive development program offers the potential for great rewards. Because of these high rewards, adaptive research is often assumed to be accompanied by high risk. However, a properly conceived and managed adaptive program actually reduces risk. This is by design—reducing risk is a major objective of adaptive techniques. Indeed, utilizing adaptive techniques entails no risk of conducting less efficient studies—the worst that could happen in an adaptive trial is that no adaptive changes would be made, leaving study performance at the accustomed level. On the other hand, every adaptive change that is made saves time, reduces costs, improves the amount and quality of information produced, or provides some combination of these benefits. Indeed, the greater risk lies in *not* utilizing adaptive techniques. Entire programs are condemned to suboptimal decision making and the inevitable consequences: unnecessary expenditures, avoidable delays, and windows of opportunity slammed shut before new drugs can make their way through the process of clinical evaluation.

The existing conventional approach to clinical studies has spawned many horror stories that reflect the risks of the current approach to clinical research. Every experienced pharmaceutical researcher has a horror story to tell. Virtually all such stories include an account of a small initial problem that grows to disturbing proportions before it is recognized and addressed. Adaptive processes can reduce the instance of such horror stories and the risks they embody by providing earlier, better indicators of incipient problems.

The potential of adaptive research to improve operations industrywide, for companies large and small, is simply too great to ignore. The potential gains in efficiency—the savings in both time and money—are dramatic. Adaptive tools and techniques are here and ready. They address many of the specific drawbacks and weaknesses of traditional methods. With concentrated attention by the industry and regulators, adaptive methodology can make important contributions to a new and more productive era in clinical research.

## 6.1 PROTOCOL

The study investigator is responsible for the review of all protocols and for the assessment of the feasibility of the clinical site to conduct the clinical research study. The investigator is also responsible for reviewing the protocol and providing input to the design so that the protocol can be properly conducted at the investigator's clinical site. The investigator is also responsible for ensuring that the research ethics board or the institutional review board approval is obtained before initiating the protocol.

Each sponsor's protocol received by a clinical site should describe the purpose, the objectives, the study design, the methods, and the planned analysis of a clinical study. The protocol must be sufficiently detailed so that the study can be conducted accurately and properly. Since the protocol often outlines the ethical, clinical, and regulatory responsibilities of both parties (the sponsor and the clinical site), it usually acts as a contract between the investigator and the sponsor.

Each protocol must be reviewed by the investigators, research coordinators, and other relevant clinical and research associates to ensure that the following takes place: (1) The study is safe; (2) the study is based on good medical science; (3) the study is ethically acceptable; (4) the objective of the study is clear and the study design, sample size, procedures, and statistical analysis will enable the study objectives to be met; (5) the protocol satisfies the clinical sites standard operating procedures (SOPs) and the good clinical practice (GCP) guidelines; (6) the protocol is financially and practically feasible for the clinical site and the investigator; (7) the investigator and clinical site have a sufficient number of potential study participants to meet the protocol enrolment goals; (8) the investigator has the sufficient staff to successfully conduct the trial; and (9) the investigator has sufficient resources and equipment to successfully complete the study.

### 6.1.1 Protocol Format

We will describe several protocol formats that are commonly used by industry-sponsored trials and by investigator-initiated trials (non-industry-funded trials).

**Industry-Sponsored Trials** The first format is the one that our institution (McMaster University/Hamilton Health Sciences) recommends in their standard operating procedures (SOPs).

**Cover Page and Table of Contents** The protocol should begin with a cover page that outlines the status of the trial, the revision date and number, the trial's full title, the study number, and the sponsor. There should also be space for signatures and dates signed for the author, the sponsor approval, and the investigator approval, as the protocol often acts as a contract between the investigator and the sponsor. The sponsor contact names and telephone numbers should also be listed to respond to investigator queries or any adverse events. A detailed table of contents, including a list of all appendices, should follow the cover page.

**Introduction** The introduction contains a brief summary of the relevant background information on the study design and the protocol methodology. Sufficient background information should include the development of the study agent or device, a description of the disease process to be studied, and the current medical treatments available. The introduction should provide enough detail for the readers to clearly understand the rationale for the study. Relevant information regarding pharmacological and toxicological properties of the test article and previous efficacy and safety experience should be included.

**Study Objectives** The objectives of the study should be clearly stated, and there should be a description on how the objectives are related to the design of the study. Both primary and secondary objectives should be included.

A brief overview of the study design, indicating how the study objectives will be met, should be provided. This part of the protocol includes a description of the study type (i.e., randomized controlled trial, prospective cohort study, phase III, multicenter, double blind, placebo controlled), details on the specific treatment groups, information on the sample size in each group required for the total trial and at each clinical site, how the study participant identification numbers are assigned, and the type, sequence, and duration of the study periods. A brief description of the methods and procedures to be used during the study should also be included. There should also be a discussion on the study design that details the rationale for selecting the study design. Critical decision points and any atypical features of the study design should be described. The treatment schedule, the dosages for the study agents, and the follow-up schedule and follow-up requirements should be discussed.

**Study Participant Population** The next section of the protocol describes the study participant population. The study's inclusion criteria (the criteria each study participant must satisfy to participate in the study) are described. These criteria can include the following: age, sex, race, diagnosis, diagnostic test result requirements, concomitant medication requirements, severity of symptoms and signs of disease, and the ability and willingness to perform study requirements and to provide informed consent. The criteria must be sufficiently detailed to provide the investigative site with the information needed to recruit eligible study participants and to ensure a homogenous study population. The exclusion criteria describes the items that would eliminate a potential study participant from being enrolled in a study. Exclusion criteria can include, but are not limited to, the following: previous medical history, pregnancy, childbearing potential, current or past therapy, severity of disease, current medical conditions, a minimum time since the last clinical study, and substance abuse problems. There should be a discussion detailing the rationale for the

inclusion and exclusion criterion to obtain the homogenous study population required.

***Concomitant Medications*** The listing of the required therapies including the dose, frequency, and duration should be detailed in this section. Required therapies are medications that are required in addition to the test treatment. The investigator must also determine whether the sponsor or the site is providing these medications and determine the accountability procedures required by the sponsor. There must also be a list of allowed medications and disallowed medications. Allowed medications are the medications that are permitted during the study, the dosage, the frequency, and the conditions under which they are permitted. Disallowed medications are medications that the study participant is not permitted to use during parts of or the entire study. The study participant and investigator are often told to document the allowed medications and the disallowed medications (if there is a protocol deviation) on the patient diary cards and on the case report forms.

***Study Plan and Methods*** The study plan and the methods portion of the protocol details the plan of action, all procedures to be followed, and the methods to be used throughout the study. The activities for each follow-up visit are clearly outlined, as well as any specific criteria that must be met before the study participant moves to the next stage of the study. For difficult testing methodologies, a separate section may be included to describe in detail the methods of the testing. If the study participant must have specific results from this testing to enter, or to continue in the study, these criteria are described. Types of study activities that would be included in this section include: medical history, type of physical examination, blood or urine testing, electrocardiograms (ECGs), diagnostic testing such as pulmonary function tests, symptom measurement, dispensing and retrieval of medication, diary card exchange, study subject number assignment, adverse event review, and the like. Each visit should be detailed in separate sections in the protocol, such as 6.1 Visit 1, 6.2 Visit 2, and so forth. The investigator should ensure that this section provides clear methods, procedures, and timings of activities.

***Study Medication Supplies*** The study medication supplies portion of the protocol describes the test treatments including placebo with formulation and dosage information. It also details the packaging, dispensing, retrieval, and accounting of these supplies. All ingredients and the formulation of the investigational test article and any placebos that are used in the study are described. The precise dosing required during the study is discussed. The method of packaging, labeling, and blinding is described. The method of assigning treatments to study subjects and the test article and study subject numbering system is detailed. If applicable, the method of blinding to make the test treatments indistinguishable should be explained. The method of test article coding, code storage, and code access is described. If a third party such as a pharmacist will be dispensing or blinding the test article, then specific instructions on how and when the blinding will occur will be detailed in this section.

The coding and study subject test article assignments for the study are detailed. Generally, all study staff and study participants are blinded to the identity of the test treatments. This section describes when a study subject treatment code assignment is given and if, and when, it will be changed. A description of where the test

article randomization code will be kept by both the investigator and the sponsor or delegate is required and the procedure for breaking this code, if necessary, should also be included. There should also be a section describing the study subject kit packaging, which should detail the administration and dosage of study medication, as well as how the elements of the kit are distributed. Generally, the medication is labeled visit 1, visit 2, and so forth for easier dispensing. Any specific instructions for the administration of the test article treatments, such as label removal, test spray, or how and when the test article is to be returned should be detailed in this section. Explicit details regarding the dosage of the test treatment are explained. Instructions for broken test article applicators or lost test articles are also described. If extra treatments are provided for emergencies, the circumstances regarding their use should be described. Explicit instructions for the storage of the test treatments at the investigative site are detailed, as well as if special conditions are required, such as refrigeration. Federal regulations and the International Conference on Harmonisation (ICH) guidelines require a complete accounting of all test materials received, disbursed, and returned.

***Discontinued-Study Participants*** The research protocol should outline how investigators will handle study participant withdrawal, dropouts, or other discontinued participant subjects. It also details how to handle these situations within the study context and whether these study subjects are to be replaced.

***Adverse Events*** Investigators should include a listing of expected adverse events from previous clinical studies with the test article. They may also include the policies and procedures for the reviewing and the reporting of adverse events that occur during the clinical study.

***Concomitant Illness*** The protocol should describe the procedure for documentation of any concomitant illness, which a study participant develops during the study. A concomitant illness is an illness, disorder, or any other medical condition that is not considered a consequence of the study medication being administered.

***Variables and Evaluations*** The investigators should describe how clinical study efficacy and safety variables will be evaluated. The studies primary and secondary variables will be identified and discussed. Descriptions of evaluations are given here including how they are recorded, measured, or calculated.

***Statistical Analysis*** It is important to provide details on how the study results will be analyzed and reported. Specifically, sample size determination, objectives or hypotheses being tested, levels of significance, statistical tests being used, and the methods used for missing data. The method of evaluation of the data for treatment failures, noncompliance, and study participant withdrawals is presented. If an interim analysis will be performed, the rationale and conditions are clearly described. A description of how the safety data and adverse events will be tabulated and evaluated is included.

***Informed Consent*** This section of the protocol describes the procedures and responsibilities for obtaining informed consent for the study.

**Study Monitoring** A description of study monitoring policies and procedures, including the right for the sponsor or method center's representatives, federal government, and/or other regulatory authorities to verify and audit the study data, is presented in this section.

**Deviations from Protocol** The method for handling protocol deviations is described.

**Discontinuation of Study** This section describes the conditions under which the study would be discontinued.

**Confidentiality of Data** The importance of confidentiality of data and the fact that the data is owned by the sponsor or by the coordinating methods center are detailed.

**Publication of Study Data** The conditions for publication of study data are outlined.

**Research Ethics Board Approval** This section states that the investigator is required to obtain research ethics board (REB) or institutional review board (IRB) approval for the protocol, informed consent form, and any protocol amendments.

**Investigator's Statement** An outline of the investigator's responsibilities and agreements are included in the protocol.

**Investigator-Initiated Trials** For investigator-initiated randomized controlled trials, the Canadian Institute of Health Research requires the following format.

**Need for Trial** The problem to be addressed and the principal research questions to be addressed are listed. There should also be a strong justification as to why a trial is needed now. Evidence from the literature, professional and consumer consensus, and pilot studies should be cited if available. References to any relevant systematic reviews should be provided and the need for the trial in the light of these reviews should be discussed. If you believe that no relevant previous trials have been done, provide details of the search strategy used for existing trials. A description of how the results of this trial will be used should be provided.

**Proposed Trial** This section of the protocol begins by stating the proposed trial design, including whether the trial is open-label, double or single blinded, and so forth. The planned trial interventions for both the experimental and control groups and the proposed practical arrangements for allocating participants to trial groups are discussed. For example, the randomization method and if stratification or minimization are to be used provide justification for using either methodology. Factors that will be stratified or minimized should be listed. The proposed methods for protecting against other sources of bias include blinding or masking. If blinding is not possible, please explain why and give details of alternative methods proposed or implications for interpretation of the trials results. The planned inclusion/exclusion criteria should be listed.

There should be a justification for the proposed duration of treatment period and the proposed frequency and duration of follow-up. The rationale for the proposed primary and secondary outcome measures and how the outcome measures will be measured at follow-up should be provided.

For the proposed sample size, include both the sample size for the control and treatment groups, a brief description of the power calculations detailing the outcome measures on which these have been based, and provide event rates, means, and medians, as appropriate. Provide a justification for the size of difference that the trial is powered to detect and mention whether the sample size calculation takes into account the anticipated rates of noncompliance and loss to follow-up.

A description of the planned recruitment rate, how recruitment will be organized, over what time period recruitment will take place, and what evidence there is that the planned recruitment rate is achievable should follow. There should be a discussion on any likely problems with compliance and loss to follow-up; the evidence that the compliance and loss to follow-up figures are based on should also be included.

The details of the planned analyses are described, including any planned subgroup analyses and the proposed frequency of analyses (including any interim analyses).

The investigators should specify whether the trial addresses any economic issues. This is not a requirement; however, it is important to justify the inclusion/exclusion of any health economic studies and give details of any study proposed.

The final section of the protocol on the proposed trial should provide an accurate budget, budget justification, and the length of the trial.

*Details of Study Team* A description of the study team must be provided that explains the overall trial management, including the role of each applicant proposed, the steering committee, the methods center, and whether a data safety and monitoring committee will be established and its composition. The role of international collaboration should be discussed, including the nature of and the need for any international collaboration. The proposed participating centers should be listed along with their experience with previous trials and estimated recruitment rates.

### **6.1.2 Protocol Amendment Procedure**

Protocol amendments can be suggested by either the sponsor or the investigator and can be made after the protocol has been finalized. A draft protocol with the proposed amendments is prepared and reviewed internally and by the investigators before it is approved. The investigator site must obtain REB or IRB approval of the protocol amendment before it is implemented.

### **6.1.3 Prestudy Requirements**

Before a study can be initiated at a clinical site, the following activities must be completed:

- Receive final protocol from sponsor or methods center.
- Receive amendments from sponsor or methods center.
- Finalize budget with sponsor or methods center.
- Distribute protocol amendments to relevant study team members.
- Receive investigator's brochure from sponsor or methods center.
- Read investigator's brochure.
- Complete qualified investigator undertaking, FDA 1572A, or investigator agreement, as required.
- Prepare informed consent form.
- Submit documentation to the REB or IRB.
- Receive REB approval and Health Canada REB application form (if applicable).
- Receive case report form (CRF) books from sponsor or methods center.
- Design source documents, as necessary.
- Send all required documentation to sponsor or methods center.
- Receive clinical supplies from sponsor or methods center.
- Inventory supplies and return documentation of receipt to sponsor or methods center.
- Plan subject recruitment strategy.
- Prepare regulatory documentation binder/file.
- File regulatory documentation received to date.
- Set up necessary local resource utilization for study (e.g., pharmacy, laboratory, etc.).
- Set up a contract with the sponsor or methods center.
- Conduct in-services with each involved department.

The investigator or delegate must send the following documents to the sponsor or methods center before the study can begin:

- Final signed protocol.
- Final signed amendments.
- Signed Qualified Investigator Undertaking Form, FDA form 1572, or investigator agreement.
- Current curriculum vitae (CVs) and medical licenses of principal investigator and subinvestigators.
- Signed financial disclosure document.
- Budget approval documentation.
- REB or IRB approval letter(s) approving protocol, consent form, advertisements, and any other relevant documents.
- Copy of REB or IRB approved consent form.
- Copy of current REB or IRB membership list or letter from REB or IRB.
- Copy of laboratory license, normal ranges, and CV of director, if required.

Finally, before each study is initiated, appropriate research staff members are informed of the requirements of the study and their role and responsibilities regarding the conduct of the study.

## 6.2 FINANCE

### 6.2.1 Reviewing an Offer to Participate in Clinical Trial

Participating in clinical trials requires a substantial commitment of both time and effort, and participation often continues for months or even years. There are usually clear financial incentives to participating in clinical trials; however, other incentives include a chance to collaborate with other clinical investigators and opportunities to improve knowledge about the disease and treatment being investigated. Another advantage, which may be offered in some trials, is the exposure to new investigative techniques or access to special equipment or facilities.

The scientific, practical, and financial implications need to be considered before agreeing to participate in a clinical trial. The first item to assess is the study question and the study methodology. It is important to ensure that it is a relevant question and that the study methodology is sound and will meet the goals of the trial. The eligibility criteria must be carefully assessed to ensure that your clinical site has sufficient eligible patients to be recruited for a clinical study. It is often necessary to perform a survey of potentially eligible patients over a 4-week period to provide an accurate estimate of recruitment rates.

It is important to assess the impact of the trial on your patients, as your primary obligation is to protect the welfare your patients. It is important to consider if the patients will be required to have any investigations or procedures that are not part of standard care, and whether these will be painful and will possibly put the patients at risk. You need to estimate how much time the patient will devote to the study and how much, if any, compensation the patient may receive.

The time required for the overall coordination, the patient enrolment and follow-up, and the data collection also needs to be carefully considered. It is best to have an experienced clinical research coordinator carefully review the protocol and case report forms to provide an accurate estimate on the time and resources required to successfully participate in a clinical trial. Tasks often take longer than anticipated, so it is often good to add in a little extra time to account for the unanticipated. It is also important to know whether the study will be published, who will write the manuscripts, and what the authorship policies are. After carefully weighing these items, you can make an informed decision to participate in a clinical trial.

### 6.2.2 Budget Considerations

The investigator should consider all potential costs and prepare an accurate budget for running the clinical trial at his or her clinical site. These costs include: (1) administrative assistant time, (2) research associate/nurse time, (3) supplies, (4) expenses incurred by the patient, (5) extra medical and hospital costs (i.e., pharmacy, radiology, laboratory tests), and (6) physician time. It is also important to include

departmental and institutional overhead costs in the budget and to have your institution's grants and contracts office, as well as the REB or IRB, review your budget.

### 6.2.3 Investigator Agreements

The investigator is responsible for the review or preparation and approval of the contracts with the sponsor, and the investigator's institution's legal advisor or delegate is responsible for legal review of these contracts. When the sponsor provides the contract, the investigator and the institution's legal advisor or delegate reviews the contract to ensure that it contains the responsibilities assigned to the investigator's site, indemnification language, budget information, reporting requirements, and any other information required by the legal council. If the sponsor does not provide a contract, the investigator's site will provide an agreement to the sponsor that covers the same elements. When completed, the authorized institutional official for the investigator site and the investigator review all agreements. Usually three originals are prepared and signed: one for the investigator, one for the investigator's site, and one for the sponsor. It is important to allow sufficient time for both the sponsor and investigator's site to review and amend the contract or agreement. If possible, this process should begin at the same time as the ethics review.

### 6.2.4 Sponsor Interactions

The investigator is responsible for complete and proper study communication with the sponsor. A number of study visits are typically required by industry-sponsored trials. In investigator-initiated trials, which often have less funding available, fewer site visits are conducted.

The first visit is referred to as the *prestudy inspection visit*, and the purpose of this visit is for the sponsor to ensure that the clinical site is equipped to perform the study properly. The investigator should provide a tour of the facility and describe the patient population base and the methods that will be used to enrol participants into the study.

If the prestudy inspection visit is successful and the investigator agrees to participate in the trial, there is an *initiation visit*. The purpose of the initiation visit is for the sponsor to ensure that the investigator and the research associates have a correct understanding of the protocol activities and the methodologies. This is also an excellent opportunity for the investigator or research associates to ask any questions about the trial. In addition, the procedures for reporting adverse events, test article storage, and laboratory tests are reviewed.

Once the study is active and research participants are being enrolled, *ongoing study visits* occur. The frequency of these visits may vary, and the purposes are to ensure that the study protocol is being followed and that all documentation in the regulatory files is up-to-date. Adverse events and protocol deviations are also reviewed and outstanding issues are discussed.

After patient enrolment is complete, a *close-out visit* usually occurs. The purpose of this visit is to review study progress, to discuss how the test article is to be returned to the sponsor, and to determine how any corrections or outstanding issues will be resolved.

Appropriate research staff must communicate regularly with the sponsor, and all critical communication, including telephone calls and emails, must be documented. The investigator or delegate must notify the sponsor about the enrolment of the first research participant, recruitment progress, and if any adverse events occur. The investigator or research associate can also contact the sponsor if there is a question regarding a patient’s eligibility status or about the protocol. All communication should be recorded in the regulatory binder.

**6.2.5 Regulatory Documentation (Essential Documents)**

Most countries take measures to regulate the development and marketing of medications and medical products. The investigator is ultimately responsible for obtaining, maintaining, and storing all required clinical study documentation at the site, although this task can be delegated to the research staff. An essential document is defined as any document that permits the evaluation of the conduct of a study and the quality of the data produced. Examples of essential documents include the study protocol, study manuals, and research ethics communications. When a study is being planned, it is important to collect and organize all regulatory documentation in an organized fashion. As the study progresses, copies of all documents are stored in the regulatory binder.

**6.3 PATIENT SELECTION**

**6.3.1 Research Ethics Board Approval (Institutional Review Board Approval)**

An ethics committee is an independent body of medical professionals and lay members. The responsibility of an ethics committee is to ensure the safety, well-being, and human rights of the research participants. Ethics committees review the protocol and consent forms to ensure that the trial is justified, safe, and that the patients are properly informed. All research involving human subjects should be referred to the local IRB or REB. The responsibilities of the IRB/REB are listed in Table 1.

**6.3.2 Feasibility**

Assessing the study’s feasibility is closely related to reviewing an offer to participate in a clinical study. The eligibility criteria must be carefully assessed to ensure that

**TABLE 1 Responsibilities of the Ethics Committee**

|                                                                                                                                                                                     |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| To review an application for ethical approval of a research protocol in a reasonable time                                                                                           |
| To consider the qualifications of the investigator                                                                                                                                  |
| To review each ongoing trial at an institution                                                                                                                                      |
| To recommend modifications to the patient information and consent form, when appropriate                                                                                            |
| To review payments to trial participants                                                                                                                                            |
| To determine that, when necessary, the trial protocol addresses ethical concerns such as consent by a patients legal representative and studies where prior consent is not possible |
| To perform duties in accordance with written operating procedures                                                                                                                   |
| To retain all relevant records for at least 3 years after completion of a trial                                                                                                     |

your clinical site has sufficient eligible patients to be recruited for a clinical study. It is often necessary to perform a survey of potentially eligible patients over a 4-week period to provide an accurate estimate of recruitment rates. If you do not have a sufficient number of patients to make participation worthwhile, completing the trial successfully is not feasible.

As mentioned previously, the time required for the overall coordination, the patient enrolment and follow-up, and the data collection also needs to be carefully considered. It is important to be sure that you and your research staff have sufficient time and resources to successfully complete the trial requirements.

### 6.3.3 Sample Size

A sample size calculation before the conduct of a trial can help to estimate an appropriate sample size and to false-negative ( $\beta$  error) results. Before calculating the sample size, the investigator should clearly state primary and secondary outcome parameters. The primary outcome parameter is the one that the investigators consider to be the most important. Subsequently, any other measures are designated to be secondary outcome parameters. The initial distinction between primary and secondary outcome measures is important because the amount of outcome parameters impacts the threshold significance level that needs to be used to determine if the result is significant or not. A significance level of  $p = 0.05$  is used by convention for the main outcome parameter. That means that a chance of 5% is being accepted to conclude that there is a significant difference between two groups, when in fact there is none (type I error or  $\alpha$  error). For any additional secondary outcome parameters, adjustments of the significance level need to be made depending on the number of analyzed parameters.

The magnitude of the difference in the primary outcome parameter that the investigators consider clinically relevant should be the basis for the sample size calculation. Alternatively, this difference can be simply hypothesized. The sample size calculation will reveal how many participants per group are necessary in order to show if that difference truly exists or not.

In addition to the hypothesized difference in the primary outcome parameter and the significance level (usually  $\alpha = 0.05$ ), the acceptable power of the study and the anticipated standard deviations of the primary outcome parameter in the two groups need to be established before proceeding with the sample size calculation. A study power of 0.8 is a conventionally accepted standard, which means that the investigators are willing to accept a 20% probability that there is no difference between two groups when a difference actually exists ( $\beta$  error). Any increase in study power and decrease of the  $\alpha$  level of significance will result in a higher sample size requirement. The anticipated standard deviations in the two groups can be either determined by performing a preliminary pilot study or from data in the literature. If no data is available, they only can be estimated.

Even at best, a sample size calculation is based upon the best available “estimate” of treatment difference between treatment groups. To improve the reliability of an a priori sample size calculation, investigators can conduct a pilot study of 20–50 patients to gain an estimate of the treatment effect in their proposed study population.

### 6.3.4 Recruitment Methods

Patient recruitment strategies vary depending on whether the study is investigating a chronic or an acute condition. For a chronic condition, research staff can screen pre-existing patient data, schedule appointments for potentially eligible patients, and identify patients who may be willing to participate in the study immediately after receiving approval from the ethics board. With a chronic condition, a known patient population can be recruited early and all at once. Patients with an acute condition can only be recruited when they present to the participating physicians; so enrolment will be staggered.

### 6.3.5 Screening

It is important to screen to identify potential patients who are eligible for participation in the clinical trial. Screening refers to identifying potentially eligible participants by applying the clinical trial's eligibility criteria. Areas that can be used for screening include hospital admission records, operating room schedules, and clinic appointment schedules. A screening log is used to maintain the screening information on each potential study participant that is screened, including if they met the inclusion and exclusion criteria, if informed consent was provided, and if they qualified and were entered into the study.

### 6.3.6 Informed Consent

Informed consent is the process by which a patient voluntarily confirms his or her willingness to participate in a clinical trial. Prior to giving consent, the study investigator or delegate must inform the patient of all aspects of the trial (Table 2).

**TABLE 2 What Patients Need to Know Before Participating in Clinical Research**

---

|                                                                                                                                                         |
|---------------------------------------------------------------------------------------------------------------------------------------------------------|
| The purpose of the research                                                                                                                             |
| The trial treatment(s) and the probability for random assignment to each treatment                                                                      |
| The trial procedures to be followed, including all invasive procedures                                                                                  |
| The subject's responsibilities                                                                                                                          |
| Any aspects of the trial that are experimental                                                                                                          |
| The reasonably foreseeable risks and benefits                                                                                                           |
| Any alternative treatment(s) that may be available                                                                                                      |
| Any compensation available to the patient in the event of a trial-related injury                                                                        |
| The anticipated payment or expenses, if any, to the patient for participating in the trial                                                              |
| The patient's participation is voluntary and the patient may refuse to participate or withdraw from the trial at any time without prejudice             |
| Who will have access to their original medical records                                                                                                  |
| The records identifying the patient will be kept confidential                                                                                           |
| If the results of the trial are published, the patient's identity will remain confidential                                                              |
| The patient will be informed if information becomes available that may be relevant to the patient's willingness to continue to participate in the trial |
| The person to contact for additional information on the trial                                                                                           |
| The foreseeable circumstances or reasons under which the patient's participation in the trial may be terminated                                         |
| The expected duration of participation                                                                                                                  |
| The approximate number of patients involved in the trial                                                                                                |

---

**TABLE 3 Three of the Most Fundamental Rights**

---

|                                                                                                                                                                                                                     |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1. The patient's participation in the research trial is voluntary.                                                                                                                                                  |
| 2. The patient has the right to refuse to participate or withdraw from the trial without providing a reason. Refusing to participate or withdrawing from the trial will not affect his/her subsequent medical care. |
| 3. The patient will be informed of any new findings that may affect his/her willingness to continue participating in the trial.                                                                                     |

---

Informed consent must be documented in a written form, signed, and personally dated by the patient or by the patient's legally acceptable representative and by the person who conducted the informed consent discussion. Conduct the informed consent discussion in a quiet room and allow adequate time for questions. During the discussion, it is vital to communicate in nontechnical language and to take into account any language barriers.

Patients who participate in research trials have many rights and they need to be informed of these rights during the informed consent discussion. Three of the most fundamental rights are listed in Table 3.

**6.3.7 Patient Confidentiality**

The principal investigator and all study staff are responsible for maintaining patient confidentiality throughout the clinical trial. Confidentiality refers to the prevention of disclosing a research participant's identity and medical information to nonauthorized individuals. The study participant's involvement in a clinical trial must be kept private between the principal investigator, the appropriate study staff, and the primary care physician. The information is only to be shared when there is written permission by the study participant. All research participants' names and data obtained from medical records must be kept confidential. Patients are identified through a number that is assigned to them at study enrollment. When providing source documentation (medical records) to the sponsor, all personal identifiers must be removed. Finally, all data must be stored in a secure area, such as a locked cabinet or a password-protected computer in a locked office.

**6.3.8 Intention to Treat Analysis**

Intention to treat analysis is a method of data analysis on the method of the intention to treat a research participant (i.e., the planned treatment regimen) rather than the actual treatment regimen given. It has the consequence that participants allocated to a treatment group should be followed up, assessed, and analyzed as members of that group regardless of their compliance with therapy or the protocol, or whether they crossed over later to the other treatment group.

**6.4 TREATMENT SCHEDULES**

**6.4.1 Supplies**

The investigator or delegate is responsible for the accurate and complete accountability of the clinical supplies (i.e., drugs, surgical equipment, laboratory equipment,

etc.) used in a clinical trial and for proper storage of the supplies according to the sponsor's written instructions. The study protocol or the investigator's brochure will provide information about the study test article, its proper use, and the required storage conditions during the trial. The study staff is responsible for assigning study identification numbers and test article numbers to the supplies and maintaining the records of the use of supplies. The test articles are often blinded, and the blind must be maintained as instructed in the study protocol. A note in the file must be prepared to describe the situations when and how the blind is broken.

#### **6.4.2 Adherence to Protocol**

It is vital that all procedures and activities described in the study protocol are followed throughout the entire trial. Adhering to the protocol ensures reliable results, high-quality research, and efficient trial progress. Any deviations from the protocol need to be reported to the sponsor as soon as possible after they occur. Most trials have specific case report forms for recording and reporting protocol deviations.

#### **6.4.3 Follow-up**

It is the responsibility of the participating center to ensure that all patients are followed up as outlined in the study protocol. Follow-up visits should be scheduled within the time frames indicated in the protocol. The research participants must be made aware of all procedures that will be performed and the time each one will take (i.e., blood tests, radiographs, gait analysis). It is also necessary to communicate with any hospital departments that are assisting with the follow-up (i.e., laboratory medicine, radiology, physiotherapy). A plan of action should also be in place to prepare for any participants who are withdrawn or who do not attend their follow-up appointment.

#### **6.4.4 Monitoring Visits**

The purpose of a monitoring visit is to verify that the rights and well-being of patients are protected. The monitor will ensure that patients are being enrolled according to the protocol, and that the consent procedure has been carried out correctly and that the patients fulfill the eligibility criteria. In addition, the monitor will check the case report forms for legibility, accuracy, and completion of all data points. Some of these are then compared with the source documentation, such as notes in the medical charts, patient diaries, questionnaires, and test results, to ensure accuracy and completeness of reporting. The monitoring visits also allow time to discuss any questions about the study protocol or issues that have arisen that are not covered in the protocol.

The monitoring visits typically occur after the first patient has been enrolled and then every 2–6 weeks, depending on the rate of patient enrollment. To prepare for a monitoring visit, the research staff should check that all the administrative paperwork is in order, assemble the source documents, ensure that the case report forms are clean and all queries are resolved, and notify all departments involved in the study of the monitor visit as the monitor may need to check these areas.

### 6.4.5 Composite Endpoints

A composite endpoint is an endpoint that is defined in terms of two or more primary clinical endpoints at the patient level. The rationale for including a composite endpoint as opposed to a primary endpoint is that diseases often need multidimensional characterization, low event rates in component endpoints, may need to account for mortality, and the treatment effect on primary endpoints may be small. For example, a cardiovascular study could have three primary endpoints: cardiovascular death, stroke, and myocardial infarction. The composite endpoint would be time to the first occurrence of cardiovascular death, stroke, and myocardial infarction.

When event rates are low, the use of composite endpoints in clinical trials allows investigators to reduce sample size and the duration of follow-up. These advantages come at a price: The interpretation of the effect on the intervention is complicated, and the combined endpoint can be profoundly misleading. It is important to report the event rate for each component of the outcome when reporting on trials using composite endpoints.

## 6.5 PATIENT RESPONSE EVALUATION

### 6.5.1 Outcome Measures

It is important to document all trial-related activities to provide a lasting record of how the trial was conducted and of the data that was collected. Study outcomes may be based on safety, efficacy, or another trial objective and must be clearly defined in the protocol. Outcomes are typically recorded on the case report forms.

### 6.5.2 Case Report Forms

Data collected during a trial should be tailored to answer the hypotheses that are proposed within the protocol. To ensure that the correct data are collected, case report forms (CRFs) are designed. Patient data from source documents, such as the patient's medical records, are used to complete the CRFs. The completed forms are sent to the coordinating center responsible for the collection of the trial data. The coordinating center will then ensure that the final data set is complete, accurate, and complies with good study methodology.

The completion of CRFs will vary from study to study. All CRFs must be completed accurately and legibly and be reported in a timely manner. They must correctly reflect the data found in the source documents (medical records). All questions must be answered in an attempt to limit the number of data queries. Any changes or corrections must be dated and initialed and should not obscure the original entry. Finally, the CRFs must be completed in accordance to the trial-specific instructions. Table 4 describes data that should be included in a case report form.

### 6.5.3 Adverse Event Reporting

A serious adverse event (SAE) is any adverse occurrence or response to a drug/intervention, whether expected or not, that requires in-patient hospitalization or prolongation of existing hospitalization, that causes congenital malformation, that

**TABLE 4 Data Often Collected on Case Report Forms**

---

|                                                      |
|------------------------------------------------------|
| Patient identification (i.e., study ID and initials) |
| Patient demographic details (i.e., age, sex, height) |
| Adherence to protocol inclusion and exclusion        |
| Baseline medical history                             |
| Diagnosis                                            |
| Medication prior to procedure                        |
| Treatment details                                    |
| Tracking of adverse events and other key outcomes    |
| Discharge details                                    |
| Follow-up visits                                     |

---

results in persistent or significant disability or incapacity, that is life threatening, or that results in death. The principal investigator is ultimately responsible for ensuring that all serious adverse events are correctly reported to the sponsor and the REB/IRB in the required time frame (often 24 hours). Typically, the following information is required: type of event, whether it is expected or unexpected, a description of the SAE, action taken, the outcome, and whether the research participants remain on the study protocol. In addition, the local study investigator is asked whether the SAE should warrant continuation of the study, changes to the protocol, or revisions to the information or consent form.

An adverse event (AE) is any untoward event that significantly affects the research participant's well-being and does not fit the criteria of a SAE. It is often optional to report adverse events to the REB or IRB; however, it is necessary to report them to the sponsor.

Before the trial begins it is a good idea to familiarize yourself with the safety profile of the product and the SAE and AE reporting procedures so that you know what to do when an SAE or AE occurs. During the trial, it is important to inform patients of any potential AEs and encourage them to report all AEs. It is necessary to follow all patients who have experienced an SAE or AE until their condition is stable or resolved.

#### **6.5.4 Data Queries**

Although every effort is made to ensure the correct completion of case report forms, errors can and do occur. To guarantee data quality, a system must be in place to check and query all data. Data queries are a necessary part of a clinical trial, as they help ensure the quality of the data and the integrity of the trial. Data queries are generated by the data management team in response to missing, inconsistent, or illegible data, or to protocol deviations (Table 5). It is best to respond to data queries as quickly as possible. It is also sometimes necessary to discuss data queries with the study monitor or project manager if clarification is required.

#### **6.5.5 Adjudication**

A blinded, central adjudication of outcomes can be used in clinical trials as a way of reducing bias and random error in determining outcome events. This process may be especially important in clinical trials when the intervention cannot be blinded,

TABLE 5 Purposes of Data Queries

|                                                                        |
|------------------------------------------------------------------------|
| To clarify or confirm data                                             |
| To request missing data                                                |
| In special cases, to request additional data not specified in the CRFs |
| As a teaching medium for the correct completion of study documents     |

such as in many surgical trials, or when the diagnosis of the primary outcome has low observer agreement. In addition to determining outcomes, central adjudication has also been used to assess eligibility of patients, protocol violations, and co-interventions.

There are many factors for clinical investigators to consider when deciding whether to use a central adjudication process for determining outcomes in a trial. Most importantly, the investigators must weigh the expected benefit of adjudication for accurate determination of outcomes against the substantial investment of resources involved and practicality undergoing this process. The investigators must also consider the potential for the adjudication process itself to bias the results of the trial.

To centrally adjudicate outcomes for a trial, it takes a considerable amount of administrative and expert time to collect the relevant information, prepare the information for review, review each case, and participate in consensus meetings. There may also be challenges involving the availability, validity, or usefulness of some documentation sources. If the treating physician is also required to make a judgment about whether an outcome occurred, it may be possible to compare the committee's judgment with the physician's to determine whether central adjudication is necessary.

Once the investigators or sponsors decide to centrally adjudicate outcomes, they must make several other decisions about the process, including who the adjudicators will be, what material must be evaluated, which judgments must be made, how to train the adjudicators, establishing a set of standardized decision rules, what the committee size will be, whether decisions will be made in pairs or by the full committee (if in pairs, whether to assign cases randomly), how to reach consensus on a decision, and how to monitor the accuracy of the process.

The agreement among adjudicators on a particular case can be affected by the number of decisions necessary, the number of choices for the outcome, and the complexity of the judgments. Disagreements can result from forgetting a decision rule, encountering a case for which there is no relevant decision rule, not having enough information, making an error, or the outcome is difficult to determine given all of the relevant information.

Outcomes assessment/adjudication committees review important endpoints reported by trial investigators to determine whether or not they meet protocol-specified criteria. Members of the adjudication committee may request radiographs, chart notes, operative reports, and other pertinent material to guide their decision making about a defined outcome. All attempts should be made to blind the committee to treatment allocation. This includes careful masking of all X rays and reports. Such committees are most desirable when the assessment of outcomes requires an element of judgment or subjectively (i.e., fracture healing), or when the intervention cannot be blinded. Ultimately, the adjudication committee members work together to limit bias in the outcomes assessment of a clinical trial.

## 6.6 DESIGN CONSIDERATIONS

### 6.6.1 Study Design (Observational Studies and Randomized Controlled Trials)

The types of study designs used in clinical research can be classified broadly according to whether the study focuses on describing the distributions or characteristics of a disease or if it focuses on elucidating its determinants (Table 6). Descriptive studies describe the distribution of a disease, particularly what type of people have the disease, in what locations, and when the disease occurred. Cross-sectional studies, case reports, and case series represent types of descriptive studies.

Case reports are an uncontrolled, descriptive study design involving an intervention and outcome with a detailed profile of one patient. Expansion of the individual case report to include multiple patients is a case series. Although descriptive studies are limited in their ability to make causal inferences about the relationship between risk factors and an outcome of interest, they are helpful in developing a hypothesis that can be tested using an analytic study design.

Analytic studies focus on determinants of a disease by testing a hypothesis with the ultimate goal of judging whether a particular exposure causes or prevents disease. Analytic design strategies are broken into two types: observational studies, such as case-control and cohort studies, and experimental studies, also called clinical trials. The difference between the two types of analytic studies is the role that the investigator plays in each of the studies. In the observational study, the investigator simply observes the natural course of events. In the trial, the investigator assigns the intervention or treatment.

One type of observational study is the case-control study, which starts with the identification of individuals who already have the outcome of interest, cases, and are compared with a suitable control group without the outcome event. The relationship between a particular intervention or prognostic factor and the outcome of interest is examined by comparing the number of individuals with each intervention or prognostic factor in the cases and controls. Case-control studies are described in greater detail later.

In the cohort study design, the cohort represents a group of people followed over time to see whether an outcome of interest develops. Ideally, this group meets a

**TABLE 6 Hierarchy of Evidence**

| Study Design                                              |           |
|-----------------------------------------------------------|-----------|
| Randomized controlled trials                              | Less bias |
| Controlled trials (e.g., controlled before-after studies) |           |
| Case-control studies and cohort studies                   |           |
| Cross-sectional studies                                   |           |
| Expert opinion, case reports, and case series             | More bias |

level of certain predetermined criteria representative of a population of interest and is followed with well-defined outcome variables. Usually, this group is matched with a control population selected on the presence or absence of exposure to a factor of interest. The purpose of this type of study is to describe the occurrence of certain outcomes with time and to analyze associations between prognostic factors and those outcomes.

Randomized controlled trials classically are held as the standard against which all other designs should be measured. In a randomized controlled trial, patients are assigned to a treatment group or a control group. The control group usually receives an accepted treatment or no treatment at all, whereas the treatment group is assigned the intervention of interest. Randomized controlled trials are thought to represent the highest quality of evidence based on their methodological strengths of randomization of patient assignment and blinding of intervention and outcome.

### 6.6.2 Trial Organization and Responsibilities

We will provide an overview of the organization of a multicenter trial with emphasis on the trial committees, methods and coordinating center, and participating sites. Figure 1 details how a trial may be organized.

The complexity of a trial with multiple participating centers and hundreds of participating investigators requires key organizing committees to overlook the conduct of the trial, to assure patient safety, and to limit bias in outcomes assessment.

The steering committee is responsible for the overall design and conduct of the trial. The members of this committee may or may not be direct participants of the proposed trial. Often the committee consists of the principal investigators, a biostatistician, a trial methodologist, and other key individuals deemed important to the design and conduct of the study. The steering committee communicates with the trials coordinating center, data safety monitoring board, outcomes adjudication committee, and participating sites on a regular basis. At the completion of the trial, the steering committee maintains responsibility for the data analysis and manuscript preparation on behalf of all study investigators and participating sites.

All clinical trials require safety monitoring, but not all trials require monitoring by a formal committee external to the trial investigators. Data Safety and Monitoring Boards (DSMBs) or Data Monitoring Committees (DMCs) have generally been established for large, randomized multicenter studies that evaluate interventions intended to prolong life or reduce risk of a major adverse health outcome.

Outcomes Adjudication Committees review important endpoints reported by trial investigators to determine whether they meet protocol-specified criteria. Outcomes adjudication is important when the primary outcome of a study requires judgement and is prone to bias in its assessment, especially if the assessment cannot be blinded.

The foundation of a large multicenter surgical trial is the methods and coordinating center. All the day-to-day activities, including centralized randomization, data management, and overall coordination of the trial, occur at this site. The coordinating center can be a contract research organization that “monitors” the trial for a group of clinical investigators. Alternatively, it can be the site of a principal investigator.

**FIGURE 1** Trial organization.

Each participating site often has more than one investigator enrolling patients for a multicenter trial. In this situation, one investigator from each site is designated as the “site principal investigator (PI).” This site PI serves as the primary contact for the methods and coordinating center and acts on behalf of the participating center. Each participating center also has a dedicated research coordinator who manages the day-to-day issues of patient enrollment, data collection, and follow-up planning. The research coordinator and the site PI work together to ensure compliance, data quality, and effective communication with the methods center.

Participating centers typically identify patients through direct within-center referral or referral from other medical centers. Clinical centers should receive complete sets of all data forms prior to joining the study. The research coordinator for each participating center will ensure that all forms are complete and faxed to the methods center as soon as completed. Each site should be given a follow-up schedule that details the type of information and forms to be completed.

**6.6.3 Data Management**

Collection of data by the site investigator is often the first step in a complex procedure leading to a clean database and final study report generation. Failure to adhere to data collection timelines can significantly delay this procedure. Case report form data pages and additional information is logged, and then the data is entered or scanned into a trial database. Any data queries are faxed or sent to the center for completion or resolution and the database is subsequently amended. Data is usually double-verified to check for accuracy of the data entry.

**6.6.4 Quality Control**

Quality control methods are operation systems and processes established to ensure the quality of a clinical trial, the accuracy and integrity of data, and the compliance with regulations. The clinical investigator is responsible for ensuring that quality control methods are conducted for each study at their clinical site. It is important for sites to have standard operating procedures (SOPs) to help ensure quality and consistency for both general research procedures as well as for procedures for each clinical study. The purpose of the SOPs is to describe in detail who will do each research task and how each task will be completed. Most research institutions have SOPs available for review.

**6.6.5 Study Close-out Activities**

A number of activities need to be completed by the study staff before the close-out of a study. Table 7 lists several of these items. It is important that everything is organized and complete for the close-out visit.

**TABLE 7 Items to Be Completed for Close-out of Clinical Trial**

---

|                                                                                 |
|---------------------------------------------------------------------------------|
| All monitoring visits                                                           |
| All case report forms                                                           |
| Any corrections on the case report forms                                        |
| Test articles from research participants                                        |
| Regulatory binder                                                               |
| Return all study material not used                                              |
| Completion report to the REB or IRB                                             |
| Arranges for secure storage of CRFs, source documents, and regulatory documents |

## 7.1 INTRODUCTION

“Collecting data that are accurate, honest, reliable and credible is one of the most important and most difficult objectives of conducting clinical research” [1]. The process of data management is composed of various discrete and interrelated activities that are intrinsically linked in an individual and building in a successive fashion. Once the processes and activities are identified, they can then be implemented and managed. Once initiated and implemented, they can be measured and monitored.

There is a need to have a structured and orderly approach to manage these complex processes, and a data management plan may help provide this structure. These plans may be referred to by various names such as data management plan (DMP), data study plan (DSP), data management study file (DMSF), and others that may be specific to the workplace or environment. In general, these plans do provide direction to conform practice to regulate the complex processes involved. Although they all will be based upon regulatory and sponsor requirements as well as good clinical practice (GCP) guidelines, the actual implementation may vary due to interpretation differences. Successful trial management demands careful planning and deliberate execution.

For the purposes of this chapter we attempt to provide a conceptual framework and structure for the components that may be included in a data management study plan (DMSP). The DMSP will be individualized to each clinical study that is implemented. This chapter is organized by components that might be included in a DMSP. The main sections to be addressed in this chapter include the quality plan, data management team structure, case report form (CRF) design and guidelines, and data acquisition and handling guidelines.

## 7.2 DATA MANAGEMENT STUDY PLAN: OVERVIEW AND DEFINITIONS

The DMSP can provide the framework for how and where the processes and procedures are defined and outlined for individual protocols or studies. The goal of the plan is to help standardize data management practice and minimize practice variations, assure compliance with regulations and institutional policies and procedures, and facilitate consistency of data management while improving study performance.

The components of the DMSP define the road map and the specifics of what, how, who, when, and why and help define the activities at the institutional level. There will be specific elements to support the activities of data management such as data collection, entry, handling, and developing discrepancy resolution guidelines. The entire DMSP should be designed in concert with quality tools that support the incremental review, periodic measurement, and adjustments to process deviations. The quality plan is a key section of the DMSP, and quality concepts and specific quality actions are included at every section in the DMSP.

The end product of the DMSP is quality data that can support testing of the hypothesis and compliance with the regulations and policies. It is important to identify the activities and personnel involved in data management prospectively. Once the trial is initiated, the defined activities must be monitored and measured

against pre-established benchmarks and thresholds to minimize deviations to the plan. The structure of the DMSP must be generic and applicable to all protocols or studies implemented while the content or specific procedures and definitions will be individualized. The DMSP should be used in concert with institutional standard operating procedures (SOPs) and is influenced by all appropriate regulatory and institutional requirements and good clinical practice (GCP) guidelines. It may even reference a manual of operations. The DMSP should emphasize quality and consistency from the design of the protocol through publication. It provides guidelines for ensuring consistent data collection, accurate data transfer, subject safety, regulatory compliance, and safety monitoring and reporting. In general, a DMSP might include the following components:

- Protocol
- Scope of work and study contract
- Data management plan
- Data validation testing guidelines
- Data entry and tracking guidelines
- Data coding guidelines
- Data handling and transfer guidelines
- Quality control and quality assurance plan
- Data management team structure
- Serious adverse events reporting and reconciliation guidelines
- Training guidelines
- Data import and export guidelines
- Study report guidelines
- Database management system specification guidelines
- Annotated case report forms
- Data storage and archiving guidelines

This chapter will describe the four sections to include in the DMSP:

- Quality plan
- Data management team structure
- Case report form design and guidelines
- Data acquisition and handling guidelines

### 7.3 QUALITY PLAN

The definition for good clinical practice is: “A standard for the design, conduct, performance, monitoring, auditing, recording, analysis, and reporting of clinical trials that provides assurance that the data and reported results are credible and accurate, and that the rights, integrity, and confidentiality of trial subjects are protected” [2]. A quality plan is a key element in the DMSP, and quality processes need to be incorporated into all components of data management activities. The purpose

of a quality plan is to decrease the degree of uncertainty in the measurement and reporting of data as well as to increase the reliability and validity of data utilized to test the study hypothesis. It should describe the quality control and the quality assurance procedures to be utilized for the study activities including the percentage of subjects for whom source documents will be monitored. Three components of the quality plan deserve particular attention: quality control, quality assurance, and continual quality improvement. Together these three approaches will measure and monitor the characteristics and traits of the data and related processes that support the clinical data management operations. They build upon each other to complement and encompass more and more processes that can be measured and analyzed and if needed, corrected. The quality components are built upon the stabilizing elements of the standard operating procedure, training processes, and basic trial conduct such as data collection and analysis activities. It is this combination of interwoven and interdependent components that facilitate the proper planning and execution of data management activities, which facilitates optimizing results.

### **7.3.1 Quality Control**

Guidance for Industry E6 Good Clinical Practice: Consolidated Guidance defines quality control (QC) as “The operational techniques and activities undertaken within the quality assurance system to verify that the requirements for quality of the trial-related activities have been fulfilled” [3]. Trial output is ultimately affected by the operational checks and balances throughout the data management processes that are performed at every step of the clinical trials process and applied to each stage of data handling that ultimately affect the trial output [1]. Identification earlier in the process will reduce errors by creating a robust checks and balance system. Implementing QC procedures will help to assure that trial procedures and processes have occurred as well as that the activities have been performed in accordance with some threshold or standard. A deviation or error may be noted soonest and adjusted when there is an established, ongoing measurement and data processing review. Since data management processes are performed by a variety of individuals, QC checks must be incorporated into the daily work flow of each data management team member. Quality control in clinical trials or clinical research should generally encompass all the individual procedures that involve protection of human subjects from research risk and affect reliability of the data in order to assure internal consistency of the trial.

Quality control checks may be thought of as snapshots that provide limited insight into the “health” of the data management activities. These snapshots will be used to decide whether to delve further in order to evaluate or assess data integrity components. QC activities may consist of written SOPs and work instructions to be followed such as the process to resolve data discrepancies or clarifications, data validation procedures, or personnel training requirements. QC checks can set pre-defined thresholds such as levels for acceptance testing for an electronic data capture tool.

The DMSP should include study-specific QC activities or steps for critical activities in the entire data management process from protocol and case report form development and subject accrual to data collection, archiving, and cleaning. QC steps can be performed in real time or midstream and some examples are:

1. Comparing programmed edit checks to the standard study-specific edit checks prior to sign off or implementation of an electronic data collection form for a study. An example could be an allowable data range that could vary across studies or populations such as age- or gender-related laboratory values.
2. Performing source document verification (visually comparing the original data source) of all the critically defined data fields just entered into a data collection instrument or computer system following data entry.
3. Following randomization of a new study subject, verifying the steps and the randomization assignment by double checking the work instruction or standard operating procedure.
4. Following the ordering of an investigational agent, a second qualified individual double checks the dosing based on the protocol investigational agent schema.
5. Reviewing and closing a univariate discrepancy as soon as the electronic database notifies the data entry operator of an expected value.

The quality assurance (QA) focus will take advantage of the cross-functional relationships of the data management team by directing efforts on searching for, identifying, and resolving patterns of weakness within one or more processes [1]. Building upon errors or inconsistencies identified at the operator level through the quality control checks, the quality assurance component of the quality plan can focus on measuring performance outcomes rather than just individual process variations.

### 7.3.2 Quality Assurance

Both QC and QA activities are intimately tied to data management. In contrast to QC, QA activities apply to actions that have been performed in the past or apply to past events. Guidance for Industry E6 Good Clinical Practice: Consolidated Guidance defines QA activities as “all those planned and systematic actions that are established to ensure that the trial is performed and the data are generated, documented (recorded), and reported in compliance with GCP and the applicable regulatory requirements” [4]. These activities can assure that predefined data quality requirements have been met and that compliance with certain standard operating procedures or specific data-handling guidelines are measured.

Two components of QA would be audits of performance and audits of systems. As the DMSP attempts to provide the structure for data management activities to occur in an organized and efficient order, QA audits will serve to measure process and outcomes of the data management activities. Performance audits would examine how closely an individual or a research site adheres to a procedure or a process. For example, a performance-focused audit surrounding data entry could include a second independent data entry operator (DEO) reviewing a sample of fields or CRFs completed by the initial DEO. Compliance with data entry guidelines or discrepancy resolution guidelines might be evaluated. An audit of a system could

involve a review of the procedure in order to identify a deficiency in the SOP versus a deficiency in the process of annotation.

These audits should be independent of all trial-related activities that should be used to examine and measure the degree of compliance to a certain procedure or measurement of a performance indicator such as queries generated per site or per study monitor.

Audit reports may address timeliness, completeness, compliance, and consistency of data as compared to the expected results. Additionally, audit reports may be used to communicate the need for corrective action plans to address deficiencies, inconsistencies, and other operational limitations that would adversely influence overall study conduct. A QA activity may include sampling a portion of data in order to assess overall confidence in the quality of a process, an outcome, or a specific task. QA activities may also be employed to ensure QC procedures have been effective in identifying and correcting errors. Some examples of QA activities that might be included in a DMSP are:

1. Assessing the data management study plan for completeness (required sections have been completed and maintained current).
2. Auditing a sample of the personnel-training file against the role-based requirements.
3. Sampling a number of serious adverse events to determine if the events were reported as required by the study protocol.
4. Running an ad hoc query to length of time each research site takes to resolve open discrepancies.
5. Reviewing the cycle times for the last three studies built by the clinical programmers to determine if each was within the defined time period (e.g., 5 days).
6. Audit query resolution processes of each in-house clinical monitor to the specific SOP.

### **7.3.3 Continual Quality Improvement**

Correcting variations in practice or compliance deficiencies must be addressed, but ongoing surveillance with the goal of improving processes is also important. The continuous quality improvement process is a natural companion to QC and QA tools. Adopted from the principles of total quality management (TQM), continuous quality improvement (CQI) serves as an additional tool to correct inefficient or ineffective processes. CQI is a method of evaluation that is composed of structure, process, and outcome evaluations that focus on improvement efforts [5]. CQI can help institutions enhance existing programs and improve effectiveness of processes because the variation in practice can be viewed from multiple angles. Effective CQI activities depend on the collaborative work environment, which is how data management operations are developed.

Drilling down to identifying a process to improve, even incrementally, can be achieved by incorporating the CQI methodology. The emphasis is on identifying the root cause(s) of the problem and then designing an appropriate intervention to eliminate or reduce the reasons for the problem. So, first a problem or issue must

be identified. Next a corrective action plan is developed. Then the plan is set in action. Finally, the results of the actions are monitored. One relatively convenient model to employ is called the FOCUS PDSA model [6]. The relatively simple steps may be utilized to quickly frame the problem, identify the reasons for the problem, and create an effective intervention. The steps are outlined below and will begin with an understanding and agreement on what the problem is and why it exists:

- Find a process to improve or a problem to correct.
- Organize the interdisciplinary team to discuss process or the problem.
- Clarify what is known and gather supporting documentation.
- Understand why the process variation occurs or the problem exists.
- Select a process improvement activity based on the above analysis.

Once the process or the problem is thoroughly understood and the remedial actions are defined, the next step is to continue through a process improvement plan as:

- *Plan* Create a timeline of resources, activities, training, and target dates to establish the completion date. Develop a data collection plan, tools for measuring outcomes, and define thresholds for determining when targets have been met.
- *Do* Implement interventions and collect data.
- *Study* Analyze the results of data collected and evaluate reasons for variation, if any.
- *Act* Act on what is learned and determine next steps. If the intervention was successful, determine if the current processes or procedure were not followed and so new procedures are not needed. Additional training may be required.

Conversely, practice variations may have resulted because procedure is antiquated or nonexistent. Finally, review of the PDCA system may be necessary as it was not robust enough to propel change. In this case it may be necessary to repeat the PDCA cycle.

Continual quality improvement builds upon the narrow or individually focused efforts of the QC checks and the broader procedure and process focused audits, organizational and system checks of the QA activities. The CQI model enhances the quality plan by directing collaborative energies toward processes not individuals. Data management is process driven. CQI efforts, likewise, focus on critical processes that require movement from one person to another and to another but from a systems perspective. CQI can be thought of as a shared effort that enables people to work together across organizational boundaries to improve shared processes [1].

A robust quality plan will force the data management team to evaluate their practices to measure how well they match their assumptions, formal guidelines, and predefined measurements of performance. In fact, it is the outputs from this plan that will form the team's quality profile. The determination and measurement of quality cannot rest in the hands of a select few. Rather it must be a shared responsibility and expectation among all participants on the data management team.

## 7.4 DATA MANAGEMENT TEAM STRUCTURE

It is important for data management team members to understand the scope of their work perfectly. The team members need to understand the deliverable or a specific work component (a portion of a larger deliverable) that they are expected to complete or assist in completing. If there are quality criteria to meet, the team members should know these quality requirements. More importantly, the data management team members should clearly understand the dependencies and relationships that exist between themselves and the other departments such as regulatory or information technology. The DMSP will include a reporting or organizational chart detailing responsibilities and lines of communication. By delineating the structure and composition of the team, energies may then be directed toward problem solving, task effectiveness, and maximizing resources to achieve the team's purpose. Sound team building recognizes that it is not possible to fully separate one's performance from those of others.

As the data management team structure is comprised of various professionals from diverse disciplines, what then are the primary activities of the data management process? In general, the primary aspects of data management consist of:

1. Handling, processing, and analyzing information for the purpose of supporting clinical research activities
2. Developing protocol-specific case report forms (CRFs)
3. Reviewing and approving programmed validation rules and edit checks in the database systems
4. Collecting data from the medical record or source documents and transcribing it into protocol-specific CRFs
5. Reviewing and evaluating data for inconsistencies, omissions, and errors.

The process of clinical data management knits together various key players who provide specialized skills and knowledge.

Depending on the work environment and setting, there may be different types of personnel performing one or more data management activities. For example, a quality specialist may perform audits in one setting and in another setting may serve as an independent review for final CRF design approval. Various disciplines and personnel comprise the data management team. As such, individual setting or environments may have their own unique set of responsibilities and the position descriptions may vary. Regardless, the key element is that we understand that various disciplines must all be interrelated to manage and process data. Some examples of personnel who are involved in the clinical data management activities are:

- *Data Manager* Core or central person who coordinates the various activities for a specific project assuring project goals and objectives are met. May develop protocol-specific CRFs, define programmed edit checks for electronic CRFs, identify critical safety data fields, and coordinate final approvals of CRFs. The data managers also may develop data entry guidelines and have other responsibilities depending upon the environment.

- *Medical Writers* Develop and prepare study protocol, safety reports, and for interim analyses.
- *Statistician* Review clinical and safety databases (or data structures and CRFs) to assure study endpoints can be measured and protocol-specific data are collected, determine safety and efficacy endpoints, conduct data safety monitoring board interim analyses. Develop or work with database programmers to create specialized statistical programs to support data integration, data reporting, and safety analysis.
- *Regulatory Specialists* Confirm human subject protection and subject safety are preserved, develop and maintain standard operating procedures or work instructions, conduct training and education classes, and maintain regulatory files; reviews initial and continuing protocol submission to the Institutional Review Board (IRB).
- *Programmers* Build study-specific data collection instrument (tool), revise multistudy clinical research database system or create study-specific database, modify eCRF or data system based on protocol amendments or sponsor safety reports. Work with statistician, study coordinator, or data manager to create data queries for reports and analyses.
- *Investigator* Responsible for study conduct at the research site, approves data collected and entered into the CRF, assures compliance with all regulatory, scientific principles, ethical, legal, and GCP standards, assures approved reports are prepared and safety information is reported to IRB, sponsor, and other investigators.
- *Research Nurse or Study Coordinator* May perform data collection and entry into CRFs, supervise data entry personnel, audit data entered by data entry personnel, coordinate site recruitment, subject screening, and enrollment, and monitoring activities, maintain regulatory binder and essential document file, coordinate training of site personnel, records maintenance, provide required documents/reports to regulatory, sponsor, institutional entities, notifies IRB/sponsor immediately of a serious adverse event (SAE).
- *Monitor* Principal link between sponsor and investigator, assure rights and well-being of human subjects protected, oversees progress of the trial and ensure study is conducted and data are handled in accordance to protocol, GCP, ethical and regulatory requirements, implements SOPs, provide site staff education, verify data is accurate, complete, and verifiable, assures CRFs are completed accurately.

Along with delineating the personnel and their roles and responsibilities in the DMSP, the plan should also include standard operating procedures (SOPs) that detail processes for data handling to assure accuracy, reliability, safety, security, and privacy. These processes will be further outlined in specific guidelines such as data entry guidelines, data-coding guidelines, and data-handling and transfer guidelines and case report form design guidelines. The data management team structure serves to clearly define role delineation from a functional framework as well as a division of responsibilities. Therefore, development of the case report forms must rely on the team members to integrate and apply study-specific guidelines, sponsor, protocol and regulatory requirements, clinical guidance, subject safety, and endpoint

measurements. It is from the case report forms that the data collection processes may occur.

## 7.5 CASE REPORT FORM DESIGN AND GUIDELINES

### 7.5.1 Overview and Definitions

Case report forms are questionnaires or instruments that are used to collect required data about cases or subjects enrolled in a study in a structured and standardized manner to facilitate reliable, consistent, and clean data for analysis. The CRFs, or data collection instruments, should be designed by investigators in order to measure and define the specific data needed to support or disprove the hypothesis or goal of the study. General purposes of the CRFs are to: (1) meet the objectives of research; (2) obtain most complete and accurate information possible; and (3) do this within the limits of available time and resources.

Ideally, CRF templates are designed to help standardize the information and data collected and facilitate collaboration and reuse for future similar studies. CRFs may be created and used in different modalities or formats including paper or electronic documents. The appearance and functionality of the CRFs will reflect the modality and how they will be used and the capabilities of the environment where they will be implemented.

### 7.5.2 CRF Design and Development

**CRF Design Best Practices** When designing CRFs, the content and structure of the data items (or questions) to be included in the CRF should be considered first rather than the modality or appearance of the CRF. It is best to design the CRFs at the same time that the protocol is being created in order to assure that data specified in the protocol is collected and consistent with the hypothesis of the study and feasible to collect. This will help to keep questions, prompts, and instructions clear and concise and help to assure that the CRF design will fit with the data flow from the perspective of the person completing it. The flow of study procedures and typical organization of data in a medical record (or data source) should be taken into account as well.

Other design issues include planning for reusability, collaboration, and standardization when possible. It is helpful to create and maintain a library of standard forms. If there are previously performed studies or pilot work that has been used for measuring similar outcomes or measurements, CRFs and previous items may be used and adapted as necessary using experiential information. Finally, design the CRF with the primary safety and efficacy endpoints in mind as the main goal of data collection and pretest and review them prior to finalization and approval.

Broadly conceptualizing the CRFs in the study. As discussed in previous chapters of the book, clinical studies generally are designed in a highly structured fashion, and many are divided into chronological periods of varying duration, with different evaluations and tests performed or scheduled for subjects at different time periods. Investigators need to determine how and when the data will be collected and

entered and what the reporting requirements will be. This information can assist in determining the design of the CRF that will fit with the data flow of the study procedures and hopefully decrease the tendency to measure data inappropriately and redundantly. Commonly used time points in a clinical study include pretreatment, screening, baseline, treatment, follow-up, and evaluation or summary points. It is important to remember that the time point a CRF is collected is important data as well as the individual data items as CRFs may be used at numerous times or only once during a study. An overall study data schedule will need to be examined along with the individual CRFs that will be collected, prior to study initiation in order to make sure that the proper data is getting collected at the right times and at the correct frequency (repeats) appropriate for analysis to test the study hypothesis(es).

**CRF Level Design** Once the overall study schedule of procedures or visits has been determined CRF designers should then look at form level issues that will facilitate or hinder data collection or entry and data analysis. First consider the type of data the CRF is used to collect and who will be using and completing it. The goal is to make it easy to use. For example, if a care provider such as a nurse or physician will be using the CRF for data collection, questions may be arranged and grouped differently than if the subjects will enter data into the form. The education level, age, language, and culture all must be considered when designing CRFs for subject entry. Likewise the skill level of the data collector in the research setting is also important to know. Questions may need to be worded for less clinically educated data collectors and more or less help made available to provide explanation of complex items. The following information should be described in the DMSP:

1. Designing for the type of data and the flow of subjects in the study.
2. Designing for who will be completing the CRF in order to assure that it makes sense to that person.
3. Ensure that a data item is collected once and only in one place to avoid conflicts in data. This will help to avoid referential and redundant data points within the CRF.
4. Grouping the same type of data together on the same forms.

For considerations of layout, format, and usability, we will focus primarily on issues related to eCRFs. For overall CRF layout and design, it is important to consider the data flow and the dependency of the items on each other when putting the items in an order or group on the CRF. The order of the items should be determined and interrelationships and dependencies between the questions clarified. For example, if the answer to question 1 determines whether the next few items will be relevant or not and skipped should be made clear on paper CRFs and programmed into electronic CRFs. These “skip patterns” can greatly facilitate either confusion or correct use and entry of data depending on formatting and programming for eCRFs.

**CRF Modality** Final considerations to overall CRF design will need to be made knowing the modality for use of the form. For example, will it be implemented electronically on a personal digital assistant (PDA) or on a paper form to be

scanned, faxed, or mailed? Once the modality(s) have been determined, different tools can be used to make the CRFs most visually conducive to clear and accurate data entry. The font size should be easily readable, copy and fax well, and the use of different styles for visual emphasis and clarity of reading should be used to help the form filler identify specific sections and complete the CRF.

### **7.5.3 Measurement Basics**

It is not practical to discuss in detail the large corpus of material on measurement theory that describes how to create questionnaires and how to design scales, as there are numerous textbooks and a large body of research on this subject. A few key practical steps that can help investigators and study staff to design data collection instruments or CRFs are contained in Sudman and Bradburn [7].

When designing items to measure standard concepts, it is best to identify standardized and validated previously used items to include in the CRFs. The use of items from standardized instruments will help assure that the items are appropriately defined. When standard validated questions do not exist, the investigator must create new questions or revise existing questions, taking into consideration question formats, phrasing, responses, and categories. Instructions for completion/prompts should be simple, clear, and sufficient for whoever is completing the form. Investigators should consult personnel trained in the development of measurement instruments, as this is complex and error prone.

When creating electronic CRFs, it is best to enter and store raw and original data rather than calculated or summary data. For example, the collection of birth date, rather than age, is more useful. Free text input are less optimal to forced selection of text choices, but many CRFs will require free text entry. Other data types may be based upon standard vocabularies such as those used to code common procedures or diagnoses, and a table look-up will help accurate data entry and collection. For more complex data types such as images, electrocardiograms (EKGs), and the like, different electronic solutions are available such as picture archiving and communication (PAC) systems and radiology information systems.

### **7.5.4 Standards for Data**

Researchers performing epidemiological and clinical research frequently participate in collaborations for reasons such as: joint-funding initiatives, to increase sample size in the case of rare diseases or outcomes, and to pool expertise and resources. When designing CRFs for collaborative research, it is important to have the entire collaborative team review and test pilot versions of CRFs. The use of standard CRFs or CRF templates with standard questions and data items will facilitate the ability of data to be merged for collaboration postcollection if the design of the CRFs cannot be done pre-data collection. Identification of useful, validated CRFs, however, is difficult for various reasons. For example, sample CRFs may not be available; there may be copyright and use restrictions; there may be multiple, different, versions of the same CRF, and the assumptions underlying the use of a particular CRF may not have been clearly documented and items may not be validated. There are efforts underway to standardize different CRFs for use in clinical research from both researchers and regulatory agencies and organizations. Unfor-

tunately, the majority of questionnaires and CRFs in existence are custom designed by individual investigators and do not achieve wide enough use that they would be expected to become candidates for standardization by different organizations.

### 7.5.5 Testing and Reviewing CRFs

Once the set of CRFs have been designed, they should be reviewed and approved by the entire study team. It is important to have the clinical study team review and test the CRFs before submitting for approval by the various regulatory committees and boards. Data management team members should review pilot and test data for accuracy (of asking, coding, set up) and analyzability. Each member of the team can evaluate the CRFs from a different perspective and purpose. This will then enable comprehensive feedback and review of the CRFs. Specific things to focus on when reviewing CRFs include:

1. The language on CRF is consistent or understandable by the persons who will be using and completing the CRF.
2. The units of the measures collected are consistent with the units used at different sites.
3. For the different types of CRFs (paper, electronic), the coding must be consistent with the database system that will be used to store the data. For example, it is important to check that the correct choice responses and data types are being collected (e.g., one or two decimal points).
4. The statistical team members can confirm that the appropriate analytical data points are complete and in a format needed by entering pilot test data.

As multiteam involvement is helpful during development of CRFs, testing and review after development can facilitate good CRFs that will work for everyone to increase the usability and data quality and reduce the time needed for cleaning data.

### 7.5.6 Summary: Well-Designed CRFs

It is important to develop and design CRFs when developing the protocol and make sure that only data items are measured and collected that can contribute to measurement of the outcomes and success or failure of the study. The balance between asking too many questions or too many data items or CRFs collected must be made to avoid unnecessary costs and burdens to the subjects and data managers. Too much and/or too little can both contribute to problems in conduct and performance and analysis of the study. By focusing on the overview of data and CRFs in the study, the CRF layout and ergonomics, the usability and CRF modality, along with appropriately designed measures, and standards for data items and databases, and finally by testing and reviewing CRFs with the entire study team, the result will be well-designed CRFs that can be used to collect the right data efficiently to produce data ready to be analyzed. By addressing these CRF design concepts in the DMSP, this will facilitate collection of clean data and will result in a reduction of queries from data managers to clarify items.

## 7.6 DATA ACQUISITION AND HANDLING GUIDELINES

### 7.6.1 Definitions and Overview

Data acquisition is the process by which the data is collected [8]. Data handling is a broad concept that we are defining as the multiple processes and activities that are utilized to transport data throughout the clinical study process [8]. The data-handling process covers the entire life cycle of the data from acquisition to archiving. The DMSP should include study-specific procedures for the data acquisition and collection and data-handling processes all necessary in assuring optimal performance, consistency, compliance, and integrity.

### 7.6.2 Data Acquisition

Data acquisition is the actual collection of protocol-specific data. This collection process can frequently be one of the most difficult and error-prone aspects of a study. Collection of data can occur by one or more methods, all ultimately being deposited or stored in the CRFs. Some methods by which data are acquired and collected include:

- Electronic or computer based—This can include eCRFs on personal computers (PC), laptops, PDAs, or other electronic devices used for data entry. Electronic data capture (EDC) can also be included in this modality type. This can be defined as automatic data collection by a device. An example is the glucose sensor monitors that automatically create electronic glucose data from the subject.
- Through in-person or telephone interviews.
- Paper-based CRFs—These can be scanned, faxed, data entered into a computer, and converted into electronic documents.
- Study subject self-administered diaries and questionnaires.
- Medical chart review and abstraction.
- Electronic imports or transfers of data from other systems (such as laboratory data).
- Sound based, telephone interactive voice response systems (IVRS) that connect telephone users using speech recognition technologies to computer systems [9].

The acquisition of various data utilizing one or more data collection methods presents a challenge. Incremental and systematic checks and monitoring should occur to determine if the data to be collected actually was collected. In addition, was data collected in the format that was expected. And, finally, was data acquired in the time frame expected.

Traditionally, paper has been used to collect and even to store clinical data for research studies. This is primarily due to the convenience of paper and the familiarity of staff and subjects with paper. The move toward more technical approaches is continuing, and for this chapter we will focus on electronic methods of data acquisition or collection for clinical studies. The different modalities that are used for data

collection into a CRF will have varying features that need to be described and included in a DMSP.

Many vendors and data management organizations are moving toward data entry into electronic case report forms often referred to as eCRFs. There are several methods that eCRFs can use to help ensure accurate data entry. The methods used should be described in the DMSP and can include:

- Use predetermined ranges of allowable and expected values.
- Provide simple data type checks, for example, ensuring valid numbers or dates in numeric or date fields. For questions that require text responses, string length checking and validation.
- Preset list(s) of choice values should be defined when possible for a restricted list of responses allowed for data entry selection.
- Skip inapplicable questions and set default values based on the response to specific question(s).
- Compute values for a question calculated based upon other values entered in the CRF.
- Intraform validation checks—In this case one value on a CRF is compared to previously entered data on the same CRF to see if it meets predefined criteria.
- Cross-form validation—In this situation, checks are made that compare the response to a question on one CRF to response(s) on a previously entered CRF, or other previously entered data.
- Spell checking—The software should perform automatic spell checking for certain text fields against online. Domain-specific dictionaries can be used for free text entry to check for spelling errors.
- Support entry and query of missing and approximate values.

Data acquisition guidelines should be included in the DMSP as these will be specific to the study and sponsor requirements. These guidelines will complement the data entry, validation, transfer guidelines, also included in the DMSP, which are based upon the project's scope of work, the study phase, system capacity, and other requirements. Following the acquisition of data, it is the handling processes that address the movement, the storage, archiving, and ultimate security of the data. Appropriate planning and safeguards must be established to address both paper and electronic data. For example, data handled electronically requires the added assurance that the integrity of recorded data are not altered, erased, lost, or accessed by unauthorized users.

### **7.6.3 Data Handling**

Individual data-handling processes may be applicable for a given environment and study, and the DMSP should incorporate appropriate sections for the processes and procedures used in the specific study. Many of the sections to be included in the DMSP for data handling will require the description of validation and testing of the processes and activities involved along with other appropriate ongoing quality

checks. For example, for studies that use a clinical data management system for managing study data, there should be sections in the DMSP on quality checks to be performed including validation and testing of the system and of software programming created for the study. Other examples include quality checks of the data processing and cleaning activities (discrepancy identification and resolution). This might involve describing the queries and reports that will be used for monitoring data entry and data-cleaning activities such as data entry completion and error rate monitoring, missing data reports, discrepancy, and discrepancy resolution reports. Based upon the different capabilities of the software systems used for the study, all or some of these activities can be performed and described in the DMSP.

A systematic approach to how the study will handle data changes or changes to data collection instruments or CRFs should be included in the DMSP. This approach should be an agreed upon process in affect prior to CRF development that details how changes in data collection instruments or CRF versions will be documented and handled. This section should also describe how all changes to data would be documented and copies of previous data stored in electronic audit trails. There should be included clear documentation in the audit trail of who, what, when, and why the change was made.

More data is now available in an electronic format and may be available for import and integration into the clinical study data management system. Examples include laboratory data and subject diary data. It is preferable for this data to be electronically transferred and imported/integrated into existing data management systems rather than be rekeyed into the system. In this case, it will be necessary to include a section in the DMSP describing the approach that will be used to perform the import and check the results in a standard way. Different studies also may require data to be transmitted to outside agencies. Data transfer (both in and out) may be specified to be compliant with standard formats or special formats required by the receiver. The format or use of data format standards such as HL7 [10] and CDISC [11] should be described in the DMSP along with methods to test and validate accuracy of the transfer(s).

**Security and Privacy of Records** The DMSP must describe [or reference the institutional standard operating procedure(s)], how the security and privacy of clinical study data will be assured throughout the data management process. This must include both electronic data and other forms of data (paper) if relevant. All the computer systems to be used must have methods to prevent unauthorized access, preserve subject confidentiality, and prevent retrospective tampering/falsification of data. Under the FDA's Title 21 Code of Federal Regulations (21 CFR Part 11) [12], access must be restricted to authorized personnel, the system must prevent malicious changes to research data through selective data locking, and an audit trail must exist. Additionally, compliance with the Health Insurance Portability and Accountability Act (HIPAA) must be assured. The HIPAA Privacy Rule describes how protected health information (PHI) may be used and disclosed. Under HIPAA, research is defined as "a systematic investigation, including research development, testing, and evaluation, designed to develop or contribute to generalizable knowledge" [13]. The conduct of research and clinical data management, in specific, must incorporate appropriate safeguards to assure compliance with this law.

Data systems also need to be adequately backed-up and recoverable in the event of catastrophic system failure. The physical and electronic security must be assured to keep the data both safe and secure, yet it must also be available to authorized users with password and authentication. Users should have assignment of role-based privileges. Database management systems should have the ability to store and/or generate deidentified data for purposes of analysis and data sharing. All systems must have robust electronic audit trails and allow for archiving and data locking.

## 7.7 SUMMARY

The process of data management is complex, error prone, and vital to reliable accurate data. A data management study plan is a structure by which these complex processes and activities can be organized to assist in a consistent performance of the actions. Beginning the DMSP with a study-specific quality plan and applying the quality processes throughout the entire data management process should result in an increase in the reliability of clinical data, decrease variation and errors, and improve on the timeliness of good clinical quality processes and outcomes that can be defined and measured.

8.1 CLINICAL DATA MANAGEMENT ASPECTS

8.1.1 Regulatory Framework for Clinical Data Management

In recent years the medical community has been involved in a great debate concerning ethical issues that include confidentiality and privacy, especially for data included in medical records or collected in clinical studies for research purposes. Furthermore, the improvements in information technology (IT), which made full paper replacement possible and new solutions for the electronic management of data available, have led the regulatory agencies to better clarify the requirements for processing personal data. For these reasons, new rules have been identified for the clinical data management process including compliance with the privacy and data protection laws when personal data are processed, compliance with good clinical practice (GCP) [1] when medical products or medical interventions are tested, and compliance with other regulatory directives when medical products are submitted to specific regulatory agencies (Table 1).

**Data Privacy** People involved in the data management process should be familiar with basic data privacy issues and should follow the principles established by their organization to ensure the privacy of research subjects and the compliance with the GCP and other international and/or local regulations [2].

Data privacy is related to the standards surrounding the protection of personal data, defined as “any information about a person who can be identified directly or indirectly” (e.g., patient names, initials, addresses, and genetic code). The privacy of any subject who participates in a clinical trial must be protected from the ethical and legal points of view. The data should be protected from accidental loss, alteration, and unauthorized access. For this reason, the implementation of appropriate security measures are required.

To guarantee data privacy, personal data must be handled separately from the clinical data and made anonymous. In addition, a written, signed, and dated informed consent should be asked and obtained from the owners of the data. The concept of data privacy is enforced in the GCP: “The confidentiality of records that could identify subjects should be protected, respecting the privacy and confidentiality rules in accordance with applicable regulatory requirement(s)” [1].

Sometimes the identification of an individual cannot be fully masked. In fact, the data management staff usually use several sources of information such as primary medical and hospital records, genetic data, economic data, and adverse drug event reports. In these cases, to ensure proper assignment of data in a clinical database, data collection instruments should be designed with the need for the minimum research subject identifiers (in general, a subject identification number and gender can be used to solve any discrepancies that might arise from transcription errors).

In addition, the application of local laws, such as the Italian one, integrates the statements of the European Union (EU) directive with a technical attachment addressed to the electronic data management [3]. These include detailed requirements related to the use of the user name and password for a secure and diversified data access that is based on the user’s profile, and the use of backup and restoration procedures in order to ensure data integrity.

**Good Clinical Practice and Other Directives** The International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) Good Clinical Practice Guidelines [1] add an additional layer on the requirements for data management of clinical data (Table 2). One of these is related to the quality control process that should be applied to each stage of data handling in order to ensure that all data have been correctly processed. Another important requirement states that any change or correction to a case report form (CRF) should be dated, signed, and explained (if necessary), and should not obscure the original entry. This must be done by maintaining an “audit trail” and should be applied to both written and electronic changes or corrections. Similar requirements have been proposed by other regulatory guidelines. For example, the Food and Drug Administration (FDA) 21 CFR Part 11 [4] establishes the requirements for electronic records and electronic signatures to be trustworthy, reliable, and equivalent to paper records and handwritten signatures. These requirements, for example, imply data encryption, digital signature standards, and other safety requirements (i.e., device checks).

**TABLE 2 Main FDA 21 CFR Part 11 and GCP Requirements**

| Requirement                                                                      | Part 11   | GCP                        |
|----------------------------------------------------------------------------------|-----------|----------------------------|
| Validation of Computer System                                                    | 11.10 (a) | 5.5.3a                     |
| Data Protection (to enable accurate record retrieval)                            | 11.10 (c) | 2.10; 4.9.1; 5.5.3f        |
| Limiting Access (limiting system access to authorized people)                    | 11.10 (d) | 2.11; 5.5.3d               |
| Audit Trail (secure, computer generated, time-stamped audit trails)              | 11.10 (e) | 4.9.3; 5.5.3c              |
| Authority Checks (to ensure that only authorized individuals can use the system) | 11.10 (g) | 2.11; 4.1.5; 4.9.3; 5.5.3e |
| System Documentation                                                             | 11.10 (k) | 5.5.3b                     |
| Record Retention (to generate accurate and complete copies of records)           | 11.10 (b) | 4.9.7                      |

### 8.1.2 From Clinical Protocol to Data Acquisition Tools

The clinical data management activities should be planned early in the clinical study process. Ideally, they should occur concurrently with the development and writing of the protocol, when the decisions about the study data to be collected and the type of data flow are usually taken. It is a crucial phase for the development of proper data management tools, and it is therefore suggested that statisticians, clinicians, data managers, study monitors, study coordinators, and database programmers be involved in it. The design of the CRF is the first step in translating the protocol requirements into data and is one of the first results of this multidisciplinary work.

A CRF can be defined as a collection of forms including a series of data items, each aimed at obtaining a single response, and composed by a text (item label) and a response field (item value); while the first represents the question to be answered, the second is the space given to the investigator to record its response [5].

### 8.1.3 Database Design

Clinicians often have difficulty in deciding what patient information is relevant to a clinical trial. In their current practice, they are able to retrieve a summary of the relevant information from individual patients' charts, but are probably unable to give a whole list of the pertinent data items. When these are identified by the multidisciplinary team, they must be organized in a structured way so that they may be easily collected and analyzed. The CRF structure is then used to design the structure of the database where the patients' data will be stored once entered through a data entry application.

Computer science and various software technologies have revolutionized the way medical information is stored, accessed, and retrieved. Today, the relational database model is often considered the founder of many different types of clinical information systems, providing the closest fit to functional requirements of the protocol [6]. In brief, this model comprises data arranged in "tabular" data structure, consisting of several columns (items/variables) and rows (observations). The key aspects of a relational database are the relationships between tables (entities) through the definition of primary and secondary keys (e.g., the patient's ID to link the patient's

demography data to his adverse events), because they ensure database integrity. This means, for example, that a row cannot be added in the “adverse events” table representing an adverse event for a specific patient, unless a row for the same patient exist in the “demography table.” In addition, a table will have the required fields for representing the entities (type of data collected), and each field will contain data of a specific type, such as characters, numbers, dates, and times. The interaction between the case report form design process and the database design process is fundamental and unavoidable: The schema identified to collect the data may influence their meaning and the structure of the database in which they are stored.

**Vertical versus Horizontal File Structure** In designing the database tables containing data about a specific “entity” (such as demography, laboratory data, etc.), the critical question that must be addressed is the following: For multiple occurrence of data items at different time points, is it easier to handle multiple records or one record with repeated data items? There are two options to consider: vertical and horizontal file structures (Fig. 1). The vertical file structure defines the concept of multiple records, while the horizontal file structure is associated to the concept of repeated data items.

To utilize a vertical file structure, a method to distinguish between the multiple occurrences of the data must be identified. This can be done by using the visit date and the visit time. Therefore, in a vertical file structure, the single record contains information on the patient’s measurements at a defined date and time. The advantages of this structure include the utilization of cross-tabulation features for reporting and analysis and the minimization of the amount of missing data and space needed for storage in the database. Several statistical packages such as SAS System require this structure for data processing. In addition, programming efforts are reduced due to the need for processing multiple records instead of multiple fields.

When a horizontal file structure is used, the information collected must be fixed and prespecified. The names of the database fields should have suffixes that help

#### Vertical

| Site | Patient | Visit # | Visit Date | Temp | SBP | DBP |
|------|---------|---------|------------|------|-----|-----|
| 5    | 1       | 1       | 10/11/2005 | 37   | 120 | 70  |
| 5    | 1       | 2       | 10/12/2005 | 37.1 | 125 | 71  |

#### Horizontal

| Site | Patient | Temp1 | Temp2 | SBP1 | SBP2 | DBP1 | DBP2 |
|------|---------|-------|-------|------|------|------|------|
| 5    | 1       | 37    | 37.1  | 120  | 125  | 70   | 71   |

**FIGURE 1** Vertical vs. horizontal data structure.

the identification of the visit time (e.g., in Fig. 1 SBP1 and SBP2 identify the patients' systolic blood pressure taken during visit 1 and visit 2, respectively). This could be a problem if data for additional visits must be collected. In addition, the limit on the number of fields or in the record length for a single table may introduce other problems that cannot easily be solved. Although this structure allows easy comparison of similar fields over time (e.g., to find the worst value), it is not a recommended approach. Furthermore, it requires more programming efforts without any benefit in program flexibility.

### 8.1.4 Data Processing

Clinical data management deals with complex medical data. Managing this data requires familiarity with medical terminology, anatomy, physiology, and pharmacology, as well as practical knowledge of how data are collected in the health care setting and documented in medical records.

The data processing process includes the following steps: data entry, data validation, data modification, medical coding, and database locking [7].

**Data Entry Methods** When a paper-based CRF is used to collect patient data, the investigator is asked to access the source patient's documentation (e.g., the medical record), fill in the study forms, and deliver them to the coordinating center (or clinical data center), usually after a data-monitoring process is carried out. Once received, the CRF undergoes an initial inspection and then is entered into the clinical database. Two options are usually available for data entry: single data entry and double data entry. With double data entry two people enter the same data independently. Any discrepancies between the first and second entry are usually solved by a third person (e.g., the data manager in charge of the study) or by the person performing the second entry (interactive or online verification). The main regulations, such as those of the FDA and ICH, do not formally require double entry or any other specific data entry process, although some have questioned the need for duplicate data entry [8]. In general, the single-entry process with proper manual review, or with double data entry of key data (e.g., the main study endpoints) will work better than a sloppy double-entry process.

**Data Cleaning and Checking** Data are usually collected and entered in the database following detailed rules and conventions that govern how the data are to be recorded (i.e., CRF completion instructions, data entry guidelines, data entry conventions, etc.). However, many errors can be made (voluntary or involuntary) during the data collection and data entry processes including misspelled names, duplication of digits, partial data collection, and inconsistencies between forms.

For this reason, a data cleaning (or data validation) process should be defined. The data-cleaning process is based on a list of activities that are planned to assure the validity and accuracy of the data, including a manual review of the data before their entry, and aggregate descriptive statistics that reveal unusual patterns in the data. However, the most powerful tool provided by the data-cleaning process is the automatic data-checking process to identify errors, protocol violations, and data completeness, inconsistencies, and duplication.

**CONTROL ON PATIENT DEMOGRAPHY**

1. Age <> Missing AND between 18-75
2. Sex <> Missing AND In(1,2)
  - If SEX=2 THEN Inclusion Criteria nr. 3 (Pregnancy) <> Missing

**DRUG ADMINISTRATION**

1. (Actual Dose/Intended Dose) between 0.95 and 1.05 (5% dose modification allowed)

**FIGURE 2** Example of a data validation plan specifications.

Example of data-checking include range checks on the variables that may reveal values that fall outside the accepted limits (e.g., age, for a specific eligible criteria of the protocol, must range between 18 and 75), and cross checks between variables, which may reveal inconsistent answers (e.g., if a patient is dead the date of death is required). Other additional types of checks such as checking whether mandatory answers are not missing, checking for invalid dates and invalid date sequences, checking that complex multifile (or cross panel) rules have been followed (e.g., if a specific adverse event occurs, other data such as concomitant medications or procedures might be expected), and the comparison of the values entered to lists of valid patterns of value, either text/character (e.g., the smoking habits could be coded as “smoker,” “nonsmoker,” and “ex-smoker”) or numerical (e.g., the same habits could be coded as 1, 2, and 3) are usually programmed and performed.

A complete validation plan for the data cleaning should be defined, for example, using a pseudocomputer language which will be easily understood and translated into a computer language (Fig. 2).

The data-checking process may be performed as a batch or as an interactive process. In the first case, data checking takes place after data entry. In the second case, it is performed during the data entry, and the data entry person receives a warning message immediately if an error is made.

**Data Modification** Data may be changed as a result of a data-cleaning procedure. In this case, both the site and the data center must retain a record of all changes to the data. Data changes (with the new and the old values) are usually recorded and documented through a data (or query) clarification form that is signed by the site investigator and kept with its original study record. Under some circumstances, data-cleaning conventions (often called self-evident changes) may specify data that can be modified without a site’s acknowledgment. Examples include appropriately qualified personnel correcting obvious spelling errors and converting values when the units are provided. For this reason it is important for the site to receive and maintain a copy of each version of such data conventions.

However, an audit trail should always reflect all deletions, updates, or additions to data that are carried out after the initial entry. In addition, it should include the date and time of the changes, the reasons for the changes, and the name of the user who was in charge of making them. An electronic audit trail can provide a clear documentation of this information (Fig. 3).

| Pt#  | Vis# | User Id | Timestamp              | Item  | Old value | New Value | Reason for Change              |
|------|------|---------|------------------------|-------|-----------|-----------|--------------------------------|
| 1001 | 1    | DM_01   | 12/05/2004<br>11.46.52 | AEOUT | 1         | 2         | Query following Medical Review |
| 1001 | 1    | DM_01   | 12/04/2003<br>10.32.46 | AEOUT |           | 1         |                                |

**FIGURE 3** Example of an electronic audit trail. An adverse event occurred at visit 1 in patient 1001; the corresponding data was initially entered on 12/04/2003 by user DM\_01. Following the data validation process, a query was issued; the investigator reply implied the change of the adverse event outcome (Item AEOUT) from 1 to 2; the modification was performed by user DM\_01 on 12/05/2004.

**Medical Coding** Wherever possible, data should be collected in a coded format, while the text format should be used to collect summaries and data that do not need to be codified. This makes data entry and the search and data analyses procedures easier. Free text can be coded using an ad hoc dictionary (with a simple list of codes) or a standard dictionary (with thousands of entries).

Data coding can also avoid possible misinterpretations. For example, consider patients with “abnormal transaminases.” The investigators from different sites could indicate this condition in the CRF with the phrases “has ALT,” “has SGPT,” and so forth. When data are analyzed, if we need to identify all cases of “abnormal transaminases,” we should search for all possible combinations of words related to the abnormal transaminases concept.

This adds further implications in data analysis. Consider, for example, the statistical tables illustrated in Figure 4 analyzing the safety profile of a particular medical intervention, where worst (maximum intensity) adverse event toxicity by patient is reported. If we consider the first table we may conclude that seven patients had abnormal transaminases of grade 1 or 2. Instead, if we consider the second table based on the same set of patients, we may conclude that five patients had abnormal transaminases. The discrepancy is due to the investigator’s use of different terms to identify the same type of adverse event occurring in the same patient (this occurs in two patients as explained in Fig. 4).

The coding process can be automatically performed during data entry by matching the text collected on the CRF to the terms included in the standard dictionary.

Several medical dictionaries are currently available. Among them, the *Medical Dictionary for Regulatory Activities* (MedDRA) [9] has become the standard dictionary for coding a patient’s medical history, medical and surgical procedures, and adverse events. In addition, it includes the standard terminology used by regulatory agencies and biopharmaceutical industries within the ICH regions, through all phases of clinical development (including postmarketing). Other well-known medical dictionaries are the *World Health Organization Drug Dictionary* (WHODRUG) [10] and the *Systematized Nomenclature of Medicine—Clinical Terms* (SNOMED-CT) [11], which are used to code medications, the International Classification of Diseases (ICD) oncology for tumor classification, the ICD-9 for classifying morbidity and mortality, and the National Library of Medicine’s Unified Medical Language System (UMLS) for classifying general medical terms.

| Investigator term | Worst CTC Grade by Patient |      |     |      |     |     |     |      |
|-------------------|----------------------------|------|-----|------|-----|-----|-----|------|
|                   | 1                          |      | 2   |      | 3   |     | Any |      |
|                   | N                          | %    | N   | %    | N   | %   | N   | %    |
| ALT               | 1                          | 5.2  | 2   | 10.5 |     |     | 3   | 15.7 |
| SGPT              | 2                          | 10.5 | 2   | 10.5 |     |     | 4   | 20.3 |

| MedDRA Primary Preferred Term | Worst CTC Grade by Patient |     |     |      |     |     |     |      |
|-------------------------------|----------------------------|-----|-----|------|-----|-----|-----|------|
|                               | 1                          |     | 2   |      | 3   |     | Any |      |
|                               | N                          | %   | N   | %    | N   | %   | N   | %    |
| Alanine Aminotransferase      | 1                          | 5.2 | 4   | 21.1 |     |     | 5   | 25.2 |
| ....                          | ...                        | ... | ... | ...  | ... | ... | ... | ...  |

| Pt# | Vis# | Event Description | MedDRA Primary Preferred Term | Max CTC Grade | Max CTC Grade per patient according to MedDRA term |
|-----|------|-------------------|-------------------------------|---------------|----------------------------------------------------|
| 1   | 1    | ALT               | Alanine Aminotransferase      | 2             | 2                                                  |
| 1   | 2    | SGPT              | Alanine Aminotransferase      | 1             |                                                    |
| 2   | 2    | SGPT              | Alanine Aminotransferase      | 2             | 2                                                  |
| 3   | 1    | ALT               | Alanine Aminotransferase      | 1             | 2                                                  |
| 3   | 2    | SGPT              | Alanine Aminotransferase      | 2             |                                                    |
| 4   | 1    | ALT               | Alanine Aminotransferase      | 2             | 2                                                  |
| 5   | 1    | SGPT              | Alanine Aminotransferase      | 1             | 1                                                  |

**FIGURE 4** Implication of medical coding on statistical analysis.

**Database Locking** The study databases must be locked to ensure their integrity for the generation of results, analysis, and submission to the regulatory agencies. Locking a study database is fundamental to prevent inadvertent or unauthorized changes once the final analysis and reporting of the data have begun. Furthermore, database closure is a critical issue in preserving the integrity of blinded randomized clinical trials when the blindness needs to be broken. Therefore, any clinical trial must have a well-defined process for closing its database and clear change-control procedures for reopening the database, if necessary.

Before locking a database, a database quality control should be considered in order to verify that study procedures for collecting and managing the data were correctly applied. This is usually performed by checking the contents of the database against the paper CRF in a sample of patients (e.g., 10% of CRFs).

### 8.1.5 Electronic Data Capture Principles

Electronic data capture (EDC) is the process of the collection of data into a persistent electronic form: This includes data entry (e.g., keyboard EDC, pen-based systems, voice recognition) and automated (or direct) data acquisition (e.g., bar code scanners, blood pressure cuff devices) [12].

The EDC processes emerged in the 1970s but languished for 20 years without having significant impact on the clinical trials arena. However, in the 1990s the development of tools for clinical trials research became more focused. With these applications data were captured and entered directly into the PC client at the investigator sites where the database application was installed; the data stored at the site were then periodically transmitted to the central server located at the study data

**FIGURE 5** Impact of EDC adoption in clinical data management. EDC adoption made the data management process faster by removing time-consuming steps in clinical data flow from source data to clinical trial data.

center (Fig. 5). Other, more sophisticated EDC systems have been developed during recent years, including those using the Internet and web technology (see following sections), and today they are commonly used by many research organizations to conduct clinical trials. The regulatory agencies themselves are today ready to accept the submissions for drug registration in which EDC tools are used.

The adoption of an EDC system has a great impact in the clinical data management process and introduces new features:

- No formal data entry exists because source data are collected and entered directly into the clinical database without first being captured onto paper; this means that transcription errors are eliminated and a double data entry is therefore not required.
- The data cleaning and editing can be performed during data entry (through the online checks), and the investigator can immediately clarify any discrepancy.
- The source data verification process cannot be eliminated; however, the number of queries issued for the clinical monitors, as well as the time they usually spend at the investigator's site, are reduced.
- The type of training and skills required of the data entry staff are different from those required when a paper-based system is used; in this case, in fact, the data entry personnel should receive training on the specific system being used in the study as well as on study-specific issues (i.e., eCRF completion guideline).

For these reasons, designing a good EDC system needs special attention to make moving from paper to EDC systems and computer programs efficient while maintaining data integrity.

### 8.1.6 Data Standards

One of the main drawbacks to the adoption of the EDC systems has been the proliferation of software to capture trial data; moreover, without the ability to share data across systems, the value of the EDC systems has been somewhat restricted to clinical researchers.

To solve this issue, the representatives from pharmaceutical industries, academic research institutions, health authorities and other research entities [i.e., clinical research organizations (CROs)], met in 1997 to develop a system of shared standards, known as CDISC (Clinical Data Interchange Standards Consortium, <http://www.cdisc.org>). Among the CDISC specifications, the Operational Data Model (ODM) describes a standard model to combine both the study data definition and the actual subject data. This standard specification allows two different systems to communicate and share the data if the source system can produce CDISC ODM format and the receiving system can read CDISC ODM format. The portability and sharing of the data is made possible by the use of the eXtended Markup Language (XML), which has been adopted by CDISC to describe the data hierarchy (see example in Fig. 6).

Other CDISC models have been developed. One of the most interesting is the Study Data Tabulation Model (SDTM) through which most common clinical data domains, variables, and their attributes are defined (i.e., name, type, length, standard definitions, code lists, etc.). The adoption of such a standard for data structures and conventions permits the sharing and application of the same, unique data structure and data-cleaning procedure to several different studies; moreover, pharmaceutical companies dealing with regulatory submissions or institutions running meta-analysis projects would be able to better integrate data from multiple studies.

In July of 2004 the U.S. Food and Drug Administration (FDA) announced the adoption of the CDISC SDTM as the standard format for submitting study data for

```
<ClinicalData StudyOID="S054T231" MetadataVersionOID="101.01">
  <SubjectData SubjectKey="1000" TransactionType="Insert">
    <StudyEventData StudyEventOID="101.Screen">
      <FormData FormOID="101.DEMOG">
        <ItemGroupData ItemGroupOID="101.DM">
          <ItemDataString ItemOID="101.USUBJID">002</ItemDataString>
          <ItemDataString ItemOID="101.SEX">F</ItemDataString>
        </ItemGroupData>
      </FormData>
    </StudyEventData>
  </SubjectData>
</ClinicalData>
```

**FIGURE 6** Example of an ODM XML file. An XML file portion describing demography data (DM) of a "Female" patient enrolled in the study S054T231 with the code 002.

registrative purposes; with such a decision the FDA intends to reduce the time for data evaluation and avoid the reorganization of large amounts of data submitted in varying formats.

### **8.1.7 Infrastructure Requirements**

Setting up an organization for clinical trials data management (i.e., data center, central coordination center) requires the evaluation of a number of issues including the selection of the optimal staff for supporting the various steps of clinical data management flow (i.e., data manager, database programmer, medical coding expert, etc.). Concerning the IT aspects, an appropriate hardware and software selection should be taken into account. The key aspect to consider is the physical security of original data sources (e.g., case report forms, electronic data files, and other original data documents), including the system used to store them. Original paper and electronic documents (servers) should be warehoused in secure rooms, or file cabinets, with controlled access. Direct access to database servers should be restricted to individuals who are responsible for monitoring and backing up the system; all other access to database servers should be controlled by logical security and should occur across a secure network protected by password access and appropriate system controls. Mechanisms should be implemented to capture and prevent unauthorized attempts to access the system (i.e., firewall); if such an attempt takes place, the administrator should be notified immediately.

The investigator sites should be considered part of the infrastructure, especially if data are stored locally at the study site before being sent to a central server (as in the case of use of “offline” systems).

### **8.1.8 Implementation of Clinical Study Data Management System**

An organization, either a company or academic research institute, may decide either to develop an ad hoc system or acquire a commercial clinical study data management system (CSDMS). Both options have some drawbacks: While developing an ad hoc system requires more effort in the system validation process and additional dedicated computer staff, buying an existing commercial system may require a lot of time to choose and evaluate it among many candidates available in the market, and, at least at the beginning, a lot of money.

The choice of the most appropriate CSDMS should take into consideration several aspects, including the availability of tools to compare double data entry sources, design user-friendly data entry forms, easily program checks for data entry validation, support the generation of ad hoc queries, and handle missing values. In addition, multiuser access regulated by user name and password, and the availability of tools to transfer data to other software packages (such as SAS System for performing statistical analysis), to simplify the coding process, to implement data dictionaries, and to perform the data backup and recovering, can be considered good add-ons.

In recent years the market has seen the launch of several solutions. These software programs help users in designing a complete data management system, without having to know any concept of data models. Oracle-based applications, such as Oracle Clinical RDC and PhaseForward Inform/Clintrial, represent the bigger portion of the market and, due to their high costs, are suitable for an environment

in which many trials are conducted. However, a number of alternative solutions, including free open-source CSDMS such as TrialDB (<http://ycmi.med.yale.edu/trialdb>) and Open Clinica (<http://www.openclinica.org>) are now available [13, 14].

### 8.1.9 Computer System Validation

The GCP requirements emphasize the importance of validation of systems, process, and data. In particular, they ask to “ensure and document that the electronic data processing system(s) conforms to the sponsor’s established requirements for completeness, accuracy, reliability, and consistent intended performance (i.e., validation)” [CFR GCP 5.5.3 a]. Similar requirements have been proposed by other regulatory guidelines. For example, the FDA 21 CFR Part 11 [4] emphasizes the need for a validation approach for any computerized system that is used to store electronic records or signatures so that they can be trustworthy, reliable, and essentially equivalent to paper records and to a handwritten signature (Table 2). In this context, the term “computer system” is used to describe the combination of hardware (servers, local area network, client PCs), software (operating system and software applications), procedures, documentation [standard operating procedures (SOPs), guidelines, manuals], and people involved in the process.

Data management software purchased off the shelf should have been validated by the vendor who originally developed it. These validations are usually referred to as “design-level validation” and do not need to be repeated by the end user.

However, the documentation of the design-level validation specifications and testing should, ideally, be available; it should ensure the completion and documentation of functional level testing, and include the documentation of the effect of any known limitation, problem, and defect on functions used for the study [15].

Additional validation activities need to be performed by the customer before the system can be used, including testing the data entry screens to ensure that the data are correctly mapped into the database structure, testing the data verification functions, the validation of any generic integrity constraints or data-checking routines running during data entry, and testing the audit trail and import/export (from/to other data formats) procedures.

### 8.1.10 Future: HER/EDC Integration

The electronic health records (EHR) systems usually include most of the data that are to be collected in a clinical study. Some examples are the demographic data, the medical history, the clinical events, and the concomitant treatments. For this reason many researchers have proposed to consider them as a primary source of information from which to automatically extract, when needed, the data requested in a study protocol [16–19].

However, this solution presents some limits. For example, some specific information related to the study treatment may not be included in the patient’s EHR or may not be properly collected. Similarly, some specific laboratory tests may not be usually performed. In addition, patient confidentiality must be addressed and correctly ensured.

Although some organizations have experimented EHR/EDC combinations, this technology is still young, and, as of today, solutions for health care providers and

hospitals are not available. Some projects to integrate the EHR and the EDC systems are still ongoing. The most important is the BRIDG (Biomedical Research Integrated Domain Group, <http://www.bridgproject.org>) project, which is a collaboration between CDISC, representing research data standards, and HL7 (Health Level Seven, <http://www.hl7.org>), representing health care data standards.

## 8.2 WEB-BASED CLINICAL TRIALS

### 8.2.1 Web-Based Clinical Trials

Telecommunication technology for the management of clinical trials has been used since the early 1990s when PC/modem-based randomization and data-monitoring systems were developed. One of the first applications is the system developed by the Gruppo Italiano per la Sopravvivenza nell'Infarto Miocardico (GISSI) for the management of the GISSI-3 trial, an Italian multicenter large-scale clinical trial in patients with myocardial infarction [20]. A computer/modem-based system allowed investigators from 200 coronary care units to randomize 20,000 patients in the trial using an automated randomization procedure running on a 24-h basis, and provided study reports and reminders [21].

Since from the mid-1990s the Internet and the World Wide Web have been proposed by several pharmaceutical industries, CROs, and international research groups as tools to support clinical research. Speed in communication, strong interaction among people involved in trial conduction, cost reduction, data quality improvement, and the use of simple and standard tools (such as the browser) to interface with study databases are the key elements for the Web's success [22–24].

### 8.2.2 Tools for Participating in Web-Based Clinical Trial

A potential investigator center who wishes to participate in a Web-based clinical trial (or e-trial) needs a personal computer, a Web browser, an electronic mail system, and access to the Internet via an Internet service provider (IP). Sometimes a printer is needed for printing documents (such as the reminder of the randomized treatment allocation) that need to be archived in the patient's file. Standard software such as Acrobat Reader may also be needed to read documents (such as operating manuals or CRFs) distributed in pdf format by the coordinating center.

A specific release of a browser (Internet Explorer 6.0 or 7.0 are more frequently suggested for this use) is often requested, as well as setting it up to accept cookies for the user's identification by the coordinating center's server.

For security and data safety reasons an Internet connection with a static IP address is suggested because this is one of the best methods to identify the computer of an investigator participating in a trial.

### 8.2.3 Why a Clinical Trial Website?

There are many reasons for a clinical trial to have a website. First, a clinical trial website provides trial personnel (coordinators, investigators, monitors, sponsors, committee members) with a powerful communication, organization, and monitoring

tool as well as with tools for the decentralization of trial activities (e.g., remote randomization and data entry). Second, the use of such a website can reduce research costs and the time required for trial completion. In addition, the remote data entry allows the building of a more accurate study database because data are entered at the same place where they are collected.

A clinical trial website is also an ideal vehicle for the dissemination of findings and information related to the trial or similar trials conducted in the past by the same group. For these reasons, a clinical trial website is developed mainly for multicenter and international clinical trials, and for those carried out by pharmaceutical companies.

**Communication among Trial Personnel** A study website can be used to provide the investigators with secretarial support through automatic trial report generation and delivery (Table 3). Examples of online reports are the list of randomized patients, the visit calendar, the list of patients lost to follow-up, and the list of CRFs and queries that are still outstanding [25, 26]. Automated tools may help investigators to organize their work. Web-based systems developed by some study groups include tools to handle the study drugs (how and when new drugs should be ordered, how drugs dispensed to patients should be registered in the database, how to handle the drug inventory, and when expired drugs should be destroyed) [27, 28] and tools to download study materials (protocol, study CRFs, and informed consent forms)

**TABLE 3 Examples of Online Reports and Information Available on a Study Website**

| Information and Reports                        | Examples                                                                                                                                                    |
|------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>For Site Investigator</i>                   |                                                                                                                                                             |
| Reports on the study's progress                | List of randomized patients<br>List of planned visits<br>List of patients lost to follow-up<br>List of outstanding CRFs/queries<br>List of uncompleted CRFs |
| Reports about the management of the study drug | Drug inventory monitoring<br>List of drugs dispensed to the patients<br>List of expired drugs                                                               |
| Study materials                                | Informed consent form<br>Study protocol<br>Case report forms<br>Study brochure                                                                              |
| <i>For Study Coordinating Center</i>           |                                                                                                                                                             |
| Geographical distribution of enrolled patients | Frequency distribution by center<br>Frequency distribution by state<br>Frequency distribution by country                                                    |
| Geographical distribution of recruited centers | Frequency distribution by state<br>Frequency distribution by country                                                                                        |
| Epidemiological data of enrolled patients      | Frequency distribution by gender<br>Frequency distribution by age<br>Frequency distribution of the study drug within specific subgroups of patients         |
| Statistics on participating centers            | List of the centers' quality indicators                                                                                                                     |

[26]. Automatic and daily procedures can aggregate data that can be hosted on the study website for the study coordinating center staff's use and to plan new strategies to improve data quality, patient recruitment, and center performance. These include epidemiological patient data, geographical distribution of patients enrolled in the trial, and information about the quality of data provided by the participating centers.

A directory on the website of the investigators, committees, sponsors, and monitors with their email addresses, as well as a directory of participating centers and regional coordinators, can also help improve communications, mainly in multicenter large-scale clinical trials [22].

The clinical trial website may be used as a virtual community in which investigators are continuously updated with the latest news on their trial. For this reason a news section of the website can provide information on trial status, trial newsletters, notification of national and international investigator meetings, reports from study committee meetings, results of similar, concomitant trials, and answers to common questions regarding the application of the trial protocol.

**Dissemination of Study Information to Public** A study website can provide detailed information about the clinical trial presented in a way that the general public can understand. They may include a geographical distribution of the study participating center and a summary of the background, aim, and design of the ongoing trial. The entire protocol (apart from any confidential aspects) can also be made available. Even if some protocols are already included in the public registries of clinical trials such as the National Library of Medicine's ClinicalTrials.gov (<http://www.clinicaltrials.gov>), in a clinical trial website more detailed information is provided. This information is useful particularly for those clinical trials allowing online recruitment by patients themselves. In this case the website provides the patients with tools to screen their eligibility, collect their data for enrollment into the study, and download the informed consent form.

**Online Randomization** Randomization is the method of randomly dividing subjects into two or more groups. In the case of two groups, one is allocated to the trial (tested) treatment and the other one to the standard (current) treatment. It is necessary to ensure that any baseline differences between groups are due to chance alone and to prevent selection bias. Several methods for randomizing have been used over the years, including minimization, biased coin, stratification, permuted block, and random number generators on computers. Web-based randomization systems allow investigators to directly include patients in a trial 24 hours a day. They are particularly useful in multicenter clinical trials where a central coordinating center serving 24 hours a day as a randomization center may not be feasible. Web-based randomization systems utilize the client/server technology and may be used directly by the investigators through the browser [29, 30]: The client software running on the investigator's PC provides a friendly interface for data collection; the server software (installed on the server located at the randomization center) processes and archives data and selects treatment allocation. Data checking is performed by the server software or at the client site. A typical online randomization system follows the steps illustrated in Table 4 to randomize a patient [21]. In particular, the checking of data validity and consistency, and the checking of the eligibility criteria may

**TABLE 4 Steps for Typical Online/Web-based Randomization**

---

|                                                                                                                                                                                    |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Automatic identification of the investigator and/or the participating center                                                                                                       |
| Entry of the patient's recruitment data (e.g., patient's initials, gender, age, systolic blood pressure, and those data useful to check if a patient can be enrolled in the trial) |
| Automatic data checking and validation                                                                                                                                             |
| Automatic check that the trial's eligibility criteria are met                                                                                                                      |
| Running of the randomization algorithm                                                                                                                                             |
| Data incorporated in the central database                                                                                                                                          |
| Notification to the investigator of treatment allocation and patient identification code                                                                                           |

---

reduce the risk of protocol errors and of noneligible patient enrollment. Web-based randomization systems are usually integrated in the study website [25] and developed in-house by the coordinating center staff. As an alternative to this service there are several online randomization programs (some free of charge and some commercial) that can generate random allocations [31].

**Online Data Collection and Validation** A clinical trial website often includes a Web-based data entry system that allows investigators to enter clinical data online as soon as they are available. Remote data entry to a central database is particularly useful in multicenter clinical trials where participating centers can be geographically separated by great distances across cities and countries [25].

With respect to traditional paper-based clinical trials, data comes directly from the investigator who is responsible for entering them in the data entry system. In this way steps in data collection are reduced, paper source documents are eliminated, and the quality of collected data is improved thanks to a real-time data validation.

The investigator is requested to fill out several electronic forms (often in HTML format) that have a layout and contents that are not too different from those of the traditional paper-based case report. Client/server technology is often used to develop Web-based data entry systems. The architecture of typical Web-based data entry systems is illustrated in Figure 7. The client application runs on the investigator's computer with the application itself running on a central Web server. The browser interacts with the Web server to submit data collected through a Web page; the Web server sends data to the database server where they are saved. Similarly, if the investigator wants to access data saved in the database server, a request is submitted to it through the Web server, which formats the database query results into HTML and sends it back to the browser as a Web page.

One of the main advantages of remote data entry is the possibility to perform real-time data validation (also called "online edit checks") before they are saved into the database server. When an invalid (or incompatible) entry occurs, the investigator is alerted and invited to make the appropriate corrections. The real-time data validation includes the edit checks already illustrated in discussion on data cleaning and checking in Section 8.1.4: checks on missing data, checks on answers to closed questions (e.g., those with "yes" or "no" as possible answers), and checks on values that must be comprised within a specific range, within a list of (pre)codified answers, or within a medical standard dictionary. Real-time data validation could also be applied to several data fields in order to perform a cross check of data entry. For example, the investigator recording the date of a serious adverse event (e.g., a myo-

**FIGURE 7** Architecture of typical Web-based data entry system.

cardial infarction) and entering a date that comes before the start of the trial could be prompted immediately, allowing for immediate correction.

Real-time data validation is usually performed on the Web server through Java or Microsoft .NET, which allows for a strong interaction with each data field. In other cases, the data validation process is performed at the end of the data entry process ("offline edit checks") with an automatically generated summary of all the invalid entries that is emailed to the investigator or posted on the trial website for future reminder.

**Data Protection and Security Issues** Security is a key issue when developing a Web-based clinical trial [22, 32, 33]. This issue becomes crucial and requires more attention when a Web-based data entry system is used to allow remote entry in a centralized database of the patients' sensitive information. Patient's (and investigator's) data that are collected through an electronic form or sent by electronic mail must be protected against any kind of interception by unauthorized users. Similarly, patients' data (and the entire database server) need protection from unauthorized access (by Internet or intranet users) once they are stored on the central database in order to avoid a fraudulent use of them or an invalidation of the trial data and results.

To address the issue of secure Internet transmissions, encryption algorithms are usually used for the data exchanged by electronic mail or data that transit on the Web during a connection between a PC/client and a Web server. The data are coded so that only the user that has the decryption key can read and interpret them. The Pretty Good Privacy (usually available among the facilities provided by many electronic mail software) is one of the most used methods for electronic mail data encryption. On the other hand, a secure Web connection is usually provided by systems such as secure socket layer (SSL) and secure hypertext transfer protocol (S-HTTP). These tools are the same usually used to ensure secure transmissions for the applications of banking and trading online. The last versions of Web browsers support these protocols and so they can be used for a connection to a secure Web server (URLs of secure Web servers start with "https://" instead of "http://").

To protect the database server from unauthorized access, firewalls (a mix of hardware and software that is located between the Web server and the Internet and that protect the local area network where the server is hosted) and tools to check the IP address of the user's computer are used. A login and a password are also assigned to each user to enter the website for data entry and editing. Based on these data, a user's profile can be created and used to enable the user (investigator, monitor, staff of the coordinating center) to enter only the website's sections for which he or she is authorized. Sometimes, a more sophisticated user authentication is reached by using digital signatures.

In addition, the database server must be placed in a secure location and antivirus and updated antivirus software must be installed on each computer on the network. When data are particularly important, experts suggest implementing a backup system (with hardware and software components) that could replace the original one in case of failure.

#### 8.2.4 Examples of Clinical Trial Websites and Web-Based Clinical Trials

Several clinical trial web sites have been developed in the last few years. Some, such as the GISSI website (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Micocarico Acuto, <http://www.gissi.org>) [20], ALLHAT website (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial, <http://allhat.sph.uth.tmc.edu>) [34], and STAR website (Study of Tamoxifen and Raloxifene, <http://www.nsabp.pitt.edu/STAR/index.html>) [35] concern large-scale multicenter (and international) clinical trials and are used to disseminate information to the public related to ongoing or concluded clinical trials. Others, such as the Southwest Oncology Group's SELECT website (and Vitamine E Cancer Prevention Trial, <http://www.crab.org/select>) [26], provide online patient enrollment, randomization, and reminder notices to the participating centers.

Some have been designed to carry out all the aspects of a clinical trial in ophthalmology [36], orthopedics [30], obstetrics [37, 38], urology [39], and in other medical fields [40]. At present, the most important experience is the INVEST (International Verapamil/Trandolopril Study, <http://invest.biostat.ufl.edu>) study, a phase IV, international, randomized clinical trial conducted by the University of Florida on the efficacy of the calcium antagonist strategy versus the  $\beta$  blocker strategy for the treatment of hypertension in patients with coronary disease [25, 28, 41]. The trial is the first trial fully conducted online. Investigators from 869 sites located in 14 countries have used the clinical trial website to randomize 23,000 patients between 1997 and 2000, to remotely collect and enter patients' clinical data and adverse reactions, to handle the drug inventory at each site, and to disseminate reports and reminders to all the investigators, monitors, and member committees of the trial. Most of the tools described in this chapter have been used to protect the database server and to be compliant with the GCP, including a firewall, user IDs and passwords, data encryption, electronic signature, and the duplication of critical services to be used in case of system failure. The use of the remote data entry, the automatic data validation, and the automatically generated and delivered reports have reduced the time for the completion of trial and the total trial costs.

Most of these Web-based clinical trial systems are developed "in-house" using the current technology available on the market (database management systems,

HTML editors, Java, ASP, PHP, etc.). In order to reduce the amount of memory needed to store the data, some of them [33, 42] used the Entity-Attribute-Value (EAV) model [43, 44] to design the database. Others also allow an offline use (e.g., without an Internet connection); in this case a Web-based stand-alone application is installed on the investigator's personal computer, and a data synchronization engine permits the centralized and the local databases to be kept up-to-date during a daily Internet connection [42, 45].

Further, a number of clinical trials are usually carried out by pharmaceutical industries and CROs through the use of Web-based clinical trial systems. In these cases the Web version of commercial clinical trial information systems (such as Oracle Clinical and Clintrial) are usually used.

### 8.2.5 Advantages and Limitations of Web-Based Clinical Trials

Clinical trial websites may provide a powerful means to conduct clinical trials [46]. Investigators can download study materials, interact more frequently with researchers, and have their problems solved in real time. They can use automatic tools to schedule their work or to enter the clinical data directly. When remote data entry and real-time data validation are implemented, a clean database can be available in a short time for statistical analyses, with reduction of transcription errors and missing data, elimination of data entry costs and reduction of printing costs. For example, researchers of the INVEST study found an 80% reduction in monitoring costs and a 50% reduction in total trial cost [25]. Other cost reductions may be obtained with the implementation of automatic randomization systems and Web-based procedures for organizing drug distribution and accountability, which would allow investigators to order new drugs only when necessary and to destroy them when expired. However, the main advantages in using clinical trial websites are the availability of a friendly and homogeneous interface (the World Wide Web) and of standard software (TCP/IP, browser, electronic mail, Acrobat Reader), which do not require training time, and the ability to centralize study information and coordinate multiple trial processes in real time. Other advantages include security and backup of a whole trial at a single location, simplified data monitoring, and dissemination of study information and results to the public and the scientific community.

Some limitations must be outlined. First, clinical trial websites need the implementation of further security tools (with respect to paper-based or electronic, but not Web-based, clinical trials) in order to prevent unauthorized users from accessing the system and the patient data. This issue is perceived as a threat on data confidentiality by investigators, study centers, and patients and may inhibit them from participating in a Web-based clinical trial. In addition, setting up and maintaining a Web-based clinical trial system requires experienced computer professionals, and further hardware and software to duplicate the key functions in case of system failure. This is particularly important in case of the use of randomization and data entry systems and for the database backup and restoring procedures.

Another limit is the availability of Internet connections. At present, these are still a problem, especially in developing countries where communication facilities are rare. The problem exists also in developed countries, however, where direct connections from hospitals or medical centers are not always available where data are collected.

Other limits include the reluctance on the part of investigators to spend time entering information (in particular when alternative paper-based methods to provide the same data are available), lack of live support personnel (that may lead to the loss of some patients), and high setup cost. Furthermore, every step of the data entry process may be protracted in certain hours of the day due to peaks in Internet traffic. For this reason, many trial groups suggest that Internet connections should be provided by reliable Internet service providers that can assure easy and fast access to the Internet.

Finally, a potential selection bias in patient recruitment should be considered if Internet access is one of the criteria to recruit centers in a trial.

### 9.1.1 FOOD AND DRUG ADMINISTRATION: HISTORY AND STRUCTURE

The Food and Drug Administration (FDA) is the agency within the Department of Health and Human Services (HHS) that is responsible for protecting the health of Americans by enforcing the Federal Food, Drug, and Cosmetic Act and other related public health laws. FDA inspectors visit manufacturing facilities to ensure that products are made correctly and labeled truthfully. The FDA also protects consumers in several other ways. It investigates the biological effects of widely used chemicals, it tests medical devices, radiation-emitting products, and radioactive drugs, and it tests food for substances such as pesticide residues. It also monitors biologics such as blood and its products, insulin, and vaccines. In addition, components such as dyes and other additives used in cosmetics, drugs, and foods are all subject to FDA scrutiny.

The most important and critical role of the FDA, however, is in the development of new drugs and medical devices, such as pacemakers. New drugs and medical devices must receive FDA approval before they can be marketed. As the FDA states:

In deciding whether to approve new drugs, FDA does not itself do research, but rather examines the results of studies done by the sponsor (that is the entity manufacturing or importing the new drug). For a new drug to be approved for marketing by the FDA, the agency must determine that the new drug produces the benefits it's supposed to without causing side effects that would outweigh those benefits [1].

In this chapter, we explain the different steps a new drug goes through before it is marketed and the involvement of the FDA in each step. Special attention will be given to FDA regulation of clinical trials. In order to understand how the FDA has evolved into the regulatory body that exists today, we begin with a brief history of the FDA and an overview of the structure and organization of the agency.

#### 9.1.1.1 Brief History of FDA and U.S. Drug Regulation

In 1820, and for the three decades that followed, the *United States Pharmacopoeia* (USP) served as a reference for physicians and pharmacists who worked in the extraction or compounding of drugs and drug components that were available at the time. No other laws against food and drug adulteration were in place at that time. In 1848 Dr. M. J. Bailey testified in Congress that more than one half of the imported medicinal products were so much adulterated that they were not only ineffective but could be dangerous [2]. This led to the Drug Importation Act, which required inspection and destruction of drugs that did not meet acceptable standards [3]. The law seemed to be successful at first as very few bad products came into the United States in the year after its passage [2]. However, the law did not achieve its goal, mainly because political influences and bribery affected inspectors who were also not working with fixed standards [2].

In 1862, chemist Charles M. Wetherill was appointed to head the chemical division in the U. S. Department of Agriculture, a precursor to today's FDA, charged with maintaining a safe food supply. In 1901, the chemical division became the Bureau of Chemistry and was headed by Dr. Harvey W. Wiley who was a knowl-

edgeable physician on the issue of food and drug adulteration and was renowned for his “poison squad” experiments [2]. Dr. Wiley’s experiments showed that some of the most commonly used preservatives at the time, such as borax, were not safe for human consumption and might lead to permanent stomach and bowel impairments. It was Dr. Wiley’s and others efforts that led to the passage of the Food and Drugs Act by the Congress in 1906, and the Bureau of Chemistry was charged to enforce that law. Later, the Sherley amendment in 1911 prohibited the labeling of medications with false therapeutic claims. In 1927, Congress authorized the formation of the Food, Drug, and Insecticide Administration from the regulatory wing of the Bureau of Chemistry, and 3 years later the name was shortened to the Food and Drug Administration. In response to the deaths of over 100 people (mostly children) from the use of the untested compound diethylene glycol to solubilize sulfanilamide, the Food, Drug, and Cosmetic Act was passed in 1938. This new act required that new drugs be tested by their manufacturers for safety and the results be submitted to the government for marketing approval via the new drug application (NDA) [3]. Importantly, the new law authorized the FDA to conduct unannounced inspections of drug manufacturing facilities. In 1940 [4], the FDA left the Department of Agriculture for the Federal Security Agency, and in 1953 the FDA became part of the Department of Health, Education, and Welfare (HEW). In 1968 the FDA became part of the Public Health Service within HEW. When the education function was removed from HEW to create a separate department, HEW became the Department of Health and Human Services in 1980.

### 9.1.1.2 Structure and Organization of FDA

The FDA consists of eight centers:

1. *Office of the Commissioner (OC)* The office of the commissioner is formed of several components, such as the history office and the office of combination products, and is responsible for the implementation of the FDA’s mission.

2. *Office of Regulatory Affairs (ORA)* The office of regulatory affairs is the office responsible for all field activities of the FDA. It ensures the compliance with FDA’s standards by [5]:

1. Monitoring the clinical trials that are conducted before a product is submitted for approval by the FDA and conducting domestic and foreign inspections of drug manufacturing facilities by the consumer safety officers.
2. Analyzing product samples to determine their adherence to FDA standards.
3. Reaching out to consumer groups and health authorities to explain the FDA’s policies and encourage compliance with the agency standards by public affairs specialists. The public affairs specialists also respond to public health emergencies caused by natural disasters and product problems.

3. *Center for Biologics Evaluation and Research (CBER)* The CBER regulates biological products [6] such as blood and blood products, vaccines, and protein-based drugs such as monoclonal antibodies and cytokines. CBER also helps advancing and licensing of products to diagnose, treat, or prevent outbreaks from exposure to bioterrorist pathogens by helping the products to rapidly meet the regulatory

requirements. CBER also works on developing procedures and protocols to advance and make available promising experimental products when there is no approved medication for the treatment of victims of terrorism [6].

4. *Center for Devices and Radiological Health (CDRH)* The CDRH regulates [7] medical devices ranging from contact lenses and blood sugar monitors to implanted heart valves. It makes sure that new medical devices are safe and effective before they are marketed, and it monitors these devices throughout their life cycle using a nationwide postmarket surveillance system. CDRH also ensures that radiation-emitting products, such as microwave ovens, TV sets, cell phones, and laser products meet radiation safety standards.

5. *Center for Drug Evaluation and Research (CDER)* The CDER regulates [8] prescription and over-the-counter (OTC) drugs. Its mission is to ensure that all prescription and OTC drugs are safe and effective. To do this, CDER evaluates all new drugs before marketing; and after a drug is marketed CDER serves as a consumer watchdog to be sure these drugs continue to meet the standards. CDER also monitors TV, radio, and print drug ads to ensure they are truthful and balanced. As a measure to counter terrorism, CDER facilitates development of new drugs and new uses for already approved drugs that could be used as medical countermeasures.

6. *Center for Food Safety and Applied Nutrition (CFSAN)* The CFSAN regulates about 80% [9] of all food consumed in the United States. The remaining 20%, which includes meat, poultry, and some egg products, are regulated by the U.S. Department of Agriculture.

7. *Center for Veterinary Medicine (CVM)* The CVM [10] regulates the manufacture and distribution of food additives and veterinarian drugs or devices that will be used on animals including both pets and animals from which human foods are derived. CVM assures that animal drugs and medicated feeds are safe and effective. In approving veterinarian drugs (whether prescription or OTC) for food animals, CVM determines that no unsafe residues or metabolites will result when the drug is used in the approved manner, and that all safety factors are considered when setting the approved levels of use.

8. *National Center for Toxicological Research (NCTR)* The NCTR [11] conducts peer-reviewed scientific research focused toward understanding critical biological events that lead to toxicity and toward developing methods and incorporating new technologies to improve the assessment of human exposure, susceptibility, and risk.

### 9.1.2 NEW DRUG DEVELOPMENT AND FDA

New drug development is a multistage process that starts by identifying a drug target, usually an enzyme or a biological process whose function is crucial to treating a disease or ameliorate a medical condition. Many isolated or newly synthesized compounds are screened for activity at the target site using high throughput in vitro assays. If the interaction is strong enough to be of any medical significance, these compounds are then tested in vivo in model animals to evaluate their pharmacological activities and acute toxicity potentials. These initial testing steps are called the preclinical studies. The FDA does not monitor these preclinical studies directly,

assuming that good laboratory practices (GLP) [12] have been followed. The sponsor's primary goal in these studies is to determine if the new compound is reasonably safe for initial use in humans and if it exhibits pharmacological activity that justifies commercial development. If the compound proves to be a promising candidate for further development, the sponsor must collect sufficient data to establish that the new compound will not expose humans to unreasonable risks when used in early-stage clinical studies. The results of these preclinical studies, therefore, are important and they must be included in the investigational new drug (IND) application submitted to the FDA for review before clinical trials can begin.

#### 9.1.2.1 Preclinical Studies and IND

Direct FDA involvement in the new drug development process begins if data from the preclinical studies indicates that the new drug candidate is effective and reasonably safe to test in humans. In this case, the sponsor can submit an IND to formally notify the FDA of his or her intent to start clinical trials on human subjects. The IND falls in two categories and three types [13]. In this section we will cover the investigative IND, and in later sections we will cover the emergency use IND and the treatment IND. For more information on INDs, the reader is referred to the CDER web page titled Drug Applications ([www.fda.gov/Cder/regulatory/applications/ind\\_page\\_1.htm#Introduction](http://www.fda.gov/Cder/regulatory/applications/ind_page_1.htm#Introduction)).

An investigator IND may be submitted by a physician who both initiates and conducts an investigation and under whose immediate direction the investigational drug is administered or dispensed. A physician might submit a research IND to propose studying an unapproved drug, or an approved product for a new indication or in a new patient population. The IND application itself has several components but the information therein falls in three main areas:

1. Results of the preclinical animal pharmacological and toxicological studies together with any previous experience with the drug in humans. This information allows the FDA to decide if the compound is reasonably safe for initial testing in humans.
2. Information on the stability, composition, and manufacturing of the drug and the drug product. This information is provided to assure that the sponsor can supply consistent batches of the drug.
3. The proposed clinical studies protocols and the qualifications of the clinical investigators who will oversee the administration of the experimental compound to assess if people participating in the trial will be exposed to unreasonable risk and if the clinical investigators are qualified to fulfill their clinical trial duties.

Submitted with the IND also are commitments to obtain informed consents [14] from the research subjects and to obtain review of the study by an institutional review board (IRB) [15]. The informed consent document is given to the participants in a clinical trial and states clearly to the participants the purpose of the trial, how long they are expected to participate, what will happen in the study, and what the possible risks or discomforts are, possible benefits, other procedures or treat-

ments that might be available and advantageous to them, and that participation is voluntary and the participants can quit at any time should they so desire. An IRB is a committee composed of at least five medical and ethical experts designated by the institution where the clinical studies are to take place to review and approve clinical trials taking place within their jurisdiction to ensure that medical and scientific standards are maintained and to protect the rights of the human test subjects. The steps of the IND application process are summarized in Figure 1. After the submission of an IND, the FDA has 30 days to respond. During these 30 days, FDA experts review the IND and decide if the new drug is safe to be tested in human

\*While sponsor answers any deficiencies

**FIGURE 1** Steps an IND takes for review and approval. (Source: FDA.)

subjects. If the FDA approves the study and the IRB approves the proposed protocols, the clinical trials can begin.

### 9.1.2.2 Clinical Trials and New Drug Application (NDA)

In clinical trials, the effectiveness of the new drug in treating a disease or controlling a condition is compared to standard treatments or to no treatment at all (i.e., placebo). Side effects, toxicity, and metabolism are also studied. Because clinical trial participants represent only a small fraction of the target patient population and because drugs can work differently in different populations, it is important that the participants be representative of the wider general population by including people of various age groups, races, ethnic groups, and genders in the trials. Clinical trials usually are conducted in three main phases with a postmarketing phase. The three main phases of clinical trials differ in three main aspects: number and type of subjects required, purpose, and duration [16].

*Phase I* Phase I is the smallest of the three phases lasting up to 3 years and requiring 20–100 healthy volunteers. The main purpose of this phase is to determine dosing, how the drug is metabolized and excreted, and to identify the acute side effects.

*Phase II* Phase II trials are slightly larger than phase I, requiring 100–500 patients with the disease or medical condition that the new drug targets and may last from 2 to 4 years. The purpose of this phase is to collect information on the safety of the new drug and its efficacy. At the end of this phase, the drug sponsor meets with the FDA to discuss the results and how to proceed next. If the results indicate that the drug may be effective and the side effects are considered acceptable, the drug moves on to phase III.

*Phase III* Phase III is the largest of all phases requiring 1000–5000 patients and may take several years to finish. In this phase, the drug safety and effectiveness are further studied; and, if a standard treatment is available, the effectiveness of the new drug compared to that standard is also examined. When more and more participants are tested over longer periods of time, the less common side effects are more likely to be revealed. Phase III also establishes other aspects of the drug development process such as marketing claims, packaging, and storage conditions.

The role of the FDA in clinical trials is (1) to help protect the rights and welfare of the patients participating in the trial and (2) to verify the quality and the integrity of the data. To achieve these goals, the FDA's division of scientific investigation (DSI) conducts inspections of clinical investigators' study sites and reviews the records of the IRBs to make sure they are fulfilling their roles in patient protection. Also, the DSI seeks to determine whether the study was conducted according to the investigational plan, whether all adverse events were recorded, and whether the subjects met the inclusion/exclusion criteria outlined in the study protocol. At the conclusion of each inspection, FDA investigators prepare a report summarizing any deficiencies. In cases where they observe numerous or serious deviations, DSI classifies the inspection as "official action indicated" and sends a warning letter or

Notice of Initiation of Disqualification Proceedings and Opportunity to Explain (NIDPOE) to the clinical investigator specifying the found deviations [17]. The FDA usually has authority over clinical trials, and it can stop an ongoing trial or halt it if serious complications develop that puts the participants at high risk.

### 9.1.3 NDA AND BIOLOGICAL LICENSE APPLICATION (BLA)

After the conclusion of phase III of the clinical trials, the sponsor submits an NDA [18] to the FDA asking the agency to consider approving the new drug for marketing in the United States. The NDA contains all animal and human data and analyses of these data together with information on the chemistry, stability, and the proposed manufacturing of the new drug. After receiving an NDA, the FDA has 60 days to decide whether to file the NDA for review by the agency experts, or, if the NDA is incomplete, not to file it. The time the FDA spends in reviewing the NDA will be discussed in the timeline section of this chapter but outcome of the review process can be approved, approvable, or nonapprovable. “Approved” means the new drug product has met all the requirements and the sponsor can begin marketing the new drug. “Approvable” means the new drug product has some minor deficiencies that need to be addressed before approval. “Nonapprovable” means the FDA will not approve the new drug product the way it is submitted due to major deficiencies.

Biologics such as blood and its products, vaccines, antibodies, and the like are dealt with the same way. New biologics are subject to the same regulations and follow the same clinical testing as new drugs. The only difference is that to apply for marketing new biologics, sponsors need to submit a BLA not an NDA. BLAs are submitted to and reviewed by the CBER.

For many drugs approved for marketing, the FDA requires the sponsor to continue submission of clinical data to further validate their safety or effectiveness. In some cases, more studies are needed to find out more about a drug’s long-term risks, benefits, and optimal use or to test the drug in different populations of people such as children. These are the reasons behind postmarket surveillance.

### 9.1.4 TIMELINE

There is no doubt that drug development is a complicated, costly, and time-consuming process. The various steps a new drug endures from its synthesis to the time it makes it to the market as a drug vary in length from an average of 2 years in the research and development phase to an average of 7 years in clinical trials, as seen in Figure 2. It is hard to estimate how long before a newly synthesized chemical compound will make its way to the market as a drug product because each new drug has a different story and a unique path. Most potential drug candidates do not even make it to the clinical trials and are abandoned in the preclinical stage. In the research and development stage, a large number of chemical compounds are screened by researchers to identify only a few promising candidates called leads. Lead identification is the most time-consuming step in the drug discovery process because once leads are identified, structural modification can optimize

**FIGURE 2** Drug discovery, development and review process. (From Ref. 19.)

their activities or properties as drug candidates. Advances in high-throughput screening technology and computational drug design methods help accelerate this stage a little but, depending on the circumstances, this stage can take up to 5 years.

Once leads have been identified and optimized, toxicity and animal studies can begin. These are less time consuming than the previous step and may take up to 3 years. After the preclinical studies are completed, the new drug sponsor needs to submit an IND and get the FDA approval to begin the clinical studies. As stated above, the FDA has a period of 30 days to decide whether to hold the clinical trials or to give the green light. Clinical trials are the most time-consuming step in the process of new drug development and are the most critical step as well, especially phase II and phase III. Because of the diverse areas investigated and the comprehensive nature of these two phases, they take a long time to finish, sometimes up to 10 years. As the clinical trials evolve and more data become available, changes in the clinical protocols may become necessary. Since each change has to be approved by the IRB, the period of time the drug remains in clinical trials is further extended. All preclinical and clinical data must be included in the NDA submitted to the FDA for approval upon completion of the clinical trials. If the NDA is filed and in accordance with the Prescription Drug User Fee Act (PDUFA; [www.fda.gov/cder/pdufa/default.htm](http://www.fda.gov/cder/pdufa/default.htm)) the CDER should complete its initial review and act on at least 90% of all NDAs for standard drugs (those for which there are no perceived significant therapeutic benefits beyond those for available drugs) no later than 10 months after the applications are received and no later than 6 months for priority drugs (those that the FDA expects to provide significant therapeutic benefits beyond drugs already marketed) [19]. A 2002 general accounting office (GAO) report on the effect of user fees on FDA review times [20] has indicated that the median approval time for new drugs has dropped since the implementation of PDUFA in 1992. As shown in Figure 3, from 1993 to 2001, the median approval time for standard new drug applications has dropped from about 27 months to about 14 months and from about 21 months to about 6 months for priority new drugs. The reason for this drop in FDA approval times was attributed to the new resources that allowed the agency to recruit more reviewers and to upgrade its resources in information technology shortening the approval times significantly. Figure 2 summarizes the timeline and the different stages of the drug development process.

Source: FDA.

**FIGURE 3** Median approval times for standard and priority drug applications based on calendar year of approval, 1993–2001. (From Ref. 19.)

### 9.1.5 COST AND PROBABILITY OF SUCCESS

Much work has gone into determining how much the drug development process may cost from start to finish. Industry estimates on total research and development costs suggest an inflation-adjusted increase from almost \$16 billion annually in 1993 to almost \$40 billion in 2004. Out-of-pocket expenses for development of a single drug are estimated at \$403 million, with capitalized expenses nearing \$800 million (2000 dollars) [21]. Time and capital requirements grow at each clinical phase. Phase I studies have been estimated to cost \$30 million and take two to three years; Phase II studies may cost \$40 million and 2–4 years; phase III studies may cost \$86 million [21, 22]. Although size, duration, and design of the study may greatly vary, one estimate suggests that phase II clinical trials can cost anywhere from \$2000 to \$10,000 per subject [22]. Consumer advocates have questioned whether self-disclosure of drug development costs by industry may present an accurate picture of true costs, as a conflict of interest may be present [23]. Nonetheless, cost analysis of taking a drug to market is a ubiquitous part of the sponsor's decision-making process. Careful study design is essential in clinical studies to maximize data output while minimizing financial and health risks to the participants.

In addition to costs of drug development, a sponsor will also incur user fees when applying for FDA approval. The Prescription Drug User Fee Act (PDUFA) was instituted to provide resources for the FDA to review applications more quickly. Other legislation establishing user fees for medical devices and animal drugs has followed. The user fee encompasses an application fee for each drug, an establishment fee to cover the site(s) of drug production, and a product fee for each drug product in the application. Table 1 provides recent figures for user fees established by the PDUFA.

**TABLE 1 User Fees for Prescription Drug Applications in Selected Fiscal Years**

|                                                                    | 2006      | 2007      | 2008        |
|--------------------------------------------------------------------|-----------|-----------|-------------|
| Applications                                                       |           |           |             |
| Requiring clinical data                                            | \$767,411 | \$896,200 | \$1,178,000 |
| Not requiring clinical data or supplements requiring clinical data | 383,700   | 448,100   | 589,000     |
| Establishments                                                     | 264,000   | 313,100   | 392,700     |
| Products                                                           | 42,130    | 49,750    | 65,030      |

*Note:* Values have not been adjusted for inflation or capitalized in any way.

Determining whether or not a drug is likely to be approved is a challenging task. As noted in Figure 2, it is estimated that only one in five drugs that begins clinical trials is approved for market. At the NDA stage, the odds are much better. Of the NDAs submitted from 1993 to 2004, most (76%) were approved by the FDA, lesser amounts ongoing (17%) or withdrawn (7%) [19]. At each phase of clinical trials, good communication between the sponsor and the FDA team is vital. The FDA can suggest specific study designs to optimize the collection of useful and required data for its drug review. Ultimately, though, the drug or product must demonstrate an excellent safety and efficacy profile in order to ensure approval. The chance that a particular drug is approved for market depends on its performance in clinical trials.

### 9.1.6 FDA MEETINGS WITH DRUG SPONSORS

The FDA has a guidance document on the subject, Formal Meetings with Sponsors and Applicants for PDUFA Products, available at its website ([www.fda.gov/cder/guidance/2125fnl.htm](http://www.fda.gov/cder/guidance/2125fnl.htm)). Briefly, it describes the types of meetings, how and when to request a meeting, when to submit information and what information to submit prior to a meeting, procedures to conduct the meeting, and documentation of the meeting's focus and outcomes. Meetings can and should be scheduled throughout the process of investigating a drug or product, but the most critical meetings are the pre-IND meetings, end of phase II meetings, pre-NDA/BLA meetings, and the labeling meetings. At each of these checkpoints, the sponsor presents its clear scientific evidence of continuing (or discontinuing) the process, while the FDA provides feedback on the sponsor's plan and suggests improvements for a successful application.

The primary goal of the pre-IND meeting is "to introduce the drug to the FDA" [24]. If the sponsor is a small company or is not well known to the FDA, a second goal of this meeting is to present evidence that the company is qualified to perform the studies. The sponsor should present all scientific information about the drug, including any potential side effects identified in the nonclinical studies. The FDA team involved at this meeting will work with the sponsor to assess and reduce risk for the phase I study population. The best outcome from this meeting is that the FDA agrees with the sponsor that an IND can be submitted (which does not guarantee its approval).

A meeting at the end of phase II is almost universally advised. This meeting should be scheduled as soon as (1) phase II clinical data have established an effective dose and revealed pharmacokinetic and pharmacodynamic profiles that support

advancement to phase III and (2) the study design for phase III trials is complete. The phase III study design will be scrutinized thoroughly by the FDA prior to and at the meeting.

The pre-NDA/BLA meeting is recommended as a time to identify any potential pitfalls that might hinder the review of the submission. Depending on the type of drug involved, the FDA may use this meeting to discern the number and type of outside reviewers that may need to join an advisory committee. At this meeting, the FDA routinely confirms that the sponsor understands the NDA submission process and its timeline.

The labeling meeting is viewed as the last step in drug/product development prior to its approval. Although this step may seem small, the prescribing information included in product labeling can make the difference between a drug with minimal impact or one with a maximal impact on the market. A company with so much time, money, and effort in the drug development would certainly be heavily invested in securing a label that will allow the greatest impact on the market that the clinical data allow. Several rounds of negotiation on the final wording can occur. Once that hurdle is reached, the new product can be released onto the market.

The FDA can classify any meetings as type A, B, or C to prioritize the scheduling of the meeting. While sponsors can request a specific designation, the FDA is the authority on the matter. Type A meetings are the most urgent, requiring scheduling within 30 days of receiving the designation. Priority among type A meetings is given to those involving issues with a submitted NDA/BLA. Type B meetings must occur within 60 days of classification and type C within 75 days. The deadline for submission of supporting evidence is specific to the meeting type. Support documents are expected to be received by the FDA 2 weeks in advance of scheduled type A and C meetings. For type B meetings, documentation must be received 1 month in advance. It is vital for sponsors to be prepared to meet these deadlines when requesting a meeting with the FDA. For more information and advice on preparing for meetings with the FDA, see Grignolo's chapter titled "Meetings with the FDA" in *FDA Regulatory Affairs* [24].

### 9.1.7 REGULATION OF DRUGS AND BIOLOGICAL PRODUCTS BY FDA

The FDA is involved in regulation of drugs and biological products as they come to market and as they remain on the market. In addition to the regular INDs and NDAs mentioned earlier, the FDA regulates processes for approving generic drugs, over-the-counter (OTC) drugs, and follow-on drugs (modified chemical entities of approved first-in-class drugs). The FDA also has special rules and/or exemptions for expanded access and accelerated approval, orphan and pediatric drugs, and drugs for antiterrorism.

Generic drugs have the same active ingredient as an already approved, brand name drug (sometimes called the innovator drug). Applications for new generic drugs are examined in the FDA by CDER's Office of Generic Drugs. In order to be approved, generic drugs must be shown to be scientifically bioequivalent to the innovator drug. That is, the generic drug must have the same physical, pharmacokinetic, and toxicokinetic profiles as its brand-name counterpart, and it must produce the same pharmacologic effect for the same intended use. The differences between

a generic and a prescription drug are produced solely by changes in inert ingredients and/or changes in pill shape. Generic drugs are approved through an abbreviated new drug application (ANDA). The NDA is abbreviated because some or most of the clinical trials do not need to be repeated. If the drug or drug product is deemed to be bioequivalent to the innovator, that is, having the same bioavailability and pharmacokinetic profile, the same target effect, and the like, then it can be reasonably assumed to be as safe as the innovator drug.

There are a number of resources available to guide companies considering entry into the generic drug market. The FDA Office of Generic Drugs has a comprehensive website ([www.fda.gov/cder/ogd/](http://www.fda.gov/cder/ogd/)) dedicated to supporting new and worthy applications to approval for market. The FDA, together with industry feedback, has produced several guidance documents for preparation of NDAs and ANDAs. These guidance documents are neither law nor FDA rule, but rather advice from both sides of the application process on what to expect and how to present a well-prepared application. These guidance documents are fluid; they have been reviewed and updated as changes in the process or industry have warranted. A searchable database of guidance documents is available on the FDA website ([www.fda.gov/opacom/morechoices/industry/guidedc.htm](http://www.fda.gov/opacom/morechoices/industry/guidedc.htm)).

The guidance document on bioavailability and bioequivalence studies for oral drugs provides an excellent overview of the studies needed for ANDAs ([www.fda.gov/cder/guidance/3615fnl.htm](http://www.fda.gov/cder/guidance/3615fnl.htm)). It includes a general pharmacokinetic study design and data analysis. Potential generic drug producers can use the pharmacokinetic profile determined in clinical trials of the innovator drug as a benchmark for subsequent bioequivalence studies. The guidance provides several details on the types of studies to be completed, including pharmacokinetic, pharmacodynamic, and in vitro dissolution studies. Distinctions are made between immediate and modified release dosage forms.

The FDA also has a mechanism by which confidential, supporting information can be considered alongside the IND, NDA, ANDA, or export application. Detailed information involving many aspects from production facilities and processes to packaging materials can supplement an existing application under consideration using a confidential document known as the Drug Master File (DMF). The DMF is not required for submission of an IND, NDA, or ANDA, nor does the DMF replace these applications. The DMF may be particularly helpful in cases of patent-pending manufacturing processes, including some that may fall under Section 505(b)(2).

Section 505(b)(2) applications are used when some of the information within the application was not generated by or for the sponsor if the sponsor has no right of reference to the information. This application differs from an NDA in that the Section 505(b)(2) can be delayed to accommodate those with patent rights and/or exclusivity protections of a particular product. For example, an application to combine two previously approved drugs into a combination drug may necessitate the use of the 505(b)(2) application if the idea of that particular combination occurred outside the company. These types of applications have also been used when changes to existing drugs occur, such as a change from a prescription indication to an OTC indication or a change in the drug formulation. Further information on the subject is available in a guidance document titled Applications Covered by Section 505(b)(2) ([www.fda.gov/cder/guidance/2853dft.htm](http://www.fda.gov/cder/guidance/2853dft.htm)).

### 9.1.8 EXPANDED ACCESS AND ACCELERATED APPROVAL

The FDA has been making great strides in expanding the access to experimental therapies intended to treat life-threatening diseases and in accelerating the approval process of these promising treatments. The expanded access mechanisms allow severely ill patients with no response to approved therapies to have access to promising treatment drugs or devices. Expanded access can be granted through treatment IND protocols, parallel track protocols, or ordinary open-label studies that are a part of some normal NDAs. Generally, expanded access is only granted after the proposed drug or product has completed much of the clinical trial phase, when safety is established and efficacy is probable. To be approved for expanded access, four conditions must be met: (1) the drug or product must be intended to treat a serious or life-threatening disease, (2) no satisfactory alternative is available to treat that disease stage in that patient population, (3) the drug must either have an established IND protocol or all clinical trials must be completed, and (4) the sponsor must be pursuing marketing approval of the drug or product. Conversely, the parallel track mechanism allows patients with HIV/AIDS who have exhausted all other treatment options access to drugs in IND trials when the patients are not eligible to complete the trials. This mechanism is specific to HIV/AIDS-related products, and it has the potential to provide access earlier in the process than the treatment IND protocol.

In addition to expanded access mechanisms, the FDA supports new drug development in serious and life-threatening diseases through accelerated approval. A sponsor can apply for designation under the fast track drug development program. The drug or device must treat a serious aspect of a serious or life-threatening illness and address an unmet medical need.

Access to unapproved drugs may also be granted by filing a special exemption (also called compassionate exemption) or an emergency IND. Patients who are ineligible for a clinical trial may still be allowed access to the drug by filing as a special exemption. This requires investigator and sponsor approval, FDA consent, and an approved modification to the local IRB. With the permission of the drug supplier, a health care provider can alternatively file an emergency IND directly with the FDA to gain access to the drug or product. The health care provider must notify the IRB of his or her intent to use the drug; in a life-threatening situation in which specific criteria are met, according to 21 CFR 56.102(d), the drug may be administered prior to IRB approval.

### 9.1.9 ORPHAN DRUGS

The Office of Orphan Products Development is the subunit of the FDA that oversees, and sometimes funds, the clinical trials of orphan drugs. Enacted in 1983 and since revised, the Orphan Drug Act has provided tax and marketing incentives to entrepreneurs who want to study drug treatments or devices that are projected to be relevant only to small markets. These drugs and devices are considered “therapeutic orphans” if the intended target population is fewer than 200,000 individuals in the United States or in the case of preventative or diagnostic drugs, fewer than 200,000 individuals in the United States per year. When a drug or biologic receives

recognition as an orphan drug, this special status allows not only tax relief for costs related to development but also a waiver of the prescription drug user fee and a 7-year exclusivity of the drug on the market, allowing pharmaceutical companies time to recoup their expenses. Some consumer advocates propose that the exclusive license provides too great a benefit to the drug manufacturer and prevents drug access by prohibitively high end-user cost [25].

A sponsor can ask for designation as an orphan drug during or after the clinical trials. The sponsor submits documentation supporting the designation that the target disease is rare and that the drug will treat the disease. If orphan drug status is established, the investigators become eligible to compete for a research grant to defray the costs of a clinical trial. At the time of writing, the grant only provides funds for clinical trials of orphan drugs. This will facilitate approval of an unapproved drug or an unapproved use of a drug already on the market to treat a rare disease.

### 9.1.10 PEDIATRIC DRUGS

Pediatric patient populations experience growth and development that can interfere with drug absorption, distribution, metabolism, and excretion and can require special care in determining safe and effective dosing. The sponsor of a new drug or product intended to treat a disease or condition relevant to the pediatric population may request orphan drug designation, provided the drug is expected to treat 200,000 or less within this population within a given year. In addition to this designation, studies on pediatric populations for more common indications are regulated and required by the Pediatric Research Equity Act (PREA). PREA requires that all new NDAs and new BLAs for new chemical entities or new indication, dosage form, dosage strength, or route of administration contain an assessment of pediatric effectiveness unless a waiver or deferral is obtained. The FDA has posted a draft guidance document ([www.fda.gov/cder/guidance/6215dft.pdf](http://www.fda.gov/cder/guidance/6215dft.pdf)).

### 9.1.11 OTC DRUG PRODUCTS

Over-the-counter drug products comprise a special class of chemicals intended to treat a health condition that consumers may self-diagnose and self-medicate. In order to approve a drug for OTC use, the FDA must find that it is both safe and effective for the marketed use. OTC drugs are characterized by low health risk and high health benefit, low abuse and misuse potential, and adequate labeling for proper use.

OTC drugs can be marketed under two mechanisms: the NDA and the OTC drug monograph. The NDA process has been described above in detail. A change in existing OTC drug dosage form, dosage strength, or route of administration or the first time an OTC chemical entity comes to market requires new approval through the NDA. A drug previously available only by prescription must undergo NDA approval prior to introduction as an OTC drug, although sometimes this can fall under the guidelines of Section 505(b)(2). The sponsor of a prescription-to-OTC application must show that the drug is safe and effective for customer use without

the aid of a health care professional. Alternatively, an OTC drug can be marketed under an existing OTC drug monograph. The monograph regulates the active ingredients within an OTC product. Changes in inactive ingredients may not require further approval prior to marketing, provided that the active ingredient in the new product meets the standards of the monograph.

### **9.1.12 BEHIND-THE-COUNTER DRUGS**

At the time of writing, the FDA is considering a third class of drugs to join prescription and nonprescription drugs: the behind-the-counter drugs. This class would be available without a prescription but would require discussion with a pharmacist. It is unknown at this time how a new class of drugs might alter the drug approval process.

### **9.1.13 DRUGS FOR COUNTERTERRORISM**

In 2002, a measure was put into place to allow fast time-to-market for drugs or products intended to counteract the damaging effects of biological, chemical, radiological, and nuclear agents. The rule is officially titled Approval of Biological Products/New Drugs When Human Efficacy Studies Are Not Ethical or Feasible, but it is commonly called the animal rule. Because testing an antidote to these toxic substances in humans is unethical and unfeasible, the FDA must rely on well-characterized efficacy studies in animals and safety studies in humans and animals to determine whether to approve new drugs or products. Such determinations can only occur when the offending agent's mechanism of toxicity is understood, when the animal endpoints relate directly to human benefits, when the drug product's effect is determined in a species comparable to humans, and when the selection of an effective human dose is possible from the data. To date, two products have been approved by this animal rule: pyridostigmine bromide to combat nerve gas and hydroxycobalamin to treat cyanide poisoning.

### **9.1.14 GLOBALIZATION AND HARMONIZATION: FDA AND ICH**

The International Conference on Harmonisation (ICH) brings together drug regulatory bodies throughout the world to formulate international standards and to streamline national and international policies for establishing safety and efficacy of new and existing drugs through nonclinical studies and clinical trials. The FDA has a large number of guidance documents relating to harmonization; so many in fact that it has further subdivided each ICH topic into categories involving safety, efficacy, joint safety/efficacy, and quality. The common technical document (CTD) that the FDA uses as a format for all its electronic NDA, ANDA, BLA, and IND submissions was designed by the ICH. The FDA encourages sponsors to use the electronic CTD in hopes that it will increase the efficiency of global marketing approval ([www.fda.gov/cder/guidance/7087rev.pdf](http://www.fda.gov/cder/guidance/7087rev.pdf)). In addition to globalization of the drug approval process, the ICH with the FDA and other agencies is examining implications of drug

interactions, including the use of drugs developed outside one's country together with cultural remedies [26].

### **9.2.1 OVERVIEW**

Phase I trials [also referred to as FIH (first in human) or FIM (first in man)] are the earliest stage clinical trials of a new drug or device typically performed with just a few persons to determine the safety and pharmacokinetics of a new drug or biocompatibility of a new invasive medical device; for drugs, dosage or toxicity limits should be obtained. These rigorously controlled tests of a new drug or a new invasive medical device involve human subjects for such evaluation. In the United States, such trials are conducted with the concurrence of the Food and Drug Administration (FDA) or equivalent regulatory authority before proceeding to further clinical investigation. While it is generally the ideal to perform no more than two (a single-dose escalating and a multiple-dose escalating) or three (for oral drugs, a feed/fasted

is also usual) phase I studies before proceeding to phase II, it is not uncommon to perform as many as eight (formulation changes, etc.).

Phase I trials are conducted following prescribed preclinical work that establishes the new molecular entity (NME) to be safe and tolerable in animal and in vitro models. The animal models chosen for such evaluation should reflect the expected response in humans as closely as possible. After preclinical work has been successfully conducted, a complete and thorough copy of all preclinical data must be submitted to the FDA in the format of an investigational new drug (IND). Subsequent to the FDA's evaluation of the data, an initial phase I trial may then commence if the sponsor has not received a response from the FDA within 30 days of the IND submission. Similar pretrial review procedures exist for other countries and for medical devices. In the United States and the European Union (EU), review and approval by an institutional review board (IRB) or ethics committee (EC) prior to trial initiation is also required.

The primary objectives phase I trials seek to accomplish are to assess safety, tolerability, pharmacokinetics, and to determine the MTD (maximum tolerated dose). They typically are small trials ranging from 20 to 80 subjects and are relatively short, only lasting 6 months or less from initiation to trial completion. In general, phase I trials are performed in normal healthy volunteers (though the guinea pig zero effects may be operative [1]). However, in special cases such as drugs for life-threatening diseases such as cancer, AIDS (acquired immunodeficiency syndrome), amyotrophic lateral sclerosis (ALS), or where the drug is a combination of two already approved drugs, patients may constitute the initial trial population.

The importance of FIM trials is crucial to the progression of the new drug molecule. Identifying a safe dose and dosing regimen is vital, and in doing so the utmost precaution and care must be taken during this stage through strict monitoring.

### 9.2.2 PURPOSE AND OBJECTIVES

As stated above, the main objectives of phase I trials are to assess tolerability, monitoring the side effects in relation to increase of the doses, and confirm the maximum tolerated dose. Additionally, establishing a safety profile is paramount. These are three of the commanding goals, providing a firm basis for investigators to determine further testing and study design strategies. It is almost certainly the most critical "go/no-go" decisive point.

Other important aims are to obtain adequate information of the drug's basic pharmacokinetics (PK) such as absorption, distribution, metabolism, and excretion (ADME). Pharmacokinetics refers to the behavior of the drug in the body. Absorption is the process of a substance entering the body. Distribution is the dispersion or dissemination of substances throughout the fluids and tissues of the body. Metabolism is the transformation of the substances and its daughter metabolites. Excretion is the elimination of the substances from the body. This data gives rise to analyzing the pharmacological effects of the drug in the human body and developing a sufficient PK model to simulate exposure and response for intended dosing regimens, incorporating variability [2]. A good dose–response curve derived from PK analysis is greatly desired. Additionally, information is sought out to determine the drug's

bioavailability. Bioavailability is defined as the ability to deliver the drug in a usable form to the disease target. Phase I studies are also intended to determine whether the drug is best delivered orally, or by injection, or through the skin and by what regimen.

Furthermore, FIM trials study the drug's structure–activity relationship (SAR) with previously evaluated compounds and mechanism of action (MOA), which provide the basis to investigate biological phenomena or disease processes. However, data regarding efficacy [pharmacodynamics (PD)], though a highly desired aspect of the drug, is rarely gathered during phase I. Some studies will often shed enough early light on possible efficacy to support the decision on further continuance of the study.

### 9.2.3 PHASE I TRIAL DESIGN

More recently, it has become the common practice to divide phase I trials into two phases or separate stages, phase Ia and phase Ib. Phase Ia studies include the first dose in humans and are typically short-term single-dose studies to confirm safety before beginning a larger, more extensive trial. The studies on average are usually comprised of six cohorts, with about seven subjects per cohort. The main design usually entails escalating the dose with each new cohort while stringently monitoring for safety, with a final objective of establishing the MTD and a solid PK profile. Oftentimes a placebo is included to provide a more accredited safety evaluation.

Phase Ib studies are typically more comprehensive repeat-dose studies with the same goals being safety, tolerability, and PK on a repeat-dose level in order to assess the drug's therapeutic effect. Other frequent questions addressed in phase Ib studies include food effects and gender differences.

Phase I trials are also different from subsequent trials in that not only are they not conducted at a sponsor's facility (no clinical trials are), but they are almost always conducted by and at contract research organizations (CROs) that have this as their business.

### 9.2.4 DESIGN TYPES

When planning a clinical trial, the design and determination of the dose range depends on the MTD established in preclinical studies. The most common trial design is dose escalation/ascending. This study involves the gradual increase of drug dosages to determine the amount that delivers the best balance of high efficacy and acceptable side effects. It is basically viewed as a building block design. The primary objective is to determine MTD. The MTD is defined as the highest dose that is tolerated with no adverse side effects observed. If the dose is not tolerated, then the dose just below is the MTD. Typically, one may dose the subject, look for adverse events, and if none are present, increase dose and repeat. One may have a fixed dose increment or an even more risky approach is to bounce around until the MTD is established. One preferred way to determine AEs (adverse events) is by comparison to a placebo group. Conducting thorough dose-ranging and dose–response studies early in product development reduces the possibility of later failed phase II or III

studies. Of drugs tested in phase I, 50–70% are abandoned because of problems with safety or efficacy [3]. At the end of each phase of dosing, typically a data safety monitoring board (DSMB) meeting is held to decide if the drug is safe enough to continue, and if yes, typically one will want to recruit more patients. When analyzing a dose-escalating study the following should be included:

- Comparison between treatment groups (sometimes several doses polled).
- Comparison of active groups versus placebo.
- Comparison of before and after dosing (temporal factors).
- Evaluate AE incidence and complete a summarization.

In some instances, mainly for bioequivalence studies, a crossover design is used. The ICH E9 [4] guideline defines the crossover design as a study in which each subject is randomized to a sequence of two or more treatments and hence acts as his own control for treatment comparisons. This simple maneuver is attractive primarily because it reduces the number of subjects and usually the number of assessments needed to achieve a specific power, sometimes to a marked extent. In the simplest  $2 \times 2$  crossover design, each subject receives each of two treatments in randomized order in two successive treatment periods; often separated by a washout period. It is the type of experiment where experimental units are given several treatments in succession. The order of treatments ought to be set by some random procedure and each subject receives both treatments. In this type of trial design comparisons within subjects are performed.

Advantages of a crossover study are that it is useful for reversible effects (e.g., bioequivalence), fewer subjects are needed, and more precise comparisons are obtained.

If applicable, one can have more than two treatments in which an extended crossover design may be applied (which the FDA has been leaning more toward since 2000). An extended crossover design includes two treatments with four periods.

Crossover designs are not flawless, however, and contain a number of problems that can invalidate the concluding results. The chief difficulty concerns carryover, that is, the residual influence of treatments in subsequent treatment periods; therefore a washout period of at least 6 half-lives is desired. The main cause of carryover is that the treatment effects lingering in PK studies, because the washout is too short thus leading to overlap of dose effects.

When analyzing a crossover study the following should be taken into consideration:

$Y = \text{period} + \text{sequence} + \text{treatment} + \text{subject (sequence)} + \text{carryover} + \text{error}.$

Subject is usually considered a random effect.

In a  $2 \times 2$  crossover, sequence is confounded with carryover—if there is a significant carryover, use the first period only.

Comparisons are intrasubject (treatment comparisons).

When analyzing a bioequivalence (BE) crossover study the following should be taken into consideration:

BE is typically testing utilizing the crossover design.

Response is area under the curve (AUC) and the peak concentration of the drug ( $C_{\max}$ ).

Key endpoint is the ratio of treatment A AUC over treatment B AUC.

A and B are equivalent if 90% confidence interval for ratio lies entirely between (0.8, 1.25) 80% and 125%.

Perform analysis on log AUC and log  $C_{\max}$ .

## 9.2.5 PHASE I TRIAL CHARACTERISTICS

The initial (true FIM) administration of a new drug must be undertaken with some circumspection. Nonclinical (animal) safety studies give good predictions of clinical safety and expected toxicity almost all of the time, with application of current scaling factors for species difference providing confidence that initial doses will present minimal risk. Still, in normal volunteers there are exceptions—particularly highly humanized proteins for which animals lack the mechanisms for response, and therefore provide no assurance of safety (as with the TGN1412 drug trial).

A similar situation occurs when phase I trials are performed in patients (or, indeed, with the first trial in patients if earlier trials were done in normal volunteers). In the latter (patient) treatment case, one should carefully consider which organ, metabolic, or protective systems may already be compromised—and therefore for which one must be very attentive to even weak indication of adverse effect [as with the FIAU (fialuridine) clinical trial].

In either of these cases, or indeed in almost any true FIM dosing, it is generally wise to offset the dosing of the initial cohort—that is, separate dosing of individual cohort members by an appropriate period of time.

Both types of these designs share many similar characteristics indicative of phase I trials. Both serve to provide the information to accurately evaluate safety, tolerability, MTD, and PK. Additionally, they are relatively short and small trials, comprised of about 20–80 subjects usually healthy volunteers, with the exceptions for trials dealing with life-threatening diseases such as HIV/AIDS, cancer, ALS, and the like. The FDA explicitly draws the distinction between a healthy volunteer and a subject or patient. A healthy volunteer is defined as a healthy person who agrees to participate in a clinical trial for reasons other than medical and receives no direct health benefit from participating. Whereas a human subject is defined as an individual who is or becomes a participant in research, either as a recipient of the test article or as a control. A subject may be either a healthy human or a patient (21 CFR 50.3).

Whether it be a healthy volunteer or a patient, they must satisfy the subject/patient criteria outlined in the sponsor's protocol and must provide informed consent. Since phase I trials incorporate dosing a person with an investigational new drug, extremely close monitoring for safety and determination of a tolerated dose is crucial.

A placebo is almost always included as a standard component in phase I trials as well. The main advantage of using a placebo is to serve as a control and decrease bias in an attempt to make some sort of quantitative assessment of the drug's efficacy. A disadvantage to using a placebo is mainly seen in trials for life-threatening illnesses, and in some such cases a placebo is not required. A common approach is

to include a single placebo subject in each cohort. By the end of an ascending dose trial, enough placebo subjects have been accumulated to allow for an estimation of placebo (and nocebo) effects.

The issue of blinding in clinical trials is imperative for the prevention of bias and integrity of the data. The ICH E9 [4] definition of blinding is as follows:

Blinding or masking is intended to limit the occurrence of conscious and unconscious bias in the conduct and interpretation of a clinical trial arising from the influence that the knowledge of treatment may have on the recruitment and allocation of subjects, their subsequent care, the attitudes of subjects to the treatments, the assessment of endpoints, the handling of withdrawals, the exclusion of data from analysis, and so on. The essential aim is to prevent identification of the treatments until all such opportunities for bias have passed.

Phase I trials are usually double blind. ICH E9 [4] definition of double blind:

A double-blind trial is one in which neither the subject nor any of the investigator or sponsor staff involved in the treatment or clinical evaluation of the subjects are aware of the treatment received. This includes anyone determining subject eligibility, evaluating endpoints, or assessing compliance with the protocol. This level of blinding is maintained throughout the conduct of the trial, and only when the data are cleaned to an acceptable level of quality will appropriate personnel be unblinded.

## 9.2.6 CRITICAL PARAMETERS TO MEASURE

### Safety

#### A. Clinical Examinations

1. Physical
2. Vital signs (usually considered as part of the physical examination)
3. Height and weight (state of dress is usually specified, e.g., socks)
4. Neurological or other specialized clinical examinations

#### B. Clinical Laboratory Examinations

1. Hematology
2. Clinical chemistry
3. Urinalysis
4. Virology (viral cultures or viral serology)
5. Immunology or immunochemistry (e.g., immunoglobins, complement)
6. Serology
7. Microbiology (including bacteriology and mycology)
8. Parasitology (e.g., stool for ova and protozoa)
9. Pulmonary function tests (e.g., arterial blood gas)
10. Other biological tests (e.g., endocrine, toxicology screen)
11. Stool for occult blood (specify hemocult or Guaiac method)
12. Skin tests for immunologic competence
13. Medicine screen (usually in urine) for detection of illegal or nonprotocol-approved medicines
14. Bone marrow examination

15. Gonadal function (e.g., sperm count, sperm motility)
16. Genetics studies (e.g., evaluate chromosomal integrity)
17. Stool analysis using in vivo dialysis
- C. Probe for Adverse Reactions
- D. Psychological and Psychiatric Tests and Examinations
  1. Psychometric and performance examinations
  2. Behavioral rating scales
  3. Dependence liability
- E. Examinations Requiring Specialized Equipment (selected examples)
  1. Audiometry
  2. Electrocardiogram (EKG)
  3. Electroencephalogram (EEG)
  4. Electromyography (EMG)
  5. Stress test
  6. Endoscopy
  7. Computed tomography (CT) scans
  8. Ophthalmological examination
  9. Ultrasound
  10. X rays
  11. Others

### 9.2.7 PK PARAMETERS TO DERIVE

The purpose of human pharmacokinetic studies is to examine the rate of absorption, distribution, metabolism, and excretion of a drug. Findings from these studies describe how the drug travels through the body and where and how it is eliminated. PK data allows for the detection of drug levels in human blood/urine samples. After PK information is obtained, a dose–response curve should be plotted that describes the change in effect on the subject caused by differing levels of dose exposure to a stressor. Studying dose–response, and developing dose–response models, is central to determining the safe and hazardous levels and dosages for the drug. A good dose–response curve is obviously highly desired.

The dose–response curve (Fig. 9.2.1) defines the relationship between dose and response based on the following assumptions: (1) response increases as dose increases; (2) there is a threshold dose—a dose below which there is no effect. The quality of results depend on the placement of time points; therefore you want to see at least a 24-hour profile, with two or three time points for each component. However, sometimes limitations arise such as the ability to draw blood, the patience of the study population, and sometimes the study design or medical needs.

Another consideration taken when evaluating PK data is the food effect, which assesses how food affects the absorption of the drug; but this is only tested for with orally administered compounds. Other vital parameters to be drawn and evaluated are listed and defined as follows:

- $AUC_{0-\infty}$  represents the total amount of drug absorbed by the body, irrespective of the rate of absorption. This is useful when trying to determine whether two

**FIGURE 1** Dose–response curve.

formulations of the same dose (e.g., a capsule and a tablet) release the same dose of drug to the body.

- $AUC_{0-T}$  represents the average concentration over a time interval,  $AUC/T$ .
- $C_{max}$  represents the peak concentration of the drug in plasma.
- $T_{max}$  represents the duration of time to reach the peak concentration of drug in plasma, beginning from administration of the drug.
- $T_{1/2}$ —half life, or the time it takes for half of the administered or absorbed dose to be cleared or metabolized.
- $V_0$ —central and peripheral. The theoretical volume in which the drug is homogeneously distributed and is basically dependent upon the lipid or water solubility of the drug and its particular affinity for given tissues or structures.
- Clearance—the volume of plasma that is completely cleared of drug per unit time.
- MRT (mean residence/residual time)—The average total time molecules of a given dose spend in the body. Thus, this can only be measured after instantaneous administration.

## 9.2.8 REGULATORY REQUIREMENTS AND ISSUES

In order to proceed into FIM or phase I trials, permission must be obtained from both the national drug regulatory authority in the country where the trial will take place [in the United States it is the Food and Drug Administration (FDA); in the European Union it is the European Medicines Agency (EMA)], and the national ethics committees, the institutional review board (IRB) in the United States. The IRB is an independent group officially authorized to approve, monitor, and review biomedical and behavioral research involving humans with the objective to protect the rights and welfare of the subjects. In the United States, the FDA and Health and Human Services (HHS) regulations have empowered IRBs to approve, require modifications to gain approval, or disapprove research. An IRB performs critical monitoring tasks for research conducted on human subjects that are scientific,

ethical, and regulatory. IRBs are required to have at least five members with varying backgrounds to promote complete and adequate review of research activities commonly conducted by the institution. The purpose of an IRB review is to assure, both in advance and by periodic review, that appropriate steps are taken to protect the rights and welfare of humans participating as subjects in a research study. The review will cover materials such as the protocol, informed consent documents, and advertisements, with special attention paid to trials that may include vulnerable subjects, such as pregnant women, children, prisoners, the elderly, or persons with diminished comprehension.

The U.S. FDA requires an IND application that includes all the nonclinical and technical data to review. Typically, sponsors will request a pre-IND meeting with the FDA to discuss safety issues related to the proper identification, strength, quality, purity, or potency of the investigational drug, as well as to identify potential clinical hold issues. The pre-IND meeting should focus on the specific questions related to the planned clinical trials. The meeting should also include a discussion of various scientific and regulatory aspects of the drug as they relate to safety and/or potential clinical hold issues. The IND application contents fall primarily into three categories: animal pharmacology and toxicology studies, chemistry and manufacturing information, and clinical protocols and investigator information. Animal pharmacology and toxicology studies are comprised of preclinical data to allow an evaluation as to whether the NME is reasonably safe for initial testing in humans. Also included are any previous experience with the drug in humans (often foreign use). Chemistry and manufacturing information includes information pertaining to the chemical composition, manufacturing methods, stability, and controls used for manufacturing the drug substance and the drug product. The chemical stability and activity of the product must also have been tested. This information is reviewed to ensure that the company can adequately produce and supply consistent and active batches of the drug. Clinical protocols and investigator information consist of detailed protocols for proposed clinical studies to determine whether the initial-phase trials will expose subjects to unnecessary risks. Also, information on the qualifications of the clinical investigators who are to oversee the administration of the experimental compound is included in order to assess whether they are qualified to fulfill their clinical trial duties. An investigator's brochure (IB), which is a document intended to educate the trial investigators of the pertinent facts concerning the trial drug they need to know to conduct their study with the least hazard to the subjects is also submitted. Furthermore, commitments to obtain informed consent from the research subjects, to obtain review of the study by an institutional review board (IRB), and to adhere to the investigational new drug regulations are included. If the sponsor has not received a response from the FDA within 30 days, the trial may begin.

### 9.3.1 OVERVIEW

New compounds are continually being developed with the intended objective that some of these will prove useful in the treatment of human diseases. Any new compound has to undergo a rigorous development process before it can be introduced for standard clinical use. New compounds are first tested for safety in laboratory and animal studies whose objectives are the characterization of the drug's pharmacology, toxicology, metabolism, and other properties.

The new compound is then tested in human subjects in phase I studies that, if successful, are the first of an eventual series in humans. These studies are designed to determine the metabolic and pharmacological actions of the drug, the side effects associated with increasing doses (to establish a safe dose range), and, if possible, to gain early evidence of activity. The focus is typically on determining the toxicity profile of the drug and on finding a potentially therapeutic effective dose.

After a suitable dose has been established in phase I trials, phase II trials are conducted with the main objective being to evaluate the drug's activity for patients with a particular disease or condition, as well as to determine the level of (short-term) side effects and possible risks associated with the use of the drug.

If sufficient preliminary evidence of effectiveness is found in these phase II trials, suggesting worthwhile potential therapeutic efficacy of the drug, the drug may be further evaluated in randomized phase III trials, where it will be compared with the current standard treatment in a larger number of patients.

#### 9.3.1.1 Phase II Trials

Although there is some variation in terminology and objectives depending on the disease or condition in question, phase II trials are usually single-armed studies with the objective being to investigate the antidisease activity of the new therapeutic regimen. Most of these trials evaluate at least one new treatment relative to a standard. So they are inherently comparative, even though the "standard" treatment information is usually historical and is not obtained prospectively as part of the phase II study itself.

In certain circumstances, there may be several candidate agents for phase II testing; the problem here is to select that which has the most potential to be effective and hence be tested in a phase III trial. This leads to randomized phase II trial designs, which seek to reduce the apparent variability in response rates observed in different studies of the same compound. Some factors that contribute to the variability include patient type, definition of response, interobserver variability in response evaluation, drug dosage and schedule, reporting procedures, and sample

size. Patients in randomized phase II studies are randomized to one of several experimental treatments, but the limited sample size of these trials does not provide sufficient statistical power to make reliable treatment comparisons.

In areas such as oncology, phase II trials often focus on both safety and efficacy of the new therapeutic regimen. Safety is usually assessed in terms of toxicity rates but is not always part of the formal design process. Efficacy is typically measured using tumor response, often the percentage decrease in tumor size compared with that before treatment commences, and so patients enrolled in phase II trials need to have measurable disease.

**Example: Phase II Trial—Carcinosarcoma of Female Genital Tract** Van Rijswijk et al. [1] conducted a phase II trial in 48 women with carcinosarcoma of the genital tract. Although the activity of the combination of cisplatin, doxorubicin, and ifosfamide was established (overall response rate 56%), they did not recommend this treatment combination but suggested that combinations “with more favorable toxicity profiles should be explored.”

## 9.3.2 PLANNING A PHASE II TRIAL

### 9.3.2.1 Choice of Endpoint

As already indicated, phase II trials seek to assess whether a new regimen is active enough to warrant a comparison of its efficacy with the standard treatment regimen in a phase III trial. Thus, appropriate endpoints need to be chosen to allow for such an assessment to be made. For example, in human immunodeficiency virus (HIV) research, suitable endpoints might include measures of viral load or immune function. In cardiovascular disease, we might look at blood pressure or lipid levels.

In certain situations, there is not necessarily an obvious measure to take. For example, in oncology, although one may regard tumor shrinkage as a desirable property of a cytotoxic drug when given to a patient, it is not immediately apparent how this is to be measured. Were every tumor of regular spherical shape, the direction in which it is measured is irrelevant. Furthermore the diameter, a single dimension, leads us immediately to the volume of the tumor. However, no real tumor will comply with this ideal geometrical configuration, and this has led to measures such as the product of the two largest (perpendicular) diameters to describe the tumor and then a reduction in this product to indicate response. Precisely what is the best measure to assess tumor shrinkage has been discussed by an international panel and reported in detail by Therasse et al. [2].

More generally, they offer guidelines to encourage more uniform reporting of outcomes particularly for clinical trials. Investigators of future trials may argue about the fine details, and no doubt in time these guidelines will need revision, but they would be foolish to ignore these recommendations when conducting and subsequently reporting their study.

If there are “justifiable” reasons why other criteria should be used, or the recommendations cannot be followed for whatever reason, then before the study commences, these should be reviewed by the investigating team. There is little point in

conducting a study using measures not acceptable to other groups, including referees for the clinical journals, as little note will then be taken of the results. The best option is to follow the guidelines for the primary endpoint, use the “local” measures for secondary reporting, and contrast the two in any discussion.

Sometimes it may be that the true endpoint of interest is difficult to assess for whatever reason. In this case, a surrogate may be sought. For example, when investigating the possibilities of a novel marker for prognosis, it may be tempting to use disease-free survival (DFS) as a “surrogate endpoint” for the overall survival (OS) time of patients with the cancer concerned. The reason being that for many cancers, relapse occurs well before death, and so the evaluation of the marker can occur earlier in time than would the case if OS was to be observed.

More generally, a surrogate endpoint is a biomarker (or other indicator) that is intended to substitute for a (often) clinical endpoint and predict its behavior. If a surrogate is to be used, then there is a real need to ensure that it is an appropriate surrogate for the (true) endpoint of concern.

### 9.3.2.2 Eligibility

Common to all phases of clinical trials is the necessity to define precisely who are eligible subjects. This definition may be relatively brief or complex depending on the substance under test.

At the very early stages of the process, it is particularly understandable that great care is taken in subject and particularly patient choice. In these situations, when relatively little is known about the compound, all the possible adverse eventualities have to be considered. This usually results in quite a restricted definition as to those that can be recruited.

Once the possibility of some activity (and hence potential efficacy) becomes indicated, then there is at least a prospect of therapeutic gain for the patient. In this case, the investigators may expand the horizon of eligible patients but simultaneously confine them to those in which a measurable response to the disease can be ascertained.

**Example: Eligibility for Phase II Trial—Gemcitabine in Nasopharyngeal Carcinoma** Foo et al. [3] specify that patients were to have histologically confirmed undifferentiated carcinoma arising from the nasopharynx, *bidimensionally measurable* disease not within any prior radiotherapy fields, be between 18 and 75 years, with an Eastern Cooperative Oncology Group (ECOG) performance status (PS) < 2. In addition there were seven clinical chemistry limits that had to be satisfied before inclusion was possible.

### 9.3.2.3 Choice of Design

There are a relatively large number of alternative designs for phase II trials. These include single-stage designs in which a predetermined number of patients are recruited, and two-stage designs in which patients are recruited in two stages and the move to stage 2 being consequential on the results observed in stage 1. Multi-stage designs have also been proposed, but the practicalities of having several

decision points have limited their use because of the inherent further delays involved with each extra stage. Most phase II trials are of a single-arm, noncomparative design. However, randomized phase II selection designs in which the objective is to select only one, the “best,” of several agents tested simultaneously, are strongly recommended in some situations.

Although the usual (single) endpoint for phase II studies typically involves some binary measure of activity, designs are available when activity is assessed by survival time, and when the dual endpoints of activity (response) and acceptable levels of toxicity are stipulated by the design.

With such a plethora of different options for phase II designs, it is clearly important that the investigators choose the design that is best for their purpose. In some cases the choice will be reasonably clear. For example, if one has several compounds to test at the same time, then the randomized selection design will be preferred to (say) a series of parallel single-arm studies. In other circumstances, the patient pool may be very limited and a key consideration will be the maximum numbers of patients that might have to be recruited. Features to guide investigators in their choice are summarized in Table 1.

In this chapter, we will briefly discuss a number of different phase II designs. However, a detailed discussion of the designs and sample size tables is beyond the scope of this chapter. Interested readers are referred to the *Sample Size Tables for Clinical Studies* [4]. The accompanying software also allows for the implementation of all the designs we discuss.

**TABLE 1 Comparative Properties of Alternative Phase II Designs**

| Single Stage       | No Stopping Rules            |                                                                                                                  |
|--------------------|------------------------------|------------------------------------------------------------------------------------------------------------------|
| Fleming–A’Hern     | Sample size fixed.           | Size determined at the design stage.                                                                             |
| Randomized         | Sample size fixed.           | Size determined at the design stage and depends on the number of compounds under test.                           |
| Two Stage          | Allow Early Termination      |                                                                                                                  |
| Gehan              | Maximum sample size unknown. | Final sample size depends on the number of responses in stage 1.                                                 |
| Simon—Optimal      | Maximum sample size fixed.   | Stage 1 sample size chosen to ensure inactive compound does not go to stage 2.                                   |
| Simon—Minimax      | Maximum sample size fixed.   | Designed for maximum sample size to be a minimum.                                                                |
| Tan—Machin         | Maximum sample size fixed.   | Stage 1 sample size chosen to ensure inactive compound does not go to stage 2.                                   |
| Two Stage          | Allow Early Termination      | Dual Endpoint                                                                                                    |
| Bryant—Day—Optimal | Maximum sample size fixed.   | Stage 1 sample size chosen to ensure inactive or too toxic compound does not go to stage 2.                      |
| Two Stage          | Allow Early Termination      | Survival Endpoint                                                                                                |
| Case—Morgan        | Maximum sample size fixed.   | Sample size chosen to minimize either expected duration of accrual or expected total study length for the trial. |

### 9.3.3 SINGLE-STAGE DESIGNS

In planning a phase II trial, there are several options to consider, including the number of stages within each design, alternative designs for essentially the same situation, as well as randomized designs. In this section, we look at the Fleming–A'Hern single-stage design. For this design, the endpoint is some measure of anti-disease activity and this translates into a measure of response.

A key advantage of such single-stage designs is that once the sample size has been determined, this translates directly into the number of patients that need to be recruited. This contrasts with, for example, two-stage designs in which the total numbers eventually recruited depends on the response rate in those recruited to stage 1.

In considering the design of a phase II trial of a new drug, the investigators will usually have some knowledge of the activity of other drugs for the same disease. The anticipated response to the new drug is therefore compared, at the planning stage, with the observed responses to other therapies. This may lead to the investigators prespecifying a response probability that, if the new drug does not achieve, results in no further investigation. They might also have some idea of a response probability that, if achieved or exceeded, would certainly imply that the new drug has activity worthy of further investigation, perhaps in a phase III randomized trial to determine efficacy. If a phase II trial either fails to identify efficacy or overestimates the potential efficacy, there will be adverse consequences for the next stage of the development process.

#### 9.3.3.1 Fleming–A'Hern

The Fleming [5] single-stage design for phase II trials recruits a predetermined number of patients to the study, and a decision about activity is obtained from the number of responses among these patients.

To use the design, the investigators first set the largest response proportion as  $\pi_0$ , which, if true, would clearly imply that the treatment does not warrant further investigation. They then judge what is the smallest response proportion,  $\pi_{\text{New}}$ , which would imply that the treatment certainly warrants further investigation. This means that the one-sided hypotheses to be tested in a phase II study are:  $H_0: \pi \leq \pi_0$  versus  $H_A: \pi \geq \pi_{\text{New}}$ , where  $\pi$  is the actual probability of response that is to be estimated at the close of the trial.

In addition to specifying  $\pi_0$  and  $\pi_{\text{New}}$ , it is necessary to specify  $\alpha$ , the probability of rejecting the hypothesis  $H_0: \pi \leq \pi_0$  when it is in fact true, together with  $\beta$ , the probability of rejecting the hypothesis  $H_A: \pi \geq \pi_{\text{New}}$  when that is true. Note that  $\alpha$  is often termed the *test size* or *significance level* and  $1 - \beta$  is referred to as the *power*.

With these inputs, Fleming [5] details the appropriate sample size to be recruited, along with the minimum number of responses that would need to be observed in order for the null hypothesis to be rejected.

However, A'Hern [6] repeated the calculations for sample size using exact binomial probabilities and, in general, these are greater than those of Fleming, although the two calculations are often in close agreement. As a consequence, his calculations should supersede those of Fleming.

To implement the design, the appropriate number of patients is recruited, and once all their responses are observed, the response rate (and corresponding confidence interval) is calculated. A decision with respect to efficacy is then made.

**Example: Fleming–A'Hern Design—Sequential Hormonal Therapy in Advanced and Metastatic Breast Cancer** Iaffaioli et al. [7] used A'Hern's design for two phase II studies of sequential hormonal therapy with first-line anastrozole (study 1) and second-line exemestane (study 2) in advanced and metastatic breast cancer. For study 1 they set  $\alpha = 0.05$ ,  $\beta = 0.1$ ,  $\pi_0 = 0.5$ , and  $\pi_{\text{New}} = 0.65$ . With these inputs, the design specifies a sample size of 93, with 55 being the minimum number of responses required for a conclusion of "efficacy." The study in the end recruited 100 patients, with 8 complete responses and 19 partial responses observed. These give an estimated response rate of 27% with 95% confidence interval (CI) 19.3–36.4% calculated using the method described by Newcombe and Altman [8]. This is much lower than the desired minimum of  $\pi_{\text{New}} = 65\%$ . For study 2, the investigators set  $\alpha = 0.05$ ,  $\beta = 0.1$ ,  $\pi_0 = 0.2$ , and  $\pi_{\text{New}} = 0.4$ , giving rise to a sample size of 47 with a minimum of 15 responses required. The trial eventually recruited 50 patients, with 1 complete response and 3 partial responses observed. These give an estimated response rate of 8% (95% CI 3.2–18.8%). Again this is much lower than the desired minimum of 40%. As a consequence, neither drug should be recommended for testing in a phase III trial.

### 9.3.4 TWO-STAGE DESIGNS

In many situations, investigators may be reluctant to embark on a single-stage phase II trial requiring a (relatively) large number of patients exposed to a new and uncertain therapy. In such circumstances, a more cautious approach may be to conduct such a study, but in a series of stages and review progress at the end of each stage. In two-stage designs, patients are recruited in two stages, and the move to stage 2 is consequential on the results observed in stage 1. The main advantage of such a design is that the trial may stop, after relatively few patients have been recruited, should the response rate appear to be (unacceptably) low. The disadvantage is that the final number of patients required is not known until after stage 1 is complete.

#### 9.3.4.1 Gehan

In the approach suggested by Gehan [9], a minimum requirement of efficacy,  $\pi_{\text{New}}$ , is set and patients are recruited in two stages. If no responses are observed in stage 1, patients are not recruited for stage 2. On the other hand, if one or more responses are observed, then the size of the recruitment to the second stage depends on their number.

To implement the design, the appropriate number of patients is recruited in stage 1, and, once all their responses are observed, a decision whether or not to proceed to stage 2 is taken. If stage 2 is implemented, then once recruitment is complete and all assessments made, the response rate (and corresponding CI) is calculated. A decision with respect to efficacy is then made. If stage 2 is not activated, the response

rate (and CI) can still be calculated for the stage 1 patients despite failure to demonstrate efficacy. This procedure applies to all the two-stage designs we will discuss.

**Example: Gehan Design—Dexverapamil and Epirubicin in Nonresponsive Breast Cancer** Lehnert et al. [10] used the Gehan design for a phase II trial of the combination dexverapamil and epirubicin in patients with breast cancer. For stage 1 they set  $\pi_0 = 0.2$  and  $\beta = 0.05$  obtaining a stage 1 sample size of 14. Of these 14 patients, 3 responses were observed, resulting in a further 9 patients needing to be recruited for stage 2. Finally a total of 4 (17.4%) responses was observed from the total of  $14 + 9 = 23$  patients with 95% CI for  $\pi$  from 7 to 37%.

### 9.3.4.2 Simon Optimal and Minimax

In the approach suggested by Simon [11], patients are recruited in two stages and there are two alternative designs.

One is *optimal* in that the expected sample size is minimized if the regimen has low activity. This implies that an important focus is to ensure that as few patients as possible receive what turns out to be an ineffective drug by not continuing to stage 2 in these circumstances. In this context, “expected” means, the average sample size that would turn out to have been used, had a whole series of studies been conducted with the same design parameters in situations where the true activity is the same.

The other, the *minimax* design, minimizes the maximum sample size for both stages combined, that is, the sum of patients required for stage 1 and stage 2, is chosen to minimize the maximum trial size within the parameter constraints as set by the design.

For either design, the designs imply that the one-sided hypotheses to be tested in a phase II study are  $H_0: \pi \leq \pi_0$  versus  $H_A: \pi \geq \pi_{\text{New}}$ , where  $\pi$  is the actual probability of response, and  $\pi_0, \pi_{\text{New}}$  are as defined before. It is also necessary to specify  $\alpha$  and  $\beta$  as for the Fleming–A’Hern design.

The trial then proceeds by recruiting  $n_{S1}$  patients in stage 1 from which  $r_{S1}$  responses are observed. Then a decision is made to recruit  $n_{S2}$  patients to stage 2 if  $r_{S1} > R_{S1}$ , where  $R_{S1}$  is the minimum number of responders required as indicated by the design. Otherwise the trial is closed at the end of stage 1. At the end of the second stage, the drug is rejected for further use if a predetermined total number of responses are not observed.

**Optimal versus Minimax** In determining which design to use, the minimax design may be more attractive than the optimal design when the difference in anticipated total sample size is small and the patient accrual rate is low. The optimal designs have smaller stage 1 than the minimax designs, and so this smaller stage 1 reduces the number of patients exposed to an inactive treatment if this turns out to be the case. In cases where the patient population is very heterogeneous, however, a very small stage 1 may not be desirable because the first patients entered into the study may not be entirely representative of the wider eligible population. In this case, a larger stage 1 may be preferred and the minimax design chosen.

**Example: Simon Minimax Design—Gemicitabine in Metastatic Nasopharyngeal Carcinoma** In a phase II trial of gemicitabine in previously untreated patients with metastatic nasopharyngeal carcinoma (NPC), Foo et al. [3] utilized the Simon minimax design. With  $\alpha = 0.05$ ,  $\beta = 0.2$ ,  $\pi_0 = 0.1$ , and  $\pi_{\text{New}} = 0.3$ , the design gives:

*Stage 1* Sample size of 15 patients: If responses less than 2, stop the trial and claim gemicitabine lacks efficacy.

*Stage 2* Overall sample size of 25 patients for both stages. Hence 10 more patients were to be recruited. If the total responses for the two stages combined is less than 6, stop the trial as soon as this is evident and claim gemicitabine lacks efficacy.

Once the phase II trial was conducted, the investigators observed 3 and 4 responses in stages 1 and 2, respectively, giving an estimated response rate of 7/25 or 28% (95% CI 14–48%).

**Example: Simon Optimal Design—Gemicitabine in Metastatic Nasopharyngeal Carcinoma** Suppose in the phase II trial of gemicitabine in metastatic NPC designed by Foo et al. [3] that the Simon optimal, rather than the minimax design, had been planned. With the same design values, we want to investigate what difference this makes to the patient numbers and responses required.

Again we have  $\alpha = 0.05$ ,  $\beta = 0.2$ ,  $\pi_0 = 0.1$ , and  $\pi_{\text{New}} = 0.3$ , but the use of the optimal design now gives the following results:

*Stage 1* Sample size of 10 patients: If responses less than 2, stop the trial and claim gemicitabine lacks efficacy.

*Stage 2* Overall sample size of 29 patients for both stages. Hence 19 more patients are to be recruited. If total responses for two stages combined is less than 6, stop the trial as soon as this is evident and claim gemicitabine lacks efficacy.

In this case, for the same design parameters, the optimal design has five fewer patients in stage 1 of the design, but four more patients if the trial goes on to complete stage 2, than the corresponding minimax design. The number of responses to be observed are the same, in each stage, for both designs, however.

**Example: Simon Minimax Design—Paclitaxel for Unresectable Hepatocellular Carcinoma** Chao et al. [12] state in their methods that a Simon [11] design was used in which if the response rate was  $\leq 3$  of 19 in the first stage, then the trial would be terminated. The authors set  $\alpha = 0.1$ ,  $\beta = 0.1$  but did not specify  $\pi_0$  or  $\pi_{\text{New}}$ . With a back calculation, it is possible to deduce that the minimax design was chosen with  $\pi_0 = 0.2$ ,  $\pi_{\text{New}} = 0.4$ , and a stage 1 sample size of 17. In this trial, 0 responses were observed in stage 1 and so stage 2 was not implemented. This implies that the response rate  $\pi$  is estimated by 0/17 or 0% with 95% CI of approximately 0–19%. Thus, even with an optimistic view of the true response rate as possibly close to 19%, this is far below the expectations of the investigators who set  $\pi_{\text{New}}$  as 40%.

### 9.3.5 PHASE II TRIALS WITH SURVIVAL ENDPOINTS

Although many phase II trials have disease response as a (binary) outcome, survival times or at least survival proportions at a fixed time are sometimes more relevant.

As already mentioned, a disadvantage of two-stage designs is that the final number of patients required is not known until after recruitment to stage 1 is complete and response in all these patients has been assessed. This poses a particular difficulty if the endpoint of concern is the time from initiation of treatment to some event (perhaps the death of the patient), which is expressed through the corresponding survival time. In this case there will be a variable, and possibly extended, period of observation necessary to make the requisite observations. However, estimates of survival at a prechosen fixed point in interval time (say 1-year poststart of treatment) can be estimated using the Kaplan–Meier (KM) technique, which takes into account censored observations. Censored survival time observations arise when a patient, although entered on the study and followed for a period of time, has not as yet experienced the “event” defined as the outcome for the trial. For survival itself “death” will be the event of concern, whereas if event-free survival was of concern, the event may be recurrence of the disease. Appropriate methods for survival time analysis are described by Machin et al. [13].

In this context, when considering the design of a phase II trial of a new drug, the investigators will usually have some knowledge of the activity of other drugs for the same disease. The anticipated survival rate of the new drug is therefore compared, at the planning stage, with that observed with other therapies. This may lead to the investigators prespecifying a survival probability that, if the new drug does not achieve, results in no further investigation. They might also have some idea of a survival probability that, if achieved or exceeded, would certainly imply that the new drug has activity worthy of further investigation, perhaps in a phase III randomized trial to determine efficacy.

#### 9.3.5.1 Case and Morgan

In the Case and Morgan [14] two-stage phase II trial designs, “survival” times are utilized in place of binary response variables. The “survival” times usually correspond to the interval between the registration of the patient into the study or the commencement of the phase II treatment, and the time at which the event of primary concern occurs, for example, recurrence of the disease, death, or either of these.

When considering the Case–Morgan designs, it is important to distinguish between *chronological* time—that is, the date on which the trial recruits its first patient, the date of the planned interim analysis, the date the trial closes recruitment, or the date all patient follow-up ends—from the time *interval* between start of therapy and the occurrence of the event. Trial conduct is concerned with chronological time while trial analysis is concerned with interval time. We denote the former by  $D$  and the latter by  $t$ .

The KM estimate at any follow-up time  $t$ , is denoted  $S(t)$ . Thus, for example, when  $t = 1$  year, the KM estimate at that time point is denoted  $S(1)$ . In general, a convenient time point, which we denote by  $T_{\text{Summary}}$ , is chosen by the investigators and the

corresponding  $S(T_{\text{Summary}})$  estimates the proportion of patients experiencing the event at that time point.

Typically, observing the event takes longer and is more variable in its time of occurrence than, for example, tumor response rate. This implies that any two-stage phase II design using such an endpoint may require a period between stage 1 and (the potential) stage 2. This time window is to allow sufficient events to accumulate for the stage 1 analysis so that a decision can be taken whether or not to continue to stage 2. The time window is added to the duration of stage 1, and its necessity may require suspending patient recruitment during this interval. Clearly, this will extend the total duration of the study. The Case–Morgan designs eliminate the need for this time window.

To implement the design, the investigators set for a particular interval time,  $t = T_{\text{Summary}}$ , the largest survival proportion as  $S_0(T_{\text{Summary}})$ , which, if true, would clearly imply that the treatment does not warrant further investigation. The investigators then judge what is the smallest survival proportion,  $S_{\text{New}}(T_{\text{Summary}})$ , that would imply the treatment warrants further investigation. This implies that the one-sided hypotheses to be tested in the study are:  $H_0: S(T_{\text{Summary}}) \leq S_0(T_{\text{Summary}})$  versus  $H_{\text{New}}: S(T_{\text{Summary}}) \geq S_{\text{New}}(T_{\text{Summary}})$ , where  $S(T_{\text{Summary}})$  is the actual probability of survival, which is to be estimated at the close of the trial. In addition to specifying  $S_0(T_{\text{Summary}})$  and  $S_{\text{New}}(T_{\text{Summary}})$ , it is necessary to specify  $\alpha$  and  $\beta$ .

With these inputs, there are then two variants of the Case–Morgan design, depending on whether we wish to minimize the expected duration of accrual (EDA) or the expected total study length (ETSL) for the trial. These are defined as follows:

$$\begin{aligned} \text{EDA} &= D_{\text{Stage1}} + (1 - P_{\text{Early}})D_{\text{Stage2}} \\ \text{ETSL} &= D_{\text{Stage1}} + (1 - P_{\text{Early}})(D_{\text{Stage2}} + T_{\text{Summary}}) \end{aligned}$$

where  $D_{\text{Stage1}}$  and  $D_{\text{Stage2}}$  are the durations of stage 1 and stage 2 of the trial, respectively, and  $P_{\text{Early}}$  is the probability of stopping at the end of stage 1.

**Example: Case and Morgan—Gemcitabine and External Beam Radiotherapy for Resectable Pancreatic Cancer** Case and Morgan [14] consider the design of a phase II trial of the effectiveness of adjuvant gemcitabine and radiotherapy in the treatment of patients with resectable pancreatic cancer. The outcome measure used was 1-year survival, and they planned to test the null hypothesis that 1-year survival is 35% against an alternative of 50%. Thus,  $T_{\text{Summary}} = 1$ ,  $S_0(1) = 0.35$ ,  $S_{\text{New}}(1) = 0.50$ . Further  $\beta = 0.1$  and  $\alpha = 0.1$ .

With these inputs, the ETSL design suggests that stage 1 recruits 54 patients and stage 2 83 patients. With the EDA design the corresponding sample sizes are 46 in stage 1 and 79 in stage 2, resulting in a total sample size of 125.

### 9.3.6 EFFICACY AND TOXICITY IN PHASE II TRIALS

In situations where the toxicity of an agent undergoing phase II testing is poorly understood, it may be desirable to incorporate toxicity considerations into the trial

design. We now discuss phase II trial designs for the situation in which both a minimum level of activity and a maximum level of (undesirable) toxicity are stipulated in the design. Such designs expand on the Simon two-stage designs discussed earlier.

### 9.3.6.1 Bryant and Day

Bryant and Day [15] point out that a common situation when considering phase I and phase II trials is that although the former primarily focuses on toxicity and the latter on efficacy, each in fact considers both. This provides the rationale for their phase II design that incorporates toxicity and activity considerations. Essentially, they combine a design for activity with a similar design for toxicity in which one is looking for both *acceptable* toxicity and *high* activity.

The design implies that two, *one-sided* hypotheses are to be tested. These are that the true response rate  $\pi_R$  is either  $\leq \pi_{R0}$ , the maximum response rate of no interest, or  $\geq \pi_{R\text{New}}$ , the minimum response rate of interest. Further the probability of incorrectly rejecting the hypothesis  $\pi_R \leq \pi_{R0}$  is set as  $\alpha_R$ . Similarly,  $\alpha_T$  is set for the hypothesis  $\pi_T \leq \pi_{T0}$  where  $\pi_T$  is the maximum nontoxicity rate of no interest. In addition, the hypothesis  $\pi_T \geq \pi_{T\text{New}}$  has to be set together with  $\beta$ , the probability of failing to recommend a treatment that is acceptable with respect to both activity and (non-)toxicity. (The terminology is a little clumsy here as it is more natural to talk in terms of “acceptable toxicity” rates rather than “acceptable nontoxicity” rates. Thus  $1 - \pi_{T0}$  is the highest rate of toxicity above which the drug is unacceptable. In contrast,  $1 - \pi_{T\text{New}}$  is the lower toxicity level below which the drug would be regarded as acceptable on this basis.)

In the Bryant and Day design, toxicity monitoring is incorporated into the Simon [11] design by requiring that the trial is terminated after stage 1 if there is an inadequate number of observed responses or an excessive number of observed toxicities. The treatment under investigation is recommended at the end of stage 2 only if there are both a sufficient number of responses and an acceptably small number of toxicities in total.

To implement the designs, the appropriate number of patients is recruited to stage 1, and once all their responses and toxicity experiences are observed, a decision whether or not to proceed to stage 2 is taken. If stage 2 is implemented, then once recruitment is complete and all assessments made, the response and toxicity rates, along with their corresponding CIs, are calculated. A decision with respect to efficacy and toxicity is then made. If stage 2 is not activated, the response rate and toxicity rates can still be calculated for the stage 1 patients despite either failure to demonstrate activity, too much toxicity, or both.

**Example: Bryant and Day Design—Ifosfamide and Vinorelbine in Ovarian Cancer** González-Martín et al. [16] used the Bryant and Day two-stage design with a cutoff point for the response rate of 10% and for severe toxicity of 25%. Severe toxicity was defined as grade 3 and 4 nonhematological toxicity, neutropenic fever, or grade 4 thrombocytopenia. They do not provide full details of how the sample size was determined, but their choice of design specified a stage 1 of 14 patients and stage 2 a further 20 patients. In the event, in these advanced platinum-resistant ovarian cancer patients, the combination of ifosfamide and vinorelbine was

evidently very toxic. Hence the trial was closed after 12 patients with an observed toxicity level above the 25% contemplated. In fact, this corresponds to a design with  $\alpha_R = \alpha_T = 0.1$ ,  $\beta = 0.2$ ;  $\pi_R^0 = 0.1$ ,  $\pi_{R\text{New}} = 0.3$ ;  $\pi_{T0} = 0.25$ ; and  $\pi_{T\text{New}} = 0.45$ . On this basis, the completed stage 1 trial of 14 patients proceeds to stage 2 if there are at least 2 responses *and* there are also no more than 2 patients with high toxicity. The stage 2 trial size is a further 20 patients, to a total of 34 for the whole trial, and sufficient efficacy with acceptable toxicity would be concluded if there were 6 or more responses observed *and* 10 or fewer with high toxicity.

### 9.3.7 BAYESIAN APPROACHES

#### 9.3.7.1 Motivation

For most of the designs discussed thus far, the final response rate is estimated by  $R/N$ , where  $R$  is the total number of responses observed from the total number of patients recruited  $N$  (whether obtained from a single- or two-stage design). This response rate, together with the corresponding 95% CI, typically provide the basic information for the investigators to decide if a subsequent phase III trial is warranted. However, even after the trial is completed, there often remains considerable uncertainty about the true value of  $\pi$ . For example, in the trial reported by Lehnert et al. [10] using the Gehan design, a 17% response rate was observed from 23 patients with the corresponding 95% CI for  $\pi$  from 7 to 37%. In the trial of previously treated patients with metastatic nasopharyngeal cancer, conducted by Foo et al. [3], a high response rate of 48% (95% CI of 33 to 63%) was reported. This result is consistent with both a true response rate as small as 33% and one as high as 63%, an almost twofold difference. The inevitable uncertainty arising from phase II trials with small sample sizes suggests that Bayesian approaches may be useful for phase II trials.

#### 9.3.7.2 Overview of Bayesian Approaches in the Context of Phase II Trials

The foundation of the Bayesian approach is Bayes' theorem, which can be expressed as

$$\text{post}(\pi|x) \propto \text{lik}(x|\pi)\text{prior}(\pi)$$

which involves combining the likelihood  $\text{lik}(x|\pi)$  with the prior distribution,  $\text{prior}(\pi)$ , to give the posterior distribution,  $\text{post}(\pi|x)$ . The  $\text{prior}(\pi)$  summarizes what we know about  $\pi$  before the trial commences, while  $\text{lik}(x|\pi)$  describes the data to be collected from the trial itself. Finally  $\text{post}(\pi|x)$  summarizes all we know about  $\theta$  once the trial is completed.

Many phase II trials involve endpoints that are binary (e.g., whether a response occurs or not). For such endpoints, the prior distribution may be assumed to be of the form

$$\text{prior}(\pi) \propto \pi^{a-1}(1-\pi)^{b-1}$$

This is a Beta distribution with parameters  $a$  and  $b$ , which can take any positive value. When  $a$  and  $b$  are integers, such a distribution corresponds to a prior belief equivalent to having observed  $a$  responses out of a hypothetical  $T = (a + b)$  patients. This is then similar to the situation modeled by the binomial likelihood distribution in which we have  $x$  as the number of responses from  $N$  patients.

Combining the above prior with a binomial likelihood results in a posterior distribution of the form

$$\text{post}(\pi|x) \propto \pi^{a+x-1}(1-\pi)^{b+N-x-1}$$

It can be seen that this too is a Beta distribution, but of the form Beta  $(a + x, b + N - x)$ .

As mentioned previously, the posterior distribution represents our overall belief at the close of the trial about the distribution of the population parameter  $\pi$ . Once we have obtained the posterior distribution, we can calculate the exact probabilities of  $\pi$  being in any region of interest or obtain summary statistics such as its mean value.

The prior distribution summarizes the information on  $\pi$  before the trial commences. The general way in which each of these are derived is as follows. The shape of a Beta distribution is dependent on the values of the parameters  $a$  and  $b$ , and each of the priors will have particular values associated with them. However, eliciting values for  $a$  and  $b$  is typically not an easy process. Instead, it is often much easier to obtain values for the mean ( $M$ ) and variance ( $V$ ) of the corresponding prior distribution. Once obtained, these values can then be used to obtain  $a$  and  $b$  by solving the simultaneous equations:

$$M = \frac{a}{a+b} \quad V = \frac{ab}{(a+b)^2(a+b+1)}$$

which give

$$a = \frac{M[M(1-M)-V]}{V} \quad b = \frac{(1-M)[M(1-M)-V]}{V}$$

More generally, prior distributions could be elicited either from relevant external data (see e.g., Tan et al. [17]) or from subjective clinical opinion [18] or a combination of the two.

For more detailed overviews of Bayesian approaches, the reader is referred to Berry and Stangl [19], Spiegelhalter et al. [20], and Tan [21]. In the particular situation of two phase II trials conducted “in parallel” using a two-stage design, Bayesian approaches allow for the information from both trials to be taken into account when making decisions regarding whether to proceed to stage 2 of each trial or not [22].

### 9.3.7.3 Bayesian Single and Dual Threshold

In the Tan–Machin (TM) two-stage single-threshold design (STD) [23, 24], the focus is to estimate, for example, the posterior probability that  $\pi > \pi_{\text{New}}$ , so that if this is

high, at the end of the phase II trial, the investigators can be reasonably confident in recommending the compound for testing in a phase III trial.

The investigator first sets the minimum interest response rate  $\pi_{\text{New}}$  and  $\pi_{\text{Prior}}$  the anticipated response rate of the drug being tested. However, in place of  $\alpha$  and  $\beta$ ,  $\lambda_1$  (the required threshold probability following stage 1 that  $\pi > \pi_{\text{New}}$ ) and  $\lambda_2$  ( $> \lambda_1$ ) (the required threshold probability after completion of stage 2 that  $\pi > \pi_{\text{New}}$ ) are specified. Further, once the first stage of the trial is completed, the estimated value of  $\lambda_1$ , that is,  $u_1$ , is computed and a decision made whether or not to proceed to stage 2. Should the trial continue to stage 2 then, on trial completion,  $u_2$  is computed. Note that the trial only goes into stage 2 if the estimate of  $\lambda_1$ , at the end of stage 1, exceeds the design value. Efficacy is claimed at the end of stage 2 only if the estimate of  $\lambda_2$ , obtained from all the data, exceeds the design value.

The design determines the sample sizes for the trial based on the following principle. Suppose that the trial was to be conducted and that  $X_1$  and  $X_2$  represent the resulting data obtained from stage 1 and stage 2, respectively. Now, suppose also that the (hypothetical) response proportion underlying  $X_1$  and  $X_2$  is just larger than the prespecified  $\pi_{\text{New}}$ , say  $\pi_{\text{New}} + \varepsilon$ , for some small  $\varepsilon > 0$ . We then want the smallest overall sample size,  $N_{\text{TM}}$ , that will enable the posterior probability at the end of the trial, denoted  $\Pr(\pi > \pi_{\text{New}} \mid X_1, X_2)$  or more briefly  $\Pr(\pi > \pi_{\text{New}})$ , to be at least  $\lambda_2$ . At the same time, we also want the smallest possible stage 1 sample size  $n_{\text{TM1}}$ , which is just large enough so that the posterior probability at the end of stage 1,  $\Pr(\pi > \pi_{\text{New}} \mid X_1)$  or more briefly  $\Pr(\pi > \pi_{\text{New}})$ , is at least  $\lambda_1$ . Tan and Machin [23] suggest planning values for  $(\lambda_1, \lambda_2)$  as (0.6, 0.7), (0.6, 0.8), or (0.7, 0.8) and also set a value of  $\varepsilon = 0.05$ .

Tan and Machin [23] also propose an alternative two-stage dual-threshold design (DTD). This design is identical to the STD except that the stage 1 sample size is determined not on the basis of the probability of exceeding  $\pi_{\text{New}}$  but on the probability that  $\pi$  will be less than the “no further interest” proportion,  $\pi_0$ . This represents the response rate below which the investigator would have no further interest in the new drug. Thus  $\pi_0$  functions as a lower threshold on the response rate, as opposed to the upper threshold represented by  $\pi_{\text{New}}$ . The rationale behind this aspect of the DTD is that we want our stage 1 sample size to be large enough so that, if the trial data really does suggest a response rate that is below  $\pi_0$ , we want the posterior probability of  $\pi$  being below  $\pi_0$ , to be at least  $\lambda_1$ . The design determines the smallest stage 1 sample size that satisfies this criterion. The trial only goes into stage 2 if the estimate of  $\lambda_1$  exceeds the design value and efficacy is claimed at the end of stage 2 only if the estimate of  $\lambda_2$  exceeds the design value.

The DTD requires the investigators to set  $\pi_{\text{Prior}}$  as the anticipated value of  $\pi$  for the drug being tested. A convenient choice may be  $(\pi_0 + \pi_{\text{New}})/2$ , but this is not a requirement. Further  $\lambda_1$  is set as the required threshold probability following stage 1, that  $\pi < \pi_0$ , while  $\lambda_2$  is the required threshold probability that, after completion of stage 2,  $\pi > \pi_{\text{New}}$ . (Note that unlike in the case of STD, it is no longer a requirement that  $\lambda_1 < \lambda_2$ .) Once stage 1 of the trial is completed, the estimated value of  $\lambda_1$ , that is  $l_1$ , is computed, and, should the trial continue to stage 2 then on its completion,  $u_2$  is computed. The latter is then used to help make the decision as to whether or not a phase III trial is suggested. As with the STD, Tan and Machin [23] suggest planning values for  $(\lambda_1, \lambda_2)$  as (0.6, 0.7), (0.6, 0.8), or (0.7, 0.8) and also set a value of  $\varepsilon = 0.05$ .

The original Tan–Machin [23] designs work on the basis of having a “vague” prior distribution. According to Mayo and Gajewski [25], this corresponded to having a prior sample size of 3. Furthermore, Tan and Machin imposed some practical constraints on the designs to encourage their adoption in practice. In particular, they constrained the total study size,  $N_{TM}$ , to be a minimum of 10 and a maximum of 90, with stage 1 size,  $n_{TM1}$ , having a minimum size of 5 and a maximum of  $N_{TM} - 5$ . For these and other reasons, Mayo and Gajewski [25] as well as Wang et al. [26] have suggested modifications to the original Tan–Machin design.

**Example: Tan–Machin STD Design—Gemcitabine in Metastatic Nasopharyngeal Cancer** Tan and Machin [23] reanalyzed the phase II trial of Foo et al. [3] for previously treated patients as if they had been designed using STD. First, they back-calculated from the two-stage Simon minimax design utilized, that this choice implied for their STD values of  $\lambda_1 = 0.728$  and  $\lambda_2 = 0.774$ , respectively. Using the actual trial data they then computed with the data at the close of stage 1,  $\Pr(\pi > \pi_{New}) = u_1 = 0.997$  (which is clearly greater than  $\lambda_1 = 0.728$ ). Further for the data at the close of stage 2, this probability was reestimated to be  $\Pr(\pi > \pi_{New}) = u_2 = 0.999$  (which is clearly greater than  $\lambda_2 = 0.774$ ). So *had* the STD been used, this reanalysis suggests that, at the end of stage 1, continuation to stage 2 would have been appropriate. Further information at the end of stage 2 very strongly recommended that gemcitabine can be considered to have sufficient activity for phase III evaluation.

**Example: Tan–Machin DTD Design—Gemcitabine in Metastatic Nasopharyngeal Cancer** Similarly, reanalyzing the chemonaïve study of Foo et al. [3], but now on the basis that a DTD was conducted, all the actual trial data gives an estimate of  $\Pr(\pi < \pi_0) = l_1 = 0.003$  or equivalently expressed by  $\Pr(\pi > \pi_0) = 1 - l_1 = 0.997$ . The estimate for  $\Pr(\pi > \pi_{New}) = u_2 = 0.445$ . Thus, we are very confident that  $\pi > \pi_0$  but not so sure that  $\pi > \pi_{New}$ . These together suggest that the response rate lies within the region of uncertainty,  $\pi_0 \leq \pi \leq \pi_{New}$ , as this has a reasonably high probability of  $0.997 - 0.445 = 0.552$  or 55%.

**Example: Tan–Machin DTD—Combination Therapy for Nasopharyngeal Cancer** A phase II trial using a triplet combination of paclitaxel, carboplatin, and gemcitabine in metastatic nasopharyngeal carcinoma was conducted at the National Cancer Centre, Singapore, by Leong et al. [27]. The trial was expected to yield a minimum interest response rate of 80% and a no further interest response of 60%. The anticipated response rate was assumed to be equal to the minimum interest response rate and the overall threshold probability at the start and end of the trial is set to be 0.65 and 0.7, respectively. The sample size of the trial was calculated using the DTD. With the no further interest response rate  $\pi_0 = 0.6$ , the minimum interest response rate  $\pi_{New} = 0.8$ , the anticipated response rate  $\pi_{Prior} = 0.8$ , the minimum desired threshold probability at the start of the trial  $\lambda_1 = 0.65$ , and the minimum desired threshold probability at the end of the trial  $\lambda_2 = 0.7$ , we obtain the following design:

*Stage 1* Sample size of 19 patients; if responses less than 15, stop the trial as soon as this becomes apparent and declare lack of efficacy. Otherwise complete stage 1 and commence stage 2.

*Stage 2* Overall sample size of 32 patients for both stage, hence 13 stage 2 patients to be recruited; if total responses for the two stages combined is less than 28, stop trial as soon as this becomes apparent and declare lack of efficacy.

### 9.3.8 RANDOMIZED PHASE II TRIALS

Most phase II trials are of a single-arm, noncomparative design. However, in certain circumstances there may be several compounds available for potential phase III testing in the same type of patients, but practicalities imply that only one of these can go forward for this subsequent assessment. Since there are several options, good practice dictates that the eligible patients should be randomized to the alternatives. This can be achieved by using a randomized phase II selection design in which the objective is to select only one, the “best,” of several agents tested simultaneously.

The randomized designs overcome the difficulties pointed out by Estey and Thall [28] when discussing single-arm trials where the actual differences between response rates associated with the treatments (*treatment effects*) are confounded, with differences between the trials (*trial effects*), as there is no randomization to treatment. Consequently, an apparent treatment effect may in reality only be a trial effect.

#### 9.3.8.1 Simon, Wittes, and Ellenberg (SWE)

The Simon, Wittes, and Ellenberg [29] design is a randomized (single-stage) phase II design that selects from several candidate drugs that with the highest level of activity. This approach chooses the observed best treatment for the phase III trial, however small the advantage over the others. The trial size is determined in such a way that if a treatment exists for which the underlying efficacy is superior to the others by a specified amount, then it will be selected with a high probability. Although details of the random allocation process are not outlined below, this is a vital part of the design implementation. Details are provided by, for example, Machin and Campbell [30].

When the difference in true response rates of the best and next best treatment is  $\delta$ , Simon et al. [29] allow for the computation of sample sizes depending on the desired probability of correct selection,  $P_{CS}$ , and the number of treatments being tested,  $g$ . The response rate of the worst treatment is denoted  $\pi_{\text{Worst}}$ .

To implement the design, the appropriate number of patients are recruited and randomized to the  $g$  groups. Once all their responses are observed, the response rates are calculated for each drug under test and that with the highest recommended for phase III testing.

**Example: Gemcitabine, Vinorelbine, or Docetaxel for Advanced Non-Small-Cell Lung Cancer** A randomized phase II trial of single-agent gemcitabine, vinorelbine, or docetaxel in the treatment of elderly and/or poor performance status patients with advanced non-small-cell lung cancer was conducted at the National Cancer Centre of Singapore [31]. The design was implemented with the probability of correctly selecting the best treatment assumed to be 90%. It was anticipated that the single-agent activity of each drug has a baseline response rate of approximately

20%. In order to detect a 15% superiority of the best treatment over the others, we wished to determine how many patients should be recruited per treatment for the trial. For the difference in response rate  $\delta = 0.15$ , smallest response rate  $\pi_{\text{Worst}} = 0.2$ , probability of correct selection  $P_{\text{CS}} = 0.90$ , and treatment groups,  $g = 3$ , the design gives a sample size of  $m = 44$  per treatment group. Thus the total number of patients to be recruited is given as  $N = 3 \times 44 = 132$ .

**Example: Non-Hodgkin's Lymphoma** Itoh et al. [32] describe a randomized two-group phase II trial comparing dose-escalated (DE) with biweekly dose-intensified (DI) CHOP in newly diagnosed patients with advanced-stage aggressive non-Hodgkin's lymphoma. Their design anticipated at least a 65% complete response (CR) rate in both groups. To achieve a 90% probability of selecting the better arm when the CR rate is 15% higher in one arm than the other, at least 30 patients would be required in each arm. In that event, they recruited 35 patients to each arm and observed response rates with DE and DI of 51 and 60%, respectively. Their follow-on study, a randomized phase III trial, compares DI CHOP with the standard CHOP regimen.

### 9.3.9 TRIAL CONDUCT AND REPORTING

In phase III trials, much emphasis has been placed on developing standards for the good conduct and reporting of clinical trials. Among the aspects looked at are issues relating to informed consent, registration of subjects, monitoring the trial, and common standards for the reporting of trials. It is well known that many trials go unreported, leading to publication bias being an important concern. This motivates proposals that all phase III trials need to have their protocols formally registered before a trial can even begin [33].

Unfortunately, the conduct and reporting of phase II trials often does not meet the high standards demanded of the phase III randomized controlled trial. All phases of the clinical trials process crucially affect the final conclusions made regarding the usefulness of new treatments. As such, phase II trials also need to be conducted and reported to the highest standards, and we advocate that the standards applied to phase III trials should also be extended to phase II wherever appropriate. Furthermore, there are some particular considerations that need to be taken into account for phase II trials, which we now discuss.

#### 9.3.9.1 Trial Conduct

Since most phase II trials are not comparative, in the taking of informed consent, only details of the procedures that are to be involved and any potential side effects and risks need to be explained. It would be important to explain to the patient that any therapeutic benefit hoped for, such as tumor shrinkage, may or may not transfer into benefit for the patient with respect to (say) increased survival or improved quality of life. In the case of randomized phase II trials of Simon et al. [29], then the usual considerations applicable to those for a phase III trial would apply.

Once consent has been taken and patients recruited into the trial, there is then a need to properly register and monitor them as for phase III trials. Moreover, unlike for phase III trials, continuous monitoring of patient responses may occur. This has particular implications should a two-stage design have been used. Typically, such designs would result in a delay in the recruitment process between stage 1 and stage 2, resulting in a longer trial. However with continuous monitoring of responses, stage 2 may be triggered before the formal recruitment to stage 1 is complete if there are already sufficient responses. Nevertheless, in such a situation, we recommend that a formal review of the stage 1 results should still be carried out.

### 9.3.9.2 What to Report

Considerable effort is required in order to conduct a clinical trial of whatever type and size, and this effort justifies reporting of the subsequent trial results with careful detail. However, there is a wide variation in the quality of the standard of reporting of clinical trials. In phase III trials, major strides in improving the quality have been made and pivotal to this has been the Consolidation of the Standards of Reporting Trials (CONSORT) statement described by Begg et al. [34] and amplified by Moher et al. [35]. CONSORT describes the essential items that should be reported in a trial publication in order to give assurance that the trial has been conducted to a high standard. This is an internationally agreed recommendation, adopted by many of the leading medical journals, although there are still some who do not appear to insist that their authors comply with the requirements.

Although the CONSORT statement primarily applies to phase III and not phase II trials, many of their principles can and should also be applied to these. In particular, Table 2 highlights some of the relevant items from CONSORT that should be applied. A diagram showing the flow of patients through the trial (Fig. 1) should also be given.

**TABLE 2 Selected Key Items Included in Phase II Clinical Trial Report**

|                                                       |                                                                                                                                                                                                                       |

**9.3.10 CONCLUDING REMARKS**

Although phase II studies are typically of modest size relative to phase III trials, the temptation to conduct these studies without due attention to detail should be resisted. In fact, these studies (imprecise though they may be) provide key information for the drug development process. It is therefore essential that they are carefully designed, painstakingly conducted, and meticulously reported in full. Table 3 summarizes the key design and conduct issues.

It is also important to again emphasize that all patients should be registered for the trial (and hence are in the trial database) and that the final report includes information on all these patients. This is particularly important if a review process of, for example, each objective response in a phase II trial may reveal that certain patients admitted to the trial were either not truly eligible, had not received the full treatment as specified by the protocol, or could not be evaluated for the endpoint. Perhaps it is unclear whether or not they had sufficient tumor shrinkage for a satis-

**TABLE 3 Design and Conduct Issues for Phase II Trials**

---

|                                                                                           |
|-------------------------------------------------------------------------------------------|
| Clearly define patient eligibility.                                                       |
| Clearly define the measures of response (and toxicity).                                   |
| Choose a single- or two-stage design.                                                     |
| Consider the importance of not proceeding to stage 2 if activity low.                     |
| Consider whether a CI or threshold probability approach is to be used for interpretation. |
| Consider the possibility of a randomized selection design.                                |
| Ensure that all patients are registered.                                                  |
| Ensure all evaluations are made.                                                          |
| Ensure the final report details information on all patients.                              |

---

factory response. It must be clear in the study protocol itself, and in the subsequent report of the study results, whether these “ineligible,” “noncompliant,” and “none-valuable” patients are or are not included in the reported response rates. This equally applies for any assessment of toxicity, whether or not toxicity is a formal endpoint for the design as it is in the Bryant–Day design of phase II.

It should also be emphasized that phase II trials should never be seen as an alternative to well-designed (large) randomized phase III trials. This is because the small sample sizes in phase II trials give rise to estimates with very wide confidence intervals (i.e., a high level of uncertainty). Hence any conclusions drawn from such trials cannot be confirmatory.

Finally, it should be noted that the results of separate single-arm phase II trials should also generally not be used for comparative purposes because of the potential confounding of treatment effects with trial effects. Consequently, an apparent treatment effect may in reality only be a trial effect. As for randomized phase II trials, their objective is to select the “best” of several agents tested for further testing in a phase III trial and not as alternatives to phase III trials.

## 9.4.1 OVERVIEW AND BACKGROUND

Phase III studies are defined as randomized controlled either single- or multicenter studies enrolling large numbers of patients with the purpose of rendering a definitive assessment of how effective the studied intervention is, compared with the current standard of care. The randomized clinical trial is characterized by two or more therapeutic treatment groups. These groups are sometimes referred to as *arms*, particularly in cancer trials. One treatment may be a placebo control in which a biologically inert substance (in a drug trial) is used. Note that while most phase III clinical trials compare two medications or devices, some trials compare three or four medications, doses of medications, or devices against each other. The protocol is the written operating manual of a trial, which ensures that researchers in different locations perform the study uniformly, allowing the data to be pooled and analyzed.

The U.S. National Institutes of Health, (NIH) organize clinical trials into five different types [1]:

*Treatment Trials* Test experimental treatments, new combinations of drugs, or new approaches to surgery or radiation therapy.

*Prevention Trials* Look for better ways to prevent disease in people who have never had the disease or to prevent a disease from returning. These approaches may include medicines, vitamins, vaccines, minerals, or lifestyle changes.

*Diagnostic Trials* Conducted to find better tests or procedures for diagnosing a particular disease or condition.

*Screening Trials* Test the best way to detect certain diseases or health conditions.

*Quality of Life Trials (or Supportive Care Trials)* Explore ways to improve comfort and quality of life for individuals with a chronic illness.

A randomized phase III controlled trial is the study design that can provide the most compelling evidence that the study treatment causes the expected effect on human health. Currently, some phase II and most phase III drug trials are designed as randomized, double blind, and placebo controlled. After preliminary evidence from phase I and II studies suggesting effectiveness of the drug has been obtained, phase III trials are designed to gather additional information to assess the overall benefit to risk relationship of the drug for possible use as a new standard of care.

Many NIH programs encourage or require the use of protocol templates, such as the ones available here at <http://ctep.cancer.gov/guidelines/templates.html>.

While following template guidelines can help guide authors, care should be exercised when using a template since not every part of a template will necessarily apply in a given study.

As is the case for all research protocols, writing a clinical protocol is a task that requires the collaboration and input of many individuals with various expertise to help reach the goal of a scientifically plausible and sound study. The writing of the protocol is of utmost importance and is a necessary condition on which the quality of the study itself depends.

#### 9.4.2 DRUG BACKGROUND AND INFORMATION

Phase III protocols, like phase I and II protocols, require a section detailing the scientific rationale for a protocol and the justification medically and scientifically of the hypothesis in question. This section should be organized in a logical and sequential manner.

First, the background section should focus on justifying the need for the study by elaborating first on where we are in the field. Here, a review of disease incidence and its impact on morbidity and mortality may help. Reviewing the results from similar prior studies or phase I and phase II studies testing the drug in question is also warranted. This will be a prerequisite to argue the need to perform the phase III trial and discuss what the trial will potentially add that would be important for patient care.

It is particularly important in phase III trials to indicate what the standard of care is in this patient population, so that if there is no standard of care an observation or placebo arm can be justified. In case there is a known standard, the control arm will usually be that standard, and the investigational drug will be used in the experimental arm(s).

If the drug in question is already established as an acceptable standard of care in the studied patient population, and the investigator wishes to perform a pharmacokinetic (PK) study with different dosing and administration schedules to be tested in several arms to determine the best dosing and schedule method, this design is that of a phase IV study.

It is important to learn about the drug and/or the intervention, and for the principal investigator (PI) to elaborate in the background section on the drug characteristics, the evidence derived from phase I and phase II trials and preclinical studies. Even though issues such as dosing, administration, and route of delivery will be expected to be detailed in the treatment plan section, it is helpful to introduce this information in the background section. Critical information will include the following: dose/dosing schedule, possible need for a vector, route of delivery, and method of preparation.

It is also advisable to discuss the possible benefits of performing the phase III trial in the background section, as this argument is closely linked to the findings of prior phase I or II studies. The benefits may not be restricted here to clinical outcome of disease but may also include ease of administration, convenience to patients, a better side effect profile, or a potential improvement in quality of life. Here, the authors may also allude to the patient population in question and elaborate briefly on the rationale behind the main inclusion and exclusion criteria as the opportunity is there to discuss these. This should be a prelude to the inclusion and exclusion criteria section in which a more detailed and complete description of these criteria is expected.

### 9.4.3 OBJECTIVES

In the initial development of a phase III protocol, it is essential for the investigator to try to answer several questions that will help in writing the protocol and define the objectives. Important questions to try to answer include: What is the expected outcome? What is the intervention? For how long will the intervention last? What patients or subjects is the intervention targeting? How many participants are needed? How can the potential benefit be optimized while minimizing potential harm?

The objectives should be stated clearly as they constitute the hypothesis in question. As in any trial, each objective needs to be discussed in the statistical section. The objective section should be concisely and simply written, often as a numbered or bulleted list. Here the authors should not include any arguments or justifications but rather be straightforward in describing the objectives. For a phase III trial the objectives usually are to compare two different approaches. For example, in a therapeutic trial the comparison usually involves two treatment plans, and the objective may seek to compare the survival of patients on each arm or the objective responses to the respective treatments. Other possible parameters may include the comparison of symptoms or quality of life parameters between arms or an assessment of the safety and tolerability of the treatment.

### 9.4.4 PRIMARY AND SECONDARY ENDPOINTS

It is important to remember that in a phase III study, as is the case in other designs, the primary endpoint will dictate the statistical method of analysis, the sample size, and stopping rules. Therefore, discussing these questions with a statistician while designing the study objectives cannot be overemphasized. For example, certain considerations such as the number of patients needed to reach statistical significance and the accrual potential in certain diseases may make the objectives difficult to achieve.

In a therapeutic trial, the primary endpoints must usually measure clinical outcome and will have the major impact on the rest of the study design as they will also influence the inclusion and exclusion criteria and the follow-up plan during or after the intervention. Secondary endpoints are usually easier to achieve and often revolve around the primary endpoints. They may include other parameters such as quality of life, assessing the ease of administration of agents in therapeutic trials, but in general they will not have as great an impact on the statistical section as the primary endpoints.

To better elucidate the choice of these endpoints, it is helpful for the author to include a section entitled Rationale for Selection of Endpoints. This will help the investigators review their decisions thoroughly and avoid major pitfalls that may result from a poor selection of endpoints. For example, choosing progression-free survival (PFS) as an endpoint for the trial may be more justifiable for certain types of malignancies such as sarcomas, which are generally incurable if being treated in the metastatic setting. Furthermore, prior interventions have not been shown to affect overall survival (OS) in this disease population—hence the rationale behind

choosing PFS as a primary clinical endpoint. The authors in this case may still be interested in looking at OS since this is a more questionable endpoint that is less likely to be reached in this disease, making it more suitable as a secondary endpoint. The authors may wish to add other endpoints as well that will be labeled exploratory endpoints and added to the secondary endpoints. These may include, for example, assessing changes in cancer-related symptoms.

#### **9.4.5 SELECTION CRITERIA FOR PATIENT POPULATION: INCLUSION AND EXCLUSION CRITERIA**

In any clinical trial, including phase III trials, selection criteria for patient enrollment must be well defined. The purpose of this process is to clearly define the subset of the general population to be investigated in the trial. When determining these criteria, it is important to consider the possible effects that the intervention may have on the subjects and any possible side effects already known or possibly anticipated by the investigator. Other important factors include the ability of the subjects to understand the nature of the intervention and be able to give a valid informed consent. In addition, for studies in which effectiveness is an endpoint, subjects will need to undergo exams that would determine the effectiveness (or lack thereof) of the intervention.

Exclusion criteria are designed to protect subjects with an expected high risk of side effects from the intervention or examinations required by the study, and to prevent the inclusion of biases in the study by including patients with serious comorbidities that could impact the outcome of a phase III trial.

The inclusion or exclusion criteria are, therefore, the medical or social criteria based on which a person may or may not be allowed to enter a clinical trial. These criteria are based on factors such as age, gender, type and stage of a disease, and other medical conditions. Careful attention should be paid while writing the inclusion and exclusion criteria since poorly written criteria have resulted in a number of ineligible and inevaluable patients being enrolled to a study, as well as the unnecessary exclusion of patients who could have been successfully enrolled.

Before proceeding with writing the eligibility criteria for a phase III trial, the investigator should be aware of certain facts: Criteria that are poorly written may dictate a poor rate of accrual to the study and may undermine its scientific validity and the ability to generalize its findings. Eligibility criteria present one of the most important obstacles to accrual to phase III clinical trials. It is imperative when writing these criteria to avoid confusion and to be simple and clear. Problems with being too selective in the inclusion and exclusion criteria include being unable to generalize the findings, limiting patient accrual, and possibly increasing the cost of the study. The investigator should aim to keep the number of criteria listed to a minimum, keeping only those necessary for the validity of the study and for the preservation of patient safety.

The study should enroll sufficient participants to be able to determine whether the endpoints of the study are met but should not enroll greater numbers than are needed to achieve statistical significance.

Factors such as the characteristics of the disease, the availability of alternative interventions, the availability of participants, the study endpoints, and the desired precision of the outcome may all influence the desired number of patients to enroll.

#### 9.4.6 TRIAL DESIGN

The study design section of a phase III protocol should include sufficient information for the participating site to develop a comprehensive clinical algorithm for enrolled patients on all arms of the study. It usually describes in a stepwise fashion all procedures required by the study.

This section may include the following: a description of the initial evaluation of patients, the treatment plan for both arms of the study, the need to use certain procedures, information on the agent(s) to be used including the investigational agent(s) or other standard agents used in the treatment plan, dose scheduling, and dose modification of all agents.

In phase III clinical trials where it is imperative to compare a new modality with the considered standard of care (or with placebo when there is no established standard of care), some fundamental principles must be followed:

1. The groups must be alike in all important aspects and differ only in the intervention each group receives.
2. The concept of randomization implies that each participant has the same chance of receiving any of the interventions specified in the study.
3. The randomization (allocation process) is carried out using a chance mechanism so that neither the participant nor the investigator will know *in advance* which will be assigned.
4. An effort should be made to avoid conscious or subconscious influences. In designing a clinical trial, a sponsor must decide on the target number of patients who will participate. The sponsor's goal is usually to obtain a statistically significant result showing a significant difference in outcome.

The number of patients required to give a statistically significant result depends on the chosen endpoints of the trial. The larger the sample size or number of participants in the trial, the greater the statistical power. However, in designing a clinical trial, this consideration must be balanced with the fact that more patients will lead to a more expensive trial. Because of their large size and relatively long duration, phase III trials are the most expensive, the most time-consuming and difficult trials to design and run, especially in therapeutic trials addressing the treatment of chronic medical conditions. In determining the sample size, it would help to have information on the nature of the condition being treated, the desired precision of the outcome, some knowledge of the effectiveness of the intervention, the usual outcome of the studied patient population with current standards of care, and the availability of alternative treatments. It is important to make sure that the objectives and study design portion of the statistical section are identical to those described in the objectives section.

It is also imperative to pay attention to the definitions of toxicities in the statistical section. These should match those in the safety and adverse events section.

The advantages of a phase III design over other study designs is that randomization tends to result in comparable groups, which validates the statistical analysis of the data and renders the study more meaningful in addressing the effectiveness of the intervention in terms of patient outcome compared with phase I or phase II designs.

Limitations of phase III studies may possibly include the inability to generalize results to all patients with the same condition or disease because of preselection criteria imposed, as participants may not represent the general study population. Investigators may be faced with challenges in recruiting patients as randomization may be hard to accept by some.

Certain parameters may render a phase I or II study to be more appropriate for a certain investigational agent than a phase III trial. Factors such as lack of effectiveness of the standard of care, therapies that have not been well investigated, or an expected dramatic response may be better investigated in a phase II study.

In summary, when writing the study design section of a phase III protocol, attention to the following items is required:

1. Make sure that a statement of the primary and secondary endpoints to be measured during the trial is included.
2. Describe the design of the phase III trial, for example, double blind, placebo controlled, parallel design. A schematic diagram of trial design, procedures, and stages would also help.
3. Describe the measures taken to minimize/avoid bias including, for example, randomization or blinding.
4. Include a description of the intervention for all arms of the trial including the control arm. This needs to encompass dosage and regimen of the investigational as well as noninvestigational drugs. A description of the dosage form, packaging, and labeling of the investigational and noninvestigational product(s) must be included.
5. The expected duration of subject participation needs to be specified, and a description of the sequence and duration of all trial periods, including follow-up, needs to be well stated.
6. Make sure to include a description of the stopping rules in the statistical section or discontinuation criteria for individual participants.
7. Take measures to assure accountability for the investigational product and the placebo if this applies.

#### **9.4.7 STARTING DOSE AND DOSE MODIFICATION**

In a phase III trial, it is important to reiterate that the drug will be administered only to randomized patients. Once the study drug has been administered to an enrolled patient, this will continue until the discontinuation criteria have been met.

These criteria should have been specified in the design section and may include intolerable side effects, a documentation of progression of disease, significant deviation from the protocol (a protocol violation), noncompliance, or a patient's decision to withdraw (these items do not need to be respecified in this section).

Under this section, it is important to specify the route and schedule of drug administration on each of the phase III study arms. It is also important to specify the time of administration if deemed important by the investigator(s). For oral medications, it should be specified whether the drug should be taken with water and with or without food. For oral medications, a mechanism for patients to report missed doses should be in place and should be specified and described in this section (e.g., a diary card).

All anticipated drug-related events should be described in the protocol as well as the investigator's brochure (IB). The authors should be clear in describing the severity of the potentially reported events, as well as the clinical guidelines they will be using to decide on the appropriate management of any of these events. A table detailing the management of study drug modifications for all the anticipated and possibly nonanticipated drug reactions should be included. This should include side effects expected of the study medication but also should offer information on the drugs used in control arms of the study (i.e., the conventional standard of care agents).

Additional sections should detail the management of specific side effects. For example, how to clinically manage mouth sores in addition to dose modifications. Information should include the method to be used for diagnosis of certain side effects. For example, "pneumonitis is to be diagnosed by bronchoscopy if suspected."

Guidelines should specify when to resume the administration of the drug, what conditions need to be met for the resumption of the drug administration, and what dose to use for each of these conditions.

Dose modification guidelines and interruption guidelines should also be included for unanticipated events such as emergencies unrelated to the drug administration. Here, it is important to specify when is it acceptable to continue the drug and keep patients on the trial, if deemed appropriate (e.g., "within two weeks from the time of interruption").

A section on formulation of the drug(s), packaging, and labelling should also be included. Here all chemical ingredients of the drug in question should be specified. Information on storage and stability should also be given (temperature and expected shelf life of the product). This is not needed for drugs used in the control arm or drugs that are considered to be used as part of the standard of care.

Dispensing of the drug and dosing compliance is usually the pharmacy's responsibility and this should be specified. The site must use the appropriate dispensing and log accountability provided by the sponsor. These logs are to be maintained by the study pharmacist. The principal investigator or a delegate is responsible for discarding all unused study drugs, and this should be clearly stated in the protocol. During the trial and after termination, patients are responsible for returning all unused supplies and any missing items should be investigated. This also applies to study drugs on phase III trials and not conventional approved drugs for treating the disease in question.

### 9.4.8 EVALUATION OF DRUG EFFICACY: WORLD HEALTH ORGANIZATION (WHO) CRITERIA

For phase III clinical trials, the investigator must determine the frequency of evaluation of response. This depends on the disease being investigated and the new agent being introduced. For uniformity and to reduce biases, responses to an intervention may need to be reviewed by a single source. For example, a central review where imaging studies are submitted from different participating centers may be designated to assess tumor response to a novel anticancer drug.

For measurements of response to an anticancer drug, measurable lesions are defined as those that can be accurately measured in at least two dimensions. Attention should be made to certain factors. For example, tumor lesions that are situated in a previously irradiated area should not, in general, be considered measurable.

Other potentially nonmeasurable lesions may include small lesions [longest diameter <20mm with conventional techniques or <10mm using spiral computed tomography (CT) scan], bone lesions, leptomeningeal disease, ascites, pleural/pericardial effusions, lymphangitis, inflammatory breast disease, abdominal masses [not followed by CT or magnetic resonance imaging (MRI)], and cystic lesions.

In general, for assessing response, index lesions should be selected. This is done on the basis of their measurability in two dimensions and their suitability for accurate repeated measurements (by imaging techniques such as CT or MRI). A sum of the longest diameter (LD) and greatest perpendicular diameter of all index lesions will be calculated and reported as the baseline sum. The baseline sum will be used as a reference by which to characterize the objective tumor response. All other lesions (or sites of disease) including any measurable lesions over and above the index lesions should be identified as nonindex lesions and should also be recorded at baseline. Measurement of these lesions is not required, but the presence or absence of each should be noted throughout follow-up.

Evaluation of index lesions for phase I, II, or III clinical trials involve definitions of response, as set by the WHO or according to the RECIST criteria [2]. The WHO criteria follow.

#### **For Index lesions**

*Complete Response (CR)* Disappearance of all known disease, determined by two observations not less than 4 weeks apart.

*Partial Response (PR)* A > 50% decrease in the total tumor load of the lesions that have been measured to determine the effect of therapy not less than 4 weeks apart. The observations must be consecutive.

For single lesion, >50% decrease in tumor area (multiplication of longest diameter by the greatest perpendicular diameter).

For multiple lesions, a 50% decrease in the sum of the products of the perpendicular diameters of the multiple lesions. In addition there can be no appearance of new lesions or progression of any lesion.

*Stable Disease (SD)* A 50% decrease in total tumor area cannot be established nor has a 25% increase in the size of one or more measurable lesions been demonstrated.

*Progressive Disease (PD)* A >25% increase in the area of one or more measurable lesions or the appearance of new lesions.

### **For Nonindex Lesions**

*Complete Response (CR)* Complete disappearance of all known disease for at least 4 weeks.

*Partial Response (PR)* Estimated decrease in tumor area of >50% for at least 4 weeks.

*Stable Disease (SD)* No significant change for at least 4 weeks. This includes stable disease, estimated decrease of <50%, and lesions with estimated increase of <25%.

*Progressive Disease (PD)* Appearance of any new lesions not previously identified or an estimated increase of >25% in existent lesions.

**Duration of Overall Response** The duration of overall response is measured from the time measurement criteria are met for CR or PR (whichever is first recorded) until the first date that recurrent or progressive disease is objectively documented (taking as reference for progressive disease the smallest measurements recorded since the treatment started, best response scan).

The duration of overall CR is measured from the time measurement criteria are first met for CR until the first date that recurrent disease is objectively documented.

Duration of stable disease: Stable disease is measured from the start of the treatment until the criteria for progression are met, taking as reference the smallest measurements recorded since the treatment started.

**Placebo Effect** In a phase III clinical trial, a placebo may be used in one of the arms. A placebo is an inactive substance given to one group of participants, while the drug being tested is given to another group. A physical or emotional change, occurring after a substance is taken or administered, that is not the result of any special property of the substance is called a placebo effect, which may be beneficial, reflecting the expectations of the participant and, often, the expectations of the person giving the substance. The results obtained in the two groups are then compared to see if the investigational treatment is more effective in treating the condition than the placebo substance [1].

## **9.4.9 TOXICITY EVALUATION**

For phase I, II, or III clinical trials an adverse event (AE) is defined as any untoward medical occurrence in a patient or clinical investigation subject administered a pharmaceutical product that does not necessarily have a causal relationship with the treatment. An AE can therefore be any unfavorable and unintended sign (including an abnormal laboratory finding), symptom, or disease temporally associated with the use of a medicinal (investigational) product, whether or not considered related to the medicinal (investigational) product. Pre-existing conditions that worsen during a study are to be reported as AEs.

The descriptions found in the revised National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (CTCAE) version 3.0 will be utilized for AE reporting. All appropriate treatment areas should have access to a copy of the CTCAE version 3.0. A copy of the CTCAE version 3.0 can be downloaded from the Cancer Therapy Evaluation Program (CTEP) web site (<http://ctep.cancer.gov>).

In addition to the definition of AEs, the safety (or adverse events) section should encompass a list of adverse events expected with the use of each study drug.

If the phase III trial involves blinding, a description of the unblinding process should be included. In addition, the human subject protection section should be included as is the case in all clinical trials and should encompass a discussion of minority representation, the inclusion or exclusion of subjects who are vulnerable because of mental capacity, language barriers or other factors, and a description of the methods for patient recruitment.

An informed consent for a phase III trial should include the following according to the Office of Human Subjects Research (OHSR) [3]:

1. Comprehension of the information provided.
2. Disclosure of relevant information to prospective research subjects.
3. Voluntary agreement of the subject, free from coercion.
4. Statement that the study involves research.
5. Purpose of the research and the length of the study.
6. Description of risks and benefits.
7. Discussion of alternative therapies.
8. Confidentiality policy.
9. Compensation for injury.
10. Contact for further questions/information.
11. Statement of voluntary participation.
12. The use of simple language and the avoidance of technical words, while being thorough and complete. The avoidance of phrases that may be coercive. The insight of a patient's advocate may be very helpful in writing the consent.
13. The principal investigator should personally review the consent form thoroughly.

#### 9.4.10 PATHOLOGY

As in other clinical trial designs, in a phase III trial, it is imperative especially with cancer-related therapies to be specific as to which pathologic subtype of cancer is to be included in the study. The inclusion and exclusion criteria should specify what pathologic subtypes are admissible to the studies and which are to be excluded. The lack of this information could result in jeopardizing the study by including patients who have heterogeneous diseases with different clinical behaviors.

If the study is multiinstitutional, the investigators may choose to have the pathology slides reviewed by a central pathology team for independent confirmation of the tissue diagnosis. This, as is the case with radiology central reviews, will minimize the introduction of subjective biases. Any discordance between the central pathol-

ogy assessment and the investigator site should be a subject for discussion between the sponsors and the principal investigator.

If the study calls for correlative examination of blood samples or archival tissues, the protocol should specify the mechanism by which the tissue is collected from the different institutions and consenting patients. It also helps to guide the participating institutions about the preferred tissue processing methods, for example, whether it is preferable that archival specimens be formalin fixed, or, if a block is not available, what is required, for example, a specified number of unstained slides to help determine a certain tissue marker. This entails a close coordination between the investigators, the central pathology labs, and the different pathology departments of participating centers.

It is strongly advisable for large phase III or multiinstitutional trials that a laboratory manual detailing the procedure of collection of material including archival material or whole blood specimens from participating patients, and shipping of the material be included as a separate document in the protocol.

#### 9.4.11 STATISTICAL CONSIDERATIONS

Given the complex nature of large clinical trials, a well-versed biostatistician is an integral part of the study design team and should be consulted in the initial planning stages. Although the study statistician will complete the statistical section of the trial protocol, investigators must have a basic understanding of the concepts involved.

##### 9.4.11.1 Hypothesis

As with any well-designed scientific experiment, phase III clinical trial investigators must begin with a hypothesis, defined as a supposition that appears to explain a group of phenomena and is advanced as a basis for further investigation [4]. The investigators must then design a trial to test the hypothesis.

In order to test a hypothesis, one must first state the null hypothesis ( $H_0$ ), which is defined as a statement that there is no difference between a standard and experimental treatment. The alternative hypothesis ( $H_1$ ) is a statement that there is a difference between a standard and experimental treatment [5]. If data from a clinical trial reject the null hypothesis, then the alternative hypothesis is proven true. There are three general rules when stating  $H_0$  and  $H_1$ :

1. The null hypothesis is the hypothesis of “no difference.”
2. Whatever is to be detected or supported should be the alternative hypothesis.
3. Statistical hypothesis are always set up in the hopes of being able to reject  $H_0$  and thereby accept  $H_1$ .

An example would be that a drug company has developed a new chemotherapy for pancreatic cancer, which it feels has a greater than 50% chance of shrinking tumors. If RR denotes response rates then:

$$H_0: RR \leq 50\%$$

$$H_1: RR > 50\%$$

Once a clinical trial is completed, the investigators must analyze the available data to make a determination on whether the data support  $H_0$  or  $H_1$ . Errors in reaching a conclusion from clinical trials can and do occur. When they occur, two types of errors that can be made are:

1. Type I error—rejecting the null hypothesis when it is actually true;  $\alpha$  is the probability of making a type I error.
2. Type II error—not rejecting the null hypothesis when it is false;  $\beta$  is the probability of making a type II error.

#### 9.4.11.2 Sample size

The number of patients to be enrolled to reach a statistically meaningful answer at the conclusion of a clinical trial is based upon the assumptions made during the planning stages of the trial.

#### 9.4.11.3 Power

Power is defined as the probability of rejecting the null hypothesis when it is indeed false or, conversely, accepting the alternative hypothesis is true when it really is true. In other words, the probability of obtaining a statistically significant result is known as the “power” of a trial. A general rule regarding power calculations of clinical trials is that as the number of planned subjects enrolled in a clinical trial increases, the power of the study increases as well. Conversely, the smaller the planned number of subjects accrued to a clinical trial, the bigger the difference between the standard and the experimental arms must be to demonstrate a statistically significant difference. Generally, the sample size of most phase III trials is adjusted to a power of either 0.80 or 0.90, assuming a difference between the standard and experimental arms is the smallest considered clinically meaningful.

#### 9.4.11.4 P Values

The  $P$  value is the probability of obtaining by chance a result at least as extreme as that observed, even when the null hypothesis is true and no real difference exists [4].

Alternatively, the  $P$  value can be thought of as the probability that the observed result is due to chance alone. Generally,  $P$  values  $<0.05$  are considered significant. The  $P$  value is calculated after the statistical test has been performed; if the  $P$  value is less than  $\alpha$ , the null hypothesis is rejected.

#### 9.4.11.5 Randomization

In clinical trials there are many sources of biases, ranging from physician judgments to patient self-selection, to referral patterns, all of which may skew data. Randomly

selecting trial subjects for either control versus experimental treatment is an effective way to minimize biases [6–10]. It is important to note that randomization does not completely remove all biases, but rather minimizes their effect on overall study results. Some investigators have argued that randomization is not absolutely necessary in all cases as matched historical or current controls can be identified. However, matching can only be performed with respect to known factors, and most investigators would agree there are many more unknown variables that cannot be accounted for in the study design. Thus without a randomization, a “statistically significant result” may be the result of a nonrandom difference in the distribution of unknown prognostic factors. Generally, for phase III clinical trials, which are large and costly to perform, randomization is a necessity to minimize the possibility of obtaining a nonmeaningful result.

There are many ways to randomize subjects, each with their respective advantages and disadvantages.

#### **9.4.11.6 Stratification**

In the case of known prognostic factors, stratifying subjects at the time of randomization may improve overall results as the study is more likely to be comparing two similar population vurses two populations that are skewed with an overabundance of a particular group. This can be accomplished by creating separate randomization lists for each stratum. For example, a clinical trial investigating a new agent in unresectable or metastatic pancreatic cancer with overall survival as the primary endpoint should prospectively stratify patients based upon locally advanced disease or metastatic disease as these two patient populations have known different survival. Otherwise, the study results may be uninterpretable due to a mixture of two patient populations with different expected survival estimates.

#### **9.4.11.7 Blinding**

Trials set so that participants do not know which intervention they are receiving are known as single-blinded trials. Those in which neither researchers nor participants know who is in the investigational or control group are called double-blinded trials. Double-blinded trials ensure that people assessing the outcome will not be influenced by knowing which intervention a participant is receiving and also that ancillary follow-up treatment will be the same.

#### **9.4.11.8 Interim Analyses**

Interim analyses are commonly performed in phase III clinical trials to evaluate current data and determine if a difference between the standard and experimental arms are sufficient enough to warrant premature disclosure of study results. Much controversy surrounds utilizing interim analysis data for stopping trials prematurely for efficacy. Supporters argue if a significant benefit of an experimental treatment is seen, why withhold treatment that may benefit patients; while detractors would argue that given more time the differences in the two treatments may vanish and stopping a trial would prevent fully evaluating the alternative hypothesis. In the setting of an interim analysis demonstrating significantly inferior results from an

experimental treatment, supporters would want to stop that trial from exposing trial subjects to an inferior experimental arm, while detractors would argue in favor of continuing the trial as the differences between the standard and experimental arms could potentially lessen or even reverse if the trial is permitted to run its full course.

In addition to ethical concerns, interim analyses also have potential biostatistical drawbacks. Fleming and colleagues reported that if interim statistical significance tests are performed every 3 months on a study planned for 3 years, the probability of reaching a statistically significant result prematurely can be as high as 26% [11]. This error is known as the type I error of the analysis plan. Therefore, in order for an interim analysis to be valid and useful, the analysis should be preplanned and not occur too frequently.

To minimize the potential negative impact of premature results influencing patients and trial investigators, phase III trials should have a data-monitoring committee (DMC) consisting of experienced research personnel [12, 13]. Due to potential conflict of interest issues with investigators and continuation of the trial, interim results are usually not shared with investigators unless the trial DMC authorizes release of the data. There are several different statistical designs for planning interim analysis [10, 14–16]. Haybittle and colleagues' method involves discounting interim differences unless the difference is statistically significant at the two-sided  $P < 0.0025$  level. If the interim differences are not significant at that level, the trial continues until its originally intended size. Other methods have a predetermined number of planned interim analyses and the  $P$  value that is used to determine statistical significance depends on the number of analyses performed during the trial.

#### 9.4.12 DATA-MONITORING COMMITTEE

Data-monitoring committees (also known as data safety monitoring boards) consist of a group of individuals with various areas of expertise charged with overseeing the conduct of a clinical trial in terms of safety and efficacy. Not all phase III trials are required to have a DMC, as in the case of low-risk trials. However, the majority of therapeutic trials will have a DMC. Depending on the sponsor and the trial, DMC membership and responsibilities will differ.

The U.S. Food and Drug Administration (FDA) defines a clinical trial DMC as:

A group of individuals with pertinent expertise that reviews on a regular basis accumulating data from one or more ongoing clinical trials. The DMC advises the sponsor regarding the continuing safety of trial subjects and those yet to be recruited to the trial, as well as the continuing validity and scientific merit of the trial. When a single DMC is responsible for monitoring multiple trials, the considerations for establishment and operation of the DMC are generally similar to those for a DMC monitoring a single trial, but the logistics may be more complex. [17]

Data-monitoring committees came into use in the 1960s. They were first utilized in large randomized multicenter trials sponsored by the federal government. The first DMC was formed as a result of an NIH external advisory group. This DMC was charged with monitoring the safety, efficacy, and trial conduct of several National

Heart Institute trials [18]. Current DMCs operate based upon the decades of experience gained since the first DMC [19]. Recently, the use of DMCs has grown in popularity. Due to issues related to conflict of interest and the use of mortality endpoints, integration of DMCs into industry-sponsored trials has been increasing.

Some governmental agencies that sponsor clinical trials may require DMCs for certain trials; however, the U.S. FDA does not currently require the use of DMCs except for research studies in emergency settings in which informed consent requirement is exempted. There are no absolute criteria for requiring a DMC, but generally accepted situations are a controlled trial of any size that will compare rates of mortality or major morbidity.

The composition of a DMC is critical; a poorly constituted DMC may put study subjects' lives at risk and also risk the scientific validity of a trial. Criteria commonly used in selecting members are:

1. Relevant experience in area of study
2. Experience on other DMCs
3. Absence of conflict of interest

Data-monitoring committees usually consist of clinicians with expertise in the area of interest and at least one biostatistician with experience with the statistical methods utilized in the trial being monitored. Depending on the trial, other potential members may include medical ethicists, toxicologists, epidemiologists, pharmacologists, or other individuals with potential interest or experience in the area of study. Ideally, members of a DMC should have no relationship to the study sponsors or investigator. In reality this is nearly impossible since members of a DMC are usually selected or nominated by the study sponsors or investigators.

In addition, DMCs should have an established charter describing the duties of the DMC prior to initiation of a study. Important components of the charter should include:

1. Meeting schedule and format (telephone versus face to face).
2. Meeting structure—ideally DMC meetings should be closed to all study sponsors and investigators, but the FDA does allow interaction between the DMC and study investigator/sponsors to clarify issues that may arise during a review.
3. Outline format of interim data to be presented to the DMC.
4. Study plan for interim analysis and stopping rules for futility for superior efficacy.

Although there are potential benefits to be derived from participation in clinical research, the investigational review boards (IRBs) and the NIH must ensure, to the greatest extent possible, the safety of study participants, that they do not incur undue risk and that the risks versus benefits are continually reassessed throughout the study period. Every clinical trial should have provision for data and safety monitoring. A variety of types of monitoring may be anticipated depending on the nature, size, and complexity of the clinical trial. In many cases, the principal investigator would be expected to perform the monitoring function [20].

### 9.4.13 CORRELATIVE STUDIES

Secondary endpoints can lead to meaningful trial results, in particular, laboratory or pathology correlatives are useful. Specimens can be obtained during the period of study enrollment and then banked for future use. Certainly, preplanned laboratory or pathological correlative studies can be fruitful, but saved specimens can prove to be invaluable for future study should new information become available or new scientific techniques are developed. The general process for evaluating the usefulness of correlative studies includes:

1. Identifying a clinical hypothesis
2. Identifying the laboratory parameters that may be influenced by the clinical treatment
3. Identifying the correlative hypothesis

An example of the utility of correlative studies is the International Adjuvant Lung Cancer Trial (IALT). This trial was designed to evaluate the effect of cisplatin-based adjuvant chemotherapy on survival after complete resection of non-small-cell lung cancer (NSCLC) [21]. Two years after the publication of the IALT results, Olaussen and colleagues hypothesized that expression of excision repair cross-complementation group 1 (ERCC1) protein could predict survival from cisplatin-based adjuvant chemotherapy in NSCLC as there is a significant amount of *in vitro* data supporting the rationale of platinum resistance to the expression of the ERCC1 messenger RNA (mRNA) in cell lines. In order to carry out their analysis, the investigators obtained 761 tumor specimens from IALT subjects and evaluated the expression of the ERCC1 protein. In the end, the investigators concluded, “patients with completely resected non-small-cell lung cancer and ERCC1-negative tumors appear to benefit from adjuvant cisplatin-based chemotherapy, whereas patients with ERCC1-positive tumors do not” [22].

An example of a prospectively designed study to bank tumor specimens is the Eastern Cooperative Oncology Group study E3200. The purpose of E3200 was to evaluate response, time to progression, and overall survival of patients with advanced colorectal cancer who have failed therapy with irinotecan and 5-fluorouracil when treated with oxaliplatin and fluorouracil with or without bevacizumab or bevacizumab alone. There were no preplanned correlative studies to be performed on the tumor specimens, but the investigators utilized the study as an opportunity to collect biologic samples prospectively for future use. One can imagine that these specimens could be analyzed at a later date to search for a biomarker of response as a wealth of clinical data for each patient was also prospectively collected during the clinical trial.

### 9.4.14 ADVERSE EVENT REPORTING

The timely reporting of adverse events that occur during the conduct of a trial is highly critical in order to maximize subject safety. Potential adverse events due to an experimental treatment under investigation must be quickly disseminated to all

study investigators so as to alert all study-related personnel to possible events and minimize future adverse events.

The International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) was convened to bring together experts from the pharmaceutical industry and the regulatory authorities of Europe, Japan, and the United States to discuss scientific and technical aspects of product registration. The overall purpose of this conference was to make recommendations to allow uniform interpretation and application of technical guidelines for product development across the world in order to minimize duplicate testing of new products. ICH defined the following terms to clarify terminology used for drug event reporting:

Adverse event (AE) is defined as “any untoward medical occurrence in a patient or clinical investigation subject administered a pharmaceutical product and which does not necessarily have to have a causal relationship with this treatment” [23]. An AE can therefore be any unfavorable and unintended sign (including an abnormal laboratory result), symptom, or disease temporally associated with the use of a medicinal product, whether or not considered related to the medicinal product.

Adverse drug reaction (ADR) is defined as “a response to a drug which is noxious and unintended and which occurs at doses normally used in man for prophylaxis, diagnosis, or therapy of disease or for modification of physiological function” [23].

Serious adverse event (SAE) is defined as “a serious adverse event (experience) or reaction is any untoward medical occurrence that at any dose:

- Results in death
- Is life-threatening” [23]

Several mechanisms have been put in place by the FDA as well as other governing bodies such as the NCI. In the case of industry-sponsored studies, the sponsor is expected to collect all adverse event data and disseminate to all study sites to alert of potential adverse events.

MedWatch, is a FDA safety information and adverse event reporting program that serves both health care professionals and the medical product-using public. The FDA receives adverse drug reaction reports from manufacturers as required by regulation. Health care professionals and consumers can voluntarily send reports through the MedWatch program as well. These reports become part of a database. The ICH has issued guidance to facilitate the standardization of the data elements for the transmission of individual case safety reports regarding safety reporting (ICH E2B), which describes the content and format for the electronic submission of reports from manufacturers.

The FDA codes all reported adverse events using a standardized international terminology, MedDRA (the Medical Dictionary for Regulatory Activities), then uses this data to monitor for potential unforeseen toxicities. The data collected through the MEDWatch program is then incorporated into the Adverse Event Reporting System (AERS), which is a computerized information database designed to support the FDA's postmarketing safety surveillance program for all approved drug and therapeutic biologic products. The ultimate goal of AERS is to improve

the public health by providing the best available tools for storing and analyzing safety reports.

The CTEP branch of the National Cancer Institute utilizes a Web-based system for the electronic submission of expedited reports on protocols utilizing a CTEP-sponsored investigational new drug (IND) known as the Adverse Event Expedited Reporting System (AdEERS) to rapidly collect and disseminate clinical-trial-related adverse events [24].

#### 9.4.15 APPENDICES (USUAL ITEMS)

An appendix contains information that is nonessential to the understanding of the clinical trial protocol but may further clarify points without burdening the body of the protocol. Each appendix should be identified by a Roman numeral in sequence, for example, Appendix I, Appendix II, and so on. Each appendix should contain different material.

Appendices should include but are not limited to:

1. Informed consent form
2. Guidelines for study-related procedures not written in the body of the protocol such as:
  - a. Pathology submission guidelines and instructions
  - b. Correlative laboratory processing guidelines
3. Any additional instructions that are to be given to the study subjects

#### 9.4.16 INFORMED CONSENT FORMS AND HIPAA

For trials subject to the requirement of the U.S. FDA, which would be virtually all phase III clinical trials, the informed consent form (ICF) must meet the requirements of Title 21 of the Code of Federal Regulations, chapter 50 [25]. The Code of Federal Regulations (CFR) is the codification of the general and permanent rules published in the *Federal Register* by the executive departments and agencies of the federal government. It can be access at <http://www.gpoaccess.gov/cfr/about.html>. Chapter 50 covers the rules governing the protection of human subjects. Each ICF must also contain the six elements listed in 21 CFR 50.25(b) that are determined to be appropriate for a study. However, the IRB governing the study has the final authority for ensuring the adequacy of the ICF. In addition, the IRB may also impose additional requirements not listed in 21 CFR.

To improve the approval process of a multiinstitutional trial sample or draft consent, documents should be developed that each study site may alter to satisfy local IRB requirements. During the course of a study, many changes and amendments are likely to be made to the protocol as well as the ICF. In order to minimize confusion of multiple versions of ICFs, version numbers and IRB approval dates should be labeled on each version of the ICF approved.

**21 CFR 50.20: General Requirements for Informed Consent** Language in the ICF must be written in simple and easy to understand terms, as the vast majority of

study participants are not likely to possess medical knowledge sufficient to comprehend the risk and benefits involved in a modern-day clinical trial. 21 CFR 50.20 states the following:

Except as provided in §50.23, no investigator may involve a human being as a subject in research covered by these regulations unless the investigator has obtained the legally effective informed consent of the subject or the subject's legally authorized representative. An investigator shall seek such consent only under circumstances that provide the prospective subject or the representative sufficient opportunity to consider whether or not to participate and that minimize the possibility of coercion or undue influence. The information that is given to the subject or the representative shall be in language understandable to the subject or the representative. No informed consent, whether oral or written, may include any exculpatory language through which the subject or the representative is made to waive or appear to waive any of the subject's rights, or releases or appears to release the investigator, the sponsor, the institution, or its agents from liability for negligence.

**Non-English-Speaking Subjects** In the case of subjects who do not possess a sufficient grasp of the English language to critically evaluate an ICF, a translated ICF document in the native language of the potential study subject should be presented. While a translator may be used intermittently, translators should not be used routinely due to potential variations between individual translators. In addition, local IRBs may have additional rules regarding foreign language ICFs; as such, investigators should consult with the local IRB before proceeding to translate an ICF since this is an expensive procedure.

In the event of an illiterate subject, provided the subject is able to (1) retain the ability to understand the concepts of the study and evaluate the risk and benefit of being in the study when it is explained verbally and (2) is able to indicate approval or disapproval to study entry, they may be entered into the study. To further validate the consenting process of an illiterate individual, it is also suggested to have an impartial third-party witness as well as videotaping the entire consent process.

**Assent of Children** Guidelines for ICFs regarding children are not specifically addressed in the 21 CFR; instead the FDA defers judgment to the IRB overseeing the particular study. For children old enough to read and comprehend, many IRBs require signatures from both the parents and the child before study entry.

### **21 CFR 50.25: Elements of Informed Consent**

- (1) A statement that the study involves research, an explanation of the purposes of the research and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures which are experimental.

The ICF must explicitly state that the purpose of a clinical trial is research as the relationship between a patient–physician is different than that between a trial participant–investigator.

- (2) A description of any reasonably foreseeable risks or discomforts to the subject.

The risks of the trial must be explicitly stated in the ICF. Many IRBs will also require quantification of risks, that is, the expected percentage of patients who are likely to experience a side effect such as nausea or diarrhea.

- (3) A description of any benefits to the subject or to others which may reasonably be expected from the research.

The potential benefits of a trial must be stated as a possible benefit and not be overstated as a likely event. Common phrases used in ICFs include “this trial may or not benefit you directly, but may help other people with the same medical problem as you.”

- (4) A disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject.

The ICF must offer alternative choices to the patient if available.

- (5) A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained and that notes the possibility that the Food and Drug Administration may inspect the records.

The ICF must contain a statement explaining the confidentiality of the subject’s medical records as they relate to the study and also state who may have access to the subject’s medical records such as the FDA, IRB, or study sponsors.

- (6) For research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs and, if so, what they consist of, or where further information may be obtained.

The ICF must contain a statement regarding compensation if any will be provided. The ICF must also explain whether there is compensation available in case of injury but must not waive or appear to waive the rights of the subject. Acceptable language includes “no funds have been set aside for,” “[the cost] will be billed to you or your insurance.”

- (7) An explanation of whom to contact for answers to pertinent questions about the research and research subjects’ rights, and whom to contact in the event of a research-related injury to the subject.

The ICF must clearly state who should be contacted in the event of questions that arise regarding study participation. Generally, the contact person listed should be the principle investigator at a study site.

- (8) A statement that participation is voluntary, that refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and that the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled.

The ICF must clearly state that participation in a study is voluntary. Common phrases used include “you may participate in this trial if you wish. Your decision to participate in this trial will not affect your care. The options to the trial are \_XXXX\_. You and your physician can discuss these options and you must decide what is best for you.”

The following are additional required elements of an ICF when applicable:

- (1) A statement that the particular treatment or procedure may involve risks to the subject (or to the embryo or fetus, if the subject is or may become pregnant) which are currently unforeseeable.
- (2) Anticipated circumstances under which the subject’s participation may be terminated by the investigator without regard to the subject’s consent.
- (3) Any additional costs to the subject that may result from participation in the research.
- (4) The consequences of a subject’s decision to withdraw from the research and procedures for orderly termination of participation by the subject.
- (5) A statement that significant new findings developed during the course of the research which may relate to the subject’s willingness to continue participation will be provided to the subject.
- (6) The approximate number of subjects involved in the study.

**Health Insurance Portability and Accountability Act (HIPAA)** In 1996, the Department of Health and Human Services (HHS) established national standards for electronic health care transactions and national identifiers for providers, health plans, and employers as a result of the administrative simplification provisions of the Health Insurance Portability and Accountability Act (HIPAA) [26]. These standards seek to prevent the misuse of confidential medical information. Penalties for breaking HIPAA regulations are severe (see below), as such investigators and IRBs must make sure to be HIPAA compliant. Penalties for HIPAA infractions are:

- (a) Be fined not more than \$50,000, imprisoned not more than 1 year, or both.
- (b) If the offense is committed under false pretenses, be fined not more than \$100,000, imprisoned not more than 5 years, or both.
- (c) If the offense is committed with intent to sell, transfer, or use individually identifiable health information for commercial advantage, personal gain, or malicious harm, be fined not more than \$250,000, imprisoned not more than 10 years, or both.

#### 9.4.17 CLOSING

Designing and implementing phase III clinical trials is a highly complex undertaking that requires good collaboration among all members of a well-trained multidisciplinary team. Involvement of the multidisciplinary team should be encouraged as early as possible in the design and conceptualization stage of protocol development. As with any scientific experiment, obstacles to the activation and implementation

of phase III trials will undoubtedly occur; however, well-written and designed trials will help to complete the study in a timely fashion.

## 9.5.1 INTRODUCTION

### 9.5.1.1 Life of a Drug

The development of a drug has many aspects in common with the raising of a child. Both processes take place in typical phases that follow an unalterable order. The next stage is generally only attainable after the previous stage has been completed. Preclinical development may be seen as the embryonic stage, the first intake of the drug as the moment of birth. This moment bears special risks that cannot be foreseen even by ideal preclinical work. “Birth deformities” of the drug may become apparent only after a few human beings have been exposed. Fortunately, such observations are not frequent since the dosage will be kept low at the beginning and then increased only in small steps, analogous to the steady and rapid growth of a neonate. Phase I can be seen as the early childhood, where the drug is tested in healthy subjects in a protected environment under ideal conditions and the constant monitoring of the producers (parents) and specially trained experts charged with tending to the “education” and “socialization” of the product. Phase II is the first systematic contact with patients. For the first time, performance is demanded, and thus this phase parallels the time in school. From now on, failures have consequences. However, some kind of adaptation is allowed as far as the potential of the new drug is concerned. The ultimate indication and dosage are not yet defined and may be adapted to new experiences as the talents of the child are detected and subsequently supported and promoted. However, at some time (at the passage from phase II to phase III) the intended use of the drug has to be determined, and in phase III the drug has to prove its ability to attain the therapeutic goals for which it was presumed qualified. This point in time resembles the moment when a decision is made on the future career or field of specialization. The evaluation of the phase III trial(s) resembles the final examinations, and the licensing of a drug is the equivalent of the degree that entitles the holder to practice a particular profession.

Many people think that with the awarding of some kind of certificate for vocational or professional qualification and the first “real” employment, that children are grown-up and no longer require their parents’ care. But any parent who has had the pleasure of bringing a child this far along the path to maturity knows that is not really the case because the personal life as well as professional careers are still full of challenges, competition, and risks. Support is further required, but not only requested and given by the parents who usually have a personal interest in the well-being of their now grown-up child, but also by friends and family members.

Likewise, many people think that with the licensing of a pharmaceutical the research investment has or should come to an end, and that the marketed drug

should just be used as it was licensed in order to earn money for its producers. But as is the case for any grown-up child, a drug faces competition, has to adapt to new environments and changing demands, may fail in certain situations, and has to be defended against suspicions and accusations. What is more, information is needed and has to be provided on many aspects and has to be propagated to the public. Thus, continuing critical support is needed and will be given not only by the producers but by many other parties such as government, funding institutions, researchers, health insurances, patient organizations, and the media. Thus, there is a need and a demand for postmarketing trials of a drug, justifying the introduction of another phase, namely phase IV, for this kind of study, and this demand is met more and more frequently as we all become more and more aware of the intricate challenges with which a “grown-up”, that is, a licensed drug has to contend.

However, unlike the premarketing phases, in phase IV there is no standard approach, no definite order of study sequence, no unique methodology, nor any agreement on optimality. Instead, there is a still growing diversity of study types, organizational forms, funding models, regulatory guidelines and recommendations, and a rich and complex scientific as well as public debate on licensed drugs.

### 9.5.1.2 Chapter Overview

In this chapter, a broad overview is provided on the wealth of methodological approaches to phase IV trials. After definition and an overview of the objectives, each approach is presented separately, including the motivation behind it, the standard design, the challenges one has to meet during conduct, the standard evaluation procedure, the interpretations and common misinterpretations, and the limitations of the approach, shedding light on the place of the approach in the concert of phase IV studies. Phase IV studies on statins, on the use of antibiotics for coughs, and on the safety profile of oral contraceptives will serve as examples. The chapter ends with a summary of the options for phase IV trials and the decisions that have to be met in the planning stage of a phase IV trial by sponsors and investigators.

### 9.5.1.3 Commitment of Phase IV

The life of an individual human being inevitably ends with death. At first glance this might not seem to be so inevitable for a drug, but, although its life time is not biologically limited, it is useful to think of a drug's life as finite. A drug may be well known, have a large market share, and may even be identified with its substance class; nevertheless, it is always at risk of being topped by a better (i.e., more effective, more easily administered, more tolerable, or safer) drug, or by a cheaper drug, or by a drug that is simply better promoted or more fashionable. It may be frivolously accused of serious adverse reactions or it may be superfluous because the disease is conquered, for instance, by a new vaccine. Like human beings, a drug may die from an accident, that is, is withdrawn from the market because of safety concerns, but usually it gradually loses its dominance; it remains on the market but exists only in a niche (a kind of “retirement”) and disappears some day without many people noticing it, possibly because it is no longer economically viable. It may survive in another form, as a generic or as part of a combination, but the patent and brand name, its identifying characteristics cease to exist.

In summary, with a few exceptions, a drug can, and certainly will, die at some indefinite future date. Undoubtedly, the death will be a severe loss not only for the producers but also for the community since the deep knowledge of the drug gained by experience over an abundance of years of application collected in phase IV studies will at least in part die with the drug. After all, an established drug therapy provides stability and confidence, like an old friendship where you know the strengths and weaknesses of the friend and have learned to live with them. Does this mean that phase IV research is futile or pointless? Should we refrain from any post-marketing research, enjoy the licensing success, and avoid the unavoidable risks of any medical research? Quite the contrary is the case. If we do not study drugs in the market, we are in danger of being surprised by speculations that can be neither proven nor rebutted, and nevertheless can end the life of a drug by ruining its image. Lipobay and Vioxx [1] and Waxman [2] are prominent examples of this. What is more, we may miss opportunities for the use of a drug that may never come to light, and this may shorten its lifetime. A series of trials with different approaches is thus not only recommendable for medical and economic reasons but an ethical commitment for manufacturers, scientists, and society alike and thus not only be taken seriously but encouraged.

## 9.5.2 DEFINITION

A phase IV trial is a clinical study where the investigational therapy includes the use of a licensed drug in the approved indication. (Studies of a licensed drug in a new indication are usually referred to as phase IIIb trials.) The term *trial* is usually reserved for studies where the drug under investigation is administered for study purposes. In a strict sense, observational studies on routine use or medical registers are not covered by this definition. Nevertheless, the term *clinical trial* is sometimes used somewhat more loosely for clinical studies in general. In this chapter, we will reserve the term *trial* for interventional studies. It should, however, be noted that this chapter will cover other approaches as well in order to give a more complete account of the diversity of options covered by the concept *phase IV study*.

## 9.5.3 OBJECTIVES

### 9.5.3.1 Starting Point of Phase IV

At the end of phase III/beginning of phase IV, there is already a considerable body of knowledge about a drug. The proof of principle was given in phases I and II. Phase II/III added some knowledge on dosage and application. From phase III we know that the drug works in a variety of clinical settings and is able to improve clinical relevant endpoints.

On the other hand, the knowledge of the drug at the time of market introduction will always be limited in some sense due to the legal restrictions, economic considerations, and the primary targeting of approval. Up to phase III, the application of the drug has taken place under the conditions of controlled trials, that is, under

steady observation and quality control, in environments that were fully aware of the research motivation behind the application, and with strictly controlled inclusion and exclusion criteria defined in order to receive a homogenous study population to minimize the risk of a negative result. In many phase III trials, the criteria are so cautiously defined that only a small percentage of the future users of the drug can be included, resulting in study populations that are not representatively selected. At the time of licensing, we only have experience on the application of a drug in a very specific population, for a limited range of doses, under absolutely ideal circumstances, and in a number of patients too small to address less frequent complications and safety concerns that nevertheless may become very relevant if the exposure to the drug is extended for routine care of patients.

### 9.5.3.2 Open Issues

Correspondingly, optimization of use and safety concerns are the most prominent reasons for conducting postmarketing trials. Just recently, questions of the financial balance have joined the club and sometimes even dominate, starting as add-ons to clinical study projects and then becoming an independent research area. The more traditional form of studies aiming at economic aspects consists of marketing trials that address the propagation and use of a drug. These studies are frequently suspected of being undertaken predominantly for the purpose of propagation by merely performing the study and not for research purposes. This suspicion indicates that there may be a conflict of interest between different study objectives in phase IV. Conflicts of interest are a minor concern in phases I–III but are rather typical for phase IV studies where the scope of research questions is broader and more stakeholders with potentially different interests are participating in the research process.

### 9.5.3.3 Study Objectives in Phase IV

Table 1 gives an overview of common study objectives in phase IV, organized according to the four main research areas of phase IV. Optimization of use is required since many decisions made in phases I–III were taken for the purpose of gaining a license for the drug. Thus, only the most promising formulations and dosages are developed and tested in a targeted study population. What is more, the decisions in phases I–III were based on experiences from small samples that were not necessarily conclusive in nature. A further process of fine-tuning is therefore desired and should be based on a solid empirical base, big enough to allow even sophisticated considerations. The first six objectives belong to this category. Furthermore, the prelicensing trials were powered for overall evaluations. But patients' reactions to a drug may vary considerably, and thus an adaptation of the therapy to different subgroups of patients and several influences on drug efficacy are required and necessitate further studies, as the other objectives of this section demonstrate.

Safety issues are critical for the life of a drug. At the time of licensing, the finalized trials have had optimal power for the proof of efficacy. However, the power of the complete database is usually far too small to draw reliable conclusions about

**TABLE 1 Objectives of Phase IV Studies**

| <i>Optimization of Use</i>           |                                                                                                                                            |

| Eco-03                               | Economic evaluation of complex therapeutic therapies that incorporate the use of the drug                                                  |
| <i>Marketing</i>                     |                                                                                                                                            |
| Mar-01                               | Accompanying and assisting the transition from clinical development to marketplace                                                         |
| Mar-02                               | Demonstration and implementation of the proper use of the drug                                                                             |
| Mar-03                               | Investigation and improvement of the compicance of physicians as well as of patients                                                       |
| Mar-04                               | Acceptance and performance of the drug in different markets, e.g., changes due to a switch from prescription to over-the counter marketing |
| Mar-05                               | Exploration of convenience of application, patient satisfaction, effects on quality of life                                                |

safety issues. This is not only due to the fact that serious adverse events are in most cases rare and may appear with some delay but also because the random fluctuation in the normal population, the treated disease itself and other medication and treatment will result in adverse events that may or may not be caused or aggravated by the drug under study. Extreme sample sizes are required to detect and validate adverse drug reactions caused by a drug in the presence of a natural background of events. Thus, other approaches in addition to randomized trials are required to address these issues, for purely economic reasons. Nevertheless, this kind of evaluation is mandatory since the public is extremely reluctant to accept even small safety risks for the sake of an average benefit in the patient population. The main reason for this reluctance presumably is the fact that a serious adverse event is always personal, while the benefit of a drug is statistical and anonymous. Thus, risk–benefit calculations do not dispense manufacturers from the commitment to meticulously search for each case when a drug might have caused harm. The objectives under the corresponding heading in Table 1 demonstrate how many different aspects of safety have to be addressed in one way or the other as soon as a drug is on the market.

Health economic studies traditionally investigate cost–benefit balances and the cost effectiveness of a drug. The limited availability of funds drives the increase in the number of such studies in phase IV. Economic studies usually require bigger sample sizes and other evaluation methods than clinical trials. Hence, economic evaluations accompanying phase III trials are usually not sufficient, and planned phase IV studies are required. Increasing competition in health markets let people ask for more direct head-to-head comparisons between therapies that help to define the place and potential function of a drug in the health care environment. While the two upper objectives in that section aim at a drug-related evaluation, more and more people take the perspective that the utility of drugs has to be judged according to their contribution to complex interventions in the health system. A statin, for instance, may be studied for its cost effectiveness (Eco-01) (see Table 1); it may be studied in direct comparison to another statin or a different lipid-lowering therapy (Eco-02), or as part of a multiway lipid-lowering program for a certain target population (Eco-03).

Marketing begins with the transition from clinical development to the marketplace. It is useful to accompany this process with a scientific evaluation. However, studies for market introduction are frequently understood as opportunities to promote the drug to physicians and patients as yet unfamiliar with the substance, making the study something akin to advertisement. The scientific aspect of the study may thus be compromised, the more so if the study is explicitly performed for the purpose of the demonstration and establishment of study drugs in the market. While these two study objectives are frequent in phase IV, they are not generally accepted by the scientific community as part of research. The scientific portion plays a greater role in compliance studies, in studies on the performance of the drug under different distribution regimes, and in the evaluation of patients' experiences and opinions when applying the drug. These three objectives are sometimes undervalued. In fact, availability, compliance, and patients' satisfaction may contribute considerably to the success of a theoretically useful drug in a certain health care setting and thus may be very important for all health system participants in order to actually reap the potential benefit of a new drug.

## 9.5.4 APPROACHES

The diversity of objectives in phase IV is reflected by a diversity of approaches. This section describes 10 approaches, defined by a characteristic methodology. Each of these approaches is useful for a certain subset of the objectives listed in Table 1. First, the motivation behind the approach is given. The design is described, followed by a summary of the typical challenges in performing such a trial. Then an accompanying example is provided. This is followed by an account of the standard evaluation. In the final sections, recommendations for interpretation of the results are offered and the limitations of the approach discussed.

### 9.5.4.1 Controlled Randomized Trials

**Motivation** Scientific conclusions are always based on comparisons. However, in everyday life as in studies, comparisons are always in danger of bias, that is, it may be that a difference is caused by other factors than the condition (in this case the drug) under study. Bias can never be definitely excluded, but it can be controlled by probability. For this purpose, a random allocation of the drug to the patient is required.

Correspondingly, the randomized controlled trial (RCT) is the gold standard for phase III trials. In phase IV, RCTs are the preferred approach for all objections related to the optimization of use, and for objectives Eco-02 and Mar-03 (see Table 1), whenever it is possible to perform such a trial. RCTs may be performed as superiority trials to prove some advantage of a drug over the comparator or as non-inferiority trials proving at least comparable efficacy of a drug to a competing active treatment.

**Design** The RCT is prospective. A study protocol has to be prepared that precisely defines the study population and describes the inclusion procedure. After inclusion, patients have to be randomized, preferably by means of an external randomization procedure. Further treatment, observation, and follow-up should be identical for all groups under comparison. A sample size calculation has to be performed in advance for the study to be adequately powered for the primary endpoint.

**Challenges** There are potential biases that may take place after randomization. To avoid differential reporting, blinding of patients, treating physicians, and readers is recommended. Differential drop-out or missing values may compromise the study and should be avoided as much as possible. Major challenges in conducting such trials are recruitment problems and limited compliance.

### Examples

1. A phase IV head-to-head comparison between two statins was performed to test the assumption that 40 mg pravastatin daily is at least equivalent to more aggressive lipid reduction by 80 mg atorvastatin daily after acute coronary syndrome [3]. The study demonstrated superiority of the more aggressive therapy.

2. To assess the efficacy of pravastatin in the elderly, a double-blind randomized trial versus placebo (PROSPER) was performed in patients aged 70–82 with a history of or risk factors for vascular disease [4]. In the conclusion, the extension of the treatment strategy from middle-aged to elderly people is recommended.

**Evaluation** In the simplest case, the evaluation of a superiority trial consists of two-group comparisons by Fisher's exact tests or chi-square tests for binary outcomes and by two-sample *t* tests or nonparametric tests for continuous outcomes. An adjustment for baseline differences between patients may increase the power of the trial but is not mandatory. The evaluation of noninferiority trials is more complex. In any case, the presentation of the results using point estimates and confidence limits is recommended.

**Interpretation** If the study conduct was regular, cause–effect conclusions can be drawn for the primary endpoint and for the significant secondary endpoints if the study is positive. Results that are not significant are harder to interpret due to the fact that failure to prove an assumed effect may follow from lack of power or low quality of the study.

The intergroup comparisons of a randomized trial may be considered unbiased with a high level of confidence. This is even true if baseline differences between groups are observed. Randomization is expected to evenly distribute chances (success probabilities) between groups, not each of the baseline characteristics. Contrary to a widespread notion, the correctness of randomization cannot be checked empirically but only by checking of the randomization procedure.

Subgroups should be prespecified and never be analyzed separately but using interaction tests. Usually, the trial is not adequately powered for subgroup considerations.

**Limitations** The ability to draw generalized conclusions about the results crucially depends on the representativeness of the study population and may be limited due to a restrictive patient selection. RCTs are optimized for intergroup comparisons but not for extrapolation to routine health care in general. Analyses that were not prespecified and any kind of intragroup comparisons are not protected by randomization and may be biased to a relevant extent, although they are derived within the framework of an RCT.

#### 9.5.4.2 Cluster-Randomized Trials

**Motivation** Drug interventions usually address the individual patient. However, several patients may be cared for by one and the same health care institution or treated by the same physician. The drug intervention itself may even be provided within the framework of a program that includes several physicians and institutions and thus groups of patients. If so, patients within one institution or program tend to be more similar in their results than patients from different programs. This kind of effect is called a *cluster effect*. If cluster effects are present, it may be recommended not to randomize patients to drugs but to randomize institutions to drug interventions on the cluster level.

**Design** In a cluster-randomized trial, clusters (e.g., general practitioners, hospitals) are randomized to the study drugs, and all patients within a cluster receive the same drug according to the same schedule. Patients should be representative of their cluster, for example, by sequential inclusion or random selection. Patients within a cluster are allowed to communicate and exchange experiences.

In phase IV, cluster-randomized trials are typically applied when the introduction and propagation of a new drug is under study or when drugs are incorporated in prevention programs or general health programs.

### **Challenges**

1. A sufficient number of clusters (30 or above) have to participate. The required total number of patients frequently is a multitude (3–5 times) of the required sample size in trials with randomization of individual patients, depending on the extent of the cluster effect.
2. Institutions in the intervention group are confronted with a significant amount of effort and extra work. Institutions in the control group have only few advantages from participating in the study. Thus, recruitment problems are frequent. Special incentives for control group institutions may be helpful.
3. Clusters should not cooperate.
4. Blinding is frequently difficult or impossible.

### **Examples**

1. To study the clinical efficacy and the cost effectiveness of a rosuvastatin-based compliance program, general practitioners were randomized to take part with their patients in the program or not [5].
2. In a cluster-randomized trial, Coenen et al. [6] study the effect of a tailored peer intervention to implement a practice guideline for acute cough for optimizing antibiotic prescribing.

**Evaluation** In the presence of cluster effects, classical statistical evaluation methods are no longer valid, resulting in too many significances. Correct, but not very efficient, is an evaluation where cluster averages are calculated and compared between groups as if they came from individual patients. The best way of analyzing clustered data is the use of a multilevel model that allows the distinction between cluster-level effects and patient-level effects. Since relevant baseline differences are more frequent than in patient-based RCTs, due to the usually small number of clusters, adjustment for baseline is recommended.

**Interpretation** Cluster-randomized trials are less balanced and thus more vulnerable to biases than individually randomized trials. On the other hand, cluster-randomized trials are better capable to cope with real-world situations and thus may be more externally valid.

**Limitations** Recruitment problems, baseline imbalances, and differential drop-outs are frequent and may compromise the between-group comparisons or the

generalizability of the trial. Despite successful randomization, it may be difficult to maintain a comparable study conduct in all random groups due to external influences on institutions.

#### 9.5.4.3 Cross-Sectional Observational Studies

**Motivation** Hypotheses concerning effect modification or suspicions of adverse drug reactions are frequently gained from samples where drug exposure data, patient characteristics, and environmental factors are collected from patients at one point in time. These studies are quick and easy to perform and evaluate since only correlations have to be analyzed, but they do not provide evidence on drug efficacy and are just hypotheses generating. In phase IV, these studies provide first impressions on potential factors for optimization of use or on potential safety risks.

**Design** Planned observational study. Selection of a representative sample from a target population, collection of data from available sources, and one-time application of questionnaires.

**Challenges** Completeness of sample and records.

#### Examples

1. By means of a questionnaire, Coenen et al. [7] study the reasons for prescribing antibiotics in general practices. They explore the answers by factor analysis, identifying three latent dimensions, one of them being “nonmedical reasons.”
2. In an observational study nested in an RCT, Little et al. [8] studied the influence of patient pressure, perceived patient pressure, and perceived medical need on the investigations, referral, and prescribing decisions of general practitioners by logistic regression.

**Evaluation** Correlation and regression analyses, data-mining techniques. Frequently, a reduction of dimensionality is helpful, for example, by factor analysis or structural equation modeling.

**Interpretation** The study results in the demonstration of associations, that is, of coincidences that may or may not be substantial.

**Limitation** The numerical extent of associations depends heavily on the other variables in the model, and the interpretation is rarely unique. Associations thus depend on other associations and cannot be generalized. Even if the associations are stable over different models and times (if cross-sectional analyses are repeated), the associations do not provide evidence on cause–effect relationships. Likewise, missing associations do not prove the absence of cause–effect relations. Moreover, cross-sectional studies are not able to demonstrate individual courses or any changes with time. Thus, these kinds of studies can only be hypotheses generating and do not provide direct evidence and require additional studies with higher levels of evidence.

#### 9.5.4.4 Longitudinal Studies/Cohort Studies

**Motivation** The duration of phase III trials is usually limited to the minimum required to demonstrate clinical efficacy. Long-term efficacy and safety remain to be demonstrated in phase IV. While it is preferable to study long-term effects in RCTs, it is frequently not possible to maintain a randomization regime over many years, for economic, practical, or ethical reasons, the more so as the investigational drug has proven to be advantageous in phase III. A prospective study of drug effects can then be performed by building a well-defined cohort of patients who are routinely treated by the drug under investigation and by following the cohort for the period of drug intake. This cohort can then be compared to other cohorts, treated differently, from the same study or cohorts from other studies (“historical cohorts”).

In phase IV, cohort studies are commonly applied to evaluate long-term tolerance and safety but also to study the associations between changes in intermediate or surrogate parameters and clinical endpoints and to learn about long-term morbidity and prognosis and their determinants.

**Design** Cohort studies are planned epidemiological, purely observational studies. Groups of patients are recruited as for RCTs, but there is no random allocation of study drugs to patients. Instead, patients qualify for the study by the treatment (“exposure”) they receive in clinical routine. Data collection and follow-up are predefined and are performed with identical procedures for all patients, that is, additional follow-up examinations may be performed for study purposes.

**Challenges** Completeness of follow-up is a daunting task, in particular if the drug intervention is lifelong.

#### **Examples**

1. Simes et al. [9] use the cohorts of the LIPID trial on pravastatin to study the relationship between lipid levels and clinical outcomes on long-term intervention.
2. In order to study the safety profile of rosuvastatin beyond the analyses within phase II and phase III trials, Shepherd et al. [10] formed new cohorts from 27 phase II and phase III trials with different comparators, according to drug and dose ranges. Frequencies of adverse events per year of drug intake were calculated for each of these cohorts.

**Evaluation** While in RCTs adjustment for baseline is only optional to increase the power of the study, in cohort studies it is mandatory to minimize the selection bias resulting from lack of randomization. Repeated measurements require special statistical model building, called longitudinal data analysis.

**Interpretation** Treatment effects are usually quantified by regression coefficients. Effects may be time dependent and effect modifiers may be present. The interpretation of results of longitudinal data analysis may thus be involved and requires professional support.

**Limitations** Even with extended baseline adjustment or inclusion of time-dependent covariates, there is still a danger of hidden bias that cannot be controlled by probabilistic calculations. The evidence level of cohort studies is thus generally considered lower than that of RCTs. On the other hand, actual patient populations are usually better represented by cohorts than by RCT populations.

Cohort studies usually take a long time and thus are not appropriate to raise or to give quick answers to safety concerns. However, in the long run they may contribute substantially to the precise specification of risk and to the exploration of mechanisms.

#### 9.5.4.5 Case–Control Studies

**Motivation** Safety concerns, however substantiated, cannot wait for resolution by prospective long-term, follow-up studies such as RCTs or cohort studies. Retrospective studies are an alternative that can strengthen or mitigate the suspicion of a side effect in a shorter time interval. Case–control studies (directly comparing cases with and appropriate controls without the symptom suspected being drug related) and similar study types (such as case cohort studies where exposure and nonexposure time intervals are compared within the same patients) are widespread retrospective study arrangements.

In phase IV, case–control studies are widely used for the analysis of specified safety concerns (Saf-02, Saf-03, Saf-04, Saf-06, Saf-07) or for the study of the influence of environmental factors and lifestyle on drug effects (Opt-11, Opt-13); see Table 1.

**Design** Cases are systematically detected based on patients' records. Controls matched for other potential factors (e.g., age, sex, primary disease) are selected from a comparable population without symptoms. Drug exposure is compared between cases and controls.

**Challenges** The validity of the study decisively depends on the use of a comparable control group. Since there is usually no “natural” control group, the choice has to be justified, or several control groups should be used. Further, a bias-free selection of cases and controls has to be guaranteed. Since the exposure (and possibly some baseline characteristic that have to be determined for adjustment) has to be investigated for past periods of time, lack of documentation may compromise the study.

**Example** Suissa et al. [11] report the results of a case–control study comparing the risks of venous thromboembolism between oral contraceptives of the first and third generations. The data stimulated a fierce debate for years on the existence of an elevated risk in third-generation brands, several new studies, regulatory activities, and even litigation due to the lack of data from trials with a higher level of evidence.

**Evaluation** The standard statistical analysis requires the fit of a conditional (i.e., stratified) logistic regression model to the data.

**Interpretation** Drug effects are determined by adjusted odds ratios calculated from the final model that are directly comparable to odds ratios from prospective studies.

**Limitations** Case-control studies are vulnerable to any type of conscious or subconscious selection. They are discussed predominantly with respect to the appropriateness of the choice of controls. Results heavily depend on the choice of model. Thus, results are rarely unanimously accepted. Evidence is considered to be moderate and only supportive to other findings.

#### 9.5.4.6 Aggregate-Level Studies/Ecological Studies

**Motivation** Relevant data may not be available on an individual level but only for communities, states, or countries (e.g., prescription rates, frequencies of side effects, environmental exposure, costs for certain medical interventions). In these cases, analyses can only be performed on an aggregate level. In phase IV, this situation frequently occurs in the exploration of environmental effect modifiers, health economic studies, and studies on safety.

**Design** Collection of data from different aggregate data collections or linkage with individual data bases.

**Challenges** Linkage of different data sources requires the existence of comparable identifiers. Different databases may use different definitions of items that do not match. Selection criteria may vary. Data quality may vary.

**Example** Juurlink et al. [12] use aggregate-level prescription claims data and combine them with hospital records in order to analyze changes in the rates of hyperkalemia after publication of the Randomized Aldactone Evaluation Study (RALES). For this purpose they use time-series analysis methods.

**Evaluation** Statistical evaluation has to take the clusters and the resulting correlation structure into account. This can be done by using time-series analysis, Generalized Estimating Equations (GEE) models, or multilevel models, by meta-analyses or metaregressions, among others.

**Interpretation** Aggregate-level studies are purely observational. The interpretation follows the rules for patient-based cross-sectional studies; see above. Additionally, the different data levels have to be taken into account when interpretations are given.

**Limitations** In addition to the limitations of other cross-sectional studies, aggregate-level studies are vulnerable to the so-called ecological fallacy. It may occur that an association observed between clusters of individuals cannot be confirmed on an individual level or may even reveal an inverse association. Likewise, associations present on an individual level may not show up in the aggregate level analysis. In particular, trend parallelism may be spurious since any simultaneous trends will be correlated even if there is no causal relation, just by random

coincidence. Thus, while aggregate-level analysis are popular with politicians, media, and the public due to its handiness, they may be and frequently are extremely misleading, the more so as the control of other potential influences is usually poor.

#### 9.5.4.7 Medical Registers

**Motivation** Due to the rapid development of electronic documentation in medicine, routine data are available for most patients and clinical conditions. The quality of these data is improving since it is being used more frequently for the management and financing of health institutions. However, documentation standards still differ. Nevertheless, it has in the meantime become possible to routinely collect such data for certain groups of patients from comprehensive databases by defining interfaces and by regular data exchange, with a justifiable amount of effort. Such databases, called medical registers or pharmaco-economic databases, allow quick answers to questions arising on the use and the safety of several drugs at the same time. Registers are almost exclusively phase IV, useful for almost all of the objectives of Table 1.

**Design** Medical registers and pharmacoepidemiological databases try to give an image of a defined target population that is as complete as possible. Cross-sectional as well as longitudinal data are collected on an individual level. There will usually be no interventions, neither for experimental nor for observational purposes.

Registers require a protocol where the procedures are defined. However, other than in planned epidemiological studies, no research hypotheses are formulated in advance but will be defined according to the current state of debate, while further data are collected. If complete and high-quality data are available from routine databases, register population can even be defined retrospectively if organized by inception.

**Challenges** The validity of a register depends on its completeness and data quality.

**Example** Graham et al. [13] retrospectively define drug-specific inception cohorts of statin and fibrate users to study the incidence of hospitalized rhabdomyolysis.

**Evaluation** Registers and pharmacoepidemiological databases include cross-sectional and longitudinal elements and are thus similar to epidemiological studies, but broader and more exploratory than those approaches. The evaluation requires complex statistical modeling. Simple univariate or bivariate statistics usually are misleading.

**Interpretation** Registers are predestinated for the determination of rates and frequencies under changing conditions. They allow the study of associations but face the same problems as epidemiological studies.

**Limitations** Registers are purely observational. While their findings are most representative, they do not provide evidence for cause–effect relationships.

#### 9.5.4.8 Surveillance

**Motivation** Once a substantiated safety concern has been established, regular surveillance becomes mandatory. Surveillance is a typical phase IV safety activity.

**Design** Spontaneous reporting systems are the earliest type of surveillance. Other ways of organization are regular survey, sentinels (a selection of institutions that report the rates of interest on a regular base), and specific pharmacoepidemiological databases/registers on drug utilization. The use of Internet platforms is still experimental.

**Challenges** Traditionally, underreporting by physicians is the greatest challenge of surveillance. Considerable effort is required to improve participation. Independence of the responsible body, transparency, a careful practice of publication, and open access can serve to convince physicians of the usefulness of their contribution.

**Examples** Several reporting systems and routine databases are run by manufacturers, agencies, and pharmacological academic institutions.

**Evaluation** Prespecified safety concerns can be addressed with advanced statistical standard methodology. Extraction of unanticipated signals within huge databases is a continuing challenge. Data-mining techniques and in particular graphical tools are used, but no general methodological standards exist.

**Interpretation** The appraisal of surveillance data should take into account both aspects of statistical significance and those of medical relevance.

**Limitations** The perception of the data is usually not free from conflicts of interest. At present, no generally accepted rules exist as to when or which actions should be taken.

#### 9.5.4.9 Systematic Review, Meta-Analysis, and Metaregression

**Motivation** With the extended use of a drug after approval, the number of studies and the body of evidence increases rapidly. Information has to be summarized not only to facilitate an overview but also to realize the advantages in statistical power and differentiation that can be gained by combining data from different studies. Reviews and meta-analyses that summarize the results are recommended for all objectives in phase IV.

**Design** Reviews can be performed on a nonformal base as systematic reviews with a qualitative summary, or on a formal base with an established statistical meta-analysis technique with quantitative summaries. The formal analysis can be performed on the patient level if it is possible to combine the individual data of several studies into one database, or on the study level if only summary measures are available by using techniques of formal meta-analysis or metaregression. Every review and meta-analysis requires the prespecification of a protocol.

**Challenges** Completeness of studies/research results is difficult to attain due to limited access to studies not published in English and in established journals. Literature searches may also be incomplete due to the reluctance of journals to publish negative results (resulting in publication bias). Reporting standards may differ between studies to an extent that prevents pooling of results. Direct access to source data may be refused.

### **Examples**

1. The Control Treatment Trialists' Collaborators combined the data of 90,056 participants from 14 randomized statin trials to further evaluate the efficacy and safety of cholesterol-lowering treatment [14].
2. The Cochrane collaboration publishes systematic reviews and aggregate-level meta-analyses to several medical fields, provided by working groups of experts.

**Evaluation** Systematic reviews should follow the rules of the Cochrane collaboration for literature search and appraisal of the quality of the collected studies. For aggregate-level meta-analysis, an established statistical methodology exists. Random effects models are generally preferred to demonstrate potential heterogeneity between studies. Individual data-based meta-analyses should be analyzed by statistical modeling similar to the model building in epidemiological studies, but including the factor "study" to demonstrate heterogeneity.

There is an open debate as to what extent reviews and meta-analyses should rely on high-quality studies with a high level of evidence (RCTs) only or should include information of nonrandomized studies.

**Interpretation** Interpretation is usually based on overall summary measures, but heterogeneity should be considered as well.

**Limitations** Even if only high-quality RCTs are used, this does not automatically translate into a high-quality meta-analysis. Selection biases and an insufficient amount of data may limit interpretation. Aggregate-level meta-analyses and metaregressions may be compromised by the ecologic fallacy, as with individual aggregate-level studies, despite randomization of the contributing studies.

#### **9.5.4.10 Health Economics/Health Technology Assessment (HTA)**

**Motivation** Costs of a useful drug intervention may be too high to be financed in certain health care settings, or advantages of drug interventions may be judged negligible because the prices for this advantage may be found to be too high. Thus, health economic evaluations or the study of changes to be expected after the introduction of a new health technology are requested to a steadily growing extent.

**Design** Costs of interventions can be evaluated directly as part of a clinical study or determined separately and then combined with clinical data. HTA uses several data sources and combines them in probabilistic models based on Bayesian decision trees.

**Challenges** Costs originate at several levels, directly in connection with health care (direct costs) and indirectly due to the consequences of being ill or disabled. A complete evaluation of costs up to the regarded level requires the use of many sources of information. For cost-effectiveness calculations or HTA, a one-dimensional measure of efficacy is required. If several aspects of efficacy are to be taken into regard, a summary measure combining information on different scales has to be used. Quality-adjusted life-years [15] is such a concept that incorporates quality of life into the efficacy measure, but this kind of measure is not unchallenged.

**Example** Hirsch et al. [16] study the cost effectiveness of rosuvastatin as compared to other statins by retrospective drug cost evaluation for the patients in a head-to-head RCT comparing rosuvastatin to atorvastatin.

**Evaluation** Costs can be compared between study groups by classical statistical methods, but care is required since cost distributions are usually extremely skewed and variable. Baseline adjustment is thus recommended. Cost effectiveness is mostly measured by incremental cost-effectiveness ratios (ICER) that reveal additional variability since denominator and numerator are subject to random variation. Since costs may vary in different settings and time periods, it is good practice to add sensitivity analyses that demonstrate the sensitivity of the results to price changes or clinical improvements.

Health technology assessment predominantly uses Markov chain Monte Carlo (MCMC) methods for the calculation of probabilities along complex decision trees [15].

**Interpretation** Health economic analyses result in imprecise estimations of costs for improvements. HTA also gives an impression of the future distribution of outcomes in patient populations.

**Limitations** The results do not allow automatic decisions on the implementation of new technologies since the definition of boundaries is a question of values and political priorities. The selection of summary measures inevitably requires the definition of subjective weights that may not be accepted by everyone.

## 9.5.5 OPTIONS

Before performing a phase IV study, authorities, sponsors, and investigators have to make some decisions crucial to the impact of the results once the study is finished. The following represent some remarks on the decision criteria.

### 9.5.5.1 Data Sources

Studies can be performed using data from literature and completed studies or collecting own data. Actually, these two options are less an alternative than usually thought. A study should always start with a review of the present knowledge, including the knowledge to be expected from ongoing studies. If information is judged to be insufficient, existing databases that have not yet been evaluated should be

checked for accessibility, data quality, and potential impact of an analysis. New studies should be planned in a way that they optimally contribute to future reviews and meta-analyses. The development of strategic plans incorporating series of parallel studies, studies with different methodology, and performance of studies conditional on the results of previous studies are as recommended in phase IV as they were in phase III. However, it has to be remembered that in phase IV, other than before approval, the manufacturer is not the only potential sponsor of studies. Since the drug is licensed, several players can perform studies as long as they have a sufficient budget at their disposal. There may be conflicts of interest between different parties. Joint sponsorships resulting in linked databases of different origin may help to regulate such conflicts of interest in advance and certainly are interesting options for future phase IV activities.

### **9.5.5.2 Experimental versus Observational Approach**

Among methodologists there is a continuing debate whether phase IV studies on safety should be predominantly RCTs or observational studies [17]. As an example, the Cochrane Institute and many supporters of evidence-based medicine prefer RCTs and meta-analyses, attributing them the highest level of evidence since they feel that bias and spurious cause–effect relationships are to be feared most. Pharmacoepidemiologists refer to the lack of representativeness of many RCTs and argue that RCTs clarify safety concerns with an unacceptable time lag insufficient to guarantee patients' safety. The debate was intensified by recent withdrawals or black-box warnings of approved drugs due to new data on previously discussed potential side effects [1]. However, the debate should not be allowed to obscure the fact that the two approaches are not exclusive alternatives. In fact, experimental as well as observational studies contribute unique information on drugs. The question should thus rather be whether the amount of unbiased information and representative information is sufficient when a funding decision has to be met. What is more, both approaches are able to validate each other, the more so if the different study types are linked directly; an epidemiologic study may well be nested within an RCT; an RCT can more easily be performed if patients are recruited within a registry framework. Phase IV gives even more freedom than the premarketing phases to combine different activities into common projects.

### **9.5.5.3 Quality Assessment, Monitoring, and Auditing**

At present, the standards of phase III are not universally applied in phase IV, as far as data quality and control are concerned. The absence of regulatory requirements and the lower level of evidence on drug efficacy of some types of phase IV studies may have contributed to this situation. However, from a methodological as well as from an economical or political point of view, there is no reason why in a pharmacoepidemiological database on drug safety, for instance, a poor data quality should be more acceptable than in an RCT for optimization of use. The collection and evaluation of spurious data is per se not reasonable and not profitable and should be avoided, the more so as spurious findings, for example, on safety, can have a similar impact on public opinion to that of correct data can have.

#### 9.5.5.4 Registration of Studies, Access to Data, and Results

In phase III, trials are performed to gain knowledge about a drug and to convince agencies of the approvability of a new drug. Phase IV trials always have to address a broader audience. Not only agencies, but also physicians, patients, the scientific community, and the public have to be convinced as far as the virtue of a drug is concerned. For this purpose, it is essential that the audience trusts the results and has confidence in the proper performance of a study. Important milestones on the way to trustworthiness are the registration of all study activities to avoid the impression that unwanted results are covered up and open access to the data and the results once a study is finished.

#### 9.5.6 IMPACT OF PHASE IV TRIALS

Up to now phase IV trials and studies are frequently understood as voluntary exercises that may or may not be performed and do not need coordination or comprehensive development plans, special quality investments, transparency, or scientific evaluation. However, this attitude contrasts with the enormous impact that phase IV trials or the lack of these trials can have on the reception and use of a drug. If extended RCTs for the optimization of use are lacking, no safety studies or registries exist, economic consequences are not clear, and the relationship to competing drugs and other therapies is open. When all available data are locked in secret databases and reserved for the management of the manufacturing company, the position of a drug on the market is extremely vulnerable, and even random observations and rumors cannot be challenged due to a lack of data for scientific authorities who are able to clarify concerns. The performance of phase IV thus is in everybody's best interest.

The limited realization of phase IV studies may in part be due to the fact that the postapproval period is only sparsely regulated. However, there are more and more voices asking for a better regulation. Pharmacovigilance in particular is thought to be organized insufficiently and ineffectively. Rules are not clear, the predictability of legal decisions is low, and the twists of public attention and opinion are not predictable either. The only way to overcome the resulting risks is the production of solid data and transparent analyses that establish generally accepted facts upon which future work can rely.

## 9.6.1 INTRODUCTION

Pharmaceutical products are developed and marketed to promote human health and protect people from various ailments. The identification or development of drugs involves a lot of time and resources, and to bring drugs to the marketing stage involves assessment of different aspects of the product in a very scientific and credible manner. Yet, the assessment of the products does not end just at marketing; assessment of drug effectiveness and, particularly, their safety continues, constituting phase IV clinical trials.

Typically, development of drugs involves several stages of experimentation in animals followed by trials in humans before large-scale phase IV clinical assessments. Animal experimentation precedes trials in humans and are intended to provide information on the acute toxicity, organ damage, dose dependence, absorption and bioavailability, the pharmacokinetics and dynamics, the metabolism, mutagenicity, teratogenicity, species specificity, and lethal dose. After animal experimentations providing encouragement for further development of the drug, clinical trials are planned that typically have three stages: phase I, phase II, and phase III conducted sequentially.

The phase I clinical studies involve a small number of healthy volunteers that allows investigators to understand the effects an investigational drug has in humans, with the goal to understand what happens to the investigational drug in the body from the time it is administered until its elimination from the body, on how human bodies react to the new drug from a safety and tolerability point of view. Study participants are monitored for the occurrence and severity of any side effects they may experience.

Phase II clinical studies are designed to evaluate the safety and efficacy of an investigational drug in patients with a specific disease or condition. Phase II clinical trials are typically conducted in a group of patients who are usually selected based upon their being at the same stage of a disease. The patients are given various doses of the drug and closely monitored to compare the effects and to determine the safest dosing regimen. In many instances, multiple phase II clinical studies are conducted to test the drug in a variety of patient populations with different indications.

Phase III clinical studies are designed to confirm the safety and efficacy of an investigational drug, and the dosage regimen chosen, in large numbers of patients with a specific disease or condition. These studies, as in the earlier phases, may involve one or more “treatment arms,” which allow the investigational drug to be compared to other available treatments or to be tested for effectiveness in combination with other therapies. The safety and efficacy of the new drug is compared to that of the currently accepted standard treatment. Information obtained from phase III studies is used to determine how the drug is best prescribed to patients in the future. The complete information available on the new drug is submitted to health authorities. But, for safety reasons, these clinical trials of drugs are designed to exclude women of childbearing age, pregnant women, and/or women who become pregnant during the study. In some cases the male partners of these women are also excluded. Also children and very aged persons are frequently excluded from these clinical studies.

The purpose of the next phase, that is, phase IV clinical study, is to increase knowledge surrounding use of a new drug by increasing the number of humans that provides information on its effectiveness and more importantly adverse events when rolled out onto the market. “There are no therapeutic roses without thorns.” Thus, the general use of a particular drug depends on availability of alternatives, the determination of the frequency and severity of adverse effects associated with the new drug, and finally on risk–benefit and cost–benefit assessments. Approval for marketing of a drug is usually granted based on adequate efficacy and safety, as demonstrated through well-designed phase I to phase III clinical trials.

It is, however, important to remember the limitations of these phases, which are conducted on a smaller number of humans and, thus, do not represent real-life situations. They generally represent only a limited population with specific characteristics and thus underrepresent the greater patient populations and provide short-term outcomes. A number of issues are monitored after marketing of drugs to determine their performance as they are prescribed in increasing numbers: Will the drug provide equal or greater benefit to people compared to other available drugs on the market? Will this be more cost effective? Will its safety profile be equal to or better than the alternatives? Will it provide better compliance?

### 9.6.2 PHASE IV CLINICAL STUDIES

Phase IV clinical trials involve the surveillance of the safety and adverse reactions of drugs in the market. With progression of medical services, the need for phase IV clinical trials is definitely greater now. Phase IV clinical trials encompass the detection, assessment, understanding, and prevention of drug-related problems. Both regulatory authorities and the sponsoring company may require phase IV studies for competitive purpose to find a new market for the drug. The safety surveillance is designed to detect any rare or long-term adverse effects of drugs over a larger patient population and for a longer time period than was possible during the phase I–III clinical trials. Withdrawal of a drug from the market or restricted to certain uses may be recommended if harmful effects are discovered by phase IV clinical trials.

Pharmacoepidemiology is the primary scientific discipline now engaged in postmarketing drug safety surveillance. The most common epidemiologic study designs used in phase IV studies are randomized trials, cohort studies, and case-control studies. Regardless of their design, all studies involve human subjects and these studies need to be conducted by qualified investigators according to a written protocol duly reviewed and approved by an institutional review and ethics board. Promotional activities conducted under the guise of postmarketing studies are never acceptable. Changing regulatory environment, increasing concerns about the safety of new drugs, and varied uses for large-scale, real-world data on marketed drugs' safety and efficacy are primary drivers of the growth seen in the phase IV study environment today.

Postmarketing study is an important element of commercialization that enables companies to expand existing markets, enter new markets, develop and deliver messages that directly compare their products with the competition, and secure a better position in competitive markets.

### 9.6.3 POSTMARKETING SURVEILLANCE

Management of patients using drugs on a long-term as well as a short-term basis raise several complex issues such as toxicity, interaction with other drugs, as well as efficacy and effectiveness. In addition, age, sex, nutritional status, disease duration, comorbidity, ability to tolerate adverse events, and socioeconomic status are important considerations that influence the outcome of individual patients taking drugs. Randomized clinical trials alone are not sufficient to address all of these issues. Multiple therapies with attendant adverse effects are also common. Thus, postmarketing surveillance is important to accumulate information of adverse effects, influence of personal attributes mentioned above, identification of risk factors, quantitative measurement of safety and long-term safety/toxicity, study of potential risk groups (children/elderly, pregnant women, etc.), and identification of new indications and unexpected beneficial effects. It, additionally, provides useful information on the patterns of use and characteristics of drug users, inappropriate use of drugs, for example, addiction, impact on compliance, the possibility of medication errors and intoxication, quality of life during drug use, and utility and cost assessments.

### 9.6.4 ADVERSE DRUG REACTIONS

Drugs are intended to improve and make life comfortable for humans. But, they definitely are not without risk and may cause lesser or greater harm to many people. The unintended effects of drugs are harmful to the recipients and generally are referred to as adverse drug reactions (ADRs). Classical examples of a few ADRs are provided in Table 1.

Adverse drug reactions might account for over 10% of all hospital admissions in some countries. For example, a prospective study conducted in a European country reviewed the cause of hospital admissions of 18,820 patients over a 6-month period and noted 6.5% of admissions to be related to an ADR. The projected annual cost of such admissions to the National Health Service of that country was very high.

**TABLE 1 Adverse Drug Reactions**

| Drug                  | Adverse Drug Reaction    |
|-----------------------|--------------------------|
| Phenyl butazone       | Aplastic anemia          |
| Chloramphenicol       | Pancytopenia             |
| Ethambutol            | Optic atrophy            |
| Erythromycin estolate | Hepatitis                |
| Aspirin               | GI hemorrhage            |
| Steroid               | Hyperglycemia            |
| Oral contraceptives   | Thromboembolism          |
| Clindamycin           | Pseudomembranous colitis |
| Reserpine             | Depression               |
| Co-trimoxazole        | Agranulocytosis          |

According to another survey published in the *Journal of American Pharmacists' Association* in 2001, the cost of identified drug-related morbidities and deaths in a North American country was much higher than expected. Costs associated with drug-related problems have been estimated to be greater since 1995. From developing countries, such information is not readily available, but it is believed that the incidence of adverse events is greater with considerable cost.

#### 9.6.4.1 Methods for Monitoring Adverse Drug Reactions

There are several methods that can be employed for evaluation and monitoring of adverse drug reactions. Selection of an appropriate method depends on factors such as program objectives and setup and the availability of human resources. A few common methods to evaluate ADRs include:

1. *Case Reports* The publication of single case reports, or a series of cases, on adverse drug events in the medical journals is an important way of compiling unreported and serious reactions.
2. *Anecdotal Reporting* Individual medical practitioners through anecdotal reports provide the majority of first reports of adverse drug reactions. They describe the occurrence of an event in association with use of a particular drug. Because of the anecdotal nature, such events need to be verified; however, confirmation may not be possible.
3. *Spontaneous Reporting* It is the principal continuing method for monitoring safety of marketed drugs. Along with the use of other methods, ADR programs are still based on spontaneous reporting system in many countries, both developing and developed. Clinicians are encouraged, and in some countries physicians are specially instructed, to report any or all reactions associated with medication. Usually, attention is focused on newly marketed drugs. Reporting of ADRs of a serious nature has also been made mandatory in many developed countries. This system is simple to operate and usually does not interfere with clinical practice to any great extent. Absence of an adequate control group is the main drawback of spontaneous reporting and, consequently, the difficulty of knowing the relative risk of treated patients. Despite limitations, voluntary spontaneous reporting systems remain the most

cost-effective approach for postmarket identification of new ADRs. Here the purpose is to register new problems or the occurrence of an increased incidence of previously reported problems. However, underreporting is one of the major limitations in the spontaneous reporting system. Despite regulations, health care professionals report only a variable proportion of adverse drug events with temporal association with a drug.

4. *Intensive Event Recording* In certain medical setups a group of people are given the responsibility to scrutinize a defined population specifically to detect adverse reactions associated with specific drugs. However, because of shorter periods of observation of individual patients and a relatively small number of people targeted in such studies, this method has not been very effective in the detection of drug toxicity.
5. *Cohort Studies (Prospective)* This is a very useful epidemiological method in which a cohort with a particular attribute (e.g., recipients of a drug) is followed prospectively and compared for some outcome (e.g., toxicity of the drug) with another cohort not possessing the attribute. Good control of data, accurate checking of outcome, good estimation of risk, study of many different outcomes, etc., are advantages of this method. Disadvantages are high cost and long wait.
6. *Case-Control Studies (Retrospective)* This is a good epidemiological study design. In this type of study the investigator selects the case group and the control group on the basis of outcome—i.e., having drug-related toxicity of interest versus not having drug-related toxicity of interest—and compares the groups in terms of their frequency of past exposure to possible risk factors. Case-control studies are relatively inexpensive, can be done quickly, and are a frequently used type of epidemiological study that can be carried out by a small team. Its retrospective nature limits the conclusions.
7. *Case-Cohort Studies* The case-cohort study is a recently developed useful modification of the case-control study. It is a hybrid epidemiological design. This design allows direct estimation of the risk ratio from a fixed cohort.
8. *Meta-Analysis* This is a quantitative analysis of two or more independent studies (already carried out) to determine an overall effect and to describe reasons for variation in study results. Meta-analysis aims to establish associations between drugs and adverse events, to estimate the frequency of ADRs, and to identify subgroups at increased risk for ADRs.
9. *Use of Population Statistics* Birth defect registers and cancer registers can be used if a drug-induced event is very frequent. If such assessment raises suspicion, then further observational studies are initiated.

### 9.6.5 PHARMACOVIGILANCE AND POSTMARKETING SURVEILLANCE

Pharmacovigilance is a relatively new and emerging science that is expected in the future to serve the purpose of postmarketing surveillance (PMS), but now it is not a well-established academic activity. Although a few universities offer specific courses in pharmacovigilance, the current curricula for training programs of profes-

sions in clinical medicine, clinical pharmacy, clinical pharmacology, and medical biology are not geared to provide all of the skills needed in this discipline. One of the reasons could be that pharmacovigilance involves a wide range of subjects, such as pharmacology, epidemiology, clinical medicine, data management, and drug legislation and communication, and they do not easily fit within the area of competence of any of the existing academic departments. It is anticipated that pharmacovigilance will be taught as an academic subject at the university level in the near future. Currently, the International Society of Pharmacovigilance (ISoP) provides specialized ad hoc training courses in pharmacovigilance. Each country might establish such an organization to provide a stronger base in effective and credible training services for relevant individuals/group of individuals.

### 9.6.6 PMS: LINKAGE SYSTEM AND DATA BANK

Many countries and related organizations involved in health care activities either already have or have the capacity to establish comprehensive databases using modern technologies at reasonable expenditure. Existence of such databases would immensely help establish a comprehensive and cost-efficient system for pharmaco-epidemiology. With the multicenter nature of such databases, postmarketing surveillance programs have new possibilities. A wide spectrum of data is covered by automated databases of general practice and, therefore, at the population level it provides opportunities for a closer look at the impact of medications. However, special methods need to be established for determining the abuse potential of non-prescription drugs, such as many analgesics, in order to determine the extent of abuse and the temporal changes over periods since marketing a new drug. For nearly last two decades, automated medical record linkage systems have been utilized to evaluate postmarketing drug safety. Recently, for adequate assessment, networks of databases have been employed to identify problems that require large or diverse populations. Despite the potentials, establishment of such an effective system might not be easy. Because it involves merging of data from different systems, their reliability, variations in coding conventions for drug formularies, and the need to protect the confidentiality of medical records are likely to make the task difficult.

The European Active Surveillance Study (EURAS) is an ideal example of record linkage for postmarketing surveillance. This is a prospective, controlled, multinational, postmarketing, nonintervention cohort study of users of oral contraceptives. The study aims to detect the incidence of rare serious adverse side effects associated with the use of new and old oral contraceptives, particularly to determine incidence of thromboembolic events. This surveillance is under routine medical practice in European countries. The study is based on postal questionnaires and semiannual, active follow-up with validation of reported events by the physicians treating those women under surveillance. To ensure low loss to follow-up rates, a multifaceted, four-level follow-up procedure has been established.

Before the introduction of automated databases, studying large cohorts of drug users was extremely expensive and required major administrative and financial efforts to assemble and ensure complete and accurate collection of the required follow-up information. The computerized information system, initiated in the late

1970s, facilitated all these efforts and allowed highly efficient research. In the United Kingdom, the general practitioner (GP) traditionally acts as a gatekeeper to services within the National Health Service (NHS). A comprehensive record of written prescriptions, outpatient diagnoses, and referral letters to hospitals resides in the individual patient's record that GPs maintained in their offices. Since the early 1990s, the database has been known as the General Practice Research Database (GPRD), belonging to the UK Department of Health, and currently it is maintained by the Medicine Control Agency (MCA). Truly population-based data is collected by GPRD, which includes both outpatient and inpatient clinical information with a size that makes follow-up possible on large cohorts of users of specific drugs.

### **9.6.7 POSTMARKETING SURVEILLANCE: FDA PERSPECTIVE**

Drug review process of the U.S. Food and Drug Administration (FDA) is recognized worldwide as a gold standard for the approval of drugs. To improve the standard, there have been significant additions during the last several decades in response to advances in medical science. Recently, drugs are approved by the FDA after comprehensive assessment, including safety evaluations. Major changes have taken place in the evaluation of new drugs, including complete understanding of their metabolism, interactions with other drugs, and potential differences of effectiveness or safety in people of different age groups, sex, and races. Focusing on the potential problems with the greatest care and importance, internal guidelines are in place to describe systematic approaches for assessment of safety through comprehensive review. Approval of drugs are granted by the FDA after a sponsor demonstrates risk–benefit assessment favoring use in specific population(s) and that the drug meets the standard for accepted safety and efficacy. It is conceivable that premarketing studies will never elucidate all the information about the effectiveness or all the risks from use of a new drug. The FDA recognizes that it is not possible to assess or anticipate all possible effects of a drug from the clinical trials that precede approval. So, the FDA has created a postmarket drug safety program designed to collect and assess adverse events following the drug's approval and marketing with an aim to detect unexpected serious adverse events and to take required action(s). The FDA collects information from adverse event reports filed by drug manufacturers, postmarketing clinical trials, and spontaneous reporting of adverse events by practicing physicians, pharmacists, and consumers.

### **9.6.8 DRUG REGULATION AND THE FDA**

In the United States, both the prescription and over-the-counter drugs are essential, and their numbers are increasing. Newly marketed drugs are saving lives, reducing suffering, and improving the quality of life of millions, as do older drugs. Despite rising costs of health care, innovative newer medicines are necessary to improve life expectancy. Also, drugs are used to prevent or slow the progress of many diseases, thus avoiding costly invasive treatments, hospitalizations, and nursing home stays. However, there are undesirable consequences by widespread use of drugs. Inherent

side effects, misuse, overuse, underuse, medication mix-ups, and intentional abuse are increasing. So, appropriate monitoring and addressing of all these problem are required. Thus, the responsibilities for oversight of the entire life cycle of drugs has been undertaken by the FDA. It includes premarket testing and development through drug approval, postmarket surveillance, and risk management. The objective of the FDA is to ensure that safe and effective new drugs are available as quickly as possible and that drugs already on the market remain safe and maintain the highest quality. The FDA maintains its efforts to translate new scientific advances into benefits for patients and to take advantage of new developments in monitoring the performance of marketed drugs. The FDA and its Center for Drug Evaluation and Research (CDER) dedicate at least half of their premarket review activities to evaluating the safety of investigational drugs and safety of clinical trial participants. The FDA's Office of Regulatory Affairs (ORA) support the premarket drug review process by monitoring clinical trials and their results.

#### 9.6.8.1 FDA: Globalization and Recent Activities in Drug Safety

At every stage of the drug life cycle, the FDA is working to improve the mechanism that supports drug safety and risk management. With the evolution of science over drug development, related activities have been expanded, and the focus is now on biomarkers and pharmacogenomics, which are likely to help maximize the safe and effective use of drugs in individual patients. More scientific methods and new tools are now in the works to target a specific drug for specific patients to maximize benefits and minimize associated risks. One of the current important objectives is to prevent adverse events by predicting drug safety problems before they can cause an insult. The aim is to combine new understandings of disease and its origins at the molecular level, including adverse events resulting from drugs, with the emerging knowledge of genetic and biologic characteristics of individual patients that determine how they will react to drug treatment. If successful, these innovative and risk-assessment-based drug development processes will improve FDA's efficiency for early disclosure of safety-related problems. Moreover, the FDA is now exploring, testing, and developing new methods of data mining, signal detection, and analysis of electronic data related to global health care.

The FDA is now very aware of the globalization trends. To respond to this global challenge in a proactive manner, the FDA has developed a variety of solutions. The FDA has entered into a number of cooperative relationships with foreign regulators to formalize arrangements for advancement of drug quality. The FDA is continuing work to encourage greater transparency and to ensure that patients and health care providers have access to emerging new safety information.

#### 9.6.9 POSTMARKETING SURVEILLANCE: AUSTRALIA PERSPECTIVE

In Australia, guidelines have been applied in industry-sponsored postmarketing surveillance studies on drug safety, and most are observational studies that used cohort design. The guidelines, however, apply for other types of studies, including case-control studies and in intensified monitoring and various forms of recorded release. The term *postmarketing surveillance (PMS) study* need not mean a mere

passive follow-up, but actually it includes scientifically rigorous studies of products that are approved for registration and marketing, and its purpose is to collect reliable information on drug safety. However, they are not clinical trials of registered products or studies designed primarily for marketing purposes despite their scientific validity. PMS studies are generally initiated by the producers but might also be requests from other parties. Their aim is very specific—drug safety question or testing a hypothesis that often results from voluntary reporting. The guidelines for postmarketing surveillance studies have been developed to design and conduct scientifically rigorous and ethical studies to maximize validity of the results and increase potentials for acquiring useful newer information on the product. The ultimate purpose of a PMS study is to find an answer to a specific medical question that is new, significant, and unlikely to be answered by existing voluntary reporting systems.

In company-sponsored PMS studies that are typically observational rather than experimental, the decision to enroll a patient needs to be made after making an independent clinical decision to prescribe a specific drug concerned a particular patient. Prior to commencement, study proposals are sent to the Australian Drug Regulatory and Advisory Council with clear statements with regards to its aims and objectives, the question of clinical significance under investigation, proposed methodology including data collection and analyses procedures, and identification of company officially designated as responsible for the study. The notification of adverse reactions occurring during the PMS study should be done according to the pharmacovigilance guidelines.

The sponsor company is responsible to provide a timely report on the study outcomes. The product to be studied must have been approved for registration in Australia, and only patients having an approved indication for use of the product can be enrolled in PMS studies. Company-sponsored PMS studies should not be a disguised marketing or promotional exercise. Any payment offered to the medical professional must be commensurate with the work involved. The guidelines describe scientific approaches that the pharmaceutical companies are encouraged to follow in designing and conducting the postmarketing surveillance studies.

#### **9.6.10 CONFIRMATION AND QUANTIFICATION IN DENOMINATOR-BASED SYSTEMS**

A number of epidemiological approaches have been developed for postmarketing surveillance and quantification. Some of them have control groups to make relative risk estimates. Population-based claims databases are large databases that can link prescription-dispensing information (e.g., drug, dose, duration, and date) to claims data for medical interventions via unique patient identifiers. These systems can generate event rates (numerators) for the denominator of exposed persons and person-years of exposure and allow comparison of rates observed in unexposed patients. Here, the limitations of the systems are: ability to record the events of interest and the reliability. The availability of medical records in some of these systems allows validation of event reports and more in-depth analysis of adverse events, making formal nested case-control studies possible. However, in the event of very rare events these databases, despite being large, might still be relatively small for acquiring adequate numbers of exposures to the drugs of interest.

### 9.6.11 UNITED KINGDOM PRESCRIPTION EVENT-MONITORING (PEM) PROGRAM

In the UK, all prescriptions for newly marketed drugs are entered into an automated database after retrieval from the British Prescription Pricing Authority. Prescription data provided to the Drug Safety Research Unit (DSRU) include the name of the patient and the prescribing general practitioner (GP). Subsequently, each prescribing GP received the questionnaires (“green cards”) 6 months after the first prescription for each of the patients. Questionnaires request adverse events during and after treatment, reason(s) for discontinuation, if any, patient age, indication for treatment, starting and stopping dates of treatment, and dosage. They are tailored for individual drugs and additional questions might also be incorporated.

Exposure-specific registry is another cohort technique employed that attempts to identify and follow patients who have been exposed to a drug but have not yet had an adverse outcome (e.g., hypertension treatment registry created before development of side effects). These registries may also be constructed on diseased populations (e.g., patients with gluten-induced enteropathy). Availability of denominator is a major advantage in these systems. Registries may provide also background rates for unexposed or differently exposed patients. Registries also might facilitate more complete follow-up of incident cases. These resources have also limitations common to other databases. Rates are provided for reported events without any control group. Limitations also include the imprecise nature of data linkage of drugs to events, and the temporal relationships between drug and events sometimes are not well established. In most claims data, unless an event leads to hospitalization, the event is not captured. Sometimes, very indirect methods are adopted, e.g., some may capture office visit events and often use of a drug is taken as an indicator of an event. In addition, claims interpreted as representing adverse drug reaction might not actually reflect the actual clinical event or an outcome of interest (e.g., not all claims of “convulsions” in such databases are actually episodes of epilepsy, and similarly, syncope, vasovagal attacks, etc., are often found events). These are limitations that prevent right quantification of the incidence of drug-related adverse reactions.

### 9.6.12 ADVERSE DRUG REACTIONS AND RESOURCE-POOR COUNTRIES

The type A reactions include normal and augmented response to drugs and are dose related; reactions are usually predictable and preventable on the basis of known pharmacology of drugs. The incidence of type A reactions is greater and usually associated with higher morbidity. It may be managed to overcome or prevent such reactions by reducing the dose, e.g., bradycardia associated with  $\beta$ -adrenoreceptor blockers and bleeding in association with anticoagulants.

The type B reactions are usually unpredictable and are often caused by immunological and pharmacogenetic mechanisms. The type B reactions are not dose-dependent, are relatively rare, often not predictable and preventable, and sometimes cause serious morbidities and death. Examples of this kind of reactions include malignant hyperthermia caused by anesthetics and many immunological reactions. It is difficult to classify other adverse drug reactions.

In resource-poor countries, frequent use of complementary medicines might interact with conventional allopathic drugs. Thus it may predispose to adverse drug

reactions, factors that need to be considered in their interpretation. A majority of drugs used in resource-poor countries are usually imported from other countries. The ingredients used in drugs may vary and the genetic makeup of the population might also vary, thus may predispose to adverse drug reactions. These factors are not usually verified among populations of resource-poor countries before approval of these drugs. Therefore, the risk of occurrence of drug-related toxicities in such populations could be very high and, in fact, remains unknown.

Due to geographic variations, poor socioeconomic condition, high cost of modern medicines, and nonavailability of physicians in most of the rural areas, the people of developing countries face greater difficulties in accessing standard health care. Drug retail shops frequently serve as the first point of contact of population for seeking health care, thus predisposing the poor people to be more vulnerable to self-medication, a potential contributor to adverse effects of drugs. Moreover, poly-pharmacy is a very common practice in resource-poor countries, which increases the incidence of adverse drug reactions. It has been demonstrated that drug toxicity sharply rises with the number of drugs consumed.

Age is another very important factor for development of adverse drug reaction—the very old and the very young are more susceptible to adverse effects of drugs due to compromised physiological reserve. The aging population is more likely to have cardiovascular, pulmonary, musculo-skeletal, and metabolic disorders that necessitate several medications; and all these predispose them to increased incidence and increased severity of drug-related toxicities. Patients with impaired kidney and liver functions and those with intercurrent illness are at greater risk for adverse drug reactions. In poor countries these are not meticulously considered by the doctors while prescribing drugs because of limitations of laboratory tests. Race genetic polymorphism and hereditary factors are known to affect the bioavailability of drugs and thus are common important contributing factors for adverse drug reactions in poor regions. Also, in poor countries, the effect of drugs may vary from place to place, depending on climatic diversity or different cultural and social backgrounds.

#### **9.6.12.1 Pharmacoeconomic Impact of Drug Toxicity in Developing Countries**

The economic impact of adverse drug events is less explored and less reported in developing countries. Adverse drug events prolong hospital stay, result in new admissions, and increase treatment cost leading to increased burden on the health care systems in resource-poor countries. It has been observed that the total cost of drug-related morbidity and mortality is exceedingly high, which exceeds the cost for treatment of the primary illness. Therefore, ADR-related admissions in developing countries with limited health care budget stretched that even further.

#### **9.6.12.2 Basic Requirements for Effective Postmarketing Surveillance Program in Resource-Poor Country**

The minimal requirement for the establishment of a working program for postmarketing surveillance of drugs requires infrastructure, funding, expertise, and a trained staff. For resource-poor countries, there may be shortcomings in all of these areas.

However, some useful activities can be established with limited financial resources if sincere efforts are undertaken. It is possible to initiate a program for concurrent surveillance during drug therapy, based on reporting of suspected adverse drug reactions by pharmacists, physicians, nurses, and patients at an affordable cost. Alternatively, a prospective surveillance before drug therapy for patients with a high risk for adverse drug reactions may be initiated.

Doctors or drug prescribers should be adequately notified regarding the drug to be monitored for adverse reactions. Information regarding suspected adverse drug reactions should be reported to the pharmacy for complete collection of data and their analyses, including patients' name, their medical and medication histories, a description of suspected ADR, temporal relationship of the event with drug administration, any remedial treatment required, and sequel and outcome. The cause(s) of each suspected adverse drug reaction need to be evaluated based on the patient's medical and medication histories, the circumstances of the adverse event, the result of de-challenge and re-challenge (if any), consideration of alternative etiologies, and a literature review. Description of each of the suspected adverse drug reactions and their outcomes needs documentation in patients' medical records.

Serious or unexpected adverse drug reactions should be reported to the drug regulatory/health authority and the drug's manufacturer. All adverse drug reaction reports should be reviewed and evaluated by the authorized pharmacy and therapeutics committee. Adverse drug reaction report information should be disseminated to health care professionals for educational purposes. In all of these processes patient confidentiality must be preserved. An organization's ongoing quality assurance activities should incorporate findings from adverse drug reaction monitoring and reporting programs.

### 9.6.13 WHO AND OTHER AUTHORITIES FOR PMS

The WHO established its program as a pilot project in 1968 initially in 10 and later in many other countries. The WHO promotes pharmacovigilance at the country level working through the WHO Collaborating Centre for International Drug Monitoring (Uppsala Monitoring Centre). This pharmacovigilance program has following objectives: greater patient care and drug safety, special emphasis on prevention of undesired drug-related toxicities, better public health safety in relation to the use of drugs, provision of reliable information for more rational use of drugs, improved assessment of risk–benefit profile to encourage safer and more effective use of medicines, the resolution of apparent conflicting interests of public health, and ensuring the welfare of individual patients.

Today worldwide many other regulatory authorities are involved in monitoring the safety of drugs. Other authorities include the United Kingdom's Medicine Control Agency (MCA) and the Committee on Safety of Medicine (CSM), the Vaccines Adverse Event Reporting System (VAERS), co-administered by the Department of Health and Human Services (DHHS), the FDA, and the Centers for Disease Control and Prevention (CDC) of the U.S., the Adverse Drug Reactions Advisory Committee (ADRAC) of Australia, and MedWatch Program of the USFDA-Canadian Adverse Drug Reaction Monitoring Program.

### 9.6.13.1 Safety Surveillance of Antiretroviral Drug and RaPID Program

In some resource-poor countries, many children have started their lives with antiretroviral therapy, but these countries have no effective and functioning pharmacovigilance system to monitor appropriate use of these drugs and collection of drug safety data. Long-time, adequate financial efforts and expertise are required to establish new pharmacovigilance programs or to strengthen the existing ones. WHO and the Uppsala Monitoring Centre (UMC) have been conducting training seminars for more than 15 years in those countries. Despite these efforts, UMC estimates that excepting a few, these countries have limited capacity; they collect little adverse drug reaction information and it is not sufficient for analysis of formulation of policies to increase patient safety. Drugs exhibiting toxicity of concern need to be removed from use or withdrawn from the market. And those are to be replaced by other suitable drugs.

The most significant benefit of the RaPID program is that it can establish a country- and disease-specific drug safety program very quickly within a reasonable period and concurrently help build institutional capacity at the country level. The RaPID program can help national drug authorities in capturing ADR data and their inclusion into UMC/WHO's Vigiflow software, and analyze them by a team of RaPID program global experts with technical expertise in HIV/AIDS, TB, and malaria and drug-related toxicities. It is important to mention that all activities of the RaPID program are coordinated and jointly developed with the national drug authority. The RaPID program is being implemented in joint technical collaboration with leading pharmacovigilance institutions from the developed and the developing countries including the Uppsala Monitoring Centre in Sweden, the national regulatory authority of Switzerland (Swissmedic), and other organizations, which provide activity-specific expertise, for example, WHO (various departments), Ecumenical Pharmaceutical Network, and the Indian Institute of Health Management Research (a WHO collaborating center). The RaPID program team has significant expertise in designing and implementing pharmacovigilance programs. With WHO (Geneva) support, the RaPID program is currently conducting an evaluation in several countries of Africa to assess their capacity for collection of pharmacovigilance data and their analyses to formulate appropriate policy related to drug use. Currently, the RaPID program team is in discussion with several countries (Nigeria, Sri Lanka, Uganda, India) and nongovernmental organizations (NGOs) (Medicines Sans Frontier, PSI, etc.) to explore collaborations and develop strategies for conducting pharmacovigilance.

### 9.6.13.2 Baseline Program in Hospitals of Resource-Poor Countries

Recently, a few hospitals in developing countries have taken initiatives and initiated spontaneous reporting programs at the facility level. ADR reporting forms are placed in different wards and out-patient departments. The doctors, nurses, and pharmacists report the adverse drug reaction, if any, to the pharmacovigilance cell, newly developed units of the hospitals. Based on the report, the cell provides relevant information to the drug regulatory authority of the country. Since its inception, the program looks very promising. Plans are under way to upscale existing spontaneous reporting programs to fully developed pharmacovigilance programs of these hospitals in near the future—its ultimate goal.

### 9.6.13.3 Possible Approach to Develop Drug Safety Monitoring Program for Hospital in Resource-Poor Country

Through awareness programs all health care providers need to be encouraged to report all suspected adverse drug reactions using a reporting form, which should be readily available all the time in all patient care areas of the health facilities including wards, out-patient departments (OPDs), and pharmacy departments. After filling out the forms, the health care provider should send them to the drug safety monitoring unit of the hospital. Data collected from these forms can be utilized to evaluate the reactions in detail. Several adverse drug reaction reporting forms are available, such as “yellow card” and “blue card” systems, and one developed by MedWatch. Generic forms can be modified to meet the local needs. The adverse drug reactions and related information of the particular drug(s) should be provided to the concerned authority. The determination of the likelihood of a causal relation between a suspected drug and an adverse drug reaction is an essential step in identifying drug toxicity. Based on the causality assessment, an adverse drug reaction can be classified as one of the following categories: certain, probable, possible, unlikely, conditional/unclassified, and not assessable/not classifiable. There are several causality assessment scales such as the WHO causality assessment scale, Naranjos scale, Karch and Lasagnas scale, Schumock and Thornton scale, European ABO system, and the Bayesian neutral scale. Any one these scales can be used to conduct causality assessments. The preventability and predictability of the adverse drug reactions can be assessed by using the specified scales. Thus, incidence of particular adverse drug reaction can be detected against the total number of drugs used in the hospital during the particular period. All data captured by the program should be entered into its database, which will be data for that particular population group(s). The relevant drug reactions data and their analyses should be periodically disseminated through adverse drug reaction bulletins, journals, and newsletters.

### 9.6.13.4 Inference for Future Buildup in Poor Countries

In resource-poor countries, it should be the responsibility of all health care workers to develop strategies for reporting, monitoring, and preventing adverse drug reactions. The drug regulatory authorities in poor countries should take the necessary steps to promote safe use of drugs in their country. Initially, the program might begin at a single hospital for consolidation and training and later might be extended to other hospitals as the program matures. Generally, people also need to be educated on the correct use of drugs and on reporting of undesirable experiences in association with drug use. The medical curriculum should include and emphasize rational use of drugs and aspects of adverse drug reactions. A formal training program for the primary health care professionals on adverse drug reactions should also be established. Postmarketing surveillance studies must be made mandatory after marketing any new drug in the country. A well-developed adverse drug reactions monitoring system can contribute a lot to the health care system if the formed teams/programs are supported by highly dedicated and well-experienced staff and good data management systems. Appropriate addressing of these issues would help establish an effective program of pharmacovigilance in resource-poor situations.

### 9.6.13.5 Data Mining in Postmarketing Surveillance

An increasing interest has developed in data mining or knowledge discovery initiatives using robust databases with development of large electronic health data storage systems in recent years. Web mining and information science can simultaneously make their application in postmarketing surveillance of drugs. Data mining processes are often performed on existing databases, for the purposes of postmarketing surveillance considering high cost for collection of data. It is difficult to determine the requirement of the necessary size of the dataset. It depends on quality of data, the background frequency of the event(s), and the strength of the association of the event with the drug; however, for even moderately rare events large databases are required.

### 9.6.13.6 Spontaneous Reporting Databases

The spontaneous reporting of adverse drug reactions by health care providers to health authorities or drug companies is an important procedure in postmarketing drug surveillance. However, spontaneous reporting systems are vulnerable to inconsistent reporting. The accuracy of the data may remain uncertain. Yet, spontaneous reporting databases contain large amounts of data. These databases could, therefore, be mined to obtain details of ADRs.

### 9.6.13.7 Prescription Event-Monitoring Databases

Prescription event monitoring (PEM) system detects adverse drug reactions by mobilizing data of high quality from family physicians on a select group of patients exposed to a specific (new) drug, for a limited period of time. Lack of an adequate control group is an important limitation of PEM database mining.

### 9.6.13.8 Linked Administrative Databases

Large linked health administrative databases, such as Medicaid in the United States, and the Ontario provincial databases contain data on millions of subjects. These might also be used as a source for data mining. The Saskatchewan-linked administrative health care utilization database and the Tayside Medicines Monitoring (MEMO) are examples of linked medical health databases. Both of them have been utilized to identify risks of benzodiazepine therapy.

### 9.6.13.9 Electronic Medical Records

Electronic medical records (EMRs) contain large numbers of data: e.g., use of tobacco products, use of nonprescription drugs, symptoms and signs of diseases, laboratory data, and social circumstances on a smaller numbers of patients. All these might be used for data mining. The availability of large numbers of variables and their combined use makes possible the generation of hypotheses and the exploration of new diagnoses or adverse events of drugs. EMR has been used by some to investigate detection of known adverse drug reactions.

#### 9.6.13.10 Other Databases

Specialist and clinical trials databases and overdose or toxicology databases might provide valuable information. Signals for liver-related ADRs have been reported from a biochemistry laboratory database at a higher rate than that reported by physicians. Poison information centers also record details of ADRs and thus might be a good contributor of pharmacovigilance activity.

#### 9.6.13.11 Data Preprocessing

Data preprocessing involves sampling and verification of data quality to ensure that data are clean. Medical data might contain erroneous data, for example, putting an age of 120 years instead of 20 years and documentation of hysterectomy in males. Data can also be used in creating new variables of interest for analysis, for example, it might be possible to estimate socioeconomic status from the postal code.

#### 9.6.13.12 Application of Data-Mining Techniques in PMS

Data mining involves a number of statistical techniques, including cluster analysis, link analysis, deviation detection, and disproportionality assessment, which can be used to determine the presence and assessment of the strength of adverse drug reaction signals. It is also a systematic process whereby large databases are searched. Combinations of variables that occur at a higher frequency than expected are mined. Research has been conducted specifically on the application of data mining techniques in postmarketed drug-related toxicity surveillance. Development of this tool is promising to optimize limited resources and improve the level of consistency in safety reviews of approved marketed drugs. An improvement in the current understanding of adverse drug reaction patterns is expected through the use of data-mining techniques. A successful data-mining tool will allow for earlier detection of safety signals and drug–drug interactions with drugs already in the market. Recently, there has been potential use of data mining and knowledge discovery in databases for detection of adverse drug events in pharmacovigilance. Knowledge discovery in databases (KDD) is a technical process that may be employed to explore potential adverse drug reactions more effectively. KDD involves selection of data variables and databases, data preprocessing, data mining, and data interpretation and utilization. Recently, the spontaneous reporting database of WHO Uppsala Monitoring and the UK yellow card scheme use data-mining methods. These data-mining methods used in pharmacovigilance are those of disproportionality, such as the proportional reporting ratio and information component, which has been used to analyze the drug-related adverse events. Examples are: association of captopril and other angiotensin-converting enzymes with cough, the association of pericarditis with practolol but not with other  $\beta$ -blockers, and the association of terfenadine with heart rate and rhythm disorders; these all could be identified by mining the database. In view of the importance of adverse drug reaction and the development of massive data storage systems and availability of powerful computers, the use of data-mining techniques in knowledge discovery in medical databases is now of increasing importance in the process of pharmacovigilance. They are likely to be able to detect signals earlier.

### 9.6.14 DISCUSSION

Postmarketing surveillance programs as well as clinical phase IV studies both are definitely essential to ensure the safety of drugs. These studies disclose beneficial and detrimental effects of drugs, including the existence of causal effects, risk factors, economic consequences, and characterization of drug use in clinical practice. Drug-related diseases impart a considerable burden to health care systems globally, which has been demonstrated well in the Western countries. The situations in the low-income countries are not very clear. There, published reports on the incidence and cost of drug-related problems are few. It is a reasonable assumption that less rigorous control of drug quality, easy availability, and indiscriminate usage create problems associated with drug therapy. A majority of drug-related problems are preventable as demonstrated by studies conducted in developed countries.

Appropriate instructions should be available on the effective use of drugs, and people should be instructed to adhere to them. Then prevention or reduction of drug-related toxicity would be possible for thousands of patients in developing countries. There, suffering could be alleviated as well as many lives could be saved, while millions of dollars would be saved annually by the society. The absence of awareness on the magnitude of drug-related problems in many societies is common. Adverse effects of drugs often manifest gradually and the symptomatology often mimic those of common illness, and usually they manifest at home and thus remain largely undetected and unrecorded. The awareness of drug-related problems is inadequate among politicians, the general public, patients, and sometimes even in professionals to trigger and stimulate a wide discussion on its prevention. So, qualified people are required in the health care system to support industry with genuine interest in disclosing these problems to everyone. An elaborative system of rules and regulations is necessary to govern the drug surveillance process. In postmarketing drug surveillance, pharmaceutical manufacturers, drug regulatory agencies, and the end users (physicians and patients) all need to play essential roles to minimize the risks.

### 9.6.15 FUTURE PERSPECTIVE

The future of postmarketing surveillance will need the proper development of research methods that would be capable to cope with the specific problems posed by the newly marketed drugs and would be able to accurately suggest adjustments for reducing severity of drug-related adverse events. Phase IV clinical studies and postmarketing surveillance, including pharmacovigilance, is now a very growing science that would offer great scope for minimizing harm to patients taking drugs. It will also reduce costs of health care systems. From small beginnings, with the appropriate technological knowledge and skills, postmarketing surveillance and phase IV studies can make important contributions to the health of people in any country. A successful postmarketing drug surveillance program needs capacity building, for example, training of professionals, optimization of computerized databases for research purposes, their joint use with traditional epidemiological methods, and so forth. The impact of new vaccines and new drugs on well-defined populations

needs assessment, which will be a critical task and from public health perspectives its impact is important. The pharmaceutical industry and its business environment should change immensely in the future. Growing competition from generic drugs, competitive product market, and limitation of resource and development costs are future problems for pharmaceutical executives, and they should plan a balanced program in this regard. The objective should be to divert resources for promotion of only those drugs that will be unlikely to be rejected by the regulatory agencies or shall not be removed from the market due to safety problems. A pharmaceutical company will need to use appropriate technology to ensure production of a safe and effective drug to ensure a favorable risk–benefit ratio. Thus, to implement a proactive postmarketing surveillance and risk management strategy, drug companies should always adapt to changing regulations to ensure compliance for eventual approval of their drug products. The pharmaceutical industries must adhere to international regulations in addition to local rules and should be regulated by a global enterprise.

Therefore, drug companies should report and communicate drug-related safety issues regularly to every country where they market their products. The adoption of advanced pharmacovigilance tools will greatly help drug companies to generate and submit reports to specific countries or regions based on their regulations. Here, specifically, signal detection and data management tools, management technology solutions, and adverse-event reporting systems will be specially helpful. Effective pharmacovigilance is needed for future successful drug safety surveillance for which radical changes are required in signal detection, use of data mining and management process, and use of these technologies in phase IV clinical trials. Thus, completion of analysis of clinical data would be quick as compared to the past. Time saving shall reduce in development costs of drug and would allow early arrival of new drugs on the market. Simultaneously, termination of future clinical trials would be possible on early detection of safety issues and, therefore, patients would be protected. Thus company resources would be saved that might be spent on modernization of their industry-based technology and development of efficient manpower.

The European Union's postmarketing surveillance system has undergone major changes over the last few years through a stronger drug regulatory and pharmacovigilance system. The EU PMS systems have the power to mandate phase IV studies and impose financial penalties on companies that fail to comply with regulations and their obligations. In recent years, the FDA has adopted many changes and many are currently under review process to have a more proactive approach to pharmacovigilance in the near future. There has been a noticeable shift forwarded by regulatory authorities, in terms of formulation of policies on risk management, and also by pharmaceutical companies in terms of incorporation of pharmacogenomics in their development programs. The purpose of these initiatives are to better predict safety issues and minimize risks as quickly as possible.

In the future, companies need to ensure a close link between premarketing and postmarketing pharmacovigilance activities to increase transparency of their activities and improve communication of information about drugs to begin risk management planning at the inception. Many companies have now agreed to voluntarily register clinical trials and will post all clinical trial data of marketed drugs, whether favorable or unfavorable, on publicly accessible websites.

### 9.6.16 CONCLUSION

Despite its four-decade history, postmarketing surveillance remains a dynamic clinical and scientific discipline. It continues to play a crucial role in meeting the challenges posed by the ever increasing range of drugs, all of which carry an unpredictable potential for harm. It is essential that previously unknown adverse effects are reported, analyzed, and their significance communicated effectively to the people, and it should be ensured that they have the knowledge to interpret that information. For all drugs, there is a trade-off between the benefits and the potential for harm. The harm can be minimized by ensuring that drugs are of good quality, safety, and efficacy and are used rationally. At the same time, expectations and concerns of the patient should be taken into consideration when therapeutic decisions are taken. The practitioners should ensure that risks in drug use are anticipated and will be managed if they occur. This will create a sense of trust among patients taking drugs. So, improvement of communication between the health professionals and the public is essential. Also, updating health professionals to understand the efficacy/risk of medicines that they prescribe is necessary for this purpose. As adverse drug reactions are a significant public health problem in every health care system, postmarketing drug surveillance systems need to be improved continuously. Simultaneously, it is a grand challenge with a fundamental problem of great social and economic importance, and the solution needs significant increases in scientific knowledge and technical capabilities.

## 9.7.1 FDA APPROVAL

### 9.7.1.1 Introduction

The Food and Drug Administration (FDA) is part of the Department of Health and Human Services (DHHS) in the U.S. federal government and is the regulatory agency responsible for marketing approval of new pharmaceutical products. Within the FDA are the Center for Drug Evaluation and Research (CDER), whose activities are the focus of this chapter, along with the Center for Biologics Evaluation and Research (which regulates vaccines and blood products), Center for Devices and Radiological Health, Center for Food Safety and Applied Nutrition, and the Center for Veterinary Medicine. The FDA has authority to write regulations relevant to interstate commerce associated with pharmaceuticals (as well as food, cosmetics, and veterinary medicines), which may then be enacted into law. Regulations may be enforceable by the FDA's compliance office. Guidelines created by the FDA, on the other hand, are meant to provide general direction to drug sponsors on many issues, without legal obligation. However, deviation from guidelines should be discussed with the agency in order to maintain a cooperative and common understanding of a drug's development.

It is important to keep in mind the FDA's concerns during drug development in order to anticipate and address them proactively during all phases of clinical development. The FDA's primary concern is always the protection of the health and rights of subjects involved in human drug research. In addition, during phases II and III the agency becomes concerned about the adequacy and quality of the scientific evaluation of the drug's safety and efficacy as part of a new drug application (NDA). This chapter will summarize the activities necessary to achieve and maintain regulatory clearance for the conduct of clinical trials and also describes some general strategies for the cooperative design of clinical programs to support marketing approval.

### 9.7.1.2 Regulations and Guidance Documents

Clinical trial conduct is governed by national laws that are supplemented by international, regional, and national guidance documents. Regulations regarding the conduct of clinical trials and the protection of human subjects involved in clinical trials in the United States, as well as many other regulations regarding food and drugs, are described in Title 21 of the Code of Federal Regulations (21 CFR) [1]. Clinical trials in the United States must conform to the regulations for investigational new drug (IND) applications, which are covered in 21 CFR Part 312 ("Investigational New Drug Applications"). Regulations regarding the content and format of NDAs are described in 21 CFR Part 314 ("Applications for FDA Approval to Market a New Drug"). Application of these regulations to the design and conduct of clinical trials will be addressed in greater detail throughout this chapter. Other important 21 CFR regulations for the clinical development of pharmaceuticals include Part 50, which covers the topic of "Protection of Human Subjects," and Part 56, "Institutional Review Boards."

In addition, the FDA has developed many guidelines for drug sponsors that provide direction regarding the application of the 21 CFR regulations, as well as

more specific information on the expectations that the FDA has for appropriate clinical study design and conduct. A key concept in the regulatory requirements for marketing approval is “substantial evidence” of efficacy from clinical trials, based on the Kefauver–Harris Amendments to the 1962 Food, Drug and Cosmetic Act, which was interpreted to mean that approval for the marketing of a new drug in the United States would be based on evidence from adequate and well-controlled investigations. This requirement would in turn imply that clinical trials had to be of sufficient size to have adequate statistical power to test important clinical hypotheses and had to meet the standard of being adequate and well controlled. To be adequate and well controlled a study has to have:

- A clear statement of objectives
- A design that permits a valid comparison with a control and provides a quantitative assessment of the drug effect
- A method of selection of subjects that ensures that they have the disease under study
- A method of patient assignment that minimizes bias
- A well-defined and reliable method of assessment of responses (outcome measures)

Several regulatory guidance documents from the FDA consider the reporting, evaluation, and interpretation of clinical trial evidence. These guidance documents were issued over a period of nearly 20 years. The first document is the Guideline for the Format and Content of the Clinical and Statistical Section of New Drug Applications [2]. This document addresses how the results of clinical studies are to be reported to the FDA. The second is the Guidance for Industry Providing Clinical Evidence of Effectiveness for Human Drug and Biological Products [3]. The agency participates in the International Conference on Harmonisation (ICH), which is a group of representatives from government and pharmaceutical industry groups in Japan, Europe, and the United States, formed to facilitate the development of mutually agreed upon guidelines for the chemical, nonclinical, and clinical development of new drugs. The guidance documents developed in ICH are then considered for adoption by national authorities in the three represented areas. The ICH guidances are powerful in that they support the design of clinical studies that are accepted internationally, increasing the efficiency of global drug development. For instance, the format issues of the NDA content and format guidelines mentioned above have been largely superseded by the ICH M4: Common Technical Document for the Registration of Pharmaceuticals for Human Use [4], which provides a structure for marketing applications that can be submitted in most all countries.

Of the ICH guidances relevant to the conduct of trials and adopted by the FDA, those most applicable to the conduct of clinical trials and support for drug registration are:

- E1B      The Extent of Population Exposure to Assess Clinical Safety: For drugs intended for long-term treatment of non-life-threatening conditions

- E2A Clinical Safety Data Management: Definitions and standards for expedited reporting
- E3 Structure and Content of Clinical Study Reports
- E4 Dose Response Information to Support Drug Registration
- E6 Good Clinical Practice: Consolidated Guideline
- E7 Studies in Support of Special Populations Geriatrics
- E8 General Considerations for Clinical Trials
- E9 Guideline on Statistical Principles for Clinical Trials
- E10 Choice of Control Group and Related Issues in Clinical Trials
- M3 Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals

Throughout this chapter, references will be made to several specific FDA and ICH guidances; however, they are all conveniently included on the FDA's website at <http://www.fda.gov/cder/guidance/>. Special attention should be paid to the ICH E9, as it also pertains to the aspect of the "substantial evidence" requirement. The FDA's current thinking on the matter of substantial evidence, meshing the views from these guidelines, can be found in a recent paper [5].

Once an organization has determined that it is interested in conducting a clinical trial in the United States, it is appropriate to begin plans for design of the protocol and its submission with supporting documentation to the FDA. The first clinical trial of a new investigational agent will require compilation and submission of an IND [6]. This submission includes information on the chemistry and manufacturing, non-clinical pharmacology, pharmacokinetics, and toxicology, as well as a summary of any previous human experience with the product. Thus, it is prudent to organize an internal team of individuals and external consultants as necessary who will contribute to the summarization of available information on the product and can address issues that may arise with regard to the IND submission. The formation of such a team is essential to establish a communication framework for discussing development issues, including regulatory submissions, meetings with authorities, responses to FDA questions, and so forth. Drug sponsors often do not adequately address cross-functional development issues, such as the implications of findings in animal studies to the clinical setting. A team appropriate to the size and structure of each organization can help to avoid neglect of such issues before they become regulatory roadblocks.

During the preparation of an IND application, questions may arise as to the contents of the submission, protocol design, or other development issues that would benefit from the FDA's input. In order to assist sponsors to best develop new products, the FDA has implemented a guidance on arranging meetings, Formal Meetings with Sponsors and Applicants of PDUFA Products [7], which is described in the next section. The first such opportunity in a product's development for a meeting with the FDA is referred to as the pre-IND meeting.

### 9.7.1.3 Consultation with the FDA

Formal meetings between drug sponsors and the FDA regarding the development of new drug products are possible in order to promote mutual understanding of issues relating to matters that arise during a research program (21 CFR 312.47).

Depending on the stage of development, these issues may involve chemistry/manufacturing, nonclinical or clinical research pertaining to the design of a development program, interpretation of study results and/or implications of research on other members of a therapeutic class, or special issues regarding a novel compound. The FDA has identified three basic types of meetings according to the timing and intention of the meeting.

- *Type A Meetings* Immediately necessary to discuss clinical holds, protocol assessments, or other development issues that are considered to be critical to the continued development of a product. Such meetings are normally scheduled within 30 days of a meeting request. An information package that includes the questions and background information for the agency to review, prior to the meeting, and that provide information necessary for their review must be submitted at least 2 weeks prior to the meeting (contents of the information package provided to the agency prior to formal meetings is described in the meetings guidance).
- *Type B Meetings* These meetings include discussions prior to submission of an initial IND (pre-IND meeting), certain meetings after completion of phase I, end of phase II, and meetings to discuss the content and format of new drug applications (pre-NDA meeting). Type B meetings are scheduled within 60 days of the agency's receipt of the meeting request and require submission of a briefing document at least 4 weeks prior to the meeting date.
- *Type C Meetings* Other meetings regarding the development and review of drug products. Type C meetings are scheduled within 75 days of meeting request receipt and briefing documentation is required at least 2 weeks prior to the meeting.

In addition to these sponsor meetings that the FDA allows, special protocol review by the FDA is also possible. A written request is necessary for each meeting desired by a drug sponsor. This request must include a brief summary of the product, type of meeting requested, an agenda and list of objectives for the meeting, along with administrative information regarding the scheduling of the meeting as listed in the meetings guidance. The reviewing division normally responds to meeting requests within 14 days of receipt of the request, at which time a mutually agreeable time and date are set for the meeting.

**Conducting and Documenting Formal FDA Meetings** After an introduction of the meeting participants and a brief discussion of the background and objectives of the meeting, the agenda of the meeting is typically driven by the list of questions and/or issues that the sponsor has submitted as part of the meeting request and briefing documentation. Agency representatives provide responses to each question or issues raised by the sponsor, and discussion takes place if necessary to clarify the agency's position. Many divisions at the FDA are now providing to sponsors prior to meetings a copy of the agency's internal meeting minutes where they discuss their responses before meeting face to face with the sponsor. Though consideration of the planned duration of the meeting is prudent, sponsors should take advantage of the opportunity of these meetings to ensure understanding of the agency's position and resolve any misunderstandings during the meeting discussion. A summary of

the proceedings normally forms the conclusion of the meeting, and the FDA prepares a written summary of the meeting as the official minutes, which is shared with the sponsor (usually within 30 days of the meeting). Any disputes regarding the minutes of these meetings may be addressed as per 21 CFR 10.75 (Administrative Practices and Procedures), 312.48, and 314.103.

#### 9.7.1.4 Investigational New Drug Applications

Key to the successful clinical development of a new product is completion and submission of an IND. The FDA's Guidance for Industry on the Content and Format of Investigational New Drug Applications (IND) for Phase I Studies of Drugs, Including Well-Characterized, Therapeutic, Biotechnology-derived Products [6], along with 21 CFR 312.22 and 312.23, provides a clear framework for the content and format of such submissions. While the required components of the IND are standardized by the Guidance and 21 CFR, the FDA has allowed some flexibility in the presentation of data in the application. Also, the agency has begun to accept electronic submissions of INDs, reducing the burdens of archiving and navigating paper-based submissions.

Whatever the therapeutic class, status of development, chemical qualities, or other product characteristics, sponsors of an IND will increase the likelihood of a positive outcome of the FDA's review if they view the application from the perspective of the agency staff who will be considering the documentation. Mindfulness of the agency's concerns for the safety and rights of subjects, and in later stages of development the quality of research design regarding establishment of a product's safety and efficacy, should be maintained throughout the preparation of the application. A logical format will also aid in the review and avoids confusion among the team that will be assembled to consider the application at the agency. Following the FDA's guidance on the content and format is a good start in this direction, but cross-functional critiquing the application by the sponsor throughout the compilation process will help to ensure that the technical information is presented effectively.

***Content and Format*** As per the regulations in 21 CFR 312.23, an IND must include the following components to be considered complete for a new drug product being proposed for clinical study.

***Cover Sheet (Form FDA-1571)*** Following a cover letter in standard business style addressed to the Center for Drug Evaluation and Research, a completed Form FDA-1571 (available on the FDA website) is required. This form provides a brief identification of the contents of the submission, along with administrative information regarding the product sponsor's responsible personnel and their contact information.

***Table of Contents*** A detailed description of the components of the application and their location within the submission.

***Introductory Statement and General Investigational Plan*** This brief section of the IND provides an opportunity to introduce the agency staff to the product, including

intentions for its development, potential indications for use, any regulatory history (within and outside the United States), and any exceptional aspects of the IND that might be important for the review team.

**Investigator's Brochure** The investigator's brochure should follow the ICH guidance on the standards for the content and format of this document.

**Protocol(s)** Phase I study protocols need not be of the same level of detail as those for phase II or III trials; however, they should minimally include an outline of the investigation including number of subjects, description of safety exclusions, doses and duration of planned treatments, and safety monitoring. Since the objectives of phase I trials are normally to assess the safety, tolerability, pharmacokinetics, and perhaps some pharmacodynamic effects of the new drug, plans for assessing each of these aspects of the product's activities should be described in a rational manner.

Phases II and III protocols are required to provide a detailed description of all aspects of the trial. In addition to the assessment of safety, efficacy measurements need to be described thoroughly, remembering that the concerns of the FDA expand to include assessment of the trial's scientific merit toward eventual submission of study results in support of a marketing application.

**Chemistry, Manufacturing, and Controls (CMC) Information** Detailed information regarding the active ingredient (the drug substance) and the drug product (the formulation, such as tablet, solution, etc.) are required as described in 21 CFR 312.23(a)(7) and the Guidance on IND Content and Format for each and all of the products being investigated in the study (including placebo and active comparators). For the drug substance, this information must include:

- A description of the drug substance, including its physical, chemical, and/or biological characteristics
- The name and address of its manufacturer
- The general method of preparation of the drug substance
- The acceptable limits and analytical methods used to assure the identity, strength, quality, and purity of the drug substance
- Information to support the stability of the drug substance during the toxicologic studies and the proposed clinical study(ies)

With regards to the drug product information, similarly detailed information is required, including:

- A list of all components, which may include reasonable alternatives for inactive compounds, used in the manufacture of the investigational drug product, including both those components intended to appear in the drug product and those that may not appear but that are used in the manufacturing process
- Where applicable, the quantitative composition of the investigational new drug product, including any reasonable variations that may be expected during the investigational stage

- The name and address of the drug product manufacturer
- A brief, general description of the method of manufacturing and packaging procedures as appropriate for the product
- The acceptable limits and analytical methods used to assure the identity, strength, quality, and purity of the drug product
- Information to support the stability of the drug substance during the toxicologic studies and the proposed clinical study(ies)
- A brief general description of the composition, manufacture, and control of any placebo to be used in the proposed clinical trial(s)
- A copy of all labels and labeling to be provided to each investigator
- A claim for categorical exclusion from or submission of an environmental assessment

The information presented in the CMC section of the IND should be prepared by or at least with the close involvement of professionals within the organization who have expertise in this area of development and experience in preparing CMC documentation for regulatory submission. An FDA guidance specific to requests for information from the FDA relevant to CMC issues at the pre-IND stage is available to assist with questions that may arise during the preparation of this section of the IND.

*Pharmacology and Toxicology Information [21 CFR 312.23(a)(8)]* A summary of the pharmacology (effect of the drug on animals) and information known about the absorption, distribution, metabolism, and excretion (pharmacokinetics) of the drug should be provided. Individual reports may be provided; however, a summary is often sufficient. The sponsor should consider the stage of development (and the FDA concerns at that stage of development) and what if any implications the results of these studies may have on the assessment of safety.

Because of the safety concerns at the FDA in reviewing IND documentation and regulating clinical trial conduct, much more detailed information is required from the results of toxicology studies compared to other nonclinical studies. Short- and long-term trials in animals need to be presented in a logical manner, paying particular attention to the implications that the results and methods used in the study have for the design of the clinical trial and the characteristics of the subjects involved in the study. ICH has issued several guidances regarding the design and reporting of toxicology studies to support clinical trials and marketing applications that the sponsor should consider. In addition, the ICH M3 guidance Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals [8] must be considered to assure that the duration of treatment in the proposed clinical study is supported by the duration and types of toxicology studies reported in the IND. Detailed listings of data from each toxicology study used to support the conduct of the clinical study must be presented in the IND.

*Previous Human Experience* A summary of any and all previous investigational and if available marketed use of the product should be provided. Individual study reports are not normally required.

**IND Review Process** Once an IND is submitted to the FDA, it is routed to the appropriate reviewing division for assembly of a review team of representatives from each of the functional areas (CMC, nonclinical pharmacology and toxicology, clinical) and initiation of the review process. The review clock starts at the date of receipt of the application at the FDA, and if no comments are received by the sponsor within 30 days, the application is considered to be cleared. No formal approval letter is typically provided by the FDA; however, if issues are identified that delay or halt the clinical trial, the agency will issue a clinical hold to the sponsor (see following section).

**Information Amendments and New Protocols (21 CFR 312.30)** New protocols and amendments to previously submitted protocols must be submitted to the FDA prior to enactment at the clinical site, in addition to obtaining necessary institutional review board approval. There is no need to await the FDA review; however, the agency may provide comments to a sponsor, which may impact study conduct.

The IND sponsors are also responsible for submitting new technical information (toxicology study reports, chemistry or manufacturing changes, etc.) to the FDA. These “information amendments” should be presented in a format that facilitates the agency’s review of the submitted information, whether or not comment from the agency is requested by the sponsor.

#### 9.7.1.5 Clinical Hold: Issues and Resolution

At any time during the review of an initial IND submission or during the conduct of a clinical program, the FDA may order a drug sponsor to delay or suspend clinical study conduct (21 CFR 312.42). Such “clinical holds” may be limited in nature to a specific protocol or stage of development (“partial clinical hold”) or may impact all clinical investigation of a product (“complete clinical hold”). There are many reasons that the agency may take such an action, including:

- Risk to the health of subjects
- Unqualified investigators
- Investigator brochure deficiencies
- Insufficient information in IND to assess subject risks
- Phase II or III study plan or individual study deficient in design

Unless there is immediate and serious risk to patients, the FDA will attempt to discuss and resolve any clinical hold issues prior to imposing the clinical hold. If necessary, the clinical hold is communicated to the sponsor and immediate action is required as described in the clinical hold letter.

Sponsors must submit an official Response to Clinical Hold in order to address the concerns of the agency. Within 30 days, the FDA will provide a response that either removes the hold or describes any outstanding deficiencies. Resumption of the clinical study on hold may not occur until official notification by FDA of its removal.

### 9.7.1.6 IND Sponsor Reporting Requirements

**Safety** Any serious and unexpected drug-related adverse event that occurs during clinical research of a product must be submitted by the drug sponsor (or designee) to the FDA, as well as all investigators participating in trials of the product. Submission of such events must occur within 15 calendar days of the sponsor's awareness of the event. If the event is fatal or life-threatening, the report to the FDA must be submitted within 7 days. Serious adverse events are any untoward medical occurrence that at any dose:

1. Results in death.
2. Is life-threatening.
3. Requires inpatient hospitalization or prolongation of hospitalization.
4. Results in persistent or significant disability/incapacity.
5. Is a congenital anomaly/birth defect.
6. Any other significant medical event that requires intervention to prevent the occurrence of one of the above.

A complete explanation of sponsor responsibilities for submission of serious adverse event reports is found in 21 CFR 312.32.

**Annual Reports** Each year, within 60 days of the anniversary date of the IND becoming effective, an annual report summarizing accumulated safety and other updates to the IND file must be submitted to the FDA. This IND annual report includes:

- A brief summary of the status of each study in progress or completed during the previous year
- A summary of frequent and serious adverse events
- A summary of all safety reports submitted in the previous year
- A list of subjects who died or dropped out of clinical studies due to adverse events
- A summary of new understandings that have been achieved regarding the drug's activity
- A list of nonclinical studies completed or in progress during the previous year and summary of significant findings
- A summary of chemistry and manufacturing changes
- An investigation plan for the upcoming year
- An updated investigator brochure (if changed in the previous year)
- Any unreported phase I protocol amendments
- Any significant foreign marketing developments (such as approvals or withdrawals)

Due to the need to integrate information from several functional groups (chemistry/manufacturing, nonclinical, clinical) into IND annual reports, a central point

within the sponsor's organization is typically identified to coordinate the compilation of this document. This is typically an activity of the regulatory affairs department of a drug sponsor; however, it may take place within a document management center or be prepared by an external vendor, depending on the size and organization of the drug sponsor. IND annual reports are submitted administratively to the IND file at the FDA. Once a product is marketed, NDA annual reports are also required; however, the IND report must continue to be submitted each year after product commercialization.

#### 9.7.1.7 Marketing Approval Requirements

**Pivotal Trials** As discussed earlier in this chapter, discussion and cooperation between a drug sponsor and the FDA is strongly encouraged by the agency to maximize the adequacy of the NDA submission to provide substantial evidence in support of the marketing application, including “adequate and well-controlled” studies that provide the information necessary for the agency to assess the safety and efficacy of the product. These “pivotal” trials will have the statistical power to reach a conclusion regarding the predetermined efficacy endpoint(s) and also contribute significantly to the safety database to allow a well-informed benefit–risk assessment by the agency. Additional studies that examine the drug's effects in special populations (elderly, hepatically impaired, etc.), are also required to elucidate the product's activity and to assist in the evaluation of a drug's safety in a less controlled environment during marketed use.

**NDA Format and Content** The overall format and content of a new drug application as described in the ICH M4 guidance includes the following administrative, chemistry/manufacturing, nonclinical, and clinical information.

#### Module 1: Administrative Information and Prescribing Information

- 1.1 Table of Contents of the Submission Including Module 1
- 1.2 Documents Specific to Each Region (e.g., application forms, prescribing information)

#### Module 2: Common Technical Document Summaries

- 2.1 CTD Table of Contents
- 2.2 CTD Introduction
- 2.3 Quality Overall Summary
- 2.4 Nonclinical Overview
- 2.5 Clinical Overview
- 2.6 Nonclinical Written and Tabulated Summary
  - Pharmacology
  - Pharmacokinetics
  - Toxicology
- 2.7 Clinical Summary
  - Biopharmaceutics and Associated Analytical Methods
  - Clinical Pharmacology Studies
  - Clinical Efficacy
  - Clinical Safety
  - Synopses of Individual Studies

**Module 3: Quality**

- 3.1 Module 3 Table of Contents
- 3.2 Body of Data
- 3.3 Literature References

**Module 4: Nonclinical Study Reports**

- 4.1 Module 4 Table of Contents
- 4.2 Study Reports
- 4.3 Literature References

**Module 5: Clinical Study Reports**

- 5.1 Module 5 Table of Contents
- 5.2 Tabular Listing of All Clinical Studies
- 5.3 Clinical Study Reports
- 5.4 Literature References

The important clinical sections of the application are modules 2.5 (Clinical Overview) and 2.7 (Clinical Summary). An outline of these sections follows:

**2.5 Clinical Overview**

- 2.5.1 Product Development Rationale
- 2.5.2 Overview of Biopharmaceutics
- 2.5.3 Overview of Clinical Pharmacology
- 2.5.4 Overview of Efficacy
- 2.5.5 Overview of Safety
- 2.5.6 Benefits and Risks Conclusions
- 2.5.7 References

**2.7 Clinical Summary**

- 2.7.1 Summary of Biopharmaceutic Studies and Associated Analytical Methods
  - 2.7.1.1 Background and Overview
  - 2.7.1.2 Summary of Results of Individual Studies
  - 2.7.1.3 Comparison and Analyses of Results across Studies
- 2.7.2 Summary of Clinical Pharmacology Studies
  - 2.7.2.1 Background and Overview
  - 2.7.2.2 Summary of Results of Individual Studies
  - 2.7.2.3 Comparison and Analyses of Results across Studies
  - 2.7.2.4 Special Studies
- 2.7.3 Summary of Clinical Efficacy
  - 2.7.3.1 Background and Overview
  - 2.7.3.2 Summary of Results of Individual Studies
  - 2.7.3.3 Comparison and Analyses of Results across Studies
  - 2.7.3.4 Analysis of Clinical Information Relevant to Dosing Recommendations
  - 2.7.3.5 Persistence of Efficacy and/or Tolerance Effects
- 2.7.4 Summary of Clinical Safety
  - 2.7.4.1 Exposure to the Drug
  - 2.7.4.2 Adverse Events

- 2.7.4.3 Clinical Laboratory Evaluations
- 2.7.4.4 Vital Signs, Physical Findings, and Other Observations Related to Safety
- 2.7.4.5 Safety in Special Groups and Situations
- 2.7.4.6 Postmarketing Data
- 2.7.5 References
- 2.7.6 Synopses of Individual Studies

The contents of each of these sections is described in detail within the M4 guidance; however, sponsors should be mindful again that this is a guidance that should be adapted to each drug product in cooperation with the agency during pre-NDA discussions as per the FDA/sponsor meeting guidance.

***FDA Review of Marketing Applications*** Once the NDA is submitted to the FDA, an initial review is conducted to consider if it contains sufficient information to complete their review. The agency then informs the sponsor of the application's acceptance and the review begins. Questions are usually raised by the agency and discussed with the sponsor during the review process, and labeling negotiations take place after the technical review is complete. Prior to completion of the FDA review, public discussion may take place in which one of the FDA advisory committees is assembled to consider specific questions for which the agency requests external advice. Advisory committees have no regulatory power but rather serve as consultants to the agency, which provides the final, formal approval action. Current standard timelines for completion of marketing application review will lead to an FDA action—approval, nonapproval, or approvable (upon completion of specific additional requirements)—within approximately 10 months.

#### **9.7.1.8 Summary**

In this first section of our chapter on regulatory approval, we have identified the basic requirements that need to be addressed in order to initiate clinical trials in the United States and the obligations of drug trial sponsors during the ongoing conduct of a clinical research program. The objective of investigational clinical studies is to achieve marketing approval of a new product and support the commercial positioning of the drug. Toward this end, we have provided a roadmap for discussions with the FDA and the preparation of essential drug applications. Though these concepts and tactics are common to most drug development projects, a customized strategy must be prepared for each new drug, which reflects its intended use and intrinsic characteristics. The FDA has developed guidance and regulations to assist sponsors in addressing most common and several special circumstances, including orphan drugs (which address diseases with small patient populations), “accelerated” or “priority” review, and accelerated development of products for life-threatening diseases not addressed with available therapies. Each of these categories of new drug products requires thorough discussion with the FDA during development in order to agree upon registration requirements. Accelerated development is considered in greater detail in the following section.

## 9.7.2 FAST-TRACK APPROVAL

### 9.7.2.1 Introduction

The Food and Drug Administration Modernization Act of 1997 has an intriguing section (No. 112) entitled Expediting Study and Approval of Fast Track Drugs (the act) [9]. In 1998, the FDA issued a Guidance for Industry: The Fast Track Drug Development Programs (the FTDD programs) [10] to meet the requirement of the act. The purpose of FTDD programs is to “facilitate the development and expedite the review of new drugs that are intended to treat serious or life-threatening conditions and that demonstrate the potential to address unmet medical needs” [9]. The act states that an application for approval of a fast track product may be approved if it is determined that “the product has an effect on a clinical endpoint or on a surrogate endpoint that is reasonably likely to predict clinical benefit” [9].

### 9.7.2.2 Fast Track Is More Than “Priority Review”

The FDA’s Center for Drug Evaluation and Research (CDER) and the Center for Biologics Evaluation and Research (CBER) have long-standing policies that describe criteria for review priority classification of marketing applications. Products regulated by CBER are eligible for priority review if they provide a significant improvement in the safety or effectiveness of the treatment, diagnosis, or prevention of a serious or life-threatening disease. Products regulated by CDER are eligible for priority review if they provide a significant improvement compared to marketed products in the treatment, diagnosis, or prevention of a disease; eligibility is not limited to drugs for a serious or life-threatening disease. A fast track product would ordinarily meet either the center’s criteria for priority review. Note, however, that for an NDA or BLA (biologic license application) manufacturers need not seek fast-track designation to be eligible for priority review.

### 9.7.2.3 Request for Designation of Drug as Fast-Track Product

Since *fast-track* programs are designed to facilitate the development and expedite the review of new drugs or biologics that are intended to treat serious or life-threatening conditions and that demonstrate the potential to address unmet medical needs, they emphasize the critical nature of close, early communication between the FDA and sponsors. Procedures such as pre-IND and end-of-phase I meetings are convened as ways to improve the efficiency of preclinical and clinical development. These meetings can help FDA and manufacturers reach early agreement on the design of the major clinical efficacy studies that will be needed to support approval. But the manufacturer of a new drug may request the FDA to designate the drug as a fast-track product concurrently with, or at any time after, submission of an application for the investigation of the drug. Within 60 calendar days after the receipt of a request, the FDA shall determine whether the drug that is the subject of the request meets the criteria. If the FDA finds that the drug meets the criteria (i.e., “serious or life-threatening and unmet medical condition” and “valid surrogate endpoint”), it shall designate the drug as a fast-track product and shall take appropriate actions to expedite the development and review of the application for approval

of such product. Under certain circumstances, the FDA may consider reviewing portions of a marketing application in advance of the complete NDA or BLA. Fast-track products may also be eligible to participate in the FDA's Continuous Marketing Applications Pilot 1 or Pilot 2 programs [11]. To facilitate FDA review, a submission for fast-track designation should contain all discussion and supporting documentation necessary to permit a reviewer to assess whether the criteria for fast-track designation are met without having to refer to information located elsewhere, yet should also not be voluminous. The amount of discussion and supporting documentation that shows that the criteria are met will vary. For example, little explanation or supporting documentation may be needed to establish that studying the drug in the treatment of a fatal condition with no approved treatment would qualify if the endpoint were mortality. More extensive explanation and supporting documentation would likely be submitted to show that for a nonfatal condition, serious or life-threatening aspects of the condition will be studied. Where acceptable therapy for the condition already exists, still more extensive discussion and supporting documentation would probably be submitted to establish that the new therapy has the potential to fill a medical need not met by existing therapy.

#### **9.7.2.4 Limitations**

Approval of a fast track product may be subject to the following requirements. The manufacturer needs to: (a) conduct appropriate postapproval studies to validate the surrogate endpoint or otherwise confirm the effect on the clinical endpoint and (b) submit copies of all promotional materials related to the fast track product during the preapproval review period and, following approval and for such period thereafter as the FDA determines to be appropriate, at least 30 days prior to dissemination of the materials. However, the FDA also may withdraw approval of a fast track product using expedited procedures if (a) the manufacturer fails to conduct any required postapproval study of the fast track drug with due diligence; (b) a postapproval study of the fast track product fails to verify clinical benefit of the product; (c) other evidence demonstrates that the fast track product is not safe or effective under the conditions of use; or (d) the manufacturer disseminates false or misleading promotional materials with respect to the product. Therefore, the fast track approval is only a conditional approval for the drug. Nevertheless, the prospect of early availability on the market of the drug has great implications for patients as well as for the drug manufacturer.

#### **9.7.2.5 Accelerated Approval Issues (I): Clinical and Surrogate Endpoints**

Since 1998 many health products have reached patients who suffered from HIV (human immunodeficiency virus), cancer, hepatitis C, and some other diseases sooner by using the fast-track act and the FTDD programs. In the mean time several scientific issues have also surfaced when following the FTDD procedures. The surrogate or intermediate endpoints and their potential in predicting clinical benefit is the major issue [12–15]. Manufacturers whose products are in fast track drug development programs may seek traditional approval based on data demonstrating an effect on clinically meaningful endpoints or well-established surrogate endpoints. Alternatively, they may seek approval under the accelerated approval regulations.

If a manufacturer seeks approval of a product in a fast track drug development program based on evidence of an effect on a less than well-established surrogate endpoint, the FDA may grant accelerated approval based on a determination that the effect on the surrogate endpoint is reasonably likely to predict clinical benefit (21 CFR 314.510 and 601.41). Drug approval under the accelerated approval regulations may also be based on demonstrated clinical effects that are not the desired ultimate benefit but are reasonably likely to predict such benefit (e.g., improved exercise tolerance in refractory heart failure might be considered reasonably likely to predict ultimate benefit) (21 CFR 314.510 and 601.41).

Section 506(b) essentially codifies in statute the FDA's accelerated approval regulations. A surrogate endpoint was defined in the preamble to the accelerated approval rule (57 FR 13234–35, April 15, 1992) as “a laboratory or physical sign that is used in therapeutic trials as a substitute for a clinically meaningful endpoint that is a direct measure of how a patient feels, functions, or survives and that is expected to predict the effect of the therapy.” Although some surrogate endpoints are recognized as well-established and have long been a basis for approval (e.g., change in blood pressure or cholesterol), the accelerated approval rule allows reliance in specific circumstances on a “surrogate endpoint that, while ‘reasonably likely’ to predict clinical benefit, is not so well-established as the surrogates ordinarily used as bases of approval in the past” (57 FR 58942–44, December 11, 1992). To meet the statutory standard for approval, which requires the submission of “substantial evidence” to demonstrate effectiveness, “there must be evidence from adequate and well-controlled studies showing that the drug will have [its claimed] effect ... That effect will, in this case, be an effect on a surrogate endpoint.” (57 FR 58943–44).

With respect to approval based on clinical endpoints other than survival or irreversible morbidity, the preamble to the final accelerated approval rule pointed out that such approval would usually be considered (like other approvals based on a clinical finding) under traditional procedures (i.e., not under accelerated approval). Approval based on clinical endpoints other than survival or irreversible morbidity would “be considered under the accelerated approval regulations only when it is essential to determine effects on survival or irreversible morbidity in order to confirm the favorable risk/benefit judgment that led to approval” (57 FR 58946). The following examples illustrate types of clinical endpoints that could be a basis for approval with a requirement for further studies under the provisions of the modernization act and the accelerated approval rule:

- Clinical endpoints measuring short-term benefit in a chronic condition where short-term benefit per se does not outweigh risk and where durability of benefit is uncertain but expected.
- Clinical endpoints measuring lesser symptoms or signs of a serious disease (e.g., weight loss, appearance) when the resulting benefits do not per se outweigh risks but are expected to lead to a favorable effect on ultimate outcome, which would outweigh risks.
- Clinical endpoints measuring substantial benefits otherwise suitable for ordinary approval but where there exists a significant but limited concern that the

treatment may adversely affect ultimate outcome. Where such concerns are minimal, ordinary approval would be used. Where the concerns are substantial, data regarding ultimate outcome would be required preapproval. Between these extremes, accelerated approval may be considered.

#### **9.7.2.6 Accelerated Approval Issues (II): Postapproval Study**

The required postapproval study of the fast track drug has a broadened definition. That is, the postapproval study does not have to be a separate study but can be a proper continuation/extension of the same study upon which the early submission for accelerated approval is based. This use of the same study for both accelerated and final approval has been a common practice in HIV. An obvious advantage of such a proper continuation of the same study, instead of initiating a new study, is that much time and resource can be saved. It is also conceivable that in certain situations of severe diseases (such as pancreatic cancer) continuation/extension of the same trial, often very large in sample size, is the only feasible way to study the treatment effect under investigation. This broadened definition may also fit in what has been discussed in the literature [16] as “seamless phases II and III,” except that the “phases” may not be labeled as such in this case. However, there are design and conduct considerations to continue a study properly so as to ensure that the final submission of the product satisfies the usual requirements of the traditional approval. For example, the protocol has to design ways to avoid excessive “crossovers” in the continuation to maintain the integrity of the trial for the later definitive endpoint.

#### **9.7.2.7 Accelerated Approval Issues (III): Control of Type I Error Rate**

Controlling the probability of type I error is an important issue from the regulatory and consumer standpoints. It should be recognized that the tentative, conditional approval of a fast track drug requires control of a different kind of type I error rate and that the level of control also needs to be considered. This stems from the fact that often an intermediate (surrogate) endpoint is used at the fast track review and the final approval is based on the confirmation of the treatment effect on the clinical (primary) endpoint.

Since the objective and endpoint often change between two possible approvals according to the design, this raises some interesting questions: Do we view the fast track approval submission as an interim analysis of the whole study or view the final analysis as a “poststudy extension” (i.e., the fast track submission is the main study)? If the fast track approval submission is an interim analysis, how does this type of interim analysis differ from the usual ones? What is the implication of the type I error rate when the first accelerated approval is only a conditional one? How should the type I error rate(s) be calculated and controlled? These issues have been discussed in Shih et al. [17].

The practice of continuation or extension of a study is not uncommon in clinical trials. But the current situation has a unique characteristic in that the continuation is to investigate a more important clinical endpoint (alias the primary endpoint), which requires a longer time to manifest than the surrogate or intermediate endpoint. When the study is to continue for a different mission, it is natural to view the

latter part as an extension. If the latter part is an extension, the first part for the expediting approval must be the main part. Therefore, the type I error rate for the surrogate or intermediate endpoint at the accelerated approval submission (the main study) and that for the primary endpoint at the final submission (the “internal” extension study) may be controlled separately, each at the conventional level.

Another popular view of this situation is that this is a two-stage design with one interim analysis. After all, the first part is an “early” submission. However, it should be noticed that there are differences in the current situation from the usual interim analyses in the group sequential design setting, at least from the outset.

In the usual group sequential design setting, study monitoring is based on a single endpoint. Here, in this situation two endpoints are involved in the sequential monitoring process. Furthermore, the two endpoints are “ordered” differently by their relative emphasis and expected outcomes at the two stages. The usual sense of overall (or experiment-wise) type I error rate means the probability of falsely rejecting any true hypothesis. However, this concept is not useful for the situation where one hypothesis ultimately dominates the other at a later time point with more data.

Shih et al. [17] showed that the final approval type I error rate only involves the primary clinical endpoint. The next question is whether the tentative, conditional approval for an early release of the drug on the market should be protected by controlling another false-positive rate prior to the confirmation. If affirmative, how much? There is no definitive answer to the above question since the answer may well be dependent on how much risk the consumers (patients) need to be protected from using a yet-to-be confirmed drug. That in turn depends on how restrictive the early use of the drug would be. It is reasonable to suggest that, if the time gap between the conditional early approval and the confirmatory final approval is short and that the use of the drug is limited by the label during this gap time, the allowance for the tentative, conditional approval type I error rate could be greater (i.e., more relaxed) than the situation of a wider use of the drug during a longer gap time. In any case, this is clearly another kind of type I error rate, which should not be confused with the one for the final approval, and Shih et al. [17] showed that these two error rates should not be added directly. Specifically, denote

$\alpha_F$  = final approval type I error rate

$\alpha_E$  = early submission type I error rate

Since the early submission can also be the final submission, the above two error rates overlap. Subtracting this overlap,

$\alpha_A$  = tentative, conditional accelerated approval type I error rate during the gap time

Shih et al. [17] suggested considering the following scenarios:

1. Control  $\alpha_F$  at 0.05 level.
2. Control  $\alpha_F$  at 0.05 level and, in addition, control  $\alpha_E$  also at 0.05 level.

3. Control  $\alpha_F$  at 0.05 level and, in addition, control  $\alpha_A$  at 0.01 level.
4. Control  $\alpha_F + \alpha_A$  at 0.05 level, for example,  $\alpha_F = 0.04$  and  $\alpha_A = 0.01$ .

Scenario 1 views that the ultimate approval is the final conclusion of the drug's efficacy, hence only  $\alpha_F$  needs to be controlled at the conventional 5% level. Scenario 2 views that the continuation of the trial is an extension study. Each section of the submission process is controlled at the 5% level. Scenario 3 controls the final submission at the conventional 5% and the tentative conditional type I error rate at 1% (implying to impose a stricter risk protection for the accelerated approval). Scenario 4 is the most conservative way of controlling the accelerated and final approvals together at the 5% rate.

In the approaches described above, the clinical and the surrogate endpoints may be controlled at different significance levels at the first stage. This is an advantage in terms of design flexibility, but not necessarily in terms of statistical power. Another approach is to test the endpoints in an ordered fashion at the interim stage so that we may use the primary and secondary nature of the endpoints and gain some power over scenario 4. This is described briefly as follows. At stage 1, we will test the surrogate endpoint first, then the clinical endpoint, since the former is considered more hopeful to show a beneficial effect in terms of statistical power. If both endpoints are "significant" at the first stage, we will stop the trial. Otherwise, we will continue. At the second stage, we reverse the order, test the clinical endpoint, then the surrogate endpoint, since the clinical endpoint is more important in the clinical sense. Compared to the previous approaches, the surrogate and the clinical endpoints are tested at about the same significance level at the first stage (e.g., 0.01) and the second stage (e.g., 0.04). This is a result of the ordering of the test and is set according to the relative importance of the endpoints at the two stages. The strategy may be viewed as an application of Holms generalized weighted procedure [18].

Other scenarios will require different statistical strategy for the type I error rates protection. For example, it might be reasonable for some cases to require early termination of the trial if the secondary endpoint is negatively significant while the primary endpoint is not at the interim stage. Conditional power of the clinical endpoint based on the result of the surrogate endpoint may also be evaluated.

#### 9.7.2.8 Examples of FTDDP

Table 1 lists the fast-track products approved by CDER since 1998 through March 31, 2005.

As discussed previously, one of the crucial questions in the fast-track approval program is how consumers should be protected from a yet-to-be confirmed but promising drug. It would be interesting to research the statistics of the time for drug manufacturers to fulfill the final confirmation submission after receiving their fast track approvals and the number of failures and successes of the confirmation submission for the list in Table 1. This would give us some idea as to how much protection there should be in comparison with the usual 5% type I error rate required for a regular new drug application.

**TABLE 1 Fast-Track Products Approved by CDER (1998–March 31, 2005)**

| NDA or BLA #       | Proprietary Name<br>(Established or Proper Name)                                                 | Applicant              | Approval Date          | Use                                                                                                                                                                                 |

### 9.8.1 INTRODUCTION

Only a generation ago, 107 people in 15 states died within a few weeks after a new drug was placed on the market. Many of the victims were children. One victim was the best friend of the doctor who had prescribed the drug for him. The S.E. Massengill Company, which marketed the drug, had been looking for a solvent to dissolve sulfanilamide, a new antibiotic. A company chemist chose diethylene glycol, a chemical normally used as antifreeze. Diethylene glycol was effective in dissolving sulfanilamide but caused renal failure in the unsuspecting patients. The company owner shirked responsibility, stating, “We have been supplying a legitimate professional demand and not once could have foreseen the unlooked-for results.” And how could they have foreseen the results? One doesn’t find what one doesn’t look for. The drug was completely legal. At that time, in 1937, the U.S. Food and Drug Administration (FDA) did not require drug products to be tested for safety [1].

The passage of the Food, Drug, and Cosmetic Act in 1938 greatly helped to improve drug safety. However, challenges in accessing and understanding drug safety data in real time persisted. Computer technology was decades away in 1938. The FDA did not develop a computerized repository of postmarketing voluntary adverse event reports until 1968. FDA scientists analyzed adverse events with paper, pen, typewriter, and perhaps a mechanical calculator. Even in the 1980s, FDA scientists had little more at their disposal to review adverse event data than a typewriter or dedicated word processor. In the 1990s, personal computers and software programs made it possible to eliminate many of the paper processes involved in adverse event analysis. However, there were still no uniform data standards and interoperable systems in place, hindering efforts to truly analyze adverse events in a systematic, computerized way. To rectify this situation, the FDA and the pharmaceutical industry began constructing a computerized repository of premarketing and postmarketing clinical trial data that would enable more efficient data analysis and decision making.

### 9.8.2 CURRENT PARADIGMS OF ANALYSIS

Challenges in systematically analyzing drug safety data continue to the present day. The typical product of a traditional analytical method is a static, paper report. Such reports usually consist of a vast number of discrete, personal, ad hoc processes that cannot typically be used to perform subsequent comprehensive *reproducible* analyses as soon as additional analyses are needed. Having an analytical method that can be subsequently audited and *reproduced* is absolutely critical because essential drug safety decisions are made from these analyses. Unfortunately, many drug safety organizations still verify the accuracy of the data they analyze by manual, ad hoc methods when comparing the data stored in a database with the primary medical records. Auditing is done by a second-party review, again by manual ad hoc methods.

Current computerized analyses of adverse events still typically consist of a vast number of discrete, often personal, ad hoc processes that mimic paper and pencil methods. Some commercial-off-the-shelf (COTS) software tools (e.g., Adobe Acrobat, Microsoft Word, Excel) do have the capability to search for specific terms

in electronic documents/case reports and do have navigational tools with hyperlinks and full-text indexing that enable researchers to create their own hyperlinks. Some other COTS software tools (e.g., SAS, Excel, Access, JMP) allow importation of electronic case report tabulations (ECRT) for more detailed analysis.

However, many of these tools, while enabling markedly faster and more detailed analysis than paper-based methods, still mimic static, one-by-one “paperlike” reports with no real-time auditing capability. Moreover, these COTS do not have integrated data analysis and automated data screening capabilities and are not optimized for systematic analyses. Furthermore, the ad hoc analyses that these COTS produce lack interactive, automatic auditing *reproducible* functions. Thus these tools are often used to produce the same dense, unwieldy paper tables of counts and percentages that were created manually before personal computers became ubiquitous.

Humans should use computers to do functional work for them in the most efficient manner possible. However, we must not delude ourselves into thinking that the mere use of a computer to analyze adverse events will magically analyze these events in a systematic, efficient way. Computers do not *automatically* produce coherent, auditable results that can be subsequently reproduced with ease. Computers must be *actively* programmed through an iterative process involving tight communication between analysts and software developers until these processes are totally functional.

### 9.8.3 WHY WE NEED A PARADIGM CHANGE

A new paradigm for computer-assisted analysis of adverse drug events is sorely needed. Critics of the current paradigm emphasize the need for more transparency in the data review process, claiming that there is the potential for suppressing negative results or for hiding safety issues in both interventional and observational studies. It is often necessary to reanalyze the data in light of new information about a particular adverse event or class of events for a drug or class of drugs months—or even years—after the initial analysis. In many such situations, it is critical to have ready access to all preclinical, clinical trial, and postmarketing data. The findings from these updated analyses are potentially so influential that they can impact drug therapy recommendations for decades. However, ready access to all of the actual data and results is still lacking in many situations.

To properly assess drug safety, we must be able to systematically tap the information captured in the massive amounts of medical data collected in both premarketing and postmarketing settings. In addition, as stated above, we must also be able to *reproduce* findings in different repositories of medical data in an auditable way. However, two major issues in studying drug safety confront us.

The first issue lies in the whole realm of the human disease process itself. Many adverse drug events mimic diseases and vice versa. Is an “adverse event” really an adverse event, or is it merely a natural occurrence of a disease process that is entirely independent of drug exposure? The science of drug safety is often complicated by the lack of objective markers of drug toxicity that can systematically separate a disease process from an adverse drug event process [2]. Clinical trials, often viewed as the gold standard to assess efficacy, are simply too limited in scope to answer safety questions in a systematic way.

The second issue involves the whole process of data collection, transformation, and presentation. At the study level, important information needed to assess the safety of a new drug is often presented in idiosyncratic ways. For example, concomitant medications are often not translated into standard drug names, and there are often subtle errors in coding of events (which we discuss further). This lack of standards hinders the creation of an integrated safety database. Later, the data that may come from numerous preclinical, clinical, and postmarketing studies are often not collected with a common data standard and are not systematically integrated into a single cumulative database before analysis. Various personnel working in different organizations or in different sections of the same organization may perform analytical tasks with nonstandardized and nonintegrated data. Even when the premarketing adverse event data of a new drug *are* incorporated into an integrated summary of clinical trial safety data, the *totality* of the safety data from *all* pre- and postmarketing research are usually *not* integrated into a coherent, analyzable database that can be used for a comprehensive, real-time analysis.

It is therefore easy to see why this current drug safety paradigm, with its lack of standards in data collection and analysis, hinders the analysis of adverse events. Without data standards in place, it is difficult to build practical, reusable tools for systematic safety analysis. With no standard tools, truly standardized analyses cannot occur. Reviewers may forget their initial analytical processes if they are not using standardized data and tools. Comprehensive reproducibility and auditability, therefore, become nearly impossible. In practice, the same data sets and analytical processes cannot be easily reused, even by the same reviewers who produced the original data sets and analyses. Not using standardized tools slows the real-time systematic analysis and reanalysis of the data because of the large number of restructuring steps needed to perform these analyses and reanalysis. These obstacles restrict the ability of analysts and senior decision makers to gain a full understanding of the entire data and the results in a timely manner. The end result is that analysts cannot routinely access the *computerized* preclinical and clinical data that supported the marketing approval of a drug, a new indication, or a new dosage schedule.

#### 9.8.4 A NEW PARADIGM: INFORMATICS

We need to transition from quasi-computerized methods, in which the different elements of the analytical process are treated as discrete, “paper report” tasks, to a comprehensive *informatics approach*, in which the entire data collection and analysis is considered as a single reusable, extensible, auditable, and reproducible system. Informatics can be defined as the science of “storing, manipulating, analyzing, and visualizing information using computer systems”[3].

To analyze adverse drug events from an informatics framework, six major infrastructure elements must be in place:

- *Data Standards and Interoperable Systems* When interoperability is in place, standard, automated software tools for systematically analyzing the data can be constructed.

- *High-Quality Data* Miscoding, duplicate records, missing data items, and other data problems must be kept to a minimum.
- *Restructuring Capabilities* There must be the capability of restructuring the data for various types of analyses in a transparent way.
- *Systematic Analysis* The data must be systematically analyzed to gain insight regarding the associations between various treatments and medical conditions. This knowledge can assist in causality assessments.
- *Reproducible Capabilities* The data and analyses must be electronically accessible in real time, easily reanalyzable, and easily reproduced, even years after the adverse event data were collected.
- *Maintenance* The database and software that comprise the data systems must be maintained.

#### 9.8.4.1 Data Standards and Interoperable Systems

The foundation of any efficient computer-assisted data analysis system is the creation and use of data standards. Data standards consist of standard data file names for each predefined file, standard data elements in each data file, standardized names for each data element, and standard definitions for each data element.

Data standards are exceedingly important because they allow for the use of “interoperable systems.” The concept of interoperable systems can be illustrated by the situation that prevailed in the American railroad industry during the nineteenth century. At that time, there were many small, local railroad companies throughout the country. Each company, however, utilized different standards of rail gauges, that is, the distance between the two parallel rails on a track. The Baltimore and Ohio Railroad used a 4-foot, 8.5-inch gauge; railroads in the South used a 5-foot, 0-inch gauge; the Erie and Lackawanna Railroad used a 6-foot, 0-inch gauge, and so forth. The onset of the Civil War exposed the absurdity of the lack of rail gauge standards when such inconsistencies made it nearly impossible to accomplish very fundamental tasks, such as materiel transport [4]. At the 2005 FDA Science Forum, Secretary of Health and Human Services Michael O. Leavitt recounted the story of rail gauge inconsistencies to emphasize the need for interoperability to advance health information technology [5]. It becomes obvious, therefore, why standardized, unique codes for all data values across all stages of drug development and during the entire postmarketing period are so essential. Comprehensive data standards allow for the creation and systematic implementation of reusable software for analyzing medical records and adverse event data. These reusable tools enable the creation of standard analysis tools that can be shared among safety analysts for enhanced communication and learning and refined as existing analytical techniques are evaluated and extended.

All data fields (patient identification, date, sex, drug names, narratives, etc.) require rules regarding the data, because some characters, such as tabs and hard return characters, can interfere with attempts to store, read, and/or reorganize the data. For example, if the data are being migrated from Oracle into other data analysis software and data fields in Oracle contain tabs and hard return characters, the data from these fields may be split into several columns and rows upon migration into the other software. This fact is extremely important because information that

is misplaced in a data file may not be readily apparent to the user without the use of systematic approaches for analysis. This missing information may have profound and unpredictable influences at all levels of drug safety analysis, including studies using preapproval and postapproval pharmacoepidemiological data.

Ideally, the data from the whole drug development program, including accumulating postmarketing data, would be integrated into a single database. This integration would simplify the process of answering important, but previously *unforeseeable* questions (remember the sulfanilamide example). For instance, is a new dose increase as safe as the previously approved dosages? Is it enough to compare the two highest dosages with each other? A better answer could be obtained if the entire integrated clinical trial data across all dosages are studied. However, as mentioned above, drug safety data from multiple sources are not usually integrated into a single database. Compounding this problem is that many people tasked with managing data are focused on preparing a small portion of the data for a specific purpose and are not trying to create a single database that integrates all of the data. Integration of the entire safety data for a drug would enable better and faster communication among decision makers in various organizations (industry, regulatory agencies, etc.)

9.8.4.2 High-Quality Data

It is essential to have high-quality data in place for interoperable systems to function efficiently. Standard data structures can only be used to full advantage if they are combined with standard terminology for values populating a data element. Yet there are many potential pitfalls in data collection and configuration for analysis. Some of the more common pitfalls are discussed here, but this list is by no means comprehensive.

**Errors and Inconsistencies in Patient Identification** Whatever system is used to identify patients in a database, it is essential that a single, unique identifier be used for each patient. This identifier must be consistent throughout the database. Errors and inconsistencies in patient identification can significantly interfere with adverse event analysis. Examples include situations in which hyphens, commas, additional zeros, or other characters are not used consistently for identifying patients. In some cases, the *same* patient in a study may have *different* patient identification numbers listed in various tables [5] (Table 1). In such situations, correctly merging patient data from multiple sources/tables becomes essentially impossible because some of the data for the same patient either will be treated as missing or will appear as data for the wrong patient. In one new drug application (NDA) submitted to the FDA, a sponsor built a “unique patient identifier” for some tables by concatenating the study identification number plus the study site identification number plus the

TABLE 1 Example of Different Types of Unique Patient Identifiers for the Same Patients in a Clinical Trial

| Unique Patient Identifier in Data Tables | Unique Patient Identifier in Narrative Table              |
|------------------------------------------|-----------------------------------------------------------|
| 8023007                                  | Patient 08-023-007 is a 48-year-old Caucasian male, etc.  |
| 8031011                                  | Patient 08-031-011 is a 61-year-old Hispanic female, etc. |

patient within-site identification number, whereas in other tables the numbers were concatenated in a different sequence. In another NDA, a sponsor separated the concatenated identifiers by hyphens in some tables but not in others. In yet another NDA, a sponsor concatenated numeric with character identifiers (the latter with leading zeroes) in some tables, but not in others. In our experience, such problems are easier to detect when systematic approaches for analysis are in place.

***Errors and Inconsistencies in Categorical Variables*** For categorical variables such as sex, race, diagnosis, and the like it is essential that the values used to designate the different categories be precisely defined and consistently used. Precise variable value definitions and their consistent use greatly simplify the analysis at hand and also future analyses. For example, a human being can readily tell that “M,” “m,” “Male,” “male,” “hombre,” “homme,” and so forth all refer to the same sex. A computer, on the other hand, cannot readily make this distinction (unless specifically programmed to do so) and will therefore treat these items as different values for sex. In one FDA submission, a sponsor coded “male” by using the code “1” in some studies and the code “2” in other studies, resulting in the finding of “pregnancies in men.” In another submission, a similar problem resulted in males developing “female breast carcinomas.”

***Errors and Inconsistencies in Formatting Dates*** It is also necessary to use standardized formats to record dates. For example, Oracle stores a date as the number of seconds since January 1, 4712 BC, and then uses various functions to display the dates in more human-friendly formats. There are many different and personal ways for recording dates; one of the authors (AS) has noted at least 25 different ways in a single clinical trial submitted for FDA review! Should February 1, 2007 be recorded as 1 February 2007, 1 Feb 2007, 1 Feb 07, or 02/01/07? This problem still exists when data for numerical dates are extracted into software programs such as Excel that do not force the user to select a unique format for dates.

***Errors and Inconsistencies in Adverse Event Coding*** Adverse events are also subject to errors and inconsistencies by coders and data entry personnel. Many of these inconsistencies become very important when adverse events are analyzed by automated software.

Adverse events need to be coded consistently with respect to letter case. Problems can occur when there is discordant coding using all capital letters, all lowercase letters, or combinations thereof, as computer software will interpret these capitalization variations as different events. Letter case sensitivity can be important when two or more words are used to describe an adverse event. For example, some databases utilizing the Medical Dictionary for Regulatory Activities (MedDRA) coding dictionary employ a coding system in which only the first letter of the first word of an adverse event is capitalized (e.g., “Atrioventricular block complete”). Failing to adhere to uniform letter case conventions across the data can result in severe errors in data analysis.

*Proper interpretation and coding* of events are also extremely important so that drug safety data can be appropriately analyzed. However, investigators and coders vary widely with respect to their health care training to properly interpret and code these events. Individual investigators may choose different terms to code the same

adverse event. Subjectivity in coding may be due to personal preferences of coders in the selection of terms versus the granularity of coding dictionaries that offer the coder a considerable array of terms to classify the reported adverse event. For example, kidney stones may be coded with a number of terms such as “kidney stones,” “nephrolithiasis,” “renal calculi,” and “renal calculus not otherwise specified.” There can also be variations in spelling of the exact same event code, such as the British spelling of “gynaecomastia” versus the American “gynecomastia.”

Coding dictionaries also change over time (sometimes even before a study is completed) because of revisions in coding terminology. In one NDA submitted to the FDA, the data were coded with different versions of the same coding dictionary without properly integrating the terms into a single coding version. Such a scenario may lead to partitioning events into too many terms and therefore mischaracterization of adverse events. Again, this misclassification, although not readily apparent, may have a profound impact on the results of the analysis performed.

It is especially difficult to code events when they occur as a constellation of signs, symptoms, and laboratory findings because a coder may inadvertently minimize or exaggerate the severity of an adverse event, depending on the selection of terms to code that event. The use of only one or two seemingly benign terms such as “muscle cramps” and “pain in limb” to describe rhabdomyolysis would not provide a comprehensive picture of the event. On the other hand, categorizing an isolated case of elevated transaminases (with no other associated laboratory findings) as acute liver failure would be inappropriate. Potential signals of adverse events may be obscured or distorted depending on how the events are grouped. Splitting events into multiple terms or grouping unrelated terms may erroneously underestimate the magnitude of a signal.

**Errors and Inconsistencies in Drug Names** Drug naming conventions are also exceedingly important. Although it may be expected that multiple names of the same medications would occur in postmarketing safety databases, this problem is also often seen in *premarketing* data. In one NDA submitted to the FDA, the data contained 900 different names for 150 unique concomitant drugs. Another NDA recorded 34,000 drug names for 2000 concomitant drugs mentioned in the study because contractors in different countries had submitted different names for the same medications.

**Errors and Inconsistencies in Numerical Data** It is also important to understand that *character* and *numeric* data are not interchangeable. Errors can occur when there is not a clear understanding between coding with characters versus coding with numbers. A variable may be inadvertently entered with character data in one study and numerical data in another study. For example, studies measuring the effects of a 30-mg dose of a drug may utilize a “30-mg” code in some studies and a “30” code in other studies. The “30-mg” code is treated as character data, but the “30” code is treated as numerical data. Efforts to successfully combine and analyze these studies may be hindered. The “30 mg” and “30” will be treated as two different doses if the numerical variable is treated as a character. If the combined variable is treated as a number, the data for the character variable will be treated as missing in some types of further analyses (e.g., regression analyses).

**Missing Information** Both premarketing and postmarketing collections of data are perpetually plagued by missing information. In premarketing and postmarketing clinical trials; patients can be lost to follow-up because of:

- Undocumented beginning and/or end of a medication or an adverse event (see Fig. 1)
- Undocumented death
- Undocumented serious adverse events
- Undocumented nonserious adverse events

**FIGURE 1** An example of new drug application (NDA) data graphically displayed for an individual patient in a dose escalation clinical trial. This graph displays and links drug exposure information, clinical adverse events, concomitant medications, clinical laboratory values, demographic information, and narratives. The graph is divided into four major sections: The x axis for all four sections depicts the same time line, and the y axis the label of each row for each section. The top section displays drug exposure data for the test drug used in various doses (coded in a gray scale). The second section displays exposure to concomitant medications over time. The third section displays adverse events over time. The bottom sections display when laboratory tests were conducted and the results. Note in the areas highlighted by framed squares that clinical and laboratory adverse events were associated with the high dose of the test drug. Other patients had the same profile with the high dose for the test drug. This was not seen with the other drugs and with the other doses studied. Note that the beginning of an adverse event is displayed (B) but not the end for many adverse events. Note that the end of a concomitant medication is displayed (E) but not the beginning for some medications. Observe in the areas highlighted by framed ovals the discrepancies in the timing of the same laboratory results in different tables, making it difficult to assess whether these values occurred before or after an adverse event or a concomitant drug.

- Failure to assess adverse events that occur more than 30 days after the last dose of a drug
- Failure to assess adverse events occurring outside a scheduled time window
- Loss of interest of a patient or unwillingness to continue in a study
- Geographical moves by patients
- Loss of insurance coverage (in a postmarketing case-control study)
- Missing records due to technical errors during data migration (see below)

Even when patients remain in a study, information regarding adverse events may not be complete. The event itself may not be coded, even when the narrative includes relevant laboratory or other data (e.g., renal failure may not be coded, even though the narrative mentions abnormal blood urea nitrogen and creatinine levels and the need for dialysis). Moreover, adverse event data (such as laboratory tests, radiological reports, biopsy reports, and hospital records) collected outside a scheduled time window, outside of the study center, or after the study is completed *might not* be included in the final database for the study. This issue is important because unexpected adverse events do not occur at known prespecified time windows. “Tight windows” of adverse event data collection can also be a problem with drugs that have a very long half-life or the potential for causing a delayed, but serious condition.

The problem of missing data is even more pervasive in postmarketing drug safety databases. Most of these systems rely on voluntary reporting for which there are no well-defined protocols. Additionally, there are significant challenges in interpreting such data because of the wide variability of reporting sources (physicians, pharmaceutical companies, patients, attorneys, etc., as well as submissions from different countries). With electronic medical records, the presence of important relevant, but unreachable, data elements may not become apparent without the use of systematic approaches for analysis. This problem may be compounded in some epidemiological studies that ignore the presence of missing information in their analyses.

**Duplicate Information** Both premarketing and postmarketing databases may contain duplicate reports of adverse events. In postmarketing databases of voluntary reports, duplicate information on the same adverse event case may be submitted by several sources. For example, submission of information on the same event may be duplicated by the treating physician, the dispensing pharmacist, the nurse, the patient’s attorney, and/or the patient himself. Submission of information by drug companies may compound the problem, even though they are attempting to comply with regulatory requirements mandating submission of adverse events. Multiple drug companies may submit information on the same case, using their own unique patient identifiers, especially when the adverse event is associated with drugs manufactured by several different companies. There may also be a series of follow-up reports for the same case as additional information becomes available. However, updated patient identifiers for the same patient may not be linked to the original patient identifier. Duplicated information on the same event may also come from several teams working for the same drug company. Despite these problems, removal of duplicate reports is absolutely essential (though challenging) because superfluous information may result in false-positive signals of adverse events and wasted analysis time.

In postmarketing electronic longitudinal medical records, redundant and potentially contradictory information may come from several sources (e.g., reports from medical residents, their supervisors, the attending physicians). In these cases time stamping of each event may help to delineate the important sequences in understanding the adverse events.

**Other Inconsistencies** Inconsistencies in drug safety data due to difficulties in standardization also include a subject's primary diagnosis, differential diagnoses, relevant medical history, relevant physical exam findings, pertinent information from hospital records, and follow-up information (all of which may be subjective). There may also be a lack of consistency in the narrative summaries for individual patients and the data supporting the narratives. Indeed, it is difficult to clearly describe in the narratives the sequence of adverse events, medication, and laboratory results by using case report forms or line listings as source information. In complex patient records, case report forms and line listings may generate uneven temporal sequences of adverse events, concomitant medications, dosages, and so forth that cannot readily be comprehended. Such data need to be visualized by tools capable of displaying the complex, interrelated information on a common time line (Fig. 1).

Additional examples of variability in data collection (which, in turn, affects data interpretation) include questionnaires and physical exam forms. Questionnaires often utilize open-ended questions that allow great variability in the type and extent of adverse event information gathered. Physical exam forms—even when designed in a checklist format—may elicit variable collection of adverse event data; what is a serious event to one clinician may not be serious to another.

#### 9.8.4.3 Restructuring Capabilities

**Reconfiguration of Data** Drug safety data from different sources are often pooled or combined in databases. Reasons for combining data vary. In the case of premarketing studies, data from different sites are routinely combined because one site may not be able to recruit enough patients for a study. Data from different studies are often combined to increase sample size and therefore statistical power for detecting an uncommon adverse event.

In postmarketing safety surveillance databases, data from different countries or from different sources (physicians, patients, drug companies) may be combined in the same database in an attempt to obtain as much information about approved drugs as possible. Pooling or combining data can allow explorations of drug toxicity among various subgroups. Having a large database allows studying possible drug–drug, drug–disease, and drug–demographic associations.

When reconfiguring the data, several issues must be borne in mind. Combining data from different data sources can obscure potentially meaningful signals of adverse drug events [6]. For example, combining data for the term “colitis” with “ischemic colitis” may obscure the presence of ischemic colitis. Also, the criteria for reporting and coding an adverse event may differ among various data sources (e.g., countries with disparate regulatory requirements and different coding dictionaries). Reference ranges for normal values may vary, depending on the reporting source. When reference ranges vary, changes from baseline grouped

by treatment assignment may provide useful information. Patient populations may also vary in different study arms or in different countries where studies are conducted. Different populations may tolerate drugs differently or have varying levels of drug sensitivity. Study design may vary among sites, especially in terms of how outliers are handled and follow-up information is obtained. The selection of analytes and biomarkers of toxicity to measure may vary depending on the reporting source and when the data were collected (criteria for toxicity and case definition may be site specific and can change over time). Duration of drug exposure (as well as drug dose) may vary among studies. Because so many factors can influence the results, the process of transforming and combining data from different sources should be documented in a way that is easy for subsequent investigators to understand.

**Reconfiguration of Databases** Not only must data from different sources be preprocessed (“cleaned”), reconfigured, and validated before analysis, but entire databases must also sometimes be reconfigured and validated. This is especially the case if the database has evolved and has been maintained over a long period of time.

A good example of an evolving database is the FDA’s Adverse Event Reporting System (AERS) database containing reports of spontaneously submitted adverse events. AERS has undergone several configurations since its inception in 1968. This database was known as the Spontaneous Reporting System (SRS) from 1968 to 1997. Adverse events were coded into SRS with the COSTART (Coding Symbols for Thesaurus of Adverse Reaction Terms) dictionary. Only 1200 event codes were present in the COSTART dictionary. COSTART was replaced by the much more granular MedDRA (Medical Dictionary for Regulatory Activities) system of coding in 1997. MedDRA contains over 15,000 preferred term event codes, of which 10,000 are currently in use in the database. When SRS was modified to build AERS, adverse events coded with COSTART terms were mapped to MedDRA terms. Moreover, drug names in AERS have been and are still collected in free text form. There is substantial variation among reporting sources regarding the manner in which drug names are ultimately listed in adverse event reports. Drugs may be listed by their generic or trade names, with numerous and creative variations in spelling, abbreviations, spacing, and punctuation (see Section 9.8.4.2 on high-quality data). Thus what is now termed the AERS database is really a data set containing data that have undergone several organizational changes during more than three decades of data collection. This mapping, recoding, organizational reconfiguration, and validation of the database has been necessary to provide a uniform format for data analysis, yet this entire process has, understandably, been labor intensive and challenging.

With electronic medical records, multiple clinical records for the same patient may be treated as belonging to different patients during anonymization and migration of electronic medical records, tainting analytical conclusions. This problem may be difficult to untangle once the anonymized data migration takes place.

Sound analytical assessments require that analysts understand the manner in which the data were collected, reconfigured, migrated, and combined. These processes should be documented in a transparent way so that future investigators can readily understand the anonymization and migration in real time.

#### 9.8.4.4 Data Analysis

Current practices require that all the data collected be “cleaned,” reconfigured, and standardized in order to perform analytical and integrative tasks. These processes are complex, time consuming, and error prone—especially when there are many different personal standards in place. This process of “data cleaning” [7], reconfiguration, standardization, and integration must be done because the data are typically collected by several different contract research organizations, each with its own independent personal data collection standards. Because of personal standards in data cleaning and reconfiguration, many investigators end up analyzing only a small portion of the safety data, resulting in missed rare but serious adverse events or risk factors. If systematic data cleaning and reconfiguration are not done initially, then even seasoned investigators will still waste time constructing a new integrated database prior to analysis.

**Size of the Database** Database size is important in assessing drug safety in both premarketing and postmarketing settings. During clinical trials in the premarketing period, the number of subjects in a drug safety database often depends on the intended use of a product. For products intended for long-term treatment of non-life-threatening conditions, subjects studied may number in the thousands. For products intended for *short-term* treatment of *rare or life-threatening* conditions for which there are few effective treatment options available, a “smaller” number of subjects are studied, but there can be great subjectivity in defining the word “small” in such cases. This subjectivity is in part a reflection of the wide spectrum of disease severity for which such products might be indicated. For products intended for *chronic* treatment of *life-threatening* conditions, the number of subjects would need to be greater, but again, there is great potential for subjectivity.

Larger databases can help with risk–benefit decisions, but how can we achieve consensus on the exact size of the number of subjects needed for the database? A clinical trial database that contains limited information on a small number of subjects will likely lack the statistical power needed to detect differences in adverse events between control and treatment groups. A researcher may specify criteria for the minimum differences of adverse event rates between the two groups in an attempt to identify important safety signals, but ultimately these criteria are arbitrary. Even when a study enrolls a large number of subjects and records a large volume of data in a database, it is difficult to adequately identify all potential risks associated with a product. Some risks will only become apparent once a product is approved, that is, when hundreds of thousands or even millions in the general population are exposed. Adverse events in the postmarketing period are often collected in a voluntary manner through the use of spontaneous reporting systems such as FDA’s previously described AERS database or drug registries (e.g., clozapine). Yet extracting safety information from these databases—even if they are large—can still be challenging because background rates for various events can be difficult to obtain systematically. What is the background rate for headache, rash, decreased appetite, appendicitis, and fatigue—events that frequently occur in the population independent of drug therapy? Moreover, how does one assess the background rate of an event in a prespecified, but non-drug-exposed population compared to the rate of the same adverse event in a similar, but drug-exposed population? For example,

how does one assess the risk of confusion in elderly diabetic patients due to the effects of a drug prescribed for diabetes from baseline rates of confusion in elderly diabetic patients who are not receiving the same diabetes drug and concomitant drugs?

**High-Dimensional Aspect of Data** The high-dimensional aspect of data collected in a study can make the analysis of these data challenging. Even a simple clinical trial may have recorded dozens of measurements for each patient. More sophisticated studies may have hundreds of measurements per patient. Complex tests measuring the physiology of a specific system, such as pulmonary function tests or echocardiography, may be impossible to standardize over many different treatment groups or over a period of time because of technological changes and interpretation of findings. Pathological specimens (e.g., biopsies) may also be difficult to classify in a systematic and objective way. Other high-dimensional data include pharmacokinetic and pharmacodynamic information in phase III clinical trials, both of which are crucial in anticipating potential safety problems, especially in patients with impaired hepatic and renal function or in patients taking many concomitant medications. The challenge then lies in how to analyze such high-dimensional data. Unfortunately, we often do not have systematic methods for reducing the dimensionality of the data to find the subset of variables for which the treatments differ and the key statistics that describe the differences without losing important interdependent information.

**Variations Among Subjects** In the premarketing phase of assessing drug safety, it is important to have a study population that is not only representative of the target population but also sufficiently diverse in terms of demographics. This diversity will bolster the generalizability of the safety analysis. Diversity in the study population can be enhanced by including both males and females and also patients in different age, racial, body weight, and risk factor groups. Yet this same variability that is so necessary in increasing generalizability also presents challenges in analyzing data. For example, there may be a great deal of variability in renal and hepatic function among elderly patients. Plasma levels of a drug can also vary greatly if patients are given the same dose regardless of body weight, body surface area, or renal and hepatic function. There may also be great differences in sensitivity to the effect of a particular drug among individual patients. These issues may also taint the analysis of postmarketing safety data, including electronic medical records. Computerized safety analysis systems (discussed below) can aid in studying the effect of these variations by automatically generating stratified analyses to adjust for the impact of these patient attributes on adverse events.

**Temporal Relationships of Adverse Events** The temporal relationship between duration of product exposure and development of an adverse event is important in assessing causality. But how can data on temporal relationships be systematically summarized in a database containing thousands or even hundreds of thousands of subjects? Temporal relationships cannot be clearly elicited if only frequencies of adverse events between treatment and control groups are compared. There can be many disparities in the subjects' time of exposure or time at risk. Toxic manifestations of drugs may not occur until several months or even years after the initial exposure to the drug. How do we systematically assess delayed toxicity of a previ-

ously prescribed drug from the effect of a newly prescribed drug? Such a scenario occurred with reported cases of pancreatitis associated with valproic acid therapy, in which some cases appeared several years after therapy [2].

Sometimes an adverse event that occurs with a different frequency in the treatment group than in the control group is also qualitatively different in the two groups. For example, suppose a rare but serious vascular event occurs more frequently and earlier in the treatment group than the control group and is more likely to lead to discontinuation in the treatment group than in the control group. We need to describe that the event occurs more frequently and earlier in the treatment group and that it is more likely to cause discontinuation of treatment. This information is difficult to convey with tabular data, but often becomes clear when the data are presented in graphical form [8, 9, Figure 2].

**Effect of Concomitant Medication** Assessing drug–drug interactions is absolutely critical in evaluating the safety profile of a drug. Interactions can occur when one drug affects the absorption, distribution, metabolism, or excretion of another drug or drugs, producing additive or antagonistic effects on the other drugs. Various foods and dietary or herbal supplements (e.g., St. John’s wort) can also interact with drugs. Yet how do we systematically assess adverse events from one drug as opposed to adverse events from concomitant drugs or supplements?

**Effect of Preexisting Disease** The adverse event profile of a drug can be confounded because of the effects of underlying disease for which the drug may or may

**FIGURE 2** A display that summarizes the duration of treatment (black squares) and the timing of serious vascular events (gray circles) for the subset of patients who withdrew from treatment because of an adverse event. Each line represents a single patient’s experience over time in days for the test (left panel) and the control drug (right panel). Patients are sorted by decreased duration of treatment. In this 1:1 randomized clinical trial there were 18 withdrawals due to a severe vascular adverse event with the test drug. This is in contrast with the control drug, with 11 withdrawals. Withdrawals with the test drug occurred sooner than with the control drug.

not be prescribed. Comorbidity can affect a drug's potential for inducing an adverse event. However, it is often difficult to separate the influence of preexisting disease when assessing the potential toxicity of a drug. How do we systematically separate the effects of a drug from a disease, the progression of that disease, or multiple diseases syndromes—each with its own varying rate of progression?

Preexisting disease, such as renal or hepatic disease, can especially influence the metabolism and excretion of certain drugs. In clinical trials, and in electronic longitudinal medical records, it is important to have sufficient variability in disease states and concomitant diseases among subjects in both the study and control groups. Investigators need to consider whether the adverse events that occur are due to abnormalities in the distribution, metabolism, and excretion of drugs as a result of underlying disease. These analyses could be systematically facilitated by having standardized ways of measuring blood (and in some cases, tissue) levels of drugs and their metabolites.

***Lack of Objective Markers of Drug Toxicity*** Some products have well-established, valid biomarkers that can be measured to track certain safety concerns. For example, a dose–response association with proteinuria, creatine phosphokinase, and urine myoglobin levels can be monitored to assess the safety of HMG-CoA reductase inhibitors (Fig. 1). However, there are often no specific markers (or pathognomonic clinical findings) of toxicity for many drugs. For most drugs under investigation—and most marketed drugs—practical tests to measure toxic drug or metabolite levels are not widely available [2]. Additionally, relying on product labeling of a drug in a similar class as a clue to investigate the toxicity of a drug is faulty, as labeling can be influenced by a number of factors including litigation and publicity.

***The Overwhelming Volume of Data to Be Analyzed*** Any given drug safety researcher—whether a statistician, clinician, epidemiologist, or safety evaluator—can only analyze so much nonstandardized data in a given time period. Premarketing databases contain very detailed data on thousands or perhaps tens of thousands of subjects. In some cases, premarketing data may have been collected over several decades for a wide array of indications. Postmarketing drug safety databases may contain millions of adverse event reports. The Composite Health Care System II database maintained by the U.S. Department of Defense contains over 9 million medical records. The FDA's AERS database contains over 2.5 million adverse event reports collected since 1968. As mentioned above, AERS utilizes the MedDRA classification system for its adverse event coding system. For these reports, approximately 10,000 MedDRA-preferred terms have been coded for 4000 generic drugs in the database. Thus over 40 million drug–event combinations are theoretically possible. This situation, compounded with the fact that the FDA currently receives over 1000 new reports of adverse events each day, exemplifies the daunting task that safety evaluators face when analyzing postmarketing adverse event data. With such a large volume of reports to review each day, exploring signals based on clinical judgment in combination with threshold reporting frequencies may not always be optimal or even practical. Such an approach makes it difficult to contextualize information regarding adverse events. How do we systematically access such huge databases to select appropriate variables for analyses? Without adequate drug expo-

sure data and baseline rates of disease processes (which may be erroneously attributed to “adverse drug events”) in specific populations at risk, how do we determine whether 20 cases of a specific drug–event combination is disproportionately frequent to merit further investigation?

**Subjective Analysis Strategies** There are also too many *subjective* analysis strategies in place. What is convincing to one analyst is not convincing to another. For example, what should be done when there are outliers in the data, that is, measured values of findings (such as laboratory values) or events that deviate substantially from the reference range? If outliers are ignored, important safety findings may not be identified; on other hand, outliers may represent errors in data collection. This was the case for one patient in an NDA submission. The patient had a serum creatinine value of 13 mg/mL (over 10 times the normal value, by any reference!) but a normal serum blood urea nitrogen (BUN) value.

**Limited Knowledge of Exposure and Reporting Rates in Postmarketing Data** Unlike clinical trials and electronic medical records in clinical practice, postmarketing voluntarily reported data contain limited information about the total number of patients exposed and the duration of exposure. This problem is compounded by the fact that adverse events are often underreported [2, 9].

#### 9.8.4.5 Reproducibility

Traditional analytical methods make extensive use of computers, but typically these methods still require constant restructuring of the data and multiple analytical tools. This endless restructuring wastes time and productivity and also makes the analytical processes difficult to document, audit, and reproduce in real time. This situation also makes it difficult to reconstruct and update analyses in real time when *new* adverse event data become available or when *new* questions need to be asked. The application of comprehensive data standards allows the use of integrated, reusable software for analyzing adverse event data. This integration facilitates the reproducibility of the results.

#### 9.8.4.6 Maintenance

Any computer database system will require maintenance. This maintenance includes such things as actively identifying and correcting data errors, ensuring that data can still be used with upgraded software and that this software can be used with upgraded hardware and data. Maintenance also includes actively testing and identifying computer bugs and adding new features and enhanced functions to the software.

### 9.8.5 EXAMPLES OF PRACTICAL COMPUTER-INTENSIVE TOOLS FOR SYSTEMATICALLY ASSESSING DRUG SAFETY DATA

#### 9.8.5.1 Background

Although 500,000 individuals were enrolled in clinical trials that were submitted to the FDA during 1990–1995 [10], the lack of a repository of clinical trial data, standardized data, and interoperable systems precludes us from efficiently tapping and

reanalyzing these data. This missed opportunity underscores the need for standardization and interoperable systems, as discussed above (see Section 9.8.4.1 on data standards and interoperable systems).

Drug safety reviewers spend a great amount of time learning the peculiarities of the data structure format and the variable names used with each NDA (and NDA supplement) submitted for marketing approval. As described above, for some NDAs the data from several studies must be incorporated into an integrated summary of safety data set and validated before performing a safety analysis; if every study uses a different data structure, this is an arduous task. To rectify this situation, the FDA is using the Clinical Data Interchange Standards Consortium (CDISC) Submission Data Tabulation Model (SDTM) format adopted as a standard by the FDA in July 2004. The implementation of such data standards allows for development of standard and comprehensive analytical tools that can automatically generate standardized and comprehensive analyses that can be used across numerous NDAs.

### 9.8.5.2 Analysis of Premarketing Data with WebSDM

An example of an analytical tool that utilizes CDISC data standards is WebSDM (Web Submission Data Manager) by Lincoln Technologies. The FDA has recently implemented WebSDM to analyze two NDAs in real time [11]. Although the original NDA data were submitted with nonstandard formats and the data had to be transformed into the Study Data Tabulation Model format before being loaded into WebSDM, the review process for these 2 NDAs was more efficient than with standard methods. In this case the data was transformed to demonstrate the concept that the use of standardized data simplifies the analytical process. WebSDM saves time because it first ensures that the data submitted to the FDA complies with CDISC format and then uses standard methods that enable automation of the analytical processes. Typically, FDA reviewers receive different data formats for each NDA; however, WebSDM eliminates the need for reviewers and supervisors to learn where the variables for analyses for each NDA are located (Fig. 3) and the different data formats for each NDA. For example, assessing potential liver injury by analyzing increases in serum alanine aminotransferase (ALT) and total serum bilirubin (TBILI) is done in one step instead of multiple cumbersome steps. It was also easier for the reviewers to fulfill the requirements of the NDA Review Template in a recent FDA guidance document for reviewers [12]. WebSDM also eliminates the need to reconfigure the data and the analytical tools for each new NDA analysis. WebSDM allows reviewers to use tailor-made, reusable tables and graphs of patient data in any NDA or supplement. The Sector Map graphical tool (with interactive drill-down capabilities) visualizes clinical trial data by highlighting higher-than-expected associations of adverse events compared to control groups. These features greatly simplify interpretation of the data. (See example with postmarketing data in Fig. 4.) These advanced graphical and analytical features are designed to simplify the interactive analysis of the clinical trial data.

### 9.8.5.3 Analysis of Postmarketing Data with MGPS and HBLR

For drugs already on the market, the FDA is utilizing the multi-item gamma poisson shrinker (MGPS) statistical algorithm [6, 9, 13] to systematically and simultaneously

**FIGURE 3** Once the data are transformed into CDISC standards and integrated with a drug safety analysis system, the data can be easily analyzed. In this figure we show a sample screen from WebSDM a drug safety analysis system being evaluated by the FDA. This screen allows the user to view different attributes of the variables in a user-specified data set. When a variable is selected, a graphical display of the data is produced on the right-hand side of the window. The user can then select to visualize a graphical display of the individual patient profiles under the variable in a different window.

detect signals of higher-than-expected drug–adverse event associations in its post-marketing drug safety databases. To identify these signals, MGPS employs a disproportionality analysis of drugs and events, combined with Bayesian shrinkage. MGPS uses the independence model as the basis for computing the drug–event expected counts. MGPS includes a Maentel–Haenszel style approach for adjusting the expected counts for potential strata heterogeneity. When applied to the FDA’s AERS database, the MGPS program systematically stratifies the data by over 1000 categories (9 categories for age, 3 for sex, and 38 for year of report) to help adjust for background differences in relative reporting rates by these variables. The FDA thus far has focused its analytical efforts on the AERS database, but MGPS can be applied to any large drug safety database. The British Medicines and Healthcare Products Regulatory Agency (MHRA) has recently begun using MGPS as part of its pharmacovigilance program. MGPS also incorporates advanced graphical tools for analysis, including the Sector Map described previously (Fig. 4).

The FDA is also exploring another statistical algorithm, the hierarchical bayesian logistic regression (HBLR), to study signals that may be influenced by polypharmacy. HBLR corrects for confounding induced by concomitant medications (each with its own potentially strong adverse event associations) throughout the database [14, 15]. HBLR uses a prior distribution (estimated from the data) to improve the modeling of the joint associations for up to hundreds of drugs with a logistic regression response variable. The HBLR adjusts for both “signal absorption” and “signal masking.” Signal absorption is a phenomenon whereby an “innocent bystander” drug is falsely signaled as being associated with a particular adverse event simply

Cerivastatin

| Rank | SOC   | Term (PT)                 | EBGM   | AERS cases |
|------|-------|---------------------------|--------|------------|
| 1    | Renal | Myoglobinuria             | 15.416 | 104        |
| 2    | Nerv  | Myasthenic syndrome       | 12.449 | 1021       |
| 3    | Musc  | Myositis                  | 12.198 | 2670       |
| 4    | Musc  | Rhabdomyolysis            | 11.501 | 12024      |
| 5    | Genrl | Organ failure             | 10.121 | 685        |
| 6    | Renal | Chromaturia               | 9.437  | 3034       |
| 7    | Renal | Renal tubular necrosis    | 9.249  | 2547       |
| 8    | Inj&P | Muscle injury             | 9.025  | 998        |
| 9    | Inv   | Myoglobin blood increased | 8.807  | 527        |
| 10   | Inj&P | Polytraumatism            | 8.497  | 1105       |

because of its frequent coprescription with another drug that is associated with that same event. Signal masking occurs in a database when there is failure to detect a weak signal for a particular drug because of the presence of other strong signals for the same adverse event, usually because of the homogeneity of drugs in the database [16]. Our initial experience indicates that HBLR may be a useful adjunct to MGPS in postmarketing safety assessments, especially in polytherapy regimens [15]. Dr. William DuMouchel has presented an overview of future empirical Bayes

**FIGURE 4** Sector map display of the MGPS data-mining profile for a drug, using a dictionary of medical terms. This display shows the safety profile of cerivastatin, a drug withdrawn from the U.S. market in August 2001 because of reports of fatal rhabdomyolysis, renal failure, and other organ failure [24]. The sector map shows strong signals for several serious muscle events including rhabdomyolysis within the Musc System Organ Class (SOC) and for renal failure within the Renal SOC. The strong renal failure signals with this drug were unexpected. In addition, there were huge differences between cerivastatin and other statins regarding the magnitude of the renal failure signals.

A sector map for data mining results is a visual presentation of data for a particular drug across all System Organ Classes (SOCs).

Each SOC is represented by a large tile in the sector map. Smaller tiles within each SOC tile represent Preferred Terms (PTs). A sector map graph is available for two-dimensional results of MGPS data mining runs.

PTs are ranked in descending order of EBGM values, a value that indicates the reporting association between a drug and an event (9). A color or a gray scale key (in this article) indicates relative ranking. The user can select to list the ranked PTs below the sector map.

Note: The primary path of a PT in the MedDRA hierarchy is used to determine where it appears in the sector map. If a PT is not in the event hierarchy associated with the configuration, it appears in a SOC tile named "Unknown".

The list of ranked PTs below the sector map includes the following information:

*Column Description*

*Rank:* Ranking of the term (combined with the drug) according to values of the EBGM values SOC containing the term.

*Term:* (PT) Specific PT.

*EBGM or other statistics used to configure the sector map*

If the Notes checkbox is checked, a Notes section provides information about the selection criteria and display options used for the graph.

- Color or shades of gray (shades of gray in this chapter), size, position in space, grouping, and ranking of tiles provide a "big picture" overview of the adverse event profile of a drug.
- Color or shades of gray: Light gray in this figure corresponds to stronger signals (high EBGM values).
- Size: A large tile (with a white border) defines each SOC (System Organ Class) in the MedDRA dictionary.
- Box size for each PT (preferred adverse event term): The box size is based on the number of serious cases of the term across all drugs in the AERS database. Thus, the box size of each PT is stable over different displays of different drugs.
- Position in space of each SOC and PT: SOC and PTs are always represented in the same area of the sector map. The position of each SOC and PT is stable over displays of different drugs.
- Grouping of PTs: PTs are grouped by high level term (HLT), high-level group (HLGT), and SOC.
- Ranking of PTs: PTs are ranked in descending order of EBGM values for each drug. EBGM: Signal Score. AERS cases: number of cases for the term in the AERS database. The PT "renal failure acute" is ranked 43rd with cerivastatin (see the top right rectangle within the Renal SOC, not displayed in the ranking for the top 10 drugs in the list below the graph) and "renal tubular necrosis" is ranked 7th with this drug. The PT "renal failure acute" has a larger box size than "renal tubular necrosis" because it has a much larger number of serious cases across all drugs in the AERS database.

methods for estimation of adverse event rates in clinical trials and active surveillance [17].

#### **9.8.5.4 Other Data Resources**

The number and size of databases containing drug safety information is growing rapidly, with some databases already containing millions of records [18, 19]. Analyzing several databases can help strengthen or refute a putative safety problem based on the results of the primary database analysis. Databases that can be analyzed include those maintained by various countries (e.g., the British General Practice Research Database or GPRD); various organizations (e.g., the World Health Organization and health maintenance organizations); various agencies (e.g., the U.S. Department of Defense, Department of Veterans Affairs, and Centers for Medicare and Medicaid Services Affairs), and others. Adapting new standard computer-intensive analytical tools to analyze data converted into standardized format will allow different experts to review each other's selection criteria and results so that conclusions can be more objectively studied and understood.

#### **9.8.5.5 Validation of New Methods**

Validation of new methods for analyzing drug safety data is challenging. There is no gold standard tool that can provide complete information about the whole spectrum of toxicity for a given drug and the magnitude and extent of this toxicity in specific subpopulations [9]. These facts, coupled with the discordant manner in which medical data are collected, make it very difficult to systematically analyze drug safety data in real time and to cross-reference multiple collections of medical data and results in a systematic way. The application of advanced computer methods offers a tremendous opportunity to analyze large databases in a timely and consistent manner and to learn about drug safety in a systematic way. These efforts will assist in creating gold-standard positive and negative signal definitions and methods given the data analyzed [20]. With these gold standards in place, we will be better able to further advance the art as well as the science of systematic drug safety assessment across databases.

### **9.8.6 CONCLUSIONS**

Even though great progress has been made since the passage of the Food, Drug, and Cosmetic Act in 1938, pharmaceutically related adverse events are still, unfortunately, responsible for a tremendous burden of pain and suffering in the United States [21], and old problems still persist around the world [22, 23]. Adverse events are also responsible for tremendous financial costs to taxpayers, insurance policyholders, insurance companies, and pharmaceutical companies. With such public health and economic costs in mind, we should carefully consider the strengths of new pharmacovigilance approaches while clearly acknowledging their limitations as well.

New tools that exploit the power of modern computer technology provide innovative approaches to help identify and investigate potential drug safety problems

in a systematic way. These new computer methods can assist in pharmacovigilance efforts because the results of an analysis from a particular drug safety database can be compared to the results from other, independent databases (e.g., clinical trial, health maintenance organization, or military medical databases). With interoperable standards in place, statisticians, epidemiologists and other analysts will be in a great position to improve drug safety and communication between all parties involved (consumers, clinicians, regulators, industry representatives, and legislators). By using the same software and data we can validate each other's selection criteria, results, and interpretation. As a result, researchers and policy makers will be better equipped to understand the limitations and biases of the data, leading to more objective decisions regarding drug safety.

### 10.1.1 INTERVENTIONAL CARDIOLOGY: HISTORY AND CURRENT PRACTICE

Coronary artery disease (CAD) affects approximately 13 million individuals in the United States and is considered the number-one killer among both men and women. It is estimated that more than 3 million individuals worldwide suffer myocardial infarctions (MI) annually because of CAD.

Remarkable changes have taken place in interventional cardiology since 1977, when Gruentzig and co-workers [1] performed a novel technique using an expandable balloon to compress obstructive lesions and reduce myocardial ischemia without a surgical procedure. Though the practice of using balloon catheters proved quite successful in the short term, long-term prognosis was less promising because of restenosis, which occurred in  $\geq 30\%$  of patients [2, 3]. This prompted the development of new techniques to remove plaque and the development of mechanical adjuncts, or stents, in order to maintain lumen patency following balloon angioplasty. Limitations in maintaining arterial patency have driven further development of interventional devices such as atherectomy catheters, stents, and laser therapy [4]. Coronary stenting after percutaneous transluminal coronary angioplasty (PTCA) was found in clinical trials to be a promising approach to reducing restenosis compared with angioplasty alone [5, 6]. Bare-metal stents (BMS) were the first type of stents used in percutaneous coronary intervention (PCI). Bare-metal stents reduced angiographic and clinical restenosis rates in de novo lesions compared to PTCA alone and decreased emergency coronary artery bypass graft (CABG) surgery. Stenting became quite prevalent in Europe in the 1980s and was increasingly used as the first line of PCI in the treatment of CAD. Methods developed in the 1990s to reduce or eliminate side effects of stenting included the administration of anti-coagulants, intravascular ultrasound, and brachytherapy. Systemic anticoagulation proved very effective and greatly reduced thrombus-associated complications. Brachytherapy was also effective at preventing in-stent restenosis, but its unfavorable side effects such as inhibition of healing around the stent and increased risk of cancer made it unsuitable for widespread use. The shortcomings of brachytherapy prompted further development of technology to maintain long-term arterial patency. This led to the emergence of stents designed to deliver drugs locally in order to inhibit neointimal hyperplasia without the serious effects of radiation or systemic drug administration. These coated, or drug-eluting, stents (DES) used various drugs encapsulated in different polymeric and nonpolymeric formulations. Drug-eluting stents were found to greatly reduce restenosis and maintain arterial patency. These advantages, combined with a lower incidence of side effects and a lower cost compared to surgical interventions such as bypass grafts, makes DES a great option for treatment of CAD [7].

Since the invention of stent devices, many clinical trials with various endpoints, sample size, and complexity have been designed. Device trials are designed to establish the safety and efficacy of the device by achieving a statistically significant difference in defined endpoints. The processes for receiving U.S. FDA approval for BMS and DES have required the submission of a pre-market approval (PMA) application; FDA requirements are evolving as stent technology has advanced. As shown in the Table 1, in clinical trials for BMS approved by the FDA, the sample size, total study duration, and clinical follow-up were lower compared to contemporary trials with DES. The primary objectives required by the FDA in the design of first-generation DES were surrogate endpoints, namely, the angiographic and intravascular ultrasound measures of the lumen diameter and the volume of plaque within the lumen. As a continuous and dichotomous variable that can demonstrate a statistically significant difference in small sample sizes, late luminal loss is a favored endpoint; in addition, its value in predicting target lesion revascularization makes it an excellent surrogate. However, the FDA has currently emphasized the need to demonstrate long-term safety of coronary stents and is shifting the focus of trials from surrogate endpoints [late loss (LL), percent diameter stenosis (%DS), and neointimal hyperplasia (NIH)] to clinical endpoints [cardiac death, MI, stent thrombosis (ST), major adverse cardiac events (MACE), and target vessel failure (TVF)]. Because of this shift, the clinical trial sample sizes for evaluating current DES are becoming larger than previously designed clinical trials. Current clinical trial designs for DES are mostly randomized, active-controlled, single-blind, parallel, two-arm, multicenter trials with clinical endpoints at 1 year and usually compare (newer) DES to (older) DES. The clinical follow-up should be designed for long-term safety (5 years) with angiographic, intravascular ultrasound (IVUS) and clinical endpoints. In addition to the complexity of procedural testing and follow-up duration, prespecified statistical hypothesis testing should be proposed for primary and secondary endpoints.

Another additional FDA requirement for the DES is evidence of continued safety in postmarket trials for the rare events such as ST. The rationale for this decision originated following the FDA warning notification of low-frequency event rates of ST involving the CYPHER stent in 2003 [8]. Current postmarket surveillance plans evaluate a variety of clinical endpoints, including Academic Research Consortium (ARC)-defined ST, as endpoints.

In conclusion, comparison of trial designs between BMS and DES reflect the increasing expectations for PMA approval by the FDA. DES clinical trials have increased in complexity in terms of trial design, study endpoints, hypothesis testing, statistical analysis, randomization, and sample size over the past 4 years. As coronary interventional therapy continues to evolve, efforts are made between the sponsor and the FDA to work collaboratively to generate evidence of efficacy and reasonable assurance of safety.

### 10.1.2 CORONARY STENT DESIGN

Stent design affects many properties of the stent, such as elastic recoil and rigidity—two undesirable stent characteristics [9, 10]. Previous studies have shown that differences in stent design and geometry can have a profound influence on late lumen loss [11] and neointimal proliferation [12], which in turn affect restenosis

**TABLE 1 Clinical Trial Summary for Bare-Metal and Drug-Eluting Stents**

| Trial Name                                | Design <sup>a</sup> | Trial Type   | Subjects         | Duration | Primary Endpoints                                                                                                                                 |

rates and requirements for postprocedural intervention [13–16]. Vascular geometry influences distributions of wall shear stress (WSS), as evidenced by branching and curvature that produce regions of low WSS. These alterations adversely affect the preferential flow environment of intravascular cells and correlate with sites of neo-intimal hyperplasia [17–19]. Studies have shown that the use of a stent with thinner struts is also associated with a significant reduction of angiographic and clinical restenosis after coronary artery stenting [13, 20–22]. Although most currently approved stents are made of 316L stainless steel [23], other materials are also used, such as cobalt chromium in the Multi-Link VISION stent (ML VISION). ML VISION is more radiopaque and elicits a less vigorous host response because of thinner struts.

Drug-eluting stents are designed to deliver a drug locally that inhibits intimal thickening by interfering with pathways involved in inflammation, migration, proliferation, and/or secretion of the extracellular matrix. Both the drug and the delivery vehicle must fulfill pharmacological, pharmacokinetic, and mechanical requirements. Besides their biological effects, the drugs' chemical properties influence pharmacokinetic parameters and the possibilities for loading on a stent [24]. Tissue levels depend on lipophilic or lipophobic characteristics, molecular weight, and the degree of protein binding of the used drug. In the FDA-approved DES, drugs used in the DES are loaded into a polymer coating, which forms a reservoir for the drug. Drugs on DES inhibit smooth muscle cell proliferation by targeting cell cycle regulators and arresting the cycle. For example, everolimus, zotarolimus, and sirolimus (the “limus” drugs) differ from paclitaxel in their mechanism of action because of the point in the cell cycle at which the dividing cells are arrested. The limus drugs block an intracellular proliferation signal, which is triggered by IL-2 and other T-cell-specific growth factors. As a result, the cells are arrested in the G1 phase of the cell cycle. Paclitaxel, however, acts later in the cell cycle than the limus drugs: It stabilizes microtubules and has potent activity against proliferation, migration, and signal transduction [25]. Preclinical and clinical data have documented that low doses of everolimus, paclitaxel, sirolimus, or zotarolimus (used, respectively, on the XIENCE V, TAXUS, CYPHER, and ENDEAVOR stents) can achieve therapeutic arterial tissue concentration with insignificant concentrations in the systemic circulation, and that the drugs are safe. The ideal drug to prevent restenosis must have antiproliferative and antimigratory effects on smooth muscle cells, but on the other hand the stent design and the drug used must also minimize the reendothelialization duration [26]. As discussed in the section on next-generation DES, the greatest and quickest reendothelialization process was observed with XIENCE V when compared to TAXUS, CYPHER, and ENDEAVOR in preclinical models.

The drugs on the DES are delivered using a vehicle that must fulfill many requirements. Drug release must be controlled and predictable. The delivery vehicle (most often a polymeric carrier) must be biologically inert (e.g., nonthrombogenic, noninflammatory), sterilizable, must follow the changes in stent configuration during expansion and deployment and must be mechanically resistant to abrasion [27–29]. The development of a coating that meets all of these criteria has been challenging. Polymer coatings are needed as carriers for most drugs since these drugs do not adhere to the metallic stent surface. Numerous substances have been proposed as potential biomaterials for stent coatings [30]. Most of the polymers currently used in commercially available DES are proprietary. The safety and biocompatibility of

acrylic polymer and fluorinated copolymer coatings have been demonstrated based upon the XIENCE V everolimus-eluting coronary stent system (EECSS) biocompatibility testing per ISO 10993-1 and the long-term use of these polymers in medical implants.

Ideally, stent design should offer both effectiveness and safety measures and optimize flexibility, tractability, visibility, and biocompatibility [12]. While stent flexibility and tractability are highly dependent on mechanical stent design, radiological visibility and host biocompatibility rely on stent material.

### 10.1.2.1 Bare-Metal Stents

The concept of the stent grew directly out of interventional cardiologists' experience with angioplasty balloons in the first decade of use (1977–1987). The rates of restenosis with angioplasty balloons were of concern. Although the artery would be opened successfully using a balloon, in a small percentage of cases, the artery would collapse after the balloon was deflated. BMS stents, inserted after balloon angioplasty, were designed to address the issues met with balloon angioplasty. The stent itself was mounted on a balloon and could be opened once inside the coronary artery. In 1986, in Toulouse, France, Jacques Puel and Ulrich Sigwart inserted the first stent into a human coronary artery. In 1994 the first Palmaz–Schatz stent was approved for use in the United States. Over the next decade, several generations of BMS were developed, with each successive stent being more flexible and easier to deliver. Despite the fact that BMS stents virtually eliminated many of the complications of abrupt artery closure, restenosis typically after 6 months occurred in about 20% of cases, necessitating repeat procedures.

Current BMSs have emerged with advanced design characteristics imparting improved performance compared to prior generations. Stent characteristics of potential importance to procedural performance include metallic alloy content, stent crossing profile, strut thickness and configuration, flexibility, conformability, polish and texture, cell structure, radial support, scaffolding, side branch accessibility, fluoroscopic visibility, delivery balloon technology, and vessel surface coverage. Some of these features also aid in reducing long-term in-stent restenosis (ISR). The importance of strut thickness in reduction of ISR was studied prospectively in the ISAR-STEREO [31] and ISAR-STEREO-2 [21] trials, which compared angiographic and clinical restenosis rates between thick- and thin-strut stents, showed lower ISR rates by approximately 40% with thin-strut stents, with either similar or different strut designs. Similar findings were noted in a retrospective review by Briguori and co-workers [20]. Fluoroscopic visibility and metallic alloy composition are also related to strut thickness. Stainless steel stents become difficult to visualize as strut thickness approaches 0.05 mm. Cobalt alloy stents have superior visibility, as well as improved deliverability, radial strength, and flexibility. Several studies have evaluated BMS versus DES, but proving differences in clinical outcomes between DES and BMS has been problematic because of strut thickness. Speculation has been raised about the thick-strut bare-metal controls used in DES trials. For example, the BASKET trial enrolled 826 patients with 1281 treated lesions. In the BASKET trial patients received either CYPHER or TAXUS in the DES arm or VISION in BMS arm. The study found no difference at 18 months regarding cardiac death/MI between treatments. Interestingly, the BMS stent used in this trial

was the thin-strut VISION stent, which is also used in the everolimus drug-eluting stent, XIENCE V. As mentioned above, studies indicated that strut thickness is important in reducing the ISR [21, 31].

Several recent clinical studies [20–22] have been conducted comparing the performance of stents with varying strut thickness. These studies indicated that when two stents with different designs are compared, the stent with thinner struts elicits less angiographic and clinical restenosis than the thicker strut stent. The VISION stent system is a next-generation BMS that can achieve good acute performance (deliverability, visibility) with thinner strut technology. Because of excellent results obtained with the VISION stent, Abbott Vascular has used the VISION stent as the platform in the XIENCE V. The ML VISION family of stents is fabricated from a L605 cobalt chromium alloy that has a thinner strut stent (0.08 mm or 0.0032 inch) and has a crossing profile of 1.07 mm. The ML VISION stent has been on the market in the European Union since 2002 and the MINI VISION since 2003. The ML VISION and MINI VISION stents have also been on the market in the United States since 2004. Medtronic's Driver cobalt nickel stent, with a smooth, modular design, a strut thickness of 0.09 mm, and crossing profile of 1.09 mm is another future generation BMS. Registry data for the Driver [32] and VISION [33] stents in mostly type B1 and B2 lesions in 3.0–4.0 mm diameter (mean 3.04–3.07 mm) vessels document excellent (100%) device success rates, and remarkably low ischemia-driven target lesion revascularization (TLR) rates at 6 months (4.3% for the VISION and 3.4% for the Driver). Angiographic in-stent restenosis (ISR) rates were 15.7% for both stents at 6 months.

In summary, the latest available BMSs have advanced design characteristics related to strut thickness and cell configuration, metal alloy composition, flexibility, crossing profile, and resultant deliverability. The next generation of DES (e.g., XIENCE V) benefits from the use of these thinner strut BMS platforms. The future generation of BMS may incorporate biodegradable materials, such as magnesium alloys, which may reduce the TLR rates.

#### 10.1.2.2 Drug-Eluting Stents

The newest minimally invasive intervention alternative to open-heart bypass surgery is PCI with a DES. The first DES, a sirolimus-eluting stent, was approved by the FDA in 2003. The introduction of DES to interventional cardiology practice has resulted in significant improvement in the long-term efficacy of PCI. DES successfully combine mechanical benefits of BMS and stabilizing the lumen with direct delivery and the controlled elution of a drug to the injured vessel wall to reduce further the neointimal proliferation. The dramatic reduction in restenosis has resulted in the implantation of DES in the clinical practice and has rapidly expanded the spectrum of new DES generations [34].

**First-Generation DES** The first-generation DESs, which combine the mechanical scaffolding properties of metallic stents with the site-specific delivery of an antiproliferative agent, have proved to inhibit vascular responses to arterial injury and reduce restenosis. The polymer-regulated site-specific delivery of an antiproliferative agent has also been shown to inhibit tissue growth after coronary stent implantation and to improve long-term event-free survival compared with BMS [35, 36].

The first-generation DES, CYPHER, was evaluated in the early sirolimus trials RAVEL ( $n = 238$ ), E-SIRIUS ( $n = 352$ ), C-SIRIUS ( $n = 100$ ), and SIRIUS ( $n = 1058$ ) before FDA approval. These trials reported a lower incidence of restenosis in patients who had received sirolimus DES, up to 8 months after PCI [37–39]. The attenuation of neointimal hyperplasia in these trials correlated with fewer TLR, an important clinical marker of restenosis. Rates of death and MI were low and comparable between study arms. These observations were confirmed in the U.S. pivotal trial, SIRIUS. Rates of death and MI, at 9 months, were, respectively, 0.9 and 2.8% for the CYPHER arm compared to 0.6 and 3.2% in the TAXUS arm.

The first-generation DES, TAXUS, was evaluated in TAXUS I ( $n = 61$ ), TAXUS II ( $n = 536$ ), TAXUS IV ( $n = 1314$ ), TAXUS V ( $n = 1156$ ), and TAXUS VI ( $n = 446$ ) trials. These trials showed reductions for the incidence of restenosis and TLR in patients receiving a slow-release polymeric paclitaxel DES compared to BMS [40]. These trends were later confirmed for slow-release and moderate-release formulations by the TAXUS II trial [41]. The pivotal trial, TAXUS IV, showed that the slow-release polymeric paclitaxel DES was associated with significantly reduced rates of in-stent binary restenosis (5.5% compared to 24.4%) and TLR (3.8% compared to 14.6%) at 9 months [42]. Furthermore, no significant adverse events were experienced in DES-treated patients in these early trials. The objective of TAXUS V was to evaluate the SR polymeric paclitaxel DES in complex lesions [43]. Finally, TAXUS VI evaluated a moderate-release polymeric paclitaxel DES, also in complex lesions [44]. Consistent with earlier TAXUS trials, the polymeric paclitaxel DES demonstrated significant reductions in the incidence of restenosis and TLR (72 and 64%, respectively) compared to metallic stents.

The FDA approved a new DES, ENDEAVOR. The ENDEAVOR IV [45] trial compared the performance of ENDEAVOR to TAXUS. Results from the ENDEAVOR IV trial demonstrated that in-stent late-loss, in-segment late-loss, and in-segment angiographic binary restenosis (ABR), respectively, were 60, 57, and 47% higher in the ENDEAVOR arm compared to the TAXUS arm. TLR was 41% higher in the ENDEAVOR compared to TAXUS with comparable MACE and TVF rates between the two arms (Table 3).

Abbott Vascular evaluated first-generation DES in the ACTION, DELIVER, FUTURE, and ZoMaxx clinical trials prior to developing the next generation of DES, XIENCE V. The ACTION trial was a randomized, parallel, three-arm, single-blind, multicenter trial designed to evaluate the safety and performance of the MULTI-LINK TETRA-D, actinomycin-eluting coronary stent system at two different drug concentrations compared to a bare-metal control. Early results of the ACTION trial indicated higher target lesion revascularization rates than expected in DES arms, driven by restenotic events. The ACTION trial was terminated in March 2002.

The DELIVER trial, was a prospective, randomized, single-blinded, parallel-group, multicenter clinical investigation evaluating the RX ACHIEVE paclitaxel drug-coated coronary stent system (CCSS) compared to the bare-metal MULTI-LINK RX PENTA stent in the treatment of patients with de novo native coronary artery lesions. The primary endpoint was target vessel failure (TVF) at 270 days. The primary endpoint was not met as powered; superiority of the RX ACHIEVE paclitaxel-eluting CCSS was not met.

The ZoMaxx DES has a phosphorylcholine coating and releases the drug ABT-578 (zotarolimus), a sirolimus derivative. ZoMaxx I and ZoMaxx II assessed the safety and efficacy of the ZoMaxx stent system compared with the TAXUS Express [2] paclitaxel-eluting stent system (Boston Scientific, Natick, Massachusetts). Although these trials demonstrated that ZoMaxx is safe to be implanted, Abbott Vascular decided not to pursue further the development of the ZoMaxx stent since a next-generation DES by Abbott Vascular, XIENCE V, had demonstrated superiority in terms of late loss to both bare-metal stent and an FDA-approved DES, TAXUS at 8 months, in SPIRIT III (see next section).

In conclusion, clinical trials for first-generation DES have proved the effectiveness of the DES in reducing the rate of ISR by directly inhibiting the progression of the cell cycle and migration of vascular smooth muscle cells, preventing neointimal hyperplasia and injury-induced thickening of the arterial wall. These trials evaluating the first-generation DES were randomized trials with more complex design, and a larger sample size when compared to pivotal studies for approval of BMS by FDA. Surrogate primary endpoints such as angiographic late loss were permitted. However, the search for improved deliverability and greater efficacy has prompted development of the next generation of DES.

**Next-Generation DES** Next-generation DESs are being designed with the goal of enhanced safety and/or efficacy compared to first-generation devices. The Abbott Vascular DES XIENCE V EECS was approved in the U.S. on July 2, 2008. This is a next-generation DES, which has demonstrated superior clinical outcomes compared to TAXUS. XIENCE V, an everolimus-eluting stent, has been designed so that the drug is released from a thin ( $7.8\mu\text{m}$ ), nonadhesive, durable, biocompatible fluorinated copolymer coated onto a low profile, flexible cobalt chromium stent with a 0.0032-inch strut thickness. Several clinical studies have demonstrated that stents with thinner struts elicit less angiographic and clinical restenosis than the thicker strut stent [20–22]. The strut thickness of the ML VISION ( $81\mu\text{m}$ ) compares favorably to those of the metallic stent platforms used on the CYPHER ( $140\mu\text{m}$ ) and the TAXUS ( $132\mu\text{m}$ ) stents [22] (Fig. 1). The thin-strut design is one element of the XIENCE V EECS (based on the ML VISION stent design) that decreases clinical risk.

**FIGURE 1** Progression towards thinner struts in XIENCE. Albuluminal coating thickness is represented in all images in figure. Data on file at Abbott Vascular.

The XIENCE V stent uses the same stent design and L-605 alloy cobalt chromium material as the ML VISION and ML MINI VISION stents. Compared to the 316L stainless steel used in TAXUS and CYPHER [23], the cobalt chromium in the XIENCE V stent is more radiopaque, thinner, and elicits a less vigorous host response than stainless steel. L-605 cobalt chromium provides both excellent strength and fatigue resistance characteristics, which enables the XIENCE V stent to have significantly thinner struts than contemporary stainless steel stents while maintaining comparable radial strength. Thinner struts, cobalt chromium material, and the MULTI-LINK stent pattern were intended for increased flexibility and conformability, and therefore better deliverability.

More rapid endothelialization with XIENCE V in porcine model, which may be due to the thin struts, has also been reported in preclinical models (Fig. 2). Evaluations of scanning electron micrographs of the luminal surface of various DES demonstrated differences in endothelial cell coverage among DES. As shown in Figure 2, XIENCE V stents had the greatest coverage compared to CYPHER, TAXUS, and Endeavor. The faster reendothelialization associated with the XIENCE V is likely due, at least in part, to the thin stent struts of the XIENCE V. A thin stent strut is incorporated in neointima more rapidly and will require less neointima to completely cover the struts. Similarly, endothelial cells may migrate up and over to incorporate a thin strut more rapidly [46].

Following favorable results with XIENCE V in the SPIRIT FIRST ( $n = 60$ ) and SPIRIT II ( $n = 300$ ) clinical trials in Europe [47, 48], the large-scale SPIRIT III trial ( $n = 1002$ ) was performed to evaluate the XIENCE V in comparison to a widely used TAXUS in patients with CAD [49]. The XIENCE V clinical trials (SPIRIT FIRST, SPIRIT II, and SPIRIT III) were conducted in single- and dual-vessel disease and met their primary and major secondary endpoints with no adverse safety signals to date. The results of these clinical trials are provided in Table 2. As shown in Table 2, the SPIRIT family trials showed significant benefits to using XIENCE V over both commercially available BMS (VISION) and DES (TAXUS).

**FIGURE 2** Qualitative assessment of endothelial cell coverage (14-day rabbit iliac). Corresponding images of each stent in the top row are shown directly below in greater magnification of the above stent image.

**TABLE 3 Perspectives from the New DES Compared to TAXUS**

| Study                              | Stent                        | In-stent LL | In-seg. LL | In-seg.<br>ABR | TLR   | TVR   | MACE  | TVF   |

<sup>a</sup>Clinical event rates for XIENCE V calculated from 284 day data.<sup>b</sup>ENDEAVOR IV results presented by M. Leon at TCT, 2007.

XIENCE V, as compared to TAXUS in the SPIRIT III trial, demonstrated (a) significant reductions in angiographic in-stent late loss ( $p = 0.006$ ), in-segment late loss ( $p = 0.004$ ), and in-segment %DS ( $p = 0.009$ ) at 8 months, (b) significant reduction in IVUS percent volume obstruction ( $p = 0.01$ ) without positive remodeling or late acquired incomplete apposition at 8 months, (c) nonsignificant trends toward less events for composite endpoints cardiac death and MI, and TVF at one year, (d) reductions in TLR and MACE rates at one year, and (e) comparable rates of thrombosis [49]. In the SPIRIT II and SPIRIT III RCT clinical studies, the XIENCE V has demonstrated not only noninferiority but superiority to TAXUS, in terms of the primary endpoints, in-stent and in-segment late loss, respectively. The SPIRIT IV clinical trial is a continued access study for continued access and was initiated in 2006 to further evaluate the safety and effectiveness of the XIENCE V EECSS and to enroll SPIRIT-III-like subjects in order to support the SPIRIT III major secondary endpoint (270-day TVF). The SPIRIT IV clinical trial is a single-blinded, multicenter clinical trial and will enroll approximately 3690 subjects at up to 70 sites in the United States. The primary endpoint of the trial is ischemia-driven MACE at 270 days. Patients will be followed out to 5 years. This study has enrolled approximately 3000 patients as of March 2008. SPIRIT IV will allow for analyzing subgroups of complex patients in a large randomized clinical trial. Furthermore, subjects enrolled in SPIRIT IV are SPIRIT-III-like subjects, so a true pooled analysis can be performed. In addition, postmarketing studies are currently being conducted internationally, which include SPIRIT V and SPIRIT WOMEN. A postapproval study, XIENCE V USA is currently also being planned in the United States. The results of a meta-analysis of SPIRIT II and SPIRIT III clinical studies obtained data at one year to support previous findings from SPIRIT II and III. The analysis indicated reductions in relative risk for both MACE and TVF, suggesting that XIENCE V has lower cardiac event rates in comparison with TAXUS, which was driven by lower TLR (XIENCE V FDA Panel, data are available at Abbott Vascular website; [www.abbottvascular.com/av\\_dotcom/url/home/en\\_us](http://www.abbottvascular.com/av_dotcom/url/home/en_us)). In the meta-analysis of the SPIRIT II and SPIRIT III RCT clinical studies, key clinical endpoints observed in XIENCE V arm were lower than those observed in the TAXUS arm. Results from several randomized clinical trials that compared commercially available DES and evaluated various clinical and angiographic endpoints have been published [45, 50–52]. The TAXi study ( $n = 202$ ) demonstrated safety of both TAXUS and CYPHER stents in various clinical and anatomical subsets [50]. Similarly, the REALITY trial confirmed the clinical safety of TAXUS in a larger subject population. In the REALITY trial ( $n = 1386$ ), the primary endpoint of in-lesion ABR rate at 8 months (primary endpoint) was comparable between TAXUS and CYPHER.

Additionally, there was no difference between the two DES in terms of MACE rates at one year [51]. In the SIRTAX trial, although sirolimus-eluting stents showed a 42.6% decrease in MACE at 9 months compared to paclitaxel-eluting stents, the rates of clinical and angiographic restenosis were low for both DES [52]. Although the first-generation DES used BMS as control stents, next-generation DES clinical trials were designed to evaluate (older) DES versus (newer) DES, which resulted in increased sample sizes and new statistical hypothesis testing. Surrogate angiographic endpoints were permitted as primary endpoints (but for longer time points) with the focus on rare safety events such as death, MI, and ST. Composite endpoints such as MACE and TVF were used in these clinical trials to evaluate both safety and effectiveness of next-generation DES.

**Future-Generation DES** Drug-eluting stents continue to evolve, with enhanced drugs, polymers, and delivery systems designed to improve outcomes for patients with CAD. Improved delivery systems allow access to lesions in vessels with excessive tortuosity. Abbott Vascular plans to evaluate a future everolimus-eluting coronary stent (EECS), which is a balloon-expandable stent fabricated from a single piece of medical-grade L-605 cobalt chromium alloy tubing, which is the same material used in the ML VISION and XIENCE V. This EECS will provide a more flexible, better delivery system profile while maintaining good radiopacity and strength. The sirolimus and paclitaxel stents, CYPHER SELECT Plus Stent (by Cordis), and TAXUS Element Stent (by Boston Scientific) are also designed with improved delivery system features and are currently on the market in the European Union (EU). In addition, clinical trials have recently begun for a sirolimus-eluting stent (by Conor and Cordis) using Conor's unique fully bioresorbable reservoir technology.

The bioabsorbable stent is a future-generation stent type. Bioabsorbable stents are an exciting class of future-generation stents because of their ability to be absorbed over time. Ideally, this allows the lifetime of the stent to be tailored to the clinical need of the disease or condition. In order to open the blocked vessel and offer mechanical support, the bioabsorbable polymeric stent must have high radial strength, low recoil, and a certain degree of flexibility while its degradation product must be nontoxic in body fluids. The bioabsorbable stent holds promise as a device system that will be able to perform its mechanical function (i.e., high radial strength and low recoil), facilitate stent placement, and deliver drugs for the prevention of restenosis. Furthermore, the stent should support the artery while the vessel heals and should gradually transfer the mechanical load to the tissue as the stent degrades over time. It is also worth noting that radiopacity is another consideration in stent design. The BVS (Bioabsorbable Vascular Solutions) stent was developed by Abbott Vascular. In March 2006, BVS started the world's first clinical trial of drug-eluting polymeric bioabsorbable stent called the ABSORB trial.

The BVS stent drug coating layer contains everolimus (antiproliferative agent) and poly-D, L-lactic acid (PDLLA) polymer at a 1:1 ratio for controlled drug release. Because of its unique stent pattern design, the BVS stent looks like a regular DES with great mechanical properties. The ABSORB trial enrolled 30 patients [53]. The procedure success rate was 100% and the device success rate was 93.5%. The safety of the device was confirmed in all 30 patients after 12 months follow-up. Only one non-Q-wave MI was reported that was related to the procedure of a nonischemic-

driven target lesion revascularization. There was no ischemia-driven target lesion revascularization, and no thrombosis occurred up to 12 months. Through 12 months, there were no protocol-defined or ARC-defined stent thrombosis [54]. Efficacy measurements of in-stent late loss was  $0.44 \pm 0.35$  mm with angiographic follow-up at 6 months and was mainly due to a mild reduction of the stent area (−11.8%) as measured by intravascular ultrasound (IVUS) [54]. At 24 months, an increase in lumen area on IVUS and optical coherence tomography (OCT), and restored vasomotion in response to vasoactive agents, has been demonstrated.

Apart from Abbott Vascular, Reva Medical Inc. (supported by Boston Scientific, Inc.) is developing its own bioabsorbable DES made from tyrosine-derived polycarbonate material and has started its clinical trial as of late 2007. Reva Medical uses a unique “slide-and-lock” geometry for its stent designs. When expanded, the stent elements slide from the compact state and lock into an expanded state, similar to safety lockouts on extension ladders. Thus the expansion is independent of material deformation and will provide steel-like scaffolding. The Reva stent is delivered by standard balloon deployment and is made radiopaque by a propriety method [55].

Although more long-term beneficial outcomes in controlled clinical studies have yet to be demonstrated, it can be anticipated that biodegradable stents offer the benefits of DES without leaving a metallic stent behind after the treatment of coronary vessel lesion.

As new approaches of stenting continue to evolve, clinical trial design requires new technology and perhaps novel endpoints to demonstrate the safety and effectiveness of these devices. For example, optical coherence tomography (OCT) and serial IVUS are used in the evaluation of biodegradable stents. More long-term safety data are required by the FDA for low-event rate endpoints resulting in larger sample size for these trials.

### 10.1.3 APPROPRIATE CONTROL GROUPS FOR PCI CLINICAL TRIALS

Coronary atherosclerotic disease has been dominated in the past by four main therapy options: CABG, optimal medical therapy (OMT), balloon angioplasty (POBA), and percutaneous coronary intervention (PCI) with BMS or DES. From 1960 to 1994, CABG surgical procedures dominated as the treatment for CAD. The CABG was eventually challenged with the introduction of angioplasty in 1977 [56]. The FDA approved the first BMS in 1996, which was followed by the first DES approval in 2003. According to the Centers for Disease Control and Prevention, the most common interventional cardiology procedure performed in 2007 was PCI with DES [57]. Several studies have compared the various treatment options of CAD, POBA, PCI, CABG, and optimal medical therapy. Despite the fact that comparative studies have been conducted, there is still the need for studies directly comparing PCI with DES to these treatments.

In the next paragraphs the key outcome of clinical trials comparing PCI to other CAD treatment options will be discussed.

#### 10.1.3.1 Coronary Artery Bypass Graft Surgery

Coronary artery bypass graft procedures are a common choice for treatment of advanced CAD. In patients with single-vessel disease though, PCI is the preferred

treatment because of the lower clinical risks associated with PCI [58]. Several studies compared PCI with BMS to CABG including the ERACI II, ARTS, SOS, and the AWESOME trials [59–63]. The results of these trials demonstrated that repeat revascularizations were higher in the PCI with BMS group compared to the CABG group in all trials. However, there was no significant difference in survival benefit between CABG and PCI with BMS. Overall results showed that PCI with BMS was a relatively safe alternative for patients who were not candidates for surgery.

When DESs were initially being introduced, primary endpoints included late lumen loss on angiographic follow-up, death, myocardial infarction, or reinterventions (RAVEL, SIRIUS). Results of these trials showed significant reduction in target lesion revascularization rates for DES. Since the first FDA approval of DES in 2003, numerous studies have shown the benefit of DES for reducing the rate of revascularization [35–41, 43, 44, 64]. As it is well established that DESs out-perform BMS at reducing revascularizations, studies comparing CABG to DES now can compare the rate of repeat revascularization as primary endpoints, such as in the SYNTAX trial.

Furthermore, trials currently underway comparing CABG to DES are designed to compare the rate of cerebrovascular accidents, as CABG have shown higher rates of CVA [64a]. The SYNTAX trial has been designed to compare PCI with DES (TAXUS) to CABG for the treatment of triple-vessel and left main disease [65]. The SYNTAX trial will compare the rate of major adverse cardiac and cerebral events (MACCE) between DES (TAXUS) and surgery with CABG. The study includes two nested registries for subjects ineligible for CABG who are treated with PCI and for subjects ineligible for PCI who are treated with CABG. Complete data from the primary objective of the SYNTAX trial is not available yet, but differences in CABG and PCI practice patterns have been observed between North America and Europe. Thus far, the rate of PCI intervention for triple-vessel disease in Europe is approximately double the rate from North America [65]. Initial reports from the SYNTAX trial in late 2008 showed similar composite rates for death, stroke, and MI in both arms, but reduced repeat revascularization rates in the CABG arm and reduced stroke rate in the PCI arm.

The FREEDOM trial is another current study to investigate CABG versus DES (CYPHER) in the treatment for subjects with CAD and diabetes mellitus [66]. The primary objective will be to assess the effectiveness of PCI compared to CABG (on or off pump) in the prevention of all-cause mortality, nonfatal MI, or stroke. Outcomes of mortality, MI, revascularization, health-related quality of life, and cost effectiveness will be addressed for a mean of 4 years.

The SYNTAX and FREEDOM trials will have completed follow-up in 2012 and 2011, respectively. The SYNTAX primary endpoint results are expected to be communicated in the fall of 2008. SYNTAX and FREEDOM will provide valuable information on CABG treatment versus DES treatment, but data for other type of DES would bring more information for choosing the best treatment options for CAD patients.

### 10.1.3.2 Drug Therapy

Pharmaceutical advances in lipid-lowering drugs, antidiabetic agents, antiplatelet therapy, and antihypertensive medications in the 1990s have provided patients and

physicians with drug therapy treatment options. The MASS II trial compared PCI, CABG, and OMT modalities in subjects with stable angina and multivessel CAD [67]. The primary endpoints were total mortality, Q-wave myocardial infarction (QWMI), or refractory angina requiring revascularization. In the MASS II trial, all three therapeutic strategies yielded comparable results with relatively low rates of mortality. The rates of additional revascularization and long-term events were found to be similar for PCI and OMT, but were the lowest for CABG. Devices used for catheter-based PCI treatments included stents, lasers, directional atherectomy, and balloon angioplasty. Since enrollment was completed before DESs were approved by the FDA, no DES was included in the PCI arm of the MASS II trial. Overall, BMS compared to DES represents up to a 60% higher rate of revascularization [68]. Despite this fact for patients with stable multivessel CAD, the MASS II trial showed that routine PCI is as good as CABG or OMT. The MASS II trial results suggest that patients with mild to moderate angina are good candidates for OMT, whereas a PCI or CABG would be appropriate for patients with symptoms that could not be controlled or were more severe.

The COURAGE trial compared outcomes of subjects initially treated by OMT with PCI versus OMT alone for significant CAD. The primary endpoint in the COURAGE trial was all-cause mortality and nonfatal MI, which may well have been a limiting factor. By selecting the primary endpoint of all-cause mortality, the rate of mortality would include the rate of death from any cause and not just a death due to cardiac events. By choosing this type of endpoint, the comparison of mortality rates would include additional noise and would not provide the most accurate comparison. Because the COURAGE trial was comparing cardiac interventions, a more appropriate endpoint might have been cardiac events. In fact, a more appropriate safety endpoint would have included all MI events rather than only the nonfatal MI. Predictably, by selecting this primary endpoint, there was no significant difference in the rates of death distinguishable between the OMT and PCI versus the OMT alone [69]. The trial enrolled  $\geq 97\%$  of PCI subjects treated with BMS compared to 3% PCI subjects treated with DES. The very low rate of DES subjects ( $< 3\%$ ) in the COURAGE trial does not allow any comparison of PCI with DES to OMT [56]. This observed bias is because the DES was approved by the FDA at a very late stage of patient enrollment in the COURAGE trial. An additional weakness of the COURAGE trial was that it was powered to show superiority of angioplasty versus OMT with a reduction in death and MI by 22% [56]; this has never been the clinical driver of stenting in stable patients, in whom the major benefit of interventional therapy is reduction of angina, and improved quality of life. Moreover, approximately 33.0% of the OMT patients crossed over to the PCI group at a mean time of 10.2 months for angioplasty, which suggests that OMT was not an adequate treatment. Another weakness of the COURAGE trial was that the investigators modified the definition of MI part way through the study because of low event rates [56]. Currently, no data are available from major trials for comparing PCI with DES to OMT. However, it was suggested that OMT may be preferred for those more stable subjects with less severe progression of CAD.

### 10.1.3.3 Plain Old Balloon Angioplasty

Earlier trials comparing PTCA to CABG used primary endpoints that focused on safety; the BARI trial, for example, examined all-cause mortality as a primary

endpoint [70]. The EAST trial also compared PTCA to CABG with a composite endpoint of death, QWMI, and evidence of ischemia at 3 years [71]. Overall findings from these trials did not differ significantly with primary endpoint results. However, revascularization rates were higher in PTCA subjects. Trials were then designed to compare POBA to medical therapy. RITA-II used a primary endpoint of death and definite MI rates at 5 years and showed comparable mortality rates. However, lower rates of restenosis were noted when angioplasty was used in conjunction with coronary stents, compared to using angioplasty alone [72]. The benefit of decreased restenosis led to less repeat procedures that reduced long-term cost of repeat revascularization [73]. As PCI with stenting was introduced, comparisons of POBA with PCI indicated that POBA was not as effective as PCI at reducing restenosis [5, 6]. Study designs then evolved to include composite endpoints including both survival and revascularization rates. Endpoints such as TVF and MACE were implemented. As stent technology expanded through the 1990s, its designs, materials, techniques, and deployment improved, such that stenting has dominated over balloon angioplasty over the last 15 years.

#### 10.1.3.4 Stenting

The FDA first approved PCI with BMS in 1996. It was later reported that 20% of subjects treated with BMS had experienced recurrent symptoms attributed to restenosis from intimal hyperplasia [74]. Despite several studies showing angiographic and clinical improvements with these catheter-based interventions, restenosis within the BMS stent continued to be a major problem that caused repeat revascularizations [5, 6, 59, 75]. Comparison of PCI with BMS to PCI with DES showed decreased rates of revascularization with DES. Currently, more than 15 analyses have been performed to evaluate the performance of DES versus BMS that have generally shown that DESs are safe and effective [76–91]. One of the largest meta-analyses comparing 19 different trials found that restenosis and MACE were greatly reduced with DES as compared with BMS [92]. A more recent study, published in 2008, showed no significant difference between DES and BMS groups in the rate of death or MI at 1-year follow-up [93].

However, the rate of revascularizations was significantly lower in the DES group, and current studies continue to support the benefit of DES compared to BMS. Trial designs comparing DES to BMS sufficiently demonstrated that safety was comparable between DES and BMS. In addition, by using composite endpoints including revascularization rates, DES showed to be a great improvement to BMS at reducing the need for repeat revascularizations. Studies continue to show comparable safety results and improved efficacy for PCI with DES compared to PCI with BMS. Future trials with next-generation DES versus BMS should continue to investigate the rates of ST and cardiac death, as trials have already shown revascularization rates were dramatically improved with use of the first-generation DES compared to BMS.

Many clinical trials have compared DES to each other. The comparison of two first-generation DES, CYPHER versus TAXUS in the REALITY [51], SIRTAX [52], and ISAR-DIABETES [79] clinical trials did not show superiority of TAXUS over CYPHER. There was no statistically significant difference in the rate of death, MI, and revascularization. ENDEAVOR IV compared the newly approved DES, ENDEAVOR, to TAXUS, and it was concluded that ENDEAVOR was noninferior to TAXUS for the primary endpoint of TVF. The SPIRIT III trial compared the next

generation of DES, XIENCE V, to TAXUS. The trial included the use of an FDA-suggested angiographic primary endpoint of in-segment late loss, in addition to a co-primary endpoint of TVF at 9 months. The follow-up results demonstrated superiority of XIENCE V to TAXUS for the primary endpoints, with lower in-segment LL. In addition, XIENCE V had fewer MIs and less repeat target lesion revascularization procedures than TAXUS, all of which suggest that XIENCE V is safe and effective for treating patients with CAD. Additional DES trials designed after the SPIRIT III trial will probably no longer use surrogate or angiographic endpoints, as the emphasis of the FDA has shifted to clinical and safety endpoints. The SPIRIT IV trial will include the rate of MACE at one year as the primary endpoint.

#### 10.1.4 PCI STUDY DESIGN ENDPOINTS

Clinical trials are designed to evaluate the safety and effectiveness of DES. Selected endpoints play pivotal roles in device approval and in their adoption for clinical use. These endpoints must serve several purposes. They must have both short- and long-term pathophysiological relevance to device performance, represent clinically meaningful events, be sufficiently defined, preferably through blinded processes, and be subjected to statistical analysis. Because of the intrinsic limitations in the ability to obtain histology, serial examinations, or other mechanistic details from human subjects, clinical endpoints for DES studies are bound to include certain arbitrary assumptions and will frequently vary across clinical trials as the result of different approaches to such assumptions [94].

##### 10.1.4.1 Clinical Endpoints

Endpoints for clinical trials evaluating devices should measure safety, effectiveness, and patient well-being.

Safety endpoints represent any adverse outcome during the course of the clinical evaluation and whether or not it is specifically related to the use of the device. Safety endpoints are measured by events such as death, MI, stent thrombosis, or composite endpoints such as MACE, TVR, death, and MI. Effectiveness endpoints refer specifically to maintenance of coronary artery luminal patency, which is assessed by measuring the relief of such flow-limiting obstructions, initially through structural mechanisms and later with preservation of the luminal dimension through inhibition of neointimal hyperplasia or restenosis. Effectiveness-driven clinical endpoints are designed to assess clinically significant restenosis, assessed objectively as a requirement for ischemia-driven repeat revascularization, either of the stented segment itself, TLR, or of the stented vessel or its side branches, TVR [94].

Effectiveness endpoints refer specifically to maintenance of coronary artery luminal patency. DESs are implanted for the treatment of obstructive CAD. Their effectiveness is assessed by measuring the relief of such flow-limiting obstructions, initially through structural mechanisms and later with preservation of the luminal dimension through inhibition of neointimal hyperplasia or restenosis. Effectiveness clinical endpoints are designed to assess clinically significant restenosis, assessed objectively as a requirement for ischemia-driven repeat revascularization, either of the stented segment itself, TLR, or of the stented vessel or its side branches, TVR

[95]. Target vessel failure, defined as any TVR, death, or MI attributed to the target vessel, is an even broader metric of failed effectiveness and adjusts for the potential bias introduced when patients who die or sustain MI before the end of the TLR endpoint time are considered to be free from TLR [94].

General considerations for DES evaluation should also include cardiovascular outcomes from the patient's perspective. The outcomes of endpoints should reflect the complex interplay between device performance, revascularization strategy, secondary prevention, and key patient descriptors [96]. Both the time course and the composite selected should characterize patient well-being related to the pathophysiology of the implanted DES device and its impact on underlying CAD outcome.

The most commonly measured clinical indicator of stent efficacy is TLR, which is defined as recurrent ischemia due to angiographic restenosis within the stent or its margins necessitating repeat revascularization with either PCI or coronary artery bypass graft surgery. TLR rates are typically 30–60% lower than the corresponding binary restenosis rates, suggesting discordance between the ischemic thresholds of angiographic and clinical measures of restenosis [95, 97]. Given the low rates of TLR after BMS implantation in the relatively noncomplex lesions typically studied in stent trials, more than 2000 enrolled patients are required in randomized trials to demonstrate a clinically relevant 30% reduction in TLR with DES. Moreover, given the low-frequency clinical event rates with DES, very large potential differences between stents (the “delta”) often are allowed in noninferiority trials to make comparative DES studies practical, degrading confidence that the clinical performances of two devices are indeed similar.

#### 10.1.4.2 Angiographic Endpoints

To reduce the sample size required in superiority and noninferiority trials, continuous angiographic indexes of long-term stent patency such as late LL and follow-up %DS have been proposed as surrogates of TLR for use in randomized studies [35, 96, 98]. However, previous DES studies have suggested that the distribution of individual LL measures is asymmetric with a rightward skew and that the relation between LL and TLR is nonlinear [36, 99]. Recently, Pocock et al. evaluated angiographic measures as valid surrogates for TLR and cutoff values that correspond with clinical efficacy [100]. Using data from 11 randomized trials, the investigators evaluated 4 angiographic measures used as surrogates for the clinical endpoint of TLR. They concluded that all four angiographic measures, instent and in-segment LL, as well as both assessments of %DS, provided a reliable estimation of TLR rates in all the trials and met the accepted criteria for surrogate endpoints. In the same report it was also concluded that %DS may have an advantage over LL as a surrogate endpoint. Therefore, Pocock et al. [100] suggested that angiographic surrogates can be used as the primary outcome measure in smaller patient populations compared to when TLR is the primary outcome, and larger trials should provide information on less frequent safety events.

#### 10.1.5 SAFETY

Clinically, safety after stenting can be measured by the rate of death, MI, or stent thrombosis or by the rate of composite endpoints such as TVF (composite of death,

MI, TVR) and MACE (composite of death, MI, TLR). Composite endpoints generated by the combination of individual endpoints provide additional statistical power to detect potentially meaningful differences between treatments. The individual components should each represent clinically meaningful events and should be linked by common elements of pathophysiology. The ARC consensus suggests two composite endpoints for DES trials, one that is device-oriented and one for overall patient-oriented clinical outcome. The device-oriented composite includes cardiac death, MI attributed to the target vessel, and TLR. The broader patient-oriented outcome composite includes all-cause mortality, any MI, and any revascularization (includes TLR), target vessel revascularization, or revascularization of nontarget vessels.

Many trials have evaluated the rates of ST after the PCI with DES versus BMS. However, there are some challenges to comparing ST rates between trials because of the differences in patient and lesion characteristics, the prevalence of diabetes mellitus (which ranged from 14 to 31%), the use of glycoprotein IIb/IIIa inhibitors (which ranged from 0 to 64%), and the use of various definitions for ST in trials performed up until 2006. Recently, the FDA, academia, and industry agreed to use ARC definitions in order to align and standardize the definitions used in clinical trials [94]. However, more than 15 studies evaluated the performance of DES versus BMS. There was no significant and consistent pattern of difference reported between the ST rates of DES and BMS. Meta-analyses of randomized trials performed with DES demonstrated that incidence of ST was not increased in patients receiving DES (0.58% for DES versus 0.54% for BMS) [86]. The overall rate of ST did not differ significantly between patients receiving sirolimus- or paclitaxel-eluting stents (0.57 versus 0.58%). In contrast, a significant relationship between the rate of ST and the stented length was found. In patients with DES, mean stented length was longer in those with ST. Per ARC definitions, the low incidence of ST was reported in the SPIRIT III trial and ST rates were low and comparable through one year for XIENCE V and TAXUS. Premature discontinuation of antiplatelet therapy has been identified as one of the predictors for ST [80]. Recent studies have reported a low incidence of DES thrombosis under prolonged therapy with aspirin plus thienopyridines, comparable to that of BMS, even in unstable clinical settings [101]. The most striking factor associated with DES thrombosis is the absence of treatment with ticlopidine/clopidogrel. In the ASPECT trial, the rate of DES thrombosis in patients receiving cilostazol instead of thienopyridines was 14.8% (4 of 27) [102]. In another study, 30% of patients discontinuing ticlopidine early after DES implantation suffered ST [103]. Furthermore, Park et al. [104] performed a trial in order to investigate the incidence, risk factors, and association of antiplatelet therapy interruption for the development of ST after DES implantation during long-term follow-up (median follow-up 19 months). In this study a total of 1911 consecutive patients with DES were enrolled. The results of this study demonstrated that the incidence of late ST was 0.6%, similar to that of metallic stents. The predictors of ST were premature antiplatelet therapy interruption, primary stenting in acute MI, and total stent length. For a rare event such as ST, using standardized definitions across postmarketing studies and registries may help to further identify predictor of ST. However, as the ST incidence is low, a large sample size is needed to accurately identify these predictors.

## 10.1.6 POSTMARKET REGISTRIES AND OFF-LABEL STENT USE

Drug-eluting stent commercialization and use is monitored by the Center for Device and Radiologic Health (CDRH), a branch of the FDA. Recently, the off-label market use of DES has been under scrutiny by the FDA. The issues surrounding the real-world use versus the approved FDA use will be discussed in the next two sections.

### 10.1.6.1 Real-World Issues

The FDA has mandated a postmarket safety surveillance plan that must include at least 2000 patients (21 CFR 820). The purpose of the surveillance is to assure that public safety is not compromised and that the product is being used in accordance with its approved indication. Postmarket registries also collect more data on low rate events, such as death, MI, and ST. More long-term follow-up on a larger subset of complex patients can also be accomplished in postmarket studies that could not be done in smaller randomized controlled trials. Complex patients with diabetes, renal dysfunction, acute MI, triple-vessel disease, bifurcations, left main coronary disease, heavily calcified lesions, and longer lesion segments are included in postmarket registries; these patients would otherwise be excluded from most preapproval randomized controlled trials [105]. Additionally, meta-analysis can be completed for indirect comparisons of treatments to determine study inconsistencies [106]. Moreover, the effect of antiplatelet therapy on ST and the compliance with dual antiplatelet therapy can be monitored in postmarket trials. In particular, the duration of clopidogrel use in combination with aspirin has not been established yet for DES. Three to six months of use was initially recommended for the first-generation DES. The American Heart Association/American College of Cardiology/Society for Cardiovascular Angiography and Interventions currently recommends up to 12 months of antiplatelet therapy with DES use for those patients not at high risk for bleeding [107]. Although the duration of clopidogrel appeared to be adequate for the selected patients in the original clinical trials, optimal duration of clopidogrel in more complex patients has not been defined. Many years of additional data are needed to characterize the effects of antiplatelet therapy on DES ST rates before conclusions can be drawn on the optimal antiplatelet therapy duration for DES patients.

Between 2002 and 2004, the CYPHER postmarketing surveillance program enrolled over 15,000 patients who received a CYPHER DES [108]. The results demonstrated safety with low rates of ST and TLR. ARRIVE-1 was a postmarket registry for TAXUS DES and enrolled over 2000 patients. The findings at 2 years showed that discontinuation of clopidogrel before 6 months was a significant predictor of ST at 1 and 2 years. In addition, rates of cardiac events at 6 months were similar for diabetic and nondiabetic patients [109]. The ARRIVE-2 registry was a postapproval study that enrolled over 4000 patients in the real-world setting. The ARRIVE-2 registry showed outcomes and usage patterns similar to those seen in ARRIVE-1 [105]. Boston Scientific pooled the data from these registries and was able to show that TAXUS DES was being implanted in more complex settings. These trials led to several ATLAS trials that aimed to expand the indications for use in these more complex procedures and patients [105]. Medtronic recently

received conditional approval for the ENDEAVOR DES and will initiate a post-approval study with a minimum of 5000 patients. In addition, Abbott Vascular is seeking approval for the XIENCE V DES in the United States and has a postmarket surveillance plan including real-world use trials in populations worldwide. The XIENCE V DES program will include up to 16,000 patients treated with XIENCE V in the United States, India, Japan, China, and Europe. The XIENCE V postmarket surveillance plan is designed to detect low rate events of cardiac death, MI, and ST. Furthermore, the XIENCE V program will monitor patients' long-term compliance with dual antiplatelet therapy.

Collectively, the XIENCE V, TAXUS, ENDEAVOR, and postmarket surveillance programs will provide a comprehensive data set for use in analyzing the low rate of events such as death, MI, and ST.

#### 10.1.6.2 Characterizing Off-Label Stent Use

Physicians may use a medical device off-label in good faith as the best available treatment option for the patient. The outcome of this off-label use can be a great benefit to the patient or may introduce considerable unnecessary risk or harm to the patient. Currently, the widespread off-label use of FDA-approved DES has prompted increased attention from regulatory agencies. Although the FDA does not regulate physician practice, it does establish guidelines for physicians to use products legally as indicated on the label. Monitoring safety- and efficacy-related information in these off-label use situations has become a considerable challenge for the manufacturer, physicians, and the FDA, making this dilemma a public health policy concern.

According to the FDA, it was estimated that 60% of DES use was off-label in 2006 [74]. Manufacturers and regulatory agencies can gather information regarding the breadth of off-label use through registries, postmarket surveillance/studies, device complaints, publications, payers, investigator-sponsored studies, professional societies, and scientific conferences. The manufacturer can gain considerable insight into the possibility of label expansion from this data because it may indicate that there are unmet needs in the market. In the case of DES, several off-label uses have prompted further studies to support approval of DES for more complex cases [105]. Some current off-label DES use involves bifurcation lesions, saphenous vein grafts, in-stent restenosis, total occlusions, acute MIs, and left main triple-vessel disease. Optimal medical therapy, BMS, and CABG therapies can also be compared against off-label DES use through explorative meta-analysis registries. A recent study compared BMS and DES off-label use versus BMS and DES on-label use. The results demonstrated that the risks of MI, death, or ST were lower for patients treated on-label versus off-label in both BMS and DES. There was also no difference observed between DES types [110]. In another recent trial comparing off-label use in DES to BMS, it was demonstrated that the use of DES was not associated with increased risk of death or MI at 1 year and that DES use continued to show lower revascularization rates in off-label use settings compared to BMS [93]. Without further data, the safety and efficacy of off-label use in all DES remains unknown.

The major disadvantage of off-label DES use is the potential for serious adverse outcomes to patients. The manufacturer may have initially sought FDA approval for an indication that was denied because of safety concerns. Physicians in everyday

practice may not be aware of the reasons why an indication was rejected or of this additional risk to their patients. Currently, there is a lack of process that can accurately analyze the outcomes of all off-label use. Patients not entered into a trial or registry may never receive long-term follow-up and their outcomes may remain unknown. The FDA has an obligation to obtain this information, yet at the same time it cannot condone the off-label practice that would generate the data needed for analysis. The manufacturer is restricted from promoting off-label use in practice. Physicians may use a DES for an unapproved indication instead of waiting for FDA approval, which can be a lengthy and complex process. The label expansion process can take as many or more resources as the initial device approval did [111]. Current FDA limitations for label expansion make this a costly and lengthy process, which ultimately may restrict the best treatment options for the patient. In the future, the industry and regulatory approving bodies must work toward a system that allows for rapid approval process while maintaining safety standards.

The practice of using DES for unapproved product indications is an increasing concern. Additional data are needed to assure the safety and efficacy of DES for the complex cases, lesions, and patients that are being treated off-label. Data should be gathered from randomized control trials, postapproval registries, or through national databases from physicians and manufacturers.

### 10.1.7 PERIPHERAL STENTS

Peripheral atherosclerotic occlusive disease or *peripheral vascular disease* (PVD) is exceedingly common in aging western societies; the prevalence of plaque in the femoral arteries of patients over the age of 70 may be as high as 74% [112]. Symptomatic PVD affects approximately 10% of the population over the age of 50, and as much as 20% of the population over the age of 70. Failure to maintain or restore adequate perfusion to the lower extremity results in nearly 250,000 lower extremity amputations annually.

Symptomatic PVD has traditionally been treated by surgical bypass grafting. First conceived in 1949 [113], and popularized in the 1980s through refinements in anesthesia and technique, bypass grafting was the accepted standard of care for nearly 50 years. Unfortunately, patient morbidity is considerable, as those requiring this invasive procedure are older and infirm, and the operation requires relatively long incisions and dissections through ischemic tissue. Hoping to circumvent the excessive morbidity of surgical bypass grafting, techniques of endovascular infrainguinal revascularization were developed in the 1980s. Percutaneous peripheral transluminal balloon angioplasty was first described in 1982, followed closely by reports of adjunctive stent implantation in 1985 [114, 115]. These techniques were adapted and enhanced over the ensuing two decades, including significant improvements in access, imaging, negotiation of chronic occlusions and, most notably, the wider application of self-expanding nitinol stent technology. Despite these refinements, maintenance of long-term patency following endovascular interventions is limited, as restenosis eventually complicates up to 50% of procedures during the first year (Fig. 3) [112, 116].

In the coronary circulation, the problem of restenosis was eventually circumvented through the development of coronary DESs [117]. Given their success, many

**FIGURE 3** Peripheral in-stent neointimal hyperplasia and restenosis. [From Scheinert, D., Scheinert, S., Sax, J., et al. (2005), *Prevalence and clinical impact of stent fractures after femoropopliteal stenting*, *J. Am. Coll. Cardiol.*, 45, 312–315.]

have theorized that this technology might also be useful in the peripheral arteries. The Sirocco stent (Cordis, a Johnson & Johnson Company, Miami Lakes, Florida) remains the first, and only, peripheral DES to be tested in clinical trials and reported in the scientific literature [118–120]. The Sirocco stent utilized the nitinol self-expanding S.M.A.R.T. stent as its platform, was loaded with  $90\mu\text{g}$  sirolimus/ $\text{cm}^2$  stent area using a 5- to  $10\text{-}\mu\text{m}$  copolymer matrix (total drug content  $\sim 1\text{ mg}$  per 80 mm stent), and delivered its drug load over a period of about 7 days [119]. A total of 93 patients were enrolled in the combined SIROCCO I and SIROCCO II clinical trials. Unfortunately, neither trial achieved its primary endpoint of a reduction in restenosis and, even after 4 years, there was no difference in any metric comparing patients treated with the bare S.M.A.R.T. stent versus the sirolimus-eluting Sirocco stent (Fig. 4) [120]. The development of the Sirocco stent was terminated; as of this writing, no peripheral DES is yet available for clinical use anywhere in the world.

Despite the disappointing results of the Sirocco studies, two other peripheral DESs are currently being tested in clinical trials. The Zilver PTX stent (Cook Inc.,

**FIGURE 4** Freedom from target lesion revascularization (TLR) in the SIROCCO II trial. Kaplan-Meier event analyses of target lesion revascularization: 92.8% for sirolimus versus 83.8% for control ( $p = 0.30$ ). Reprinted from Duda, S. H., Bosiers, M., Lammer, J., et al. (2006), Drug-eluting and bare nitinol stents for the treatment of atherosclerotic lesions in the superficial femoral artery: Long-term results from the SIROCCO trial, *J. Endovasc. Ther.*, 13, 701-710.

Bloomington, Indiana) contains approximately  $300\mu\text{g}$  paclitaxel (PTX)/ $\text{cm}^2$  stent area [121]. Similar to the ACHIEVE stent tested in the DELIVER clinical trial [122], paclitaxel is applied directly to the Zilver PTX stent; there is no polymer system serving to control its release. Interim clinical results from a small trial have recently been presented [123]. Sixty patients with symptomatic PVD were randomly assigned to undergo endovascular intervention with either the Zilver PTX stent ( $n = 28$ ) or percutaneous transluminal balloon angioplasty alone (PTA,  $n = 32$ ). Patients in whom PTA yielded suboptimal intraoperative results (16/32) were secondarily randomized to receive either a Zilver PTX stent or a bare nitinol Zilver stent. Although no angiographic results have been reported to date, the safety of this approach is suggested by the equivalent incidence of total events in the two groups after 6 months (incidence of death, revascularization and/or worsened Rutherford score in the PTA and Zilver PTX groups was 91 and 89%, respectively). Further testing of the safety and efficacy of the Zilver stent is ongoing in the 480-patient DESTINY trial using a similar design. Nearly half the patients have been recruited as of this writing.

Lastly, an everolimus-eluting nitinol stent has also recently entered the clinical phase of development. The Dynalink-E device (Abbott Vascular, Santa Clara, California) contains approximately 225 µg everolimus/cm<sup>2</sup> stent area, which is released slowly through incorporation in an ethylene vinyl alcohol (EVAL) copolymer. Enrollment was recently completed in the STRIDES First-in-Human clinical trial in Europe and initial results are expected in 2009.

In summary, endovascular intervention has become the treatment of choice for many patients with symptomatic PVD. Similar to percutaneous coronary intervention, it is hoped that the persistent and frequent problem of restenosis can be ameliorated through development of effective DES.

### 10.1.8 FUTURE TECHNOLOGY

#### 10.1.8.1 Future Stents

Although the development and testing of the first-generation DES focused to a considerable degree on efficacy parameters, including restenosis, recent concerns over late clinical events have prompted refinement of the design criteria for succeeding generations of coronary artery devices.

Most new investigational balloon-expandable DES systems have lowered crossing profiles by thinning stent struts with the use of a cobalt chromium alloy, while investigational self-expanding DESs often use nitinol as the platform material. To further lower crossing profile, guidewire-based stents are currently under development [124]. Fully biodegradable stents are also being developed, with deliverability and performance to be determined in future clinical trials. New bifurcation-dedicated stents will secure branch accessibility to offer better deliverability in complex lesion morphologies. As noted, experimentation in stent design is already realizing multiple-lesion stenting and the *in situ* customization of stent length [124].

First-generation DESs have significantly lowered the rate of TLR compared with BMS. Rather than simply targeting further reductions in restenosis rates, efforts to improve efficacy are shifting toward a lesion-specific approach, including the design of stents dedicated to bifurcation lesions. Another future direction is a disease-specific approach, using DES as local drug delivery devices. So conceived, DESs present the possibility of expanding options for the local pharmacologic modulation of lesions. Potential therapeutic uses still in the investigational stage include myocardial protection at the time of infarct and the stabilization of vulnerable plaque.

Identifying long-term safety issues with the first-generation DES has reignited clinical interest in the development of stents that are more biologically based, including fully biodegradable stents and stents using biomimetic and biodegradable polymers. Important performance criteria for future DES agents include more cell-type specificity, broader safety margins, and greater facility at promoting endothelialization and healing. In addition, future vascular biologic findings on the mechanisms of restenosis will shed light on the potential relationship between gene therapy and local agent delivery. Safety is the perpetual challenging issue in the field of medicine. For interventional cardiologists, the recent recognition of a possible increase in late

clinical events in patients with DES has forced a reexamination and redefinition of the requirements of the ideal DES. Although previous DES clinical trials placed great emphasis on efficacy, especially midterm angiographic and clinical results, these findings pale in comparison to ensuring long-term safety for our patients.

New therapeutic agents such as proteins, nucleic acids [small interfering ribonucleic acids (RNAs) and large deoxyribonucleic acid (DNA) plasmids], viral delivery vectors, and even engineered cell therapies require specific delivery designs distinct from traditional smaller-molecule approaches on DES. While small molecules are currently the clinical standard for coronary stenting, extension of the DES to other lesion types, peripheral vasculature, and nonvasculature therapies will seek to deliver an increasingly sophisticated armada of drug types. In parallel with PCI procedure evolution, new technologies such as OCT will be introduced for measuring safety and effectiveness of new devices. The application of these new technologies to PCI procedures may require validation of new safety and effectiveness measures.

#### 10.1.8.2 Cardiac Tissue

Another alternative method for increasing coronary vascularization is the transplantation of stem or progenitor cells [125, 126]. These cells not only produce a variety of growth factors and cytokines but participate structurally in the formation of new vascular tissue and myocytes.

Promising results from experimental studies promoted the initiation of clinical trials of stem cell technologies [127, 128]. Stem and progenitor cells are being tested in patients with both acute MI and chronic ischemic heart failure [125, 129–136]. Improved wall motion or increased perfusion were demonstrated in most study patients. BOOST is a randomized controlled clinical trial [135] in which 60 patients with ST-segment elevation were randomly assigned to either a control group that received optimum postinfarction medical treatment or a bone-marrow-cell group that received optimum medical treatment and intracoronary transfer of autologous bone marrow cells 4.8 days after percutaneous coronary intervention (PCI). After 6 months, mean global left ventricular ejection fraction (LVEF) had significantly increased in the bone-marrow-cell group, compared to the control group. However, most studies at present are limited by the small patient enrollment, and recently some papers reported that bone-marrow-derived hematopoietic stem cells do not transdifferentiate into cardiac myocytes in ischemic myocardium [137, 138].

#### 10.1.8.3 Genetic Advances

A number of vehicles are used to transfer DNA into heart tissue, including purified DNA, DNA/lipid complexes, adeno-associated viruses, or adenovirus [125, 139]. An advantage of this approach appears to be production of angiogenic factors that is localized and sustained but not indefinite [140]. Apparent disadvantages are the possibilities of vector toxicity or an immune response to the gene therapy vector.

The efficacy of gene transfer approaches to therapeutic angiogenesis is now being tested in clinical trials. Early uncontrolled open-label clinical trials have generally given positive results, although the possibility of a placebo effect has not been excluded [126, 139, 141–147]. Controlled phase II trials are providing positive but

not definitive results. This is promising since the patient population being studied has failed all other therapies and is likely to be refractory to intervention. However, most of the efficacy measures, studied to date, have been surrogate endpoints such as exercise tolerance time, angina, or perfusion. While these measures are useful in suggesting clinical efficacy, hard clinical endpoints such as mortality, MI, and the need for revascularization should be studied. Long-term follow-up data are also needed. An important observation is that the safety results of these trials indicate no major problems. Potential side effects such as worsening of atherosclerosis, retinopathy, or cancer have not been observed in clinical trials.

Two large phase III clinical trials (AGENT 3 and 4) were designed to evaluate further the safety and efficacy of Ad5FGF4. Both trials were designed as randomized, double-blind, and placebo-controlled trials [141]. In each trial, the recruitment goal was 450 patients, and these patients would be randomized to 3 groups (placebo group, adenovirus (Ad) human fibroblast growth factor (FGF) gene (Ad5FGF-4) at a dose of  $10^9$  vp group, and Ad5FGF-4 at a dose of  $10^{10}$  vp group). In January 2004, enrollment was stopped (416 patients in AGENT 3 and 115 patients in AGENT 4) because interim data analysis of AGENT 3 indicates that the studies will provide insufficient evidence of efficacy. However, enrolled patients' follow-up continues and final data will be presented in the near future.

### 10.1.9 CONCLUSIONS

The development of DES represents an exciting area of breakthrough technology, which has generated an enormous literature in parallel with widespread use in a short period of time. Interaction of innovative stent platforms, polymers, and molecular entities, as well as pharmaceutical adjuncts such as dual antiplatelet therapy, present a unique degree of complexity for systematic ongoing evaluation of these devices, their optimal use, and their real safety and performance results. Toward this end, clinical trials and DES industry programs have developed a broad variety of endpoint definitions, which differ across a heterogeneous array of cutoff values, timing of endpoint assessment, and outcome composites. The number of stents currently under investigation is substantial. They are all loaded with drugs that interfere with pathways in the process of inflammation and neointimal proliferation. However, the process of restenosis is a sequence of complex events that has been partly elucidated over the last 2 decades. Locally acting DESs provide the opportunity to interfere with the various mechanisms responsible for each step in the restenotic cascade [148], and a wide variety of different agents are currently available. Johnson and Johnson's sirolimus-eluting stents (SES), Boston Scientific's paclitaxel-eluting stents (PES), Medtronic's zotarolimus-eluting stents, and Abbott Vascular's XIENCE V everolimus-eluting stents have received FDA approval. Recently, in view of late adverse events after stent implantation, the FDA has called for long-term monitoring of safety outcomes in the postapproval context. It is therefore likely that postmarket programs for new DES will have larger sample size and longer follow-up in order to identify the true incidence of late stent thrombosis, a low frequency event. Such programs resemble traditional pharmacovigilance in their scope and size, which are likely to be global, and once implemented and successful, can result in restoration of confidence to the DES arena.

## 10.2.1 INTRODUCTION

Dentistry is rapidly entering an era of evidence-based practice, and individual patients and society are demanding that clinical practice and public health policy decisions be based on the best available science. Well-designed randomized oral health clinical trials (RCTs) are needed because they provide the highest level of scientific evidence [1]. It is very difficult for oral health practitioners, researchers, and sponsors who have not been directly involved in large oral health RCTs to truly understand their complexity, challenges, and expense. Moreover, few oral health investigators have appropriate training or clinical trial experience. These factors have contributed to the relative lack of large phase III multicenter oral health clinical trials.

Clinical trials in oral health have mainly focused on the diseases of dental caries and periodontal disease, but a limited number have involved other oral diseases and conditions. These include chronic facial pain, particularly associated with the temporomandibular joint, acute pain after extraction of third molars (wisdom teeth), xerostomia (dry mouth), and various oral mucosal diseases. With the advent of evidence-based dentistry, more clinical trials are needed to establish the efficacy *and* effectiveness of prevention and treatment for a wide variety of oral diseases and conditions.

Oral health trials share many things in common with clinical trials in general, but they have several unique challenges. This chapter focuses on phase III oral health clinical trials in terms of design and analyses, regulatory and management issues, and challenges of conducting trials involving specific oral diseases.

## 10.2.2 PROMINENT DESIGN ISSUES IN ORAL HEALTH CLINICAL TRIALS

Design issues of special interest in oral health clinical trials include: advantages and disadvantages of so-called split-mouth and cross-over designs, single versus multicenter trials, use of active versus negative controls, identification of clinically meaningful endpoints, independent sampling (sites versus subjects) and multilevel modeling, randomization and potential bias due to confounding factors, examiner training and calibration, and trial duration.

### 10.2.2.1 Split-Mouth and Cross-Over Designs

The parallel design in which subjects are randomly assigned to receive either an active or a control (placebo) intervention is the standard design used in clinical trials. However, oral health clinical trials often use a “split-mouth” design in which various segments of the dentition are randomly assigned to treatment and control arms. Furthermore, many toothpaste and oral rinse studies use a cross-over design that in its simplest form randomizes subjects to one of two arms of a trial, followed by a “washout” period, after which they are assigned to the other arm. An investigator testing the longevity or integrity of dental sealants, composite restorative materials, or dental implants may wonder which study design would be the most appropriate for the trial. One could either use a split-mouth, cross-over, or a parallel design.

The main weakness of the split-mouth design is that treatments may have effects on segments of the dentition other than those to which they were assigned; the outcome of a split-mouth design is the treatment effect plus the sum of these effects [2]. The split-mouth design removes the between-group variance in estimating treatment effect, but it may include effects from treatments administered to other parts of the dentition. As such, it has the potential of biasing the trial against finding differences between treatments. When considering use of this design, it is important to estimate the within-patient correlation of treatment effect; if it is small, little gain in efficiency is obtained by using the split-mouth design; if it is moderate to high, the gain in efficiency should be weighed against the potential disadvantages of the split-mouth design including potential bias, potential difficulty in subject recruitment (there must be similar disease in two quadrants of the mouth), and complexity of the statistical analysis [3]. A split-mouth design may be appropriate if the “carry-across” effect from one tooth site or treatment segment to another is minimal. Unfortunately, there is no easy method to test for a carry-across effect in a split-mouth study, and the investigator would have to be convinced that potential carry-cross effects in the trial are negligible. The parallel design avoids these potential sources of bias and facilitates straightforward statistical analysis. The main weakness of the parallel design compared to the split-mouth and cross-over is it will require many more subjects to achieve comparable statistical significance. In spite of this constraint, the parallel design is generally preferable for diseases such as periodontal disease and caries.

Cross-over designs could be appropriate for short-term trials investigating outcomes that are reversible, such as gingivitis, plaque, and even for some types of chronic pain. However, cross-over trials have limitations due to possible treatment carry-over effect from one period to the next period and the possibility of a patient learning effect that can bias the results. In an attempt to minimize these concerns, a washout period is introduced between active treatment periods. Overall, for plaque and gingivitis trials, the double-blind parallel randomized trial is preferred to the double-blind cross-over design, except possibly for a professionally applied treatment that does not leach into the saliva or affect the oral microflora [4].

### 10.2.2.2 Single versus Multicenter Trials

The need for generalizability of results and the number of patients required for a clinical trial are important considerations when designing clinical trials. Multicenter

trials are conducted to generate results that can be generalized to the population at large. For many dental diseases, community water fluoridation, cultural norms, tobacco use, diet, and many other factors may contribute to trial outcomes. Therefore, regardless of size, the outcome of a single-center trial may only be applicable to a particular sample of subjects. Another important reason for using multiple center sites is that there may be insufficient subjects at a single enrollment site that meet trial enrollment criteria. Adequate numbers of subjects are frequently not available for large dental implant and periodontal disease trials; multicenter studies are often needed to enroll enough subjects in these trials. Earlier caries clinical trials were conducted at several schools in a single community (single-site trial). This was possible because most of these trials focused on preventing, rather than treating dental caries. Moreover, caries was very common and it was cost effective to recruit sufficient numbers of qualifying subjects in schools. As caries rates have declined in developed countries, it is much more difficult to find subjects who are at risk for developing new caries. This has necessitated the use of much larger, multicenter caries prevention trials, often involving 800–1500 patients per group.

### 10.2.2.3 Use of Active versus Negative Controls

For ethical reasons the majority of recent caries clinical trials have used active rather than negative controls. This is because fluoride has proven to be effective in preventing dental caries and many feel that it is not ethical to include a nonfluoride (negative) control group. If the purpose of a trial is to demonstrate that a new agent or product is superior to the current standard (positive control) agent or product, the minimum difference ( $\Delta$ ) judged to be clinically meaningful between the new agent and the standard would be smaller than if a negative control group were used. Use of a positive control would also require increased sample size. Alternatively, because of improved taste, less cost, ease of application, or reduction in side effects, the purpose of a trial may be to demonstrate, for example, that a new fluoride agent is as good as the standard fluoride agent (positive control). In these trials, a noninferiority trial design generally aims to demonstrate that the new agent or product is not inferior to the standard. A value for clinical comparability or equivalence for the new agent must be defined ( $\Delta$ ) a priori in order to define how close the primary clinical outcome for the new agent ( $\mu_N$ ) must approximate the outcome using the standard agent ( $\mu_S$ ) for it to be considered at least as good as the standard ( $\Delta = \mu_N - \mu_S$ ). To establish efficacy of nonfluoride agents for caries prevention, use of negative controls may be possible. For these trials, the magnitude of the clinically important difference in the development of new caries over a specific time period must be defined. The rate of new caries over time is often called the caries increment.

### 10.2.2.4 Identification of Clinically Meaningful Endpoints

Outcomes in randomized clinical trials must be clearly specified, measurable, valid, and reproducible. It is also important that pivotal phase III clinical trials have clinically meaningful endpoints [5]. As defined by a 1999 joint National Institute of Health–Food and Drug Administration (NIH–FDA) workshop on biomarkers and clinical endpoints [6] a *clinical endpoint* is a characteristic or variable that reflects

how a patient feels, functions, or survives; a *surrogate endpoint* is a biomarker intended to substitute for a clinical endpoint and is expected to predict clinical benefit (or harm, or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence; and a *biomarker* is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or (pharmacologic) responses to a therapeutic intervention.

True validation of surrogate endpoints that are used in clinical trials in medicine is rare [5] and oral health clinical trials are no exception. Hujoel pointed out that there has been widespread use of periodontal variables such as probing depth, clinical attachment level, and bleeding on probing that have not been validated for use in clinical trials [7]. He suggested that true endpoints such as tooth loss, pain, bleeding after tooth brushing, and other subjective quality of life measurements should be used in pivotal trials of periodontal disease [7]. In a caries trial, reducing pain from caries would be more meaningful than reducing the level of *mutans streptococci*, and in a clinical trial of xerostomia change in subject-perceived oral dryness would be more meaningful than a statistically significant change in inflammatory salivary proteins. Surrogate endpoints can greatly increase efficiency and decrease costs of clinical trials, and more research is needed to validate their use in oral health clinical trials [8].

#### 10.2.2.5 Independent Sampling (Sites versus Subjects) and Multilevel Modeling

Because clinical measures of oral disease such as caries and periodontal disease can be obtained at many sites in the dentition, there has been confusion as to whether individual sites within subjects or subjects themselves should be the independent unit of analysis in clinical trials. A unique feature of many dental clinical trials is their complex data structure that frequently involves clustered observations of multiple measurements repeated over time within each subject. This introduces multiple levels of structural data dependency; it is clear that sites are correlated or clustered within subjects and that sites cannot be used as independent sampling units in statistical analysis [9].

Collection of a large number of data items from each subject is often necessary because dental disease is tooth- and even tooth-site-specific. That is, diseases such as caries and periodontal disease can progress at very few tooth sites in an otherwise healthy dentition. Unless all sites are evaluated, it is possible that localized progressive disease will remain undetected. The criteria for progressive disease and the protocol for delivering rescue or additional treatment should be specified beforehand in the trial's operations manual. With so many measures, it can be difficult to screen repeated measures to determine if disease is stable or progressing, and redundant checks are needed to compare measures collected over time. Web-based or electronic chair-side data capture can facilitate this process.

There are 32 teeth in the adult dentition. It is common to measure various periodontal parameters at 6 sites per tooth (mesiobuccal, midbuccal, distobuccal, distolingual, midlingual, and mesiolingual) and caries on 5 surfaces per tooth (occlusal, mesial, distal, buccal, and lingual). Therefore, it is possible to include measurements of up to 168 sites (excluding third molars = 28 teeth  $\times$  6 sites per tooth) in periodon-

tal trials and 128 sites in caries trials (excluding third molars there are 16 posterior teeth  $\times$  5 surfaces per tooth plus 12 anterior teeth  $\times$  4 surfaces per tooth). Since it is clear that sites cannot be treated as independent units of sampling, it is common to aggregate site-based data at the patient level. Depending on the specific trial, typical patient-level periodontal outcome measures have included (1) mean clinical attachment loss, (2) mean probing pocket depth, (3) number of sites with bleeding on probing, (4) extent of clinical attachment loss, and (5) extent of probing pocket depth (using a specific threshold, e.g., 3, 4, or 6 mm). Use of such aggregated data at the patient level may be appropriately used in conventional statistical analyses with the subject as the independent unit of observation. Although statistically correct, this may result in loss of detailed information at the site level; it is clear that the variance in periodontal parameters may be attributed to factors at both the site and the subject level [10]. In this regard, use of multilevel modeling (MLM) can be a valuable statistical method to assess disease progression over time at all levels of the natural hierarchy of tooth sites within subjects [11, 12]. Multilevel modeling of periodontal data has demonstrated that there is considerable variation at all levels of analysis and that MLM can be a more powerful research tool than single-level techniques for the analysis of hierarchical dental data [13].

#### 10.2.2.6 Randomization and Potential Bias Due to Confounding Factors

Common confounding factors that could lead to selection or confounding bias in oral health clinical trials include age, sex, socioeconomic status, educational level, smoking, diet, oral hygiene, exposure to fluoride and baseline caries level (for caries), use of medications that influence salivary flow, and alcohol use (for oral cancer). Smoking should be considered a strong confounder or effect modifier in periodontal disease, and in most cases it is helpful to separately compare treatment arms among smokers and nonsmokers [14].

Proper attention to randomization procedures assures comparability between treatment groups in clinical trials by minimizing selection and confounding bias [15]. However, small sample clinical trials are prone to imbalances in known and unknown factors that may affect treatment outcome [16]. For relatively small sample trials, use of stratified randomization to achieve balance between test and control arms for factors that may affect treatment outcome should be considered. As noted by Schulz and Grimes, proper randomization takes little time and effort but results in major rewards in terms of scientific accuracy and credibility [15].

#### 10.2.2.7 Examiner Training and Calibration

As stated by Fleiss in the very first sentence of his classical text *The Design and Analysis of Clinical Experiments* [17]: “The most elegant design of a clinical study will not overcome the damage caused by unreliable or imprecise measurement.” Because of the complexity of oral disease measurements, examiner training and calibration are essential components of any oral health clinical trial. For example, it is common for oral health clinical trial examiners to record measurements on 28 teeth in *each subject's mouth* for probing depth, clinical attachment level, gingivitis, dental plaque, and dental calculus ( $n = 168$  sites for each parameter) plus tooth mobility ( $n = 28$ ) for a total of 868 separate measurements per patient at each evalu-

ation visit. This is an enormous task and to minimize examiner fatigue and subject discomfort, only essential data that are needed to measure trial outcome should be collected.

Proper training, calibration, and certification of examiners to prespecified standards of discrimination and standardization are essential. The use of multiple examiners makes this task even more complex, time-consuming, and costly because inter- *and* intraexaminer variability must be minimized by training and repeated calibration. Examiners should be trained and calibrated using patients whose severity and extent of disease is similar to the trial population because measures of examiner reliability may be artificially inflated if patients used in calibration exercises are healthier than study participants. For periodontitis trials, calibration statistics such as percent agreement within a specified threshold will be artificially high if subjects used for calibration have only early or localized disease. Examiners should be recalibrated during the trial using a subsample of subjects (e.g., 5%) to ensure consistent evaluation of trial outcomes. Interim assessments are important because experienced examiners trained at the beginning of a trial may slowly revert to their original techniques or methods over time [18]. It is important that measurement error be expressed in terms that are meaningful to the clinician while retaining statistical validity [19]. There is within-subject clustering of agreement for various oral disease measures and failure to account for dependence among site-level measurements can result in a false sense of precision in examiner reliability estimates [20]. Because examiner calibration and reliability is such a major issue in oral health clinical trials, details of examiner training and reproducibility data should be reported in publications.

#### 10.2.2.8 Trial Duration

As with all clinical trials, the duration of oral health clinical trials depends on many factors including the specific disease being investigated, trial design, numbers and enrollment criteria of subjects to be enrolled, the intervention, and the primary outcome variable. It has been recommended that gingivitis trials be at least 6 months in duration [21] and that periodontitis trials be 9 months [19]. Cross-over designs would require a trial at least twice as long as a two-arm split-mouth or parallel design. Caries trials should be 3 years in duration and include at least one interim examination in addition to an assessment at baseline and at the end of the trial [22]. Ideally, clinical outcomes should be monitored for at least 3 years in trials of direct dental restorations (amalgams, resin-based composites) and for 5 years in trials of indirect restorations (crowns, inlays). In reality, outcomes are rarely assessed after 3 years, even though the materials are designed to last much longer in clinical practice.

### 10.2.3 PROMINENT STATISTICAL ISSUES IN ORAL HEALTH CLINICAL TRIALS

Obtaining multiple measurements for each subject in many dental clinical trials provides the opportunity to analyze data at the subject, tooth, and site level. Analysis will depend on the primary purpose of the trial and trial design. Most dental clinical

trials use a parallel design with randomization of treatment to subjects and a statistical analysis focused on a subject-level primary outcome measure. Outcomes could also be analyzed at the individual site or tooth level, but within-mouth correlations must be considered in these analyses. In this regard, generalized estimating equations (GEE) [23, 24] and other methods such as an incidence density method [23, 25], Poisson regression models [26], survival methods [24, 27, 28], and specific non-parametric procedures for ordinal-scaled outcome measures have been proposed [29, 30]. Using GEE is one example of a marginal approach, that is, a population average method that provides estimates at the population level, rather than for individual subjects. Various conditional approaches can be used if the focus is on individual subjects; in dental clinical trials, a conditional model is probably more appropriate. A mixed-model approach can be used to account for repeated correlated observations within subjects.

### 10.2.3.1 Clinical Significance

Phase III RCTs must have sufficient sample size to yield results that are statistically *and* clinically significant. Clinical significance is a matter of judgment and may be defined as the minimal magnitude of difference between test and control interventions that would cause clinicians to change their standard of clinical practice or that would inform public health policy. In other words, it answers the question “Is the difference between the groups large enough to be worthwhile?”

It is often difficult to reach consensus on what constitutes clinical significance. It becomes a trade-off between the size of the intervention effect that is considered to be clinically superior and the size that is considered to be equivalent. It also may involve a compromise between what is desirable and what is practical for testing in a clinical trial. In any event, to properly estimate sample size for a trial, clinical significance for the outcome variable must be defined a priori. For example, if a 3-year phase III RCT demonstrated that subjects using an inexpensive over-the-counter (OTC) caries prevention product had a clinically meaningful (i.e., 20% reduction) average reduction in 0.6 new carious surfaces per subject compared to appropriate control subjects, it would have major public health significance and would substantially impact the OTC market for caries prevention. Using the formula from Pocock [31], if we assume a standard deviation in 3-year caries incidence of  $\sigma = 3$  surfaces, a difference in caries increment ( $\Delta$ ) = 0.6 surfaces,  $\alpha = 0.05$ , and  $1 - \beta = 0.80$  (power), the sample size for each arm may be estimated at 395. That is,  $2 \times 395 = 790$ , or almost 800 subjects would be needed for the trial. The actual number of subjects required for screening would be much larger because of the need to identify subjects at high risk for developing dental caries.

### 10.2.3.2 Confidence Intervals versus *p* Values

Two basic statistical methods are used to assess the role of chance in estimation and hypothesis testing. The confidence interval (CI) is used in estimation and the *p* value is used in hypothesis testing. A 95% CI is the default value for most clinical trials. It is a frequency-based interval estimate of the unknown true difference between treatment groups based on what would happen under multiple replications of the same study. A desirable property of the 95% CI is that its range or width represents a measure of the precision of the estimate in addition to its significance. For example,

suppose a 3-year caries trial compared two fluoride toothpastes (500ppm vs. 1000ppm fluoride) and reported mean (SE) caries DMFS increments of 1.75 (0.1) and 1.55 (0.08), respectively, and that the difference of 0.20 (SE = 0.13;  $p = 0.12$ ) had an associated 95% CI of  $-0.06$  to  $+0.46$ . There was no statistically significant difference in the effectiveness of the two toothpastes because  $p = 0.12$ . It is important to note that the probability value ( $p = 0.12$ ) does not provide an estimate of precision. The clinical significance of the trial outcome may be better appreciated by an inspection of the 95% CI for the difference in DMFS increments. The statistical significance of the difference between treatment outcomes can be seen in the 95% CI because the value 0 (representing no difference between fluoride toothpastes) lies within the confidence interval estimate. Moreover, in this study, a fairly high level of precision of the estimated difference was achieved because the confidence interval was fairly narrow ( $-0.06$  to  $+0.46$ ). Sample size would need to be increased if a higher level of precision (narrower CI) is desired.

#### 10.2.4 REGULATORY ISSUES

Most materials used to restore tooth structure are considered medical devices by regulatory agencies such as the U.S. FDA. One specific center within the FDA, the Center for Devices and Radiological Health, regulates products such as dental restorative materials, electric toothbrushes, and dental implants [32]. Each device is grouped by medical specialty and assigned a class (class I, II, or III) based on the level of control needed to ensure safety and effectiveness of the device. Standards to guide the manufacture and performance of various dental materials have been developed by two large organizations, the dental committee of the International Organization for Standardization (ISO), and the American Dental Association, which develops performance standards in conjunction with the American National Standards Institute. Each publishes its own set of standards [33, 34], which are used by dental manufacturers worldwide.

Most individuals seeking FDA clearance for new dental materials must submit a 510(k) application. Many of these products will be classified as class I or class II devices. Class I devices may be exempt from premarket review provided that the device is appropriately registered with the agency. Most class II devices require demonstration of substantial equivalence to another legally U.S.-marketed device. Substantial equivalence means that the new device is at least as safe and effective as the predicate [35]. In some instances, clinical data is needed for FDA clearance of the new device, especially if the manufacturer asserts differences in claims or intended use. Because many new dental materials are similar to older materials, they are classified as class II devices. As such, phase II trials are sufficient and they are not tested in phase III clinical trials.

#### 10.2.5 MANAGEMENT OF ORAL HEALTH CLINICAL TRIALS

##### 10.2.5.1 Roles and Responsibilities of Trial Personnel

Each staff member involved in a trial must understand, accept, and be capable of performing his or her role. Specific roles and responsibilities should be assigned

before the trial begins and monitored regularly throughout the trial. While clinical data may be collected by qualified personnel (e.g., dental hygienists), licensure as a dentist is generally required to diagnosis oral disease. For example, in a clinical trial of periodontal disease, it is common for a dental hygienist to perform clinical assessments and collect dental plaque samples or oral biospecimens.

Typically, however, a licensed dentist must also examine each subject or review the clinical and radiographic findings to establish that the patient has the condition or disease specified by the protocol. For caries trials, a nondentist may determine the presence of cavitated lesions (areas of pitted or soft tooth) or photograph and assess fluorescent images of teeth, but a licensed dentist is usually required to establish a diagnosis and provide (or supervise) the trial intervention. Institutional review boards may look unfavorably on a study in which the patient is not examined, diagnosed, and monitored by a dentist.

Therapists must be competent and experienced in treating or managing the disease or condition under study. Patients enrolled in clinical trials should receive the same quality of care that is delivered in nonresearch clinical settings. Dental hygienists or general dentists typically deliver nonsurgical periodontal therapy and in caries trials, treatment is usually provided by licensed and experienced dentists. For severe periodontal disease, treatment involving surgery, or for other interventions outside of the expertise of general dental practitioners, treatment should be provided by specialists or dentists with advanced training or experience.

Study masking or blinding is an important feature of clinical trials that serves to minimize bias during data collection and assessment [16]. Masking can be defined in terms of the participant, the therapist, and the examiner. Treatment of oral disease tends to be procedurally oriented, and therapists in most oral health trials are not masked. Masking participants also can be difficult in some trials. Consider a trial that compares a nontraditional, minimally invasive treatment for dental caries to conventional restorative care (i.e., dental fillings). Because conventional care involves removal of tooth decay with a high speed drill and requires local anesthesia, subjects receiving the minimally invasive therapy would also need to receive local anesthesia (regardless of the need) to maintain masking. For periodontitis trials, it can be difficult to mask examiners because some treatments may produce more gingival recession (resulting in more exposed tooth root) than others. An experienced clinical examiner could unintentionally note such changes following some treatments. To minimize potential bias, patients should be instructed to refrain from discussing treatment or treatment-related signs or symptoms with trial examiners. Patient complaints, such as tooth sensitivity, can be discussed with the study coordinator or lead investigator, provided these individuals do not collect, record, or discuss data with examiners.

#### **10.2.5.2 Data Coordination Center**

Trial coordination and data management are essential to the success of any clinical trial. Large multicenter trials need a data coordinating center (DCC). The DCC helps design the trial, collects data from all centers, manages data, provides day-to-day guidance on protocol implementation, provides trial monitoring, oversees examiner training and calibration, ensures data quality, and analyzes data. Often, the trial statistician is part of the DCC. In most contemporary clinical trials, the

DCC facilitates data input at individual clinical centers by providing computer software and information technology (IT) support.

### 10.2.5.3 Data Collection

A primary focus of the investigative team should be to collect quality data. Rigorous monitoring is needed to ensure that data are collected according to trial protocol. Study personnel should carefully review study forms before the end of each subject visit so that errors or omissions can be identified and immediately rectified. Data collected on paper forms should be submitted to the DCC in a timely manner. The DCC should review data collection forms for completeness and send queries to enrollment sites when errors are detected or suspected. Missing data or data entry errors should be corrected as soon as possible because a long duration between error identification and correction leads to greater likelihood for error.

Oral health clinical trials frequently collect information about a participant's medical health. If medical information is collected as part of a trial, it should be collected by staff who are well versed in medical terminology and who are able to verify its accuracy and completeness. If data is abstracted from medical records, this task should be performed by someone who is familiar with the medical record format. In our experience, trained nurses working in the medical care facility are best suited to perform these tasks. Using "in-house" nurses also helps protect patient privacy because medical records do not leave the facility and because nurses are usually well trained in privacy issues.

### 10.2.5.4 Recruitment

Even the best designed and most innovative clinical trials will fail if recruitment efforts fail. Investigators should not underestimate the amount of effort needed for successful subject recruitment. Like all trials, oral health trials should have detailed recruitment plans in place before it begins. Investigators often overestimate the prevalence of a condition or disease in the population they plan to study. The "take all comers" environment of clinical practice often causes clinicians to overestimate the number of available patients for trials. Recruitment and participation in oral health clinical trials have been discussed elsewhere [36–41]. It must be emphasized that recruitment will be more successful when trials have relatively few exclusion criteria. Limiting exclusion criteria also increases the likelihood that trial results will be generalizable and embraced by community practitioners.

Institutional review board-approved fliers and advertisements can be posted in busy public places or played on radio or television. While this may yield large numbers of initial inquiries, enrollment success with these methods is often relatively low because people typically have only a cursory understanding of their oral health. For example, enrollment in periodontal disease trials is usually limited to people with disease severity that can only be determined by a periodontal examination. Mass media advertisements for periodontal trials often attract people with a wide variety of periodontal conditions such as gingival recession due to toothbrush abrasion, gingivitis, and even nonbacterial inflammatory conditions such as desquamative gingivitis. If mass media advertising is used, appropriate attention and

resources must be committed to screen potential subjects for trial participation. This can include initial telephone screening for inclusion and exclusion criteria, followed by a clinical examination. Recruitment from dental clinics is often productive and trials can be advertised by posting fliers in waiting areas and patient examination rooms. However, it is critical that investigators establish an ongoing relationship with clinic staff. We have found that simply posting fliers or placing pamphlets in dental clinics is unproductive. Successful recruitment requires that study personnel have regular and substantive contact with clinic personnel to remind them of the trial and its importance. Importantly, recruitment of patients from clinics or private offices should be a “seamless” process. Clinic staff should make patients aware of the study and of the potential benefits of participating. However, once a patient expresses interest in the trial, study personnel, not a clinical staff member, should guide the patient through the consent, screening, and enrollment processes. Because clinic staff are very busy providing patient care, they cannot be expected to perform burdensome tasks such as scheduling trial appointments, distributing enrollment forms, or collecting data. Milgrom et al. [40] reported that recruitment for oral health trials can be enhanced by using concurrent recruitment methods, accurately estimating the costs and time required for recruitment, and regular monitoring recruitment efforts. They also found that newspaper public service advertisements and campus posters were the most effective means for recruiting subjects with periodontitis in a university setting [41].

Active clinical research centers may regularly screen patients recruited from print and broadcast advertisements to identify subjects for possible participation in clinical research. It must be stressed that screening volunteers for research generally requires institutional review board approval. Those who are screened should be encouraged to seek needed dental care if relevant trials are not planned for the near future because some patients for financial or other reasons might defer treatment in the hope they will be enrolled in a trial.

Unfortunately, most dental diseases are quite prevalent in minority and underserved populations [42]. It is critical that research be conducted in partnership with these populations so that disparities in oral health can be addressed. Research investigators should partner with community leaders from underserved populations to make sure that people from underserved populations are made aware of trials that are available for their participation. Moreover, barriers for participation by underserved populations need to be addressed. For example, investigators should consider establishing satellite clinics in underserved communities or provide taxi vouchers if transportation to the main study site is an impediment to trial participation. Provision of on-sight child care and extended or nighttime clinic hours may also make participation in clinical trials more feasible.

While clinical trials must satisfy the Belmont principles of respect, beneficence, and justice, patients and communities may demand more from investigators for their participation. Educational programs on disease prevention may help investigators obtain community trust and reduce the burden of oral diseases. For trials that recruit in underserved communities, study personnel should provide information about community or low-cost clinics where participants can receive care for non-study-related oral diseases. Despite elaborate advertisement and recruitment efforts, enrollment in clinical trials will not be successful if people perceive they are not being treated with respect and compassion. Everyone involved is more likely to be

engaged and enthusiastic if they are treated with respect, appreciate the importance of the trial, and are not unduly burdened as a result of their participation.

### 10.2.5.5 Provision of Standard of Care

Participants randomized to the control group in RCTs often receive “standard” therapy; these are termed positive-controlled trials. Alternatively, control subjects may be monitored rather than treated. These are termed negative-controlled trials. Occasionally, trials will include positive and negative controls. In planning a positive-controlled trial, it is necessary for investigators to decide what constitutes the “standard of care.” In planning a positive controlled trial, it is necessary for investigators to decide what constitutes the “standard of care” [43].

For dental caries, common and scientifically proven methods to remove caries include lasers, high-pressure water jets, and traditional high-speed rotary drills [44]. The definition of standard of care can impact how a new treatment compares to the standard in terms of clinical outcomes, but also how patients perceive the new treatment. Consider a trial designed to explore patient preferences for a new restorative technique. The new treatment may compare differently if the standard involves the use of a noisy high-speed drill and placement of a dental amalgam filling versus a method in which tooth decay is removed with a laser and replaced with a tooth-colored filling. Because both methods are used in clinical practice, each could satisfy the legal definition of standard of care.

Professional societies typically do not attempt to define standard of care but instead may publish practice guidelines or parameters of care [45]. Nonetheless, the standard of care in dentistry includes an examination to identify disease so it may be appropriately treated. Patients with oral disease should be referred for treatment if it is not part of the trial protocol, and those with oral signs and symptoms of medical disorders should be referred to a health care provider for assessment and care. Examples would include patients with oral disease suggestive of uncontrolled diabetes, or those with mucosal lesions that are suggestive of conditions such as pemphigoid, pemphigus, lichen planus, or a variety of blood dyscrasias.

The American Academy of Periodontology’s (AAP) parameter of care for gingivitis [46] recommends that patients with gingivitis receive education, personalized oral hygiene instruction, and a tooth scaling. It is also recommended that the use of antimicrobial and antiplaque agents or devices be considered for patients who are unable to clean their teeth adequately and that overhanging tooth restorations, ill-fitting prostheses, or other conditions that retain dental plaque be corrected. In gingivitis trials, the test intervention should be compared to treatment that is consistent with these guidelines.

The AAP’s parameters of care for chronic periodontitis [47, 48] clearly outlines the importance of a personalized oral hygiene instruction and the provision of nonsurgical and maintenance care. In positive-controlled periodontitis trials, control subjects should receive treatment that is consistent with these guidelines. For trials involving periodontal surgery, patients should be managed according to these guidelines either before trial enrollment or before they are randomized to receive surgical treatment. This is important because periodontal surgery is ineffective in the presence of inadequate plaque control [49].

### 10.2.5.6 Use of Nontreatment and Delayed Treatment Controls

When considering the use of placebo or untreated controls in oral health clinical trials, the consequences of not providing care or delaying it must be carefully considered. The ethics of using untreated controls may vary according to the oral disease being studied. For example, the ethics of using untreated controls differ in trials of gingivitis versus trials of premalignant oral lesions. Gingivitis is an early form of periodontal disease that does not affect the supporting structures of the teeth; it is reversible with simple oral hygiene procedures such as tooth brushing and flossing and does not cause destruction of periodontal support. People with gingivitis could be included in a delayed treatment group, provided there is monitoring to ensure that there is no progression to periodontitis and loss of tooth support. Conversely, delaying treatment of premalignant oral lesions could put patients at risk for developing cancer and would raise serious ethical concerns.

Chronic periodontal disease is a slowly progressing disease that can lead to tooth loss. Tooth loss generally occurs over many years and the risk for progressive disease is relatively low, even in untreated patients over a 3-year period [50]. In a recent study of pregnant women with periodontitis, it was found that only 0.28% of sites in untreated control subjects had progressive disease over 20 weeks [51]. Despite the low risk for disease progression, it is important to monitor subjects in clinical trials and provide early rescue treatment as soon as evidence of progressive disease is found. For nonsurgical periodontitis trials, untreated control subjects with progressive disease should receive scaling, root planning, and oral hygiene instruction. Depending on the patient's periodontal status and oral hygiene, previously treated subjects may be re-treated with mechanical therapy alone, receive local or systemic antimicrobials, or be treated surgically.

Oral health trials of long duration sometimes use community-based controls. In these trials, initial treatment and follow-up care is administered to test subjects while control subjects are referred to community dentists for treatment and follow-up care. These trials are uncommon in oral diseases because the trials tend to be of rather short duration. However, oral disease prevention trials may require long-term follow-up and use of community-based controls should be considered. A concern with this approach is the lack of available dental care in some communities. If a trial recruits from low socioeconomic or underserved populations who have limited access to oral health care, requiring control subjects to seek care in community settings may not be ethical.

In all oral health trials, untreated or delayed treated control subjects should receive follow-up evaluations at the same time intervals as test subjects. Because patients with periodontal disease are typically seen for follow-up care every 3–4 months, participants in periodontitis trials also should be examined and receive follow-up care at this interval. Examinations should include full-mouth periodontal probing with radiographs as needed. For dental caries trials, participants should be examined at least semiannually; more frequently for high-risk subjects. Depending on the specific trial, these examinations may include visual assessment, clinical probing, tooth transillumination, and use of other imaging systems. Intraoral radiographs should be obtained as indicated by caries risk.

### 10.2.4 CARIES CLINICAL TRIALS

Dental caries is a chronic, slowly progressing infectious disease caused by acid produced from microorganisms and fermentable carbohydrates. Dental caries can affect enamel, dentin, and cementum; clinically, it occurs on a continuum from initial mineral loss to complete tooth destruction [52]. Caries can occur on the coronal or root surfaces of the teeth and on smooth surfaces or occlusal pits and fissures. Historically, the primary purpose of caries prevention and/or treatment has been to restore function and prevent tooth loss.

Traditional methods for assessing caries focused on cavitated lesions using the Radike or the World Health Organization (WHO) DMFS indices [53]. The Radike DMFS index diagnoses active caries (D) at the cavitated level, whereas the WHO index allows for four different levels of active caries, scored as D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub>. D<sub>1</sub> and D<sub>2</sub> scores indicate noncavitated lesions, whereas D<sub>3</sub> and D<sub>4</sub> are gradations of cavitated lesions. For comparability, the Radike DMFS index is labeled D<sub>3</sub>MFS to indicate assessment of cavitated lesions. Past evidence of caries is evaluated by counting restorations (F), and missing teeth (M). In caries clinical trials, incidence (new disease or caries increment) is calculated as the difference between the final and initial D<sub>3</sub>MFS scores. Historically, caries trials were conducted over 3 years and included a baseline, final, and at least one interim D<sub>3</sub>MFS scoring. The 3-year caries mean increments were compared for the test groups using linear models, after adjusting for important covariates. A common summary measure was the percentage reduction in caries incidence for a test agent compared with a reference (control) agent. D<sub>3</sub>MFS indices tend to overestimate caries experience because teeth, especially in adults, can be missing or filled for reasons other than caries. Despite its limitations, the D<sub>3</sub>MFS index has been widely used in caries trials. It is sufficiently sensitive to detect differences in relative efficacy of a wide variety of fluoride delivery systems, including water fluoridation, fluoride mouth rinses, dental office fluoride application, and fluoride dentifrices.

Dental caries has declined in many developed countries over the past few decades [54], and the rate of caries progression through dentin has slowed [55, 56]. As a result, caries activity has extended into and beyond late adolescence. While fluoride can enhance enamel remineralization, a caries-resistant outer shell of enamel can sometimes mask dentinal caries, making caries difficult to diagnose without using radiographs. As a result of changes in caries rates, prevention and treatment trials are more expensive, which may increase the possibility that newer, potentially superior anticaries agents may never be tested in phase III trials.

Since the 1980s, additional methods have been developed for diagnosing caries at the precavitated state. These include modifications of the visual-tactile method, such as the D<sub>1</sub>MFS [57], the International Caries Diagnostic Assessment System (ICDAS) [58] and sophisticated technologies such as fiber-optic transillumination (FOTI) and digital fiber-optic transillumination (DIFOTI) [59], quantitative light-induced fluorescence (QLF) [60], DIAGNOdent [61], and electrical conductivity measurement (ECM) [62]. Although these methods need to be more fully validated before they are accepted for use in pivotal clinical trials, they have the potential to improve diagnosis of precavitated carious lesions. Use of newer and more sensitive diagnostic methods also could change the focus of therapy from “drilling and filling”

decayed teeth to remineralizing or reversing early caries lesions. It could also reduce the length, size, and cost of caries trials.

A major issue that has plagued caries trials is high rates of subject dropout. Earlier caries trials commonly reported findings based on a per-protocol analysis rather than using some method to impute data for dropouts. Use of a per-protocol analysis that ignores subject dropouts risks introduction of unknown bias. For example, if a test mouth rinse, which has an unpleasant taste and stains the teeth, is compared to a pleasant tasting, nonstaining control rinse, test subjects who use the rinse regularly may be more likely to drop out of the study than irregular users because of the unpleasant side effects. This would introduce a bias against finding a favorable effect. By using data imputation methods, such as an intention to treat analysis, one may minimize the effects of unknown bias in a trial. There are many other methods available to impute missing data from dropouts that are covered elsewhere in this text.

Future caries trials, regardless of whether they score dental caries at the precavitated or cavitated level, will require refined analytical methods such as proposed at the Glasgow Conference on Dental Caries [22]. The new primary caries measures are ordinal scaled variables that are refinements of the traditional DMF scoring system. One new diagnostic system being investigated is the ICDAS method [58], which accounts for possible remineralization or “healing.” Previous analytical approaches did not consider that carious lesions could be reversed, and necessarily considered observed longitudinal reversals as examiner error. Today, investigators must distinguish “real” reversals from those due to examiner error. In the future, more emphasis on examiner training and calibration will be required to estimate the frequency of these reversals during caries trials.

Clinical performance of dental materials used to replace carious tooth structure is usually judged with U.S. Public Health Service (USPHS) Guidelines or Ryge criteria developed by Cvar and Ryge in 1971 [63]. These criteria have been modified and expanded over the last 40 years for evaluation of new dental materials. Criteria in the current system include color match, quality of margins, cavosurface marginal discoloration, anatomic form, recurrence of caries around the margin of the restoration, surface texture, postoperative sensitivity, proximal contact, and occlusal contacts [64]. Calibration training materials for investigators evaluating clinical outcomes of dental materials are available online [65].

## 10.2.7 PERIODONTAL CLINICAL TRIALS

Periodontal disease is an inflammatory disease that affects the surrounding and supporting tissues of the teeth (periodontium). It is usually divided into the two broad categories of gingivitis and periodontitis. These common infectious diseases are caused by pathogenic microflora in the dental biofilm (dental plaque) that forms daily on the teeth [66]. Gingivitis, the mildest form of periodontal disease affecting 50–90% of adults worldwide [67], is readily reversible by simple, effective oral hygiene. Estimates from a large survey based on partial mouth examinations indicated that about 22% of U.S. adults had mild periodontitis and 13% had moderate or severe disease [68].

A variety of interventions have been tested in clinical trials involving gingivitis and periodontitis ranging from nonsurgical mechanical therapy and attempts to improve oral hygiene to surgical and pharmacologic approaches. Outcomes generally include indices of dental plaque and gingival inflammation for gingivitis [21] and measures of periodontal pocket depth, clinical attachment level, and radiographic measures of alveolar bone support for periodontitis. The American Dental Association (ADA) published guidelines for clinical trials of products designed to control plaque and gingivitis [21]. For ADA acceptance, a product must demonstrate efficacy in two trials, each of which must include a placebo arm and follow subjects for at least 6 months. The guidelines further specify outcome measures for gingivitis and plaque as measures of safety including effects on the oral soft tissues, teeth, toxicology, and microbiology.

The ADA also has published guidelines for periodontitis trials [69] and others have published suggestions for the conduct of periodontitis trials [70]. These recommend that new treatment methods should be compared to basic periodontal therapy consisting of thorough scaling and root planing, oral hygiene instruction, and regular maintenance care. Moreover, it has been suggested that the primary response variable should be clinical attachment level, but that it is important to document changes in probing depth since this is a meaningful measure to many clinicians [19]. Gingival inflammation and bleeding should be used as secondary response variables. Radiographic measures of disease may be useful as primary response variables if safe, reproducible, and valid methods to assess change are utilized. Microbiological monitoring should be a secondary response variable because of numerous questions concerning sampling methodology, quantitative expression of data, and meaningful interpretation in terms of relevance to disease activity. It has also been recommended that the length of periodontitis trials be a minimum of 9 months if claims of superiority or equivalency are made compared to basic periodontal therapy [19]. As with most other diseases and conditions, there is a lack of validated surrogate outcomes for periodontal clinical trials and much more research is needed in this area [8].

### 10.2.8 DENTAL IMPLANT CLINICAL TRIALS

Dental implants have been used to replace missing teeth for over 20 years [71]. Usually, implants are made of commercially pure titanium or titanium alloys. Compared to smooth or machined surfaces, roughened surfaces increase surface area and promote earlier and more complete osseointegration [72]. Most implants are placed in the alveolar bone and are termed endosseous implants. Although dental implants can be used to retain maxillofacial prostheses and provide anchorage during orthodontic treatment, this discussion is limited to situations in which implants are used to replace natural teeth.

Implant failures are classified according to time after initial placement in bone. Early failures, occurring weeks or months after the implant is placed, result from excessive surgical trauma, postoperative infection, or early micromovement of the fixture. Late failures, occurring months or years after artificial tooth or teeth are attached to the implant(s), can be caused by peri-implantitis or occlusal trauma. Peri-implantitis is a destructive inflammatory disease caused by many of the same

microorganisms associated with periodontitis of natural teeth. Occlusal trauma occurs when the biting force on dental implants is excessive, causing loss of the intimate contact between the alveolar bone and the implant. This loss of contact may manifest as decreased radiographic evidence of bone support, as a peri-implant radiolucency, or clinical mobility of the implant.

Dental implant studies have several unique features. Much of the information regarding implant success comes from case series and retrospective studies rather than randomized controlled trials. Relatively few trials have been reported that compare two or more implant treatments or designs. The success of implants depends in part on the amount and density of the surrounding alveolar bone. The highest success rates tend to be in the anterior region of the mandible [73] where there is often abundant dense cortical bone for implant anchorage. Therefore, randomization in dental implant trials should take into account jaw location of implants and other possible confounding factors such as number of implants placed, occlusal force distribution, and type of prosthesis supported by the implant(s). This is especially true for trials that have relatively few subjects (even hundreds of subjects) because randomization without appropriate stratification may result in an unequal distribution of important selection and confounding factors among the treatment groups.

Implant trials generally follow participants for 1–5 years, which is longer than most oral health clinical trials. The longer duration is dictated in part by the U.S. FDA but also by the need to evaluate longer-term stability of the bone-to-implant interface. Implant metal or surface treatments that are biocompatible over the short term may have relatively high long-term failure rates if, for example, the oxide or metal surface corrodes or fractures over time. Longer follow-up is also needed to evaluate outcomes after the prosthesis (artificial teeth) are fixed to the implant(s). A variety of outcomes are used in dental implant trials to judge efficacy, including implant and prosthesis survival, annual rate of radiographically determined bone loss, and prosthetic complications (e.g., screw loosening, implant fracture, soft tissue inflammation). While most trials track implant or prosthesis survival as a primary outcome, use of patient-centered outcomes should be considered because the ultimate goal is to improve patient function, comfort, and esthetics. It may also be important to evaluate if specific implant designs require more frequent follow-up care related to, for example, loosening or breakage of screws or other devices that attach prosthesis to implants. Because implants can remain immobile and asymptomatic until bone loss approaches their apex, trials occasionally compare crestal bone loss rates rather than implant survival. The annual rate of bone loss around a “healthy” functioning implant is less than two-tenths of a millimeter a year [74] and “failing” implants typically exhibit a higher rate of loss. By longitudinally comparing sequential, standardized radiographs over time, it may be possible to compare bone loss rates between implant designs. However, at the present time, the rate of alveolar bone loss is an unproven surrogate marker for implant survival. Although less powerful than a randomized clinical trial in terms of design and interpretation, a nonrandomized observational prospective cohort study could be used to compare bone loss to historical “normal” rates of bone remodeling. Occasionally, investigators use composite outcomes to compare implant treatments, where “events” are defined as combinations of implant loss, excessive alveolar bone loss adjacent to the implant, and persistent inflammation or pain. As with periodontitis trials, investigators have studied associations between various biochemical or microbiological measures and

implant survival [75], but there is currently insufficient data to support use of these surrogates in clinical trials. Clinical trials can also be designed to compare various treatments for peri-implantitis. Because peri-implantitis affects the soft tissue cuff surrounding the metal fixture, outcomes for these trials are similar to those used in periodontitis trials, and include probing depth, gingivitis indices, and radiographic measurements of alveolar bone.

With the increasing awareness that dental implants are a predictable treatment option for replacing missing teeth, there is a growing interest in exploring the use of dental implants as an option for addressing extensive dental treatment needs. These trials would randomly assign patients with extensive dental treatment needs to have either: (1) conventional dental treatment involving periodontal, endodontic, and restorative care or (2) tooth extraction and replacement with dental implants. For these trials, it will be necessary to evaluate patient-centered outcomes and cost-benefit ratios of various treatments using methods such as those reported by Zitzmann et al. [76].

## 10.2.9 OTHER ORAL CONDITIONS

### 10.2.9.1 Xerostomia

Saliva is an important component of the system that maintains oral health. It modulates oral microbial ecosystems, plays a critical role in preventing dental caries, lubricates oral tissues, and facilitates swallowing. Patients with decreased saliva production have an increased risk for dental caries, tooth loss, mucosal candidiasis, and decreased quality of life. While many bodily diseases are associated with decreased salivary output (or salivary flow rate), the most pronounced decreases are found in patients with Sjögren's syndrome and individuals who have received radiation to the head and neck for treatment of cancer.

Sjögren's syndrome is an autoimmune exocrinopathy typified by an intense lymphoplasmocytic infiltration of the salivary and lacrimal glands. Affected individuals have partial to complete loss of their ability to make saliva and tears, but the precise processes responsible for this loss of function are yet to be defined. Medications for Sjögren's syndrome can be classified into three groups: (1) drugs that stimulate remaining functional salivary and lacrimal tissue (cholinergic agonists) [77, 78], (2) anti-inflammatory agents that attempt to decrease autoimmune activity, thereby restoring glandular function [79], and (3) lubricating agents that improve patient comfort [79, 80]. The two agonists approved for use in Sjögren's syndrome in the United States are pilocarpine HCl (Salagen) and cevimeline (Evxoxac). In most clinical trials, treatment is evaluated using subjective patient reports of changes in oral and/or ocular dryness and objective measures that quantify saliva and/or tear production. Occasionally, trials involving anti-inflammatory agents measure the amount of lymphoplasmocytic infiltration in the minor salivary glands using a gradation scale [81]. Other outcomes might include levels of serum autoantibodies and other markers of autoimmune disease that are commonly found in these patients.

Cholinergic agonists [82] and mucosal tissue lubricating agents are often used to manage patients with radiation-induced xerostomia. Only small studies have tested the efficacies of different lubricating agents for relief of oral dryness [83] and trials

to *prevent* radiation-induced xerostomia have involved amifostine [84] and other strategies to exclude the salivary glands from the radiotherapy field. These prevention trials need to evaluate patients at least one year postradiotherapy to determine long-term efficacy.

### 10.2.9.2 Mucosal Candidiasis

The oral mucosa may become infected with opportunistic fungal pathogens, including *Candida* species. These infections are most common in symptomatic HIV-infected patients, patients who have certain types of immunodeficiencies (primarily T cell and phagocyte deficiencies) and individuals undergoing cancer therapy. Both systemic and topical antifungal agents have been tested and approved as therapies for mucosal candidiasis and most phase III trials have been conducted in people with HIV infection [85]. However, candidiasis trials have not used consistent methods to diagnose infection and judge cure. Moreover, erythematous mucosal lesions caused by fungal infections may be ignored because of diagnostic difficulties associated with these infections. The most widely used diagnostic criteria in Phase III trials is a positive culture for *Candida* and presence of a white patch on the oral mucosa that rubs off, leaving bleeding or redness. A “clinical cure” may be defined as the absence of clinical lesions, with or without negative culture. If the trial employs cultures as an outcome measure, a negative culture for *Candida* is termed “mycologic cure.”

### 10.2.9.3 Mucosal Diseases

The two most common mucosal diseases treated by dentists are aphthous ulcerations and oral lichen planus. These diseases are believed to be mediated by infiltrating T lymphocytes; both can be idiopathic or develop after exposure to certain medications; and both may be chronic and have a major impact on quality of life. Clinical trials of treatment and prevention of these diseases usually enroll subjects with the most severe forms of disease. Since both diseases are mediated by lymphocytes, most drugs used to treat these diseases have been topical or systemic anti-inflammatory agents.

Clinical trials of oral lichen planus (OLP) usually require that patients have histopathologic evidence of OLP as an entry criterion. Various scales using objective methods to assess therapeutic response are available to semiquantify the clinical appearance and mucosal surface area affected by the lesions [86]. The primary outcome of many studies involves symptomatic scoring such as the amount of oral pain or burning sensation. The therapeutic portion of trials may be 4 weeks, with additional follow-up for one month [87, 88]. Unfortunately, most patients with symptomatic OLP of moderate severity have persistent disease; therefore, long-term outcomes (i.e., disease severity at 6 months) should be assessed.

Oral aphthae typically persist for 7–14 days after eruption. Patients with the most severe forms of the disease continually develop new lesions, which can cause significant oral pain and limit food intake. The most common outcome measures in trials for recurrent aphthous ulcerations include amount of oral pain, duration of an individual ulceration, and number of new ulcerations in a defined time period [88]. Therefore, trials should be of sufficient duration (4–6 months) to determine the impact of the therapy on development of new lesions.

### **10.3.1 INTRODUCTION**

Dermatology is a relatively young medical specialty [1, 2]. For many years diseases of the skin were not considered processes involving an individual organ but rather the manifestation of greater alterations within the whole human body. As a result of this school of thought, skin conditions fell under the practice of general medicine until the early eighteenth and nineteenth centuries. It was then that European physicians became increasingly curious about skin diseases and began to consider the skin as an organ that could be independently studied, diagnosed, and treated.

During this time, an analytical approach to dermatology emerged, and physicians increasingly relied on clinical observations to uncover cause-and-effect relationships between various exposures and skin diseases.

In America, it was not until the late nineteenth century that dermatology was established as a clinical discipline [2]. It was then that American dermatologists began to study in Europe, the academic epicenter for the specialty at the time. These physicians would learn about progress made in the field and would model their American practices after those of their European counterparts. During this period, although progress was made in establishing dermatology as a specialty in America, there was little emphasis placed on dermatological research. The scarcity of research in the field prompted the formation in 1937 of two organizations: the American Academy of Dermatology and the Society for Investigative Dermatology [2–4]. One year later, the Society for Investigative Dermatology published its first *Journal of Investigative Dermatology*. Both the creation of these societies and the publication of this journal were the first of their kind, as no previous journals or organizations had focused primarily on dermatology research.

Today, there are over 200 dermatology specialty journals and the importance of clinical research in the field is unquestionable [5]. In the last 15 years, the approach of medical practice in general has become more evidence based, and there has been a corresponding shift in clinical dermatology [6]. The evidence garnered from various research trials has significantly shaped the way physicians care for their patients, and the results of clinical research studies often guide dermatologists in treatment decision making. In this setting, the accurate design and execution of dermatology clinical trials is paramount.

Given the current diversity within the specialty, there is a large range of dermatology topics under study (Table 1). Although the majority of trials are therapeutic in nature, there are also quality of life studies and research projects investigating the response of skin disease to environmental exposures and other stressors. The structure of therapeutic trials in dermatology varies based upon what disease and treatment method is being studied. Dermatological therapeutic treatments include topical, oral, and subcutaneous drugs, phototherapy, lasers, and other devices. Each of these therapies presents unique considerations when designing and implementing clinical trials, and later these will be discussed in further detail.

Dermatology is a wonderful field for conducting clinical trials, as there are many advantages to studying the skin. First, it is an accessible organ that can be easily

**TABLE 1** Examples of Common versus Rare Debilitating Diseases in Dermatology

| Most Common Diseases          | Rare Diseases                                 |
|-------------------------------|-----------------------------------------------|
| Acne vulgaris                 | Epidemolysis bullosa                          |
| Actinic keratosis             | Blistering diseases: Pemphigus and pemphigoid |
| Nonmelanoma skin cancer       | Toxic epidermal necrolysis                    |
| Contact and atopic dermatitis | Cutaneous T-cell lymphoma                     |
| Cutaneous fungal infections   | Ichthyosis                                    |
| Herpes simplex and zoster     | Scleroderma                                   |
| Human papillomavirus          | Erythrodermic psoriasis                       |
| Melasma                       | Lichen planus                                 |
| Psoriasis                     | Pityriasis rubra pilaris                      |
| Acne rosacea                  | Pyoderma gangrenosum                          |

seen, touched, measured, and sampled. This is a benefit not achievable with other organ systems and allows for unique treatment options, readily observed patient responses, and less invasive study procedures. Further, given the symmetry of dermatological lesions, subjects may serve as their own controls, which is advantageous since it requires the recruitment of fewer subjects to a given trial. Lastly, the duration of clinical trials is generally shorter than in other areas of medicine. Endpoints may be easily recognizable as early as 12 weeks, which makes the skin an ideal organ system to study, especially in pilot programs. Overall, these characteristics permit rapid trials with straightforward treatment schedules and endpoints. In addition, dermatology is one of the only areas of medicine in which study subjects may evaluate their specific responses to treatment, allowing investigators to collect data on patient perceptions of improvement. These data are important when considering quality of life issues and other psychosocial factors that are associated with disease states. When a clinical trial has successful findings, these unique attributes of studying the skin have the potential to not only influence overall patient care but also to greatly impact patients' self-esteem and sense of well-being [7, 8]. An additional benefit to conducting dermatology clinical trials is that diseases of the skin manifest in both adults and children, so there is a demographic of patients from which to draw a study subject population.

Of course, there are multiple challenges associated with conducting dermatology clinical trials. Unlike other medical specialties that use biological markers or other objective tests as indicators of health or disease, many dermatology measurements are inherently subjective. Two physicians may differ in their assessments of the same patient simply because of varying degrees of interpretation. This interobserver variability can potentially lead to different results reporting and reductions in standardization across study centers and clinical facilities.

A second issue involved in conducting dermatology clinical trials is the influence of market constraints on the selection of diseases being studied [6]. Given the high costs associated with conducting studies, the pharmaceutical industry often sponsors research. The focus of industry sponsors is of course affected by fiscal concerns, which sometimes means that rare, serious skin diseases are studied less frequently than more common and sometimes less debilitating disorders.

The progress made in dermatology because of clinical trials research is significant [9]. Acne vulgaris is just one example of a condition that has seen drastic treatment changes because of clinical research [10]. Over the past century, many conclusions regarding the causes and remedies for acne have been made. Previously, sulfur and mercurials were two of the topical treatments used for acne, but today new acne treatments have been derived based on the understanding of acne's pathogenesis. Systemic therapy has evolved to include the use of oral antibiotics, and a number of topical drugs including various antimicrobials and retinoids are now the mainstay of treatment.

Similar advances have been made in psoriasis treatment. The earliest therapy for this skin disease was coal tar. Although today this is rarely used as primary therapy, many preparations for psoriasis do contain coal tar. Clinical trials have provided advancements allowing topical corticosteroids and phototherapy to emerge as methods for improving psoriatic lesions. Current dermatology psoriasis therapies include highly successful intravenous and injectable biologics, many of which are antibodies.

Advances in acne and psoriasis are just two examples of the progress made in dermatology because of the results of clinical trials. The future advancement of dermatology depends greatly on the ability to demonstrate improvements in patient care through clinical research [6]. The remainder of this chapter will focus on the guidelines, considerations, and other factors involved in the effective design and operation of these studies.

### 10.3.2 OVERALL STUDY DESIGN CONSIDERATIONS IN DERMATOLOGY

The aim of this section is to give a broad overview of some of the distinctive aspects involved in designing and conducting dermatology clinical trials.

#### 10.3.2.1 Drug Therapy Trials

The study design used in a dermatology clinical trial largely depends on the particular skin condition under investigation. The gold standard of therapeutic dermatology trials for common skin conditions is the randomized controlled trial [6]. Some drug studies compare placebo to a new medication of interest in order to evaluate its efficacy and safety in treating a particular disease. In dermatology clinical trials, placebos may be in the form of a vehicle (i.e., cream, ointment, lotion, foam, etc.) or in the form of a pill, subcutaneous injection, or infusion. Placebo, however, is really a misnomer when designing a study of an active topical versus its vehicle control. The effect of moisturizing the skin with any topical has beneficial effects on many skin conditions ranging from wrinkles to eczema to psoriasis and can easily result in improvements in the 20–30% range on many scoring scales. Care must be taken when designing these studies to make sure that the sample size is large enough to compensate for this effect.

In a blinded study, it is imperative that the investigator remains unaware of the treatment assignment. In trials that use placebo, avoiding unblinding is not an issue since the vehicle or other placebo can generally be made to look exactly like the actual drug under study.

However, there are a great number of dermatology trials that compare a drug already established in treating a condition to another, newer drug. In these instances, when trials are double blinded or investigator blinded, the potential exists for the subject or investigator to easily distinguish between the two drugs under study, especially in the case of topical treatments. For example, in a study comparing an ointment to a lotion, the study subject is aware of the treatment assignment based on the type of topical she or he is given. As a result, additional considerations are required in the study design to protect against investigator unblinding. In these trials, the protocol should state that study coordinators or other study staff members are responsible for drug administration and collection, drug application instruction, and any other aspects of the trial that involve transactions with the medication(s) under study. Furthermore, protocols should include guidelines for study staff to educate subjects to not discuss with the investigator the type of study medication they are using. For example, enrolled subjects should use the term “study medication” or “study drug” when discussing their participation with the investigator, rather than descriptions such as ointment, lotion, gel, and the like. In these trials,

subject and study staff education is of utmost importance in order to avoid potential investigator unblinding and bias. Study protocols should clearly outline medication dispensing, application, drug collection, and education procedures in accordance with these considerations.

Dermatologists also conduct open-label clinical trials, where both the investigator and patient are aware of the treatment assignment. By and large, open-label trials in dermatology are used to study rare diseases, as the subjects enrolled to these trials in the dermatology setting often require immediate therapy, rendering placebo use unsuitable. The guidelines mentioned above to avoid investigator unblinding do not apply here, given the nature of the study design. However, it is of utmost importance that the investigator remain as impartial as possible when measuring outcomes in this patient population, so as to avoid biasing study results. Whenever possible, the same investigator should be involved in the evaluation of disease throughout an open-label trial in order to minimize additional differences resulting from interobserver variability. Scoring scales, photography use with subsequent evaluation by a blinded observer, and patient perception of improvement assessments may play particularly important roles in these studies. Another valuable element to ensure objectivity in open-label trials is to have multiple assessors conducting subject evaluations or to design a trial where the treating physician is different from the investigator appraising subjects' response to treatment. These features should be incorporated into the study design where applicable to maintain impartiality.

#### **10.3.2.2 Device Studies: Phototherapy and Laser Trials**

The earliest trials involving lasers and phototherapy compared actual therapy to simulated treatment for placebo comparison. However, today very few, if any, trials are done using sham light and laser sources since the efficacy of phototherapy and laser treatment to ameliorate certain disease symptoms has been well established. Most current studies done in these areas investigate whether a particular light source or laser type is superior to another for a given indication, whether a light source or laser is better than no treatment, or whether a light source or laser type works better with or without adjuvant drug therapy. The latter typically involve placebo use for comparison. The double-blind or investigator-blinded study design frequently involves randomizing subjects to treatment regimens and assessing efficacy and monitoring adverse effects of treatment. For example, one group of subjects might be randomly assigned to treatment with conventional ultraviolet B (UVB) phototherapy and compared to another group of subjects that undergoes narrow-band UVB phototherapy to assess which offers better disease response and patient safety. In phototherapy trials of this type, the risk of investigator unblinding is rarely an issue since technicians typically administer light treatment to subjects. This is useful since the investigator may remain unaware of the subjects' treatment assignment and conduct assessments in an unbiased manner. Laser clinical trials differ in this respect since, especially in new studies, the investigator is often involved in the treatment of subjects. Therefore, one way to avoid potential bias in the design of these trials is to state that the treating physician should not be the investigator who is conducting subject skin assessments. Additionally, photography may be incorporated into clinical trials of this type to provide objective evidence of skin modifications.

Some laser and phototherapy studies use symmetrical target lesions on the same subject for the purpose of left–right comparisons. Left–right comparisons involve treating two similar target areas on opposite sides of the body and comparing outcomes. For example, if an investigator is interested in seeing if a topical drug works better than placebo in combination with a light source, a double-blind study might be done where one side of the body is treated with a placebo vehicle, and the opposite side of the body is treated with the topical drug. Both areas would be exposed to the light source and outcomes would be measured to see if the drug did increase the efficacy of the phototherapy treatment. Although this method requires the recruitment of fewer individuals and is advantageous for gathering data on how two particular treatments affect the same subject, this approach does allow for greater chance of error. Subsequently, the study staff must take great care to meticulously record accurate drug/placebo application, outcome measurements, and drug safety assessment information. Protocols using this study design should contain guidelines to avoid error, and source documents should be thoughtfully designed and well labeled in order to capture correct information.

Additionally, there are open-label trials done with phototherapy and lasers in dermatology. For example, some of the light studies involving biologics are open label. Similar to therapeutic trials that use open-label design, these studies typically involve subjects with more advanced disease and require investigators to be as impartial as possible in their subject assessments. Photography and other more objective methods of recording outcomes may be useful in these trials to correlate with physician assessments, and these should be considered when designing such a study.

Finally, for all dermatology studies, regardless of therapy type, timelines for follow-up visits should be outlined in the study protocol and occur at the given time intervals or within the “visit window” identified in the study protocol. The visit window is the amount of time around a designated study visit that a subject has to complete the visit without it being considered a protocol deviation. For example, if the protocol designates week 2 as occurring on day 15 and there is a 3-day visit window, then the day 15 visit can technically occur anytime between days 14 and 16 and still be within study protocol. The same holds true for the laboratory assessments for a particular visit. If, for example, blood specimens were not able to be obtained at the week 2 visit, and it occurred on day 14, then the subject has until day 16 to return to the clinic for a blood draw before being considered a protocol deviation.

Although not obtaining all study data at a given visit is not advisable, on occasion it may be unavoidable. At follow-up visits, all medical exams, investigator assessments, subject questionnaires, laboratory collection, and redispensing of study drug should occur as outlined in the study protocol. If a study drug could potentially be associated with reproductive risks, the protocol should state that women of reproductive age have regular urine pregnancy tests done while on the study and that subjects of both sexes who are sexually active report their method of contraception. In addition, adverse events and concomitant medication taken should be reviewed with the study subject. A copy of the subject’s diary should be taken to include as a part of the source documentation if it is to be redispensed to the subject and proper study drug administration instructions should be reviewed with the subject. It is advisable to ask subjects how they take their study drug in order to eliminate

study staff coaxing and ascertain exactly how subjects are taking their study drug. It is also advisable to include a study checklist in the source documentation to verify that all study-related information is collected at follow-up visits.

### 10.3.2.3 Determining Study Size

One of the first steps in developing a clinical trial is deciding what number of subjects to enroll. Preliminary studies typically offer a good starting point in this process by providing information on the anticipated size needed to obtain a desired outcome [11, 12]. However, when deciding upon a final sample size, thought must be given to both statistical and clinical significance.

For clinical trials that address common skin conditions and diseases, patient recruitment is typically not a difficult issue, and obtaining large sample sizes for trials is uncomplicated. However, dermatologists conducting these trials should consider that too large a sample size may lead to a situation of a statistically significant finding that holds no real clinical relevance [11]. This is because as sample sizes grow exceedingly larger, even the smallest differences that are not necessarily useful to patient care may be detected. Further, in dermatology it is especially important to prospectively consider the hypothesized central outcome of a trial, given that patient perceptions of improvement play a significant role in evaluating clinical significance. For example, a study that has the statistical power to show that drug A for acne is slightly better than drug B will only really be clinically useful if the subjects on trial felt that their acne indeed improved on drug A [12, 13].

Conversely, for rare, more serious dermatological diseases, the opposite challenge exists. Recruiting adequate numbers of study participants within a reasonable time frame proves to be logistically and economically difficult [11]. Often, these smaller trials may fail to statistically conclude that a relationship exists, even if one does, simply because the study sample size is not large enough. As a result, it is often the most devastating diseases that are the hardest to research. Investigators conducting trials with these patient populations should be aware of the challenges and thoughtfully plan subject recruitment strategies to ensure adequate subject enrollment.

Similar problems exist for detecting differences in rare outcomes or uncommon side effects between groups. For example, even if a sample size is large enough to determine efficacy, it may still be too small to ascertain useful data on safety and dosing schedules [11]. Therefore, it is necessary in these instances to appropriately design a trial that will have a large enough number of subjects to ascertain reliable safety and outcome results.

### 10.3.2.4 Patient Selection and Recruitment Methods

At the outset of a clinical trial, it is important for the investigator to define a study's target population. In dermatology, a study population is defined in terms of any combination of the following characteristics: age, gender, race, complexion, skin phototype (type I pale white skin to type VI dark brown or black skin), previous photodamage, duration of disease, and severity of disease. The disease under study dictates which characteristics are of significance. Of note, several major dermato-

logic diseases occur predominantly or prominently in the pediatric population ranging from eczema to acne. Designing studies for this age group, of course, requires additional considerations, ranging from assenting patients, minimizing discomfort, and designing ethically appropriate studies for this age group.

All required baseline characteristics should be clearly outlined in the protocol. This is imperative in understanding which treatments work in a given patient population and is especially useful when translating study results to the patient care setting since a more standardized subject population yields a greater ability to detect true differences in study outcomes. Scoring instruments, which will be discussed in later sections, are used to grade subject disease severity and are helpful tools that may help determine which subjects should be enrolled to a particular trial. Protocols should state exactly which scoring scale or grading method should be used to assess disease at baseline and throughout the study.

Inclusion/exclusion subject criteria should contain directives regarding the use of other therapies to treat the skin disorder under study. Typically, studies require no use of such medications for a period of 14–30 days before the start of study drug. This time frame is often referred to as the “wash-out” period. The wash-out period ensures that all subjects enrolled to a trial have comparable baseline off-treatment characteristics. Enrollment criteria should also include information regarding past therapies used to treat the skin disorder under study. In some cases, it may be necessary to exclude a subject from a study if it is deemed that a prior therapy used could affect study participation and outcomes. Additionally, a protocol should specifically state if moisturizers, cleansers, or other skin products may be used by enrolled subjects. This is because various emollients and cleansers contain ingredients that may improve certain dermatological conditions and potentially affect clinical outcomes.

Dermatology is unique in that people who have skin conditions are able to identify their own diseases. As a result, subject recruitment outside of the clinic setting is a common and successful approach. Unlike other areas of medicine that recruit subjects from clinic patient populations, dermatology clinical trials are often advertised to the general public in the newspaper or in flyers. This method provides a great advantage to subject enrollment strategies since it reaches a much greater sample population.

Given that the sample population is from the general public, potential subjects who respond to trial advertisements must be screened thoroughly. Their medical histories and medications must be completely reviewed prior to enrollment to assure participant safety and subject eligibility. In addition, it is the responsibility of the investigator and study staff to assess subject compliance. For phototherapy trials, especially, where subjects are required to undergo treatments as often as three times per week, it is imperative that participants are willing to cooperate with study protocol procedures. Monetary or other incentives may be offered to increase patient recruitment and compliance. However, these incentives as well as any advertisements used in the study must be approved by the ethics committee of the participating institution to ensure that they coincide with federal regulations.

Regardless of how the subject is recruited, she or he must sign an informed consent form (ICF) before any study procedures are performed, as mandated by 21 Code of Federal Regulations, CFR 50.20. This may or may not occur at the screening visit. Subjects must be given ample time to consider if they want to participate in

the research study and should be allowed time to discuss the study with their physician and families. Furthermore, the ICF should clearly outline any potential risks associated with treatment, including reproductive risks for men and women.

#### 10.3.2.5 Patient Compliance

Monitoring patient compliance in clinical trials is essential to the acquisition of real outcome data and the conduction of a sound study [14–16]. It is imperative that subjects adhere to protocol visit schedules and that they comply with a stated treatment program. Prior to enrollment, subjects are asked to read the informed consent form, which describes what is entailed in study participation and gives information on potential benefits and risks. Subjects have the opportunity to ask questions and are only enrolled if they are amenable to study procedures. In most dermatology drug trials, studies are designed to be brief with few visits. This typically translates to increased patient compliance because it is less intrusive to the lives of subjects. However, for phototherapy trials, assessing and maintaining patient compliance becomes more of an issue since subject lives may be affected more by numerous, frequent study visits.

There are several ways to maintain an acceptable level of compliance among subjects. First, the simple act of calling patients to confirm appointments helps to remind them about their study visits. Second, short wait times and efficient execution of study visits help to make participation less of a chore for subjects. It is important to consider that subjects have issues that come up that may preclude them from maintaining a strict study schedule. Although these should be kept to a minimum, exceptions can be made for patient scheduling conflicts, and these should be reported to the investigational review board (IRB) of record and/or the study sponsor.

In addition to ensuring that subjects are seen at visits according to protocol, it is also important to make certain that they are properly using their study medication. This involves constant education of study subjects at visits. In dermatology clinical trials, for example, application techniques for topical drugs should be reviewed at each visit. Protocols must clearly and specifically outline how subjects should use medication and emphasize drug application reeducation by study staff. Whenever possible, especially in the case of topical and injected drugs, the first treatment should take place in the clinic so that proper dosing and drug administration practices may be established. In addition, for oral, subcutaneous, and topical treatment administrations that subjects perform at home, drug compliance logs should be completed by the subjects and collected at each visit in order to monitor patient adherence. Study protocols should specify that subjects return all medication at the end of study or at stated intervals throughout the trial to assess consumption. For oral and subcutaneous drugs, this is useful in ensuring that patients did indeed take the medication. An added benefit in collecting study medication for trials involving topical drugs is that bottles and containers may be weighed and the actual amount of drug used by each patient may be collected as data. Typically, drug containers are measured at dispensing, then again when returned by the subject at a time interval determined in the protocol. The difference in the two weights yields the amount used by the subject. When comparing patient outcomes, this information is valuable in evaluating subject responses in relation to the amount of drug applied to the skin.

Additionally, this measurement is helpful for assessing drug safety and efficacy since too much of a study drug could cause adverse reactions, while too little may be associated with inefficacy.

Subjects must also be instructed on the amount of time they have to take a dose of study drug, if one is missed. This is referred to as the “dosing window.” It is important that subjects are instructed to call the study staff if they do miss a dose of study drug and to record the missed dose in a study diary. In addition, the protocol should indicate that subjects should be instructed to record in their study diary any adverse events experienced and concomitant medications taken. The diary should be brought with each subject to all study visits. All of the above instructions should be reviewed at all study visits with the subject to make sure that the study protocol is being followed.

Common adverse events experienced in topical clinical trials include erythema, pruritus, irritation, and scale at application sites. These events are expected with most topicals in a small to moderate percentage of patients depending on the ingredients being studied. Some studies will therefore assess for these changes at each visit proactively and separately from the other adverse events in order to ensure uniformity of data collection.

It is important to note that study subjects may differ from “real” patients in that they are more motivated to adhere to treatment schedules and visits [6]. Monetary incentives combined with a general interest in seeking out investigational treatment make subjects in research studies a typically more compliant patient population. For dermatologists involved in clinical trials, it is useful to keep this in mind since a treatment or visit schedule that is inconvenient for study subjects has a high probability of translating into decreased acceptance by dermatology patient populations.

10.3.2.6 Disease and Quality of Life Measurement Instruments

Capturing appropriate data for dermatology clinical trials almost always involves the use of scoring instruments (Tables 2 and 3). These have been developed, tested, and established as reliable ways to obtain data points [17]. Scoring instruments serve

TABLE 2 Common Scoring Systems Used in Dermatology Clinical Trials

| Disease                                      | Scoring System                                        |
|----------------------------------------------|-------------------------------------------------------|
| Acne vulgaris                                | Acne lesion counts (papules, pustules, comedones)     |
|                                              | Leeds acne grading technique                          |
|                                              | Pillsbury scale                                       |
|                                              | Cook’s acne grading scale method                      |
| Atopic dermatitis                            | Scoring for atopic dermatitis (SCORAD)                |
|                                              | Eczema area scoring index (EASI)                      |
| Psoriasis                                    | Psoriasis area and severity index (PASI)              |
|                                              | Psoriasis severity index (PSI)                        |
|                                              | Lattice system—Physician’s global assessment (LS-PGA) |
|                                              | Overall lesion assessment (OLA)                       |
| Acne rosacea                                 | National Rosacea Society Rosacea Clinical Scorecard   |
| Nonspecific skin disease scoring instruments | Physician’s global assessment (PGA)                   |
|                                              | Dermatology index of disease severity (DIDS)          |

**TABLE 3 Acne Grading Systems**

| Name of Grading System                     | Scale                                                                                                                                                                               | Method                                                                                                                                                              |
|--------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Leeds acne grading technique               | Number of inflammatory and noninflammatory lesions present                                                                                                                          | Based on counting lesions and grouping them into noninflammatory and inflammatory categories                                                                        |
| Pillsbury scale                            | 1 (mildest) to 4 (severe)                                                                                                                                                           | Based on number of inflammatory and noninflammatory lesions                                                                                                         |
| Cook's acne grading scale method           | 0 (least severe) to 8 (most severe)                                                                                                                                                 | Uses photography to document acne severity                                                                                                                          |
| Global acne grading system                 | Grade: 0 (no lesions) to 4 ( $\geq 1$ nodule)<br>Global score: 0 (no acne) to $\geq 39$ (very severe acne)                                                                          | Takes into account location of lesions, and each location is given a factor rate. Factor rate $\times$ grade = local score. The Global score = sum of local scores. |
| Grading scale for overall disease severity | 0 (clear, no inflammatory lesions) to 6 (severe, numerous comedos, papules, and pustules, with larger inflamed lesions extending over much of the face, erythema may be pronounced) | Based on descriptive definitions of disease severity. Investigator selects the number that most closely identifies the extent of the subject's acne.                |

as standardized assessment methods to assure the reliability of clinical trials. The use of grading scales offers better consistency in reporting subject responses and allows for direct comparisons among clinical sites and studies. Global assessments, severity scores, and/or other more specific assessments are used in dermatology clinical trials. In general, global assessments are conducted by the study investigator at regular intervals to evaluate the response of total body disease. Severity scales are used to monitor changes in disease states such as pigmentation, pruritus, and induration that correlate with certain levels of disease involvement. Dermatology scales and scoring systems frequently incorporate body surface area (BSA) calculations in order to provide more accurate descriptions of the extent of disease.

The disease under study dictates the use of a particular scoring system. For example, there is the Psoriasis Area and Severity Index (PASI) for psoriasis and the Scoring for Atopic Dermatitis (SCORAD) for atopic dermatitis. These disease-specific scoring instruments will be considered in detail in later sections. Because many of the scoring systems are subjective, the most reliable way to maintain consistency in disease measurement is to adequately educate investigators and study staff in reporting guidelines and to ensure that within each research site, whenever possible, the same investigator conducts subject assessments throughout the trial. Keeping the number of evaluators to a minimum increases the integrity of reporting due to less interassessor variability.

In addition to disease-scoring systems, dermatology clinical trials often monitor patient perceptions of improvement, patient global disease assessments, and quality of life data [18]. These instruments should be administered at baseline and at the end of study or at another study time point. The administration schedule of these

instruments and the determination of which measurements are used should be clearly indicated in the protocol.

Instruments that assess subject perception of disease vary in the types of questions asked since the data collected depends upon which disease is under study. Generally, questions ask subjects to grade the severity of their disease and rate the level of disease-associated symptoms they have experienced. However, to measure how the life activities of subjects are affected by skin disease across disease states, the majority of therapeutic trials in dermatology use the Dermatology Life Quality Index (DLQI) [19]. The DLQI is not disease specific, and subjects answer by choosing “very much,” “a lot,” “a little,” “not at all,” or “not relevant” in response to 10 questions. Topics on the questionnaire range from how skin disease affects work and extracurricular activities to interpersonal relationships and sexual activity. For pediatric trials that enroll subjects between the ages of 5 and 16 years, there is the Children’s Dermatology Life Quality Index (CDLQI), which includes questions regarding how skin disease affects friendships, school work, sports, and other pediatric life issues.

Although not as widely used, the Skindex-29 is another measurement of skin disease’s impact on the quality of life. Skindex-29 is a shorter version of the original 61-question Skindex quality of life questionnaire. The newer version has been shown to be easier and faster to complete and a more effective measure of patients’ quality of life than its earlier form. It is composed of 30 questions that address three subscales: emotion, function, and symptoms. Patients answer questions on a scale of “0 = Never” to “4 = All the time,” and the higher the score, the greater impact the disease has on quality of life.

Typically, these quality of life measurements are administered at baseline and then again after an interval of treatment in order to assess whether a given therapy has improved subjects’ quality of life (Table 4). Given that dermatological diseases are visible, subjects often have stress related to how people respond to them and interact with them. This can have a major affect on how patients feels about themselves and their disease. Consequently, the quality of life measurements are extremely useful methods for predicting how successful a particular treatment is at ameliorating the psychosocial aspects of having skin disease [19].

### 10.3.2.7 Source Documentation in Dermatology

The importance of meticulous data collection in clinical trials cannot be over-emphasized. The design of source documents that capture all necessary information for a given trial is vital to the successful execution of a clinical study. This section explains several types of source documents that are useful in conducting dermatology clinical trials. Given the visual characteristic of the specialty and the limited availability of objective testing methods for monitoring disease, dermatology clinical trials typically rely on diagrams, photography, and the use of target area measurements in documenting subject response to treatment.

Target area measurements are typically used to monitor the response of one area of the skin. At baseline, the investigator determines a target area and measures its dimensions using a ruler. The dimensions of the target area are recorded at baseline and at subsequent study visits as a way of monitoring the skin’s response to therapy. It is important to designate whether the greatest dimensions should be measured

**TABLE 4 Quality of Life Metrics Used in Dermatology Clinical Trials**

|                                                                                  |                                                                                                                                                                      |
|----------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Facit fatigue scale                                                              | Measures how skin disease affects a subject's energy level and ability to complete daily activities.                                                                 |
| Beck depression inventory                                                        | Measures how skin disease affects a subject's appetite, appearance, sexual desire, health, and weight.                                                               |
| EuroQoL-5D (EQ-5D)                                                               | Measures how skin disease affects a subject's mobility, self-care, usual activities, level of pain/discomfort, and anxiety/depression.                               |
| EuroQoL-Visual analog scale                                                      | Feeling "thermometer" where patients rate subjective health status.                                                                                                  |
| Dermatology life quality index (DLQI)                                            | Measures how skin disease affects interpersonal relationships, sexual activity, work, and extracurricular activities.                                                |
| Children's dermatology life quality index (CDLQI)                                | Measures how skin disease affects friendships, school work, participation in sports, and other pediatric life issues.                                                |
| Psoriasis disability index                                                       | Measure how psoriasis affects the quality of life, level of discomfort/disability and associated stress of subjects with this skin condition.                        |
| Psoriasis index of quality of life (PSORIQoL)                                    |                                                                                                                                                                      |
| Psoriasis life stress inventory                                                  |                                                                                                                                                                      |
| Skindex-29                                                                       | Measures the effect of skin disease on subjects' emotions, symptoms, and day-to-day functioning.                                                                     |
| Quality of life index for atopic dermatitis (QoLIAD)                             | Measures the effect of atopic dermatitis on subjects' work and school activities, social functioning, and self-esteem.                                               |
| Melasma quality of life scale (MELASQOL)                                         | Measures the effect of melasma on subjects' daily functioning and level of disease-associated impairment.                                                            |
| Dermatology-specific quality of life instrument for contact dermatitis (DSDL-CD) | Measures how contact dermatitis affects subjects' level of discomfort, interpersonal functioning, self-care activities, work or school performance, and self-esteem. |
| Dermatology-specific quality of life instrument for acne DSQL-acne               | Measures how acne vulgaris affects subjects' level of discomfort, interpersonal functioning, self-care activities, work or school performance, and self-esteem.      |

as lesions may not be uniformly shaped. Monitoring target areas offers the added benefit of assessing other changes in the skin, namely adverse reactions to therapy. Any changes seen in the skin in the target area may be documented by the investigator in writing and followed over the course of a trial.

A major limitation of using target lesions when other areas of the body are also being treated is that they may not capture what is happening clinically elsewhere for a patient. Some skin diseases respond differentially to treatment based on body region. For example, psoriasis on the legs is often substantially harder to treat than other body regions and may lag in terms of improvement.

Body diagrams are a useful method for capturing the location of disease involvement. Investigators illustrate affected skin by using a writing instrument to shade in areas of disease involvement on a blank body diagram. By completing new front and back body diagrams at baseline and at regular intervals throughout a study, investigators may monitor a subject's overall response to disease and have a better clinical picture as to how different body areas respond to a particular treatment.

Photography plays a similar role in monitoring treatment response but warrants additional considerations regarding consistency and subject confidentiality. Study

protocols that incorporate photography should include specific guidelines explaining exactly how photographs should be taken for the trial. An outline of photography procedures should contain parameters to be used for all subjects at all study sites. For example, to maintain consistency the same backdrop should be used for all photos, a color chart and patient identification card should be in the photograph's field of view, the same film, camera, and camera focal length should be used for all photos, the same number of photographs should be taken at the same study intervals, and all subjects should be dressed and positioned for photographs similarly. In addition, appropriate measures must be taken to protect subject confidentiality. Photography of subjects' faces should be avoided unless this area is being monitored for study treatment response. Only designated study staff and the study sponsor (when applicable) should have access to the photographs. In cases where a subject's face is photographed, no subject photos should be used in publications prior to the removal of identifying characteristics, for example, the blacking out of a subject's eyes. Any use of photography in a clinical trial must be included in the study's informed consent form, as it is never appropriate to take photos of study subjects without their understanding and written permission.

### 10.3.2.8 Clinical Trial Registration

In January 2005, the International Committee of Medical Journal Editors (ICMJE) issued a statement requiring all phase II, III, and IV clinical trials to be registered in order to be considered for publication in any of their 11 member journals [20, 21]. This directly affects the dermatology clinical trials process since the major dermatology journals are associated with the ICMJE.

The ICMJE provided requirements for the registry database, including that it must offer free public access, must be supervised by a not-for-profit organization, have the ability to be searched electronically, and have a mechanism to confirm registration data legitimacy. The purpose for establishing such a registry is to prevent the discerning coverage of clinical trial results in medical journals [20]. In the past 50 years, nearly half of all clinical studies have not been published, leading to incomplete knowledge about therapeutic effectiveness [21]. Some of this stems from the preference of medical journals to publish positive results, which demonstrate the effectiveness of a new treatment, or those that show noninferiority, with two treatments showing equivalent efficacy. This bias consequently has led to the underpublication of negative or inconclusive findings and to the nondissemination of these study conclusions. The concern is that this underreporting leads to incomplete understanding of therapeutic efficacy, potential duplication of research efforts, and reduced integrity in study design and methodology. The latter issue is of considerable importance since it is paramount that investigators maintain the original study question and aims throughout a clinical trial. Registration would ensure increased veracity by precluding the potential for outcomes to be altered as data are interpreted.

### 10.3.3 SUMMARY

Collectively, the prevalence of skin problems surpasses other medical conditions such as hypertension, obesity, and cancer [22, 23] and has profound effects on health

and quality of life. What makes the skin such a unique and interesting organ to study in clinical trials is that the endpoints are often easily and quickly discernable and that the therapeutic modalities are so varied, ranging from topicals to immunotherapy to devices. The overall relative health of many skin disease patients also reduces the chances of confounding illnesses affecting the safety or interpretation of events in studies. In general, the field has also made tremendous progress in terms of methodology and scoring systems, and advances in imaging techniques will likely improve our ability to detect and measure change in the future. Lastly, while many studies, of course, do not succeed, we have seen tremendous successes in the past decade, with subjects experiencing dramatic improvements in both their health and quality of life, an experience that is greatly gratifying for investigators and subjects alike.

### **10.4.1 GENERAL INFORMATION ON EMERGENCY CLINICAL TRIALS**

Emergency medicine is a global discipline that functions as a cornerstone for secondary disease prevention; therefore it is one of the many tools for implementing primary disease prevention programs [1].

In general, clinical trials involve the administration of the study drug to healthy human volunteers or to patients under the supervision of a qualified investigator, usually a physician, pursuant to a reviewed protocol. Human clinical trials are typically conducted under protocols that detail the objectives of the study, as well as

the parameters used to monitor the safety and efficacy criteria that are going to be evaluated. Moreover, it is very important to recognize that each clinical trial must be conducted under the auspices of an institutional review board (IRB) that considers, among other factors, ethical factors, the safety of human subjects, the possible liability of the institution, and the informed consent disclosure that must be obtained from participants of the clinical trial. Although the goal of this is to obtain safety and efficacy data, the overriding consideration in the studies is the safety of the study participants.

Research in the specialty of emergency medicine continues to blossom because this department is often considered as a desirable place to conduct clinical research due to the broad and undifferentiated spectrum of acute conditions encountered [2]. For this reason, there are some specific aspects when studying emergency medicine that have to be taken into account. One of them is the emphasis on ultra-rapid diagnosis and treatment to save the critically ill emergency patient [3]. Moreover, it is necessary to evaluate the use of a particular treatment; clinicians have to establish the parameters to be evaluated at the onset. These parameters include objective response rate, survival, disease-free survival, or duration of response. Toxicity is also commonly identified. The parameters of interest for a specific trial design are defined before the initiation of the study and analyzed at the completion.

Another characteristic of emergency clinical trials is that usually physicians working in the emergency department do not stay for a long period of time, and therefore it is especially critical for them to standardize the protocol to be used, as well as the ease of using it, for the physicians who are incorporated in the supervision of the trial [4].

Human clinical trials typically are conducted in three sequential phases, although sometimes they are overlapped. Phase I clinical trials represent the initial administration of the investigational drug to a small group of healthy human subjects or, more rarely, to a group of selected patients with the targeted disease or disorder [5]. Normally, this type of clinical trial is not developed in the emergency setting. Phase II clinical trials involve a small sample of the actual intended patient population and seek to assess the efficacy of the drug for specific targeted indications, to determine dose-response and the optimal dose range, and to gather additional information relating to safety and potential adverse effects. In the emergency room, these types of clinical trials involve mainly cardiovascular diseases such as acute ischemic stroke, acute stroke, cardiopulmonary resuscitation, acute myocardial infarction, and refractory angina patients with left ventricular dysfunction [6–9].

Once an investigational drug is found to have some efficacy and an acceptable safety profile in the targeted patient population, phase III clinical trials are initiated to establish further clinical safety and efficacy of the investigational drug in a broader sample of the general patient population. Phase III trials are randomized comparisons of two or more treatment options, often comparing a standard treatment to a new or more complex therapy. Emergency research phase III trials are related to several clinical conditions such as myocardial infarction, acute coronary syndromes, surgery, chronic obstructive pulmonary disease, hemorrhages, surgical pain, sepsis, and traumatic brain injuries [10, 11].

Phase IV trials are generally considered as “postregistration” trials, that is, trials of products that have already a marketing authorization.

It is also very important for the development of clinical research in emergency medicine to design and draw anticipated conclusions in order to note whether the trial is prospectively randomized with concurrent controls or is a clinical trial with historical controls. Proponents of randomized trials believe that one is more certain of equality between the two groups by a concurrent randomization process. This will reduce the bias of selecting control subjects from a historical pool and will also reduce the influence of improvements in management or different physicians who treat the patients in different periods of time. Furthermore, due to the specific characteristics of these clinical trials in emergency medicine, all of them require a special review and approval of trial proposals by an ethics committee.

In conclusion, there are some specific aspects that have to be taken into account when conducting clinical trials in emergency medicine due to the special conditions mentioned above.

#### 10.4.2 CLINICAL TRIALS INVOLVING EMERGENCY PATIENTS

Clinical trials involving emergency patients should be prospective trials, designed to evaluate emergency care treatments, answer specific questions, and more likely to answer the question correctly. In emergency medicine research it is mandatory that the prospective IRB reviews and approves the protocol designed for the study before it starts.

There are numerous potential barriers to conduct randomized controlled trials with emergency patients because of the specific characteristics mentioned below [12, 13]. Low incidence rates of emergency patient events require pooling of centers to conduct research, that is, in many occasions the trials have to be multicentric depending on the pathology investigated. A large number of emergency patients are required to attain diverse and representative study samples. In order for the precise development of a clinical trial, an infrastructure is needed to test the efficacy of treatments, as well as the transport and care that precede the arrival of emergency patients to the hospital emergency departments. A specific mechanism is needed to study the process of transferring research results to treatment settings.

A related challenge has been the difficulty for even large multicenter networks to gather sufficiently large sample sizes necessary to study treatments in the emergency medicine. Therefore, clinical trials in the emergency department need an infrastructure capable of overcoming inherent barriers to emergency medicine research. This infrastructure provides the capacity to conduct multicenter research studies to support research collaboration among medical investigators [14]. It should provide the test ability to collect, transfer, manage data from all sites, and determine availability, completeness, and agreement of core data from electronic and chart review. Despite these well-designed infrastructure multiinstitutional prospective trials, emergency medicine is complex due to:

- Training for investigators and staff is more difficult than those from single-center studies. This is especially critical for emergency departments where the physicians do not usually work for long periods.

- In the setting of emergency situations, randomization is not a simple process. Since researchers do not know when, and may not know where, the emergency is going to occur; it may be technically difficult to effect a randomization [15].
- Protocol development much more explicit because of the high rate of mobility of the physicians in this department.
- Quality control for maintaining high standards of quality and data management.
- Uniform standards for clinical research. Strong emphasis on training and standardization and include “good clinical practice” training.
- Site monitoring requirements of all centers regardless of whether observational or interventional study.
- Data transmission and security. It is necessary to involve epidemiologists and statisticians at the very beginning of the study. It is also essential to rely on independent data center/data manager. Paper data forms should be simple electronic, Web-based data entry of de-identified data, with logic and range checks. Original data forms/source documents at local site. Double data entry should be considered as a quality check—controversial queries for missing or inconsistent data.
- Multicenter studies are becoming more common, and the variability in local IRB assessments can be problematic if IRBs have different standards.
- Costs are high, and budgets tend to underfund training, site monitoring.
- Keep study simple, focused, and well budgeted.
- Accuracy measurement of predictor and outcome variable.

#### 10.4.2.1 Subject Recruitment

There is a paucity of clinical trials in emergency patients. This is partly due to difficulties in recruiting participants. Insufficient enrollment of patients is the most common reason for discontinuing emergency medicine studies. Failure to recruit members of specific populations to trials that require adequate representation reduces the external validity of the study results [16]. Frequently, the origin of these problems lies in the ethical issues surrounding clinical trials in this population [17]. In fact, recruitment is one of the most significant challenges to completing a research study on time and on budget. In most trials in emergency research, recruitment takes longer, is more expensive, and produces fewer subjects than planned. Subject recruitment can be difficult in the emergency department environment mainly because when patients present with acute symptoms, the emergency physicians are focused on life-saving interventions, not on study enrollment [18]. Though causes of recruitment difficulty have been documented in medical trials, little is known concerning recruitment in emergency medicine studies. Many reasons for this poor recruitment rate for emergency studies include:

- The subject recruitment should be made following established guidelines for protection of participant’s rights. The IRB now has an obligation to consider a strict inclusion and exclusion criteria document about subject recruitment.

- In life-threatening situations, relatives present many inconveniences for their relative to participate in a clinical study.
- Limited size of the emergency population, specially patients in critical situations.
- Plans for sampling and recruitment.
- The increased bureaucracy, reporting, and costs of clinical trials after the implementation of the European Clinical Trials Directive and U.S. Food Drug Administration (FDA) guidance for emergency research has led to a sharp decline in the initiation of clinical trials and in participant recruitment throughout Europe and North America [19].
- Regulations for clinical trials: Researchers have always been concerned about the effects that the regulations might have on clinical trials in emergency situations in patients with impaired consciousness. Examples include research on cardiac arrest, stroke, head trauma, spinal cord injury, gunshot wounds, major trauma, cardiac arrest, and poisoning. These regulations impose the need for prior consent from a personal or professional legal representative before a patient could be recruited into a clinical trial [20]. In most cases the regulations are only applicable to trials of drugs. Nonmedicinal trials and trials of clinical care continue to be governed by common law [21]. Federal regulations allow for waiver of consent in situations where there is more than minimal risk to participants, provided there is a prospect of direct benefit to participants and a number of other conditions are met. The conditions include the following:
  - The study could not be carried out without the waiver.
  - Consultation with community representatives occurs before the study starts.
  - Public disclosure is made before and after the study.
  - A therapeutic window is defined, and the researcher commits to try to locate a surrogate/legally authorized representative who can give consent within that window before proceeding to waive consent [22].

Recently, an amendment of the United Kingdom's Medicines for Human Use (Clinical Trials) Regulations allows unconscious patients in emergency situations to be enrolled in clinical trials without prior consent provided it has been approved by the appropriate ethics committee [23].

These difficulties could involve inadequate recruitment, which could reduce the ability to detect treatment differences.

In conclusion, strategies for the recruitment of the patients susceptible to be included in an emergency clinical trial are fundamental. Successful recruitment depends on multiple factors such as population, potential subjects, pathology, available alternatives, transportation availability, population demographics, and general or specific interest in medical research or science within the community.

#### **10.4.2.2 Emergency Clinical Research in Pediatric Population**

The well-known difficulties of conducting studies in young patients, along with the limited economic returns to pharmaceutical companies for pediatric drugs, have led

to a scarcity of pediatric studies and therefore a scarcity of knowledge about drug safety and efficacy in children [24]. The lack of scientifically evaluated medicines for children has been recognized as an area that requires correction [25]. Moreover, clinical trials in children have special ethical constraints [26].

Experimentation on children is considered by many to be unethical, resulting in difficulties to obtain critical safety data. Clinical trials are subject to detailed scrutiny by the various regulatory bodies. They have recently recognized the need for pharmaceutical companies to invest in pediatric medicines. The majority of marketed drugs are either not labeled, or inadequately labeled, for use in pediatric patients [27]. This is because, as we have stated before, there is a paucity of clinical trial works in children, which leads to the frequent use of off-label and unlicensed medications in this very vulnerable group [28].

The pediatric population is constituted by a wide range of individuals of substantially varied physical size, weight, and stage of physiological development. The differences between adults and children mandate strategies to improve this situation rather than continually relying on extrapolation from adult studies. In the protocols for clinical trials for pediatric emergency room it is mandatory that:

- Each trial should answer one primary study question.
- Sample size estimation based on error rates and clinically important difference must be calculated.
- Allocation concealment, randomization, and blinding are critical to prevent selection and ascertainment bias [29]. Clinical trial design must be practical, and a trial is more likely to succeed if a simple design is utilized, with minimal interference with school and work.
- Standardization of the intervention is important for the results validity, and study centers should be selected on the basis of the trial objective. The effects of dropouts, cross-overs, and missing data should be handled with an intention-to-treat analysis.
- Sample selection, informed consent, and valid outcome measures are specific challenges in the pediatric population [29].

Efforts should be made to increase the number of well-designed, randomized controlled trials in pediatric emergency patients. Therefore, new strategies have to be established between the pharmaceutical industry, the European Union (EU), and the U.S. regulatory bodies and pediatric centers to facilitate effective trials work. In this regard, The EU decided to support the development of a European register of clinical trials in children as part of the Fifth Framework Thematic Programme “Quality of Life” in 2002. DEC-NET (the European register of clinical trials on medicines for children—drug evaluation in children), supported by the EU, was created to provide the scientific community with a flexible tool for promoting communication and collaboration among researchers, disseminating clinical trial results, and facilitating patient access and recruitment to trials [30]. The project DEC-NET currently involves members of four countries: France, Italy, Spain, and the United Kingdom. DEC-NET fits International Committee of Medical Journal Editors criteria, is free of charge, and is designed to be used by the general public and health professionals [31]. It is unique in that it is the first population-oriented

clinical trial register. Such a register represents a useful source for planning new studies, promoting communications and collaborations between researchers, facilitating patient access and recruitment into trials, preventing trial duplication and inappropriate funding, and identifying the therapeutic needs of children that remain neglected. It will also allow active monitoring of new or evolved knowledge of drug therapies [32].

### 10.4.3 ETHICAL ISSUES IN EMERGENCY CLINICAL TRIALS

The ethical aspects of an emergency clinical trial cannot be separated from the scientific objectives. Segregation of ethical issues from the full range of study design components demonstrates a flaw in understanding the fundamental nature of research involving human subjects. Recognition that good science and good ethics are inextricably bound together in clinical research is today's reality. Thus, the ethical conduct of a clinical trial does not end with the formulation of study design or the obtainment of a signature on the informed consent form [33].

To improve the study design and conciliate science and ethics, some authors recommend that every protocol include a specific section in which the ethical considerations are exposed: the design and conduct of the study, selection and recruitment of participants, and the conduct of the consent process be presented, discussed, and justified, not in terms of ethics-based regulatory requirements but in true fulfillment of the investigator's responsibilities (as a scientist and moral duty) to ensure that the proposed study is sound, ethically and scientifically [34].

Patients attending an emergency department are entitled to assume that they will be treated in accordance with the best available evidence. The emergency physician has a responsibility to expand the fund of knowledge that underpins best evidence by means of clinical studies of new technologies and interventions. However, there are inherent difficulties in undertaking clinical research in an emergency department setting. Patients are usually frightened, often in pain, and sometimes have impaired cognition. Practitioners use case-based reasoning to apply bioethics to these clinical situations, usually giving most weight to patients' autonomy and values but also incorporating other relevant bioethical principles, including those encompassed in professional oaths and codes. Emergency clinicians must be able to recognize bioethical dilemmas, have action plans based on their readings and discussions, and have a method through which to apply ethical principles in clinical settings [35].

Other aspects that can help for the ethical consideration of the emergency clinical trials could be the randomization to treatment, which must occasionally be completed in the context of a clinical emergency. Furthermore, patients take on trust the fact that the clinician will act in a professional manner and not misuse the authority of his or her position. The researchers must be committed to the principle that self-promotion must not take precedence over the best interests of the patient.

The moral obligation of emergency researchers to do well, beneficence, must be tempered by nonmaleficence. That is, the expected bad effects of an intervention must be weighed against the anticipated benefits. The type, amount, and probability of harm should be effectively communicated to subjects, and the physician should

take account of the fact that what constitutes a harmful effect, or a beneficial effect, may be particular to the individual subject. Justice and equality of access are inalienable rights that must be respected in participants and nonparticipants alike [35]. The researcher must be a good communicator, demonstrating openness and effective listening. Benefits may flow from a research study in favor of the patient or to society. When discussing the benefits of a proposed study, one must distinguish between therapeutic and nontherapeutic research. Researchers are obliged to consider the potential benefit to the patient when balancing potential risks associated with any protocol. Researchers are entitled to expect that their work is regarded as honest until shown to be otherwise.

Although it is uncommon, misconduct occurs in most countries. Several causes of misconduct have been described, including pressure to publish, financial inducements, and simple vanity. Misconduct in researchers must not be tolerated and must be reported promptly. There should be a named person within the organization who is responsible for the receipt of complaints of the misconducted research [36].

In order to ensure the good practices for emergency clinical trials, an IRB was established. The IRB was created to maintain ethical standards of practice in research, to protect subjects of research from harm, to preserve the subjects' rights and to provide reassurance to the public that this is being done. It is not intended to impede good research but facilitate it, approving studies of good quality, not badly planned or poorly designed protocols. The IRB has numerous protection responsibilities that include initial and continuing review of the study protocol and related documents, review of the documentation of informed consent, and review of reports of unanticipated problems and of adverse events [37].

In emergency clinical research the IRB will make an assessment of the risks and benefits represented by the proposal, taking into account the likelihood and severity of any risk to subjects and patients and weighing this against the potential for benefit. IRBs should ensure that a monitoring plan exists for each individual study site and that there is a data-monitoring program for multisite studies. Second, the IRB should certify investigators' understanding of compliance with regulations governing the subjects' safety during the trial, including adverse reaction reporting and the collection of relevant study documents. Finally, the IRB should review the safety monitoring board reports and query investigators as needed to determine whether additional safeguards are necessary [38]. These recommendations seem reasonable because the structure and function of IRBs would enable them to perform these roles better than the other entities involved in the monitoring of clinical trials. In addition, the suggested roles would add an efficient framework to the role that IRBs can play in the safety monitoring of human subjects [39].

#### **10.4.3.1 Informed Consent**

"Informed consent" means the knowledgeable consent of an individual, or his or her legally authorized representative, who is able to exercise free power of choice without undue inducement or any form of force, fraud, deceit, duress, or other form of constraint or coercion. This document will be used with subjects or their legally

authorized representatives in feasible situations. The information in the consent document will be also used when providing an opportunity for a family member to object to a subject's participation in the clinical investigation.

One of the most important ethical dilemmas in emergency department research is the difficulty of obtaining genuine informed consent from research subjects [40]. Patients with life and death emergencies such as those with head injuries and impaired consciousness are unable to give informed consent to participate in clinical trials. Nevertheless, controlled clinical trials are essential in such situations to identify effective ways to prevent death and long-term disability.

On the other hand, emergency department research on new treatments for cardiopulmonary arrest, neurologic emergencies, and major trauma is challenging, controversial, and necessary [41]. The critical nature of the illness requires immediate treatment; emergency medicine research often takes place when patients are in distress or even unconscious, making a thoughtful discussion of risks and benefits impossible. This would particularly affect vulnerable people exposed to acute, life-threatening conditions where available treatments are unproved or unsatisfactory, and the collection of valid scientific evidence, which may include evidence obtained through randomized, placebo-controlled investigations, is necessary to determine the safety and efficacy of particular interventions [42].

Randomized, controlled trials should be designated as minimal risk, allowing IRBs to approve their conduct with a waiver of informed consent if obtaining it is not feasible. These clinical situations are: the patients will not be able to give informed consent as a result of their medical condition; the intervention involved in the research must be administered before consent from the subjects' legally authorized representatives is feasible; or there is no reasonable way to identify prospectively the individuals likely to become eligible for participation in the research [43].

In these clinical trials the potential sources of risk that must be considered are physical risk from study treatments, the loss of individualized care, risk from non-therapeutic components of the research protocol, and the psychological impact of participation. The risks of research participation should be considered in comparison with the risk of nonparticipation; for example, the risks specific to research participation should be considered separately from the risks inherent to the treatment of the potential research participant's underlying condition. Therefore the risk–potential benefit balance for every arm of the study is at least as favorable as the risk–potential benefit balance for any therapy available outside of the research protocol. Moreover, participation in the study does not present added medical risk above the risk inherent to the research participant's underlying condition. The incremental risk of such a clinical trial would not exceed the threshold of minimal risk [44].

Participation in an randomized, controlled trial carried out without the waiver from informed consent requirements may pose no more than minimal risk when:

- Genuine clinical equipoise exists [45].
- All of the treatment options included in the research study fall within the current standard of care.
- There is no currently available treatment with a more favorable risk–benefit profile than the treatments included in the study.

- The nontherapeutic components of the research are safely under the minimal risk threshold.
- Research protocol provides sufficient latitude for treating physicians to individualize care when appropriate.

Moreover, it is very important to consider the potential negative psychological impact for research participants or their families in risk assessment [46]. However, a patient involved in a research protocol that has been reviewed for scientific and ethical quality is more protected than the one who receives an unproved treatment at the discretion of a provider who believes that it may help. Abboud et al. [47] reported that some patients in the emergency department would prefer to receive an unproved, potentially helpful drug if they were in cardiac arrest, neurologic emergencies, or major trauma, but a much smaller proportion would participate in a randomized trial comparing a new drug with a placebo. Patients were also less willing to participate in studies that evaluated highly invasive interventions [47].

In 1996, the FDA regulations were revised to include the report 21 CFR 50.24, which allows for an exception from informed consent requirements for a very limited class of research in emergency settings [19].

In this regard, European Union 2001/20/EC directive is a cornerstone of a Europe-wide harmonization of the provisions governing clinical trials and can be expected to foster and facilitate multinational clinical research. Article 5 outlines the conditions for research in incapacitated patients unable to give informed consent. The article, however, is framed to address the needs of individuals who are incapacitated for long periods, many even permanently [48].

A clinical trial can only be done if informed consent of the legal representative has been obtained. The directive may not only affect unconscious people. Patients with acute myocardial infarction have been enrolled in clinical trials so far. Many of these have severe pain on admission and receive treatment with opiates: Can they give informed consent, particularly those with cardiogenic shock. Research in the acute care setting is already difficult and this directive will make it even more difficult [49].

Both, the U.S. federal regulations of 1996 [19] and the 2001 European Union directive combined have resulted in an extremely limited number of emergency research studies that have been completed or are ongoing under an exception from informed consent [50].

On the other hand, poor readability of informed consent forms has been a persistent problem in clinical research. The low educational attainments of many patients with mental illness might suggest a still greater problem in emergency room settings. This problem is even worse in emergency department setting due to the stress of the patient, the severity of illness, or even the conscious level of the patient. This fact not only affects the patient but also his or her family. In most cases, a considerable level of education, consciousness, and calmness is necessary to understand the informed consent documents used to enroll subjects in emergency medicine research. Mader and Playe [51] reported that the length and complexity of the consent forms increased as risk to the subject increased. In conclusion, informed consent documents used in emergency medicine research may be too complex for the average patient to understand [51].

Hence, it is desirable to design a consent form to meet all of the regulatory requirements while maintaining a level of reading comprehension suitable for the general population. This is a difficult task for investigators, methods of reducing the complexity of forms, as part of improving the overall consent process, are much needed. IRBs are charged with safeguarding potential research subjects with limited literacy but may have an inadvertent role in promulgating unreadable consent forms [52].

#### 10.4.4 TYPES OF CLINICAL TRIALS IN EMERGENCY DEPARTMENTS

In this section, we describe the most common randomized clinical trials carried out in emergency medicine. Diseases with an acute process and high morbidity and mortality are prime candidates to develop research in the emergency department. Observational studies provide useful but potentially biased information about the effect of interventions. Because of their ability to deal with bias, randomized clinical trials are the optimum vehicle to obtain a true estimate of the effect of interventions, including emergency research.

We have selected those randomized clinical trials that include patients suffering from cardiovascular alterations or central nervous system affections conducted in the emergency department.

##### 10.4.4.1 Cardiovascular Alterations

**Atrial Fibrillation** Atrial fibrillation is the most prevalent arrhythmia in hospital emergency departments and is a serious disease associated with a high mortality rate. However, the management of atrial fibrillation in this scenario is variable and frequently inadequate. Some randomized controlled trial involved patients diagnosed as having atrial fibrillation in the emergency department, and their main objective was to compare drugs strategies.

Dermican et al. [53] compared the effectiveness of intravenous diltiazem and metoprolol in the management of rapid ventricular rate in atrial fibrillation. Forty patients met the inclusion criteria. All the enrolled patients received information about the study and signed written informed consent. The authors concluded that diltiazem and metoprolol were safe and effective for the management of rapid ventricular rate in atrial fibrillation. However, they concluded that diltiazem allowed patients to recover the rate of control effect earlier and that the percentage of ventricular rate decrease was higher than with metoprolol [53].

Another example was published by Davey and Teubner [54] who conducted a prospective, randomized, double-blind, placebo-controlled trial in an adult emergency department, enrolling patients suffering from rapid atrial fibrillation, to examine the safety and efficacy of magnesium sulfate infusion, in addition to usual care, for acute rate reduction in patients with atrial fibrillation, and a rapid ventricular response rate. In all 199 patients were randomized, 102 received magnesium sulfate and 97 received placebo. The trial results showed that the addition of magnesium sulfate to standard rate reduction therapies enhances rate reduction and conversion to sinus rhythm in patients with rapid atrial fibrillation [54].

Thomas et al. [55] carried out a study to assess the efficacy and safety of rapid high-dose intravenous infusions of amiodarone and sotalol for heart rate control and rapid reversion to sinus rhythm in patients who came to the emergency department with recent-onset symptomatic atrial fibrillation. One hundred and forty patients gave informed consent and were randomized. They received 1.5 mg/kg of sotalol infused in 10 minutes, 10 mg/kg of amiodarone in 30 minutes, or 500 µg of digoxin in 20 minutes. Electrical cardioversion was attempted for patients who did not convert to sinus rhythm within 12 hours. This clinical trial provided evidence that the rapid infusion of sotalol or amiodarone in patients with symptomatic recent-onset atrial fibrillation results in rapid control of ventricular rate. Even with high-dose rapid infusions, all 3 agents are associated with a poor overall reversion rate within 12 hours. Almost all patients were returned to sinus rhythm with the combination of pharmacological therapy and electrical cardioversion [55].

Kim et al. [56] performed a prospective, randomized pilot study of a traditional approach of hospital admission versus an accelerated emergency-department-based strategy with low-molecular-weight heparin and early cardioversion to sinus rhythm, in a cohort of patients with uncomplicated atrial fibrillation of a single university hospital. The primary endpoints were length of stay and total actual direct costs. Eighteen patients were randomized over a 15-month period. The new strategy resulted in a shorter length of stay at potentially lower cost [56].

This kind of assays has to be conducted in a very short period of time, therefore, it is extremely important to design them very accurately and control very sharply their follow-up in order to satisfy the proposed objectives. Especially, the protocol assay and patient recruitment and informed consent have to be strictly defined before starting the clinical trial.

**Myocardial Infarction** Advances in the treatment of myocardial infarction such as coronary care units, patient education, improved emergency response systems, and reperfusion therapy has reduced mortality. Thus, trials using mortality alone as an endpoint may no longer be feasible even in survivors of a heart attack, unless a very high risk group is studied. This has led to increased use of combination endpoints, such as cardiovascular mortality plus nonfatal myocardial infarction. Development of randomized clinical trials for management of ST-elevation myocardial infarction developed by a community-based emergency medical service, emergency department, or cardiovascular service is recommended.

Moreover, due to the involvement of numerous medical services in clinical trials, there are many types of clinical trials concerning different therapeutic approaches for the treatment of acute myocardial infarction [57]. To identify the characteristics of these assays, we have selected a study carried out to explore the effect of treating with glycoprotein IIb/IIIa receptor antagonist patients suffering from thrombolysis ST-segment elevation myocardial infarction, as an example of acute myocardial infarction clinical trials in the emergency environment design.

**Thrombolysis ST-Segment Elevation Myocardial Infarction** The importance of the dissolution and prevention of thrombosis in treating patients with ST-segment elevation myocardial infarction has motivated the development of novel therapies targeting platelet aggregation and thrombus formation [58].

Several randomized clinical trials have been developed in the emergency setting using glycoprotein IIb/IIIa receptor antagonists.

Abciximab is an antibody fragment that dose-dependently inhibits platelet aggregation and leukocyte adhesion by binding to the glycoprotein (GP) IIb/IIIa, vitronectin, and Mac-1 receptors [59]. The beneficial effects of using abciximab with stent placement in patients with acute MI compared to stent alone were demonstrated in the double-blind ADMIRAL study [60]. Three hundred patients with acute myocardial infarction were enrolled in a double-blind fashion either to abciximab plus stenting (149 patients) or placebo plus stenting (151 patients) before they underwent coronary angiography. The ethics review board of the Pitié-Salpêtrière Hospital approved the protocol, and the study was conducted in accordance with the Declaration of Helsinki. Signed informed consent was obtained from the patients. Clinical outcomes were evaluated 30 days and 6 months after the procedure. The angiographic patency of the infarct-related vessel and the left ventricular ejection fraction were evaluated at 24 hours and 6 months. The results of the trial reported that compared with placebo, early administration of abciximab in patients with acute myocardial infarction improves coronary patency before stenting, as well as the success rate of the stenting procedure, the rate of coronary patency at 6 months, left ventricular function, and clinical outcomes [60].

The large CADILLAC study randomly assigned 2082 patients with acute myocardial infarction to undergo PTCA alone (518 patients), PTCA plus abciximab therapy (528), stenting alone with the MultiLink stent (512), or stenting plus abciximab therapy (524), using a 2-by-2 factorial design [61]. The study was approved by the institutional review board or ethics committee at each participating center, and consecutive, eligible patients provided signed informed consent. In this study, both primary objectives were met; stenting alone was superior to percutaneous transluminal coronary angioplasty, and stenting alone was not inferior to percutaneous transluminal coronary angioplasty plus abciximab [61].

In this regard, a recent meta-analysis of eight randomized trials conducted on abciximab as adjunctive therapy to mechanical revascularization for ST-elevation myocardial infarction showed that abciximab, as adjunctive therapy to both primary angioplasty and fibrinolytic therapy for STEMI, is associated with a significant reduction in short-term reinfarction rate, whereas the benefits in reducing mortality are observed only in association with primary angioplasty [62]. Abciximab is not associated with an increased risk of intracranial hemorrhage (except in combination with fibrinolysis in elderly patients), whereas a higher risk of major bleeding complications is observed only in association with fibrinolysis [62].

Eptifibatide is an intravenously administered glycoprotein IIb/IIIa receptor antagonist that acts at the final step of the platelet aggregation pathway. Two clinical trials showed that concomitant administration of eptifibatide in patients undergoing elective PCI reduced thrombotic complications [63]. One of them was the IMPACT-II (Integrilin to Minimize Platelet Aggregation and Prevent Coronary Thrombosis II), a multicenter, double-blind, placebo-controlled trial, enrolling 4010 patients undergoing elective, urgent, or emergency coronary intervention. Patients were assigned one of three treatments: placebo ( $n = 1328$ ), a bolus of 135  $\mu\text{g/kg}$  eptifibatide followed by an infusion of 0.5  $\mu\text{g/kg/min}$  for 20–24 hours ( $n = 1349$ ), or 135  $\mu\text{g/kg}$  eptifibatide bolus with a 0.75- $\mu\text{g/kg/min}$  infusion ( $n = 1333$ ). All patients provided informed consent. Their results showed that the treatment strategy with eptifibatide

135/0.5 reduced rates of early abrupt closure and ischemic events at 30 days [63]. The other study was the ESPRIT (Enhanced Suppression of the Platelet IIb/IIIa Receptor with Integrilin Therapy), which is a randomized, placebo-controlled trial to assess whether a novel, double-bolus dose of eptifibatide could improve outcomes of patients undergoing coronary stenting. A total of 2064 patients undergoing stent implantation in a native coronary artery were enrolled. Immediately before percutaneous coronary intervention, patients were randomly allocated to receive eptifibatide, given as two 180 µg/kg boluses 10 minutes apart and a continuous infusion of 2.0 µg/kg/min for 18–24 hours, or placebo, in addition to aspirin, heparin, and a thienopyridine. The protocol was approved by each of the respective institutional review boards, and informed consent was obtained from all patients. The authors concluded that routine glycoprotein IIb/IIIa inhibitor pretreatment with eptifibatide substantially reduces ischemic complications in coronary stent intervention and is better than a strategy of reserving treatment to the bailout situation [64].

Moreover, the PURSUIT (Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) trial, which included 10,948 patients with non-ST-elevation acute coronary syndromes, tested the hypothesis that inhibition of platelet aggregation with eptifibatide would have an incremental benefit, beyond that of heparin and aspirin, in reducing the frequency of adverse outcomes. Patients with ischemic chest pain within the previous 24 hours and who had either electrocardiographic changes indicative of ischemia (but not persistent ST-segment elevation) or high serum concentrations of creatine kinase MB isoenzymes were enrolled in the study. They were randomly assigned, in a double-blind manner, to receive a bolus and infusion of either eptifibatide or placebo, in addition to standard therapy, for up to 72 hours (or up to 96 hours if coronary intervention was performed near the end of the 72-hour period). Because this was the first large-scale study using higher doses of eptifibatide than those previously used, it was specified in the protocol that the study would be stopped for the lower-dose group after the independent data safety and monitoring committee had conducted an interim review of safety data, provided the higher dose had an acceptable safety profile. After 3218 patients had been randomly assigned to treatment groups, the committee recommended dropping the lower dose. Eptifibatide significantly reduced the primary endpoint of death and nonfatal myocardial infarction at 30 days compared with placebo [65]. Studies are now evaluating eptifibatide in high-risk patients with non-ST-elevation acute coronary syndromes (NSTEMI-ACS) and a planned early invasive strategy in the EARLY-ACS (Eptifibatide Administration prior to Diagnostic Catheterization and Revascularization to Limit Myocardial Necrosis in Acute Coronary Syndrome) trial and in patients with primary PCI for STEMI in comparison to abciximab in the Eptifibatide versus Abciximab in Primary PCI for Acute Myocardial Infarction trial. After the completion of these trials, the value of eptifibatide in patients undergoing PCI in different indications could be determined based on the evidence thanks to the trials carried out [66].

Tirofiban is a small, synthetic nonpeptide, competitive GP IIb/IIIa antagonist with high specificity and high affinity for the GP IIb/IIIa receptor.

Multicenter phase III open-label, multinational investigator-driven clinical trial of single high-bolus dose tirofiban versus abciximab and sirolimus-eluting versus bare metal stent in acute myocardial infarction was performed. The objective of the study

was to evaluate, with a 2-by-2 factorial design, the safety/efficacy profile of 4 interventional strategies of reperfusion: tirofiban given at high-bolus dose (bolus of 25 µg/kg over 3 minutes), followed by an infusion of 0.15 µg/kg/min for 18–24 hours versus abciximab and sirolimus-eluting stent, as compared to bare-metal stent implantation in primary percutaneous coronary intervention. In a head-to-head comparison, tirofiban 10-µg/kg bolus followed by a 0.15-µg/kg/min infusion was found to be inferior to the standard dose of abciximab in patients undergoing percutaneous coronary intervention. Insufficient platelet inhibition with low-dose tirofiban may likely explain these results. Subsequently, a high-bolus dose of tirofiban followed by standard infusion was tested and evidence suggests that in this dosing tirofiban may be as effective as abciximab and have a comparable safety profile [67].

In conclusion, glycoprotein IIb/IIIa receptor antagonists inhibit the binding of ligands to activated platelet GP IIb/IIIa receptors and, therefore, prevent the formation of platelet thrombi. Glycoprotein IIb/IIIa inhibition to PCI for treatment of STEMI has substantially lowered the incidence of recurrent ischemic events and has improved early survival.

#### 10.4.4.2 Central Nervous System

Clinical research involving patients with neurologic emergencies has increased in the emergency department. We have highlighted randomized clinical trials studying therapeutic treatments for stroke.

**Stroke** The National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Study was a randomized, double-blind trial of intravenous recombinant tissue plasminogen activator (t-PA) for ischemic stroke, when treatment was begun within 3 hours of the onset of stroke. The trial was divided in two parts: Part 1 (in which 291 patients were enrolled) tested whether t-PA had clinical activity, as indicated by an improvement of 4 points over baseline values in the score of the National Institutes of Health stroke scale (NIHSS) or the resolution of the neurological deficit within 24 hours of the onset of stroke. Part 2 (in which 333 patients were enrolled) used a global statistic test to assess clinical outcome at 3 months, according to scores on the Barthel index, modified Rankin scale, Glasgow outcome scale, and NIHSS. Informed consent was obtained for all patients. This study showed that treatment with intravenous t-PA within 3 hours of the onset of ischemic stroke improved clinical outcome at 3 months, despite an increased incidence of symptomatic intracerebral hemorrhage [68].

Randomized double-blind placebo-controlled trial of thrombolytic therapy with intravenous alteplase in acute ischemic stroke (ECASS II) has assessed the safety and efficacy of intravenous thrombolysis with alteplase (0.9 mg/kg body weight) within 6 hours of stroke onset. The trial protocol was reviewed and approved by local independent ethics committees or institutional review boards according to the regulatory requirements of the participating country, and carried out in accordance with the ethical principles of the Declaration of Helsinki. Informed consent was obtained from each patient (or from his or her legally authorized representative) before enrollment in the study. The results do not confirmed a statistical benefit for alteplase. The trend toward efficacy should be interpreted in the light of evidence from previous trials. Despite the increased risk of intracranial hemorrhage,

thrombolysis with alteplase at a dose of 0.9 mg/kg in selected patients may lead to a clinically relevant improvement in outcome [69].

The ATLANTIS study was a randomized controlled trial whose objective was to test the efficacy and safety of rt-PA in patients with acute ischemic stroke when administered between 3 and 5 hours after symptom onset. Its current approved use is limited to within 3 hours of symptom onset, which restricts a lot the number of patients who can be treated, since most stroke patients present more than 3 hours after symptom onset. This study found no significant rt-PA benefit on the 90-day efficacy endpoints in patients treated between 3 and 5 hours. All patients or their legal representatives signed an informed consent, which was previously approved by the correspondent institutional review board [70]. The risk of symptomatic ICH increased with rt-PA treatment. These results do not support the use of intravenous rt-PA for stroke treatment beyond 3 hours [70].

Hacke et al. [71] performed a meta-analysis of the recent large stroke trials, including NINDS [68], ECASS [69], and ATLANTIS [70] in order to draw conclusions about the best use of tissue plasminogen activator (t-PA) for ischemic stroke [71]. This study demonstrates that onset to treatment time is critically associated with improved functional outcome [71].

As opposed to the post hoc analysis of the NINDS trial, where an effect of time was not found in the prespecified analysis of the 90- and 180-minute groups, this larger meta-analysis sample nicely demonstrates a greater likelihood of good outcome, OR 2.8, for treatment in the 0- to 90-minute time frame versus OR of 1.6 and 1.4 for the 90- to 180- and 180- to 270-minute time frame. Interestingly, time from symptom onset did not influence the likelihood for hemorrhage conversion. The meta-analysis solidifies the rationale for the investment of significant public health effort in the development of emergency medicine service and hospital-based teams to treat stroke rapidly [72].

A study to investigate the feasibility and safety of a combined intravenous and intra-arterial approach to recanalization for ischemic stroke has been recently performed: 81 subjects with a baseline NIHSS  $\geq 10$  were enrolled. The median time to initiation of intravenous rt-PA was 142 minutes as compared with 108 minutes for placebo and 90 minutes for rt-PA-treated subjects in the NINDS rt-PA Stroke Trial ( $p < 0.0001$ ) [73]. The 3-month mortality in IMS II subjects was 16% as compared with the mortality of placebo (24%) and rt-PA-treated subjects (21%) in the NINDS rt-PA stroke trial. The rate of symptomatic intracerebral hemorrhage in IMS II subjects (9.9%) was not significantly different than that for rt-PA-treated subjects in the NINDS t-PA stroke trial (6.6%). IMS II subjects had significantly better outcomes at 3 months than NINDS placebo-treated subjects for all endpoints (OR  $\geq 2.7$ ) and better outcomes than NINDS rt-PA-treated subjects as measured by the Barthel index and global test statistic [73].

#### 10.4.4.3 Sepsis

Several studies have demonstrated the importance of early and adequate antimicrobial therapy in reducing the mortality and morbidity of patients with severe sepsis. About 6 to approximately 17% of empirical antibiotic selection were judged to be inappropriate according to subsequent microbiology and higher antimicrobial susceptibility as a result. It reflects the diversity in the presentations of infectious

diseases and the limited microbiological reports available from the first-line emergency physicians. Timely diagnosis and selection of appropriate antibiotics/treatment in the treatment of those patients is a challenge for an emergency physician more than ever before.

Rivers et al. [74] performed a prospective, randomized study to evaluate if the efficiency of early goal-directed therapy before admission to the intensive care unit effectively reduces the incidence of multiorgan dysfunction, mortality, and the use of health care resources among patients with severe sepsis or septic shock. This study was approved by the institutional review board for human research and was conducted under the auspices of an independent safety, efficacy, and data-monitoring committee: 263 patients were enrolled, 130 were randomly assigned to early goal-directed therapy and 133 to standard therapy. The result of the trial showed that hospital mortality was 30.5% in the group assigned to early goal-directed therapy, as compared with 46.5% mortality in the group assigned to standard therapy. Furthermore, mean APACHE II scores were significantly lower, indicating less severe organ dysfunction, in the patients assigned to early goal-directed therapy than in those assigned to standard therapy. The authors concluded that early goal-directed therapy provides significant benefits with respect to outcome in patients with severe sepsis and septic shock [74].

Another study tested the hypothesis that in the setting of undifferentiated symptomatic hypotension, the presence of hyperdynamic left ventricular function (LVF) on focused ED echocardiography would be a specific finding for sepsis as the etiology of shock [75]. This clinical trial was preplanned as a secondary analysis of 184 patients enrolled in a randomized clinical trial to investigate the role of an ultrasound protocol in evaluating the etiology of undifferentiated hypotension in the emergency department. Written informed consent was obtained from all patients. A final diagnosis of septic shock was made in 38% (39/103) of patients. Of 103 patients 17 had hyperdynamic LVF with an interobserver agreement of  $\kappa = 0.8$ . Hyperdynamic LVF had a positive likelihood ratio of 5.3 for the diagnosis of sepsis and was a strong independent predictor of sepsis as the final diagnosis with an odds ratio of 5.5 [95% confidence index (CI) 1.1–45] [75]. They conclude that among emergency department patients with nontraumatic undifferentiated symptomatic hypotension, the presence of hyperdynamic LVF on focused echo is highly specific for sepsis as the etiology of shock [75].

Drotrecogin alfa (activated), or recombinant human activated protein C, produced dose-dependent reductions in the levels of markers of coagulation and inflammation in patients with severe sepsis [76]. PROWESS, a randomized, double-blind, placebo-controlled, multicenter trial, was conducted to evaluate whether treatment with drotrecogin alfa activated reduced the rate of death from any cause among patients with severe sepsis. The institutional review board at each center approved the protocol, and written informed consent was obtained from all participants or their authorized representatives. A total of 1690 randomized patients were treated (840 in the placebo group and 850 in the drotrecogin alfa activated group). The mortality rate was 30.8% in the placebo group and 24.7% in the drotrecogin alfa activated group. However, the incidence of serious bleeding was higher in the drotrecogin alfa activated group than in the placebo group [77]. More studies are required to evaluate the possible beneficial effect of this drug. In this regard, Vincent et al. [78] performed the ENHANCE trial, a multiple-country, single-arm, open-label, trial in

order to provide further evidence for the efficacy and safety of drotrecogin alfa (activated) treatment in severe sepsis. Patients with known or suspected infection, three or four systemic inflammatory response syndrome criteria, and one or more sepsis-induced organ dysfunctions were recruited: 2434 adults entered, 2378 received drotrecogin alfa (activated), and of these, 2375 completed the protocol. Appropriate informed consent was obtained from all patients or their legal representative. The 28-day all-cause mortality was approximately the same as in the PROWESS trial (25.3% vs. 24.7%). However, patients in ENHANCE had increased serious bleeding rates compared with patients in the drotrecogin alfa (activated) arm of PROWESS. Increased postinfusion bleeding suggested a higher background bleeding rate. Intracranial hemorrhage was more common in ENHANCE than PROWESS. The authors concluded that ENHANCE provides supportive evidence for the favorable benefit–risk ratio observed in PROWESS and suggests that more effective use of drotrecogin alfa (activated) might be obtained by initiating therapy earlier [78].

### 10.4.5 CONCLUSIONS

Lately some clinical trials have been conducted in emergency departments, thus showing that the emergency-department-associated difficulties can be overcome. In spite of this there is a very short time frame between the admission of the patient and his or her inclusion in the clinical trial. With a well-designed protocol and a strict follow-up of it, as well as with very delimited functions of each physician, it is feasible to conduct a clinical trial in the emergency department, of course, without forgetting to obtain previously the signed informed consent.

To sum up, few clinical trials have been developed up to now in the emergency departments due to the associated difficulties. However, when possible, they have been demonstrated to be very useful for the physicians in order to know which is the best strategy when a patient arrives at the emergency department, especially in diseases related to the cardiovascular or central nervous system. For clinical trials in the emergency department to be feasible, it is crucial to have previously the designed protocol (which has to be very precise and, of course, approved by the corresponding committees), having the informed consent (clear and strictly redacted), the physicians must be trained for the protocol to be conducted, and the infrastructures have to be adequate for conducting the specific protocol.

### **10.5.1 PREFACE AND INTRODUCTION TO EVIDENCE-BASED GASTROENTEROLOGY**

Traditionally, clinical decisions were based on experience, but sometimes experience may be misleading. We are often prone to remember the best and the worst cases of a disease. The natural course of diseases is fluctuating and humans have the capacity to recover spontaneously. The unsystematic collection of data and limitations in human processing limits the credibility of recommendations based only on experience. Accordingly, evidence-based medicine combining clinical experience with research evidence is gradually replaced by traditional experience-based

practice. Evidence-based gastroenterology involves literature searches and quality assessments to identify the most valid research. The internal validity of a trial refers to the credibility of the results and depending on its quality and risk of bias. Low-quality trials have a considerable risk of bias and low internal validity. High-quality trials with adequate bias control have a high internal validity. With a low internal validity of a trial, the assessment of its external validity becomes irrelevant because the results lack credibility. If the internal validity is adequate, assessment of the external validity is still necessary before the trial results are used in clinical practice. The external validity of clinical trials depends on the extent to which the results may be extrapolated. The external validity depends on the characteristics of patients included, treatment regimens, and the trial setting. In clinical practice, treatments are often used for larger patient groups with less strict selection criteria. The results of a trial with highly selective inclusion criteria performed at a specialized unit may, therefore, be difficult to extrapolate and use in general clinical practice.

### 10.5.2 DEFINITIONS AND CLASSIFICATION OF CLINICAL TRIALS

Research in gastroenterology deals with diseases of the digestive system, including the esophagus, stomach, intestine, liver, gallbladder, and pancreas. In clinical gastroenterology most trials assess the effects of various drugs, but interventional procedures may also be subject to clinical trials, such as efficacy and safety of endoscopic therapy and primary as well as secondary prevention. Large, high-quality randomized clinical trials and systematic reviews of several randomized clinical trials are considered the gold standard. However, the clinician often has to judge a number of clinical trials with inconsistent results and numerous methodological deficiencies. If no randomized clinical trials are available, observational studies may be considered the best available source of evidence.

### 10.5.3 OBSERVATIONAL STUDIES

The classical observational study designs are case-control studies, cohort studies, case series, and case reports. Cohort studies follow a group of patients (cohort) pro- or retrospectively. Case-control studies are based on patients with certain diseases or genetic characteristics (cases) and controls without the specific property but otherwise similar prognostic profile. Cohort studies start out with the identification of the intervention, for example, a group of patients undergoing stricturoplasty for Crohn's disease [1], whereas case-control studies initially identify a group of patients with a certain disease, for example, cases with colorectal cancer and matched controls without the disease, before attempts are made to detect the influence of intervention, for example, use of antidepressants [2]. Case series describe the outcome of a certain group of patients, for example, patients who were treated for presumed exacerbation of Crohn's disease but were subsequently found to have underlying small-bowel carcinoma [3]. Case reports describe unusual cases of individual patients with rare diseases, unusual adverse events, or treatment effects, for example, development of subfulminant hepatitis B after treatment with infliximab for Crohn's disease [4].

Prospective cohort studies are generally considered the most valid observational design. If a disease is rare, or if the course of a disease is protracted, performing a prospective cohort study may, however, not be feasible. For example, the development of cirrhosis and liver failure after infection with hepatitis B or C takes several years [5]. In that case, retrospective cohort studies or case-control studies may be considered.

Although randomized controlled trials are the gold standard for evaluation of intervention effects, this does not mean that observational studies have little or no value. However, if interventions have dramatic effects in line with penicillin for pneumonia as compared with no treatment, randomized controlled trials are not required. Observational studies may also provide important information when we are unable to perform randomized controlled trials, for example, if assessing behavior or if requiring extremely large samples of patients for the assessment of rare adverse events. In other cases, randomized trials may be unethical, for example, if the causative agent is considered potentially harmful. Furthermore, the evidence generated in observational studies may also be useful if complementary or the basis of randomized controlled trials. Although important information may sometimes be contained in observational studies, the information should only be used with due care considering the risk of biases.

One of the most important roles of observational studies lies in the postmarketing surveillance of adverse events. Rare adverse events may be difficult to detect in randomized controlled trials because very large samples are necessary. One example is terlipressin, which has been assessed for treatment of hepatorenal syndrome [6]. Today, only few randomized controlled trials have addressed this question. None of the trials detected serious adverse events. However, one case report suggested that terlipressin may be associated with worsening of cerebral hyperemia [7]. Another case report suggested that terlipressin may be associated with acute ST-segment elevation myocardial infarction [8]. Therefore, performing observational studies that are sufficiently large to detect the risk of serious adverse events seems highly important. One example is the introduction and widespread use of laparoscopic cholecystectomy in the 1990s, which was associated with a dramatic increase in the incidence of bile duct injuries [9]. Several studies have reviewed the outcomes of surgical management of bile duct injuries, but data on the current incidence of injuries are scarce. The completion of a large prospective cohort on the outcomes of laparoscopic cholecystectomy today may provide important information to patients as well as health care workers. The information may also be used in the planning of future randomized controlled trials that are considered necessary to determine whether patients fare better with or without the intervention.

Another important role for observational studies lies in the evaluation of intervention effects on long-term outcomes. The practical difficulties in maintaining long-term prospective randomized controlled trials can make the task impossible. One example of such a situation is the treatment of chronic hepatitis C with antiviral substances, for example, interferon and ribavirin [10]. Chronic hepatitis C has a protracted course. To determine whether antiviral therapy affects morbidity or mortality, patients need to be followed for decades. This may logistically be nearly impossible. Furthermore, the risk of attrition bias is considerable and increases with the duration of follow-up. Finally, the efficacy of today's recommended antiviral treatment for chronic hepatitis C (interferon or peg interferon combined with riba-

virin) may for ethical reasons be prohibitive for preserving a nontreatment control group. Several randomized controlled trials have been performed, but all have focused on biological response, that is, clearance of the hepatitis C virus RNA (ribonucleic acid) from the blood. None of these trials have established whether the demonstrated efficacy of treatment translates into a meaningful effect on clinical outcomes [10]. Therefore, we have to rely on observational studies to determine the outcome of treatment.

As previously described, a retrospective study design, which is used in some observational studies, increases the risk of bias due to factors that change with time, recall bias, and differential measurement errors [11, 12]. However, one of the most important limitations in prospective as well as retrospective observational studies lies in the risk of selection bias. In observational studies, prognostic factors determine whether patients are allocated to intervention or control groups. This is known as confounding by indication, which may lead to systematic differences between comparison groups [13]. When systematic differences exist, estimates of intervention benefits may be incorrect. It is impossible to determine the size of the effect of the differences on the estimated intervention effects, why separate evaluations of individual trials or studies are necessary. In some cases, differences may be derived from analyses comparing groups of several observational studies and randomized controlled trials. One example may be found in a systematic review on artificial and nonartificial support systems for acute and acute-on-chronic liver failure [14]. The review included observational studies as well as randomized controlled trials. Formally, the inclusion criteria used in the different studies and trials were comparable. All patients who were allocated to the control groups received comparable standard medical regimens. When the results of the individual randomized controlled trials were combined in a meta-analysis, the support systems did not appear to reduce mortality significantly compared with standard medical therapy. Although inclusion criteria and the characteristics of included patients at baseline were similar, the control group mortality rates were significantly higher in the observational studies than in the randomized controlled trials. No significant difference was found when comparing the mortality rates of patients allocated to the intervention groups. Accordingly, the observational studies found a statistically significant positive effect of the intervention as compared with the randomized controlled trials. This difference suggests that the observational studies had a skewed allocation of patients with the worst prognosis to control groups. Thus, the observational studies may have overestimated the intervention benefit. The strength of the association warrants separate evaluations in different situations, although observational studies are generally more susceptible to bias than randomized controlled trials. In a similar review, considerable differences were found between estimated intervention effects in comparisons of observational studies and randomized controlled trials [13].

Analyses of all comparisons showed that the effect estimates in the observational studies ranged from an underestimation of effect by 76% to an overestimation of effect by 160% [13]. In another methodological study, odds ratios generated by 168 observational studies and 240 randomized controlled trials within 45 different topics were compared [15]. All trials and studies were included in a meta-analysis with binary outcomes. Overall, the observational studies tended to generate larger summary odds ratios suggesting a more beneficial effect of the intervention. Bias associated with nonrandom allocation has also been analyzed in a review with

studies that compared randomized controlled trials with observational studies [16]. The review reported that nonrandom allocation was related to overestimation as well as underestimation of treatment effects. The variation in the results of observational studies was increased due to haphazard differences in case mix between groups.

Four strategies for case-mix adjustment were subsequently evaluated by generating nonrandomized studies from two large randomized controlled trials [16]. Participants were resampled according to allocated treatment, center, and period. None of the strategies adjusted adequately for bias in historical or concurrent controlled studies. Logistic regression was found to increase bias due to misclassifications and measurement errors in confounding variables as well as differences between conditional and unconditional odds ratio estimates of treatment effects.

#### 10.5.4 RANDOMIZED CONTROLLED TRIALS

Random allocation means that all patients have a known chance of being allocated to one of the intervention groups and that the allocation of the next patient is unpredictable [17]. To keep the allocation of patients unpredictable, both adequate generation of an allocation sequence and adequate concealment of allocation are required. The allocation sequence may consist of random numbers generated by computers or tables. Allocation concealment may consist of randomization through independent centers or serially numbered identical sealed packages. If the next assignment is known, enrollment of certain patients may be prevented or delayed to ensure that they receive the treatment that is believed to be superior. Theoretically, serially numbered sealed envelopes may provide adequate allocation concealment, although there is some evidence suggesting that this may not be true. In some cases, envelopes were opened before or after patients were excluded [18]. In other cases envelopes have been transilluminated [19]. The adequacy of using serially numbered sealed envelopes therefore seems debatable.

In theory, adequate randomization is necessary to obtain adequate control of bias. On the other hand, empirical evidence is necessary to determine whether the effect of randomization is only hypothetical or whether randomization affects the results and subsequently the conclusions drawn from randomized controlled trials. To address this question, two methodological studies of cohorts of clinical trials estimated the association between the methods of randomization and the effects of intervention [20, 21]. All trials were included in meta-analyses. One study included trials from the field of obstetrics and gynecology [20] and one included trials from a variety of disease areas [21]. Neither of the studies revealed a significant association between allocation sequence generation and intervention effects, but both showed that allocation concealment methods were significantly associated with estimated intervention effects. The analyses made in both methodological studies illustrated that inadequate allocation concealment was associated with significantly more positive estimates of intervention effects. These results suggest that inadequate allocation concealment may lead to exaggerated intervention effects. On the other hand, the results may also show bias due to selective publication of small or low-quality trials with positive results [22, 23]. Because there is no defined gold standard, it may be difficult to determine whether the trials with or the trials without

adequate allocation concealment were more correct. To address these concerns, a subsequent study used very large randomized controlled trials as a reference group [24]. The reference group included randomized controlled trials with more than 1000 participants. Each of the included trials, that is, the trials in the reference group and the smaller trials, were included in the meta-analyses. Each meta-analysis contained at least one large trial. Subsequently, analyses were performed to compare the results of trials in the reference groups with the results of the smaller trials. The analyses showed that, on average, the small trials without adequate allocation sequence generation or allocation concealment overestimated intervention benefits. The results of the small trials with adequate generation of the allocation sequence or adequate allocation concealment were not significantly different from the results of the trials in the reference group.

These results support the importance of adequate randomization to bias control in randomized controlled trials. Similar subsequent methodological studies of randomized controlled trials have also examined the association between randomization and intervention effects [25]. The evidence generated in these studies was combined in a random effects meta-analysis including the summary results from the individual studies. The results suggested that odds ratios were about 12% more positive in trials without adequate allocation sequence generation as compared to odds ratios in trials with adequate allocation sequence generation. Therefore, trials reporting inadequate methods may overestimate intervention benefits due to inadequate bias control. Similarly, odds ratios generated in trials without adequate allocation concealment were about 21% more positive than odds ratios generated in trials with adequate allocation concealment. Both components of randomization process therefore seem to be important. However, the meta-analyses on the effect of allocation sequence generation and allocation concealment also found that there was a considerable heterogeneity between studies. The heterogeneity may be related to the disease area, the type of intervention, trial inclusion criteria, and the classification of adequate randomization in the individual methodological studies. The variation suggests that caution is required when making inferences and recommendations for assessment of bias control. Using the described components as exclusion criteria, for example, disregarding all trials without adequate allocation concealment is not justified. Simply reducing the estimated intervention effect in randomized controlled trials that do not describe adequate allocation concealment seems also problematic. Thus, the quality of individual trials and meta-analyses has to be evaluated separately.

Many trials are described as randomized without reporting randomization methods. A number of cohort studies of randomized controlled trials suggest that the proportion of trials with adequate allocation sequence generation ranges from 1 to 52% (median 37%) [25]. The proportion with adequate allocation concealment ranges from 2 to 39% (median 25%). Some of the variation may depend on the disease areas evaluated or different classifications of randomization methods in the cohort studies, or other factors [26, 27].

Whether the lack of reported randomization methods reflect the actual conduct of a published randomized controlled trial is difficult to establish. In theory, inadequate reporting may hide important flaws in the design of a trial. On the other hand, a high-quality randomized controlled trial may be overlooked because of inaccurate reporting. In a methodological study, the reported methods used for allocation

concealment were extracted from the published reports of 105 randomized controlled trials [28]. The reported allocation concealment methods in full-text publications were subsequently compared with the information on allocation concealment obtained through direct communication with the author(s). The results of the study showed that several trials had adequate allocation concealment methods that were not described in the published report [29]. Another methodological study reached a different conclusion [30]. This study compared the reported descriptions of the methods used for allocation concealment in publications and protocols of 102 randomized controlled trials. The analyses showed that most of the trials with unclear allocation concealment in the published trial reports also had unclear allocation concealment in the protocol. The evidence concerning the discrepancies between the conduct and report of randomized controlled trials is equivocal. Additional evidence is needed to clarify this question.

In 1999, an observational study including all 235 randomized controlled trials published in the journal *Hepatology* from the initiation in 1981 through August 1998 was published [31]. Only 52% of the included trials reported adequate generation of the allocation sequence. The proportion of trials reporting adequate allocation concealment was 34%. In a similar observational study of all 383 randomized clinical trials published in the journal *Gastroenterology* as original articles from 1964 to 2000 were reviewed [26]. The individual authors in all of the included publications had described the trials as being randomized. However, only 42% of the trials reported adequate generation of the allocation sequence. The proportion of trials reporting adequate allocation concealment was 39%. Unlike the study on randomized controlled trials published in *Hepatology*, the reporting quality improved significantly in the mid-1990s.

Nevertheless, both studies found that there was still room for improvement. Whether these findings were specific to these two journals was evaluated in a subsequent study including 616 hepato-biliary randomized controlled trials published from 1985 to 1996 in 12 different MEDLINE-indexed journals [27]. All trials were described as randomized by the individual authors. However, the reported generation of the allocation sequence was only described in 48% of the included trials. Fifty-two percent of the trials did not include a description of the methods used for generation of the allocation sequence. In 38% of the included trials, the allocation concealment was described adequately. In the remaining 62% of the trials, the allocation concealment was not described. A number of analyses were performed to evaluate potential predictors for adequate reporting of the randomization methods, that is, allocation sequence generation and allocation concealment. These analyses focused on the importance of funding and disease area. Based on the published reports, 47% of the trials received no external funding, 30% were funded by non-profit organizations, and 23% were funded by for-profit organizations. The proportion of trials with adequate allocation sequence generation and allocation concealment was not significantly different among trials funded by profit or nonprofit organizations. When these trials were combined and compared with the trials not reporting external funding, the analyses showed that trials with external funding were significantly more likely to report adequate generation of the allocation sequence. The proportion of trials with adequate allocation concealment was insignificantly different in the two groups. Further analyses revealed that also the proportion of trials with funding was insignificantly different within different disease areas. However,

the proportions of trials with adequate generation of the allocation sequence or adequate allocation concealment were significantly associated with the disease area. Trials dealing with interventions for some disease areas reported adequate randomization methods significantly more often than trials in other areas. Several other aspects, including the sample size and number of clinical sites, have been suggested as potential predictors of the quality of the reported randomization. However, additional studies in this area are still warranted to establish the different patterns.

### 10.5.5 BLINDING IN RANDOMIZED CONTROLLED TRIALS

In randomized controlled trials, the term *blinding* refers to keeping participants, health care providers, data collectors, outcome assessors, or data analysts unaware of the assigned intervention. Double blinding may refer to blinding of participants and health care providers, investigators, data collectors, judicial assessors, or data analysts. The specific methods used to maintain blinding in trial reports are often missing. Furthermore, many researchers disagree on the correct definition of double blinding. It is therefore recommended that, in individual trials, the term double blinding is provided with clear information about who were blinded and how the blinding was performed. Sometimes the nature of the intervention precludes double blinding, but blinded outcome assessment and data analyses are usually possible. To ensure adequate double blinding, the interventions compared must be similar. If an intervention is compared to no intervention, an identical placebo must be used. Any difference in taste, smell, or appearance may destroy blinding. One example may be found in a randomized controlled trial on the effect of nicotine gum on smoking cessation [32]. The trial compared the effect of nicotine gum versus a placebo gum. The authors tried to disguise the placebo gum by preparing wrappings, which suggested that the contents included nicotine. However, Wrigley's chewing gum was used as placebo. It seems likely, therefore, that participants correctly guessed whether they belonged to the intervention group or the control group.

Another example of a break in blinding is found in a randomized controlled trial on ascorbic acid for the common cold [33]. The trial was described as using a double-blind randomized design. Participants were employees of the National Institutes of Health. As no established effective treatment was known, a placebo containing lactulose was used to maintain blinding. However, the results of the trial turned out to be questionable because many participants tasted their capsules and guessed in which group they were.

Although there is a clear theoretical association between blinding and the control of bias, empirical evidence is required to determine the actual size and direction of the association. Six methodological studies of randomized controlled trials have analyzed the association between double blinding and intervention effects [25]. Each of the randomized controlled trials was included in meta-analyses assessing binary outcomes. Analyses were subsequently performed to compare odds ratios in randomized controlled trials with or without blinding. Two of these studies revealed that randomized controlled trials without double blinding overestimated intervention effects compared to randomized double-blind trials. The remaining four methodological studies found no significant association between blinding and estimates

of intervention benefits. To combine the empirical evidence generated in the methodological studies, a random effects meta-analysis was performed. This meta-analysis showed no significant differences between odds ratios of intervention effects in groups of double-blind trials compared to trials without double blinding. The meta-analysis did, however, reveal a considerable difference between study variation that may be related to the nature of the disease or the intervention. The meta-analyses included trials from various disease areas including cardiology, gynecology, obstetrics, psychiatry, and smoking cessation. Accordingly, the interventions assessed included diagnostic measures and drugs as well as surgical procedures. The variation may reflect that some interventions are difficult to blind. If we perform double-blind trials on, for example, drugs associated with adverse events blinding may be ineffective. The type of outcome may be equally important. Hard outcomes may be less prone to assessment bias than subjective outcomes. Therefore, trials evaluating the effect of drugs on, for example, mortality may be less susceptible to bias than trials evaluating the effect of drugs on pain. The effect of blinding is highly unpredictable, and separate analyses of the effect of blinding in individual trials and meta-analyses are warranted.

In a cohort study including 616 hepato-biliary randomized controlled trials published during 1985–1996, only 34% were double blind [27]. The proportion of double-blind trials varied significantly in different disease areas. Trials on interventions for gallstones were significantly less often double blind as compared to, for example, trials on portal hypertension. To some extent, the variation reflects that some interventions are more difficult to blind than others. One example is endoscopic procedures. Some trials have attempted to perform “sham” endoscopy, but maintaining the blinding in such cases is obviously difficult. Blinding the effect of drugs may also be difficult if there are specific characteristic effects (e.g., lowering of blood pressure and heart frequency when using  $\beta$  blockers for prevention of bleeding esophageal varices). Characteristic adverse effects associated with treatment may also cause a break in the blinding. If the maintenance of adequate blinding is questionable, it may be relevant to test the possibility of a break in blinding before performing the trial [34]. The results of such pretrial assessments may be used in the development of the final trial protocol. In some cases, we do not need empirical evidence to establish that blinding is impossible for patients or investigators, for example, when assessing endoscopic procedures or interventions such as liver support systems [14]. Trying to maintain blinding may only result in making the trial more complicated. However, it is always possible to maintain some form of blinded outcome assessment or blinded data analyses. Unfortunately, very few studies on randomized controlled trials in gastroenterology report on these aspects.

### 10.5.6 SAMPLE SIZE CALCULATIONS AND STATISTICAL POWER

Random error may occur in any direction and subsequently lead to false-positive (type I error) or false-negative results (type II error). In randomized controlled trials, the risk of random error depends on the sample size and the size of the intervention effect. The larger the sample size and the intervention effect, the smaller the risk of random error. Accordingly, small trials on interventions with moderate

effects have a substantial risk of being subject to random error and consequently to produce false-positive or false-negative conclusions. Large randomized controlled trials on the same interventions with moderate effects have a lower risk of random error than the small trials. Small trials on interventions with substantial effects have a smaller risk of generating results that lead to false-negative or false-positive conclusions than small trials on interventions with moderate intervention effects. One way to determine the risk of random error is to calculate confidence intervals or levels of statistical significance. Confidence intervals and the level of statistical significance provide an estimate of the error that may occur and thus reflect the precision of the statistical estimates. However, these estimates do not tell whether they are clinically significant or meaningful.

Confidence intervals are related to the concept of the statistical power. The larger the confidence interval, the less power a study has to detect differences between outcomes in groups of patients allocated to the intervention or the control group. Sample size calculations are required in randomized trials because inadequate statistical power can lead to false-negative results. The calculations should account for the minimum relevant treatment effect, acceptable probabilities of type I and II errors and losses to follow-up [35]. The first parameter, that is, the minimum relevant treatment effect, is adjustable and sensitive. If you reduce the relevant difference by half, four times as many patients are needed. The risk of a type I error ( $\alpha$ ) is usually set to 5% and the risk of a type II error ( $\beta$ ) is usually set to 10 or 20%. Subsequently, the statistical power ( $1 - \beta$ ) is 90 or 80%. The power of a trial reflects the risk of overlooking intervention effects. Suppose you want to perform a trial on a specific treatment, for example, a drug that reduces mortality from 40 to 20% and you set the risk of a type I error ( $\alpha$ ) to 5% and include 90 patients both in the treatment arm and the control arm, your trial will have 80% power to detect the true treatment effect. If you repeat the trial a 100 times, 20 of the trials will overlook the true treatment effect. If you evaluate the same drug, but include 45 patients in each treatment arm instead, the sample size corresponds to a power of 55%. If you repeat the trial a 100 times, 45 of your trials will overlook the true treatment effect. If you search for evidence and identify 100 randomized controlled trials, the entire sample of trials must be evaluated. Including a subgroup of trials, for example, the trials overlooking the intervention effect, means that your conclusions become incorrect. In practice, looking at larger samples of randomized controlled trials may be done through a systematic review, making a meta-analysis of the trials.

In a cohort study including all 235 randomized controlled trials published in the journal *Hepatology*, from the initiation in 1981 through August 1998, were assessed [31]. All trials dealt with hepato-biliary diseases. Only 26% of the trials reported sample size calculations. In similar cohort studies of randomized controlled trials from various disease areas, sample size calculations were only reported in 8–38% of the trials included [25]. This is unfortunate because the sample size calculations provide crucial information about the reliability of the results. If the preset sample size remains unreported, it becomes difficult to evaluate whether the planned sample size was reached or whether the trial was extended beyond the planned size or was terminated at an arbitrary time point.

Two studies evaluated statistical power in trials with statistically insignificant outcomes [36, 37]. Both studies found that most trials had insufficient power to detect clinically relevant treatment effects. The relatively small sample size of randomized

trials suggests that only a few have the recommended statistical power [25]. For example, one observational study included 383 randomized controlled trials published in the journal *Gastroenterology* [26]. On average, the randomized controlled trials included 43 patients per intervention arm (standard error of the mean was 4 patients). If you perform a trial with 45 patients per intervention arm, the trial will have a 90% power to detect a reduction in rates of mortality from 60 to 25% (if the risk of a type I error is set to 0.05). However, very few interventions have such dramatic effects. If we repeat the trial, evaluating a drug that reduces mortality rates from 60 to 40%, the statistical power of the trial will decrease to 39%. Therefore, it seems likely that a number of trials overlooked clinically important significant intervention effects. In a randomized controlled trial including patients admitted with bleeding esophageal varices, the effect of emergency sclerotherapy with sodium tetradecyl sulfate was compared with octreotide infusion [38]. The trial included only 100 patients, although the sample size calculations reported by the authors showed that a sample size of 1800 patients was required. This means that the trial had a 5% chance of demonstrating a statistically significant result, if the treatment effect estimated—also by the authors—was correct. The authors concluded that emergency sclerotherapy and octreotide infusions were equally efficacious in controlling variceal hemorrhage. The conclusion is debatable considering the low statistical power of the trial. Here it is again important to remember that absence of evidence is no evidence of absence. The fact that no significant intervention effect was identified does not mean that it does not exist. It is possible that we simply used the wrong method to look for such an effect. A number of studies have evaluated the sample size of published randomized controlled trials on hepato-biliary and other gastroenterological diseases. Similarly, the average sample size of randomized trials in clinical gastroenterology suggests that effective interventions may have been disregarded based on insufficient grounds. Much larger trials are necessary to conclude that an intervention is ineffective or that two interventions are equally effective.

Sample size calculations are required before performing randomized controlled trials because inadequate statistical power may lead to false-negative results [39]. The calculations should account for the minimum relevant treatment difference, acceptable probabilities of type I and II errors, and losses to follow-up [35, 40]. The first parameter is adjustable and sensitive. If you reduce the relevant difference by half, four times as many patients are needed. The risks of a type I error ( $\alpha$ ) is usually set to 5%. The risk of a type II error ( $\beta$ ) is usually set to 10 or 20%. The corresponding power ( $1 - \beta$ ), which indicates the risk of overlooking an effect of the intervention, is usually set to 90 or 80%. In cohort studies of randomized controlled trials, sample size calculations were reported only in 8–38% of the included trials [25]. Without having preset the sample size beforehand, the reader is unable to assess whether the planned sample size was actually reached or whether the trial was extended beyond the planned size or perhaps terminated at an arbitrary time point.

### 10.5.7 FOLLOW-UP AND ATTRITION BIAS

Adequate follow-up is essential to avoid attrition bias. Nearly all clinical trials have some missing data due to losses to follow-up, which may affect the results, because they may be related to prognostic factors [41]. Development of methods to obtain

data on patients who are lost to follow-up and to account for losses to follow-up is important. Also, to achieve an adequate or fair interpretation of the results obtained, a clear description of follow-up is essential [42]. In a study on 235 hepato-biliary randomized controlled trials, the numbers or reasons for dropouts or withdrawals were not reported [31].

Several analytical strategies for dealing with missing data have been proposed [43]. One of the most popular methods is to perform the analysis by using the intention-to-treat principle, including all originally randomized patients. The alternative strategy, which is to perform a per-protocol analysis excluding data from patients who were lost to follow-up or had other protocol deviations [43, 44]. However, there are several problems associated with the design of per-protocol analysis. If, for example, an intervention has adverse effects causing dropouts lost to follow-up, the per-protocol analysis will overestimate the benefit of intervention. In a systematic review about randomized controlled trials on interferon and ribavirin for chronic hepatitis C, several patients were lost to follow-up in the individual trials [10]. Many of the protocol deviations and losses to follow-up reflect the occurrence of adverse events related to the use of interferon and ribavirin. An analysis, accounting for all patients randomized, was therefore required to obtain a valid result. If per-protocol analyses were performed, the intervention benefit may have been overestimated, which is why intention-to-treat analysis is generally the most reliable strategy for performing the analyses in systematic reviews and randomized controlled trials.

### 10.5.8 SYSTEMATIC REVIEWS

It is debatable whether large randomized controlled trials or systematic reviews provide the best evidence when comparing different interventions. Large randomized controlled trials are often considered the most reliable sources of evidence for assessment of intervention effects. However, a number of cohort studies of hepato-biliary and gastroenterological trials suggest that many trials are too small and have inadequate bias control [26, 31, 45]. The size of the individual trials suggests that several have inadequate statistical power and are too small for identification of significant intervention benefits. One way to overcome these problems is to perform a systematic review using meta-analysis of the identified randomized controlled trials. In meta-analyses, the results of individual trials are combined in a common statistical analysis to increase the statistical power of inferences. Traditional reviews often count the number of supportive trials and choose the view receiving most votes. This may lead to false-negative conclusions if trials are underpowered. In a systematic review, a meta-analysis of 12 randomized controlled trials was performed to compare the effect of interferon with ribavirin versus interferon alone for patients with chronic active hepatitis C, who had not previously responded to antiviral therapy [10]. The primary outcome was sustained clearance of the hepatitis C virus. The sample sizes of the included trials suggested that no single trial had sufficient statistical power to detect clinically relevant differences in treatment effects, while three trials in the systematic review showed a statistically significant difference, suggesting that interferon with ribavirin was the most effective treatment for viral clearance. A narrative review, counting the number of positive and negative trials, may, therefore, reach the conclusion that no significant differences in effect can be

identified. However, when the results of the individual trials were combined in a meta-analysis, the results clearly showed that adding ribavirin to interferon significantly increased the chance of achieving a virological response.

Performing a meta-analysis has other potential advantages than increasing statistical power. The combination of several trials in a meta-analysis increases the extent to which results can be generalized. Furthermore, systematic reviews and meta-analyses make it possible to identify publication bias, or other biases, and to evaluate the risk of overestimated intervention effects due to inadequate bias control. The main disadvantage of systematic reviews is related to their observational design. Subgroup analyses in systematic reviews generally require prospective evaluation [14]. Methods for identification and selection of trials are necessary to avoid bias. If bias in the individual randomized controlled trials remains undetected [46–48], the results of the meta-analysis may be false positive. Therefore, some systematic reviews may remain inconclusive (in spite of statistically significant results) if trials with inadequate bias control are the only available. In a systematic review of randomized controlled trials, the effect of antibiotics and nonabsorbable disaccharides on the development of hepatic encephalopathy was assessed [49]. The results of the meta-analyses of trials identified and included showed that antibiotics had a significantly more positive effect on hepatic encephalopathy as compared to nonabsorbable disaccharides. However, in the included trials the quality of bias control was inadequate and it was impossible to make recommendations useful for clinical practice, although the findings were both clinically and statistically significant.

### 10.5.9 PUBLICATION BIAS AND RELATED BIASES

Observational studies have demonstrated that clinical trials with a positive outcome (i.e., demonstrating a statistically significant superiority of the intervention) are significantly more likely to be published than negative trials showing no statistically significant differences between the experimental intervention versus the placebo or other comparative intervention [22]. Such selective publication of trials is known as publication bias. The risk of publication bias is related to the sample size. Small trials with negative results tend to remain unpublished, while, for example, hepatobiliary randomized controlled trials are cited more often if the reported results show a statistically significant difference. Publication bias and related biases affect the possibility of identifying the trial. Thus, trials with positive results are more likely to be identified and included in, for example, systematic reviews and meta-analyses. Such biases may influence our inferences about intervention effects so that the benefits are overestimated. Different proposals have been made to allow identification of publication bias in meta-analyses so that the results and conclusions may be adjusted for the risk of bias.

### 10.5.10 CONCLUDING REMARKS

Evidence-based medicine—although extremely time consuming—is gradually replacing the traditional experience-based clinical practice. The number of randomized controlled trials and observational studies performed within the fields of

gastroenterology and hepatology is steadily increasing. The first step for the evidence-based practitioner is to identify the relevant clinical trial. The second step is to assess the internal validity of the research identified, and the final step is to evaluate its external validity so that the evidence may be used in clinical decision making. A number of methodological studies including clinical trials from several disease areas have been made to develop general guidelines for the validity assessment. These guidelines also apply to clinical trials in gastroenterology. Sample size calculations, randomization methods, blinding, and follow-up are important components in the maintenance of adequate bias control, which is important both in the planning stage and during subsequent interpretation of the results. The general methodology is therefore relevant, not only for researchers but also for clinicians using evidence-based medicine in daily practice. Nevertheless, a number of surveys suggest that there may be considerable gaps between evidence and practice. One such survey included specialists in gastroenterology, hepatology, and internal medicine [50]. The survey showed that several treatments and diagnostic procedures were still used, although there was no significant evidence to support their use. On the other hand, some of the treatments based on statistically and clinically relevant beneficial effects in systematic reviews of randomized controlled trials were not used. Additional measures aiming at bridging the gap between evidence and clinical practice are therefore warranted. Also a number of initiatives have been performed to improve the quality of clinical trials, for example, the Baveno conferences on trials in portal hypertension [51]. Hopefully, similar initiatives will be made in other areas of gastroenterology and hepatology to improve the quality of health care.

### **10.6.1 INTRODUCTION**

Developments in reproductive health are often low profile, but the sheer number of women with gynecological problems means that, if effective interventions exist, a massive overall health and financial benefit can be expected in the population. This chapter focuses on benign gynecology rather than gynecological oncology. Benign gynecological conditions such as chronic pelvic pain, heavy

menstrual bleeding, and subfertility may be treated with suboptimal therapies if there is not a commitment to the development of new drugs and a thorough evaluation of the relative merits of existing ones. There remains a burden of disease in women's health that could be alleviated if clinical care was built around evidence-based interventions.

Randomized control trials (RCTs) are widely accepted as a gold standard for scientific evaluation of all treatments. This is as true of gynecology as other specialties, yet there are much fewer trials in this speciality by comparison [1]. In addition to political and financial barriers to drug evaluation, there are methodological problems to be overcome. This chapter will highlight the issues regarding the design and analysis of RCTs that are pertinent to benign gynecology.

## **10.6.2 DRUG DEVELOPMENT PROCESS IN GYNECOLOGY**

The process of evaluation of new medicinal products will follow the same stepwise escalation of evaluative techniques as within other areas, but there are specific issues to consider at each phase within gynecology.

### **10.6.2.1 Phase I: Safety and Pharmacokinetics in Healthy Population**

The main difficulty for these trials is to find a "normal" population in gynecology. A large number of premenopausal women are either taking some form of hormonal contraception, so not undergoing normal menstruation, or actively trying to become pregnant, and therefore they would not want to expose themselves or their fetus to the risk of an intervention of unproven safety. Trials limited to postmenopausal women can only comment on the safety and bioavailability of that drug in that limited population.

### **10.6.2.2 Phases II and III: Efficacy and Effectiveness in Target Population**

Generally, phase II trials recruit a narrow population with the condition of interest, with no comorbidities, and compare the new intervention against placebo. There are ethical considerations regarding placebo where active, albeit not very effective, treatments exist. The acceptability of the route of administration may be of equal importance to its effect, especially if it affects compliance with a drug regime. So whereas oral contraceptives may be as efficacious as injectable alternatives, women may consider the latter preferable and more reliable.

### **10.6.2.3 Phase IV: Long-Term Safety and Effectiveness**

Interventions for some gynecological conditions, such as endometriosis, may require long-term use without a reduction in effectiveness or tolerability. Long-term follow-up of all trial patients is required to assess overall effectiveness without bias from participant withdrawal. Assessment of safety and teratogenicity may require use of systematic reviews to collate low-frequency events.

### 10.6.3 EXPECTED EFFECT SIZE AND SAMPLE SIZES OF CLINICAL TRIALS

In gynecology, it is realistic to expect small to moderate effects, even when compared to a placebo, to be clinically worthwhile. However, because the conditions are often extremely common, for example, menorrhagia or chronic pelvic pain, when aggregated over the population, even a small effect can result in a huge impact on women's quality of life and productivity. Hence trials have to be large to be able to show small differences in effect with sufficient power.

If the process of randomization is strictly performed, the two groups of an RCT should be equivalent, and then it follows that any difference in outcome should be due to chance or genuine treatment effect. This still leaves the difficulty of distinguishing what is due to chance. It is usually very easy to spot a highly successful drug in a common condition with serious outcomes such as myocardial infarction. However, this is not generally the case in gynecology, where the effect size is often moderate or small, especially when looking at pain outcomes and when the condition is chronic or self-limiting. In these cases trials need to be large. Small trials will sometime give nonsignificant results. This may be taken to mean that the treatment does not work, when in fact there were too few participants in the trial to demonstrate a small effect [2]. This is why estimates of a treatment's effectiveness are preferable to simply quoting  $p$  values, to highlight the degree of uncertainty around any estimate of effect.

For a given postulated treatment effect, the power of a trial is the probability that a significant result will be obtained in the trial, if the treatment effect is as predicted. Given the expense and immense effort, it becomes unacceptable in gynecology to run a trial that has only a 50, 60, or even 70% chance of spotting a genuine treatment effect. A "power" of 80% is, by convention, the minimum required to be confident of avoiding a falsely negative result and 90% power is preferred. Increasing the power of the trial to detect a difference means increasing the sample size. For example, if the number of women in a particular group with dysmenorrhea who eventually opt for a hysterectomy is 50%, in order to have a 90% chance of detecting whether a new treatment reduces this proportion by half, to 25%, a trial would need to recruit 150 women, whereas at 80% power, it would require 117 women. Unfortunately, intervention in gynecology is seldom that effective.

When anticipating the treatment effect, and hence estimating the sample size, one should consider what the minimum clinically important difference between the two treatments might be, or in other words, the degree of improvement that would lead to a change in the clinician behavior or acceptance by women. For example, if a 25% proportional increase in fertilization rate is considered beneficial and there is a 70% failure rate (or 30% fertilization rate), then to demonstrate this effect with a new therapy, such as low-dose aspirin, would require 256 women to achieve a 53% failure rate, as shown in Table 1. Note that this is not the same as reducing the failure rate by 25 percentage points from 70 to 45%, a proportionally much bigger drop requiring about 132 women. In a high prevalence condition such as dysmenorrhea [3], a reduction from 50% opting for hysterectomy to 45% would still be worthwhile, but would require over 4000 women and hence suddenly a very large trial, requiring an immense effort to complete.

**TABLE 1 Sample Sizes for a Range of Differences between Control and Experimental Arm Rates**

| Control Arm Rate | Proportional Reduction of Rate <sup>a</sup> |             |                       |             |                       |             |
|------------------|---------------------------------------------|-------------|-----------------------|-------------|-----------------------|-------------|
|                  | 50%                                         |             | 33%                   |             | 25%                   |             |
|                  | Experimental Arm Rate                       | Sample Size | Experimental Arm Rate | Sample Size | Experimental Arm Rate | Sample Size |
| 0.80             | 0.40                                        | 46          | 0.53                  | 94          | 0.60                  | 164         |
| 0.70             | 0.35                                        | 62          | 0.46                  | 132         | 0.53                  | 256         |
| 0.60             | 0.30                                        | 84          | 0.40                  | 194         | 0.45                  | 346         |
| 0.50             | 0.25                                        | 116         | 0.33                  | 262         | 0.375                 | 494         |
| 0.40             | 0.20                                        | 164         | 0.26                  | 390         | 0.30                  | 712         |
| 0.30             | 0.15                                        | 242         | 0.20                  | 588         | 0.23                  | 1246        |

<sup>a</sup>Assuming 80% power.**TABLE 2 Sample Sizes for Different Standardized Effect Sizes, Assuming Two Equal Groups**

| Power | Standardized Effect Size |      |      |
|-------|--------------------------|------|------|
|       | 0.5                      | 0.33 | 0.20 |
| 80%   | 128                      | 292  | 788  |
| 90%   | 172                      | 388  | 1054 |

When considering continuous outcome measures, the sample size calculation is not based on proportions but on anticipated differences between the mean and the outcome for each group, so a slightly different approach is taken. It is generally accepted that a standardized difference of 0.2 standard deviations can be considered to be a small effect size, 0.5 a medium effect and 0.8 a large effect. As differences between treatments are unlikely to be large, and small to moderate effects can be clinically significant, it is possible to calculate sample sizes for clinical trials based on standardized effect sizes. Table 2 shows the sample sizes for various effect sizes at 80 and 90% power.

If the standard deviation of the outcome measure is known, the difference in means can be predicted too. For example, if the mean length of stay in a hospital following hysterectomy is 5.3 days and standard deviation is 1.3, and the sample size was sufficient to detect a small to moderate effect size of 0.33 standard deviations, a trial of 292 women comparing hysterectomy with uterine artery embolization would be powered to detect increase or reduction in length of stay of at least  $1.3 \times 0.33 = 0.43$  days.

One of the alternatives used to avoid very large sample sizes, especially when comparing a new with a standard intervention, is to conduct a “noninferiority” trial. Here the objective is not to demonstrate superiority, which can require large numbers, but to establish that the effect of the experimental intervention in comparison to the standard is not more than some pre-stated small difference, called a noninferiority margin. Hence here clinicians determine the amount of noninferiority they are willing to accept. With the above dysmenorrhea example, if clinicians

were prepared to accept the new intervention does not increase the rate of hysterectomy by more than 5%, then the sample size would be 2460. As the direction of effect being assessed is one sided (the experimental intervention is not inferior to the control intervention), a one-sided hypothesis test is performed. There are limitations with this method: If the experimental group performs better than the control, it cannot be concluded to be superior as the trial was not designed to test this hypothesis and sample sizes are very dependent on the margin at which one accepts noninferiority. So it is important that the noninferiority margin selected is small enough to not exceed that which has clinical relevance, and that the standard intervention is already established as superior to placebo [4].

#### 10.6.4 AVOIDANCE OF SYSTEMATIC BIASES

In order to detect moderate, but meaningful, differences between treatments, it is important that causes of bias are minimized as much as possible. Biases almost universally tend to exaggerate the true effects of a treatment [5–7]. Figure 1 demonstrates the key biases possible in a badly designed trial. The importance of a sound randomization process to avoid selection bias cannot be overemphasised. This will ensure the comparability of the treatment groups at the start of the trial. An independent telephone service or coded drug containers are appropriate randomization

**FIGURE 1** Outline of trial, its quality features that minimize the risk of bias and issues specific to trials in benign gynecology.

methods; tossing a coin, odd and even hospital identification numbers, or allocating participants in order of arrival would not be. The point is not the degree of “randomness” but the extent to which the next allocation cannot be predicted, or in other words, the ability to conceal the allocation from the clinician recruiting the patient. For concealment to be maintained, the randomization process must be indefatigable. For example, if envelopes containing the randomized allocation are used, it is possible for the researchers in this case to manipulate the order of opening of the envelopes, or even resealing opened envelopes that do not contain the preferred allocation, thereby introducing selection bias. For the trial to be concealed, the randomized allocation should be provided by a third party once all eligibility criteria have been confirmed and the participant committed to the trial.

Even the strictest randomization process can be undermined if patients do not receive the treatment to which they are allocated. Postrandomization withdrawals can be minimized by careful screening of potential patients against the eligibility criteria. However, compliance with allocations may diminish if treatment is not instigated soon after randomization. This can be a particular problem in fertility studies, where it is not unusual to randomize women at the start of a cycle, but due to many reasons the embryo transfer procedure may not be carried out in that cycle, and alternative methods are chosen for subsequent cycles [4].

Blinding should not be confused with concealment. Blinding is a method in which trials can attempt to eliminate both performance and measurement biases, by keeping participants and clinicians unaware of the treatment allocation after randomization. Performance bias can occur if there are differences in groups related to co-interventions or supportive care, making it harder to disaggregate the effect of each intervention. Should this potentially be a problem, a standardized care protocol should be agreed upon for all patients and, of course, details of other interventions recorded to detect significant deviations between the groups. Detection or measurement bias can arise if there are differences in the way outcomes are measured or interpreted. Objective measurements are less prone to measurement bias than subjective measurements but may not capture the outcome of interest.

There are different levels of blinding:

- Single blind—Usually when the patient does not know to which treatment arm she has been allocated. Gynecological surgical procedures can be blinded from the woman by use of drapes to obscure her view or sham incisions.
- Double blind—When both clinician and patient do not know which treatment is being given, as in the typical placebo-controlled trial.
- Triple blind—Neither the clinician, patient, or the person performing the outcome assessment are aware of the treatment. This is the most difficult to achieve, but potentially some gynecological assessments, for example, urodynamics, could be blinded to allocation.

Patients should always be analyzed in the group to which they were randomized in an “intention to treat” analysis, as this helps retain the benefits achieved by randomization. If, for any reason, participants move from one arm of the trial into the other, all participants must be analyzed in the group to which they were originally allocated and not in their new group. While intention to treat analysis may underestimate the true treatment effect if it is “diluted” by cross-overs, it will more closely

reflect the clinical reality outside of the trial and provide an anticipated effect of pursuing a particular treatment policy.

Attrition bias can arise if there are systematic differences in the degree of follow-up of trial participants. This can arise if a more intensive follow-up for one treatment group is built into the protocol or where there are different rates of participant dropout between the groups. This can be a particular problem in some gynecological conditions such as chronic pelvic pain, where women may decide that the treatment is ineffective and opt out of the trial to seek alternative therapies. Trials where a drug has side effects as troubling as the primary complaint will experience a high degree of noncompliance. This has been observed in a trial of the levonogestrel-releasing intrauterine system when used for heavy menstrual bleeding. The device often has an unpredictable effect on the menstrual cycle in the first 6 months of use that women decide it is preferable to have it removed than wait to see if it has a beneficial effect on their periods.

In these circumstances, every effort should be made to continue to collect follow-up data on all participants, regardless of compliance, again so that an intention to treat analysis can be performed. However, it is inevitable that some women will withdraw their consent to provide data to the trial. One solution is to perform a per-protocol analyses excluding patients with missing data from the analyses. Alternatively, imputation of missing data may be considered. Possible imputation strategies include carrying forward the last observation to the missing time point or estimating the most likely outcome, based on the outcome of other participants in the trial. If patients with missing data are mainly outliers, the precision of the effect size by per-protocol analyses may be increased. But if losses to follow-up are related to prognostic factors, side effects, or lack of response to treatment, per-protocol analyses may overestimate the treatment effects [8]. Reasons for loss to follow-up should be recorded, if possible, to determine the degree of differential loss to follow-up and to establish whether such losses are random or will bias the results.

Unfortunately, following patients through to the prespecified end of the trial is a particular problem with trials of benign gynecology, as participants tend to be otherwise healthy, not have a life-threatening condition and are relatively young and mobile. To avoid, or at least make every attempt to reduce, the number of patients lost to follow-up, multiple identifiers and contact details for participants should be taken at the start of the trial. Follow-up by postal questionnaires direct to the participants is notoriously difficult to sustain and yet is the most appropriate method of collecting quality of life information. A meta-analysis of methods of improving the response rate to postal questionnaires identified a number of useful strategies, such as contact before the questionnaire is sent, provision of a prepaid envelope, and using a short, interesting questionnaire, in addition to obvious monetary incentives—all of these should be considered at the outset of the trial [9].

### 10.6.5 CHOICE OF APPROPRIATE OUTCOME MEASURES

Unlike cancer trials, where we are interested primarily in mortality, or obstetric trials where perinatal mortality is a suitable outcome measure, in gynecology the effect of a drug is often on disease-specific symptoms. One has to decide on the most

important outcome measure to use in determining the effectiveness of a drug, that is, whether the treatment is likely to have an effect on that outcome and how the outcome is to be measured.

Ideally, the primary outcome measure should be as important to the women as to the clinician or policy maker. Examples include measuring pain on a visual analog scale for dysmenorrhea [10], assessing sexual function by means of a specific questionnaire [11] in vulvodynia, or counting days of absence from work or usual activities for premenstrual dysphoria. Use of a generic quality of life questionnaire will allow the impact of a treatment to be directly compared to other conditions but tends to focus on physical dimensions of quality of life and may not be sufficiently sensitive to respond to the changes in different aspects of life quality experienced by treating benign gynecological conditions [12]. Disease or symptom-specific quality of life questionnaires capture the more subtle features of a benign condition, particularly those that are important to the patient. The number of available instruments is increasing, but not all exhibit sound psychometric and measurement characteristics; so they should be reviewed for quality before use [13].

Although the main aim of any trial is to determine the effect of a treatment on the primary outcome measure, there are usually other pertinent criteria that are also of interest, such as sexual function or health service resource usage. While the trial sample size is calculated in order to detect a clinically meaningful difference in the primary outcome, the trial may not have sufficient power to detect significant differences in secondary measures. If one looks at too many outcomes simultaneously, it is likely that one will turn out to be statistically significant, due to the play of chance, even in a trial of an ineffective intervention. Thus primary and secondary outcomes should be defined in advance and not chosen once the analysis has been done, on the basis of statistical significance.

Another issue in gynecological research is that the outcome of interest can occur a long time in the future, for example, the ultimate need for hysterectomy. It is often impractical to wait many years to answer such questions, so an alternative is to use a surrogate outcome that predicts the future outcome of interest, for example, using a laboratory marker [14]. Intermediate outcomes are also sometimes proposed as surrogates are for low-frequency events that would otherwise require prohibitively large trials to demonstrate an effect. However, this is not a wholly satisfactory method. If surrogate outcomes are used, it is necessary to ensure that they correlate with clinically relevant measures and they capture the whole of the clinically relevant effect. Hence, ideally, any surrogate should be previously validated. Polycystic ovary syndrome (PCOS) is a common cause of infertility; so the aim of any intervention would be to increase the chance of delivering a healthy baby. Intermediate outcomes are pregnancy and ovulation rates, and there are a host of biochemical and biometric surrogates. Yet the best correlation between surrogate outcomes and the desired clinical endpoint is the correlation between ovulation and pregnancy in women with PCOS taking clomiphene citrate [15] or metformin [16]. However, factors unrelated to PCOS, including male sperm quality and maternal age, will impact on live birth rate, as demonstrated by the meta-analysis of metformin in which there was no evidence of increased clinical pregnancy rate [16].

### 10.6.6 CHOICE OF APPROPRIATE ANALYSIS

Many of the common benign gynecological conditions are chronic and lack a definitive “endpoint.” Long-term observations of continuous outcomes such as severity of pain or menstrual blood loss are required. Choosing a particular time point for analysis of outcomes may be fairly arbitrary in the course of the condition. Measures that are collected at multiple time points from each trial participant are likely to be more closely related to each other than the variation between different participants. Multilevel modeling takes into account this hierarchy of data and gives the advantage of being able to estimate overall effect over time, utilizing all available information. An overall treatment effect, with confidence intervals can be estimated from the model.

### 10.6.7 MULTICENTERED TRIALS

The design, execution, and analysis of a trial might have done all that is possible to eliminate imprecision and biases. The results in this case will be reliable and “true” for the participants studied. But will such results also be generalizable to the wider population? One way to improve generalizability, or external validity, is to recruit a wide and heterogeneous population with the condition of interest, with few exclusion criteria. Another is to recruit from many clinical centers. This approach limits the effect of the peculiarities of single-center studies that make it difficult to replicate results in other settings. Increasing the number of recruitment centers also improves the ability to accrue large numbers rapidly within trials.

### 10.6.8 META-ANALYSIS

With the multitude of problems that can arise in gynecological trials, it is imperative that new data should be considered in relation to previous trials and the impact of the results discussed [17]. The best way to achieve this is through the use of meta-analysis to add the results of the trial to those already available. The larger the amount of evidence, the less likely there is to be overemphasis on any particular trial, which can give misleading findings. Investigation of subgroup effects is often not possible from published data meta-analysis due the manner in which studies are reported. Collection of individual patient data from the primary studies to perform a meta-analysis is the most reliable method of assessing the totality of the evidence overall and within subgroups, but this requires considerable effort to organize and goodwill on behalf of the original trial authors [18].

### 10.6.9 CONCLUSION

Trials in benign gynecology typically deal with chronic conditions where there is no definite endpoint but an expectation of gradual change on a continuous outcome measure. One exception is infertility studies where the outcome is a successful

pregnancy, but even here intermediate outcomes are often chosen. Most trials require the recruitment of large numbers to evaluate small to moderate effect sizes reliably. Outcome measures need to employ clinically important measures that impact life facets important to patients. In this regard, disease-specific quality of life tools require validation. Data-analytic approaches need to employ intention to treat principles using survival analyses when outcome is time dependent (infertility) or multilevel modeling of repeated measures in chronic conditions such as chronic pelvic pain. In summary, large, multicenter trials with simple entry criteria, robust randomization, consistent execution, and appropriate analysis are required.

### **10.7.1 INTRODUCTORY REMARKS**

After a new chemical entity (NCE) has successfully passed the hurdle of the first-in-man study(ies), the pharmacokinetic (PK) and pharmacodynamic (PD) characteristics of the NCE must be fully elucidated to support drug efficacy and drug safety claims for a regulatory submission. Clinical pharmacology/biopharmaceutics components include an understanding of the drug's (1) absorption, distribution, metabolism, and excretion (ADME) profile, (2) behavior at different dosage regimens

and/or dosage forms, (3) behavior under diverse or impaired physiological conditions (special populations), (4) potential interactions with coadministered medications or herbal supplements (DDI), and (5) specific PD characteristics that may affect the efficacy and/or safety of the drug. Clinical pharmacology/biopharmaceutics studies are generally conducted in healthy subjects unless the drug is a biological response modifier and cannot be studied in healthy subjects. Exceptions are special population studies which include subjects with physiological characteristics different from the standard healthy volunteer population or typical target patient population. PD studies may be conducted in either healthy subjects or a patient population depending on the PD endpoint of interest.

This chapter focuses on the diversity of physiological effects on NCE PK in people who distinguish themselves from the average adult patient population for which the NCE is being developed. The first section of this chapter provides a definition of criteria which define a special population and general study design considerations common to all special population studies. The subsequent sections address specific objectives, design considerations, statistical analysis, data interpretation, and regulatory requirements for studies conducted in geriatrics, renal impairment (RI), hepatic impairment (HI), women, ethnic, and obese populations.

### **10.7.2 GENERAL CONSIDERATIONS FOR ALL SPECIAL POPULATION STUDIES**

Special populations encompass a wide variety of people who are physiologically different from the average patient population for which the NCE is being developed and who are frequently not enrolled in sufficient numbers in routine phases I–III clinical trials with a PK sample collection component to allow appropriate characterization of NCE PK and potential risk factors. NCE exposure information in special populations (HI, RI, geriatrics, women, and race) is required as part of the drug registration package. The PK and/or PD data will be used to justify and negotiate the dosage regimen for populations at risk and are a critical component of the drug label. Depending on the PK/PD characteristics of the NCE, dose adjustments may be required in some populations while the use of the NCE may be restricted or contraindicated in others. Potential NCE PK/PD differences have been observed as a result of:

- Physiological progression in life (e.g., pediatric, adolescent, adult, or geriatric populations)
- Lifestyle (e.g., obesity, dietary habits)
- Disease state (e.g., renal or hepatic impairment)
- Gender (males versus females)
- Race (e.g., Japanese populations)
- Genetics/genomics (e.g., poor/extensive metabolizers, differences in receptor composition/affinity resulting in differences in efficacy or adverse-event profiles)

Most formal special population studies are conducted during the later part of phase II development or in parallel with phase III when the therapeutic dose range is

known and the likelihood is high that the NCE will be submitted for registration. Trials such as RI and HI studies are conducted in a multicenter setting, have slow recruitment rates (especially in the severely impaired populations), take a long time to complete, and tend to be expensive. For this reason, they are only conducted to complete the submission package, thus satisfying labeling requirements. Some studies are conducted early(ier) in the development program to either provide data for the subsequent phase II/III program or NCE development in another regions (e.g., Japan).

Dedicated/formal PK studies are routinely conducted in geriatrics, HI, or RI, while data on other special populations may come from integrated population pharmacokinetic (PopPK) analyses of clinical data. For example, formal gender comparison studies have become less common since the U.S. Food and Drug Administration (FDA) 1993 guideline to include women as part of the phase I clinical development and the advent of PopPK approaches [1]. When the nature of the NCE limits drug administration to the intended target population, the regulatory agencies recommend to include subpopulations in the integrated phase II/III development program or to conduct a smaller dedicated “phase I-like” trial in the patient subpopulation.

Study design considerations have many similarities across the various special populations (Table 1). Drug disposition in the special population (sometimes divided further into subpopulations) is compared to that of a control population which has undergone similar study procedures. Standard inclusion and exclusion criteria apply to all special population studies with some modification for elderly, renal, and hepatic impairment populations discussed below. Safety assessments are the same as in other later stage clinical PK study and consist of standard assessments such as physical examination, clinical laboratories (hematology, coagulation, serum chemistry, and urinalysis), vital signs, 12-lead electrocardiograms (ECGs), and adverse events (AEs) plus any safety parameters specific to the NCE. The frequency of safety assessments during the study conduct tends to be held to a minimum unless significantly higher exposure is expected or the drug is known to affect vital signs or cardiac conduction. In special cases, NCE-specific PD markers [e.g., central nervous system (CNS) tests, specific laboratories such as glucose or coagulation assessments] may be evaluated more extensively in order to determine whether PD differences are observed in the population of interest and whether the PD changes are a result of changes in drug disposition.

Most formal special population studies include a control group as one arm of the study design. While special population results can be compared to historical NCE PK data obtained in separate study(ies) of similar design, there is an inherent risk that the regulatory authorities do not agree with the selection of the control study and request other (less favorable) comparisons which then become part of the drug label. The regulatory authorities request control groups to be closely matched to either the special population or the intended patient population. Environmental or behavioral aspects such as diet and smoking habits may also be considered in the selection of the control population since these factors are known to affect NCE PK. It would be difficult to design one “fit-all” control study for the various special population comparisons. Based on the author’s experience, inclusion of a control group in each special population study is the preferred approach.

Special population studies are most commonly conducted as single-dose studies assuming the NCE PK is predictive of steady-state PK. Linear PK should be extended

**TABLE 1 Typical Design Features for Special Population Studies**

| Consideration For            | Geriatrics<br>>65 years                                                       | RI                  | HI                  | Gender           | Ethnic                           |

**Note:**

*Matched:* Demographically matched to special population or indicated patient population.

*C/H:* Oral or depot contraceptives or hormonal replacement therapy; sometimes vitamins, herbal, and limited over counter medications permitted.

*Fasted:* For –10 hours to 4–5 hours postdose; (+) small snack may be required in more severely ill 1–2 hours prior to dose administration; (other) may receive other than standard meals.

*Extended:* For at least 24–48 hours beyond standard sampling times; (+) may need extension.

*Minimal:* (+) Two to three additional postdose vitals/ECG or more extensive if significant PK differences are expected.

to all analytes measured (parent drug and active/toxic metabolites). The single dose chosen can be the anticipated upper end of the therapeutic dose range, since age or disease state generally affects not  $C_{\max}$  but instead overall exposure [area under the curve (AUC)]. However, if the NCE has a narrow therapeutic window and/or a significant difference in exposure is expected, a dose in the lower to midrange of the therapeutic window may be more appropriate. For example, due to the lower body weight (WT) in the Japanese population, NCE  $C_{\max}$  may be different in addition to AUC, which may potentially require a lower dose in this population comparison.

A multiple-dose study may be required if the NCE (and/or metabolite) has either dose or time-dependent PK. Dose selection and dosing frequency should be carefully selected to avoid accumulation of the NCE and/or metabolites to unsafe levels. A dose escalation scheme may be employed to titrate to safe drug levels, or NCE PK parameters may be predicted by modeling the expected effect which the special population is thought to have on drug disposition.

Most of the special population studies, especially those following a single dose of NCE, are conducted under confinement. Subjects are screened and then return to the clinic either the day prior (preferred) or on the morning of the dose administration. Subjects are generally housed during the majority of PK sample

collections and may not be released until the study is completed (last PK sample collected). Healthy (male) volunteers are generally housed in a dormlike setting, while women and elderly tend to have a semiprivate setting. In these healthy populations it is acceptable that the study is conducted under restricted conditions and it is general practice to lock rest rooms (in the case of urine collection), limit access to water fountains, and have controlled access within the facility (e.g., to entertainment rooms). In RI and HI, subjects are managed in a hospital-like setting instead. Considering that many of the subjects are rather ill, every attempt is made to provide as much privacy and freedom (within study restrictions) to keep them comfortable.

General dietary considerations and restrictions are similar to those in any typical phase I study and should reflect the NCE requirements. In most cases, NCE PK is assessed under controlled fasted conditions (e.g., fasted for 10 hours prior to 4–5 hours following dose administration) to avoid introduction of additional variables into the study design. The RI and HI patients may require modifications to the composition of the meal (e.g., salt content) and/or permitted snacks. In a study comparing race (e.g., Japanese versus U.S. population), the content of meals may be purposefully different for the ethnic group of interest to maintain typical dietary habits as part of the factors influencing NCE PK.

The length and frequency of blood (and urine) collections depend on the expected outcome of the study. In geriatric, RI, and HI studies it is worthwhile to extend blood sampling for at least 24–48 hours beyond the sampling scheme employed in routine healthy volunteer studies, even if a minimal effect NCE PK is expected. If the special population is conducted as a multiple-dose study, the PK should be assessed both after single-dose administration and at steady state.

Special population studies are targeted to address potential “extreme” exposure conditions for the NCE which may alter levels of active/toxic metabolites relative to parent concentrations. Metabolites known to be involved in the efficacy and/or safety profile and presenting >10% of circulating parent levels should be considered for analysis. A 10% cutoff is a general guide only, since the decision to evaluate metabolites also depends on relative potency and/or the extent of protein binding of the metabolite compared to parent drug. To reduce costs associated with serial metabolite sampling, collections can be limited to three to four samples at times when the highest metabolite concentrations are expected.

Altered free drug concentrations can change NCE distribution and/or elimination, which may affect safety or efficacy. Blood samples should also be collected to assess protein binding if the NCE (and/or metabolites) are highly bound, the NCE is known to exhibit nonlinear binding, or its binding might be affected by metabolites. In most situations, protein binding is assessed in select samples encompassing the entire concentration range (e.g., around the time of maximum concentration followed by two to three more samples at representative times across the sampling period).

Pooled urine collection is of relevance when significant quantities of parent drug or metabolites are excreted into urine. If the renal elimination of NCE and metabolites is negligible, urine collections are not necessary with the exception of the RI study. Pooled urine intervals are generally collected for 0–12 and 12–24 hours postdose and in subsequent 24-hour intervals over the entire study period. More

frequent sampling during the initial elimination phase is only recommended for NCEs which are likely not quantifiable over a 12-hour collection interval.

Data are analyzed to describe the PK of the NCE and/or metabolites using either noncompartmental or compartmental methods [2]. The noncompartmental approach is simpler and potentially less subjective. Compartmental modeling approaches are useful if further simulations of the NCE PK are required. Typical PK parameters are time ( $t_{\max}$ ) to maximum concentration ( $C_{\max}$ ), area under the concentration-versus-time profile (AUC) collected over appropriate intervals, minimum concentration ( $C_{\min}$ ) over the dosing interval for multiple dose studies, NCE clearance (CL), volume parameters ( $V_d$ ), apparent terminal elimination rate constant ( $k_e$ ), and half-life ( $t_{1/2}$ ). Following a single dose, the estimation of AUC from time zero to infinity [AUC(0– $\infty$ )] should not exceed more than 20% for NCE (and 30% for metabolites) and samples should be collected sufficiently long to adequately characterize  $t_{1/2}$ , and  $k_e$  in the population of interest as well as the control group. For drugs that are highly bound, PK parameters are preferably expressed in terms of unbound concentrations. If urine data are collected in the study, the amount ( $A_e$ ) or fraction of dose ( $f_e$ ) excreted and renal clearance (CL<sub>R</sub>) are also assessed. Changes in CL<sub>R</sub> can be evaluated with regard to its relative impact on total clearance for the population of interest.

The PK parameters are presented descriptively for each treatment. For most studies measures of exposure (AUC and  $C_{\max}$ ) are compared as primary PK parameters across categorical population groups using an analysis of variance (ANOVA). The statistical analysis is performed on the log-transformed PK parameters and the model may include other demographic variables if applicable. The 90% confidence interval for the ratio of the least-squares (LS) treatment means is calculated for the various populations. Lack of population difference is established when the calculated confidence interval for the ratio of the LS means falls within the predefined confidence interval limit of the “no-effect” boundary for the study. Statistical methods may also be employed to test for significant differences in other relevant parameters ( $t_{\max}$ ,  $t_{1/2}$ ); however, these parameters are generally only summarized descriptively. Where differences in PK parameters can be described as a function of a continuous variable such as creatinine clearance (CL<sub>CR</sub>) in stage II RI studies, a statistical regression model may be more appropriate for data analysis.

Irrespective of the statistical approach, a no-effect boundary should be defined prior to study conduct which is used to assess the significance and clinical implications of any identified PK differences. The criteria should be based on clinical relevant changes in drug PK rather than the narrow statistical window of the 80–125% confidence interval traditionally applied in bioavailability/bioequivalence studies [3, 4]. A wider boundary is acceptable as long as the boundary can be justified with available clinical data. No-effect boundaries can also be defined for the slope of a regression analysis, for a population analysis, or for PK–PD modeling. If “clinically relevant” boundaries are not known prior to study start, the analysis plan should clearly differentiate between predefined narrow bioequivalence boundaries and clinically relevant changes in drug PK. If the 90% confidence interval for the LS mean ratio of the PK measurement falls within the predefined boundary, any changes in drug PK for the special population group can be considered not clinically relevant and do not require any dose adjustments. In the case of RI and HI studies, the small clinical sample size and/or high intersubject variability may preclude meeting tight

statistical criteria and result in statistical interpretation of confidence intervals which are inconclusive.

The data obtained in the special population studies must be evaluated in the context of all available PK, safety, and efficacy information to optimize drug therapy. PopPK analyses assess the contribution of factors to the intersubject variability in modeled NCE volume of distribution and clearance. These factors include demographic covariates [such as age, gender, race, body mass index (BMI) and/or WT, and height], physiological covariates (creatinine clearance, concurrent diseases, etc.), and lifestyle covariates (such as concomitant medications, smoking/drinking habits). The analysis model minimizes PK parameter variability in order of importance (i.e., statistical significance) of the various covariates. Results of PopPK analyses may further support the findings in special population studies, provide mechanistic explanations for apparent NCE PK differences, or alternatively show that statistically significant differences between populations may not have clinical relevance within the overall variability in the population estimates for the PK parameter.

Regulatory expectations have been formulated in various U.S., European, and International Conference on Harmonisation (ICH) guidance documents (see below) and provide detailed information on how the findings of the special population studies should be summarized in the drug label. The special population subsection within the clinical pharmacology section should briefly summarize any findings and describe any dosing adjustments or precautions required in the special population. If clinically relevant changes in drug disposition were observed, a statement should be included in the precautions/warnings section with further reference to the dosage and administration section. The latter should contain detailed instructions for the physician to adjust the NCE dose in the special population or to indicate that the NCE should not be used in the affected population. The reader is referred to the various guidance documents references in the sections below.

### 10.7.3 GERIATRIC POPULATION

The geriatric population has been arbitrarily defined as subjects/patients who are 65 years or older. While use of medications generally increases with age, many clinical trials have an upper age cutoff to exclude elderly subjects due to the concern that these subjects (a) are more frail and at potentially higher risk to have treatment-related AEs, (b) have underlying diseases that might affect the NCE PK and thus study objectives, (c) are receiving one or more comedications which are part of the studies' exclusion criteria, (d) have veins that are more difficult to access for blood collection, (e) require different housing conditions than young volunteers, and (f) may not be able to appropriately reason and express a choice when signing an informed consent [5].

As people age, the body undergoes physiological and composition changes [6]. The elderly tend to have lower lean body mass, lower total body water, and higher total body fat, which may affect the volume of distribution and half-life of highly lipophilic drugs. Gastrointestinal function changes with age, gastric pH increases, and adsorptive surface and motility decreases. Unless the NCE has a high first-pass extraction ratio, the absorption of drugs is unlikely to exhibit age-related changes in absorption. Glomerular filtration rate (GFR) and tubular secretion decrease with

age, which may increase half-life for drugs which are predominantly renally excreted [7]. Changes in hepatic metabolism are more complex. Liver mass as well as hepatic blood flow tend to decrease with age, which may affect drugs with low intrinsic clearance as well as those with high extraction ratio; however, there are conflicting reports in the literature whether an actual change in the intrinsic ability of the liver to clear drugs (true intrinsic clearance) exists in the geriatric population or whether the observed changes in metabolism are secondary to an array of related physiological changes [8].

Data in the geriatric population are a regulatory requirement unless the NCE is not indicated in this population. The FDA and ICH guidance documents outline the expectations of the regulatory community [9, 10]. The FDA has further issued a guidance document describing the content and format for geriatric labeling in U.S. submissions [11]. While the FDA focuses on the changes of age-associated conditions with regard to drug disposition characteristics (and that of active/toxic metabolites), the ICH guidances suggest that the elderly should be studied not only with a new NCE but also during the development of new formulations and new combinations of marketed drugs or for new indications which include geriatric patients in the indication. A separate study in the elderly may not be required for drugs with low systemic availability (e.g., some topical drugs) where age differences in PK are unlikely to be of significance.

In a formal elderly PK study, an appropriate number of male and female subjects 65 years of age and older is enrolled along with an equal number of young controls. Generally the number of subjects for each group does not exceed 20; however, the total number of subjects should be large enough to allow statistical comparisons. Since geriatric subjects are generally easy to enroll, a sample size which results in 80% power to detect a clinically significant difference between groups within the specified no-effect boundary is desired. The geriatric population may be further stratified into two to three age subgroups with an equal number enrolled in each age range. Some study designs are also stratified by gender with an equal number of young and elderly male/female subjects enrolled in each age group.

Subjects should be generally healthy within the criteria expected of a geriatric population. Wider inclusion criteria will be required on preadmission body mass index (BMI) values, vital signs, ECGs, and clinical laboratory evaluations to accommodate age-related physiological changes. Elderly are frequently taking multiple medications for various conditions (including hormone replacements, vitamins, and herbal supplements) and the inclusion/exclusion criteria must be specific enough to allow inclusion of a representative geriatric population while ensuring that the PK objectives of the study are not compromised. Geriatric PK studies are generally conducted under standard fasted conditions and meals are withheld for approximately 14 hours. The author has observed that the long fast can lead to a higher incidence of AEs (e.g., dizziness or nausea) in the elderly, who are less tolerant of extended fasting than healthy young subjects.

Pharmacokinetic sampling, safety collections, and data analyses follow the criteria outlined in the previous section. The AUC and  $C_{\max}$  are compared as primary PK parameters across categorical age groups using an ANOVA. Since age is a continuous variable, a statistical regression model may be employed if a graded age difference in NCE PK is apparent. If the NCE is excreted to a significant extent, it is advisable to collect urine data ( $A_e$  or  $f_e$  and  $CL_R$ ) and determine  $CL_{CR}$  in this

population. In the case of differences in drug disposition, the renal excretion data from the geriatric population can be correlated with the results obtained in the RI population for mechanistic interpretation of the results.

The elderly are more sensitive to CNS agents and may respond differently to cardiovascular agents than younger adults [12]. Phase I studies for CNS or cardiovascular drugs usually include a PD component. PD results can be evaluated using similar statistical methods as for categorical comparison of PK parameters. The objective for the PD component is the determination of whether PD changes occur and, if the case, whether the PD changes are a result of changes in drug disposition or whether the PD changes also occur in the absence of PK changes.

The PK results of definitive geriatric PK studies are frequently supplemented with the modeling results of phase II/III studies. These analyses may substantiate the findings of the definitive elderly PK study or alternatively may identify other factors that may have contributed to the apparent age-related changes in PK (e.g.,  $CL_{CR}$ ). At the current time, PopPK results are only considered supplementary in the registration package and have not replaced the formal PK study in the geriatric population.

#### 10.7.4 RENAL IMPAIRMENT

There are various kinds of kidney diseases. Chronic renal failure, in which the kidney can no longer cope with the load of endogenous and exogenous substances that must be excreted, is the most relevant with regard to affecting the PK of a NCE and/or its circulating metabolites [13]. Patients with RI can be categorized into two distinct subpopulations: those with various degrees of diminished renal function and those who require artificial means to remove the buildup of electrolytes, body waste, and drug product by dialysis methods such as hemodialysis, hemofiltration, hemoperfusion, and peritoneal dialysis. Patients with various degrees of diminished renal function are further categorized into distinct groups based on the severity of their disease. The FDA and European Medicines Agency (EMA) recommend the categorization of the RI population into five groups, as outlined in Table 2 [14, 15]. The use of categorical renal function groups provides a means of balancing patient enrollment across the RI spectrum and establishes uniformity in data presentation across various drug submissions.

PK data in the RI population are a regulatory requirement unless the NCE is not indicated in this population or a strong case can be made based on disposition

**TABLE 2 Categorization of RI Patients**

| Group | Description               | Estimated Creatinine Clearance (mL/min) <sup>a</sup> |
|-------|---------------------------|------------------------------------------------------|
| 1     | Normal renal function     | >80 mL/min                                           |
| 2     | Mild renal impairment     | 50–80 mL/min                                         |
| 3     | Moderate renal impairment | 30–50 mL/min                                         |
| 4     | Severe renal impairment   | <30 mL/min                                           |
| 5     | ESRD                      | Requiring dialysis                                   |

<sup>a</sup>EMA (2004) further normalizes the renal function groups to body surface area with creatinine clearance expressed in mL/min/1.73 m<sup>2</sup> [15].

and physiochemical properties of the drug that renal disease will not alter drug PK. FDA and EMEA guidelines specify when RI studies are indicated and how the RI data should be utilized in the registration package [14, 15]. If the target patient population is likely to include RI patients and the PK (or PD) of the NCE and/or its active/toxic metabolite is likely to be affected by changes in renal function, studies should be conducted to assess whether dose adjustments are required. RI studies are recommended for NCEs with (a) a narrow therapeutic index and (b) primary elimination of the NCE and/or active/toxic metabolites via the renal route (excretion and metabolism) or (c) a combination of high hepatic clearance and significant protein binding. An RI study is considered unnecessary if an NCE has a wide therapeutic window and (a) is primarily metabolized by the liver, excreted into the bile, or eliminated via the lungs, (b) is a topical drug that is not absorbed, or (c) is intended only for single-dose administration. Confirmation by the agency that a study in RI is not required for drug approval is advised to avoid a potential hold or rejection of a submission until appropriate renal impairment data are available.

The FDA and EMEA distinguish between a traditional approach assessing the NCE PK in patients with varying degrees of renal function (full-study design) and an adaptive two-stage approach (reduced/stage design) [14, 15]. The latter is recommended if the NCE and/or metabolite PK are not likely to require dose adjustments in RI. Stage I consists of a study comparing only the extremes, that is, healthy controls versus patients with severe RI (also see Table 2). If the PK difference between the two extremes does not warrant a dose adjustment, no further studies are needed. Alternatively, if PK in severe RI patients is altered to the extent requiring dose adjustments, patients with a lesser degree of RI should also be studied in a follow-up trial (stage II).

The regulatory agencies recommend RI studies in NCEs with narrow therapeutic margins even if an impact of RI on the NCE PK is unlikely, since RI may affect the disposition of drugs that are exclusively eliminated by nonrenal routes (highly metabolized or excreted into bile). Changes in drug elimination due to changes in protein binding are the most obvious causes of altered PK [16, 17]; however, diseases secondary to RI may also contribute to PK changes. The combination of physiological changes in RI can increase or decrease absorption by altering GI motility, transport mechanisms, and metabolism, blood flow to the kidney and other organs, and hepatic metabolism. Physiological explanations for these changes have been summarized by various authors [18–21]. Other underlying physiological changes secondary to RI include various forms of cardiovascular disorders such as hypertension, coronary artery disease, congestive heart failure, arrhythmias, lipid abnormalities, diabetes mellitus, peripheral neuropathy, and diabetic retinopathy [22–24]. Patients with severe RI (GFR < 30 mL/min) are those most affected by these physiological changes. Low urine production results in a higher accumulation of toxins in the circulation, which puts an additional strain on alternative routes of NCE elimination. Contrary to common belief, patients with end-stage renal disease (ESRD) who complete hemodialysis immediately prior to drug administration can have lower drug exposure for non-renally eliminated drugs compared to the other renal function groups [25]. While the reason for this finding is not well understood, one possible explanation is that the process of dialysis removes a large amount of endogenous material which otherwise would “clog up” the NCE’s elimination routes.

Studies of ESRD patients are conducted to determine whether dialysis may result in lower drug concentrations (i.e., patients might require replacement doses) and/or whether dialysis can be used in the treatment of overdose situations. A significant portion of the NCE is likely to be removed during dialysis if an NCE and/or active metabolite is water soluble, has a low nonrenal clearance, a low molecular weight (<500 Da), and low protein binding, and its volume of distribution is small (<1 L/kg) [20, 26]. On the other hand, if the NCE has a large unbound volume of distribution or high nonrenal clearance, dialysis is unlikely to contribute to removal of the NCE to any great extent.

#### 10.7.4.1 Design Considerations in RI

In the formal renal PK study, an appropriate number of male and female subjects with RI are included in the study along with an equal number of non-RI subjects who match the demographics of either the RI patients or the target population. Ideally, subjects should be known to the investigator long enough to establish the presence of reasonably stable renal function. For example, serum creatinine concentrations should not vary by more than approximately 0.4 mg/dL over a 3-month period prior to the initial screening. Other means of documenting stable serum creatinine concentration or stable creatinine clearance up to 6 months prior to the initial screening can be used as long as they are well specified. Since RI patients are harder to recruit due to restrictions in inclusion/exclusion criteria, the author recommends widening the age range to at least 70 years of age rather than the typical 65-year cutoff. The number of RI patients should be sufficiently large to allow appropriate statistical analyses, but the time it will take to enroll patients should also be considered.

In stage I, an equal number of patients with severe RI are enrolled along with an equal number of healthy controls. In the extended design (stage II), the different RI function groups generally contain a minimum of 8–10 subjects per group and one control group of similar size and demographic characteristics which brackets all RI groups. Patient enrollment should be closely monitored so that patients within each renal function group are evenly distributed (e.g., not all patients with mild renal impairment have a creatinine clearance  $CL_{CR}$  of >65 mL/min). This becomes important at the time of data analysis if PK parameters are regressed on  $CL_{CR}$ .

Creatinine clearance can be directly measured using serum and urine creatinine concentration or calculated by one of several formulas using serum creatinine concentrations only. If  $CL_{CR}$  is directly measured using both serum creatinine and urine creatinine, it is advised to collect urine for 24 hours and to draw the serum creatinine sample at the midpoint of the urine collection interval. In ESRD patients who produce urine, serum creatinine concentrations should be obtained at the beginning and end of the urine collection. The average of the two serum creatinine values provides a more accurate estimate since serum creatinine is likely to increase over time between dialyses. If  $CL_{CR}$  is measured using serum creatinine only, the FDA recommends using the Cockcroft–Gault formula in adult subjects and the formulas by Schwartz in children and infants from birth to one year of age (see Table 3) [27–29].

Inclusion and exclusion criteria should clearly define which underlying diseases are acceptable. Patients with any major illness (other than renal disease

**TABLE 3 Formulas to Calculate Creatinine Clearance from Serum Creatinine Concentrations**

| Group                            | Formula                                                                                                    | Reference |
|----------------------------------|------------------------------------------------------------------------------------------------------------|-----------|
| Adults (>12 years)               | $CL_{CR} = \frac{(140 - \text{age}) \times \text{weight}}{72 \times \text{Serum}_{CR}}$ (0.85 for females) | 27        |
| Infants less than 1 year         | $CL_{CR} = \frac{0.45 \times \text{length}}{\text{Serum}_{CR}}$                                            | 29        |
| Children 1–12 years <sup>a</sup> | $CL_{CR} = \frac{0.55 \times \text{length}}{\text{Serum}_{CR}}$                                            | 28        |

Note: Serum<sub>CR</sub>: serum creatinine in mg/dL; age in years; weight in kg; length in cm; CL<sub>CR</sub> in mL/min.

<sup>a</sup>Schwartz initially presented this equation with plasma creatinine for children up to 20 years of age [28].

and associated stable illnesses such as hypertension and diabetes mellitus) such as hepatic, GI, cardiovascular, adrenal, hematological, or obstructive airway disease should be excluded. Patients with mild hepatic and GI diseases should be evaluated carefully to determine if these might affect the pharmacokinetics of the NCE. All underlying diseases should not interfere with the study conduct or pose an unjustifiable risk to the study participant. Wider inclusion and exclusion criteria are required on preadmission vital signs, ECGs, and clinical laboratory evaluations to reflect the nature of the patients to be enrolled. Restrictive inclusion/exclusion criteria will affect the enrollment rate.

Subjects with RI will require concomitant medications. Patients whose medication is likely to interfere with the NCE PK should be excluded. Subjects receiving medications that are unlikely to interfere with the study medication (or vice versa) should receive their regular scheduled medication at a time different from the scheduled NCE dose whenever possible (e.g., withhold all nonessential medications  $\geq 12$  hours prior to and  $\geq 4$  hours following NCE administration). Patients receiving ranitidine and other H<sub>2</sub>-receptor antagonists may be asked to withhold their medications for  $\geq 36$  hours prior to dosing, if medically acceptable, and to use alternate measures (e.g., antacids) to control their symptoms. Antacids should be held for at least 1 hour prior to dosing and 2 hours postdose. For medication that must be administered near the time of the NCE administration, dosing should be scheduled either 1–2 hours prior to or 1–2 hours after administration of the study medication whenever possible. Some over-the-counter herbal supplements are associated with drug interactions; others may affect physiological parameters such as blood pressure, blood glucose, kidney function, and electrolyte balance in renal disease patients [30]. Patients requiring herbal supplements for medicinal purposes should be carefully evaluated prior to study enrollment.

The timing of meals in renal studies is similar to those in any typical phase I study and should reflect the NCE requirements. With progression of the disease, renal patients may require modifications to the composition of the meal (e.g., salt content) and/or permitted snacks. Patients with severe renal disease and with ESRD may have restrictions with regard to the volume of fluid intake, which needs to be taken into account in the design of the study.

Pharmacokinetic sample and safety collections follow the criteria outlined in Section 10.7.2 with the exception that urine samples are almost always collected in

RI studies. The FDA guidance recommends that unbound drug levels are determined in each sample unless the drug exhibits relatively low extent of binding (defined by the FDA as the extent of binding being less than 80%) and that PK parameters are calculated based on unbound concentrations [14]. In the stage I design, the primary exposure PK parameters ( $C_{\max}$  and AUC) are compared between RI patients and the control group using an ANOVA model with the appropriate confidence interval boundaries. Secondary parameters, including protein binding results, are summarized descriptively. In the stage II design, the primary PK parameters are most commonly regressed against the patients'  $CL_{CR}$ .

Since screening  $CL_{CR}$  values may have been obtained three to four weeks prior to dose administration, it is advised that  $CL_{CR}$  is obtained again on the day of pharmacokinetic sampling to avoid potential misclassification of the patient. In RI studies that the author has conducted, the “during study conduct”  $CL_{CR}$  estimates generally correlate well with those obtained during screening, but there may be changes in some patients in either direction of renal function. In some cases, patients “categorized” into a renal function group during screening fell into the adjacent renal function group during study conduct (e.g., a patient with  $CL_{CR}$  of 27 mL/min at screening had  $CL_{CR}$  of 33 mL/min during the actual study). If regression analysis is used to model the PK parameters to renal function, these small shifts do not affect the interpretation of the data, while categorical ANOVA analysis may be affected by shifting one subject from one category to another. The other PK parameters are generally presented descriptively.

Serum creatinine values are generally collected as part of the clinical laboratory package in phase II/III. The  $CL_{CR}$  can be calculated for the majority of patients and is available as a potential covariate for PopPK analysis. However, most phase II/III studies do not include a large enough population with decreased RI function and the  $CL_{CR}$  range tends to be too narrow to allow determination of meaningful differences. For this reason, the data generated in the definitive phase I study are not always supplemented by PopPK analyses. One of the exceptions would be the situation where the NCE cannot be studied outside the therapeutic target population. The regulatory agencies have requested that an attempt is made to include subpopulations in the integrated phase II/III development program and to utilize PopPK analysis approaches to elucidate the relationship between relevant PK parameters and renal function. However, the number of patients must be large (and diverse) enough to allow detection of PK changes requiring dose adjustments.

#### 10.7.4.2 Special Considerations for Dialysis Patients

The most common forms of renal replacement therapy in patients with ESRD are hemodialysis and continuous ambulatory peritoneal dialysis (CAPD). Both processes involve the principle of diffusion; however, hemodialysis is considered the most efficient artificial means of toxin and drug removal. During hemodialysis, blood is dialyzed against a dialysate medium across a permeable membrane. The extent of toxin and drug removal during hemodialysis is governed by the rate of blood flow through the dialyzer, the rate of dialysis flow, the surface area and type of dialysis membrane, and the dialysis medium [13]. In CAPD, the peritoneal membrane serves as the dialysis membrane to the dialysate in the peritoneal cavity. Toxin removal in

CAPD occurs through osmosis and diffusion from the small blood vessels in the walls of the abdominal cavity, the viscera, and the interstitium through the peritoneal membrane. For more information on CAPD, the reader is referred to reviews of advantages and disadvantages of CAPD and its influence on drug pharmacokinetics [31, 32]. Studies in CAPD patients are only recommended for the NCEs likely to be administered in this patient population.

Renal dialysis studies are conducted both “between” and “during” the scheduled dialyses regimen. The decision of what time in the dialysis cycle the PK information is collected depends on the objectives of the study. Determination of potential accumulation of the NCE and/or metabolites in the ESRD population will include patients between their scheduled dialysis while the use of hemodialysis as a means of drug removal would require drug administration during the patients’ hemodialysis regimen. The length of PK sampling is restricted between dialysis since ESRD patients undergo hemodialysis every 48–72 hours. PK sampling between dialysis regimens is rarely longer than 48 hours, which may introduce error into results for half-life and AUC assessments. Potential shorter PK sample collection should be taken into account when NCE PK data are compared across studies. It is recommended that drug administration be scheduled at least 1 hour after completion of the dialysis before dosing to allow for balance of the patient’s fluid level. PK sample collections, data analysis, and statistical comparisons for between-hemodialysis PK studies are performed as previously described and include categorical comparison of the primary exposure PK parameters to a control.

When assessing the NCE PK during hemodialysis, the timing of dose administration and potential fluid loss during analysis should be considered. Hemodialysis sessions generally last around 3–4 hours. NCE administration most often occurs prior to the start of the dialysis. Optimal results, especially if the dialysate is measured, will be obtained if the dialysis is started around the time of maximum exposure, since potential drug removal is proportionate to blood concentrations. Hemodialysis will remove accumulated water along with waste material. Determination of the difference in patient weight immediately before and following hemodialysis accounts for this fluid loss/weight loss and can be used as covariate or correction factor during data analysis and interpretation.

Collection of data regarding relevant equipment and conditions during hemodialysis is important since the extraction efficiency of the hemodialysis is affected by the type of dialyzer, dialysis membrane, and membrane surface area against which the blood is dialyzed. The ionic strength and type of the dialysate (dialysate potassium, dialysate calcium) and blood and dialysate flow rate will also affect the extraction ratio. Dialysis conditions are optimized to a given ESRD patient and are likely different between study subjects and study sites. The subject’s case report form should allow for documentation of all pertinent dialysis components.

The PK sample collections, data analysis, and statistical comparisons for during-hemodialysis PK studies include categorical comparison of the primary exposure PK parameters to a control using an ANOVA model with the appropriate confidence interval boundaries. However, AUC comparisons frequently focus on the partial AUC interval obtained during the hemodialysis since the dialysis window is so narrow. In addition, these studies typically include the estimate of dialysis clearance. Lee and Marbury have described a variety of methods to determine dialysis clearance [33]. Calculations may be based solely on blood/plasma concentrations or

can include dialysate concentration. Blood samples are collected during three stages of the study: (a) prior to start of dialysis, (b) during dialysis, and (c) during postdialysis treatment. During dialysis, blood samples can be removed directly from the lines entering (prefilter or arterial sample) and leaving (postfilter or venous sample) the dialysis chamber, while serial venous blood samples are collected prior to and following dialysis. The following information should be recorded in the subject's case record form to allow determination of dialysis clearance: (a) blood flow into the dialyzer, (b) hematocrit in the pre- and postfilter blood samples during dialysis to allow for conversion of blood dialysis clearance to plasma dialysis clearance, and (c) optional endogenous molecules such as blood urea nitrogen (BUN) and/or creatinine to assess the extraction efficiency of the hemodialyser (based on standard markers) and to permit comparison to the NCE and/or metabolites.

If the objective of the study is to determine percentage of dose removed during dialysis, collection of dialysate is required. Collection of dialysate may allow for a more accurate estimate of dialysis clearance than can be obtained from blood/plasma data [33]. It should be noted that dialysate can be a difficult matrix to assay for drug concentrations. Analytical method validation can be difficult to develop due to the high salt content of the dialysis medium. Dialysate flow rate should be collected as part of the study information. Although dialysis flow rate is specified as part of the dialysis procedures, measurement of the total dialysate volume is also recommended since it provides confirmation of the reported dialysis flow setting. Incorrectly recorded flow rates or variation in outputs of the dialyser can be easily detected if the preset flow did not deliver the total intended volume and PK calculations may be performed with an "adjusted" or "corrected" flow rate based on measured dialysate volume.

For the detailed derivation of dialysis clearance the reader is referred to the article by Lee and Marbury [33]. The authors discuss different direct methods such as arteriovenous (AV) difference, recovery rate, or cumulative dialysate methods as well as those derived from plasma pharmacokinetic parameters obtained between and during dialysis. If both plasma and dialysate data are available, data calculated by more than one approach can be compared.

In simplified form, the AV difference approach is based on a flow rate multiplied by the extraction efficiency of the hemodialyser (E). Blood dialysis clearance ( $CL_{HD-b}$ ) is thus calculated as

$$CL_{HD-b} = \frac{Q_{bi} [C_{bi} - C_{bo}]}{C_{bi}} \quad (1)$$

$$CL_{HD-b} = \frac{Q_{do} C_{do}}{C_{bi}} \quad (2)$$

where  $Q_{bi}$  is the blood flow entering and  $C_{bi}$  and  $C_{bo}$  the blood concentrations entering (i) and leaving (o) the dialysis chamber. The quotient term  $(C_{bi} - C_{bo})/C_{bi}$  is the extraction ratio based on blood/plasma concentration alone. Here  $Q_{do}$  is the dialysis flow leaving and  $C_{do}$  is the dialysate concentration leaving (o) the dialysis chamber. The assumption is made that ultrafiltration differential and backdiffusion are negligible compared to the blood and dialysis flows.

Since blood flow rather than plasma flow is measured as part of the study and the drug concentrations are derived from plasma samples,  $CL_{HD-b}$  needs to be converted to plasma dialysis clearance ( $CL_{HD-p}$ ) using

$$CL_{HD-p} = Q_b \{ [K_p * Hct + (1 - Hct)] \} E \quad (3)$$

where  $E = (C_{pi} - C_{po})/C_{pi}$  and  $C_{pi}$  and  $C_{po}$  are the plasma concentrations of the blood entering (i) and leaving (o) the dialysis chamber;  $K_p$  is the partition coefficient between RBCs and plasma and Hct is the hematocrit. If both the hematocrit and the partition coefficient of the NCE between RBCs and plasma are known, the assessment of  $CL_{HD-p}$  using the AV model is most accurate. If the  $K_p$  approaches zero (i.e., the analyte does not distribute into RBCs), the equation is reduced to reflect the physiological plasma flow:

$$CL_{HD-p} = Q_b (1 - Hct) E \quad (4)$$

Alternatively, assuming that  $K_p = 1$ , Equation (4) reduces to

$$CL_{HD-p} = Q_b E \quad (5)$$

Equation (5) is the most common equation used to assess  $CL_{HD-p}$  from plasma data in the absence of any other information. As an approximation,  $Q_b$  in Equation (5) can be corrected by the blood-to-plasma NCE concentration ratio ( $C_b/C_p$ ) to estimate plasma blood flow and  $CL_{HD-p}$ .

If dialysate data are available,  $CL_{HD-p}$  can be calculated by two basic methods: the recovery rate method and the cumulative dialysate method. In both methods, the assumption is made that the dialysis flow stays constant over the interval of observation. The percent recovery is calculated as the fraction of drug recovered in the dialysate relative to the administered dose. These methods are identical to those employed for the calculations of renal clearance and percent of dose excreted into urine. For this reason, the equations are not presented in this section. Since ESRD patients undergo hemodialysis only every two to three days and the NCE is likely administered more frequently, it might be of interest to assess the percent dialyzed value both for the “actual dose” studied during hemodialysis and for the likely “total dose” (sum of all the doses a patient would have received during one hemodialysis cycle) to determine if dose adjustment in ESRD patients is needed.

### 10.7.5 HEPATIC IMPAIRMENT

The liver is the main metabolizing organ in the human body. Hepatic function exhibits a slow decline with increasing age (decrease in liver weight and hepatic blood flow) [8]; however, these decreases are generally not considered of clinical relevance with respect to drug disposition. On the other hand, a wide etiology of pathophysiological mechanisms is known to cause a decrease in liver function and may alter the PK characteristics of drugs. HI tends to be a heterogeneous disorder due to both structural and functional abnormalities. In the western world including the United States, the most common cause of HI is chronic alcohol abuse leading

to liver cirrhosis. On a worldwide basis, viral infections (hepatitis B and C) are the main contributors to HI. Liver disease may also develop secondary to other diseases such as congestive heart failure or cancer and may not always be immediately recognizable.

In contrast to RI, there are no good endogenous markers which allow characterization of hepatic function (such as bilirubin, albumin, or prothrombin time), nor do model drugs which are exclusively cleared from the liver lend themselves as exogenous markers [34, 35]. While various clinical variables such as ascites, encephalopathy, nutritional status, peripheral edema, and histological liver assessments have been studied, none of the various clinical approaches has shown similar predictability of liver function as the use for serum creatinine (or  $CL_{CR}$ ) for RI. For pragmatic reasons, the Child–Pugh classification for alcoholic cirrhosis and portal hypertension has been adapted by both U.S. and European regulatory agencies as a means to allocate HI patients to hepatic function groups [36–37]. The Child–Pugh scale is based on the encephalopathy grade, degree of ascites, serum bilirubin and albumin concentrations, and prolongation in prothrombin time, as illustrated in Table 4. Based on the total number of points for each of the grading criteria, subjects are classified into mild (Child–Pugh grade A: 5–6 points), moderate (Child–Pugh grade B: 7–9 points), or severe (Child–Pugh grade B: 10–15 points) HI groups. A normal control group would have a grading of less than 5.

It should be understood that the Child–Pugh scale was not originally developed to categorize HI patients for the purpose of predicting drug PK. The FDA guidance provides alternative classification scales such as the Maddrey–Carithers discriminant function and Mayo risk scores for primary biliary cirrhosis as alternative clinical measures of liver function, but with the implementation of the FDA and EMEA guidelines, the Child–Pugh scale has become the classification system that is most commonly used [38, 39].

The PK data in the hepatic impairment population are a regulatory requirement unless the NCE is not indicated in this population or a strong case can be made based on disposition of the NCE that HI will not alter drug PK. The FDA and EMEA guidelines specify when HI studies are indicated and how the HI data should be utilized in the registration package [38, 39]. HI studies are indicated for almost all drugs likely to be used in subjects with HI. Drugs with >20% of hepatic

**TABLE 4** Categorization of HI Patients

| Points                                | 1        | 2       | 3        |
|---------------------------------------|----------|---------|----------|
| Encephalopathy grade                  | None (0) | 1–2     | 3–4      |
| Ascites                               | Absent   | Slight  | Moderate |
| Bilirubin, mg/dL                      | <2       | 2–3     | >3       |
| Albumin, g/dL                         | >3.5     | 2.8–3.5 | <2.8     |
| Prolongation in prothrombin time, sec | <4       | 4–6     | >6       |

*Note:* Encephalopathy grade:

- Grade 0: normal consciousness, personality, neurological examination, and electroencephalogram (EEG)
- Grade 1: restless, disturbed sleep, irritable or agitated, tremors, impaired handwriting, 5cps waves on EEG
- Grade 2: lethargic, time disoriented, inappropriate, asterixis, ataxia, slow triphasic waves on EEG
- Grade 3: somnolent, stuporous, place disoriented, hyperactive reflexes, rigidity, slower waves on EEG
- Grade 4: unrousable coma, no personality/behavior, decerebrate, slow 2–3cps delta waves on EEG

*Source:* From [38, 39].

metabolism or elimination (of parent drug and active/toxic metabolites) are considered to be extensively metabolized and a change in exposure may be clinically significant and thus require dose adjustment or contraindication in this population. If the extent of metabolism or biliary excretion is unknown, the agency assumes the drug to be highly metabolized, and hence a HI study is required. If the drug has a narrow therapeutic window, the HI study is recommended even if <20% of the drug and active/toxic metabolites are eliminated by the liver.

The guidelines consider only a few situations where a HI study may not be required (unless clinical concerns suggest otherwise): the NCE (a) is not to be used in patients with HI or (b) is intended for single-dose use only or (c) has a wide therapeutic window and <20% of parent and/or active/toxic metabolites are eliminated by the liver or (d) is gaseous or volatile and the drug and its active/toxic metabolites are primarily eliminated via the lung.

As in the case of RI, HI is associated with secondary physiological changes or disease states that may affect the NCE PK in this population. For this reason, it is prudent to obtain confirmation by the agency that a study in hepatic impairment is not required for drug approval to avoid a hold or rejection of a submission until appropriate hepatic impairment data are available.

The FDA and EMEA distinguish between two approaches in the design of HI studies [38, 39]. The extended approach assesses the NCE PK in patients with varying degrees of hepatic function compared to a control group. The reduced design only includes subjects with a Child–Pugh category of moderate which are compared to a matched control group. The latter is recommended if the NCE and/or metabolite PK are not likely to require dose adjustments in HI and subjects with a Child–Pugh category of mild are unlikely to provide a signal (e.g., clinically significant change in exposure). Under the reduced scenario, the findings in the moderate Child–Pugh category would be applied to those of the mild category, and dosing in the severe category would likely be contraindicated in the label. This approach has the disadvantage that significant findings in the moderate HI population would be extrapolated to the mild category and could result in contraindication of the drug in any subjects with HI. Under those circumstances, a second study in patients with mild HI may be required if this population is part of the target patient population, which could potentially delay the registration package.

The alternative is the full approach described by the agencies in which at least six subjects with HI are enrolled into each of the three Child–Pugh categories outlined in Table 4 along with a control population of similar or greater size. Six evaluable subjects per treatment arm appear to be a low number; however, subjects with HI are notoriously hard to enroll, especially if they fall into the moderate and severe HI categories. The number of subjects is therefore a compromise between what is feasible and what is minimally needed to obtain data likely to produce meaningful results. Since these studies are not intended to prove statistical equivalence between HI and healthy controls, the sample size in these trials are large enough to provide a signal for a clinically relevant change in NCE exposure. Control subjects should demographically match those in the HI population. In the reduced design, control subjects can be matched one to one, while in the full design their age and gender are matched across the demographic range of the three HI groups. For details with regard to the selection of HI subjects, inclusion/exclusion criteria, and study design the reader is referred to the review by Bonate and Russell [40]. Subjects should be

known to the investigator long enough to establish the presence of reasonably stable disease. They should not have clinically significant changes in their disease status over at least a 3-month period prior to the initial screening. Examples of clinical changes would be worsening clinical signs of hepatic impairment or worsening of total bilirubin or prothrombin time by more than 50%. If a previous diagnosis classified the hepatic dysfunction a result of cirrhosis, copies of documentation of any clinical information used to make the previous diagnosis should be available. Documentation may include clinical evidence of portal hypertension, a positive liver biopsy, hepatic ultrasound, computed tomography scan, and/or magnetic resonance imaging.

Inclusion and exclusion criteria should clearly define which underlying diseases are acceptable. Patients with any major illness (other than liver disease and associated stable illnesses) such as renal (e.g.,  $CL_{CR} < 50 \text{ mL/min}$ ), GI, cardiovascular, adrenal, hematological, or obstructive airway disease should be excluded. Patients with mild renal and GI diseases should be evaluated carefully to determine if these might affect the pharmacokinetics of the NCE. All underlying diseases should not interfere with the study conduct or pose an unjustifiable risk to the study participant. As in the case of RI, subjects with HI tend to require concomitant medications and similar study considerations apply.

The HI study is generally conducted as a single-dose study and the highest proposed therapeutic dose is selected unless safety concerns warrant a lower dose. In the full-study design, treatment administration can be structured to study the NCE PK and tolerability sequentially. Subjects with mild HI are dosed first. Once tolerability has been established, dose administration proceeds to the moderate HI group and then to the severe group. The study could be stopped after completion of any HI category. This design, while safer, will increase the duration of the study since moderate and severe HI populations are increasingly harder to enroll and enrollment of these populations cannot start until the previous category has completed the study.

The PK sample and safety collections as well as data analysis follow the criteria outlined in Section 10.7.2. The FDA guidance recommends that protein binding is performed for drugs that are highly extracted by the liver (extraction ratio  $> 0.7$ ) and are extensively bound to plasma proteins (fraction unbound  $< 10\%$ ). Unbound fraction should be determined at least at trough and maximum plasma concentration and clearance and volume parameters are appropriately expressed in terms of both unbound and total concentrations [38]. In both the extended and reduced study, the  $C_{max}$  and AUC are compared across categorical population groups using an ANOVA with the appropriate confidence interval boundaries. Secondary parameters including protein binding results are summarized descriptively.

The results of HI impairment studies are frequently difficult to interpret. Due to the small sample size, the study has low power resulting in wide 90% confidence intervals. As a result, the 90% confidence interval for the LS mean ratio of the PK measurement rarely falls within the no-effect boundary or the even more restrictive 80–125% if a no-effect boundary is not available. If the criteria are not met, it has to be concluded that HI has an effect on NCE PK. It is not always clear if the effect is clinically relevant. The FDA guidance states that dose adjustments should be reflected in the label in the case of an obvious effect, that is, in the case that the clearance of the NCE is significantly impaired. The definitions of obvious and

clinical significance need to be put in context with PK and safety data. Exposure–response relationship analysis with emphasis on the upper safety limits of exposure obtained from both phase II/III trials (representative of typical patient exposure) and phase I trials (high-exposure comparison) may be explored to defend the case for the labeling recommendations made to the regulatory agencies. NCI PK metabolism (enzymatic pathways, percent of drug eliminated by the liver, and disposition of metabolites by the liver) and the overall sensitivity of drug disposition to other physiological and external changes will also play a role in the decision if and how dose adjustments in the HI population are proposed. In spite of the difficulties in conducting and interpreting data of HI studies, these investigations are critical to the registration package to support dosing decisions in this population.

### 10.7.6 WOMEN IN CLINICAL TRIALS

Inclusion of women in clinical trials has drastically changed over the last 15 years. Up to the early 1990s, women were routinely excluded from phase I clinical trials using the argument that the benefit–risk ratio was too high to allow inclusion of women into all types of phase I trials, especially prior to completion of reproductive toxicity studies which, in the United States, are not required until women of childbearing potential are enrolled into phase III studies [41]. The definitive gender comparison was generally conducted in the later stages of drug development, unless the NCE characteristics required the data to support phase II or III clinical trials.

The FDA Guideline for the Study and Evaluation of Gender Differences in Clinical Evaluation of Drugs reversed the previous FDA policy which excluded women with childbearing potential from early drug studies unless it targets a serious or life-threatening disease [1]. The 1993 guideline requires women to be included in all phases of the clinical drug development program for agents that are indicated for women. The guideline states that the FDA can place an investigational new drug (IND) or specific studies on hold if a sponsor proposes to exclude women or men with reproductive potential because of a risk, or potential risk, or reproductive toxicity from the use of an investigational drug product. In 1998, the FDAMA Women and Minority Working Group Report was issued which reviewed the 1993 guideline and recommended not to generate further gender-related guidelines but to institute a permanent tracking system to gather, search, and evaluate demographic data and potential deficiencies with regard to the inclusion of women in clinical trials [42]. The ICH has a website dedicated to ICH and women which shares the results of a recent review of the existing ICH guidelines and regulatory experiences in the three ICH regions: the United States, European Union (EU), and Japan [43]. In the posting, the ICH concluded that the current ICH and regional guidelines should be consulted for guidance on demographic considerations and that there was no need for a separate ICH guideline on women as a special population in clinical trials. The U.S., EU, and Japanese surveys showed that, in general, women were adequately presented in pivotal trial populations and that some form of gender effect was generally conducted and expected, be it a subpopulation analysis and/or formal PK/PD studies. The EMEA published the ICH findings as part of the ICH Guidelines Step 5 [44].

In today's environment, women (both those of childbearing and non-childbearing potential) are routinely included in phase I clinical trials unless specific NCE

characteristics preclude women from participating. Inclusion/exclusion criteria are worded such that women must adhere to stringent criteria in order to avoid pregnancy over the duration of the study. Women who are pregnant or lactating are always excluded unless the study is specifically conducted in one of these populations. A negative (serum or urine) pregnancy test result prior to enrollment and on check-in prior to drug administration is required for women of childbearing potential or who are perimenopausal. For women of childbearing potential (including perimenopausal women who have had a menstrual period within one year) appropriate birth control [defined as a method which results in a low failure rate, i.e., less than 1% per year, when used consistently and correctly, such as implants, injectables, some intrauterine contraceptive devices (IUDs)], sexual abstinence, or a vasectomized partner during the entire duration of the study are stipulated. It should be noted that many clinical protocols no longer restrict birth control methods to females and also require a barrier contraceptive method for males.

The majority of phase I trials include women who are taking oral contraceptive medications provided that they do not change their regimens throughout the course of the study. Similarly, postmenopausal women are permitted to continue their hormone replacement therapy throughout the study duration. The important point is that the medication is not changed during the study conduct to avoid potential changes in NCE PK across treatments. Exceptions to permitting systemic birth control medication or hormone replacement therapy are the cases where (a) the NCE is known to affect efficacy/safety of the medication (e.g., NCE induces liver enzymes), (b) the NCE is evaluated in a drug–drug interaction study in which the other administered drugs may affect efficacy/safety of the medication, or (c) the contraception/hormonal replacement medication may interfere with the objectives of the study.

Since PK data in women are generated throughout the entire drug development program, PopPK analyses of phases I–III PK data have become accepted not only in the United States but also the EU and Japan and have essentially replaced formal PK studies as the venue to assess potential effects of gender on drug disposition. If an NCE requires a formal PK study in women, the number of male and female subjects enrolled is based on the intrasubject variability of the NCE and is sufficiently large to perform the statistical comparison of the primary PK endpoints. Inclusion/exclusion criteria are described above. PK sampling, analysis, and statistical approaches reflect those described in Section 10.7.2.

### 10.7.7 ETHNIC CONSIDERATIONS

When an NCE is introduced into a new region, there is always the concern that ethnic differences may affect the drug's efficacy or safety and that dosage adjustment may be required. Ethnic differences in drug disposition may derive from three different sources: differences in (a) subject size and weight, (b) metabolism and transport due to the diversity of the cytochrome P-450 (CYP) family and transport proteins, and (c) food consumption (dietary) habits. With regard to physiological differences, the Asian population tends to have a smaller body size and lower WT and BMI than a typical U.S. or European population, which can result in higher exposure ( $C_{\max}$  and AUC) in the Asian population. A recent example is the 25.6% higher AUC(inf)

of fosfluconazole in Japanese subjects compared to Caucasians, which could be explained by the difference in BW between the two populations [45].

The diversity of the human CYP family has been well established. At least 57 human CYP isoforms have been identified to date; however, only 10 of these isozymes contribute to drug metabolism. The isoforms CYP3A4, CYP2D6, and CYP2C9 are the main contributors. Most of the CYP isozymes exhibit some form of genetic polymorphism and have structurally altered alleles with reduced or deficient catalytic activity. Ethnic differences in the make-up and polymorphism of CYP isozymes have been extensively reviewed [46–49]. The frequency of the deficient allele expression varies across ethnic groups, and the differences are thought to be likely a result of regional evolutionary diversification and environmental factors. There are also instances of variant alleles that may only be expressed in some ethnic groups but not in others [50]. Genetic polymorphism is not restricted to drug-metabolizing enzymes but has also been reported for drug transporters with affinity to chemotherapeutic agents such the multidrug-resistant *p*-glycoprotein (MDR1), multidrug resistance protein 2 (MRP2), and a breast cancer resistance protein [51, 52]. Genetic differences in metabolism and transport can be considered intrinsic ethnic variations independent of any environmental factors.

Food consumption habits are considered external factors and vary across ethnic groups within and across regions. Dietary constituents have been reported to alter the activity of various isozymes of the CYP family, phase II enzymes, and transporter systems and thus contribute to both inter- and intrasubject variability in drug PK. Harris et al. provide an in-depth review of various food constituents and their effect on metabolism enzymes and transport systems [53]. Dietary effects have been described for CYP3A4 (e.g., grapefruit juice, Seville orange juice, red wine, St. John's wort, garlic), CYP12 (e.g., caffeine, grapefruit juice, jufeng grape juice, cruciferous vegetables, charbroiled meat), CYP2E1 (ethanol, watercress), and phase II enzymes (vegetables) and *p*-glycoprotein (fruit juices, St. John's wort). For this reason, foods that contain complex mixtures of phytochemicals such as herbs, spices, teas, fruits, and vegetables may affect the activity of enzymes or active transport mechanisms and contribute to ethnic variations in drug disposition.

In 1998, the ICH issued the Guideline E5: Ethnic Factors in the Acceptability of Foreign Clinical Data to provide direction to the pharmaceutical industry when drug submissions are considered in more than one region with likely ethnic diversity [54]. The ICH and FDA subsequently issued a follow-up questions-and-answer document to formally respond to common questions regarding the type and extent of bridging studies required to support submissions in new regions [55, 56]. While this guidance is directed towards regulatory strategies for a bridging data package including PD, efficacy, and/or safety bridging studies, it recognizes the importance of appropriate characterization of pharmacokinetics as part of the data package. Pharmacokinetic processes which are biologically or biochemically mediated have the potential to exhibit differences between ethnic groups [57]. If the NCE characteristics are known, it should be possible to identify drugs that are likely to exhibit race differences in PK. Drugs which have a wide therapeutic range, flat concentration-versus-effect profile, linear PK, minimal metabolism, high/nonvariable bioavailability, low protein binding, and low potential for drug–drug interactions fall into the classification of less likely to be sensitive to ethnic factors. Those with

opposite characteristics, metabolized by a single pathway or polymorphic enzyme, and likely coadministered with multiple medications are more likely to be sensitive to ethnic factors. The ICH considerations for NCE classification as either less likely or more likely to be sensitive to ethnic factors based on their PK characteristics are provided in Table 5.

With the emerging globalization of drug development, more drugs from the Western market (United States/Europe) enter the Asian market (such as Japan). For this reason, the comparison of these two populations has become of particular interest. Many of the newer drug applications are employing PopPK approaches to assess ethnic differences in drug disposition. Data may be compiled across one or more phase II/III studies or may also include appropriate PK data from phase I control populations. The data may come from clinical trials conducted either in the population relevant to the new region or in the new region. As long as the PopPK model is robust enough and a sufficiently large number of subjects of the desired ethnic group is available for the analysis, the analysis results should be able to discern race-related differences in PK. Recent examples of PopPK analysis including Japanese subjects are the modeling of PK parameters for (a) olmesartan, which has shown the absence of ethnic differences in drug clearance between Japanese and Westerners, (b) telmisartan, which contributed differences in food intake conditions across populations to the differences in telmisartan PK, and (c) darifenacin, which exhibited a lower bioavailability in Japanese males [58–60]. The above three examples illustrate the diversity of results across different NCEs.

Since formal studies in a different ethnic population are often part of the drug's transition into a new region, the design of the trial is often adapted to a specific

**TABLE 5 NCE Sensitivity to Ethnic Factors**

| Less Likely to be Sensitive to Ethnic Factors                                                                        | More Likely to be Sensitive to Ethnic Factors                                                                                                        |
|----------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------|
| Linear PK                                                                                                            | Nonlinear PK                                                                                                                                         |
| Flat PD (effect v. concentration) curve for both efficacy and safety in range of recommended dosage and dose regimen | Steep PD curve for both efficacy and safety (small change in dose results in large change in effect) in range of recommended dosage and dose regimen |
| Wide therapeutic dose range                                                                                          | Narrow therapeutic dose range                                                                                                                        |
| Minimal metabolism or metabolism distributed among multiple pathways                                                 | Highly metabolized, especially through single pathway, thereby increasing potential for drug–drug interaction                                        |
| High bioavailability, thus less susceptibility to dietary absorption effects                                         | Metabolism by enzymes known to show genetic polymorphism                                                                                             |
| Low potential for protein binding                                                                                    | Administration of prodrug, with potential for ethnically variable enzymatic conversion                                                               |
| Little potential for drug–drug, drug–diet, and drug–disease interaction                                              | High intersubject variation in bioavailability                                                                                                       |
| Nonsystemic mode of action                                                                                           | Low bioavailability, thus more susceptibility to dietary absorption effects                                                                          |
| Little potential for inappropriate use                                                                               | High likelihood of use in setting of multiple comedications                                                                                          |
|                                                                                                                      | High likelihood for inappropriate use, e.g., analgesics and tranquilizers                                                                            |

From [54].

need in the NCE's development program and may take on many forms. Regulatory guidelines do not pose any limits on the study design of formal PK comparisons across ethnic groups but rather focus on the type of data that are required for ethnic comparisons. Traditional ethnic PK studies may follow the design outlined in Section 10.7.2 in which a single high-end therapeutic dose of the NCE is administered in an equal number of the healthy ethnic group (e.g., Japanese) and healthy Western or Caucasian controls in a parallel-group design. Alternative approaches may include the administration of more than one dose strength to each subject in either a randomized or ascending-dose cross-over design [61–63]. Administration of multiple dose levels across the anticipated therapeutic dose range allows determination of dose proportionality of the NCE as well as comparative PK. The decision of whether to randomize or escalate doses may depend on the likelihood of ethnic differences in the NCE and the timing of the study within the overall development program. From a statistical perspective, a randomized cross-over design is preferred; however, safety considerations may outweigh the need for a balanced design.

Pharmacodynamic markers such as blood glucose levels to determine the relative changes (RC) in glycemia values may be employed to relate potential differences in NCE exposure to a clinically relevant pharmacological response. Thomsen et al. was able to demonstrate that the higher exposure to repaglinide, an insulin secretagogue, in Japanese subjects was associated with a greater decrease in the RC values in this population [61]. If the drug cannot be safely administered in healthy subjects, a formal PK study may be conducted in the target population. A recent report summarizes the results for cefacitabine, which was administered twice daily for 14 days to an approximately equal number of Caucasians and Japanese subjects with breast cancer [64]. Blood and urine data were collected on the first and last day of drug administration and data analysis followed standard approaches [ANOVA with 90% confidence interval (CI) for the ratio of the LS means]. When drug development is scheduled to occur simultaneously in different regions (e.g., United States and Japan), one consideration might be to include both a Western and Japanese population in a “first-in-man” dose tolerance study conducted in one of the two regions. PK, PD, safety, and tolerance data allow early determination of potential ethnic differences in NCE behavior and appropriate adjustment in a global development program.

The same inclusion/exclusion considerations apply for ethnic comparisons as for other special population comparisons. Where possible, subjects should be healthy and free of concomitant medications, and the study should be powered with a sufficient number of subjects to allow statistical comparisons. Control groups should be age and gender matched whenever possible. The standard age range may require minor adjustment if regional requirements stipulate a higher minimum age for a typical phase I population. The population should be representative of the new ethnic region. If the formal PK study is not conducted in the new ethnic region (e.g., Japanese subjects are studied in the United States), inclusion criteria should clearly define the appropriate population. The study may be restricted to only include first-generation (Japanese) subjects or may be extended to second (or later) generation(s) of the ethnic population if no generation differences are expected. Since ethnic differences in NCE PK are partially attributed to differences in diet and life-style, a decision needs to be made whether the two populations are to receive the same meals during their study conduct period or whether the subjects

should receive meals that are consistent with their typical diet. In the case of a comparison to Japanese subjects, inclusion of smokers may be required since a higher number of Japanese smoke and exclusion of smokers might limit enrollment or is not representative of a typical population in the new ethnic region.

In summary, PK data relevant to all ethnic populations targeted for treatment need to be part of a submission package. Both formal PK studies or PopPK analysis of clinical trials can support the registration package. How the data are generated will depend on the NCE characteristics and the NCE development program.

### 10.7.8 OBESITY

Obesity can be considered a nutritional disorder and is defined as a state of excess body fat and body weight in proportion to an individual's height. The weight-to-height ratio, BMI, is used to determine whether an individual is obese. An adult with a BMI in the range of 20–24.9 is considered normal, an adult with a BMI of 25–29.9 is considered overweight, and individuals with a BMI of 30 or greater are considered obese [65, 66]. The number of obese adults and children has tremendously increased over the last 10–20 years, especially in the Western nations. Obesity is now recognized as a global epidemic and a significant health risk. While no linear relationship exists, obesity is associated with hypertension and more severe cardiovascular diseases, dyslipidemia (e.g., high total cholesterol or triglyceride levels), type 2 diabetes, gallbladder disease, osteoarthritis, some cancers (endometrial, breast, and colon), pulmonary disorders, and sleep apnea/sleep-disordered breathing [66–68]. Obesity in children and adolescents between 6 and 19 years of age is increasing more rapidly than obesity in adults. This population is especially at risk for many comorbid conditions such as hypotension and diabetes at an early age, which will affect their long-term health and life expectancy [69].

Obese subjects are becoming a major target population for drugs in the future. Use of medications in this population is twofold: (1) drug products are marketed and in development to treat obesity and (2) this population requires medications to treat the secondary illnesses described above. In the first scenario, the medications are specifically developed for the obese population. Regulatory expectations for the clinical evaluation of obesity drugs are outlined in both U.S. and European guidance documents [70, 71]. In contrast to drug development in most other therapeutic indications, first-in-man and other early clinical pharmacology studies are usually performed in obese subjects who are otherwise healthy. Furthermore, the majority of subsequent clinical pharmacology and biopharmaceutic studies with the exception of specialized phase I studies such as RI and HI studies and formal QTc studies will be conducted in the obese population. For obesity drugs, this population is considered the target population and does not represent a special population.

For the second scenario, obese subjects can be considered a special population rather than a target patient population. Effect of obesity on drug disposition has been studied as early as the late 1980s when obesity was first recognized as an emerging nutritional disorder, and it was found that modifications in body weight can affect drug distribution into tissues [72, 73]. While slightly liposoluble molecules are less likely affected by increases in body fat, lipophilic drugs may have a higher volume of distribution in the obese population and therefore a longer half-life. For

this reason, dose adjustments may be different in obese subjects based on the physicochemical characteristic of the drug.

The effect of obesity on the PK in various drug classes, including anti-infectives, anticancer, CNS, obesity, anesthetics, and beta blockers, has been reviewed [74]. Drug disposition in the obese can be altered not only due an increase and change in body mass (lean WT plus fat WT) but also due to intrinsic physiological changes and concurrent disease. While drug absorption is unlikely to be affected by obesity, both drug distribution and elimination may be altered. Blood flow into fatty tissue is poor, hemodynamic conditions in obesity may be altered, and livers in obese subjects may suffer from fatty infiltration which may lead to HI. Obesity may be associated with RI, and exposure of drugs which are primarily eliminated by the kidney may increase. However, obese subjects have larger kidneys than nonobese subjects [75], and the clearance of some renally eliminated drugs is not substantially affected [74, 76]. The effect of obesity on CYP was reviewed by Kotlyar and Carson, who concluded that changes in CYP activity differed across isozymes [77]. CYP3A4 activity was reported to decrease while that of CYP2E1 appeared to increase. The authors considered the findings regarding other CYP isozymes (1A2, 2C9, 2C19, and 2D6) inconclusive.

Since the potential effect of underlying diseases and intrinsic changes other than body mass are difficult to assess, all dose recommendations to date have been related to weight (i.e., milligram-per-kilogram recommendations). Different weight algorithms have been employed. The most common approaches are total, lean, or ideal body weight [73]. Recently use of predicted normal body weight (PNWT) has been proposed [78]. The PNWT corrects for excess fat weight (in relationship to lean body weight) that is above the weight of fat normally expected and may therefore be a better standard weight descriptor to describe body size for dose adjustments in obese patients. However, it remains difficult to predict the impact of obesity on PK, and each drug may behave differently. For drugs with a narrow therapeutic index, a study in obese subjects may be indicated. Anticancer agents are one category of drugs where the understanding of the influence of obesity is patchy and the outcome of treatment in this population may be detrimental due to the narrow therapeutic window of these agents. Toxicity for obese patients is impacted by appropriate dose adjustments and outcome data have suggested that obese patients may have a lesser disease-free survival and overall survival [79]. Based on his review, Navarro [79] recommends prospective studies to address optimal chemotherapy dosing in the obese population.

While formal obesity PK studies are currently not a regulatory requirement, it might be advisable to obtain PK information in the obese population if (a) the drug is likely prescribed in this population, (b) the physiochemical properties of the NCE suggest potential differences in drug disposition, and (c) the drug has a narrow therapeutic window. The data can be derived from either PopPK approaches or a formal study. The design of a formal PK study follows that outlined for HI with categorical comparison of the obese population to matched controls. Two subpopulations have been defined for obesity: moderately obese subjects with BMI values in the range of 30–39 kg/m<sup>2</sup> and morbidly obese subjects with BMI values equal to or greater than 40 mg/m<sup>2</sup>. PK data are compared in equal numbers of a group of obese subjects and demographically matched nonobese subjects. Designs may include only moderately obese subjects or may be further stratified between moderately and morbidly obese subjects [76, 80]. The decision to include morbidly obese subjects

depends on the likelihood that these subjects are a substantial part of the target patient population. Inclusion/exclusion criteria for secondary diseases and comedications follow the same considerations described for RI and HI studies and will vary between the obesity categories. Since the onset of secondary illness is not linearly related to obesity, there is a sufficiently large pool of reasonably healthy subjects with moderate obesity; however, morbidly obese subjects will likely require lenient inclusion/exclusion criteria. The number of subjects enrolled in each of the treatment arms will depend on statistical and logistical (in the case of morbidly obese) considerations, while PK sampling and data analysis strategies are the same as described for the other special populations.

In the current environment, formal studies in obese subjects are rarely performed for registration purposes and the majority of data derive from PopPK analyses. PopPK approaches are appropriate if the database contains a sufficiently large number of obese subjects with a wide enough BMI range to allow comparison to nonobese subjects. Since morbidly obese subjects are unlikely to be included in standard phase II/III safety and efficacy studies, PopPK analysis will rarely provide PK information for these subjects and a formal PK study may be needed if data in this population are required for a particular registration.

### 10.7.9 CONCLUSIONS

Pharmacokinetic data in special populations are registration requirements if the target patient population is likely to include the special population(s). U.S. and European regulatory guidelines require formal PK studies in geriatric, RI, and HI impairment subjects while PK data in other special populations such as women, ethnic groups, and obese subjects may be obtained by using population analysis approaches. Exceptions to these rules can be found in the specific regulatory guidelines. Study designs for formal PK studies carry common features across all special populations with special considerations to age- or disease-related inclusion/exclusion criteria and comedication requirements that are less restrictive than those in healthy normal subjects.

Over the last 5–10 years, population analysis approaches have obtained greater acceptance in the international community and PopPK results have either supplemented PK data of formal studies or replaced those of formal studies. Population analysis approaches are powerful tools to discern intersubject variability in PK parameters and are only limited by the inclusion/exclusion criteria of clinical studies which may preclude enrollment of (sufficient numbers) of a special population of interest. While the use of population analysis approaches to understand the effect of demographic, physiological, genetic, or life-style covariates on drug disposition, efficacy, or safety response to drugs is likely to increase over the next years, formal PK studies for some populations such as RI and HI will continue to be required to the limited enrollment of these subjects in the phase II and III program.

### 10.8.1 INTRODUCTION

When we look at past medical history, we can only find a few definite treatments that focus directly on their etiology, such as vaccination for some infectious diseases, vitamin C for scurvy, and, recently, gene therapy. The evidence for presently accepted treatments in our practice is insufficient; it ranges from a scattered presence to total absence. Unfortunately, apart from a few dichotomous results, we cannot expect qualitatively definite results of treatment for all clinical cases. The effect of the interventions is usually assessed quantitatively, comparing before and after treatment, according to certain outcome measures. The key to solving many of the problems in medical practice is to establish valid and reliable methods of evaluating the differences in the outcomes before and after treatment.

I started my postgraduate training as an orthopedic surgeon and then shifted my career to rehabilitation medicine. I am not, by any standard, an expert in all of the subjects covered here: clinical epidemiology, biostatistics, and related fields. However, I have had chances to join teams to organize clinical trials [1, 2]. I would like to describe the necessary steps for conducting a clinical trial from the standpoint of a clinician.

The term *evidence-based medicine* (EBM), which is the integration of best research evidence with clinical expertise and patient values, has already established wide popularity, even in the musculoskeletal field. When we review the clinical trial trends in the musculoskeletal field, we notice several characteristic points, which are obviously different from other areas.

In the musculoskeletal field, there are the typical clinical trials that use placebo-controlled, double-blind methods, such as drug trials for osteoporosis or rheumatoid arthritis. However, if we wish to compare one interventional procedure with another, the double-blind design is often impossible to do methodologically. Only in an open-label trial, where patients know about their treatment, is it possible to conduct the trial under random allocation. With such limitations, we have to suppress various biases as much as possible. Another point that needs attention is the selection of outcome measures suitable for musculoskeletal disorders. Even though there are primary malignant tumors, such as osteosarcoma or a cancer lesion as secondary

metastasis, which are sometimes lethal, the majority of musculoskeletal disorders that develop clinical manifestation are not life-threatening but do impair function. We have to use outcome measures for observing the functional ability of the patients, not for the numerical laboratory data.

In this chapter I would like to discuss the following:

1. Definition of musculoskeletal disorders
2. Background of clinical trials
3. Methodological assessment for clinical trials
4. Preparation of necessary tools for clinical trials
5. Data analysis and interpretation
6. RCT and our future direction

## 10.8.2 DEFINITION OF MUSCULOSKELETAL DISORDERS

### 10.8.2.1 Musculoskeletal Disorders

The term *musculoskeletal disorders* refers to conditions that involve the supporting structures of the body, such as the trunk and the bones and joints of the extremities. In other words, musculoskeletal disorders involve locomotor functions that have suffered from trauma, diseases, anomalies, and inevitable aging and are mainly attended to by orthopedic surgeons.

Musculoskeletal disorders are the most common cause of severe, long-lasting pain and physical disability affecting hundreds of millions of people in the world. The extent of such problems and the growing burden is described as “age quake” instead of earthquake. The impact on society from these disorders, combined with the recognition that our health care resources need to be used more efficiently, has led to the organized movement of the “Bone and Joint Decade 2000–2010” [3]. This umbrella organization is attempting to raise social awareness of the suffering and pain of musculoskeletal disorders, as well as the growing burden and cost to society that will come with this age quake. We need to advance clinical research in order to reduce the burden of musculoskeletal diseases.

### 10.8.2.2 Aims of Treatment

The aims of treatment for musculoskeletal disorders are not to reduce mortality or morbidity but to increase mobility and function, to relieve pain, or to improve quality of life. We have to assess the results of our interventions with a view to the improvement in disability or functional limitation after treatment. In this field, the clinical indicators are neither a 5-year survival rate nor an infantile survival rate. Our aims are to improve the health-related quality of life of the millions of patients suffering from musculoskeletal disorders such as joint diseases, spinal disorders, severe trauma to the body and extremities, and deformity and crippling diseases in children.

When we talk about outcome measures in disability assessment, the key issue to be discussed is what “function” and “disability” mean and how to measure them.

### 10.8.2.3 Concept of “Construct”

Our function or ability is measured in accordance with conceptual “construct” [4]. We cannot measure this function or ability directly.

In the past, orthopedic surgeons mainly evaluated the amount of disease involvement in view of physiological or biochemical parameters, pathological findings, and impairments such as range of motion or muscle strength. It was thought that these indicators were objective and independent of the unreliable responses or feelings of patients. However, are these indicators truly reflective of the needs of patients and their families to know how much they can expect as a result of treatment? Their expectations and questions would be more like, “Can I walk again?” or “Will she be able to live by herself as before?”

When a certain standardized scale is not available to measure the function or ability of interests, a new construct, according to a concept for measurement, has to be made.

Conventional clinical indicators, such as a 5-year survival rate or an infantile mortality rate, have been recognized as very important health measures in assessing health conditions in society, but lately, the situation has been changing. The recent close-up of patient-based outcome measure is deeply related to this trend [5]. We have to recognize the demand and organize those types of outcome measures for the individual [6].

### 10.8.2.4 Assessment of Function and Quality of Life (QOL)

Functional assessment, from the physician’s point of view, has been mainly used to evaluate problems at the impairment level. Traditionally, orthopedic surgeons have used clinician-based outcomes such as pain score, measurement of range of motion, muscle manual test, or X-ray findings. However, due to various biases and poor judgments of accuracy levels, clinician-based outcomes often affect the clinical ratings on the functional status of patients [7].

For the past two decades, new outcome movements have placed importance on patient-based functional assessment and measurement of health-related quality of life [5, 8].

It is because the statistically significant changes of the visual analog scale (VAS) for pains, from 68 to 42, do not mean any improvement for the patient with chronic pain. The improvement of knee flexion range of 35° does not answer the questions from patients and their families.

The end result of health services should take into account the experiences, preferences, and values of the patients [9]. The discomfort described by patients should be managed properly. We have to evaluate and treat the patient not the disease.

The so-called health-related QOL became the main target of the outcome measures related to patients’ values. As well, of course, it is clear that health-related QOL assessments alone are not enough. In 2001, the World Health Organization (WHO) proposed a new “health” concept called the International Classification of Functioning, Disability and Health (ICF) [10], which describes the pluralistic conception of functional disabilities [11]. Based on the ICF concept, for example, we would assume the problems associated with patients with knee osteoarthritis were as follows:

|                           |                                                    |
|---------------------------|----------------------------------------------------|
| Health condition          | Osteoarthritis                                     |
| Impairment                | Knee pain, limited joint movement, muscle weakness |
| Activity limitation       | Difficulty in mobility-related daily activities    |
| Participation restriction | Difficulty in participating in social life         |

Many items and domains in the outcome measures should be constructed to identify all the characteristics of subjects, with a view to disability and impairment. Irrgang and Anderson [12] described the process for developing such a new measure for health-related quality of life when they designed clinical research related to the knee. In many cases, several outcome measures must be combined to cover every aspect from functional impairment to quality of life.

### 10.8.3 BACKGROUND OF CLINICAL TRIALS

#### 10.8.3.1 Meaning of Clinical Trial

Two related statistical factors have to be considered in order to evaluate the quality of clinical studies. This is essential for the understanding of the quality of studies based on the level of evidence. First, in clinical trials we deal with human beings as research objects. Each human being is different; response is always uncertain, backgrounds vary, and mental influence is inevitable. We should compare groups that are similarly distributed, except for the specific factor that is the target of assessment. Thus, observed differences at the assessments can be directly attributed to the study targets. Second, we mainly evaluate an extracted specimen of limited numbers and then extrapolate the conclusion toward the source population. We attribute the presumption from the sample population to the general population, using statistical inference techniques. Using the statistics observed in the investigated samples, the parameters of the source population are estimated. Depending upon these two premises, we use sampling, randomization, comparison, and other statistical methods. This is a statistical outlook of the world around us.

#### 10.8.3.2 Estimate and Testing

When we treat a patient, we regard him or her not just as a single case but as a representative case among many patients with the same disorder. This concept of patient treatment had already been described by Hippocrates in ancient Greece. There are two important statistical concepts we should consider, probability and confidence interval.

The first topic is the probability, that is,  $P$  values that the result would arise by chance. Depending on the choice of cut-off level ( $P < 0.05$  or  $P < 0.01$ ), we apply a different level of “statistical significance” to the trial. If we find a result in the statistically significant range, we could reject the null hypothesis that there is no real difference between two groups. But a  $P$  value in the nonsignificant range just shows that either there is no difference between the groups or there are too few samples to reveal a difference, if it actually exists.

Also, if we repeated the same trial hundreds of times, we would not get the exact same result each time. We cannot omit an incidence in each trial because we usually conduct only one trial, but we could find a particular level of difference on average

with a 95% confidence interval. If we conducted a trial with a much larger sample size, we would be more likely to show whether a significant result exists or not. The answer is in the comparison of the 95% confidence limits and the clinical significant levels. Very narrow 95% confidence limits suggest definitive results and exclude any clinical obscurity in comparisons. The confidence intervals reveal whether the trials support the result and to what extent and whether any further studies need to be done to reinforce the result.

### **10.8.3.3 Various Biases**

The results of a trial consist of three parts: (1) true value, (2) random error (imprecision) by chance, and (3) systematic error (bias) by other factors. We cannot eradicate random error, but we can eliminate the other biases by using well-designed study protocols. The goal is to suppress the biases as much as possible and improve the quality of the trial; different study designs require different steps to reduce systematic errors. In clinical epidemiology textbooks, there are various biases pointed out such as sampling bias, selection bias, and information bias.

Confounding is the distortion of an association between two factors brought about by the association of another extraneous factor; for example, the association between lung cancer and alcohol consumption is confounded by smoking. The methods of controlling confounding in the design of a study are: restrict the participants to the study, match individuals with other comparison groups, or use random allocation. In the analysis of a study, restrict once again the participants in the data to stratify the individuals into subgroups according to categories of confounding factor and use multivariate methods.

### **10.8.3.4 Methods of Clinical Trials**

To assess the effectiveness of a certain intervention, it is necessary to compare the baseline (before state) with the result (after state) of treatment. But generally speaking, the more abnormal value often shows more improvement.

Detected improvement does not always imply that the intervention was effective. Several other factors may have contributed to the same kind of improvement; such possible factors are natural recovery, “regression to the mean” phenomenon, or the psychological effect called placebo effect. We have to compare with control to get the true change rates by test intervention.

In most clinical trials called controlled trials, there is a group receiving a certain treatment and a comparative group. An essential premise of this kind of trial is that there is genuine uncertainty as to which treatments will be best for the patient. It is this uncertainty that justifies random allocation of patients after the consent forms to enter the trial have been given. Therefore, patients should have the targeted disease and satisfy all the required conditions, that is, inclusion criteria.

### **10.8.3.5 Types of Clinical Studies**

If there were a clinical question about a patient’s management, we should perform a clinical study, no matter what the study design is. The basic structures of a study design consist of a combination of some dichotomous divisions.

1. *Experimental (Interventional) Study or Observational Study* In experimental study, a population is selected for a planned trial of a regimen whose effects are measured by comparing the outcome of the regimen in the experimental group with the outcome of another regimen in the control group. Observational study is a nonexperimental study that does not involve any intervention.
2. *Comparative or Noncomparative Design* In a comparative design, the study design has a control group to compare with the active group. In a non-comparative design, there is no control group to compare with the active group.
3. *Intergroup or Intragroup Design* This is comparison of interventional effects among the groups, or comparison in the same single group, before and after the intervention.
4. *Cross-Sectional or Longitudinal Design* This is the directionality of the study. Data are collected at a single time point or collected at two or more time points and followed up later. But some cross-sectional studies refer retrospectively to experiences in the past.
5. *Retrospective or Prospective Design* This is a part of longitudinal studies. Data are collected at baseline points and other points in the past or future. The timing of data collection is also called concurrent, historical, or mixed.

Considering these dichotomous divisions, a widely used basic study design is a parallel design, which compares the groups, or a cross-over design, which compares the before and after. In the parallel design, subjects are divided into two or more groups, each group receives each treatment concurrently, and the results of treatment among the groups are compared. In the cross-over design, subjects receive two or more treatments at stated intervals and the effect of treatment, within the same subject, is evaluated. The cross-over design has the advantage of a smaller sample size than the parallel design but requires caution to minimize the fluctuating effect of disease severity (“order effect”) and maintain the stability of patients’ symptoms using a “wash-out period.”

The randomized controlled trial (RCT) provides the most powerful proof of treatment efficacy:

*Randomized Controlled Trials* Subjects are randomly allocated into two or more groups. The groups are followed up for a specified time period and assessed in terms of outcomes defined at the start of trials. As the groups, on average, are identical except for the intervention as study target, any differences in outcomes are attributed, in theory, to the interventions.

*Open label* Subjects know which treatment they are receiving.

*More Sophisticated Randomized Controlled Trials*

*Single blind* Subjects do not know which treatment they are receiving.

*Double blind* Neither subjects nor investigators know who is receiving which treatment.

### 10.8.3.6 Random Allocation

Blinding patients to which treatments they are receiving is thought to be essentially important because the effect of the psychological expectations of the patients are

suppressed. In drug therapy, blinding is achieved with a placebo as a control. However, in certain situations, such as a comparative trial between surgery and nonsurgery, blinding is not easily possible. Double-blind techniques for surgical treatments are tentatively proposed; the anesthesiologists and surgeons in charge will maintain silence about treatment choices and patients and the persons assessing the outcomes will not be aware of the treatment choices. Because of the technical difficulty of being unaware of allocation, we sometimes have to accept that patients would know the treatment they received.

Random allocation is done immediately after completing the original registration for a trial with informed consent. However, patients often hesitate to enter a trial because, at the time of registration, they do not know which treatment is indicated for them. Zelen proposed a new method called “randomized consent design” in which random allocation is already performed at the candidate stage of being involved in a trial. Explanation of informed consent is done only about the allocated treatment [13, 14].

#### **10.8.4 METHODOLOGICAL ASSESSMENT FOR CLINICAL TRIALS**

Because of the explosive increase in health care information, all clinicians must be careful of scientific evidence regarding efficacy of treatment methods based on available medical literature. How are we to distinguish the good from the bad among the flood of information? We need a systematic way to select medical information including RCTs.

##### **10.8.4.1 Significance of Clinical Trials**

The practice of EBM is a process of self-directed, life-long, never-ending learning for our patients. Clinicians need to have the most up-to-date clinical information. Our goal is to continuously strive to improve our medical knowledge by scientific methodology. The introduction of newer information technology and medical knowledge has improved the practice of medicine. If we can properly manage to get all of the clinical information from contemporary medical practice, we will be able to master all of the medical experiences of that same period. The collected results could be the most verified medical knowledge that we have ever had.

In the musculoskeletal field, in-patients are, in most cases, operated on, but the majority of out-patients and some in-patients are treated with a combination of conservative therapeutic methods. We need to develop a systematic strategy for the indication and selection of various treatments. The accumulated results of RCTs could be the essential medical information for the most up-to-date treatments.

##### **10.8.4.2 Critical Evaluation of RCTs**

Randomized controlled trials are now regarded as having superior clinical significance, that is, the gold standard for proper treatment, and are recognized as the primary way to provide rigorous proof of efficacy. However, considering the mixture of facts and errors found in the results of studies, we have to check each step of the trial process, even in the case of RCTs. All trials can be scored on methodological

quality according to a few criteria. Basically, these criteria consist of four main categories [15–17]:

1. Design and study population
2. Description of intervention
3. Measurement of outcomes and follow-up
4. Data presentation and analysis

In the recent analyses, these 4 categories were usually further subdivided into a set of nearly 20 items, each with a given weight [18]. Various scales for quality assessment are now available and after some modifications, those for musculoskeletal disorders have been employed in several systematic reviews and meta-analyses [19, 20]. Introduced here is one of the sophisticated examples of a criteria list for assessing quality of trials in a published article (Table 1).

### **10.8.5 PREPARING NECESSARY TOOLS FOR CLINICAL TRIALS**

On the basis of my personal experience, the next few sections describe the minimum essential steps in conducting a clinical trial (Table 2); the reader should refer to appropriate textbooks for further reading [21–26]. Recently, this kind of information has also been available on the Internet; the Resource Center for Randomized Trials [27] is an example. The Resource Center has various activities, and one of the useful services is a Web-based library for accessing information about trials; there are checklists for trials, consent forms for participants, and patient information leaflets. Other public information on clinical trials is also provided by the U.S. government [28].

#### **10.8.5.1 Developing Protocol**

The first step in conducting a trial is developing the protocol. When the details of how the trial is to be conducted are determined, it is essential to reduce various relating biases. Farrell and Spark [29] described a protocol checklist as a detailed method to use when conducting a trial (Table 3). Developing a protocol takes a long time, sometimes up to a few years to get funding, secure ethical approval, and organize a trial collaboration team. I think the best thing for anyone planning a trial for the first time to do is to refer to some successful protocols. Many protocols are now available on the Internet. A protocol should clearly show how outcomes will be measured, data collected, and the analysis conducted.

#### **10.8.5.2 Patients**

Use of inclusion/exclusion criteria is important to make it possible for the trial results to be more reliable. Inclusion criteria are used to identify appropriate subjects, keep them safe, and able to answer the research questions. Exclusion criteria are also very important in participant recruitment to avoid unnecessary involvement of inappropriate subjects in the study.

**TABLE 1 Criteria List for Assessing Methodological Quality of Trials**

| Heading      | Subheading                     | Descriptor                                                                                                                                                                                                      |
|--------------|--------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Title        |                                | Identify the study as a randomized trial.                                                                                                                                                                       |
| Abstract     |                                | Use a structured format.                                                                                                                                                                                        |
| Introduction |                                | State prospectively defined hypothesis, clinical objectives, and planned subgroup or covariate analyses.                                                                                                        |
| Methods      | Protocol                       | Describe                                                                                                                                                                                                        |
|              |                                | Planned study population with inclusion or exclusion criteria.                                                                                                                                                  |
|              |                                | Planned interventions: their nature, content, and timing.                                                                                                                                                       |
|              |                                | Primary and secondary outcome measure(s) and the minimum important difference(s), and indicate how the target sample size was estimated.                                                                        |
|              |                                | Reasons for statistical analyses chosen, and whether these were completed on an intention-to-treat basis.                                                                                                       |
|              | Assignment                     | Mechanisms for maintaining intervention quality, adherence to protocol, and assessment of fidelity.                                                                                                             |
|              |                                | Prospectively defined stopping rules (if warranted).                                                                                                                                                            |
|              |                                | Describe                                                                                                                                                                                                        |
|              | Masking (blinding)             | Randomization (e.g., individual, cluster, geographic).                                                                                                                                                          |
|              |                                | Allocation schedule method.                                                                                                                                                                                     |
| Results      | Participant flow and follow-up | Method of allocation concealment.                                                                                                                                                                               |
|              |                                | Describe                                                                                                                                                                                                        |
|              |                                | Mechanism for maintaining blind and allocation schedule control.                                                                                                                                                |
|              |                                | Evidence for successful blinding.                                                                                                                                                                               |
|              |                                | Provide a trial profile summarizing participant flow, numbers and timing of randomization assignment, interventions, and measurements for each randomized group.                                                |
|              | Analysis                       | State estimated effect of intervention on primary and secondary outcome measures, including a point estimate and measure of precision (confidence interval).                                                    |
|              |                                | State results in absolute numbers when feasible (e.g., 10/20, not 50%).                                                                                                                                         |
|              |                                | Present summary data and appropriate descriptive and inferential statistics in sufficient detail to permit alternative analyses and replication.                                                                |
|              |                                | Describe prognostic variables by treatment group and any attempt to adjust.                                                                                                                                     |
|              |                                | Describe protocol deviations.                                                                                                                                                                                   |
| Discussion   | Discussion                     | State specific interpretations of study findings, including sources of bias and imprecision (internal validity) and discussion of external validity, including appropriate quantitative measures when possible. |
|              |                                | State general interpretation of the data in light of the available evidence.                                                                                                                                    |

In spite of application of well-defined inclusion/exclusion criteria, it is commonly thought that about half of all clinical trials do not achieve their planned sample size [30]. As a recruitment strategy, necessary sample size is calculated to cover the expected number of dropout cases. It seems to me that the calculated number of the sample size is just for reference as an appeal to the cautious attitude of the researcher when conducting the trial.

### 10.8.5.3 Interventions

Treatments in musculoskeletal disorders, apart from surgical interventions, are classified into “drug therapy,” “therapeutic exercise,” “physical agents,” “orthotics and devices,” “education or care packages,” and “others.” When these intervention methods are indicated in the experimental group, it is important how comparative methods are selected in the control group. It is impossible to use the double-blind technique with placebo in musculoskeletal disorders because the comparative control is obviously different from the experimental content for the trial participants. The patients already know which treatments have been allocated and only

the assessors are unaware of the allocation results. This “open-label method” is often indicated in this field.

#### 10.8.5.4 Outcomes

The content of outcomes used in clinical trials should be important to patients, usually the five D’s: death, disease in clinical course, discomfort in symptoms, disability in activities of daily living (ADL), and dissatisfaction in QOL. There are many de facto standards for outcome measures in musculoskeletal disorders (Table 4).

Another important point in the use of outcome measures is the timing of application. Follow-up periods for outcome measures are categorized as short term (less than 6 weeks), intermediate term (6 weeks to 1 year), or long term (more than 1 year follow-up).

In an RCT, the results basically underestimate the difference between the comparative groups because the analysis is conducted with a more conservative standpoint for assessment (an intention-to-treat principle), and that will tend to dilute the estimate of the true difference. The content of interventions often fluctuates depending upon its nature, application timing, and patients’ adherence. When the patients receive the strict treatment, they can expect more obvious efficacy than that reported.

#### 10.8.5.5 How to Choose Right Outcome Measures

As an example, there is a quick-reference book that summarizes and evaluates more than 150 outcome measures for each joint of the extremities [39]. As Suk et al.’s handbook does not include the outcomes for spinal disorders, we have to have proper outcome measures for those, including neck and back problems [40, 41] (Table 4).

The necessary information for selecting outcome measures is as follows:

1. Goal of measurement
2. Nature of measurement: questionnaire, performance rating, physical properties
3. Specific population for which the instrument was developed
4. Format of measurement: number of items, response options, minimum and maximum score
5. Issues related to feasibility: time needed to perform the measurement, required equipment, and training

For clinical researchers, outcome measurements are essential for the advancement of their studies. To assess the overall quality of an outcome measure, three major elements should be considered: content of construct, psychometric evaluation, and clinical utility.

The conventional methods of studying the dimensional structure of measures are principal component analysis and factor analysis; Cronbach’s  $\alpha$  is calculated to determine the internal consistency of the dimensions. Outcome measures usually consist of one or more domains that reflect the concept of supposed construct.

**TABLE 4 Widely Used or Highly Qualified Outcome Measures for Musculoskeletal Disorders**

---

It is very important to review, integrate, and consolidate the information with measuring instruments for cross-cultural use [6].

#### 10.8.5.6 Questionnaires

The clinical utility of an outcome measure is divided into two parts: patient friendliness (acceptability) and clinician friendliness (feasibility) [42].

If we want a questionnaire to be user friendly, for both patient and clinician, and to improve clinical utility, the questionnaire has to be refined repeatedly. The content of the questionnaire must be limited to the minimum amount of information needed and be designed to be filled out easily. Even in the case of multiple choice or fill-in-the-numeral forms, there are some problems involved in interpreting the data.

Recently, the content of questionnaires that has only been determined by so-called expert staff is no longer regarded as sufficient for assessing content validity. We have to include the opinions of patients during the development process of the questionnaires in order to check content validity and face validity (these are often used interchangeably).

## 10.8.6 DATA ANALYSIS AND INTERPRETATION

### 10.8.6.1 Sample Size

The sample size of a trial is calculated based on the estimate of primary outcome [43]. I would like to show an example of how to calculate a sample size from the difference between the two means.

We have to recognize a way of denying null hypothesis, which is always associated with false-positive and false-negative rates. The former (false positive) is known as the type I error, that is, significance level  $\alpha$ . The latter (false negative) is the type II error  $\beta$ , and  $1 - \beta$  is the power. The sample size is given here in the condition of two groups' comparison, and randomization in equal group numbers.

$$\text{Sample size } N = \frac{4(Z\alpha + Z\beta)^2}{\Delta^2}$$

where  $Z\alpha$ ,  $Z\beta$  are standardized normal deviates for given  $\alpha$ ,  $\beta$ , and  $\Delta$  is standardized effect size.

$$Z\alpha = Z_{1-\alpha/2}; \alpha = 0.05 \text{ in two-sided, then } Z_{1-\alpha/2} = Z_{0.975} = 1.96$$

$$Z\beta = Z_{1-\beta}; \text{ a power of } 1 - \beta = 0.9, \text{ then } Z_{1-\beta} = Z_{0.9} = 1.645$$

$$\Delta = \mu A - \mu B / \sigma; (\mu A - \mu B) \text{ is difference between the two means, and } \sigma \text{ is standard deviation of the endpoint}$$

If you set  $\Delta$  less than 0.1, approximately 0.5, or more than 1, it means a small, moderate, or large standardized effect, respectively.

Sample size is noted in the majority of articles on clinical trials. Sample size depends on whether we want much more power to test the difference among the groups or we want to estimate the precision of the confidence interval. If we have an available working hypothesis, we can calculate the necessary sample size according to other similar studies. The result of the calculations only indicates the number required for the data analysis. Usually, we have to add a few more cases, expecting that there will be some dropouts.

### 10.8.6.2 Intention to Treat

Intention to treat (ITT) is a conceptual principle and is not defined as a specific technical procedure. One widely used procedure is to review the data in detail when the treatment and follow-up have been completed and all the patient information has been collected, that is, at the time that all the data has been frozen. Once allocation has been done, it is the ITT principle to analyze as if the original allocation was continued, even after the intervention itself was changed. The “last observation carry-forward” method is able to cover the deficit data when the trial has been in progress for some time (more than two check points).

However, even such principles cannot be maintained at analysis in the following cases:

1. Criteria unfit for inclusion, even after allocation
2. Complete loss to follow-up

### 10.8.6.3 Multiple Comparisons

We must cut down the working hypotheses to one main one. In a usual trial comparing two groups, a statistical test provides a figure of  $P$  value as the boundary line for the verdict of hypothesis. If the calculated  $P$  value for the primary endpoint is less than the predefined line (usually  $P < 0.05$ ), we will deny the null hypothesis of no difference between the groups. However, if we use more than one endpoint, there are more than two comparisons arising (sometimes this situation becomes much more complex with multiple comparisons). In such a situation, a false-positive rate is no longer  $\alpha \times 100\%$  and increases according to the number of multiple comparisons.

### 10.8.6.4 Post Hoc Analysis and Subgroup Analysis

It is the nature of things that the therapy-responder group has a better prognosis and the nonresponder group has a worse result. That is a typical post hoc analysis. Grouping allocation should be provided at the beginning and after disclosing the result, retrograde grouping is not permitted.

At times, clinicians like to know whether certain types of patients show more obvious benefits from interventions than others, knowing that a sample group of interest is a mixture of various types of patients. This is the subgroup analysis, for example, mild or severe cases, young or old patients. Some subgroups could easily reveal positive effects by chance, even if the overall trial results are negative. A common mistake is to mix the  $P$  value of more than 0.05 in all data-combined analysis and less than 0.05 in one or more subgroup(s). This may lead to the false conclusion that a certain subgroup has a favored result by chance, in spite of the fact that the true result is negative. When you plan a subgroup analysis at the design stage, advance adjustment in sample size should be considered.

### 10.8.6.5 Data Synthesis and Combined Result

If there are several numbers of articles available for review, systematic review, is regarded as an “infrastructure” of the information system supporting EBM practice.

In regards to treatment, the pathway of systematic review is very logical; so the results provide the most accurate and authoritative guidelines for therapy. To avoid potential problems in interventional studies (clinical trials), only RCTs should be included, with complete follow-up information, blinded outcome assessment, and analysis based on intention to treat. This is applicable to an epidemiological research in observational studies, but it is still unable to solve all the problems of biases.

Meta-analysis is defined as a statistical synthesis of the numerical results of some trials (quantitative systematic review) that all examined the same question. It is a type of research that attempts to reanalyze and combine the results already reported, mainly as RCTs.

The assessment of methodological quality for meta-analysis has been recognized to be very important because even the conduct of an RCT is no guarantee of unbiased outcomes from such a study. Even meta-analysis and systematic reviews should be scrutinized carefully and analyses based on small studies should especially be treated with caution.

#### **10.8.6.6 Side Effects**

We have to pay sufficient attention to avoid adverse effects. In the case of surgery, examples of adverse side effects are nerve injury, infection, bleeding, secondary osteoarthritis, and even death. Some side effects occur even in conservative therapy.

We cannot say that treatment side effects are out of the question, even if there is no obvious difference in the frequency and degree of adverse effects between the treatment group and the control group in a certain RCT. An RCT is not an appropriate design to assess side effects because an RCT basically suppresses the number of patients to a minimum and the incidence of side effects is usually low. The role of the trial steering committee and the data-monitoring committee should be established and the range of their responsibilities defined. These committees have to take necessary actions such as early stopping, considering the results of the interim analysis, or the frequency and content of side effects. I realize that relatively small size trials do not often have the side effects and other problems that would stop a trial, but large multicentered trials have the latent possibility of such troubles.

#### **10.8.6.7 Reporting Clinical Trials**

After completing a clinical trial, an important step is to report the results, whether positive, negative, or equivocal. Selective reporting, in which only positive studies are published, often distorts a true situation; this practice is called “publication bias.” When meta-analysis is performed as a clinical trial overview, it is definitely important to include all relevant unpublished trials to gain overall results.

The International Committee of Medical Journal Editors, which consists of several leading medical core journals, decided that clinical trials should be registered in advance [44, 45]. If clinical trials are not registered in advance, journals might refuse to publish a report of a trial. This is an important step in avoiding publication bias and other inappropriate analyses.

Article writing is regarded as a form of communication or “dialog,” even in the case of a scientific journal; that is the object of our communication. The writer of an article must be aware of the target audience. Consolidated Standards of

**FIGURE 1** Example flowchart of trial according to CONSORT statement.

Reporting Trials (CONSORT) is one of the examples of such a checklist or flowchart to be used, as well as the instructions for improving the quality of reporting randomized controlled trials when a paper is to be submitted [46, 47] (Fig. 1). Also suggested through discussions at a conference was a guideline for reporting systematic reviews or meta-analysis referred to as the Quality of Reporting of Meta-analysis (QUOROM). The discussions resulted in the creation of the QUOROM Statement, which consists of a checklist and flowchart [48].

### 10.8.7 RCT AND FUTURE DIRECTIONS

At the close of this section, I would like to talk about how to apply the results of an RCT to daily practice, as well as mention the potential problems when reaching the limit of a statistical outlook.

### 10.8.7.1 Impact from RCT to Daily Practice

Medical practice is a life-long, continuous process of self-learning, and, as clinicians, we are required to keep up-to-date on various medical developments. Evidence-based medicine is our way of integrating individual clinical expertise with the best available evidence to assist us in making decisions about each patient's care. Reported results of RCTs make it possible to cover the majority of our activities systematically, from daily practice for patient care to writing and reading scientific papers.

Evidence-based medicine is regarded as a new paradigm in medical practice, equal to the Human Genome Project. However, there is still much confusion and misunderstanding about the concept and content of EBM; it is often limited to searching the literature and reading articles, and to serving cost cutters and suppressing clinical freedom. The use of clinical guidelines or the managed care system is seen as intimidating the discretion of doctors in clinical practice. EBM is also seen as the fashionable trend of a group of medical academics armed with epidemiological and statistical jargon, but there are more serious basic problems behind such a statistical paradigm.

### 10.8.7.2 Internal Validity and External Validity

In clinical practice we are always surrounded by a condition called the "gray zone" [49]. Of course, there are many factors involved in this obscurity. I would like to focus closer attention on a statistical outlook of the world around us, that is, internal validity and external validity.

These are concepts relating to the extrapolation of the relationship between sample and source populations. In an experimental trial like an RCT, internal validity is high because the difference between the experimental group and the control group is thoroughly controlled only for the target issue, and by chance. However, external validity is low when the results from the sample with several specific premises are brought into a general finding in the mother population. On the contrary, in an observational study, such as a cohort study, there are many confounding factors involved and internal validity is low in surveyed samples. External validity in an observational study is high because a real situation in a resource population reflects just what it is (Fig. 2).

### 10.8.7.3 Quantitative Study and Qualitative Study

Clinical trials cover a wide range of medical fields and use very diverse methods. The data used is basically divided into quantitative, such as laboratory data, and qualitative, based on verbal information collected (mainly used in psychology or nursing science at present). Behind the methods of investigation and analysis in these quantitative and qualitative approaches, there is an obvious difference in concepts [50].

The general concept for study design consists of the following characteristics (Table 5):

1. Aims of study
2. Methods of outcome measurements

**Observational Study**

Cross-sectional Study  
or Cohort Study

Internal Validity: low  
External Validity: high

**Interventional Study**

Randomized Controlled Trial  
Blind & Placebo-controlled

Internal Validity: high  
External Validity: low

**FIGURE 2** Relationship between sample and mother population.

**TABLE 5** Comparison Between Quantitative Research and Qualitative Research

|                                | Quantitative Research | Qualitative Research    |
|--------------------------------|-----------------------|-------------------------|
| Study design                   | Intervention          | Observation             |
| Methods                        | Survey, experiment    | Interview               |
| Question setting               | Enumeration           | Classification          |
| Reasoning                      | Deductive             | Inductive               |
| Sampling method                | Statistical model     | Theoretical model       |
| Closeness to the truth         | Internal validity     | Credibility             |
| Applicability/generalizability | External validity     | Concept transferability |
| Consistency                    | Reliability           | Dependability           |
| Neutrality                     | Objectivity           | "Confirmability"        |

3. Selection of subjects

4. Analytic methods and provided results

In a conventional quantitative study, the main strategy is to make up a working hypothesis and test it. An RCT is a typical example of this type of strategy and is inseparable from biostatistics for data analysis. To generalize the results from samples, such as the rejection of null hypothesis in the majority of confirmatory studies, requires estimating and testing as a basic procedure. The advance of computer technology makes possible the use of multivariate analysis and the ability to search and verify potential factorial structure, even without a working hypothesis.

This technique makes it easy to analyze latent factorial structure, which occurs in some observational studies, from a calculated relationship of how the weight distribution among explanatory variables accounts for the tendency of objective variables. Therefore, this exploratory study makes it possible to investigate and verify risk factors or to produce a model of a certain phenomenon. The distinction between the term “quantitative” study and “qualitative” study will be more obscure once the quantitative studies move toward an exploratory nature from a confirmatory one for testing hypothesis.

On the contrary, a qualitative study does not always follow the deductive logic of applying the result from a sample to the mother population. Researchers try to categorize the verbal information received from subjects to establish a coding system for the data and generalize a new concept in order to build a new theory or model. It is good enough to select the subjects that fit the aim of a study as one likes. It would be possible to produce an epochal qualitative study that could produce a unique, clinically significant theory that would never have been yielded by a confirmatory study using hypotheses testing. A qualitative study is able to make progress in building up a new and significant theoretical system [51]. However, good or bad, theory is totally dependent upon the capability of the researcher.

#### 10.8.7.4 Further Suggestions

If a certain intervention shows obviously successful results for an otherwise lethal condition, we do not require RCTs and do not wait for more studies to be conducted. We can get the evidence from the basic sciences, properly designed follow-up studies, or proper cross-sectional trials.

We need to be careful not to become so skeptical as to assume that if a study is not an RCT it would have no value or use. We also need to recognize the limitations of a statistical approach through RCTs. At each step, we continue our efforts to track down the best evidence to answer our clinical questions and promote cost-effective prevention and treatment for musculoskeletal disorders.

### 10.9.1 INTRODUCTION

Patients with cancer have their diagnostics and treatment in different departments of virtually every hospital. Still, when it comes to research, most of it would be conducted either in specialized cancer centers or in oncology departments of larger hospitals. We can say that oncology as a distinct branch of medicine indeed developed due to clinical research. Without clinical research, oncology as a discipline would not exist. Without clinical research, our only guidelines would be statements like “I think ...” or “I remember two similar patients ...”.

Many oncologists are sceptical in their attitude toward new developments. This is not unexpected. The nature of the disease itself with its unpredictable course and many false hopes do not support overt optimism at every new idea. Nevertheless, a healthy degree of scepticism should not be understood as pessimism. Looking from the perspective of one or two years, no dramatic progress may be apparent. Still, in the long run, the battle against cancer is a story of hundreds of small victories. Fifty years ago, only a tiny minority of cancer patients with truly limited disease could hope for a successful cure by surgery. For the rest, cancer stood as an invincible stone wall. Systematic clinical research led to erosion of this wall, piece by piece. Hematological malignancies and pediatric tumors, testicular cancer, breast, prostate, gastrointestinal, lung cancer—the prognosis of each of these tumors in terms of cure, prolonged survival, or quality of life has improved significantly. Thousands of clinical trials have contributed to this gradual progress.

Our understanding of how the treatment works and why it is effective in one patient but fails in another apparently similar case lags behind clinical experience. In the past, we used to apply treatments and hope for some 30% chance of remission, at the same time often ignoring the fact that the majority of patients did not benefit from the treatment and experienced only its side effects. In the past, we used to say that cancer was not one disease but about 200 different diseases. We then gave up hope for a single miracle drug against cancer and accepted the fact that each of these diseases demands a different treatment. In the future, we may need to go further in our individualized approach. Relatively common diseases such as breast cancer or non-small-cell lung cancer are now subdivided into separate entities, depending on phenotypic and genetic characteristics of tumor cells. Clinical research in oncology is turning into a truly team venture: pathology, molecular biology, genetics, and immunology provide essential information for individual classification of a tumor. So deep is the change in methodology that we can speak of a new era of clinical research in oncology [1]. Better understanding of tumor biology and of pharmacogenomics will lead to much more individualized assignment of treatment and, consequently, to more predictable outcome.

Final introductory remarks deal with professionalization of clinical research. What used to be an amateur activity several decades ago is now almost entirely in the hands of professionals supported by pharmaceutical companies or (rarely) public funds. Among clinicians, only a tiny minority of senior “opinion leaders” will be asked to participate in the design of clinical trials; for the rest, clinical research has become synonymous with recruiting patients and filling clinical record forms (CRFs). While increased funding from private funds and from for-profit companies led to important new discoveries, professionalization of clinical research has also

its dark side. It typically produces large multicenter trials focusing on common cancers where substantial profits are expected and often ignores rare tumors; yet, taken together, these rare tumors comprise more than half of all patients with cancer. Commercial interests often prevail over honest scientific evaluation of research proposals, and many promising initiatives and ideas remain unexplored. In the phase of designing a new trial, sponsors do not listen to creative young physicians. While we need large multicenter trials, we should also support simple, innovative, small trials not necessarily sponsored by industry. In a world where every new idea is tested and retested, size of a trial is of minor importance. What matters are innovative potential, reliability of research methodology, quality of the data, and fair reporting [2].

### **10.9.2 GENERAL COMMENTS ON ETHICAL ISSUES**

In any branch of medicine, ethics is at the beginning and at the end of every discussion on clinical research. Ethical issues are crucial when planning a clinical trial, throughout its actual performance, and when formulating experience and implications for routine treatment and for further research. Oncology is not an exception to this general rule.

We here offer four general statements on ethics of clinical cancer research. Some specific comments and recommendations will be made also in other parts of the text.

#### **10.9.2.1 Ethical Demand for Research**

Considering the enormous burden imposed by cancer on every patient and on society as a whole, it would be unethical not to search for new effective and safer approaches to treatment. During the past five decades, clinical research led to an improved outlook for virtually every cancer. Systematic clinical research is not only ethically acceptable but indeed an obligation for everybody in the field of oncology.

It is estimated that only between 3 and 10% of cancer patients participate in clinical trials [3], with even lower representation of elderly patients and minorities [4]. Since it is clear that our progress in the field of oncology critically depends upon the proportion of patients enrolled in clinical research, low recruitment of patients into clinical trials is not only a problem for the researchers but indeed for society as a whole. While public understanding and support for medical research generally increases, refusal of an eligible patient to participate in a clinical trial is not uncommon [5]. Time-consuming procedures for actual performance of a clinical trial with physician's time as a diminishing resource, and the impact of greater demands in a climate of decreasing health care resources have a negative effect on accrual [6, 7]. To increase trial participation, there is a critical need for infrastructure to support trials, especially additional support staff and research nurses [8]. Other obstacles to clinical research include legal restrictions, as seen in the European Union Clinical Trials Directive [9] or in the Declaration of Helsinki [10]. These documents should be critically discussed and, hopefully, amended. Please see the excellent discussion on this matter by Harris [11].

### 10.9.2.2 Ethical Obligation of Patients

From the legal standpoint, a patient with cancer is absolutely free to accept or to refuse participation in clinical research. From the ethical standpoint, however, a patient has a moral duty to participate in a clinical trial that has passed an independent scientific and ethical review and that does not present an unproportionate burden or risk. This moral duty is based on the fact that patients of today expect to be treated according to the best current knowledge. This knowledge increases continuously and is derived from the past clinical research. Patients of today, therefore, benefit from the fact that patients of yesterday participated in clinical trials—and have a moral duty to contribute to the medical knowledge that will also benefit them, future generations of patients, and society as a whole [11].

### 10.9.2.3 ALARA Principle and Positive Ethical Balance

In the practice of clinical research, ethical puritanism is rarely achievable. In spite of meticulous plan and execution of a trial, some “ethical costs” are inevitable. Instead of speaking of zero ethical costs, we follow the philosophy of ALARA—*as low as reasonably achievable* [12]. We also speak about a positive balance between the benefits of a trial (as applicable to patients in the trial and to society as a whole) and ethical costs.

Practical possibilities for lowering ethical costs and for a positive balance between benefits and ethical costs in clinical research will be presented in Sections 10.9.4 and 10.9.5.

### 10.9.2.4 Patient with Cancer with Comments on Informed Consent and Real Patient Autonomy

Among patients with cancer, we can rarely speak about full autonomy. Patients are not only medically uneducated but also under serious physical and emotional burden of the disease.

In spite of this well-recognized burden of malignant disease, information offered to cancer patients during recruitment for clinical trials is often very extensive, written in a complicated medical and legal jargon, and with detailed description of all possible and rare complications of the treatment. Such extensive and frightening information does not add to patient’s autonomy. Rather, many patients sign consent forms without an attempt read such an extensive text, leading to a diminished autonomy. According to a survey among physicians recruiting patients for randomized clinical trials, 42% of patients were not fully informed about the trial [13]. In another survey, the majority of patients who recently signed consent for participation in a trial did not recognize the nonstandard treatment nature of the trial (74%), the potential for incremental risk from participation (63%), or the unproven nature of the treatment (70%) [14]. An additional argument against extensive text of informed consent comes from Eastern Cooperative Oncology Group, which randomized patients between the standard consent procedure to an easy-to-read consent statement. A simplified text did not affect patient comprehension and resulted in significantly lower consent anxiety and higher satisfaction [15].

Even from a purely legal standpoint, it should not be too difficult to prove that many patients with cancer sign consent without being fully competent and/or do not have a free choice.

If we accept limited patient's autonomy as a reality, then we have to accept also the fact that many patients do not rely on rational considerations but simply trust their doctor. Thus, while we need patient's consent, the responsibility stays with the physician. Physician's paternalism, whether we agree with it or not, is often a reality. A physician who is also a clinical researcher should be aware of the delicacy of his or her role. He should be aware that his relation to the patient does not derive from a contract, but rather from a patient's trust. As he cannot get rid of a certain degree of paternalism, he has to strive constantly to push his role of a physician ahead of his role of a researcher.

In concluding this section, we recommend that the information for patient is adjusted to his or her real condition: brief, understandable, with realistic presentation of the problem and also offering some hope. While patients have the right to full information, they should not be excluded from research in case they opt for a simplified procedure. Rather than continuing with what is increasingly obvious to be a fiction—that fully informed consent has been obtained—we should perhaps move to a consent protocol that is basically simple consent in the presence of full information. A summary paragraph to each information sheet would allow the patients to focus on that alone if they choose to do so [16].

### 10.9.3 DIFFERENT MEDICAL PROBLEMS IN CLINICAL TRIALS

Understanding the medical problem is essential for choosing appropriate methodology for a clinical trial. We will briefly review some specific medical problems in oncology and offer comments on the research methodology.

#### 10.9.3.1 Prevention of Cancer

Various food supplements, hormones, hormone antagonists, antiviral vaccines, other substances, and even surgical procedures have been studied with the aim of cancer prevention [17–21]. While a critical coverage of this area would be clearly out of the scope of our discussion, we here offer some specific recommendations.

- Before initiating a trial, its scientific background should be thoroughly discussed. A clear distinction should be made between the two possibilities: to delay or to prevent occurrence of a particular cancer. Cancerogenesis is a long process. From the experience on secondary cancers induced by radiation or anticancer drugs, we know that there is an interval of at least 5 years between the carcinogenic mutation and clinical detection of cancer. On short terms of a few years, we may expect only a delay of occurrence of a cancer that was already in its subclinical form. If we speak about real prevention, we cannot expect a detectable effect on clinical incidence of a particular cancer in less than 8–10 years.
- The population of persons at an increased risk for a particular cancer should be clearly defined. Even so, we are dealing with healthy persons and not with

patients. The intervention studied should impose a negligible risk and minimal discomfort to participants.

- The control groups are either “pure” controls or are given placebo. Compliance is often poor: Subjects in the intervention group may not follow the procedure, while subjects in the control group may get the substance (such as a food supplement) from other sources. Besides, it is unrealistic to expect good compliance in a trial that continues over many years. Suboptimal compliance leads to dilution of the results and demands a greater number of subjects involved.
- To prove that an intervention lowers the incidence of a relatively rare event, many thousands of individuals have to be followed over a long period.
- Trials of cancer prevention are commonly linked to a program for early detection of a particular cancer. Impact of the intervention upon the incidence of a particular cancer is the obvious objective of such a trial. Still, the real value of an intervention among healthy individuals would be reduction in mortality from any cause, coupled to uncompromised quality of life. As an example, antiestrogens given to healthy women at an increased risk for breast cancer led to reduction in the incidence of breast cancer; yet, most of the prevented tumors were highly curable hormone-dependent cancers. The incidence of the more malignant hormone-resistant cancers remained almost the same, and there was no reduction in mortality. Furthermore, an increase in endometrial cancer and more frequent thrombo-embolic events were observed; the impact of antiestrogens upon subtle differences in the quality of life of healthy women remains unknown. Therefore, incidence of a particular cancer should not be the principal objective of a trial and should be regarded as a temporary surrogate endpoint.

### 10.9.3.2 Induction (Neoadjuvant) Therapy

Induction systemic therapy prior to definite local treatment with surgery and/or radiotherapy is a very promising approach that is increasingly used in apparently localized tumors [22–28]. Compared to adjuvant (postoperative) systemic treatment, induction therapy has several advantages: Treatment of micrometastatic disease begins immediately; the tumor may shrink and become operable in a higher proportion of patients; clinical, radiologic, and pathologic evaluation of response to systemic therapy will be important for further treatment strategy. The potential dangers of induction therapy in operable disease are resistance to chemotherapy, in which case a tumor may actually grow during induction treatment and become inoperable, and the risk of an increase in the incidence of perioperative complications. Prior to randomized trials, solid data from phase II trials should provide a reliable estimate of these risks.

It is essential that induction therapy and local treatment with surgery and/or radiotherapy are part of the same treatment protocol with precisely defined timing and as short a gap as possible between systemic and local treatment. Tumors that shrink during induction therapy will often regrow rapidly. If the interval between induction therapy and local treatment is too long, accelerated repopulation of the tumor may quickly annihilate all the benefits of combined treatment [29].

### 10.9.3.3 Adjuvant Therapy

Patients at an increased risk for relapse after local treatment are often given adjuvant chemotherapy, aimed at reducing this risk. Such a strategy has been widely accepted in breast cancer [30], lung cancer [23], and several gastrointestinal cancers [22]. Many new trials are in progress to improve the ratio between efficacy and side effects for the existing indications and to study this approach for new indications.

A substantial proportion of patients offered adjuvant treatment might be cured of cancer with local treatment alone. As an example, a recent trial among 1146 patients with early breast cancer has shown a 65% 10-year disease-free survival after surgery and adjuvant chemotherapy, compared to 60% after surgery alone ( $p < 0.01$ ) [31]. This experience has been presented as evidence for the indication of adjuvant therapy. Yet, these figures can be interpreted also from a different angle. We can say that 60% of patients were cured by surgery alone; that 35% had a recurrence in spite of adjuvant therapy; and that only 5% actually benefited from adjuvant treatment. It is clear, then, that the benefit of a prolonged disease-free interval and of improved survival should be weighted against side effects of the adjuvant therapy, and it is therefore essential that studies of adjuvant therapy include assessment of quality of life.

Planning a trial of adjuvant therapy has several elements in common with trials of cancer prevention. As there is no possibility for individual assessment of response, we have to enroll a large population of healthy individuals or patients after successful local treatment, and we usually measure the success with time to event (diagnosis of cancer in the case of prevention trials, time to progression in adjuvant treatment). In both instances, we should understand that time to event is only a surrogate endpoint: It is only an improvement in overall survival that validates the results. While some cancers or some recurrences of cancer that we wish to prevent are still curable, it is also important that the prognosis of what we wish to prevent is generally dismal. If this were not the case, it would make no sense to engage in prevention of a highly curable situation.

### 10.9.3.4 Trials of Concomitant Radiochemotherapy

In this section, we are dealing with two distinct categories of patients. In the first are patients with truly localized cancer such as early laryngeal or cervical cancer. A high proportion of these patients are cured either by surgery, by surgery and postoperative radiotherapy, by radiotherapy alone, or by combined irradiation and chemotherapy. When the prospects with each particular treatment are good, the decision regarding the treatment depends on patient's preferences, on side effects of each of these treatments, and on the expertise and influence of particular oncologists. The second category are patients with inoperable locally advanced disease without overt distant metastases for whom surgery is not an option.

During the past decade, there was an explosion of trials of concomitant radiochemotherapy. When nonsurgical treatment with curative intent is applied, head and neck cancers, lung, esophageal, gastric, colorectal, pancreatic, cervical and bladder carcinomas, many brain tumors, sarcomas, and most pediatric tumors are now all treated with concomitant radiotherapy and chemotherapy [32–41].

While a certain degree of uncertainty regarding the true advantage of combined-modality treatment persists, we can be confident that the trend of combined-

modality treatment will continue. Irradiation, probably to higher total doses and possibly with different schedules of fractionation will be combined with new drugs, all with the aim of achieving a better local and systemic control of the disease at the expense of acceptable toxicity. It is more than clear that both the effect against the tumor and the pattern of acute and late toxicity of combined-modality treatment are unpredictable. "Wishful thinking" should be avoided, and well-designed phase I and II clinical trials are needed [42]. In this section, we will present a selection of recent accomplishments and of basic knowledge important for the design of combined-modality trials.

Radiotherapy of today is virtually incomparable to what this treatment used to be just two decades ago. Modern technology has allowed very precise targeting of the tumor and of critical healthy tissues. Since the coverage of the tumor by radiation is much more precise and the margin of healthy tissues is getting smaller, we see fewer side effects along with higher efficacy of radiotherapy in eradication of a tumor. Instances of "individual hypersensitivity to radiation" (which in fact often represented cases with grossly imprecise dosimetry) are now rare and treatment with radiotherapy can proceed to higher total doses with predictable and acceptable toxicity.

The technological advances of radiotherapy are important not only for trials of radiation alone but also for the design of combined-modality trials. It is extremely important to understand that radiotherapy with the total dose and the fractionation that used to be standard radical radiotherapy one or two decades ago is now a sub-optimal treatment. As an example, 60 Gy in 30 fractions over 6 weeks used to be a standard for radiotherapy of lung cancer in the 1980s and early 1990s; today, the optimal dose is from 64 to 74 Gy, and in some trials even higher [43].

A reader familiar with radiobiology may skip this paragraph. For the rest who are just interested in combining radiation with drugs, it is essential to understand the importance of fractionation upon tumor control and upon the pattern of acute and late side effects of irradiation. Regarding *tumor control*, the classical and still valid advice is: "Give as many fractions as possible in as short a total time as possible." Hyperfractionated irradiation and hyperfractionated accelerated irradiation with more than one small fraction per day were tested and proven to be superior to standard radiotherapy for head and neck and lung cancers [44, 45]. Hyperfractionation produced more *acute side effects*, which were usually transient and rarely extended into chronic toxicity. On the other side of the spectrum of fractionation, we have hypofractionation with fewer large fractions of radiotherapy. While this approach is useful for palliation where the total dose is low, hypofractionation cannot be recommended for treatment with curative intent. Severe *late and permanent toxicity* was observed in trials of hypofractionated radiotherapy.

It is clear that even at very high doses, radiotherapy alone cannot cure many tumors. The concept of synergistic effect of radiotherapy and chemotherapy has been tested in vitro and confirmed in dozens of clinical studies. It was shown that most cytotoxic drugs enhance the effects of radiotherapy [46]. The broad term "radiosensitization" encompasses several phenomena: additive effect (most cytotoxic drugs) [47], true radiosensitization (gemcitabine, cisplatin when applied less than 30 minutes prior to irradiation) [48, 49], and selective sensitization of hypoxic tumor cells, which are generally resistant to irradiation (mitomycin C) [50].

Drugs that enhance the effect of irradiation on tumor also contribute toward greater side effects upon normal tissues. In radiobiological terms, adding drugs to irradiation means that each fraction of irradiation is “worth more”. At the same total dose, not only can we expect more control of the tumor but also more pronounced acute and late side effects. The simplest, but possibly not the optimal solution, is lowering of the total dose of irradiation. From the logistical perspective, adhering to the standard fractionation is the easiest way; proper attention to late side effects is essential. Hyperfractionation is another approach [51]. In addition to possible better tumor control, its clear advantage is that the maximal tolerated dose would be defined by acute and transient, rather than late and permanent, toxicity.

A detailed discussion of each particular clinical situation would be clearly beyond the scope of this chapter. In concluding this section, we wish to emphasize that the design of combined-modality treatment is a true team venture. Only optimal collaboration of radiation oncologists and medical oncologists will result in a trial that will improve the prospects of this category of patients.

### 10.9.3.5 Systemic Treatment of Advanced Cancer

Systemic treatment of advanced cancer is a rapidly expanding and exciting area of medical research. Experience on systemic treatment on advanced cancer is indeed the rostrum of cancer research. Virtually all anticancer drugs and their combinations are first tested in patients with advanced cancer.

Clinical trials of advanced cancer differ from the other previously mentioned topics in three fundamental aspects. As already mentioned, the first difference is their innovative potential. The second one is willingness of patients to participate and to agree to virtually every proposal that might prolong, improve, or save life. When suffering from advanced cancer, many patients do not wish to exert their full autonomy. A researcher in charge of the trial and a physician in charge of recruitment and care for patients in a trial should be aware of limited patient’s autonomy and, consequently, of physician’s great responsibility.

The third difference is in the choice of endpoints. For all other previously mentioned areas, survival is (or at least should be) the main endpoint. In clinical trials of advanced cancer, we have a choice of several endpoints. While survival is important, it is not always the main endpoint: With incurable disease, other factors such as quality of life come into play. A detailed discussion on endpoints follows in the next section.

Since thousands of clinical trials on treatment of advanced cancer are reported each year, an attempt to present a list of references would be clearly inappropriate. What needs to be mentioned, however, is a recent trend for biological or targeted treatments tailored to specific phenotypic or genotypic characteristics of a tumor. In common and in rare cancers, molecules that exert very specific inhibition of proliferation of tumor cells on a variety of levels from the cell membrane to the nucleus have found rapid application in clinical trials and in regular medical practice [52–57]. Clinical research with these drugs often requires additional information from pathologists; additional consent from the patient to study the tissue blocks is also required. While collection of tissue samples during the trial is a significant burden for all participants, it is virtually impossible once the trial has been

completed. Hence, it is important that these elements of research are provided during the initial version of the protocol.

Eligibility of a particular patient for the new treatment often depends upon results of detailed characterization of the tumor. Many patients will therefore sign informed consent, only to find out that they are not eligible for the expected treatment. It is highly desirable that these patients are offered an alternative treatment within the same treatment protocol. Such a provision in the treatment protocol is not only desirable from the ethical standpoint but will also enable the researchers to follow all subjects in the group, regardless of the characteristics of the tumor. In this way, the results may be compared to trials without such characterization.

#### **10.9.3.6 Palliative Treatment**

This section would be incomplete without a word on the need for clinical research in palliative treatment. For obvious reasons, informed consent should be simplified. Challenges include identifying a target population, avoiding selection bias in the face of clinician and patient denial of serious illness, developing eligibility criteria for a seriously ill population, minimizing high patient refusals due to illness, and accurate reporting of all screened and eligible participants [58].

### **10.9.4 TYPES OF CLINICAL TRIALS**

The main mission of clinical research is testing ideas for improved diagnostics and treatment under controlled setting and then offering the experience either for further research or for clinical practice. If this is to be accomplished, the experience from clinical research should be relevant for its further application. At the same time, we should not forget that patients participating in clinical research have their individual priorities, which may change with time. Design and conduct of a clinical trial, therefore, involves a delicate balance between patient's interests and objectives of research.

#### **10.9.4.1 Phase I Trials**

For obvious reasons of acute toxicity and long-term mutagenic effects of anticancer drugs, phase I trials in cancer research are not performed on healthy volunteers. The research subjects in phase I trials in oncology are patients with cancer who have progressed after all conventional therapies. In addition, patients participating in phase I clinical trials are selected for absence of any significant comorbidity. This assures that dose-limiting toxicity and maximal tolerated dose are established with a proper degree of certainty. Since the response to treatment is not among the main objectives, patients in phase I research often suffer from a spectrum of different cancers.

Phase I clinical trials test new drugs on patients resistant to one or several standard combinations of drugs. While the possibility of life-threatening toxicity is not negligible, the chances for an objective response to therapy with a new drug are below 5% [59, 60]. These chances are even smaller for the initial subgroups of patients who are offered only very small doses of the new drug. A reasonable compromise should seek a balance between patient's safety, which demands only very

gradual increases of the dose of the drug, and patient's expectations to derive benefit from the new drug, a possibility that can only be expected with higher doses of the drug [61].

In addition to the commonly discussed situation of testing a new drug as a single agent, phase I trials are done (or at least should be done) also for new combinations of drugs that have already been approved for use and for new combinations of drugs and concomitant irradiation. In testing such a treatment, one drug, an existing combination of drugs, or irradiation are applied in the standard dosing and intervals, while a new drug is added upon this treatment in progressive doses or at progressively shorter intervals. Patients in this type of trial usually suffer from a well-defined diagnosis and stage of disease. In addition to assessment of toxicity, objectives of a trial include response rate, time to progression, and survival. For this reason, the term phase I–II trial is often used for this type of research. While terminology is of minor importance, it is very important that this step is not omitted. Testing a new idea straight in a phase II or even phase III trial often leads to premature closure of the trial due to unexpected toxicity.

#### 10.9.4.2 Phase II Trials

Phase II clinical trials stand between the very early experience of phase I research and eventual testing of this experience in a phase III trial. Early promising experience in phase I, information on pharmacokinetics and metabolism of drugs, and (to be sincere) commercial interests lead to definition of patients in whom a new drug, or a new combination of drugs, will be tested. Eligibility criteria for phase II trials include a precise diagnosis and stage of disease. Precise evaluation of toxicity remains among the main endpoints. For this reason, patients with severe comorbidities are usually excluded from early phase II trials.

When compared to phase I or phase III trials, phase II trials are easier to organize and cheaper. Number of patients is much smaller than in randomized trials. Many phase II trials are designed by individual researchers in academic institutions and may be conducted even without substantial support from industry. Flexibility in design and short time between idea and actual activation of a trial are the main advantages of such trials.

Experience from phase II trials is a most valuable basis for phase III trials and for preparing meta-analyses. However, two remarks are appropriate. The first one goes to honesty in performing small or single-institution trials. The key factor is unbiased registration of patients into the trial. In final reports, many single-institution trials include only patients who have completed a certain number of treatment cycles and exclude those with early withdrawal due to complications, disease progression, or patient's refusal. Biased registration of patients in single-institution trials is probably the most common form of fraud in clinical research and is the easiest way of improving the results. Unless we are strict in implication of a rigid formal procedure for registration of patients, this form of scientific dishonesty is virtually impossible to discover: In an institution treating thousands of patients, an outside observer cannot identify additional patients who also started the same treatment and were later excluded from the report. To prevent this, patient's entry into a clinical trial should be formal and in written form registered with a person who is not under the physician's authority. From the moment of registration, the patient is included in the trial, regardless of the actual course of disease or treatment.

The second remark is on application of experience from phase II trials for clinical practice. Experience on selected groups of a few dozens or a few hundred patients is far too scarce to be taken as “pure gold.” Let us repeat that promising experience from phase II trials gives support for further phase II research (possibly with wider eligibility criteria) and for phase III trials but should not be uncritically applied in clinical practice.

#### 10.9.4.3 Phase III Trials

Phase III clinical trials present a bridge between clinical research and the application of its experience in clinical practice. It is, therefore, essential that the experience from a phase III trial is applicable to a broad population of patients. Elderly patients and those with common comorbidity (hypertension, diabetes) should not be excluded from research if they are later to be treated with the same drugs. Rather, they may be offered an adjusted treatment schedule [62]. If this is not feasible, it is essential that the authors make a clear statement on limited applicability of the experience.

The ethics of randomized clinical trials have their basis in the uncertainty principle [63]. To maintain the uncertainty throughout the trial, it is essential to keep the recruitment period as short as possible. We have to avoid a possibility that an interim analysis would show a clear, yet statistically nonsignificant, superiority of one treatment over the other. As a rule of the thumb, we propose that the recruitment period should not be longer than double the expected median time to event (e.g., with 12 months as expected median survival, recruitment period should not extend beyond 24 months).

Many randomized clinical trials face the problem of slow recruitment. The most common reaction to slow recruitment is to seek participation of additional cancer centers. Sometimes this works, sometimes it does not; and it is not rare that a trial has to close due to poor recruitment. A general rule that “prevention is better than treatment” may be applied also to the problem of slow recruitment. Quite often, the problem of slow recruitment is not due to a small number of centers but due to a small proportion of eligible patients in each center who actually participate in a trial. Even in lung cancer, the most common cancer worldwide, it is quite common that a single institution recruits fewer than 10 patients within, say, 3 years, out of 100 or more eligible patients. The burden of complicated and time-consuming CRFs has an important negative impact upon recruitment of patients into clinical trials. A busy physician treating several hundred new patients per year does not dare to register more than a dozen patients for multi-institutional clinical trial. The narrow point is not the number of eligible patients, nor registration, nor treatment: It is the fear of CRFs with thousands of unnecessary data and hundreds of replies to queries. Developing a simple CRF is therefore essential for quick recruitment and, indeed, for success (or failure) of a trial. Whenever feasible, a randomized trial should follow the principles of a “large simple trial” and collect only the essential information [64].

#### 10.9.5 ENDPOINTS

Endpoints in clinical trials in oncology are an interesting topic, yet they are rarely discussed. Few physicians really understand all biases behind simple words such as

response, time to progression, survival, and quality of life [65]. Let us briefly discuss these biases.

### 10.9.5.1 Response to Treatment

Response to treatment is now understood as objective evidence of regression of the tumor. Other indications of response such as symptomatic improvement are assessed under quality of life.

In objective evaluation of response, most clinical trials nowadays follow the RECIST guidelines (Response Evaluation Criteria In Solid Tumors) [66]. The procedure involves three steps:

1. Definition of target lesions. At least one and not more than five lesions in any organ affected by cancer should be defined as measurable. Other lesions are declared as nonmeasurable.
2. Measurement of target lesions during or after treatment. The same method (e.g., CT scan) should be used prior to treatment and at evaluation of response. Nonmeasurable lesions are also evaluated for their complete disappearance, persistence, or obvious progression.
3. Confirmation of response after a minimum of 1 month since establishing a response.

By definition, *complete response* means complete resolution of all measurable and nonmeasurable disease for more than 1 month. *Partial response* is defined as >30% reduction in the sum of all measurable lesions for more than 1 month, along with no evidence of progression of nonmeasurable disease. *Progression* is either >20% increase (in comparison with the smallest measurement) in the sum of all measurable lesions, or obvious progression of nonmeasurable disease, or any appearance of a few lesions. *Stable disease* is what remains between partial response and stable disease.

While these three steps are straightforward and should be easy to follow, evaluation of response in the practice of clinical trials is far from devoid of any bias. *Definition of target lesions* is often not done during registration of a patient for a clinical trial. Researchers are allowed to enter patients on the basis of meeting the eligibility criteria, while the target lesions are defined later in the course of treatment. This would be acceptable if all lesions of a tumor would follow the same curve of regression or progression. Still, this is not the case. The tumor population on different sites of disease is heterogeneous. In addition, there is a variable proportion of the accompanying inflammatory reaction that contributes to the bulk of a tumor, as measured radiographically. Chemotherapy itself also does not reach the same concentration in all tissues. For these reasons, we often see considerable heterogeneity in response among different organs affected by the disease, and even within the same organ. A posteriori definition of target lesions opens a possibility that those responding better will be measured, leading to an increase in response rate.

*Measurement of target lesions* is also not free of a bias. Most tumors are not round and do not shrink or progress evenly in all directions. The longest diameter is often not relevant: A lung tumor may extend into an interlobar fissure, and its longest diameter may remain unchanged even if the tumor shrinks considerably. Measuring

the tumor in other directions allows a bias similar to the one described in the previous paragraph: A posteriori definition of the direction in which response to treatment is most clearly seen leads to an increase in response rate.

*Confirmation of response* is a demand that is not always strictly followed. Even if they declare adherence to the RECIST criteria, not all researchers confirm partial remission after another month. From the clinical point of view, this seems logical: After an objective response has been documented, there is no urgent need for early repeat examinations; reevaluation every 2 or 3 months is sufficient. Finally, confirmation of response is not feasible in certain situations such as induction chemotherapy prior to surgery or irradiation where local treatment immediately follows induction chemotherapy.

### ***Recommendations and Personal View on Evaluation for Response to Treatment***

1. Target lesions for measurable disease should be defined at the time of registration of the patient for the trial.
2. Unidimensional measurement of measurable disease is not free of a bias. Precise volumetric analysis (which is quite feasible with modern computerized radiology) of predefined lesions might offer more information than unidimensional measurements and would better reflect true regression or progression of the disease.
3. Early confirmation of response does not contribute to objective evaluation and adds the burden of unnecessary diagnostics.

#### **10.9.5.2 Time to Progression**

Time to progression is defined as the interval from start of treatment until progression (see previous section for definition of progression). On the first glance, time to progression is clearly defined. Still, at least two comments may be added—one from statistical point of view and the other from the clinical standpoint.

Quite often, we read about very small differences in time to progression of 1 or 2 weeks; yet, the average interval at which the tumor is evaluated may be once every 2 or 3 months. Looking at such data with the eyes of a statistician, the situation is similar to measuring centimeters with a 1-meter scale. Unless the number of patients is really very large, differences in time to progression smaller than half of the interval between measurements should be taken with great caution.

From the clinical standpoint, very frequent exams for eventual progression may not be justified. Also, a clinician may feel that a certain treatment is still considered beneficial, in spite of minor radiological progression. A useful addition to time of radiologic progression might be *time to clinically meaningful progression*, defined as a moment when the treatment has to be changed or a new treatment modality introduced.

#### **10.9.5.3 Survival**

Survival appears as the most clear endpoint. Yet, even survival is not free of a bias.

Survival is a function of prognostic factors (such as stage, histology, age, gender, and performance status), of a specific treatment under consideration in a particular

trial, and of the treatment after progression (sometimes called “salvage treatment,” a term that is often too ambitious or misleading). Although second-line treatment rarely cures patients, it may considerably prolong survival. A trial protocol should therefore define the general guidelines for treatment at the moment of progression. Type of second-line treatment and proportion of patients who actually received such treatment should be included in the report. This will ensure that eventual difference in survival is not due to unbalanced second-line treatment.

When speaking about survival as “the ultimate endpoint,” we most often focus on statistically significant difference and do not consider the fact that a difference in survival also has to be clinically meaningful. Provided the trial is large enough, even a 2% difference in survival can become statistically significant. It is important to note that although the difference between two groups may be statistically significant to a very small probability value, the difference may be of no clinical significance [67].

In general, advantage of one treatment over another will shrink when the treatment is taken from the research setting into general use: Broader selection of patients and physicians with varying degree of expertise in the treatment and in management of complications contribute to inferior results. When improvement in survival is small, statistical significance is not the only criterion for accepting a new treatment. In such instances, the concept of clinically meaningful difference should be applied. A judgment on the applicability and relevance of the research data for the general population, on the burden of the new treatment for patients, and on the costs should be thoroughly discussed before the new treatment is accepted as a routine.

#### 10.9.5.4 Quality of Life

When it comes to incurable disease—and advanced cancer still most often falls under this category—quality of life is of at least equal importance as the other endpoints we just discussed. While we all recognize the importance of quality of life, we are far from agreement on how to approach this issue in clinical trials.

Assessment of quality of life is now regularly included in most treatment protocols [68–70]. Still, the majority of published reports do not present data on quality of life. Most often, we are left with the data on toxicity, which partially reflect quality of life but cannot offer a comprehensive picture. In a survey of randomized clinical trials for advanced breast cancer, assessment of quality of life added relatively little value to other endpoints in helping select the best treatment option, apparently largely because of suboptimal methodological standards [71].

Two fundamental reasons are behind this lack on information on quality of life. The first one is that in any particular trial, data on quality of life are virtually always incomplete. They are most often missing for those patients who do not do well—and for whom evaluation of quality of life would be most important. Patients with progression and/or severe toxicity fail to return for follow-up examinations and do not respond to the questionnaire. In such instances, one cannot avoid a bias in an analysis of an incomplete series of questionnaires [72].

The second reason for rare inclusion of quality of life issues in reports of clinical trials is the difficulty in analyzing the data. Instruments for assessment of quality of life include from 10 to more than 30 questions; a protocol often includes two

instruments (such as observer's and patient's scale). If presenting only one or two items from the lengthy quality of life questionnaire, the author could be blamed for a bias. If all the data are presented and analyzed, the volume of information is such that a separate paper might be needed.

Unlike other endpoints, quality of life data are rarely—if ever—presented in meta-analyses. The reason is inconsistency in instruments and in reporting.

The current trend in assessing quality of life of cancer patients is to use increasingly complex instruments. I am not in favor of this approach. That the mental, physical, and social domains, each containing many dimensions and items, all contribute to quality of life is uncontroversial. What is controversial is the weight of the different dimensions in overall quality of life. It has been shown to be very different between different patient populations. For individuals, assuredly complex systems, the many dimensions and items of quality of life interact, probably sometimes in chaotic ways. In these conditions, the weights of isolated items in individuals become for all practical purposes meaningless. The classical endpoints of discrete health-related functions and duration of survival are increasingly perceived as unacceptably reductionistic [73].

In our single-institutional clinical trials, we use our own simplified scale for assessment of quality of life: How do you feel, in comparison with your feeling prior to treatment?

1. Much worse
2. Worse
3. About the same
4. Better
5. Much better

Such a simple scale follows the idea that it is the patient who can best describe his or her quality of life; It is of lesser importance what precisely this means for an individual patient. The approach may be unscientific, but it is reliable, easy to use, and easy to analyze.

### 10.9.6 CONCLUSION

Most methodological issues of clinical research are similar in every field of medicine. An attempt to present a comprehensive overview of the methods of clinical research in oncology would inevitably lead to overlapping with other chapters. General questions of design of a clinical trial, its organization, statistics, and regulatory issues are to be found elsewhere in this volume. In this chapter, we focused on specific questions of design and conduct of clinical research in oncology. The choice of issues was admittedly personal, as were the views and proposals. Some dilemmas of a clinical oncologist who is also involved in research were discussed, all with the aim of facilitating research.

Our progress against cancer critically depends upon the quality and quantity of clinical research. A positive attitude of patients toward participation in clinical research, removing the obstacles that restrain physicians to enter patients into

clinical trials, and the relevance of research for regular medical practice are the three crucial points. We hope that this chapter will contribute toward a better performance on all these three points.
