### 10.10.1 INTRODUCTION

Age-related macular degeneration (AMD) is the leading cause of vision loss in the developed world, and it is estimated that approximately 1.2 million Americans currently suffer from severe vision loss caused by this disease [1–4]. This number is likely to increase considerably as the population in developed countries ages.

Two main types of macular degeneration have been traditionally recognized: the nonexudative (dry), composed of atrophic changes of the retinal pigment epithelium as well as deposits beneath it, and the exudative (wet) in which abnormal blood vessels develop under the retina causing blood and fluid leakage. Approximately 10–20% of nonexudative AMD will eventually progress to the exudative form, which is responsible for the majority of cases of severe visual loss from AMD [4, 5].

The traditional AMD classification criteria were revised in 1995 by the Age-Related Maculopathy Epidemiological Study Group, and the criteria for diagnosis of AMD became stricter. Patients with minimal or moderate nonexudative age-related changes in the macula were reclassified as having age-related maculopathy (ARM). By definition, advanced retinal pigment epithelium (RPE) atrophy and clumping is now required for nonexudative AMD, and the presence of choroidal neovascularization (CNV) is a requisite for the diagnosis of exudative age-related macular degeneration [6]. Currently, an estimated 85–90% of patients with age-related macular changes are ARM patients who exhibit drusen and only mild to moderate RPE changes and are typically minimally symptomatic with mild blurred central vision, difficulty reading, color and contrast disturbances, and metamorphopsia. The remaining 10–15% of patients with macular changes, who fall under the modern definition of AMD, tend to describe painless, progressive, moderate to severe blurring of central vision and moderate to severe metamorphopsia, which can be acute or insidious in onset [6].

Although some subtypes of exudative AMD are potentially treatable, the currently available treatment modalities offer limited efficacy; therefore, great interest exists in delaying or ceasing the progression of ARM or more effectively treating the factors leading to vision loss once it becomes AMD. At present, the only widely accepted method of intervention for ARM is the use of high-dose antioxidants; however, this only slows progression in some patients and does not reverse any damage already present. Once AMD becomes exudative, the treatment scheme offered to patients varies largely among physicians, as no standard therapy has been established and approved. Options currently available include laser photocoagulation, photodynamic therapy (PDT) with verteporfin, and intravitreal pegaptanib sodium. Only a minority of patients with exudative AMD shows well-demarcated “classic” CNV amenable to laser treatment, and at least half of the patients undergoing thermal laser photocoagulation suffer persistent or recurrent CNV formation within 2 years. In addition, since the treatment itself causes a blinding central scotoma when the CNV is located subfoveally, many clinicians do not treat subfoveal CNV with thermal laser. In 2000, PDT was approved by the U.S. Food and Drug Administration (FDA) as treatment for subfoveal CNV; however, it only limits vision loss and often requires multiple retreatments. Pegaptanib sodium, a vascular endothelial growth factor (VEGF) inhibitor, was approved by the FDA on December 17, 2004, and was available to physicians in January of 2005; however, its administration requires intravitreal injections every 6 weeks. Because of these treat-

ment limitations, alternative therapies for exudative AMD are being developed and include new types of photodynamic therapy, transpupillary thermotherapy, growth factor modulators, radiation, and surgical therapy. A major limitation for the design of effective treatment is still our lack of true understanding of the underlying etiology of the disease.

### 10.10.2 DIAGNOSIS

Any patient who exhibits signs and symptoms consistent with exudative AMD undergoes a thorough dilated fundus exam, stereo color fundus photography, and rapid sequence fluorescein angiography (RSFA). RSFA, which is usually the initial angiographic study, will reveal leakage—the hallmark of CNV. According to the distance from the foveal avascular zone, the leakage is classified as subfoveal, juxtafoveal (1–199  $\mu\text{m}$ ) or extrafoveal (200–2500  $\mu\text{m}$ ). In addition, indocyanine green (ICG) angiography is performed as an adjunctive study in patients with poorly delineated CNV. ICG can better delineate choroidal circulation because the near-infrared light (795–810 nm) absorbed by ICG tends to penetrate the retinal pigment epithelium better than can the shorter wavelength of light absorbed by fluorescein. Also, unlike fluorescein, ICG is strongly bound to plasma proteins, which prevents diffusion of the compound through the fenestrated choroidal capillaries, and permits better delineation of choroidal details. When a CNV is suspected, angiography is customarily performed within 72 hours of any planned treatment since CNV morphology and resulting treatment parameters can evolve rapidly.

The Macular Photocoagulation Study (MPS) defined two RSFA leakage patterns for CNV [7]. “Classic” CNV presents as discrete early hyperfluorescence with late leakage of dye into an overlying neurosensory retinal detachment. “Occult” CNV is categorized into two basic forms: late leakage of undetermined source, or fibrovascular pigment epithelial detachments. (PEDs). Late leakage of undetermined source manifests as regions of stippled leakage into an overlying neurosensory retinal detachment, without a distinct source identified on the early frames of the angiogram. Fibrovascular PEDs present as irregular elevations of the RPE associated with stippled leakage into an overlying neurosensory retinal detachment in the early and late frames of the angiogram.

### 10.10.3 NONEXUDATIVE AGE-RELATED MACULAR DEGENERATION

#### 10.10.3.1 Antioxidants

The treatment options for ARM and nonexudative AMD are limited; therefore, prevention of disease progression is viewed as critical. Currently, the only evidence-based intervention comes from the Age-Related Eye Disease Study (AREDS) [8]. This multicenter, U.S. National Institutes of Health (NIH)–supported investigation was a double-masked, randomized, prospective, clinical trial that enrolled 4357 subjects into 1 of 4 treatment groups: placebo, antioxidants (vitamins C and E plus  $\beta$ -carotene), zinc/copper, and antioxidants plus zinc/copper. The study was based on the theory that oxidative damage to the retina may contribute to the development of AMD [9–12] and a smaller, randomized, placebo-controlled clinical trial

that suggested zinc might provide protection from vision loss due to AMD [13]. AREDS concluded that “patients with extensive intermediate sized drusen, at least 1 large drusen or noncentral geographic atrophy in one or both eyes, or advanced AMD or vision loss due to AMD in one eye should consider taking a supplement of antioxidants plus zinc” [8]. The formulation (Ocuvite PreserVision, Bausch & Lomb, Rochester, New York, and ICaps, Alcon, Inc., Fort Worth, Texas) containing high doses of vitamin C, vitamin E,  $\beta$ -carotene, copper, and zinc lowered the risk of developing advanced AMD by 25% in the study [8]. Importantly, another study demonstrated that  $\beta$ -carotene supplementation increased the risk of developing lung cancer in smokers; therefore, the antioxidant formulation should exclude  $\beta$ -carotene when taken by tobacco users [14].

### 10.10.3.2 Drusen Ablation

It has been proposed that the aging RPE accumulates remnants of incomplete degradation of phagocytosed rod and cone membranes, and such accumulation results in the presence of metabolic debris and, over time, drusen formation [15, 16]. Laser treatment at or near a large drusen will often lead to resolution of the drusen, and sometimes this will be accompanied by an improvement of visual acuity. Based on the knowledge that drusen constitute a risk factor for exudative AMD, it has been proposed that laser treatment to promote clearing of drusen may result in a reduction of the risk of CNV formation. A randomized multicenter clinical trial, known as CNVPT (Choroidal Neovascularization Prevention Trial) evaluated 432 eyes treated with argon green laser. The study showed significant drusen reduction in the treated group; however, it also suggested that argon green laser treatment might increase the risk of CNV development [17]. Another study also showed that treatment with laser photocoagulation results in significant drusen reduction compared with observation at 2 years, but no differences were observed in CNV occurrence between groups [18]. In addition, two prospective randomized clinical trials are currently in progress to evaluate the effects of laser-induced drusen reduction on AMD. The NIH has supported the CAPT (Complications of AMD Prevention Trial) study, which is evaluating low-intensity argon green laser photocoagulation in patients with bilateral drusen. The study completed enrollment of 1052 patients in March 2001, and the 5-year results should be available this year [19]. The PTAMD (Prophylactic Treatment of AMD) study, a multicenter randomized prospective placebo-controlled clinical trial sponsored by Iridex Corp (Mountain View, CA) has completed enrollment and is currently in progress [20]. It is designed to evaluate the effects of extrafoveal subthreshold infrared diode treatment on stopping the progression of exudative AMD.

### 10.10.3.3 Rheopheresis

Some researchers believe that lipid deposition in sclera and Bruch's membrane leads to scleral stiffening and impaired choroidal perfusion, which in turn could adversely affect the metabolic transport function of RPE. The affected RPE would in consequence be incapable of efficiently metabolizing and removing material shed from the photoreceptors, leading to its accumulation and drusen formation [21, 22]. Based on this theory, it has been speculated that apheresis could be of benefit to

AMD patients by improving ocular blood flow and by limiting the concentration of circulating macromolecules involved in drusen formation, Bruch's membrane degradation, and retinal pigment epithelial cell dysfunction. OccuLogix LP (a joint venture between TLC Vision Co, Mississauga, Canada, and Vascular Sciences CO, Tampa, Florida) developed the Rheofilter membrane differential filter (MDF) system based on the concept of apheresis, to filter high-molecular-weight proteins and lipoproteins from the blood. A randomized prospective, double-masked pilot study involving 30 patients showed vision improvement in a significant number of patients undergoing rheophoresis. Currently, in the United States the MIRA-1 (Multicenter Investigation of Rheophoresis for AMD) is a multicenter, randomized, placebo-controlled trial of patients with large soft drusen without advanced AMD in at least one eye, and elevated serum cholesterol, IgA or fibrinogen at screening. This phase III trial was interrupted after about one-half of the planned 180 patients had been recruited due to loss of capitalization by the sponsor. An interim analysis performed on 43 patients who completed the one-year visit revealed an improvement in mean acuity of greater than one line in treated patients, compared to a mean loss of almost two lines in controls. The study has now been resumed and 185 patients have been enrolled. On November 17, 2005, OccuLogix announced that all final study visits had been completed for the MIRA-1 trial, and results would be analyzed by the end of December 2005. They were planning to file for FDA approval in the first quarter of 2006 [23].

#### 10.10.4 EXUDATIVE AGE-RELATED MACULAR DEGENERATION

##### 10.10.4.1 Thermal Laser Photocoagulation

Traditionally, ophthalmologists have used thermal laser destruction of CNV as the primary treatment of exudative AMD based on the results of the Macular Photocoagulation Study (MPS), a large, randomized, multicenter, prospective set of clinical trials comparing laser photocoagulation to observation. These studies, which were initiated in the 1980s and supported by the NIH, demonstrated that laser photocoagulation of certain types of CNV lowered the risk of large reductions in visual acuity compared to observation alone. In these studies, patients were deemed eligible for laser photocoagulation if they manifested classic CNV as determined by RSFA.

Unfortunately, only 13–26% of patients with exudative AMD presented with classic CNV eligible for laser treatment, and it became unclear whether laser photocoagulation was beneficial in a majority of patients, as they were not eligible for laser therapy in the MPS [7, 24]. Moreover, at least half of the enrolled subjects suffered from persistent or recurrent CNV formation within 2 years of treatment [24–26]. Although the arm of the MPS exploring treatment of CNV under the fovea suggested that laser photocoagulation is better than observation, treating subfoveal CNV with thermal photocoagulation is not a common practice because of the immediate central scotoma from the collateral retinal destruction. Given the large number of limitations posed by thermal laser photocoagulation, researches have searched for alternative means of subfoveal CNV treatment using a variety of laser derivatives [27, 28].

#### 10.10.4.2 Transpupillary Thermotherapy

Transpupillary thermotherapy (TTT) occludes the CNV by slowly heating the subfoveal choroidal neovascular complex with infrared (810 nm) diode laser light. The infrared wavelength is thought to traverse the retina and RPE to maximally affect the CNV, while minimizing thermal injury to the neurosensory retina. Laser application covers the entire CNV complex with a single large spot. Although the precise mechanism of CNV destruction is unclear, one study, using color Doppler imaging, suggested TTT leads to alterations in choroidal blood flow [29]. An uncontrolled phase I/II safety and efficacy study involving 113 patients showed that patients with occult CNV receiving TTT compared similarly to the verteporfin-treated patients in the verteporfin in photodynamic therapy (VIP) trial at 6 and 12 months [30]. Similarly, another uncontrolled trial with 69 patients found that TTT use compared favorably to the natural history of occult CNV [31]. The Transpupillary Thermotherapy of Occult Subfoveal Choroidal Neovascular Membranes in Patients with Age-Related Macular Degeneration Trial (TTT4CNV), the first randomized, prospective, double-blind, placebo-controlled study evaluating the effectiveness of TTT for occult CNV (or up to 10% classic CNV), enrolled 303 patients between March 2000 and March 2003 and is now following subjects [32].

#### 10.10.4.3 Photodynamic Therapy

Photodynamic therapy (PDT) utilizes laser light and intravascular dyes (i.e., photosensitizers). After intravenous injection, once sufficient time passes to concentrate the photosensitizer in neovascular tissue, the CNV is stimulated with a specific wavelength of light to react with water and create oxygen and hydroxyl free radicals [33]. These free radicals, in turn, react with cell membranes of the pathologic endothelium to induce occlusion by massive platelet activation and thrombosis, while still preserving the normal choroidal vasculature and nonvascular tissue [34, 35]. Ideally, the intensity of the exciting wavelength is low enough to spare the non-neovascular irradiated tissues from thermal damage. Important variables in this reaction include the intravascular concentration of dye, the photochemical behavior of the dye, the interval between the injection and the onset of irradiation, the intensity and specificity of the exciting irradiation, and the duration of irradiation [36–38].

**Verteporfin** The U.S. FDA approved verteporfin (Visudyne; QLT Therapeutics, Inc., Vancouver, Canada, and Novartis Ophthalmics, Bulach, Switzerland) in April 2000 for patients with “predominantly classic” subfoveal CNV caused by AMD, which demonstrates a characteristic early and well-defined RSEA stain to over 50% of the CNV complex. Similarly, marketing approval was granted in Europe in July 2000, and it is currently commercially available in over 70 countries for predominantly classic CNV.

In 1999 and 2001, the 1- and 2-year results of the Treatment of AMD with PDT (TAP) study were published. TAP consisted of two randomized, prospective, double-blind, placebo-controlled phase III trials with 609 subjects. First-year data reported the proportion of eyes with less than 15 letters of visual acuity loss on a standardized eye chart was 67% in the treated group versus 39% in control group

( $p < 0.001$ ) when the CNV was predominantly classic; however, no significant differences in visual acuity were demonstrated when the area of classic CNV was less than 50% of the entire complex. In addition, it was noted that 90% of the subjects required retreatment at 3 months, and an average of more than three retreatments over the first year [39]. Second-year follow-up data reported that 59% of treated eyes had a favorable visual outcome versus 31% in the control group when the lesion was predominantly classic [40]. The TAP trial was unmasked at 2 years of follow-up. An open-label extension to 36 months of 124 of the 159 original TAP participants with predominantly classic CNV revealed that visual acuity remained nearly constant and required fewer retreatments [41]. Because of the success of the TAP trial, the verteporfin in photodynamic therapy (VIP) trial, another randomized, prospective, double-blind, placebo-controlled clinical trial, was developed to examine many of the patients who fell outside of the inclusion guidelines set by TAP.

The VIP trial was designed to evaluate the treatment efficacy of PDT in 339 subjects with total occult subfoveal CNV, classic CNV with a visual acuity better than 20/40, or CNV secondary to pathological myopia. One-year results of the occult AMD arm showed no significant difference between visual acuity outcomes in exudative AMD patients treated with verteporfin and placebo (51% PDT and 54% placebo treated had unfavorable visual outcomes, respectively). However, 2-year follow-up data revealed that 55% of the treated subjects with occult CNV had an unfavorable outcome versus 68% in the placebo group ( $p = 0.023$ ). On average, the verteporfin-treated patients received five treatments over 24 months of follow-up. Based on this data, the study group recommended verteporfin for purely occult subfoveal CNV that demonstrated recent disease progression in all patients except those with large lesions with good visual acuity [42]. Because the FDA desired additional data before approving verteporfin for occult CNV, the Visudyne in Occult (VIO) trial was developed as a 24-month study to analyze patients with only occult CNV. Enrollment of 364 subjects was completed and is currently in the second year of follow-up as per the recommendation of the Data and Safety Monitoring Committee [43].

Several other trials have evaluated the efficacy of verteporfin in a variety of clinical situations previously lacking sufficient data. Retrospective TAP and VIP data suggested some treatment benefit for smaller minimally classic lesions. The Visudyne in Minimally (VIM) classic trial was thus initiated as a randomized, prospective, double-blind, placebo-controlled clinical trial designed to study the use of verteporfin in patients with minimally classic CNV. Phase II data on 117 patients suggests that small, recently progressive, minimally classic CNV might benefit from verteporfin therapy [44]. Two-year follow-up data revealed that fewer verteporfin-treated eyes lost three or more lines of vision on a standard visual acuity chart or converted to a predominantly classic lesion as compared to placebo [45]. Consequently, a phase III study [the visudyne minimally classic (VMC) trial] was started in late 2003 to further evaluate verteporfin in minimally classic CNV. On April 1, 2004, the U.S. Centers for Medicare and Medicaid Services (CMS) agreed to reimburse physicians for PDT of occult and minimally classic subfoveal CNV (less than 50% of CNV complex with early well-defined hyperfluorescence on RSFA) from AMD, provided that the lesion is four disk areas or less in size at least three months prior to initial treatment and evidence of progression (i.e., loss of five or more letters

on standard visual acuity charts, increase of at least one disk diameter, or appearance of blood) within 3 months of treatment.

Because 80% of vision loss in verteporfin-treated patients occurs within 6 months of developing CNV, the Verteporfin Early Retreatment (VER) trial was designed as a phase III study of 323 patients to compare the benefit of retreatment in 6-week intervals versus the standard 3 months. Twelve-month interim results of the 2-year trial did not show improved outcomes when compared to the standard treatment [46]. Additionally, the Verteporfin with Altered (Delayed) Light in Occult (VALIO) study was developed to evaluate whether delaying the light application to 30 minutes after the initiation of verteporfin infusion (versus the standard 15 minutes) would improve outcomes in occult CNV. Phase II data at 6 months of follow-up show the group treated at 30 minutes postinfusion lost 1.3 lines of vision while the standard 15 minute postinfusion treatment group lost 2–3 lines, which was not statistically significant. One-year data substantiated the 6-month findings [47, 48].

At the moment verteporfin is the only approved PDT agent, but additional photosensitizing products are under study and development.

**Rostaporfin** Rostaporfin (Photrex; Miravant Medical Technologies, Santa Barbara, California) is a purpurin with a structure similar to chlorophyll that absorbs maximally at 664 nm. Like verteporfin, the preconstituted solution is intravenously infused over 10–20 minutes. In December 2001, enrollment for a phase III placebo-controlled, double-masked clinical trial involving 920 patients was completed. Two-year follow-up data found that 58% of patients receiving a 0.5 mg/kg dose of SnET2 lost less than 15 letters compared to 42% of placebo patients ( $p = 0.0045$ ). Rostaporfin was well tolerated and demonstrated an acceptable safety profile [49]. On September 30, 2004, the FDA requested an additional confirmatory clinical trial before final marketing approval.

#### 10.10.4.4 Radiation Therapy

Since choroidal neovascular membranes are composed of rapidly proliferating pathologic endothelial cells, they may be sensitive to agents that inhibit cell division. Consequently, radiation therapy has been suggested as a treatment for subfoveal CNV. Given an apparent dose–response effect, some groups have delivered ionizing radiation to the macula using modalities that may limit the exposure of ionizing radiation to normal radiosensitive structures of the eye, such as the optic nerve or lens. These methods have included stereotactic external photon beam irradiation of the posterior pole, brachytherapy, in which radioactive plaques are sutured to the posterior pole of the eye and explanted several days later, and proton beam irradiation, which deposits almost all of its energy at the desired depth in the eye at a point called the Bragg peak and undergoes little scattering [50, 51].

Although some of the early pilot studies suggested a possible benefit, conflicting reports regarding the efficacy of radiation therapy for exudative AMD have since been published. Two prospective controlled studies, using a relatively large number of low ionizing radiation fractions, failed to show a treatment benefit for external beam radiation [52, 53]. However, two smaller prospective controlled studies using a smaller number of higher radiation fractions demonstrated a statistically significant vision benefit over controls [54, 55]. Because of the positive outcomes, a

prospective, controlled, pilot study to evaluate external beam radiation on CNV in a small number of high-energy fractions was sponsored by the National Eye Institute. An interim analysis of this study, known as the AMD Radiotherapy Trial (AMDRT), found that at 12 months follow-up 43% of radiated eyes and 50% of nonradiated eyes demonstrated a moderate visual loss ( $p = 0.60$ ) [56].

#### 10.10.4.5 Surgical Therapy

Some vitreoretinal surgeons have attempted to remove CNV with direct surgical excision, which can yield impressive results in CNV secondary to histoplasmosis and multifocal choroiditis. However, the results were disappointing for exudative age-related macular degeneration. Researchers speculate the CNV of AMD has a different morphology and grows both anterior and posterior to the RPE. The damaged RPE that remains after CNV removal causes atrophy of the underlying choriocapillaris leading to retinal disorganization [57–60]. In 1998, the National Eye Institute of the National Institutes of Health awarded funding to the submacular surgery trial (SST). This study was designed as a randomized, multicenter, prospective clinical trial comparing surgery with observation to specifically evaluate patients with large or poorly demarcated new subfoveal CNV, submacular hemorrhage from CNV associated with exudative AMD, or subfoveal CNV due to presumed ocular histoplasmosis (POHS) or idiopathic causes.

Patients were followed for 2 years and assessed for stabilization or deterioration of visual acuity (VA), change in contrast sensitivity, cataract development, surgical complications, and quality of life. Of 454 patients with subfoveal choroidal neovascularization enrolled, 228 study eyes were assigned to observation and 226 to surgery. Median VA losses from baseline to the 24-month examination were 2.1 lines (10.5 letters) in the observation arm and 2.0 lines (10 letters) in the surgery arm. Median VA declined from 20/100 at baseline to 20/400 at 24 months in both arms. Moreover, rhegmatogenous retinal detachment occurred in 12 surgery eyes (5%) and 1 observation eye. In conclusion, it was determined that submacular surgery does not improve or preserve VA for 24 months better than observation, and it is therefore not recommended for patients with subfoveal choroidal neovascularization caused by AMD or with submacular hemorrhage from CNV [61, 62].

#### 10.10.4.6 Antiangiogenic Therapy

**Vascular Endothelial Growth Factor Inhibitors** Animal and clinical studies have identified vascular endothelial growth factor (VEGF) as a key mediator of ocular angiogenesis [63]. Upregulation of VEGF expression has been reported in experimentally induced CNV in rats, and it has also been shown that VEGF is capable of inducing intraretinal and subretinal neovascularization [64]. In human clinical trials, particular attention has focused on the development of pharmaceutical agents to block VEGF expression or neutralize it once expressed. Investigators have inhibited preretinal neovascularization in experimental models with antibodies against VEGF. Others have shown similar effects using VEGF-neutralizing chimeric proteins, which were constructed by joining the extracellular domain of high-affinity VEGF receptors with IgG [65].

**Pegaptanib Sodium** The anti-VEGF pegylated aptamer, pegaptanib sodium (Macugen; Eyetech Pharmaceuticals, Inc., New York, and Pfizer, Inc., New York), demonstrated both safety and efficacy in clinical trials. This intravitreally administered polyethylene glycol (PEG)-conjugated oligonucleotide was specifically designed to bind and neutralize VEGF<sub>165</sub>, hypothesized to be the predominant VEGF isomer associated with CNV in humans. A phase I trial, involving 15 subjects receiving a single injection of pegaptanib sodium, demonstrated 80% with stable or improved vision at 3 months. More impressively, 27% of the patients had significantly improved vision: A finding missing from many of the other standard AMD treatment modalities [66]. Although small, a phase II trial involving 21 patients supported the phase I data, and, when pegaptanib sodium injections were combined with PDT, 6 of 10 (60%) patients had significantly improved vision versus 2.2% treated with PDT alone [67].

The VEGF Inhibition Study in Ocular Neovascularization (VISION), two phase II/III, multicenter, randomized, placebo-controlled studies, completed enrollment of 1186 subjects in July 2002. The 2-year follow-up data revealed less vision loss for subjects maintained on pegaptanib sodium than those who only received the medication during one year ( $p < 0.05$ ). In the group given pegaptanib at 0.3 mg, 70% of patients lost fewer than 15 letters of visual acuity, as compared with 55% among the controls ( $p < 0.001$ ). The risk of severe loss of visual acuity (loss of 30 letters or more) was reduced from 22% in the sham-injection group to 10% in the group receiving 0.3 mg of pegaptanib ( $p < 0.001$ ). More patients receiving pegaptanib (0.3 mg), as compared with sham injection, maintained their visual acuity or gained acuity (33% vs. 23%;  $p = 0.003$ ). As early as 6 weeks after beginning therapy with the study drug, and at all subsequent points, the mean visual acuity among patients receiving 0.3 mg of pegaptanib was better than in those receiving sham injections ( $p < 0.002$ ). Among the adverse events that occurred, endophthalmitis (in 1.3% of patients), traumatic injury to the lens (in 0.7%), and retinal detachment (in 0.6%) were the most serious and required vigilance. These events were associated with a severe loss of visual acuity in 0.1% of patients [68]. Based on these results, the FDA approved the use of pegaptanib sodium to slow vision loss in people with neovascular AMD on December 20, 2004 [69].

**Ranibizumab** Ranibizumab (Lucentis, Genentech Inc., San Francisco, and Novartis Ophthalmics, Basel, Switzerland), an intravitreally injected, recombinant, humanized, monoclonal antibody Fab fragment designed to actively bind and inhibit all isoforms of VEGF, has shown promise in early human trials. A phase Ib/II randomized, single-agent study found that 94% of the 50 patients receiving ranibizumab had stable vision and 44% had significantly improved vision at 6 months [70]. Additional trials have since then been initiated to provide more definitive evaluation of the clinical benefit of ranibizumab in patients with predominantly classic or minimally classic/occult CNV.

The MARINA (Minimally Classic/Occult Trial of the Anti-VEGF Antibody Ranibizumab in the Treatment of Neovascular AMD) is a phase III randomized, prospective, double-blind, placebo-controlled trial initiated in 2003 with the objective of comparing ranibizumab against verteporfin for minimally classic or occult CNV. A total of 716 patients were enrolled in this study and randomized 1:1:1 to sham injection or to ranibizumab (0.3 or 0.5 mg) injected intravitreally monthly for

24 months. Preliminary analysis of one-year MARINA data revealed that approximately 95% of patients treated with ranibizumab lost fewer than 15 letters at one year, compared with approximately 62% in the control group ( $p < 0.0001$ ). On average, the patients treated with ranibizumab had a significant improvement in visual acuity relative to their visual acuity at study entry, whereas the control group experienced a substantial decrease from baseline in mean visual acuity [71].

The ANCHOR (Anti-VEGF Antibody for the Treatment of Predominantly Classic Choroidal Neovascularization in AMD) is a multicenter, prospective, randomized, multicenter, double-masked phase III trial designed to compare a combination ranibizumab/PDT therapy to verteporfin PDT alone in 423 subjects with predominantly classic exudative AMD. This trial is still ongoing in centers in United States, Europe, and Australia [71].

The FOCUS (RhuFab V2 Ocular Treatment Combining the Use of Visudyne to Evaluate Safety) study is a randomized, single-masked phase I/II trial investigating the safety, tolerability, and efficacy of ranibizumab in combination with verteporfin PDT versus verteporfin PDT alone in patients with subfoveal predominantly classic CNV due to AMD. Enrollment of 162 patients has been completed and a preliminary analysis of one-year data indicate that approximately 90% of patients treated with the combination of ranibizumab and PDT had stable or improved visual acuity, compared with approximately 68% of patients in the control arm of PDT alone ( $p = 0.0003$ ) [71].

The Phase IIb, multicenter, randomized, double-masked, sham Injection-controlled study of the Efficacy and safety of Ranibizumab (PIER) study started enrolling approximately 180 patients in September 2004 with the objective of comparing 3-month intravitreal dosing intervals to the standard 1-month intervals [72].

**Pigment Epithelium-Derived Factor Inducer** Researchers have attempted to stimulate intravitreal production of native pigment epithelium-derived factor (PEDF), a naturally occurring potent antiangiogenic protein deficient in eyes with CNV, using gene therapy [73]. PEDF inhibits angiogenesis by inducing apoptotic death of endothelial cells stimulated to form new vessels [74]. In a laser-induced CNV murine model, choroidal neovascularization was reduced after intravitreal PEDF was produced from an adenoviral vector [75]. One study demonstrated that increased intravitreal PEDF results in 85% inhibition of neovascularization in laser-induced CNV, transgenic VEGF, and retinopathy of prematurity models. GenVec, Inc. (Gaithersburg, Maryland) has developed a PEDF producing adenovirus vector, AdPEDF (pigment epithelium-derived factor on an adenovirus vector), and completed recruitment of 51 patients in five states for phase I human trials in August 2004. Interim 12-month results of 24 patients revealed no dose-limiting toxicities or related severe adverse events [76].

**Cyclo-Oxygenase-2 Inhibitor** It is likely that a whole cascade of soluble factors play a role in ocular angiogenesis and CNV development. Cyclooxygenase-2 (COX-2) is expressed in neovascular structures, especially human cancers. Thus, it has been proposed that a cyclooxygenase-2 inhibitor might control neovascularization associated with AMD. Orally administered celecoxib (Celebrex; Pfizer, Inc., New York), a COX-2 inhibitor, significantly reduced angiogenesis and prostaglandin production in basic fibroblast growth factor (bFGF)-induced neovascularization of

rat corneas [77]. The National Eye Institute is conducting a phase I/II safety and efficacy trial comparing the use of PDT and celecoxib to PDT alone. The double-masked, randomized, placebo-controlled prospective study completed enrollment of 60 participants.

**Squalamine** Squalamine (Genaera Co., Plymouth Meeting, PA), an antiangiogenic aminosterol originally found in the body tissues of the cancer-resistant dogfish shark, acts as an inhibitor of growth factor signaling, including VEGF, integrin expression, and cytoskeletal formation. Systemic intravenous administration has inhibited iris neovascularization in primate models, oxygen-induced retinopathy in murine models, and laser-induced CNV in a rat model [78–80].

Three phase II clinical trials are currently underway to evaluate its role in AMD treatment. The largest, MSI-1256F-209, is a 100-patient prospective, randomized, controlled trial evaluating the effects of 20 or 40 mg given intravenously every week for 4 weeks followed by maintenance every 4 weeks for 48 weeks followed by 12 months of observation for exudative AMD. The second trial, MSI-1256F-208, is a 45-patient prospective controlled trial evaluating the effects of 10, 20, or 40 mg of intravenous squalamine given initially in combination with verteporfin PDT and then alone for an additional 6 months followed by 12 months of observation for exudative AMD. Preliminary results from this trial showed that subjects treated with 40 mg of squalamine lactate and concomitant PDT gained an average of 0.4 letters in visual acuity compared to study entry, while those treated with PDT alone lost an average of 4.8 letters [81]. The last trial, MSI-1256F-207, is an 18-patient open-label, parallel group trial comparing three doses of intravenous squalamine given weekly for 4 weeks followed by 4 months of follow-up on exudative AMD. On October 4, 2004, the U.S. FDA granted fast-track designation to squalamine.

**Steroid Compounds** Corticosteroid compounds have long been known to possess angiostatic properties as they alter extracellular matrix degradation and inhibit inflammatory cells, which invariably participate in neovascular responses [82]. Intravitreal administration of corticosteroids has become very popular as the blood–ocular barrier is bypassed, more constant therapeutic steroid levels are achieved, and systemic side effects are minimized. These injections have demonstrated efficacy in subretinal and preretinal neovascularization in animal models [83, 84].

**Triamcinolone Acetonide** Uncontrolled pilot studies evaluating CNV in AMD have employed the off-label use of intravitreally administered triamcinolone acetonide (Kenalog; Bristol-Myers Squibb, New York) because of its long half-life and corticosteroid properties. One study of 30 eyes receiving a single triamcinolone acetonide injection reported that 11 eyes experienced improved or stabilized vision within 1–3 months of treatment with regression of the CNV to inactive fibrosis, 15 experienced a similar outcome, except for slow extension and exudation from recurrent CNV, while 4 experienced no obvious treatment benefit [85]. In later publications, studies reported a favorable effect on the course of the disease over 6-, 12-, and 18-month follow-up; however, the lack of controls complicated the ability to compare treatment efficacy to the natural course of the disease [86–88]. The authors proposed that intravitreal triamcinolone had a beneficial effect on AMD-related CNV through inhibition of leukocytes, including macrophages, which normally

release angiogenic factors [85–87]. A randomized, double-masked, placebo-controlled clinical trial of 151 eyes receiving a single 4-mg injection of intravitreal triamcinolone found significant antiangiogenic effects at 3 months after treatment; however, no beneficial visual acuity effect was seen at 1 year [89]. The authors speculated that triamcinolone might be efficacious at a higher or more sustained dose or in concert with other modalities.

Visagen (Regenera Limited, Nedlands, Australia) is developing a triamcinolone acetonide formulation that is being developed strictly for intraocular applications. Regenera Ltd. anticipates sponsoring clinical trials in an attempt to formally gain approval for several ophthalmic indications in the near future. A different group is developing a preservative-free formulation that theoretically decreases the 0.8% sterile endophthalmitis rate observed with traditional intravitreal triamcinolone acetonide injections [90].

**Anecortave Acetate** In 1985, a class of steroid with minimal glucocorticoid or mineralocorticoid activity was developed and is now undergoing evaluation in human trials as anecortave acetate (Retaane; Alcon Laboratories, Inc., Fort Worth, Texas) [91]. The lack of corticosteroid activity minimizes commonly encountered intraocular pressure elevation and accelerated cataract formation [92]. In addition, anecortave acetate was formulated for injection into the subtenon space with a specially designed cannula. A phase II/III randomized, prospective, placebo-controlled trial involving 128 patients designed to evaluate the clinical safety and efficacy of juxtascleral injection of anecortave acetate versus placebo for the treatment of subfoveal CNV, found that baseline vision ( $p = 0.01$ ), stabilization of vision ( $p = 0.03$ ), and prevention of severe vision loss ( $p = 0.02$ ) were statistically superior to baseline at 12 months; however, the dropout rate was nearly 50% [93].

Another phase III study designed to compare anecortave acetate 15-mg suspension to visudyne PDT in patients with exudative AMD was carried out over a 12-month period. The study enrolled 530 patients with the primary objective of demonstrating that anecortave acetate 15 mg is noninferior to PDT in patients with predominantly classic subfoveal CNV. It was shown that no difference existed between the two treatment groups ( $p = 0.4305$ ) [94].

A new study (C-02-60) evaluating anecortave acetate suspension versus a sham administration procedure for prevention of progression from dry AMD to exudative AMD is currently enrolling patients. The objective of this study is to determine the safety and efficacy of anecortave acetate suspension for treatment of patients with nonexudative AMD who are at risk of progression to exudative AMD, in an attempt to arrest the development of choroidal neovascularization. A total of 2500 patients are to be enrolled in this 4-year study [95].

**Implantable Corticosteroids** Because intraocular corticosteroids have shown antiangiogenic effects with repeated intravitreal administration, the efforts to develop sustained-release intraocular implants have received special attention, in an attempt to achieve near constant intraocular steroid concentrations without repeated injections. One study demonstrated CNV inhibition using triamcinolone acetate microimplants in a laser-induced CNV rat model [96]. Furthermore, researchers at Bausch & Lomb (Rochester, New York) and Control Delivery Systems (Watertown, MA) have developed Retisert (also known as Envision TD), a nonbiodegradable intra-

vitreal implant that releases fluocinolone acetonide for up to 3 years. Phase III studies involving diabetic macular edema were promising for resolution of retinal leakage compared to placebo. However, the study also reported that after one year 58.5% of subjects receiving the 0.5-mg implant developed serious side effects such as increased intraocular pressure, vitreal hemorrhage, and cataracts, complications that occurred in only 10.7% of the standard care group. The patients will be followed for an additional 3 years to monitor the safety of the implant. Enrollment is complete for a phase II study to evaluate the effects of Retisert on exudative AMD. However, development in this indication has been discontinued [97]. Similarly, a biodegradable dexamethasone implant (Posurdex; Allergan, Irvine, California) has shown safety and benefit in recent phase II trials for macular edema from diabetes mellitus, branch or central retinal vein occlusion, uveitis, or surgery. No trials are currently evaluating Posurdex on AMD.

Given the complexity of AMD and our limited understanding of its pathophysiology, the current design of therapeutic modalities relies largely on the evaluation of a large number of candidate treatments in order to define those who offer clinical benefit. Until our knowledge of physiological processes responsible for macular degeneration increases, treatment will likely depend on a combination of approaches to limit the underlying CNV. This combination approach is already largely reflected in the design of currently ongoing clinical trials.

### 10.11.1 INTRODUCTION

This chapter introduces then explores in detail, issues and practical aspects of the context and conduct of paediatric clinical trials. Investigators need to be alert to the unique obligations that come into play when study participants are infants, children or young people. These obligations are ethical, procedural, legal and social. Investigators also need to be aware of the multiplicity of interests that operate in paediatric research so that projects can be successfully managed to completion. Ideally, realistic and reasonable paediatric trials will cause minimal harm and will meet expectations of parents, caregivers, investigators, sponsors and the public for meaningful and clinically useful outcomes.

This chapter presents the scope of challenges and opportunities in the paediatric speciality, to help support clinical trials that are child-centred, worthwhile and rigorous. Paediatric research is an area characterised by local procedural variation and rapid change in regulation, case-law, scientific evidence, scholarly opinion, public concern and professional guidelines. Consequently, this chapter provides common signposts, rather than prescriptive maps, that can be set in place by investigators as they lead the way in particular trial journeys. By the end of this chapter, investigators should have a breadth of view on issues involved in paediatric trials to enable them to apply technical information to the context of paediatrics. Investigators should also be able to reflect on their own standpoint and responsibility as trial leaders, sponsors or team members who are knowingly putting infants, children or young people at some level of risk in order to answer a question. Investigators should be able to seek out specialized paediatric trial sources after reading this chapter, having first gained a broad understanding of issues that must be proactively managed for successful trial completion.

### 10.11.2 DEFINITIONS

#### 10.11.2.1 Paediatric Population

The United Nations Convention on the rights of the child [1] defines a minor as anyone under the age of 18. While there are local variations to the legal age of adulthood, and while the clinical responsibility of the paediatric speciality may extend to 21 [2], the UN Convention should normally be observed for the purposes of trial research. For this chapter, the previable or viable foetus is not included however these are recognised as responsibilities of paediatrics [2] and specialist research sources should be consulted commencing with policy and guideline statements of relevant bodies for example, the American Academy of Pediatrics [3].

#### 10.11.2.2 Off-Label Use

Many drugs used in paediatrics are off-label and one reason underpinning the need for clinical trials is to reduce this practice:

“new drugs and biologicals [need to] include adequate pediatric labeling for the claimed indications at the time of, or soon after, approval. However, because such labelling may

not immediately be available, off-label use (or use that is not included in the approved label) of therapeutic agents is likely to remain common in the practice of pediatrics ... The purpose of off-label use is to benefit the individual patient. Practitioners may use their professional judgment to determine these uses ... The off-label use of a drug should be based on sound scientific evidence, expert medical judgement, or published literature” [4, p. 181].

### 10.11.2.3 Therapeutic Orphan

Drugs which are not approved by the Food and Drug Administration [USA] as safe and effective in children are prescribed daily. This is due in part to the fact that many drugs released since 1962 carry an “orphaning clause” in the package insert such as, “not to be used in children, since clinical studies have been insufficient to establish recommendations for its use ... Is the physician breaking the [USA] law when he prescribes drugs ... which carry the ‘orphaning clause’?. No, he is not. The physician may exercise his professional judgement in the use of any drug. However, if he deviates from the instructions in the package insert and adverse reactions occur, he must be prepared to defend himself in court if there is a malpractice suit” [5, p. 811].

### 10.11.2.4 Paediatric Investigation Plan

This is the term used in the European Union by the European Medicines Agency (EMA).

[It is] a development plan aimed at ensuring that the necessary data are obtained through studies in children, when it is safe to do so, to support the authorisation of the medicine for children. ... The paediatric investigation plan includes a description of the studies and of the measures to adapt the way the medicine is presented (formulation) to make its use more acceptable in children ... The plan should cover the needs of all age groups of children, from birth to adolescence. The plan also defines the timing of studies in children compared to adults. In some cases, studies will be deferred until after the studies in adults have been conducted, to ensure that research with children is done only when it is safe and ethical to do so [6].

### 10.11.2.5 Minimal Risk

Minimal (the least possible) risk describes procedures such as questioning, observing and measuring children, provided that procedures are carried out in a sensitive way, respecting the child’s autonomy and that consent has been given ... It is expected that research of minimal risk would not result in more than a very slight and temporary negative impact on the health of the person concerned [7, p. 15].

## 10.11.3 OVERVIEW OF UNIQUE ASPECTS OF PEDIATRIC TRIALS

This section overviews key issues that make paediatric clinical trials unique. Paediatric clinical trials seek answers about intervention effectiveness and safety—there is nothing unique about this—but to get answers, these trials are unique in requiring infants, children and youth as participants. The sample characteristics and needs thus dominate trial decisions. Paediatric populations present design challenges for trial

investigators. As participants they have inherent and continuous change in body structures, function, activities and participation, there is constant change in their social relations, exposure to physical environments, family and community influences—this continuous change is evident even when they are in good health. The scale and variability of change increases if there is illness, disease, disability or injury. Continuous underlying change in participants must therefore be anticipated in trial question, design and protocol decisions.

Paediatric populations also bring investigator responsibilities and accountabilities that extend well beyond those normally encountered in trials with adults. Young participants are inherently *vulnerable* and those who have illness or disease appear particularly exposed to the possibility of suffering. Adults make trial decisions on behalf of youngsters and act towards them in ways that may help or harm both their daily life and their life chances. Their vulnerability presents dilemmas for all involved in clinical trials. For adults to purposefully involve youngsters in studies with potential or known risk seems incompatible with obligations to protect and nurture them. For institutions, like hospitals, established to care and help, knowingly exposing youngsters to risk seems a betrayal of civic duty. These moral contradictions are a necessary and inevitable part of paediatric trials. They underpin the heightened emotion and public interest that accompanies paediatric trials. But without sound paediatric clinical trials greater harms may be perpetrated as parents, carers, medical and health personnel use clinical interventions on children at large without adequate or sometimes any scientific evidence to inform their decisions.

Clinical trials must be conducted, but their planning and accountabilities must also anticipate and accommodate paediatric participant vulnerability. Investigators who are aware of this *moral context* will ensure that questions are not only worthwhile, but also that protocols are explicitly child-centred, of rigorous design, and well conducted. It is the heightened moral context of paediatric clinical trials that is unique as infants, children and young people, not investigators, parents or sponsors, must live with the trial experience and the short and long term consequences of participation. Trial investigators who are aware of the moral context will also anticipate potential public interest and consider in advance how the lay-person might construe issues such as recruitment, design, funding, sponsorship, personnel and study procedure. Paediatric trial project planning thus needs to include strategies for public communication, public liaison and accountability trails.

The inherent vulnerability also means that a paediatric trial is one where child participants are the focus of many interested parties. *Stakeholders* include parents and guardians, medical, legal, health, and policy personnel who act as gatekeepers to and watchdogs of paediatric population participation. The media, pharmaceutical companies, organised advocacy and lobby groups play vigilant and vigorous roles in the initiation, public presentation and interpretation of trials. Stakeholder authority and influence can make the planning and conduct of paediatric trials a complex and delicate campaign of personal, professional, industry and community politics—in addition to the usual demands of a complicated scientific project. Proactive communication with stakeholders is needed regarding the question, study rationale, study conduct, regulation adherence, avoidance of conflict of interest, transparency and accountability of processes and records, and importantly the need for trials to

prevent current and future suffering caused by the use of interventions that have no scientific support.

Paediatric trials necessitate a careful balance of common sense, technical precision, and adherence to highly prescriptive regulation. Given the sensitivity of research with children, successfully engaging in paediatric trials is as much about identifying a *moral purpose*, communicating trial values and visions, ensuring justice for participants, and scanning the strategic context for threats and opportunities as it is about the study question, procedural diligence, protocol development and project management.

These “soft” project factors can publicly or professionally derail an otherwise well intentioned and well constructed trial if not proactively managed. They can destroy an investigator’s reputation even when no malicious intent or negligence was involved. The “front page of the paper” by-line may be all a public needs to discredit a researcher, damage institutional confidence and undermine a much-needed program of paediatric health research. Careful consideration of not only the scientific merit of the question, design and regulatory obligations, but also of the moral *politics* of paediatric trials is thus required. For some investigators, the interests and authority of stakeholders and gatekeepers seem like obstacles to research, however any experienced trial researcher knows these factors are just part of the “package” that is a paediatric trial.

Paediatric practice is also inherently *multidisciplinary* and the design of clinical trials must be robust enough to anticipate an array of potentially confounding factors in a child’s life emanating from health services, schools, community and family, including parental use of off-the-shelf medications, complementary medicines and alternative therapies. A clinical trial that is child-focused rather than variable focused will take into account the multiplicity of influences that may affect body structures, ability to participate in protocol requirements, recruitment, retention, confounding factors, and the short and long term consequences of trial participation.

Finally, participation, protocol adherence, study retention and the safety of young participants ultimately relies on *parent and caregiver* expertise and their understanding of and commitment to trials. Engaging parents and caregivers as protocol partners is critical to study success. Providing appropriate learning opportunities for parents to understand not only the study purpose and participants demands but also children’s rights to assent or decline participation are needed. This understanding goes to the heart of informed consent. Consideration of parent and caregiver perspectives in protocol design is essential, particularly in relation to the logistic and time demands on parents for intervention adherence and presentation of the child for outcome data measure collection. Paediatric clinical trials work better if the protocol can be reasonably integrated into the daily life of families as part of a sustainable routine.

This section of the chapter has provided paediatric investigators with an orientation to unique issues in paediatric trials. The following sections explore issues in more depth, however the following *caveats* apply. This chapter is introductory. Specialized paediatric sources, such as the Helms and Stonier (Eds) *Pediatric Clinical Research Manual* [8] which is regularly updated and has sub-speciality supplements, or the many speciality research related web-sites of regulatory bodies or professional societies should also be consulted. Research, scholarship policy and

commentary associated with paediatric research changes quickly. Investigators must therefore ensure they inform themselves about local requirements, contemporary conventions, up-to-date regulation, current public concerns, scholarly opinion and relevant scientific evidence available at the time of study commencement. A matter of months can dramatically change the paediatric research context as case law, public interest, media “frenzies”, local administration or new evidence can change what could be reasonably expected in an investigation plan. Particular attention should also be given to the most recent scientific evidence emerging from the paediatric sub-specialty under study, be that oncology, cerebral palsy, infectious disease or whatever, including evidence relating to effective sub-speciality trial methodologies. Different sub-specialities bring unique challenges relating to measurement, recruitment, consent and retention. Successful sub-speciality precedent studies can also help inform trial plan decisions. But caution! Precedent studies may have been conducted in different regulatory and social contexts making their methodologies unsuitable for contemporary replication even though the scientific findings may be rigorous and relevant.

The remainder of the chapter begins with the policy context. Policies have been developed to protect vulnerable infants, children and young people in research and to promote ethical practice. Conventions, regulations, recommendations, guidelines, and institutional review boards are introduced. The chapter continues with an exploration of issues that are particularly challenging in paediatrics: trial questions, participant characteristics, investigation plans, consent, assent, safety and monitoring.

#### 10.11.4 CONVENTIONS

Regulatory requirements compel investigators, sponsors and research partners to scope and conduct research in certain ways. Investigators and trial partners must comply with regulations or face consequences that may include prosecution and penalties ranging from public “naming and shaming” to fines or in cases of criminal conduct imprisonment. The existence of regulations means that clinical research can not only be weak or rigorous, it can also be lawful or unlawful. Investigators and members of institutional ethical review boards therefore have a duty to keep up-to-date with regulatory requirements as ignorance is normally no excuse. Understanding legal obligations, particularly those for paediatric populations, is as important as understanding scientific methods and the needs of youngsters. Investigators cannot work on the basis of what has been done in past practice or research, nor can they apply the same level of autonomous discretion they may use in their clinical life, as research-related regulations change over time, the standards for research decision-making are more prescribed and tests of due diligence, fair hearing and procedural fairness in research may be tighter.

A good place to start in understanding the regulatory context of paediatric research is with landmark conventions. These state agreed international positions on matters of importance that relate to the human condition. The United Nations (UN) General Assembly “Convention on the Rights of the Child” 1989 is probably one of the most important foundations for the paediatric speciality [1]. Although

not all countries have ratified this convention, the influence of the convention on national standards is enormous. In summary, the convention identifies that: human rights apply to children without exception; the child's best interests are the primary consideration and highest priority; children have a right to the highest attainable level of health; and they have a right to information and respect of their opinion [1]. While clinical trial plans would almost never cite the Conventions on the Rights of the Child as a methodological source and there is no mechanism to directly register trials as convention compliant with the UN, it is principles in this convention that local regulations around the world usually aim to embed and enforce.

Practically, investigators can use this convention to reflect on whether or not their study question or plan is "just". Investigators have a duty to act justly towards participants [9] and tests of justice may go beyond local regulatory requirements. The convention can provide some insight into what might reasonably be considered just. If one accepts the principle that children everywhere in any society should have human rights, then just study protocols should seek to preserve and protect those rights. Just protocols will thus include strategies to inform, listen to the opinion of and seek assent of child participants, even when parental permission has already been granted. The principle of "best interests of children", if accepted, also means that the best interests of child participants and children in general are high priorities in study decisions. In some way children must benefit, whether that is directly through trial participation or indirectly through study outcomes that enhance the well-being of children in general. Finally, the just trial will support the principle that children have a right to the highest attainable health, particularly in relation to weighing up trial benefits and risks to individual children and children in general.

Other international agreements relating to research may also apply to paediatric investigation. The most notable is the Declaration of Helsinki [10]. Clause 25 specifically relates to child involvement in medical research and it focuses on consent and assent. The United Nations Convention on the Rights of Persons with Disabilities [11], and the Declaration on the Rights of Indigenous Peoples [12] may also be relevant for studies that have targeted or incidental recruitment of youngsters from these groups. Both these conventions are relatively new, and not all countries are signatories, but again they provide a benchmark for investigators to consider whether or not the study question and plan is "just".

Conventions are thus an important and a useful background to investigator development of an ethical standpoint towards young participants. They help identify what might be considered just treatment. But most investigators do not use them. Instead they follow local regulations and procedures that codify ethical requirements. Local regulations may or may not be adequate for the moral context of paediatric clinical trials. Here is where the utility of "benchmark" regulations comes into play for investigators around the world. Although they may not apply locally, benchmark regulations provide guidelines and procedures that usually embed principles from conventions or declarations in their construction. Benchmark regulations can thus act as a guide, along with local requirements, for investigators to consider what a reasonable person would expect in a just paediatric study. The benchmark regulations of most influence are now explored. Both relate to medicines for children however the principles and processes are useful to inform research-

ers who work with other clinical interventions as they highlight the need for clear standards, accountabilities and procedural precision.

### 10.11.5 BENCHMARK REGULATIONS

One of the most significant developments in Twenty-first century paediatric clinical research has been the release of regulations in the European Union (EU) and the United States of America (U.S.). While other countries have local standards and regulations that must be consulted by investigators and adhered to in plan development and reporting, the sheer scale of the EU and U.S. regulations impact on numbers of trials and participants makes them global benchmarks that can inform and guide clinical trial decisions anywhere. This section first overviews where regulations and related sources are located, as any paediatric investigator will need to continually update and check rulings and applications of regulations. Then the EU and USA regulations themselves will be introduced, and examples of regulations from other jurisdictions that may be helpful will be provided.

The regulations and support material of the EU are easily located. A web-search using any popular search engine and the general term “paediatric clinical trial” will reveal links to the European Agency for the Evaluation of Medicinal Products (also known as European Medicines Agency, EMEA) (<http://www.emea.eu>) in addition to independent sites that hold related articles, opinion pieces, conferences and training announcements on the general topic of paediatric clinical trials and often the EMEA initiative specifically. These related items can be EMEA sponsored, or independent and they often maintain a lively watch on the EMEA initiative from an investigator and industry perspective. Sites such as these, together with subspecialty resources in particular fields available through scholarly journals, professional societies and consumer groups, help investigators understand the motivations, agendas, obligations and impacts of the EU regulation from a broader perspective. The latter can help inform the strategic decisions that need to be made by trial leaders in project planning and management. From the home page of the EMEA Medicines for Children a wealth of official resources is also available to investigators including the regulation itself, guidance for applicants, access to scientific advice, decisions and opinions on applications and importantly, paediatric related information. The latter includes information on paediatric needs, clinical trials, priority list off-patent medicines and presentations. Importantly, the decisions and opinions on particular trial applications, including class waivers and product-specific decisions are included on this site.

The EU *Regulation (EC) No 1901/2006 amended*, the “Paediatric Regulation”, came into force in January 2007, and investigators, industry and the public are still exploring the material effect it may have on paediatric research activity. The paediatric regulation aims to increase the number and availability of medicines that can be used in the paediatric population, by providing rulings, guidance and incentives to investigators, sponsors and institutions to develop paediatric specific products and to develop paediatric prescribing information for other medicines. Mechanisms to license and provide clinician and parent information are also included. One of the features of the Paediatric Regulation is the establishment of a new Paediatric Committee of the European Medicines Agency [13]. This scientific committee has

the authority to make decisions and provide opinions on applications to do research and on outcomes of that research in relation to product use. The Committee is multi-disciplinary, brings together renowned experts in fields of general practice, paediatric medicine, pharmacy, pharmacology, research, pharmacovigilance, ethics and public health. Health care professionals and patient associations are also part of the collective expertise.

The Paediatric Committee has an onerous task to ensure paediatric medicine approval is based on rigorous quality, safety and efficacy data. Strategies used by the Committee include: requiring paediatric investigation plans (PIPs) and data to be submitted to regulatory authorities; assessing PIPs and providing decisions and opinions; monitoring of the PIP compliance; supporting a paediatric research network; implementing key public communication strategies such as the use of a common symbol for medicines that have an approved paediatric use; and training investigators. In addition the regulations provide an incentive to investigators and sponsors by providing an additional six months on the supplementary protection certificate if completed PIP information is included in the Summary of Product Characteristics. For off-patent products, there is the incentive of a paediatric use marketing authorisation which has a ten year data and market protection period. The regulation also provides for establishment of a European data base of paediatric clinical trials, part of which will be publicly available.

Access to U.S. regulations is less straightforward. There are multiple web-routes to access relevant information, and the best route will depend upon the study question. One is to go direct to the U.S. Department of Health & Human Services (HHS) (<http://www.hhs.gov>), thence to the Office for Human Research Protections (OHRP) (<http://www.hhs.gov/ohrp/>). Another is to start with the U.S. Food and Drug Administration (FDA) (<http://www.fda.gov>) and consult the various pages to do with clinical trial practice that may include adults as well as children (<http://www.fda.gov/cder/pediatric>). One page, for example, provides direct links to all FDA regulations relating to good clinical practice and clinical trials (<http://www.fda.gov/oc/gcp/regulations.html>). There is also the Office of Pediatric Therapeutics (<http://www.fda.gov/oc.opt/>).

The history and recent state of USA regulations that inform paediatric research has been reviewed by Diekema [14]. He provides a concise guide to critical incidents and key sources, most notably the *Code of Federal Regulations, 45 CFR 46, Subpart D Additional Protections for Children Involved as subjects in research* 1983. Others are the *Best Pharmaceuticals for Children Act* 2002 and 2007 [15], and the *Pediatric Research Equity Act* 2003 [16] that re-established the FDA's authority to mandate paediatric drug development [17]. Informative guides and regular updates on paediatric issues have been developed and are available through HHS sites of the OHRP and FDA. An example is the *Guidance for Clinical Investigators, Institutional Review Boards and Sponsors: Process for Handling Referrals to FDA under 21 CFR 50.54; Additional Safeguards for Children in Clinical Investigations* [18]. Apart from linked guidelines, these sites provide "current thinking" of the agencies in relation to key issues variously presented as "frequently asked questions" or "guidelines". Further they provide aide-memoirs for investigators such as the "pediatric points to consider" that include a summary of unique review concerns for paediatrics, including study justification, study design, ethical issues, and pediatric protocol checklists. Later stage trial results should be reported to the clinical trial registry

and data base in accord with Regulation S3807. There are also incentives in regulations to encourage paediatric pharmaceutical research, such as six month exclusivity on manufacturer marketing licensing if the company “fairly responds” to FDA requests.

While the OHRP site provides guidance and recommendations for paediatric study conduct, it also highlights areas where compliance is required under the U.S. HHS Regulation. Compliance is specifically required for HHS supported research, but the aspects identified may provide useful benchmarks to alert investigators outside the HHS or USA for potentially high stake paediatric trial issues. As thinking may change and as there is acknowledgement that alternative approaches may be considered by the authorities, investigators are advised to check these sites for changes, opinions and rulings as part of trial planning.

Internationally, many countries have regulations that apply to research with human subjects and specifically to paediatric populations. Most feature principles and practice requirements or recommendations that are consistent with the broad approach of the EU or U.S. and related international conventions. Australia for example, has the National Health and Medical Research Council statements including the *Australian Code for the Responsible Conduct of Research* [19] and the *National Statement on Ethical Conduct in Human Research* [20]. Canada has the Medical Research Council Tri-Council policy statement on *Ethical Conduct for Research Involving Humans* [21]. Some other countries have statements on the conduct of research in humans, but have little that specifically relates to paediatric populations. For example, India has the *Ethical Guidelines for Biomedical Research on Human Participants* [22]; and South Africa has a *Code of Research Ethics* [23]. Both have only limited clauses relating to child research.

In addition to benchmark and local regulations for paediatric research in general, investigators need to be alert to any special provisions for particular groups. In Australia, for example, there are particular guidelines and requirements for research involving indigenous people [24]. Other countries may have similar provisions that should be consulted and integrated into PIPs. There are also special provisions in Australia for research that is conducted outside the country [25] and similar approaches may be taken in other nations. The particular vulnerabilities of unaccompanied children, foster children, wards of the state, and emancipated children also need attention if they are to be target or incidental participants. A lack of attention to any of these regulations can have a significant impact on the conduct of a trial or the reputation of investigators, sponsors or institutions involved.

### 10.11.6 RECOMMENDATIONS AND GUIDELINES

In addition to regulatory requirements and recommendations from statutory or government sponsored institutions, trial investigators, coordinators and employees may also be need to be registered or accredited professionals, subject to the Codes of Conduct, recommendations, guidelines or prescriptions of their professional societies or registration Acts. Depending on local conditions these may be enforceable. Each paediatric speciality and sub-speciality may also have requirements, guides

and resources. Investigators are urged to consult these at an early stage. Investigators should also satisfy themselves that they and their team members are meeting relevant professional obligations in addition to prescribed regulations, as the conduct of some assessment, intervention or outcome measure procedures may require a registered or accredited practitioner. Examples of professional societies that have guidelines for research are: the Royal College of Paediatrics and Child Health [26]; the European Academy of Paediatrics (formerly the Confederation of European Specialists in Paediatrics) [27] that provides guidance ranging from official statements to commentaries and summary presentations, for example that provided by Kurz [28]; and the American Academy of Pediatrics [3]. Profession and sub-speciality specific guides must be sought out by investigators to inform trial decisions, and if none exist, this should be noted somewhere in trial planning records so that the due diligence of trial leaders in this regard can be noted.

There are also guidelines from esteemed practice and research institutes that could be considered and used as methodological sources in trial plans. One is the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). This organisation has produced many resources including the oft-cited, *Guideline for Good Clinical Practice E6 (R1)* [29] which applies to the conduct of clinical trials, including essential documentation and archive guidelines; and the guideline for *Clinical Investigation of Medicinal Products in the Pediatric Population E11* [30], that contains a series of guidelines for drug development and registration processes. These supplement more general ethical guidelines for biomedical research [31]. The Medical Research Council [7] provides an ethics guide for *Medical Research Involving Children* that clearly summarizes key points unique to paediatric trials. Guidelines for international research [25, 31], and research involving human participants in developing societies may also be relevant to investigators working across international boundaries.

Guidelines from esteemed bodies can relate to particular paediatric populations and sub-specialities. For example, the Society for Adolescent Medicine has issued *Guidelines for Adolescent Health Research* [32]. Others such as the National Institute for Clinical Excellence (NICE) (<http://www.nice.org.uk/>) provide specialist resources on “best practice” approaches that can be incorporated into research protocols and general care of young people. While NICE guidelines cover public health, health technologies (including medicines, treatments and procedures) and clinical practice (for specific diseases and conditions) applicable within the National Health Service of the United Kingdom, they are useful practice benchmarks. Examples of approved guidelines include: *Improving Outcomes with Children and Young People with Cancer* [33] and *Feverish Illness in Children—Assessment and Initial Management in Children Younger than 5 years* [34]. Other guideline projects are underway for children. For example, *Prevention of Unintentional Injury in Children under 15* (due April 2010) and *Guidance on Looked After Children* (due September 2010). While there are no obligations on researchers to observe these guidelines in trial plans, they are useful practice benchmarks which may be required when arguing the case for equipoise in intervention or control groups.

In addition to professional society and advisory bodies, there are industry developed guidelines and issues papers. One example is the Association of the British Pharmaceutical Industry publication *Current Issues in Paediatric Clinical Trials* [35]

that reported on a conference covering matters such as regulation, ethics, parent perspectives, national frameworks and the industry perspective.

### 10.11.7 INSTITUTIONAL REVIEW BOARDS

Institutional review boards are often referred to in regulation as the local means to assess, approve and monitor studies. New investigators generally focus their approval efforts on these local bodies, and may not initially be aware of the recommendations, guidelines, regulations and conventions referred to earlier. Paediatric trial investigators should, however, set their views beyond local board requirements. A local compliance approach that breaches standards set in conventions or benchmark regulations may not be considered “reasonable” or “just” in the mind of the public or the law if a trial goes awry.

Notwithstanding the need for a broad view by investigators, many local boards are subject to regulations and guidelines at a national level and this may make local compliance adequate. For example in Australia, Human Research Ethics Committees are established through a formal process involving registration with the Australian National Health and Medical Council. Their conduct and reporting lines are mandated. In another example, local Institutional Review Boards in the U.S. have limits to their approval authority indicated by the level of risk and benefit incurred by research participants [14, 36]. So in some areas, there may be natural links from local boards to national regulations and international conventions, but this should not be assumed.

Institutional review boards that consider and approve paediatric trial research need to ensure that they have access to appropriate expertise to make informed decisions about research with youngsters. Local boards that approve paediatric research may later be on the defensive if problems arise and they did not have adequate paediatric expertise in place to make their decisions robust. Barret [37] for example, suggests that research ethics committees should have members with practical experience in working with sick children so that they can assess whether or not risks to young participants are acceptable, protocols are workable, opportunities are provided for children to withdraw, and whether their autonomy is respected. Ethics committees also need to consider whether the research team has the paediatric capacity to do the study. Drawing on ICH [30], Kurz and Gill [38] recommend that paediatric trials should be done by “medical and scientific personnel who are familiar with GCP [good clinical practice] guidelines and are capable of a trusting relationship and communication with the child and parents ... in ... a child-friendly atmosphere with a paediatric infrastructure and personnel” (p. 43).

While ethics committees can interrogate researcher profiles as part of the approval process, local boards may make assumptions based on researcher reputation that is not backed up by documentation in the applications. This can easily happen if the researcher is a local who is well known for their expertise, or if a leading international researcher is involved and local boards do not feel comfortable interrogating his or her expertise. This can create later problems for boards if the appropriateness of the decision to approve research is challenged and the grounds for the decision about researcher capacity were scant. Paediatric investigators should therefore take some care in preparing the expertise statement that most institutional review board

applications require. It may be worthwhile to detail paediatric clinical, professional and research expertise relevant to the study topic, and to demonstrate that, between all team members, there is capacity for all study demands. In Australia, many institutions also require risk assessment prior to or following institutional review board approval for trial insurance purposes. It is not uncommon, for example, for subject and/or study-specific insurance to be required by some institutions for invasive clinical trials. The risk assessment outcome may depend upon the demonstrated paediatric research capacity of the investigation team.

### 10.11.8 TRIAL QUESTIONS

Trial questions need to be worthwhile and ethical. They need to be “honest and valid” [39, p. 836]. The technical skills involved in the development of trial research questions have been covered elsewhere in this handbook, as have the general ethical principles of beneficence, maleficance and clinical equipoise, so this discussion will explore what principles underpin a worthwhile ethical paediatric trial question.

Paediatric clinical trials ask questions about the safety and efficacy of interventions for infants, children or youth. Kurz and Gill [38] proposed that paediatric should therefore “focus on the knowledge, cure, relief, or prevention of diseases of children. Biomedical studies must be devoted to reducing suffering and improving the prognosis of diseases” (pp. 42–43). To do this ethically, questions need to meet tests of relevance, benefit, originality, achievability, timing, and minimal harm. These are now explored.

The first issue facing investigators is whether or not the question is *relevant* to children and thus whether the involvement of young participants is essential rather than desirable. A high threshold needs to be met in this regard. The Royal College of Paediatrics and Child Health [26] identifies that research should only be conducted in children if the question cannot be answered by studying adults. Further, it identifies that involvement of children in clinical research will be required when an illness or condition only occurs in children, or has features that are more pronounced or have greater impact in young people. In such instances, research will be needed if there is no treatment information available or when what is known is inadequate. Paediatric research participation will also be required if the condition is in the general population but there is no paediatric treatment or there is only adult intervention evidence available [26]. Generally, paediatric inferences should not be drawn from adult studies, although occasionally a treatment will have a long history of use in children that initially relied on adult data but has subsequently been complemented by consensus expert paediatric opinion [26]. In such instances, the weight of consensus expert opinion may mean that an exception can be made and a paediatric inference can be drawn. The Medical Research Council [7] provides five questions for researchers to help determine whether or not the involvement of children is essential or whether findings from adult studies would be adequate. These questions cover [7]: age specificity, developmental understanding, implications for pharmacokinetics, applicability of adult-style therapy and issues of later life disease prevention.

The second issue facing investigators is whether or not answers to the trial question will *benefit* children. Benefit to children is essential [30]. The Royal College of

Paediatrics and Child Health [26] identifies that paediatric research must not only be well designed and well conducted but it must have a real prospect of benefiting children. Benefits to children may be direct through trial participation in treatment or control groups or indirectly to children in general—even though there may not be benefits to individual trial participants. Benefit needs to be self-evident in the trial question and study description [40]. The Royal College of Paediatricians proposed that the following issues help make potential benefits to children clear [26]: *magnitude* of the condition including severity, how *common* it is and how findings will be used; how *probable* it is that research will achieve aims; who specifically will *benefit* from the research (whether it is child participants or children in general); whether benefit to children will be *limited* because treatment is expensive or hard to deliver; the *type* of intervention and whether a less invasive one could be used; the *timing* of benefits in terms of duration or later impact; and finally the whether the *range* of child participants is adequate in terms of potential benefits [26].

One simple way for investigators to consider benefit, is to imagine that the study is finished, the trial question has been answered, then adopt the perspective of a public health official, a general practitioner, a parent or a child and ask “so-what?” What material benefit to children would accrue from the result? Does it merely confirm something already known? Is it interesting but not essential for child health and care? Is there any reasonable likelihood of direct benefit to participants or benefit to children in general? What would the “reasonable person” think about the study if they also knew the costs, risks and demands made on health care staff, participants and families to get the answer? Would the reasonable person agree that some children need to be exposed to risk to benefit children at large? Would the lay-person feel as Smyth [41] does, that “we are all aware of the dramatic impact which results of clinical trials have had on the care and survival of children” (p. 835), and “there is an energy and dynamism which is both exciting and invigorating for paediatric clinical research” (p. 837).

While common sense, careful scholarship and the “so-what?” test suffice for many trials, some studies and teams may benefit from involving ethicists in early stages of question development to ensure that a careful and considered approach to justice and benefit is taken. This is particularly important when trial interventions or measures may involve discomfort, distress or pain; or where the illness or condition brings inherent suffering or risk of death that may be exacerbated or alleviated by trial processes. A clear and scholarly beginning position on the issue of benefit to children not only helps investigators ensure their trial question is child-centred, but it also helps sponsors and participating institutions monitor progress of the trial and develop public and stakeholder communication plans.

The third challenge for investigators is to ask a question that can actually be answered. Is it *achievable*? Is it a question that the investigation team has the capacity to answer from the point of view of expertise, population access, resources and infrastructure? A question may not be realistic if there are insufficient potential participants for the study time frame; if the testing regimen is not physically or emotionally tolerable, or fails to accommodate family routines or responses; if sufficient funding, expertise, infrastructure or consumables are not guaranteed; if a-priori protocols for intervention, child care and data analysis are not transparent or cannot be adhered to; or if the findings are not going to be available or disseminated in ways that will grow the knowledge base to benefit children in general.

One of the most important issues to consider in weighing up whether a trial question is achievable is the capacity of the team. Clinical proficiency and research interest is not enough—the team as a whole needs to have the expertise to conduct all aspects of the trial. This may mean investigators must expand team membership to fill skill, knowledge and labour gaps that range from statistical analysis, ethical question design, budget management, regulation compliance, use of clinical procedures, to interpretation of findings and writing. Clinical professionals new to research sometimes learn the hard way that a good research idea is not necessarily question that can be investigated. Alternatively these researchers don't learn, they don't use structural and capacity building strategies to get the study done, and instead they can blame anyone involved in or connected to the project! The experience can leave clinical staff, managers, families, patients and researchers themselves disillusioned about the research experience and sometimes about each other. This is a particular risk for professionals who are attempting trial research in environments where they are already overloaded with clinical responsibilities and have limited prior experience of the technical and time demands of trials.

Turning a good idea into an achievable question requires a combination of scholarly, managerial and political skill that almost always involves long term collaboration of multidisciplinary experts. It almost never involves the “deity-like-researcher” leading followers or directing an operational team from a geographical or organizational distance. Such studies have inherent structural risks that make them prone to mistakes. Successful paediatric trials are always a team effort. They always involve the building of relationships over time with trust, respect and recognition. They always take effort on the part of the research leader to build and maintain a climate of open scholarly enquiry. Without such effort, mistakes may not be reported, good staff may leave, people fear betrayal or theft of their ideas or reputations, team politics rather than child participation can absorb emotional energy and the high test of ethical practice required in the moral context of paediatric practice is undermined. For paediatric researcher leaders there is, quite simply, no way to “delegate” a paediatric trial. Senior investigators must be involved in every aspect of trial planning, conduct, interpretation and writing as directors, collaborators or hands-on players. To do anything else is to risk allegations of being “front-men” or “poster girls” for trial sponsors, research institutes, or servants of their own “brilliant” careers—even when this is not true.

In addition to issues of team capacity, achievable questions rely on practical details such as estimating whether or not required sample sizes are attainable given the incidence of the condition, the recruitment target population, recruitment methods and time available. Many paediatric clinical populations are very small, hard to access, and may have high decline rates in recruitment. Trial planners may need more than epidemiological data to estimate whether or not they have a reasonable likelihood of recruiting the needed sample—they may need local “on-the-ground” informants who can estimate the impact of recruitment methods on limited potential participants. The target sample size must not only account for the clinical effect size of the intervention in question but also appropriately deal with the confounding variable of developmental maturation, and practical issues such as likely decline rates and drop outs. Trial questions that require good luck to achieve sample sizes should be put to one side. This is hard for researchers to do, particularly if the question is their passion, however it must be done. Underpowered trial findings can

be worse than no findings at all—they give the illusion of reliable evidence. They are all too common in paediatric research. A review of trials published in the *Archives of Disease in Childhood* from 1982 to 1996, found that half the trials had 40 participants or less, which in the case of the trials reviewed meant that they were often under-powered [42]. Researchers should ask themselves “what is the point?” if an adequate sample size cannot be assured. Their attention should turn to more realistic questions or less rigorous research designs.

The fourth challenge for investigators is to ensure that the trial question is *new*. Questions should not be asked when answers are already known. The case of originality should be made clear in “study rationale” sections of institutional review board and investigation plan applications. The case for originality must be strong, scholarly and set in an international context. The strength of evidence should be compelling: systematic reviews, when rigorously conducted, provide a strong evidence base to demonstrate gaps or failings in current knowledge that can be used to justify originality.

Fifth, investigators need to be confident about the *timing* of trials that involve children—they should only be done when the knowledge base is “ready”. The nature of the trial should have a good fit with knowledge already available. ICH guidelines suggest [29, 30]: Phase 1 or 2 paediatric trials are acceptable only when diseases being targeted are entirely or predominantly found in children; phase 2 or 3 trials are acceptable in children for serious diseases where no adequate treatment exists but only after safety and tolerability information has been gained from adult studies; and, Phase 2 or 3 paediatric trials are acceptable for conditions in the general population after there has been considerable research work in adults [29, 30].

Finally, trial questions need to balance anticipated harm with expected benefit and harm should be of “*minimal risk*”. Minimal risk can denote the type of procedure for data collection or intervention where only “very slight or temporary negative impact” might occur [7, p. 15], or where the risk is about the same as that in daily life, or with comparable treatments. Under regulation, [43] potential risks to research participants must be identified and minimized and the prospect of direct benefit to research participants must be maximised. Risks in this instance refer to: “any harm including physical injury, pain, distress, psychological harm, social economic or legal harms that might occur if physical injury occurs, or the potential harms that may be caused if research related information is shared with others” [43]. This places heavy obligations on investigators to identify and describe what potential risks might be. The Royal College Paediatrics and Child Health [26] provides a guide to likely harm description by identifying five aspects to consider: the *magnitude* of severity; the *probability* of harms occurring; whether the *type* of intervention is invasive or non-invasive including psychosocial procedures; the *timing* of potential harm in terms of immediate duration or later effects; and finally issues of *equity* relating to the overuse of children who have many medical problems and are used in research because they are more easily accessible. In assessing harm control, intervention and placebo conditions need to be considered—even placebos may cause harm—antihypertensive drug studies is a good case in point as this raises ethical issues regarding consent and trial design for a condition known to cause harm if left untreated [44].

While there is a requirement to assess likely risk, there is also an obligation to minimize whatever harm must be done to answer the trial question. There needs to

be an appropriate balance between the harm done and the benefit achieved: “expected benefit must exceed recognizable risks [and] serious predictable risks should be avoided” (38, p. 43). These are subjective judgements that must be made by investigators, institutional review boards and families of participants. Some judgements are easy—effective treatment should not be withheld from child participants. Other decisions about design and procedures are harder. The National Academy of the Sciences [45] provides a guide that may be helpful: researchers should consider the potential for age-related risks of harm; whether or not children are really needed; screening for known vulnerabilities; how demanding the protocol adherence is and risks arising from this; the use of only necessary procedures to answer the question; use of rigorous research designs; use of existing knowledge to estimate likely type and magnitude of risks; inclusion of adverse event information in data collection and reports of findings; ensuring investigator research and paediatric capacity; assuring appropriateness of the research setting for children; inclusion of safety monitoring, emergency arrangements, stopping rules for discontinuation; having clear guidelines for data use; and a plan for secure archiving [45].

To estimate and minimize likely harm, investigators must describe the level of risk of an intervention or outcome measure procedure. Defining level of risk is, however, a fraught task. It is one that involves value judgements because currently, risk assessment lacks an empirical standard even though risks are supposed to be identified, quantified and compared [39]. Some paediatric leaders have identified the need for guidelines [46, 47], although the use of guidelines is not universally supported [48]. Inadequate though they are, investigators should thus consult whatever regulation guidelines underpin their institutional review board requirements and ensure they benchmark their risk rating to the relevant regulation using scientific evidence for support. If there is limited scientific evidence available, the National Academy of Sciences [45] guidelines provide a framework for researchers to describe, as best they can, their strategies to minimize harm.

Researchers should also be aware that risk perception varies from the lay-person to the expert. As Afshar et al. [39] suggest: “experts usually assess harm in terms of mortality or morbidity, while a lay person may perceive harm in terms of severity, reversibility, the effect on future generations or influence on personal life. The main consideration should be the acceptability to non-experts, which in pediatric research are parents and older children. The most direct way of determining risk acceptability is to inform participants of the probability and magnitude of harm, and ask them about their preference” (p. 837). Whether or not the risk, discomfort and suffering caused is ultimately reasonable will depend on the question, interests of the child, preferences of the parents, likely benefit and comparison to likely harm in usual clinical practice.

### 10.11.9 PARTICIPANT CHARACTERISTICS

Infants, children and youth have unique body system and social attributes that need to be considered in trial research. Probably one of the most quoted phrases in paediatric research that emphasizes their unique position comes from the Royal College of Paediatrics and Child Health [26]: children are “not small adults”. While every trial will need to investigate participant characteristics relevant to the sub-speciality,

there are some common issues relating to developmental change that should be considered in all fields. These include ages, stages, incidence and heterogeneity of paediatric disease and vulnerability. These issues can be managed as potential confounders as they are known and some aspects to consider are reviewed below. Paediatric trial investigators must also be alert to the possibility of confounders that may be unknown but somehow inherent in the fact their participants are youngsters.

Investigators need to consider how the variable of *age* will be managed in the trial. Age is a proxy-indicator of developmental change and age, as a covariate, needs to be measured and controlled for. The ICH [30] recommends age should be defined in completed days, months or years, using the following stage categories: preterm newborn infants; term new born infants (0 to 27 days); infants and toddlers (28 days to 23 months); children (2 to 11 years); and adolescents (12 to 16 or 18 years depending upon the region). These categories may be used as participant inclusion/exclusion criteria in a study to restrict age variability; alternatively study specific age limits can be set that reflect the sub-speciality study question. In some studies, age may be less of a concern, however it must always be prospectively accounted for, usually by being treated as a continuous covariant in analysis particularly if participants “move” from one age category to another in the course of the study. Different end-points can be set for different age ranges, however every age strata and end-point increases the numbers required in samples.

ICH [30] age related *stages* also provide investigators with specific guidance on factors to consider in relation to drug trials. These factors may also be useful in other types of clinical studies. Investigators are, for example, alerted to [30]: the need for assessment of causes of low-birth weight in preterm newborn infants to determine whether they are immature or growth retarded; or the increased reliability of oral absorption in infants and toddlers; or the increased drug clearance (hepatic and renal) for most pathways in children; or the possibility of hormonal change affecting results of clinical studies in adolescents [30]. Kurz and Gill [38] point out that there are many differences in “physiology, pathology, pharmacokinetics and pharmacodynamics between children and adults” (p. 42); and further, growth and development can influence side effects, dose relative to body weight or surface area, severity of disease, pathological agents and natural history [38]. Investigators should consult the ICH [30], speciality trial resources such as Helms and Stonier [8], and make specific enquiries regarding age related factors in their sub-speciality. This is particularly important when [37]: considering invasive procedures such as the use of repeat blood samples in infants and children as blood volume may limit what can be done; testing off-label or unlicensed applications; or when using surrogate markers, measures of quality of life, pain or other outcomes not validated for use in children [37].

The *incidence and heterogeneity* of disease in children has also been identified as a practical challenge in paediatric research [37]. Some diseases in children are rare which creates challenges for recruiting adequate trial sample sizes. For others, individual responses can vary with age.

The *vulnerability* of young participants is a critical aspect to consider in trial research. As the *European Union Clinical Trials Directive 2001/20/EC, Article 3* states, “children represent a vulnerable population with developmental, physiologi-

cal and psychological differences from adults”. In the distant and not-so-distant past vulnerable children were exploited for medical research purposes particularly if they were institutionalised, disadvantaged or had disabilities [39]. Today, conventions, regulations and guidelines identify these actions were unacceptable, however a child’s inherent vulnerability means the risk of exploitation is always present. It was their vulnerability and perceived inability to give informed consent that lead to the post-World War Two tradition of excluding children from medical research following the establishment of the Nuremburg Code Directives for Human Experimentation 1949. Since post-war years, there is growing recognition of the need for high quality paediatric research “so that tomorrow’s children receive new and better treatments and clinicians have real evidence on which to base their decisions” [41, p. 837]. So children are now permitted to be involved in research, but with a particularly cautious and sensitive approach to acknowledge their vulnerability—this caution and the complexity of regulatory and administrative arrangements to protect them are perceived by some as “barriers” particularly in relation to drug development, but it applies equally to other clinical interventions [49]. “Barriers” are, however, better than the alternative if they are efficiently designed and managed. Barrett [37] says children are the most vulnerable patient group in research—they have fewer rights, problems expressing themselves and the potential for lasting benefit or harm from a research experience. Notwithstanding their vulnerability, she argues that paediatric trial research is essential: “because of the failure to recognise their needs and to perform appropriate research, children are denied access to safe and effective treatment that adults would demand as a fundamental right. Children have become therapeutic orphans” [37]. These “orphans” have been identified since the mid 1960’s when use of adult drugs for children through off-label or off-licence prescription was recognised as a common practice [50] and the term has since been used to identify these medicines [5, 51, 52]. In most cases physicians have little “wiggle room” as adult drugs may be potentially or demonstrably effective for children and the alternative is to provide nothing. Professional societies have tried to grapple with this problem as off-label use can mean that third-party reimbursement or government subsidy of these drugs is not permitted, and physicians may be exposed to law suits in the event of adverse reactions. The ultimate solution to the expanding family of “orphans” is the production of research that involves child participants in rigorous trials under the “parental” scrutiny of regulation, rules, reporting and peer review.

#### 10.11.10 PAEDIATRIC INVESTIGATION PLANS

Other parts of his handbook have explored the preparation of trial protocols and plans in detail. These principles and practices apply to paediatric trials too and will not be reviewed again. This section therefore highlights the special features of paediatric investigation plans that researchers should be aware of at study commencement. These features include the need for plans to be child-centred and family focussed, publicly accountable, regulation compliant, and multi-disciplinary.

Investigation plans need to have the *needs and experience of the child* as the centre-piece of development. Only the minimum number of children required for

adequately powered study design should be used. Measures should aim to demonstrate the quality, safety and efficacy of interventions for infants, children and young people. Consequently, measures selected, data collection procedures, the timing of collection, personnel involved and the study environment should be planned in such a way that developmentally appropriate and supportive approaches are used. The ICH [29, 30] recommends the following ways to minimize discomfort and distress in paediatric participants: only use personnel knowledgeable and skilled in dealing with infants, children and youth and their age-appropriate needs including skill in performing paediatric procedures; use physical settings with furniture, play equipment, activities, and food appropriate for participant's ages; aim to have the study conducted in familiar environments that may include usual places of care; minimize pain and discomfort in procedures wherever possible for example by appropriate anaesthesia, and collect research data through routine clinical tests rather than additional procedures.

Selection of methods should be based on *research evidence* from development and sub-speciality literature, together with advice of paediatric research specialists [8]. Trial plans from adult studies should not be “adapted”, but rather a fresh approach taken with the needs and attributes of children at the core of plan decisions. All personnel involved in the trial should be trained not only for the technical requirements of their role, but also for interaction with children. The trial manual or handbook should focus on the behaviour required of study personnel towards children and their families and this should be monitored for consistency throughout the study. Special training for the identification and management of paediatric adverse events should be required in study plans and a climate of openness encouraged by trial leaders so personnel feel compelled to report mistakes or gaps and are respected and valued for doing so—even if they made the mistake. Outcome measures should consider the child as a person and the demands and influences that will be made on him or her throughout the course of the study. How will the study requirements affect their daily routine, their opportunity for play or rest, their contact with friends and family, their use of favourite toys or electrical devices, the protection of their personal privacy? Things that are of marginal or no interest to researchers may be critical for the wellbeing a child or adolescent.

Apart from the notion of “minimal harm” and “benefit” there is the practical matter of what a child can *reasonably tolerate*. There is little point, for example, in setting a battery of performance tests to measure outcomes if the child can only concentrate long enough for one of them; or setting a number of blood collections if total blood volume in the child is too small; or administering medications or conducting procedures that assume adolescents are not sexually active or that they will openly tell guardians if they are. Obvious errors can be made by even experienced investigators if they focus on outcome measures and forget that they come from a child.

Trial investigation plans should also be *family focussed*. Parents and caregivers know their infants, children and youth better than anyone else. They must feel committed to and interested in the trial to first give consent, and then to maintain involvement. For any recruitment, retention, intervention or outcome measurement strategy to be successful in a paediatric clinical trial, the commitment, expertise and adherence of parents and caregivers is critical. For children in care, consent by authorities as well as carers may also be required. Investigation plans should use

recruitment and retention strategies that have been found to be effective in other trials with participants who are minors including: contact and scheduling methods (such as the use of multiple contacts for recruitment, maintaining a log of cohort follow-ups, making phone calls to contacts to locate participants), reminders (for example letters to remind of appointments), family friendly visit arrangements (such as scheduling data collection visits at the same time as routine health care visits), reimbursements (for example of transport costs), financial incentives (reimbursing for their time), non-financial incentives (such as thankyou letters), and tracking methods to monitor participation (such as regular team meetings to follow up cohort participation) [53–55]. A concerted effort to retain participants is essential. Even though “intention to treat” principles can be used in analysis, drop-outs do threaten internal and external validity of studies and limit the level of inference that can be drawn from findings.

Practically, families may need to adapt their schedule, expend resources, provide transport or other support to enable a child to participate in a trial. The question, the demands on them, the likely benefit and harm to their child will influence their decision to be involved and stay involved. If investigation plans fit into family priorities and schedules their continued involvement is more likely as it is part of a *sustainable* routine. This is particularly the case if trials require special visits for data collection. Even if a child is continually available to researchers, for example if they are hospitalised, the family must still be the focus of plan activities. Many families, for example, would expect that any trial related activity would occur in their presence and that may mean adjusting data collection or intervention schedules for study personnel. Further, families are important sources of trial information—they are usually more alert to changes in the child, are aware of more potentially confounding factors, and if their involvement as “trial partners” [17] is acknowledged by study personnel, they are more likely to adhere to protocols and provide helpful information regarding the study conduct or the child’s response.

In multi-cultural or multi-lingual societies it is important to provide information that can be understood by parents and care-givers. A common practice is translation—this should be done by professionals with expertise in health using usual process of “back-translation” to verify accuracy. But there may be more to consider—the content, presentation, method of recruitment and parent communication may require accommodations to ensure understanding and cultural acceptability. Local advisers and community members should be involved in trial planning stage rather than making adjustments as the variability of the population presents itself.

PIPs need to be publicly accountable and they need to adhere to regulatory requirements. The EMEA, for example, requires all PIPs to be submitted for consideration and to be approved by the Paediatric Committee before study commencement. Once approved, the plan is binding on investigators and sponsors. Results need to be submitted at study series conclusion in accord with the plan specifications. Investigators conducting studies outside these EMEA requirements, are well advised to mimic the transparency and provide a publicly accountable research plan as it is probably one of the best ways to manage potential criticisms or allegations of child “exploitation”. This is particularly important if clinical research organisations are employed to conduct studies: as contractors they can benefit from a clear public plan as it holds them to account at the same time as protecting the investigators and the children.

Perceptions or actual cases of exploitation in medical research do happen. Niles [56], for example, quotes Dembner, an author from the “Boston Globe” February 18, 2001 who, under the gut-wrenching title of “Dangerous dosage to make pediatric medicine safer: Thousands of children are being used to test drugs originally designed for adults” states: the “potent combination of vulnerable children, ambitious researchers, potential profits, and weak oversight can hold great peril for these children”. While the particular facts and opinions surrounding this article are not pertinent here, it is apparent that the title and commentary are, in general terms, both true and false when it comes to pediatric medicines. Yes there are thousands if not millions of children receiving adult drugs—and yes some are involved in testing these drugs—but what is the alternative? To let children go untreated and suffer? To wait until specific paediatric drugs have been developed? Not to test? To ensure only those researchers with no ambition, or those companies with no obligation to shareholders, or those universities with no interest in private funding, engage in pediatric research? To consider that the elaborate regulatory and reporting arrangements in many places are weak and can be bundled together with those that are genuinely sloppy? No wonder we are all so cautious and careful in our PIPs and no wonder there are so many “barriers” to pediatric trial research when the newspaper by-lines such as this can come hurtling into view. The best we can do as pediatric investigators is ensure that our research does meet high standards and that there is opportunity for transparency and accountability in what we do and how. PIPs that comply with reporting requirements and are clearly child-centered can protect investigators and children, and encourage the public to engage in a more informed dialogue. If investigators do not need to register with the EMEA other strategies such as submission to “trial banks” or publication of the PIP/protocol with the trial findings, or publication in open-access or independent journals can be a way to achieve transparency. Such strategies may address some of the concerns regarding potential and actual conflict of interest that have been expressed by researchers themselves [57]. There is an urgent need for informed, realistic and open public, researcher and sponsor dialogue around complex issues of trial funding, independence and ‘cross subsidizing’ of research, researchers, clinical or administrative staff through research funding and PIP transparency could help.

Investigation plans must also be tailored to *multidisciplinary* study teams. In particular, communication strategies for multidisciplinary personnel within and outside the trial are needed. All trial personnel should have a trial manual or handbook that specifies what they need to do, that uses “quick reference” and visual cues to help guide and reinforce required behaviour. Photographs, flow-charts, check-lists and so on may be useful. Small reminder posters, cue notes on files, regular follow up, thankyou or reminder calls, occasional presentations by researchers can help keep a multi-disciplinary team consistent and equivalent in their trial behaviour. These strategies can also help people feel valued and retain their commitment and enthusiasm. For clinical staff not connected with any trial activity, there may also be a need to provide information. Many parents seek the opinion of their doctor about whether or not their child should get involved in a trial [56]. Consequently, researchers should prepare information and communication strategies. Researchers could for example, contact local doctors, teachers, case-workers, therapists etc as a matter of routine. They could provide parents with information sheets that can

be given to those people parents believe are important in helping them make decisions.

### 10.11.11 ASSENT AND CONSENT

This section of the chapter explores issues of consent by parents and adults and of assent by participating children. Not enough paediatric research is conducted as there are so many apparent barriers [49] involved—trying to avoid harm, fear of litigation by sponsors and investigators, and concerns about ethics on the part of potential investigators. While great care must be taken by investigators to protect children from unnecessary risk, children ultimately have the most to gain from well intentioned and well constructed paediatric trials. Requirements relating to consent and assent can be arduous and can vary from place to place [e.g., 6, 7, 15]. Investigators must be aware of regulations that apply in jurisdictions in which their research is being conducted, as consent has legal meanings and implications, particularly in relation to the “competence” of a person, including a child, to give consent.

One way of conducting responsible research is to ensure that those who act on the behalf of children are well informed [40, 58]. If adults who make decisions for children and act towards them are well informed about research and ethical issues, paediatric needs and the autonomy and potential apprehension of children about medical procedures, then agreeing to participate in paediatric trials is done properly. The Royal College of Paediatrics and Child health [26] provides guidelines on consent that cover strategies to ensure consent is freely given, informed and that explanation, information and where possible study findings are available. But even with these safeguards not all parents read consent documents and not all have these documents explained properly to them [59]. Parents and caregivers are vulnerable to coercion, influence and intimidation even when they are well intentioned if they are not properly informed [31]. Consequently, researchers need to take the time and consider how best to explain to parents and children what will happen and why, why it is important and why children in general will benefit [60, 61]. When parents have the study specific and context relevant information they can reflect on their child’s involvement with all relevant issues laid bare. They need to be able to understand their right to withdraw and the difference between trial interventions and usual therapy [59]. If an open approach is taken, “it is now widely accepted from an ethical perspective research can be carried out on children, when there is no expected benefit for them individually, provided there is minimum risk, strict safeguards and no objection from either the child or parents” [62, p. 202]. The Medical Research Council [7] provides a helpful flow chart of processes involved in seeking consent that may be a useful procedural guide.

Explicit informed consent to participate in a clinical trial is a standard ethical requirement. In the case of paediatric trials, parental consent or consent from a person with parental responsibility on behalf of the child is necessary [63]. As noted in the last paragraph, for parental consent to be valid it must be freely given and informed. The parent can permit, approve, or agree to anything that is clearly not against the interests of the child [63]. Parental consent to something that might harm the child is not valid. The Belmont Report, cornerstone of all international ethics guidelines [64], requires protection of children regardless of parental permission.

“Minimal risk” is acceptable for parent consent and is generally accepted to be equivalent to risk encountered in the normal course of a child’s everyday life. Parents have the responsibility and authority to choose activities that define their child’s risks and benefits [65]. thus, parents can consent on their child’s behalf when the risks are equivalent to the normal risks of childhood [65]. They can also consent when the risks are comparable to other available options—referred to as “clinical equipoise” [66]. Demonstrating clinical equipoise is particularly difficult in paediatric studies—Afshar et al. [39] recommend that “genuine uncertainty about the superiority of 1 treatment over another is essential to motivate clinicians and patients to participate” (p. 838). Parents cannot and should not consent to risks that are not comparable to other available options or that go beyond minimal risk.

The process of obtaining informed parental consent is complex. Consent to treatment is usually in the child’s best interest but consent to research may not be [37]. Research benefits may be for the paediatric population at large and may not necessarily be for the individual. Or there may be little benefit at all. Why, then, do parents consent to research? The decision to participate in a trial is known to be influenced by parental, child, trial and investigator factors [67, 68, 69]. The two main reasons parents say they consent to trial participation are—contributing to clinical research and to benefit their child [70]. Caldwell, Butow and Craig [67] found parents may perceive benefits to include the offer of hope, better care, access to new treatments, access to help and information, parent-to-parent support, and the altruistic motivation of helping others.

Even though parents may support the general notion of paediatric research trials they may not want their own child involved [39]—parents fear causing harm or hurt. Parents may object to the notion of their child being used as a “guinea pig”, especially where the trial methodology involves random assignment and placebo controls [67]. Preparation of participant information sheets can help counter fears and facilitate successful recruitment. Investigator factors such as doctor recommendations, doctor invitations and communication of trial information also affect decision-making from the parent’s perspective [67]. Parents also seek out the views of their own doctors to help inform trial participation decisions [56, 68]. Parent knowledge, beliefs and emotional responses coupled with an understanding of their child’s preferences will affect decision-making [67, 68]. Other parent factors that can influence consent rates are the parent’s socio-economic background with people from lower strata agreeing more often [71, 72], parent understanding of right to withdraw, trial versus usual therapy, and the voluntary nature of participation [59]. The context of study invitations and recruitment conditions also affect consent rates and the validity of consent given. Parents in emergency or acute medical situations may not be in a state any reasonable person would consider was acceptable for making consent decisions on matters relating to harm and short or long term potential effects. Time for reflection may affect agreement rates—the longer parents are given to reflect on risks, the less likely consent will eventuate [37]. Parents of chronically ill children or children with disabilities may also be “research savvy” and able to weigh up issues in the light of previous research experience, while others may not be able to differentiate research activity from usual treatment even when this is pointed out. There is a debate in medical practice emerging about how consent for interventions should best be given [73] and this will have implications for research consent procedures.

In paediatric research, consent of parents is not enough. Even if it is given in an informed and fair manner, the interests of the child remain paramount [1]. Since children may have only a limited understanding of what the research involves, it is hard to think of their participation as anything other than “involuntary” [61]. So how do investigators observe the same ethical principles of respect, justice and beneficence as they do in adult research? Assent provides the answer. Where positive agreement can be obtained from children capable of giving it, studies should be discussed with them in age appropriate ways such as stories or photographs, and assent sought [31]. Determining whether or not a child can decline or assent in an informed manner involves a judgement about their capacity to reason [74]. Researchers must be cognisant of the child’s developmental level both when explaining research procedures and the likely outcomes, and when judging the child’s capacity to give consent [19, 20, 25]. It is understood that “children become capable of assent when they are capable of understanding the research in question and making a prospective decision whether to participate” [77, p. 233]. If a child refuses to participate and gives a reason for this that makes sense given their age, then this may be enough to indicate “competence” and hence their ability to decline in an informed manner. Welthorn and Campbell [75] suggest the age of nine years might be a useful guide and this is the intellectual age recommended by the American Academy of Pediatrics [76]; Wendler recommends the age of 14 years as suitable because at this age they can usually understand research questions [77]; and Koren et al. [78] suggest more general indicators of “maturity”—such as when they are old enough to be a “baby-sitter”—are adequate. Regardless of competence to assent, children must be given the opportunity to object. Sustained dissent should be respected in all cases even if the child is too young or unable to give assent [79].

The process for acquiring assent involves the researcher thinking about the issue from the child’s point of view. Assent statements should be written in language that is at the comprehension level of a 6-year old child, in large font using the active form [39]. It is similar to the process of converting medical jargon into plain English for adult participants on information sheets. Study participation benefits and risks are different when viewed from the child’s perspective. A child wants to know [80]: Will it be fun? Will it hurt? What will happen to me? Do I have to? Will there be parental consequences if I say no? Will assent lead to other desirable incentives, such as time off school, undivided attention of a parent, new toys and treats as rewards for good behaviour, or perhaps even the possibility of making a worried parent happy?

Children should be asked to assent only to research procedures that they are capable of understanding [79]. A child cannot become fully informed via a standard written participant information sheet and so will rely on environmental cues to confirm their impressions as part of the assent process—Is my parent looking comfortable or anxious around the investigator? Does the setting give any clues that it will be painful despite what I am being told? Does the investigator seem trustworthy to interact with? Do they provide toys and play with me? Stop when I say no? Make me fail repeatedly? An investigator who attends to the child’s emotional and environmental context in addition to providing factual information is more likely to gain the child’s agreement. The investigator should keep a written record of the assent procedure which demonstrates that they “provided the child with all the necessary information in an age-appropriate fashion, that the child understood the informa-

tion, and that the child voluntarily agreed to participate in the research project” [80, p. S32]. The investigator records are probably more important than obtaining a child’s signature, because it is not until children are older that they understand the symbolic meaning of a signature [80].

The process of gaining assent from children and parents together gives rise to many grey areas for ethics. Children and parents do not always agree. Balancing the wishes of a child who refuses to assent to research procedures against the parent’s decision and right to enrol their child in a potentially beneficial trial is a complex ethical dilemma. Ethical issues regarding consent and confidentiality become even more complex when adolescents are participants, as they may not want their parents’ involvement, but in studies where harm is greater they may need adult assistance [32].

Other issues involved in consent relate to processes and delegations. Children may have parents or care-givers, but they may not be the people who hold legal responsibility for the child. Families may be separated and careful attention to agreement of relevant adults is needed. Agencies, government or other adults may hold the authority to consent. Once in a study, parents and the children always have a right to withdraw and this should be told at the beginning and throughout the study.

Adequate recruitment and retention of homogenous participants, to paediatric research trials, is extremely challenging. Many diseases common in adults are rare in children, so it is hard to recruit sufficient numbers for statistical significance. There are temptations to “water down” high standards and consent procedure requirements in the interests of study completion. Pressure on investigators to attain sample sizes, increases the risk of parents being inappropriately pressured to enrol children to participate in trials, because the available numbers are so small. Coercion at any level is unethical even though good numbers are needed for rigorous research. Investigators must carefully plan and design trials that are clinically feasible in terms of likely sample size. It is unprincipled to enrol child in studies that cannot ever be completed due to sampling frame limitations. Recruitment and referral strategies can influence consent rates: referral by health care professionals leads to high consent rates [55], sample size attainment is more likely if large numbers of potential candidates are approached [55]. Recruitment incentives also positively influence consent rates, but their use should be informed by appropriate ethical standards [3]. Payment and reimbursement of costs have been used to provide compensation for study participation and retention to study completion [39, 81].

### 10.11.12 SAFETY AND MONITORING

Safety in clinical trials is both a process and an outcome. Safety information is an aim of trial studies. At the same time, the duty of care for trial participants means that trial processes must plan for prompt action in response to suspected and identified adverse events. Trial plans and reports therefore need to clearly outline what strategies, decision-points and decision-makers will be involved in identifying, referring, confirming and responding to suspected adverse events.

Safety of trial participants needs to be considered before, during and after the trial. Before the trial, a careful exploration of the existing evidence base should be

made to assess potential adverse events and these should be monitored and measured. If the information base relates only to adults, then a careful watch on paediatric participants may be needed as developing systems and structures may respond differently to adults [29, 30]. Before the trial, processes to monitor protocol adherence, inspect participant files and receive reports from trial and other clinical staff about suspected adverse events need to be in place. Training should be provided to everyone involved in the trial so that they know how and when to make reports of suspected adverse events. A culture of openness and respect is needed so that mistakes or adverse events are reported promptly and the honesty and vigilance involved in making that report is valued by the team. After a trial, there may be a need to continue safety and monitoring processes through long-term follow up studies. This is particularly important for paediatric trials or trials where the condition is chronic and treatment long term, as participants are growing and adverse consequences of an intervention may not be apparent initially but may emerge later in life [30]. Sammons and co-investigators [82], identified through a literature review of therapeutic clinical trials, that only 2% of studies reported use of safety monitoring committees, and only 11% of studies reported adverse events including deaths. They came to the conclusion that every paediatric trial should have an independent safety monitoring committee to assess the likelihood of risk, monitor the progress of participants and quickly respond to observed differences [82]. Independent risk assessment and safety monitoring is helpful not only for study integrity, but also for protecting children, increasing parent confidence in the well-being of their children, and demonstrating due diligence by investigators. Safety monitoring should be done by personnel with paediatric expertise, access to expert advice regarding the subspecialty, ready access to trial material, and the authority to compel action if the safety of trial participants is in doubt.

### 10.11.13 CONCLUSION

This chapter provided an introduction to common issues that are unique or pronounced in paediatric clinical trials and an outline of those issues are critical to their initiation, conduct and success. The tone adopted in the chapter was that of the “guide on the side”. These trials, perhaps more than others, require sponsors, investigators, trial coordinators and project managers to adopt a personal moral standpoint towards participants and appreciate the social context of clinical research. This chapter provided common signposts that should be helpful in whatever unique trial journey investigators, sponsors and workers may lead, recognising that the technical and procedural issues covered in other Handbook chapters will apply, and the unique evidence of sub-specialities will need to be sought.

While morality, ethics and participant characteristics feature in every trial, in paediatrics they are critical to design integrity and the public success of a trial. A perfectly crafted paediatric trial can bring down an investigator’s lifetime reputation, a company’s global brand, or reduce the esteem of institutions if the study was not child-centred and astute to the multiplicity of factors associated with participant vulnerability and their capacity to reasonably and meaningfully participate in trial requirements. The complexity and demands of paediatric clinical trials can drive some investigators, sponsors and institutions to wonder whether or not they are

worth doing. There are many perceived and actual barriers [49]. Paediatric trials are not for the faint hearted. They demand the highest intellectual capacity and ethical stance for planning, implementing, monitoring and reporting. These trials require enormous good will and generosity from sponsors, investigators, trial employees, parents/carers, and the children themselves. They are inevitably time intensive in ways that are hard to anticipate, they can be very costly with small, hard to locate and recruit samples. The financial and reputation rewards may be few and the risks are great for all concerned. There is, however, an urgent need for the brightest and best in health care to commit to paediatric clinical trials and do more of them.

Routine and widespread use of interventions with little or often no paediatric research evidence continues apace with potentially catastrophic results. Investigators, sponsors and institutions can sometimes feel caught between a rock and a hard place, as they are castigated for off-label, unscientific practice whilst suffering sometimes justified but often unwarranted public torment regarding involvement of children in trials. The irony of public concern for paediatric trial participants is that there appears little or no concern for the millions who daily receive interventions without any scientific evidence to inform parent or professional decisions. Notwithstanding the demands, risks and rigours of paediatric trial research, there is an urgent and compelling moral and practical need to involve outstanding investigators, sponsors and institutions in rigorous, community supported and well understood paediatric trials so that we are able to benefit children.

## APPENDIX: FACTS SUMMARY

Paediatric clinical trials are urgently needed to support use of clinical interventions with infants, children and youth who regularly receive off-label, off-licence or scientifically unsupported treatment.

Paediatric clinical trials require investigators to understand the moral context of their research as participants are vulnerable.

Conventions, regulations and policies from esteemed professional societies provide guidance on principles and practices that deal with implications of the moral context.

Paediatric trial questions must be worthwhile, relevant, new, achievable, timely, pose minimal risk and must benefit children.

Paediatric investigation plans need to be rigorous, evidence based, equal to the capacity of the team and resources available and benchmarked to appropriate standards and regulation particularly in relation to consent.

Safety of participants and external monitoring of adverse events are critical study processes that underpin the quality of study findings

### 10.12.1 INTRODUCTION

Dementia is a health problem affecting millions of people worldwide. Its prevalence increases with age and it is almost always a disease of the elderly. The impact of this disorder lies not only in the loss of patient autonomy and caregiver burden that ensue as it progresses but also in its marked economic effects. With improving health care management in both affluent and developing countries, a rise in the aging population and subsequent rise in dementia cases are anticipated.

Alzheimer's disease (AD) is the leading cause of dementia. In the United States alone, AD was estimated to affect 4 million Americans in 1990 [1]. This number is expected to rise to 8.5 million by the year (2030) [2] and 14 million by the year (2050) [1]. The overall prevalence rate of AD is 2–3% at age 65 [3]. This is estimated to double every 5 years so that almost 50% of individuals 85 years and older may be affected by this disorder [3]. The United States is spending \$100 billion per year to care for individuals with AD [4, 5].

The large population affected by dementia and the unmet need for more efficacious treatment have led to randomized controlled trials. The largest numbers of trials have been done with cholinesterase inhibitors (ChE-Is), the first class of agents approved by the U.S. Food and Drug Administration (FDA) for the treatment of AD. Recently, trials led to the approval of memantine, an *N*-methyl-*D*-aspartate (NMDA) antagonist as a treatment for patients with moderate to severe AD. These trials of approved agents are very influential in determining how future trials of antidementia agents will be conducted for AD, vascular dementia (VaD), and other entities such as mild cognitive impairment (MCI). Lessons learned from these trials will guide trial conduct not only for symptomatic agents with AD but also for compounds that may have disease-modifying effects. This chapter reviews published trials to derive guidelines on how future trials may be conducted. We concentrate on trials of AD and MCI only.

### 10.12.2 DEFINING AD, MCI, AND VaD

Precision in clinical diagnosis is essential to ensure valid outcomes in clinical trials. Randomized controlled trials in AD and MCI have utilized various diagnostic criteria to guarantee subject homogeneity.

Mild cognitive impairment had been a diagnostic dilemma from the time that the term was coined. Most regard it as a transition state between normal aging and early AD. More recently, new concepts of MCI emerged, making assessment and management more complex. Some regard MCI as incipient AD [6] (see Table 1).

Currently, MCI can be classified on the basis of the affected cognitive domain/s [7]—single memory domain, single non-memory domain, and multiple cognitive domain with or without involvement of memory. The amnesic type or the single memory domain deficit is the one that is closely correlated with AD. The rest of the MCI types may lead to either AD or other dementia syndromes, broadening the possibility of patient outcome. At the moment, therapeutic trials have limited recruitment to the amnesic type of MCI [8, 9] since this is the most certain prelude to AD. A majority of studies have adopted delay to progression to AD using a survival type of outcome as the research design approach.

**TABLE 1 Criteria for Amnesic Mild Cognitive Impairment**

- 
1. Memory complaint, preferably corroborated by informant
  2. Impaired memory function for age and education
  3. Preserved general cognitive function
  4. Intact activities of daily living
  5. Not demented
- 

**TABLE 2 DSM-IV Criteria for Diagnosis of Alzheimer's Disease**

- 
- A. Alzheimer's disease is characterized by progressive decline and ultimately loss of multiple cognitive functions, including both:
    1. Memory impairment—impaired ability to learn new information or to recall previously learned information.
    2. At least one of the following:
      - a. Loss of word comprehension ability (aphasia)
      - b. Loss of ability to perform complex tasks involving muscle coordination (apraxia)
      - c. Loss of ability to recognize and use familiar objects (agnosia)
      - d. Loss of ability to plan, organize, and execute normal activities
  - B. The problems in A represent a substantial decline from previous abilities and cause significant problems in everyday functioning.
  - C. The problems in A begin slowly and gradually become more severe.
  - D. The problems in A are not due to:
    - Other conditions that cause progressive cognitive decline, among them stroke, Parkinson's disease, Huntington's chorea, brain tumor, etc.
    - Other conditions that cause dementia, among them hypothyroidism, HIV infection, syphilis, and deficiencies in niacin, vitamin B<sub>12</sub>, and folic acid
  - E. The problems in A are not caused by episodes of delirium.
  - F. The problems in A are not caused by another mental illness: depression, schizophrenia, etc.
- 

Source: From [10].

Alzheimer's disease is a progressive degenerative disorder which leads to cognitive decline that is severe enough to cause functional deterioration. Several criteria are available to clearly define this entity: *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) [10] (Table 2); *International Classification of Diseases*, tenth revision (ICD-10) [11]; and the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) [12] criteria (Table 3). The level of diagnostic certainty is indicated in the NINCDS-ADRDA criteria. Neuroimaging has been included for the purpose of excluding other dementias in the differential diagnoses. Its postconsensus sensitivity and specificity of the diagnosis of AD range from 0.83 to 0.95 and 0.79 to 0.84 [13–15] while clinicopathological sensitivity and specificity are 0.64–0.86 to 0.89–0.91 [14, 16]. Interrater reliability is moderate [14]. The NINCDS-ADRDA criteria for AD has been regularly used in trials due to its established validity.

### 10.12.3 SEVERITY OF DEMENTIA

It is essential for dementia severity to be specified in clinical trials to ensure patient homogeneity and gauge treatment response. The spectrum of dementia depends on

**TABLE 3 NINCDS/ADRDA Criteria for Diagnosis of Probable Alzheimer's Disease**

its longitudinal course, which is defined by three domains: cognition, behavior, and function. Generally, dementia severity can be divided into three stages. In the early and mild stage the initial manifestations of minor memory impairment emerge with concomitant decline in complex activities. In the moderate stage, behavioral changes become more prominent, with involvement of cognitive domains other than memory, typically language and visuospatial skills. Behavioral changes become more apparent at this point and patients have more difficulty in coping with daily activities such as housework and hobbies. In the severe stage, patients are unable to live without assistance and they manifest with more disturbing behavioral symptoms. Institutionalization is common in this stage of the illness.

The Global Deterioration Scale (GDS) [17], Clinical Dementia Rating (CDR) [18], and Mini-Mental State Examination (MMSE) [19] are instruments that are frequently used for assessing dementia severity. Both the GDS and CDR are global assessment instruments which examine cognition, function, and behavior. The MMSE, however, is limited to the measurement of cognition in terms of orientation, attention, memory, language, and figure copying. It has been regularly used as an instrument for the staging of dementia since it examines the “core” manifestations of the disorder which are the main target of therapeutic trials.

The MMSE was formulated by Folstein as a practical method of grading the cognitive state [19] of psychiatric inpatients. Advantages of this instrument are its

<sup>b</sup>In this trial sMMSE was used instead of MMSE.

brevity and ease of administration. It has an adequate sensitivity of 86% and a specificity of 92% when a cutoff score of 23–24/30 is used [20]. Its ceiling and floor effect, though, lessens its sensitivity in detecting mild and severe cognitive impairment, respectively. MMSE scores are influenced by age and education. The presence of within-subject and between-subject variability challenges the applicability of MMSE scores; they have wide standard errors of measurement. The natural variability of the disease also contributes to score fluctuations. Despite these caveats, the use of MMSE is widespread in the staging of dementia and is commonly used to define a restricted range of dementia severity for patients included in clinical trials (Table 4).

#### 10.12.4 ETHICAL CONDUCT OF DEMENTIA TRIALS AND INFORMED CONSENT

Research trials involve experimentation and, to protect human subjects, various guidelines have been implemented. As in all research studies involving human subjects, the principles of minimization of harm, beneficence, and veracity are maintained in dementia trials. Conduct of dementia trials is complicated by inclusion of subjects with varying severity of cognitive impairment, a condition that makes them vulnerable to exploitation.

A multitude of “ethically approved” randomized controlled trials in dementia therapy have been conducted in the past years. From these studies, acetylcholinesterase inhibitors have been approved as a class of drugs that is effective and safe in AD patients. In 2001, the American Academy of Neurology issued guidelines in the management of AD and it described acetylcholinesterase inhibitors as the standard drug for this disorder [42]. Thus, assignment of subjects to placebo in future clinical

trials will be unethical since a standard drug is already available. Administration of this standard drug to all the groups in a dementia clinical trial becomes necessary.

Determination of the capacity to consent is the most discussed aspect of dementia trials. Differing levels of disease severity produce differing levels of incapacity and challenge the ability of the patient to participate in consent discussions. The presentation of the purpose, methodology and procedures, risks, benefits, and alternatives must be very clear and simple for cognitively impaired subjects to comprehend. The extent of the subject's grasp of the details of the study and decision-making capacity should be evaluated. This involves examination of (1) understanding of the relevant facts of the trial disclosed to the patient, (2) appreciation of the research risks and potential benefits, and (3) reasoning in terms of comparing options and drawing consequences from these options [43].

If a subject is deemed incompetent to give informed consent, proxy consent is obtained from an individual who has the capacity and legal authority to give it. Typically, the caregiver is given this task since he or she is the one who addresses the daily needs of the subject and knows the latter's preferences. Competence and benevolence of the caregiver must be ensured in these circumstances.

In the mild to moderate stages of the disease process, the subject will still be able to contribute to research trial decisions. The investigator must ensure that the subject is still part of the choices made by the proxy. Later, the subject loses the ability to participate meaningfully and the caregiver becomes the sole decision maker. It is at this point that assent (or dissent) should be obtained from the subject. This is judged behaviorally based on the cooperativeness of the subject with the study procedures [43]. Consistent resistance of the subject with study procedures may be taken as dissent, a probable basis for discontinuation from the study.

### 10.12.5 GENERALIZABILITY OF CLINICAL TRIAL RESULTS

A drug's value is ultimately tested once it is marketed in the targeted population. The terms "efficacy" and "effectiveness" distinguish between how well the intervention/drug *can* work under ideal circumstances such as that in clinical trials and how the intervention/drug *does* work under "field conditions" such as that in the community [44]. The drug's applicability depends on the inherent characteristics (demographic and medical) of the cohort of subjects enrolled in the clinical trial and how representative they are of the population who will eventually use it. Subject selection by using inclusion and exclusion criteria potentially limit the generalizability of the results of the clinical trial. The National Institute of Mental Health Clinical Antipsychotic Trials of Intervention Effectiveness (NIMH-CATIE) is an example of an effectiveness study proposal of psychotropic use in AD with a methodological design that assures applicability of the results in the community setting [45].

In randomized controlled trials of acetylcholinesterase inhibitors, recruitment bias was observed toward subjects who are healthier, better educated, younger, and of higher socioeconomic status [46, 47]. This has the effect of excluding subjects who have complicated medical histories and are taking specific medications. Caregivers may be more aggressive in seeking medical help when their relatives are in the early stage of dementia, exposing the patients to a higher probability of being recruited.

Another confounding factor on the generalizability of trials is the drug's eventual applicability in different ethnic populations. Randomized controlled trials require major funding and, for this reason, these are conducted in affluent countries. This fundamentally explains why Caucasians compose the greater part of the subjects in trials globally. However, there is a mixture of ethnic populations in the United States and Caucasians should not dominate disproportionately. Examination of the population recruited in acetylcholinesterase inhibitor trials which were conducted in the United States show that the samples were 91–99% white [46]. Problem may arise due to differences in the pharmacokinetics of the drug in various ethnic populations resulting in varied first-pass metabolism and systemic bioavailability. Activity of the cytochrome P450 enzymes differ among various ethnic groups, possibly leading to disparate side-effect profiles, dosaging, and efficacy.

Highly specialized centers conduct clinical trials. Involved physicians have expertise in handling dementia cases and are highly motivated to recruit patients. Complete laboratory and neuroimaging work-up are also on hand. Subjects in these centers are diagnosed with precision and handled differently as compared to those in the community setting. There is stronger and more accessible patient support system in trial centers. This may have great impact in the care of dementia patients since it would result in better compliance and fewer problem behaviors. This setting again distinguishes clinical trials from routine care.

### 10.12.6 OUTCOME ASSESSMENTS IN DEMENTIA TRIALS

Alzheimer's disease affects primarily the memory with subsequent involvement of other cognitive domains. This change causes concomitant deterioration in function and behavior. The efficacy of antidementia drugs therefore should be evaluated based on these domains: cognition, behavior, and function.

The efficacy of an antidementia drug is measured through various outcome assessment scales and psychometric tests. As required by the FDA, the cognitive improvement that results from drug administration should be supported by (1) positive change in a performance-based cognitive instrument and (2) clinically meaningful effect seen globally [48]. These two factors comprise the primary outcome measures in dementia clinical trials. Secondary outcome measures are included to further document the effect of a drug on the other aspects of the subject's life. These secondary outcome measures do not need to be positive for the drug to be approved and marketed. Assessment scales examining the subject's quality of life, noncognitive behavioral symptoms, and economic impact of the illness usually compose the secondary outcomes.

Outcome measures must possess certain properties before these can be employed in clinical trials. The instruments must have been proven valid, reliable, and sensitive. Validity confirms whether the tool measures what it is intended to measure. Reliability (test/retest, interrater and/or intrarater) refers to the replicability of results so that the same value will be obtained under multiple circumstances. Sensitivity is the capacity to detect change over time, especially with treatment. It is best if the instruments are effective in detecting changes even in the extremes of the spectrum of the illness, eliminating floor and ceiling effects. Other important properties are ease of use and short administration time and availability of multiple equivalent forms to avoid practice effects with repeated use. Ideally, these should

be independent of demographic and socioeconomic factors such as gender, education, and cultural background.

### 10.12.6.1 Primary Outcome Measures

**Performance-Based Cognitive Assessment** Cognition is composed of multiple domains, all of which are inevitably affected at the late stage of dementia. Consensus on cognitive domains that may be assessed include the following: memory, attention, processing speed, visuospatial function, praxis, language, executive function, and abstraction [49]. A combination of different psychometric tests can fully evaluate these domains. However, it is more appropriate for disease-specific instruments to be used in a chronically progressive illness so that it can appropriately reflect the outcome at study endpoint.

The Alzheimer's Disease Assessment Scale (ADAS) was designed to evaluate the severity of both cognitive and noncognitive manifestations of AD patients [50]. Cognitive domains include memory, orientation, language, and praxis while the noncognitive domains include mood state and behavioral changes. The cognitive portion has a maximum score of 70 with a higher score indicating more severe impairment. Its advantages include short administration time, ability to detect changes from the mild to severe stages, and being appropriate for patients in different environments [50]. There is excellent interrater and test/retest reliability of the ADAS-cog at 0.99 and 0.92, respectively. It is the most widely used objective cognitive assessment scale in dementia randomized controlled trials (RCTs). The ADAS-cog is the prevailing primary outcome measure of efficacy that evaluates changes in the core manifestations of dementia. The ADAS-cog lacks tests examining executive function, a domain that is affected frequently. The Alzheimer's Disease Cooperative Study (ADCS) has extended the ADAS-cog by adding two executive tests, a cancellation and a maze task.

**Global Measures** The overall clinical impact of an antidementia drug is evaluated using global assessment scales. These assess the multidimensional manifestations of the illness in terms of cognition, behavior, and function. There are two categories of global measures: (1) global severity scales, which ascertain the absolute severity of the patient's condition, and (2) global change scales, which determine the overall improvement or deterioration of the subject. Global scales have less structure, thus partially avoiding the influence of subject characteristics and rating variance. The available global scales were specifically designed for use in AD or primary degenerative dementia so that results are specific to the illness. These are sensitive measures for long-term assessment of efficacy since changes can be quantified when other assessments are affected by floor effects.

Global assessment scales of change were developed to measure a "clinically meaningful" treatment effect that translates into practical usefulness. All of the measures are seven-point scales which are rated as follows: 1 = very much improved, 2 = much improved, 3 = minimally improved, 4 = no change, 5 = minimally worse, 6 = much worse, 7 = very much worse. These assess change from a specified baseline. Unlike the symptom scales, these are relatively unstructured, relying on an experienced clinician to conduct a thorough and accurate interview on which the

**TABLE 5 Global Outcome Measures (Severity and Change Scales) Utilized in AD and MCI Trials as Either Primary or Secondary Measure of Efficacy**

| Global Outcome Measures          | RCT That Used Outcome as Primary Measure of Efficacy | RCT That Used Outcome as Secondary Measure of Efficacy |
|----------------------------------|------------------------------------------------------|--------------------------------------------------------|
| Severity                         |                                                      |                                                        |
| CDR (global and/or sum of boxes) | [39]                                                 | [8, 26, 27, 35–37, 54, 58]                             |
| GDS                              | [34]                                                 | [8, 22, 25, 28, 32, 41]                                |
| Change                           |                                                      |                                                        |
| CGI [51]                         | [23, 24, 34, 55]                                     | [39]                                                   |
| CIBI [52]                        | [25]                                                 |                                                        |
| CIBIC Plus [52]                  | [21, 22, 26, 27, 29–33, 38, 40, 41]                  |                                                        |
| ADCS-CGIC [53]                   | [36], MCI version [9]                                |                                                        |

*Note:* CIBIC-plus: Clinical Interview Based Impression of Change plus caregiver information; CGIC: Clinical Global Impression of Change.

rating will be based. Even though reliability is compromised with this format, the sensitivity to measure meaningful change is retained so that it remains as one of the primary efficacy measures.

The first global assessment scale was the Clinician Global Impression (CGI), an unstructured instrument that was widely used in neuropsychopharmacological trials [52]. The CGI was first utilized in a dementia RCT involving tacrine by Davis et al. with ADAS-cog as the other primary measure of efficacy [23]. However, significant improvement was only noted in the ADAS-cog but not in the CGI, which indicated the latter's lack of sensitivity to the treatment effect of tacrine. A guideline-based global assessment scale, the Clinical Interview Based Impression (CIBI), was then developed which was used in the 30-week tacrine trial by Knapp et al. [25]. Both ADAS-cog and CIBI yielded significantly positive results which led to the FDA approval of tacrine. Several global assessment scales emerged to further improve the instrument's reliability (Table 5). To date, CIBIC plus is the most frequently used global assessment instrument in dementia RCTs.

Global severity or staging scales such as the CDR scale [18] and the GDS [17] are frequently used as entry criteria or as secondary outcome measures. The CDR is a worksheet-based semistructured interview that evaluates six domains: three cognitive (memory, orientation, judgment, and problem solving) and three functional (community affairs, home and hobbies, and personal care). Rating is based on a five-point scale in which 0 = none, 0.5 = questionable dementia, 1 = mild impairment, 2 = moderate impairment, and 3 = severe impairment. It can be scored in two ways: (1) as a sum of boxes (SB) by obtaining the sum of the ratings of each of the six CDR domains/boxes and (2) as a global rating based on a scoring system wherein the memory box/domain is the main consideration. Preference for this instrument is due to its clinically based assessment and high interrater reliability resulting in a level of agreement of 80% [56]. The GDS is also a useful instrument in staging primary degenerative dementia. It is capable of accurately delineating stages of dementia throughout the course of AD [17]. It rates cognitive decline based on a seven-point scale with the following scoring system: 1 = none, 2 = very mild, 3 = mild, 4 = moderate, 5 = moderately severe, 6 = severe, 7 = very severe. Interrater and test/retest reliability are high, both at 0.92 [57].

### 10.12.6.2 Secondary Outcome Measures

**Mini-Mental State Examination** The MMSE may be included as an entry criterion or as a supplementary measure of cognition [8, 21, 23, 25–28, 32, 34, 36, 38, 39, 41, 54, 55, 58]. Compared to the ADAS-cog, its result is better understood by non-AD specialists and can be easily translated into more practical terms. However, its limited sensitivity makes it a poor primary outcome measure.

**Activities of Daily Living** Functional impairment is an essential component of the clinical syndrome of dementia. It is required for the clinical diagnosis of dementia and included in the NINCDS-ADRDA criteria [12] and the DSM-IV criteria [10]. The resulting dependence affects not only the patient but also the quality of life of the caregiver and becomes an important factor that leads to institutionalization. Changes in activities of daily living (ADLs) are frequently included as a secondary outcome measure. Functional deterioration is only moderately correlated with the cognitive status of patients with AD [59] and seems to be an expression of other integrative abilities of the individual. This makes functional assessment all the more important in clinical trials since cognitive tests cannot fully gauge improvement in other aspects of the patient's life.

Drug effect in terms of reversibility, stabilization, or slower deterioration of ADLs can be monitored through the use of functional assessment scales [60]. Different instruments for this purpose have been developed for AD (Table 6), incorporating either basic or instrumental/complex ADLs or both. It is necessary for complex ADLs to be incorporated in the examination since functional deterioration occurs in hierarchical order, initially affecting difficult tasks before simpler ones. Ideally, caregiver information should be obtained for data reliability since loss of insight as the disease progresses makes self-report impossible.

These functional assessment scales were used as either primary or secondary outcome measures of efficacy in different dementia RCTs (Table 7)

**Neuropsychiatric Symptoms** Neuropsychiatric manifestations are common in AD. They reflect the underlying neuropathological and neurotransmitter changes in the brain. Incidence increases with disease severity but symptoms are variable and differ among afflicted individuals. Assessment of these behavioral manifestations is essential since it can influence the individual's state, further aggravating the existing cognitive and functional impairment. Presence of disruptive behavior increases caregiver burden and is one of the determinants of eventual nursing home placement. These symptoms can also predate the onset of dementia and may present in MCI.

Several instruments that measure behavioral symptoms are available and employed in dementia clinical trials. These are used as primary outcome measures when the target symptom is behavior (e.g., with psychotropic agents) and as secondary outcome measures when the target symptom is cognition (e.g., with cholinergic agents) and behavior is evaluated as an auxiliary effect. Characteristically, these can be categorized into broad-spectrum scales when they sample a comprehensive range of symptoms and focused scales when more items are dedicated into the subtleties of a particular behavioral domain [64]. Some characterize the symptoms by their frequency and severity, which is very helpful in gauging the disruptiveness of the behavior and becomes an indirect measure of caregiver burden. Frequently used

**TABLE 7 Functional Assessment Scales Utilized in Different Dementia RCTs as Primary or Secondary Outcome Measures of Efficacy**

| Functional Assessment Scale | RCT That Used Scale as Primary Outcome Measure | RCT That Used Scale as Secondary Outcome Measure |
|-----------------------------|------------------------------------------------|--------------------------------------------------|
| PSMS and IADL               |                                                | [21, 23, 25, 34, 39, 40]                         |
| PDS                         | [32, 33]                                       | [23, 25, 28]                                     |
| DAD                         |                                                | [22, 30, 31, 40]                                 |
| ADCS-ADL                    | Adapted to severe state [41]                   | MCI version [8]; [29, 37, 38]                    |
| ADFACS                      | [54]                                           |                                                  |

assessment scales in dementia clinical trials are the following: Neuropsychiatric Inventory (NPI) [65], Behavioral Pathology in Alzheimer's Disease Rating Scale (BEHAVE-AD) [66], CERAD Behavior Rating Scale for Dementia (CBRSD) [67], Cohen Mansfield Agitation Inventory (CMAI) [68], Cornell Scale for Depression in Dementia (CSDD) [69], Brief Psychiatric Rating Scale [70, 71], and Positive and Negative Syndrome Scale (PANSS) [72].

The NPI, BEHAVE-AD, and CBRSD are examples of broad-spectrum scales developed primarily for the evaluation of dementia patients (Table 8). These are valid and reliable instruments that can be used in clinical and research settings. The NPI is widely used in dementia clinical trials due to its comprehensive list of symptoms that commonly occur in individuals with dementia. It also has accompanying questions for every symptom so that appropriate probing can be done and includes a frequency and severity component for every symptom category. Major dementia RCTs [22, 28–30, 37, 40, 41] have used the NPI as a standard gauge of behavior outcome. CBRSD was used in the trial by Sano et al. [58] as a secondary outcome measure. The BEHAVE-AD was more frequently employed in trials involving psychotropic agents [74–76].

The CMAI and CSDD are focused scales. These are useful when particular symptoms are targeted by the clinical trial. For example, the CMAI was used as a primary outcome measure to demonstrate the efficacy of risperidone in agitation and aggression in subjects with AD [76]. The CSDD was likewise the primary outcome measure in the sertraline RCT [77] that determined the drug's effect on depression in subjects with AD.

The BPRS and PANSS are broad-spectrum scales that were developed for use in psychiatry populations. These have been employed in several dementia trials involving psychotropic agents since it covers a variety of symptoms aside from psychosis. The BPRS was the primary measure of efficacy for the control of agitation and aggression in dementia in carbamazepine [78] and divalproex sodium RCTs [79]. The PANSS has five symptomatic dimensions (negative, positive, excitation, cognitive, and depression) and the quetiapine trial [80] used the excitation component (PANSS-EC) to evaluate the drug's efficacy in agitation that occurs in dementia.

**Other Measures of Efficacy** Aside from treatment efficacy, pharmacoeconomics, caregiver burden, and quality of life in dementia have been addressed in dementia RCTs. Although these are not required as outcome measures for drug approval,

their usefulness is based on a more practical aspect of efficacy, one that can be seen and experienced in daily life. Caregiver burden scales determine the impact of dementia on the people who are considered direct health care providers. They experience stress and burden. One way of determining burden is by recording how much time is spent attending to the patient. This can be assessed using the Caregiver Activities Time Survey, the Caregiver Activity Survey [81], or the Caregiver Time Questionnaire [82].

The economic impact of dementia is overwhelming since the burden extends to the national level. It is directly related to the number of people affected by the disorder and the duration of the disease [83]. Incurred costs include (1) medical resources used to treat the illness (medication, cost of institutionalization, etc.), (2) nonmedical resources, and (3) lost productivity caused by disability (both patient and caregiver) [83]. Since maintenance of patients with dementia eventually translates into cost of care, some RCTs include pharmacoeconomic measures. The AD2000 trial [84] determined the health care cost of dementia from the societal perspective in terms of delaying institutionalization or requiring other health services and the cost-effectiveness of the drug (donepezil). Reisberg et al. [41] similarly evaluated this effect by utilizing the Resource Utilization in Dementia (RUD) [85], which assesses the burden on the caregiver and provides AD-related health economics data, in a memantine trial.

Quality-of-life scales encompass the overall effect of the treatment on the patient in terms of social, psychological, cognitive, and functional well-being. Either the patient or the caregiver's quality of life can be assessed. However, information will be derived mainly from the caregiver once the patient's communication problems emerge.

Transcultural application of these instruments may alter their validity and reliability. Interpretation of results should therefore be done with caution when these are used outside the cultures in which they were developed.

### 10.12.7 CLINICAL TRIAL DESIGNS

The FDA requires that agents tested should be superior to placebo in terms of its cognitive and global effects. The standard format of antidementia drug RCTs is the parallel group design wherein there is direct comparison between the experimental and placebo group. In this head-to-head comparison, the active drug and placebo are allocated to different subjects randomly. The 12-week tacrine study by Farlow et al. [24] utilized this design, although randomization of subjects was stratified. Alzheimer's disease drug trials (acetylcholinesterase inhibitors, NMDA antagonists, psychotropics, SSRIs, etc.) follow this standard format due to its straightforward approach. This design was also used in the MCI trial of Salloway et al. [9] comparing donepezil with placebo. Between-patient variability can deleteriously affect the outcome of parallel group studies and cannot be eliminated with this format. The crossover design eradicates this confounding variable by applying the treatment sequentially to the same subject. Aside from reducing error variance, sample size is diminished since subjects can be used several times in the analysis while increasing the statistical power of the clinical trial. However, this strategy is rarely used primarily due to difficulty in reobtaining baseline values during the

TABLE 8 Comparison of Characteristics of NPI, BEHAVE-AD, and CERAD, CBRSD

| Instrument Characteristics | BEHAVE-AD                                                                                                                              | CBRSD                                                                                                                                                                 | NPI                                                                                                                                                                                                                                                                                               |

**FIGURE 2** Randomized start design. (Adapted from [86])

treatment shift. There is also uncertainty if the changes noted with the second treatment are due to the remaining or carry-over effect of the first one. The required washout periods of the drugs are unknown and may be lengthy, causing prolongation of the clinical trial.

The current trend in antidementia drug development is toward disease modification. The above-cited study designs are adequate for measuring symptomatic change (has no effect in the survival and function of degenerating neurons) and are less applicable to assessing disease modification. A variety of trial designs have been suggested to assist in establishing disease-modifying effects. Paul Leber [86] suggested the randomized withdrawal and randomized start designs to determine the disease-modifying effect of the antidementia drug (Figures 1 and 2). The randomized withdrawal design (Figure 1) is based on the hypothesis that withdrawal of a disease-modifying drug will not produce loss of the incremental changes noted compared to the withdrawal of a symptomatic drug. The major drawback of this design is the uncertainty as to how long the subjects need to be observed to determine the outcome. Consequently, it will require a considerable number of subjects since attrition is expected to be high secondary to the length of the trial and with-

drawal of a treatment that may be beneficial to the subject. Blinding is also compromised since everyone becomes aware that all patients are taking placebo at the end of the trial. These potential limitations led to the formulation of the staggered start design (Figure 2) which has two phases: The first is similar to a placebo-controlled, randomized, parallel study while the second entails all subjects to be given the active treatment. A significant drug placebo difference should be existent after the first phase before the second phase can be started. If the active drug has a disease-modifying effect, the placebo group's performance cannot catch up with that of the treatment group in the second phase of the study.

Sano et al. [87], utilized a time-oriented, valid outcome measure to assess disease progression that includes the main domains affected in AD—cognition and function. The survival design examines the longitudinal course of dementia to measure the antidementia drug effect on disease progression. Endpoints are not primarily based on neuropsychological tests, unlike in other trial designs. Instead, readily observable, clinically meaningful endpoints that represent disease progression are utilized. The primary efficacy outcome measure is the time to reach specified endpoints. Similarly, Mohs et al. [54] used a survival design to evaluate the length of time the function is preserved in AD patients with the use of donepezil.

Amnesic MCI lends itself to use of survival designs since longitudinal examination of patients can reveal either progression or nonprogression to AD. Most MCI clinical trials used this study design with progression to AD as the endpoint [8, 88]. A limitation of this scheme is the difficulty in precisely defining progression to AD.

An enrichment design was utilized in the tacrine study of Davis et al. [23]. The first or enrichment phase consisted of finding the “best dose” response of each patient to tacrine as defined by the ADAS without producing intolerable side effects. Subjects who continued in the subsequent parallel group randomized controlled trial were the “enriched population” or those who had a potential to respond to the treatment as seen in the first phase of the study. RCTs which include subjects who have a higher risk of acquiring AD such as those with positive family history, presence of ApoE4 alleles, presence of cerebrospinal fluid (CSF) AD biomarkers, hippocampal atrophy on magnetic resonance imaging/computerized tomography (MRI/CT) scan, or bilateral temporoparietal hypometabolism on positron emission tomography (PET) scan are recruiting an “enriched population.” A drawback of this study design is the potential to skew the outcome favorably toward the active drug and in the end limit the generalizability of the findings. Enrichment design for an antidementia drug is useful in proof-of-concept studies or as a means of entering the market by showing evidence of its efficacy. However, it should be followed by a trial that employs less restrictive designs so as not to limit the generalizability of findings.

#### 10.12.7.1 Special Clinical Trial Design Features

Long-term drug trials may incorporate special design features to improve accuracy of findings and to confirm additional hypotheses. Single-blind run-ins added before initiation of the double-blind phase involve administration of placebo to both treatment groups for a specified period of time without the knowledge of subjects and caregivers. Its primary aim is to minimize the “placebo effect” to which the initial changes from baseline may be contributed. By doing this, both groups equally start

at the same level. The galantamine efficacy and safety trials utilized this feature [29–31].

Single-blind washout periods are sometimes done at the end of the double-blind treatment. This entails administration of placebo to both treatment groups in an effort to determine the withdrawal effect of the study drug. In the donepezil trials [26, 27], the washout periods showed the return of the performance of the donepezil group to baseline values—an indication that the observed improvement after drug administration was a symptomatic and not a disease-modifying effect. This is also useful for the assessment of untoward reactions secondary to drug removal and to gain information on how long the clinical response is sustained after drug discontinuation.

Open-label extensions conducted after the double-blind study is a method of determining safety of prolonged treatment. Limited efficacy data are collected in open-label extensions.

### 10.12.7.2 Randomization

Randomization allocates subjects to treatment arms wherein each arm is exposed to a different condition. Usually only two arms are employed in phase III trials: experimental and control. In phase II or when several treatment strategies are available, additional treatment arms become necessary. For example, in the MCI trial by Petersen et al. [8], three arms were utilized and subjects received (1) 2000 IU of vitamin E daily, (2) 10 mg of donepezil daily, or (3) placebo. Sano et al. [58] likewise expanded the treatment allocation by means of a  $2 \times 2$  factorial design to further examine treatment combinations. Four treatment arms were used: (1) selegiline and  $\alpha$ -tocopherol, (2) placebo and  $\alpha$ -tocopherol, (3) selegiline and placebo, and (4) placebo only. Multiple treatment arms are used to compare response to different dosages of the drug [26–32, 36].

### 10.12.7.3 Length of Clinical Trials

Duration of the trial and number of recruited patients are very important factors that contribute to the validity of the outcomes of the RCTs. Duration of phases II and III should be long enough to ensure that the efficacy and safety of the drug are adequately explored. Efficacy of antidementia drugs cannot be seen before 3 months of drug exposure and may be evident only after 6 months. Although longer duration (>6 months) is ideal, the number of subjects completing the study and their compliance are concerns in longer studies.

Adequate clinical trial length is essential in demonstrating treatment effect in a progressively deteriorating disorder. Drug effect (symptomatic vs. disease modifying), target symptoms (cognitive vs. noncognitive/behavioral), and outcome measures (biological vs. assessment scales) are important factors that should be considered in determining the trial length. Trials with insufficient duration can yield inaccurate and potentially misleading results in view of the fact that small but important changes from baseline may remain undetected. Longer trials ( $\geq 1$  year) are ideal considering the chronicity of the disorder being examined, but ethical, attrition, and compliance problems may be encountered which could com-

promise study interpretation. Winblad et al. [28] conducted the first published long-term (1-year) efficacy and safety study of donepezil on AD while the AD (2000) trial [84] has extended the duration to 2 years. Most trials involving agents that may have a neuroprotective or disease-modifying effect are conducted for 1 year (Table 4) since time must be allotted for their structural effect to become apparent.

Neuropsychiatric symptoms are encountered throughout the spectrum of dementia and may even herald its onset. Numerous studies have been conducted involving psychotropics (typical and atypical), anticonvulsants (carbamazepine and valproate), and antidepressants [selective serotonin reuptake inhibitors (SSRIs)] to determine which agent alleviates these symptoms. Patterns of analysis may be either (1) reduction in emergence of behavioral symptoms wherein asymptomatic patients are followed up longitudinally to determine which regimen has fewer symptoms at endpoint or (2) comparing which regimen produced more change/reduction in the behavioral symptoms from baseline to endpoint. The length of the trials is notably shorter than those addressing cognitive symptoms, ranging from 6 to 12 weeks, since acute symptomatic improvement is the goal.

### 10.12.8 STATISTICAL ANALYSES

Subject noncompliance and dropouts always complicate clinical trials. These subjects cannot be excluded from analysis since they may have demographic or disease characteristics that are different from those who completed the trial and adhered to the treatment randomly assigned to them. It is for this reason that most clinical trials use the intention-to-treat principle, which provides unbiased and reliable interpretation of treatment effect. Intention-to-treat analyses typically include all subjects who were randomized to treatment, received at least one study drug dose, and provided a baseline assessment and at least one postbaseline assessment. It is a conservative method that makes it possible for the potential treatment benefit on patients to be evaluated regardless of whether or not they completed the study. With this, the random assignment of subjects to treatment groups is preserved during data analysis and potential bias is reduced [44]. This differs from the fully evaluable (per-protocol) population analysis wherein those who completed the entire phase of the study and remained compliant to the treatment regimen based on compliance rules set prior to study initiation are the only ones included.

Analysis of longitudinal data can be problematic since missing data are evident. Different methods of statistical analysis have been adopted to treat these data sets. The most widely used technique that addresses missing data is the last observation carried forward (LOCF), a method in which the subject's last available assessment is imputed for all remaining unobserved response measurements. It has the advantage of preserving the sample size, but it presumes that the subjects' responses have been constant from the last observed value to the trial endpoint. This unwarranted assumption about the missing data may result in either underestimating or overestimating the treatment effects. Type I errors can be generated from this so that a treatment difference can be falsely endorsed when in fact there is none. Despite these caveats, the method is frequently used due to its simplicity and ease of implementation and relatively conservative method of treating data. On the other hand, an observed cases (OC) analysis utilizes only the data of subjects remaining in the

trial at a specified point in time. In this method, a direct relationship of the data used and the obtained results is observed. However, loss of power and subsequent validity of results may occur since data of the noncompleters are unexploited. Results that are statistically significant for both types of analysis clearly support their accuracy. Conversely, cautious interpretation of results should be done when results are significant only in the OC analysis.

All statistical analysis should be planned in detail prior to the initiation of the clinical trial since changes afterward may introduce bias in the system. However, changes that are made prior to breaking of the blind still have limited implications for study interpretation. Analyses that are made afterward are less compelling. This also applies for specification of subgroup analysis, which is done on the basis of an expectation of a larger treatment effect in some subgroups than in others [44].

Clinical trials with survival data require different statistical treatment since subjects have varying endpoints producing asymmetries in data distribution. If the data from the subjects who did not make it to the endpoint are excluded, bias may be introduced into the results. Studies using the survival design have three general objectives: to estimate the time to event, to compare the time to event between/among the groups, and to determine the relationship of the covariables to the time to event. The hazard ratio and survival time are two important functions that are examined to generate the answers to these questions [89]. The Cox proportional-hazards regression and Kaplan–Meier analysis were used to evaluate these, respectively, in the trials of Mohs et al. [54], Sano et al. [58], and Petersen et al. [8]. The Cox proportional-hazards model controls for any bias in the predetermined covariates among the treatment arms since these change over time. It is used to estimate the hazard ratio, which is the risk of progression to an event over time in the treatment group versus the placebo group. The Kaplan–Meier method provides survival time estimates to clinically evident decline or to a chosen event (e.g., death, institutionalization, or loss of the ability to perform basic ADLs).

An adequate sample size ensures that the treatment effect can be reliably derived from the clinical trial at a specified endpoint. For ethical reasons, the sample size should be well justified; samples too small or too large are not warranted. Factors that affect sample size determination are the power of the study to detect a drug–placebo difference and the chosen level of significance of the statistical tests. Confounders and attrition rate should be considered in sample size determination, for which it should be adjusted appropriately.

The study should have enough “power” to accurately detect the smallest possible difference in the primary outcome measure that has clinical significance produced by the treatment. Power is usually set at 80% so that there is a 20% probability of missing the difference between the treatment and placebo group. Some clinical trials use a power of 90% to further reduce the chance of a false-negative result. The level of significance, or *p* value, is the probability of incorrectly identifying a treatment difference between the treatment and placebo arm when actually there is none (false-positive result). By convention, a value of  $\leq 0.05$  is frequently used. Sample size is inversely proportional to the chosen level of significance while it is directly proportional to the power of the study.

Sample size calculation is based on the primary outcome measure and how much change is required to produce a clinically meaningful effect. Previous phases II and

III clinical trials and longitudinal studies establish these changes. For example, in the ADAS-cog a four-point change is utilized for 6-month trials and seven-point change for 1-year trials for clinically significant change to be detected [90]. For the CIBIC-plus a 0.3–0.4 change is usually targeted [26, 40]. In the 1-year study of Mohs et al. [54] where preservation of function was determined as an effect of donepezil, power was calculated based on functional performance, that is, the 1-year value for significant functional decline in the placebo and donepezil group based on a previous study. Most base the power of the study on one of the primary outcomes (either ADAS-cog or the global assessment) while some base it on dual outcomes (both ADAS-cog and global assessment) [21, 22].

### 10.12.9 DRUG–PLACEBO DIFFERENCE

The drug–placebo difference is the discrepancy between the deterioration of the placebo group and the improvement, stabilization, or reduced deterioration in the treatment group [46]. It is derived by determining the difference between the mean change from baseline scores of the actively treated and placebo groups at a specified endpoint. The FDA requires proof of efficacy in terms of statistically significant improvement on specified outcome measures in the treatment group.

The effect size is the definitive basis of a drug's efficacy. It is determined by dividing the drug–placebo difference by the standard deviation using specific outcome measures.

A summary of the drug–placebo differences of the RCTs in MCI and AD based on outcome measures can be seen in Tables 9, 10, and 11. The drug–placebo difference varies among the studies and among the class of therapeutic agents. The range of treatment effect produced by acetylcholinesterase inhibitors in the ADAS-cog is 2–3.9 and 0.2–0.47 in the global assessment scales among subjects with mild to moderate AD. Among the other class of therapeutic agents, only Ginkgo biloba [55] produced significant drug–placebo difference in the ADAS-cog, but this was not supported by the global evaluation.

### 10.12.10 PLACEBO RESPONSES

Use of a placebo arm in a RCT is a standard procedure as long as it is ethical and feasible. Comparison of drug–placebo outcomes determines the investigational drug's efficacy. In AD, it is expected that an efficacious drug will produce improvement or stabilization in primary assessments while the placebo group continues its course of deterioration.

Irregularities in the placebo response are apparent in some clinical trials (Figure 3). Factors that contribute to this effect are fluctuation of the symptoms, methodological inconsistencies, and the beneficial effects of improved medical care provided during the study. It is hypothesized that placebo effects or trial effects can result from the attention that subjects receive from health care providers involved in the study. In some studies, the occurrence of adverse events in the placebo group can approach the level of occurrence observed in the treatment group. Placebo and trial effects may account for the initial improvement that is seen in the placebo

**TABLE 9 Drug–placebo Differences on ADAS-cog and Global Assessment Scales among Various Therapeutic RCTs in MCI and Mild to Moderate AD (Intent-to-Treat Analyses<sup>a</sup>)**

| Agent/Study                     | ADAS-cog          |                                   |                   | Global Assessment Scale<br>(CGI, CGIC, CIBIC-Plus) |
|---------------------------------|-------------------|-----------------------------------|-------------------|----------------------------------------------------|

Note: Included trials have duration of ≥6 months and either have data at 6 months or have graphs from which data can be extrapolated.

FIGURE 3 Mean change from baseline (intent-to-treat analyses) in ADAS-cog scores of placebo groups of different acetylcholinesterase inhibitor clinical trials with duration of 3–6 months in mild to moderate AD (mean change from baseline derived from available data while other values were extrapolated from graphs): ▲ [31], ■ [33], ● [22], ⋯ [29], ○ [27], ◆ [21], ✱ [30], ■ [26], ◊ [32].

**FIGURE 4** Mean change from baseline (intent-to-treat analyses) in ADAS-cog scores of placebo groups of two 1-year clinical trials involving estrogen replacement and Ginkgo biloba (mean change from baseline derived from available data while other values were extrapolated from graphs):  $\triangle$  [36],  $\bullet$  [55]. Patients in the estrogen clinical trial had an MMSE range of 14–28 while those in the Ginkgo biloba trial had an MMSE range of 9–26. Other trials not included due to unavailable mean ADAS-cog scores of change from baseline along the course of the trial.

group in the first few weeks of some clinical trials [21, 22, 26, 27, 29, 30]. Deterioration is inevitable in trials of symptomatic agents despite these initial improvements and fluctuations.

The expected rate of change in the ADAS-cog scores annually in patients with AD is seven to eight points [91]. This varies depending on the severity of the cognitive impairment; less severe patients have a slower rate of decline [90]. This is evident in the Ginkgo biloba trial [55], for example, which included subjects with a lower range of MMSE scores and higher magnitude of decline, compared to those in the estrogen trial, which included subjects with higher MMSE scores (Figure 4).

#### 10.12.11 ATTRITION AND ADVERSE EFFECTS

Clinical trials suffer from subject dropout and the effects of attrition must be anticipated in trial design. Dropouts are more commonly due to refusal to follow up, lack of efficacy, violation of study protocol, and presence of adverse events.

Diminution of the subject pool is expected as the length of the trial is increased due to dropouts. Attrition is a potential problem because each dropout is equivalent to lost data, which may eventually lead to inadequate sample or, worse, skewing of the outcomes. Selective attrition can produce changes in the subject pool so that it inadvertently becomes unrepresentative of the subjects that originally entered into the study. Results become unreliable in this setting.

**TABLE 12** Gastrointestinal and Selected Other Adverse Events in Placebo Group (Percent of Occurrence) of Acetylcholinesterase Inhibitors in Mild to Moderate AD Clinical Trials

| Adverse Events          | Donepezil |      |      |      | Rivastigmine | Galantamine |      |      |
|-------------------------|-----------|------|------|------|--------------|-------------|------|------|

*Note:* Included are adverse events with rate of occurrence that differed by at least 5% between the treatment group and the placebo.

Adverse events (AEs) is another cause of subject dropout. Adverse events are defined as newly emergent events/symptoms occurring after the first dose of the study drug or clinically significant worsening of a preexisting condition after the first dose of the study drug. Treatment emergent signs and symptoms (TESSs) is another term that is frequently used to indicate AEs. A serious adverse event (SAE) pertains to any event that is considered life threatening, resulting in hospitalization, permanent disability, or death. Occurrence of a serious AE that is deemed related to drug exposure may be grounds for withdrawal of a drug that is already released in the market. Clinical trials include tolerability and safety studies critical to determining any AEs that may occur with a drug.

Both the active treatment and placebo group experience AEs and all are reported whether these are deemed related or not related to the drug exposure. AEs range from incidental symptoms, part of the inherent deterioration of the disorder, secondary to existent medical disorder or related to drug exposure. Subject variability may account for the assortment of symptoms encountered as AEs and they can be observed among placebo groups as well as active intervention groups (Table 12).

Most AEs in acetylcholinesterase inhibitor trials are causally related to the drug's mechanism of action. Consistent findings are cholinergic manifestations that are usually transient and mild, although some may be moderate in severity. These are dose related and studies which utilized a forced titration rate increased cholinergic

AEs in subjects [22, 26]. In comparison, those that employed a longer dosage titration schedule had lower incidence of these AEs and better drug tolerability [27].

Deaths occur during clinical trials. The probability of its occurrence is increased in a dementia trial due to an expected lower survival rate in this population and the age of the subjects included. Deaths have been rare in most trials and were judged to be unrelated to the drug intake.

### 10.12.12 PRESENTING CLINICAL TRIAL RESULTS

The CONSORT statement was developed in (1996) [92] with the purpose of improving the accuracy of conducting and reporting RCTs. This obligates investigators to provide transparency as to the details of the trial from recruitment of subjects to its results. By following the CONSORT criteria, investigators are more likely to conduct ethical trials and produce valid, unbiased results. CONSORT criteria make it easier for readers to evaluate and understand the RCTs and there is an assurance that the results can be relied upon. Inadequate reporting of RCTs has led to biased interpretation of results with overestimation or underestimation of treatment effects. Currently, a 22-item CONSORT checklist and a flow diagram are available for use and these are constantly updated and modified [93].

Table 13 shows how CONSORT criteria can be applied to trials of AD and MCI.

### 10.12.13 DISEASE-MODIFYING TRIALS

Disease-modifying drugs have been the focus of dementia management for some time. The methodological strategies of clinical trials involving this class of therapeutic agent are apparently different from those involving symptomatic agents since the former target the neurodegenerative process of AD. Patients in the early stage of AD should ideally be included since they will receive the most benefit from disease intervention. Evidence of disease course alteration can be established in longer trials, that is,  $\geq 1$  year, since the natural progression of AD needs to be observed. This will also ensure that the treatment effect is not due to disease fluctuation that is present in AD. A larger sample population is necessary since attrition rate is expectedly higher in clinical trials with longer duration. Outcome measures other than neuropsychological tests such as biomarkers need to be employed to support the disease-modifying effect of the therapeutic agent. Use of biomarkers as surrogate endpoints can also reduce the required sample size and the duration of clinical trial, saving on time and resources. Pharmacoeconomic measures should also be integrated to justify long term societal benefits from the drug.

## ACKNOWLEDGMENT

The authors wish to acknowledge Lynn Fairbanks, Ph.D., a professor in the Department of Psychiatry and Biobehavioral Sciences, UCLA, for her special contribution in the statistical section of this chapter.

**TABLE 13 Features of Current MCI and ADRCT as These Are Adapted to CONSORT Checklist**

| Paper Section and Topic                                                    | Item | Examples of Features of MCI and Dementia Trials                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |

### **10.13.1 INTRODUCTION**

The wide scope of current urological practice has led to a proliferation of research and clinical trials in this specialty. As a surgical subspecialty devoted to the medical and surgical care of patients with genitourinary disorders, both pharmaceutical and device trials have equally important roles in the advancement of the future care of the urologic patient. Pharmaceutical trials are ongoing for conditions such as erectile dysfunction, urinary incontinence, and oncology to name a few. Significant advancements in surgical instrumentation such as robotics and prosthetic devices for the treatment of genitourinary diseases are also being witnessed and are the

subject of clinical investigation. The objective of this chapter is to provide an overview of the objectives, design, and implementation of clinical trials specifically relevant to those conducting urological research. While many of the domains covered in the chapter are subjects commonly faced by researchers in other specialties, we will attempt to highlight issues of particular importance to urological investigators.

## 10.13.2 BASICS

In this section we provide an overview of the issues related to the development of clinical trial objectives and the study populations of importance in urological research.

### 10.13.2.1 Clinical Trial Objectives

The first and most important step in designing any clinical trial is defining the study objective [1]. Careful attention to the formulation of the primary and secondary study objectives will allow investigators to design a quality clinical trial that is adequately powered to answer the study question and avoid many potential pitfalls.

This crucial first step attempts to formulate the primary question or that question that is most significant to be answered by the trial. This may seem self-evident, as this objective is likely the reason the trial was initiated in the first place. However, more often than not the initial concept is too broad or poorly defined to be useful as a primary question. Investigators must ask themselves whether this primary objective can be realistically addressed with a clinical trial. The sample size calculation is based on the primary question. In some instances, that calculation may reveal that more participants would be needed than would be expected to be available in a reasonable time frame. Reevaluation of the primary outcome measurement may provide a more realistic number of participants that would be needed for the trial.

When designing a study to evaluate a new treatment or drug to treat a disease such as cancer, the urological researcher should ensure the most clinically relevant outcomes will be assessed. Time to disease progression, disease-specific survival, and overall survival are just a few of the commonly determined measurements. The effect of the study treatment may or may not be evident for several years, depending on the disease process, and the effect of the study treatment. Therefore, the investigators will need to define how these study endpoints will be assessed over time.

In formulating the primary question, investigators may either seek to prove a hypothesis [2] or to show a lack of a difference in outcomes between participants and controls. An example of the former would be the situation where investigators hypothesize that patients receiving a study drug for the treatment of prostate cancer may have a decrease in cancer-specific mortality. At other times it is beneficial to show that there is no difference between subjects and controls such as when an intervention is deemed to be unnecessary. An example of this would be the argument against the routine placement of a ureteral stent following uncomplicated ureteroscopy where investigators demonstrated that there was no advantage in the placement of a stent [3].

While formation of a clear primary objective is of the utmost importance, secondary objectives must also be defined. These may be evident at the start of the study or may become clear through collection of data designed to address the primary objective. Using the above example of a drug for the treatment of cancer, if the primary objective is to demonstrate an improvement in cancer-specific mortality, a secondary objective may be to see which subgroups in particular benefit from this effect. Whenever possible, these secondary objectives should be outlined at the commencement of the trial. Additionally, secondary objectives may be distinctly separate from the primary question such as determining whether there are any adverse effects from the drug or a difference between subjects and controls with respect to quality of life issues. The primary objective is used for power and sample size calculation; therefore, it is not uncommon for secondary objectives to be inconclusive and lack power due to small sample size.

Urologists have several tools to evaluate outcomes in clinical trials. While questionnaires are able to evaluate subjective outcomes, the study design should also include objective measurements. Objective measurements must be relative to the disease under study and be considered to be part of the standard of care or evaluation of that same patient population.

The International Prostate Symptom Score includes symptom, bother, and quality of life scores that are useful in accessing primary and secondary outcomes in several types of urology trials [4]. The International Index of Erectile Function (IIEF) can be used to evaluate the primary outcome in erectile dysfunction trials, and secondary outcomes of other trials affecting the male population where the evaluation of sexual function is relevant [5]. Quality of life measurements are commonly utilized in urologic trials as secondary objectives. The SF-36 Health is considered the most comprehensive instrument to measure general health-related quality of life (HRQOL) [6]. Various validated instruments are also available to assess a number of specific urologic conditions. The UCLA Prostate Cancer Index was devised to assess health-related quality of life in patients with prostate cancer [7]. The Ureteral Stent Questionnaire (USSQ) uses both the visual analog scale (VAS) and quality of life questions to evaluate the patient's stent-related symptoms [8]. Specific urological questions, either as primary or secondary outcomes, can be evaluated in the trial by using the VAS to assess the effect of the study treatment on participants' perceived results, ranging from pain to treatment effectiveness or reduction of urinary symptoms [9].

#### **10.13.2.2 Study Population**

Careful selection of the study population will improve the chances of successfully answering the study question in a meaningful and convincing fashion. Well-defined inclusion and exclusion criteria must be clearly defined in the study protocol. In general, a simple approach to defining the study population begins with including the entire population at large and methodically narrowing the definition of the eligible subject. To illustrate this process we consider the example of a large prospective urological study, The Prostate Cancer Prevention Trial (PCPT) [10, 11]. The objective of PCPT was to assess the effect of the drug finasteride for the prevention of prostate cancer. The first step toward selecting the study population in this trial was to identify those individuals with or at risk for prostate cancer. In the case of

prostate cancer, young men are much less likely to manifest the disease; therefore, the designers of the PCPT trial opted to include only those men 55 years of age or older. As this study looked at the development of prostate cancer in men without the disease, it was important to include only men with a normal digital rectal exam (DRE). One must also be aware of potential confounding conditions that may detract from the ability to assess for the condition being studied. Benign prostatic hyperplasia (BPH) may result in a benign rise in prostate specific antigen that may be perceived as potential prostate cancer. To minimize the impact of BPH, men with an American Urological Association symptom score of 20 or greater were excluded from the study.

Randomized clinical trials usually have at least one control group as well as one or more treatment groups. While this tends to increase the costs of the trial due to the greater number of subjects required, it is essential to statistically answer the primary study question.

Control subjects may be assigned as either negative or positive controls. In the setting of a pharmaceutical trial, a patient receiving a placebo (i.e., sugar pill) would be a negative or passive control, meaning that they are not getting active treatment. Still, patients in placebo arms of studies often report improvement or deterioration in their condition, demonstrating the so-called placebo effect. This is a well-described phenomenon in urology, especially noteworthy in benign prostatic hyperplasia clinical trials. Improvements in symptom severity in particular may range from 5 to 15% for placebo or sham treated cohorts for both medical and minimally invasive device treatment trials of BPH patients [12].

A negative control may be used either alone (if no gold standard treatment exists) or in conjunction with a positive control arm. A positive or active control may be used when there is a current treatment that is considered the standard of care for a particular disease or condition. The control arm consists of patients receiving the standard treatment while subjects in the experiment arm receive the treatment under investigation. By actively treating both treatment and control groups, investigators hope to demonstrate superiority of the experimental treatment over the established standard. It has been suggested that active controls may protect patients and should be routinely utilized [13, 14].

Subject-to-subject variability is controlled by choosing a cross-over design. In a cross-over medical device trial, subjects can be used as their own control. Cross-over trials can be considered when the study includes two or more interventions. The interventions may be two separate treatment devices or one may be a placebo treatment. Each subject in the clinical study is assigned a randomized treatment group, allowing a period between interventions for a “wash out” of any carry-over from the previous intervention. Patients treated as part of the cross-over design are then followed from the baseline of the study’s schedule as outlined in the protocol. In studies with a placebo arm, patients who were randomized to the placebo arm are offered open-label study treatment at a predetermined time. Often this is defined as when the study treatment is unblinded and revealed to all of the participants [15].

### 10.13.2.3 Ethical Considerations

Research has been ongoing throughout human history; however, it has not always been carried out in a fashion that would be deemed ethical by today’s standards.

Modern investigators must be acutely aware of the ethical aspects of clinical trials and should strive to exceed the expectations of their research review boards. Given the nature of the urological patient population, significant ethical issues are not infrequently encountered in the course of urological clinical trials.

The formulation of a relevant and important research question helps to lay the foundation for ethically sound research [16]. Researchers must thoroughly consider the relevance of their research proposal, ensuring that it is based on solid scientific principles and that the results of the study are likely to improve patient care or enhance knowledge in the field [17]. Patients enrolled in a clinical trial should be confident that their participation should ultimately result in a valuable scientific contribution [16].

In order to best protect the rights of individual patients, investigators should adhere to the principles of autonomy, beneficence, and justice [18]. Autonomy implies that the individual should make important decisions intentionally and free of external influence. Beneficence centers on the responsibility of the investigator to maximize the positive outcome of the trial for each patient. This is a fundamental principle of the Hippocratic oath along with the responsibility to “do no harm” and thereby minimize the potential negative outcomes of the trial [19]. Justice dictates that the design and implementation of a clinical trial be fair to participants. The selection of subjects should be free of bias, and drawn from a relevant patient population.

The Council for International Organizations of Medical Sciences (CIOMS) and the World Medical Association (WMA) have both published guidelines for the ethical management of biomedical research. The WMA Declaration of Helsinki (Ethical Principles for Medical Research Involving Human Subjects) was first adopted in 1964 and has undergone several revisions with the most recent in 2000 [20]. The CIOMS International Ethical Guidelines for Biomedical Research Involving Human Subjects consists of 21 guidelines relating to ethical justification scientific validity of research, informed consent, and equity regarding burdens and benefits among other issues [21]. Each set of guidelines provides an excellent framework for the ethical conduct of biomedical research and are of benefit when preparing a research proposal for institutional review.

No clinical trial may be deemed ethical without a properly formulated and freely given informed consent. Not only must this consent be legal according to the laws of the nation where the study is to be performed but should also conform to the ethical guidelines laid out by the WMA and/or CIOMS. Additionally, in the event that pertinent information becomes available during the course of a trial, it is the investigators' responsibility to advise the participants of any information that pertains to the informed consent [1]. First, the potential study subjects should be provided with an overview of the proposed research to decide whether they would be interested in inclusion into the trial. This includes informing subjects of their responsibilities during the trial (i.e., taking of medications, follow-up appointments), as well as any procedures that will be performed. There should be an honest and open dialog between the individual obtaining the consent and the prospective subject with no attempt to mislead or deceive. The consent must be given voluntarily with participants entering the trial of their own free will with no fear of reprisal should they decline (i.e., withholding of care). Subjects must be told why they are appropriate candidates for the trial (inclusion criteria) and what would make them ineligible (exclusion criteria).

Participants must be informed of all potential risks and benefits of participation in the trial at the time of consent. Risks may include but are not limited to potential physical or mental injury as a result of participation in the study. Additionally, the investigators should provide the patient with an explanation of what will be done to minimize these risks. The benefits of inclusion in the trial may include an improvement to the patient's symptoms or condition, although the patient should be made aware that this is not guaranteed. It is essential to explain any alternate treatments that are available to the subject, including the standard drugs or procedures that would be used in his or her situation and make the patient aware if any of these will be withheld due to inclusion in the study. An example of this would be a trial studying a new form of ureteroscopic lithotripsy. The patient should be made aware of the potential risks of the procedure (i.e., ureteral injury, failure to fragment the stone) as well as possible benefits (i.e., improved stone fragmentation). Additionally, participants must be made aware of alternative procedures such as laser lithotripsy that would be withheld in order to study the new device. The described benefits should also include the potential benefits to society as a whole such as improved stone-free rates using the new technology.

Confidentiality is an important ethical consideration when carrying out a clinical trial and should be maintained from consent through to the study conclusion. Personalized information including subject name, date of birth, and ethnicity along with any other personal identifiers must remain confidential. Study participants should be notified at the time of consent if any personal identifiers will be disclosed during the course of the trial and what measures will be taken to maintain confidentiality. In the event that the trial requires the use of video or photographic data, patients should be aware that they have the right to access such files should they wish to do so.

Participants should be provided with written material summarizing the above information in lay language that is clear and understandable. This information should include appropriate contact information for the reference during the course of the study. The informed consent document must be signed and dated by both the participant and the individual obtaining consent, although verbal consent may be allowed at the discretion of the review board in some instances.

#### **10.13.2.4 Review Boards**

While the actual requirements to conduct research vary based on the country in which the trial is to be conducted, most nations have adopted a model that incorporates an institutional review board (IRB) or a research ethics board (REB). The general mandate of the IRB/REB is to objectively review research proposals involving the use of human subjects and to ensure that trials are ethically sound according to the previously described principles. The board protects the rights of individual participants in research trials through external review to assess the relevance and ethics of proposals and to make certain that confidentiality and safety are maintained by investigators. In general, ethics boards are comprised of multiple individuals of both genders, at least one of whom should be from a nonscientific discipline. Additionally, one or more members may be appointed from outside of the institution at which the research is to be conducted [16].

Researchers embarking on a trial should be aware of the principles of ethical research and identify any potential pitfalls that may delay approval of the ethics application. The primary research question must be clear and relevant, and all secondary objectives should be stated. Relevant statistics such as the sample size calculation must be performed ahead of time to justify the required number of participants. Any potential risks to participants should be addressed in the application as well as measures through which the investigators will minimize these risks and deal with adverse events should they arise. While guidelines are, for the most part, consistent between institutions, researchers should make themselves familiar with the requirement at their institution. This preparation will help to avoid any unnecessary delays.

### **10.13.3 SPECIFIC ISSUES WITH SURGICAL DEVICE TRIALS**

#### **10.13.3.1 Regulatory Issues**

Urologists employ a wide array of surgical devices ranging in complexity from simple guidewires to robotic operating systems. Each of these devices must pass through regulatory safeguards prior to introduction into clinical use. Issues relating to drug trials are covered elsewhere in this text; however, we feel it necessary to briefly touch on matters relating to device trials and how this may differ from pharmaceutical trials.

The U.S. Food and Drug Administration (FDA) Center for Devices and Radiological Health oversees the development and marketing of new devices in the United States. If the investigational device study presents a significant risk to the subjects, an investigational device exemption (IDE) application must be completed [22]. The IDE must be approved by the FDA, and the individual site(s) institutional review board prior to study initiation. The process of IDE approval is often lengthy, and once approved the clinical study must be conducted according to the IDE regulations (CFR 812). If an investigator or a sponsor proposes that the device under study does not pose a significant risk (NSR) to the participants, and the ethics board agrees and approves the study, no FDA/IDE application is needed.

Medical devices are classified by risk, with class I devices being lowest risk, and class III devices being the highest risk as defined by FDA standards [22]. FDA class I devices (i.e., handheld surgical instruments) present minimal potential harm to the user and require the least amount of regulatory control. Class II devices include instruments such as uroflowmeters, monitors, pump systems, and X-ray devices. These devices require additional special controls including special labeling requirements, mandatory performance standards, and postmarket surveillance. Class III devices (class III/IV in Canada) have the strictest regulatory controls and include devices that support or sustain human life or lack sufficient safety information to assure safety and efficacy (e.g., ureteral stents, penile prostheses, microwave thermotherapy units).

The process in Canada is similar. Medical devices are regulated by Health Canada's Therapeutic Products Directorate under the Food and Drugs Act [23]. The goal of this regulation is to ensure that medical devices available in Canada are safe and effective and of sufficient quality for general distribution. Once Health Canada

approval has been secured, the local institutional review boards are then able to proceed with their review of the research protocol. Health Canada is entitled to ask the sponsor for any information it deems necessary to make a sufficiently informed decision on the safety of the product (additional information request). The cycle of Health Canada issuing the request, the time for the sponsor to compose its response, and a new review time of 30 days from Health Canada's receipt of the response may further prolong the review cycle. Health Canada differs slightly by stratifying devices from class I to class IV but follows the same general principles as the FDA.

If an investigator or a sponsor proposes a study using a device previously approved for the same application, a Health Canada Clinical Trial Application (CTA) is not required. However, if the study proposes to use an approved device for another indication or in association with a drug not previously approved for the same indication, a CTA must be submitted to Health Canada [24].

For specific details on the regulatory process in countries outside North America, interested researchers should contact the relevant national health department's regulatory branch.

### 10.13.3.2 "First-in-Man" Studies

First-in-man trials present a particular concern for drug studies, especially since March of 2006 when six healthy volunteers were administered the study drug TGN1412 and subsequently developed multiorgan failure requiring intensive care [25]. Fortunately, there were no deaths involved with this trial. However, this brought to light particular issues regarding first-in-man trials. In 2007, the Royal Statistical Society published a study focusing on statistical consideration for first-in-man studies [26]. They recognized that first-in-man studies are vital in the development of new drugs and devices and such trials must have a high level of safety. Recommendations were made for improvement in the areas of preparatory clinical work, experimental design (particularly with respect to drug dosing), risk assessment, and communication.

With respect to device trials, first-in-man studies may be slightly less cumbersome to undertake. Regulatory bodies require evidence that the safety and effectiveness of the device has been established as far as possible prior to human use, that the study will accomplish its objectives, and that trial subjects are protected to every possible extent. For first-in-man studies, it is generally easier to justify small subject numbers. However, the "pilot" study can often be omitted through the appropriate use of preclinical and bench-top studies where the risks to patients can be shown to be minimal.

### 10.13.4 SUMMARY

The specialty of urology is a fertile ground for the astute scientist with many opportunities for cutting-edge drug and device research. Only through the conduct of properly constructed clinical trials and the proper interpretation of study findings, however, will our patients truly reap the benefits of this activity. It is hoped the

information provided in this chapter will aid those considering urological investigation and inspire a commitment to the highest quality research endeavor.

10.14.1 KINDS OF DISEASES REPRESENTING TARGET IN THIS FIELD

Cognitive disabilities, especially memory disturbances and cognitive deficits, posttraumatic brain injury (TBI), and poststroke are important targets for clinical pharmacological trials given their important epidemiological and social impact (see Table 1).

Until a few years ago, patients with dementia, stroke, or TBI faced a bleak future with a diminished quality of life, reduced productivity in terms of their capacity to work and contribute to family life, and dependence on caregivers. Without a cure or any means of alleviating the patient’s symptoms, for example, by prescribing drugs that slowed the progression of a degenerative disease or neurorehabilitation to restore some of the brain function lost through stroke or traumatic brain injury, the doctor’s role was reduced to advising the patient on coping strategies. However, over recent years and thanks to new scientific data, the treatment of brain diseases has undergone a revolution.

10.14.1.1 Dementia

Brain changes leading to cognitive decline and dementia, and their relation to disability, are key topics requiring investigation at the population level. Global aging is a recent phenomenon. Its potential impact on social and economic aspects of more developed countries highlighted aging as an important issue toward which resources must be directed. Dementia is an increasingly common diagnosis in our aging population, and the numbers are expected to rise exponentially in coming years. Alzheimer’s disease (AD) alone actually affects 4.5 million people in the United States [2], while millions more are currently affected by vascular dementia (17.6% of all incident dementia [3]), Lewy body disease, and frontotemporal dementia. Each of these is a distinct entity, though overlapping symptoms and comorbidities occur frequently. Within the past two decades research has progressed rapidly on multiple fronts, including epidemiology, etiology, pathology, diagnosis, and treatment. It is important for clinicians to recognize early signs and symptoms of dementia and to note critical differences among them. Dementia research has moved beyond description of symptoms and clinicopathological correlation to the elucidation of risk factors, the pathobiology of the disease process, and, most important, to the first generation of dementia treatments. Furthermore, the question of how to divide aging phenomena into categories of healthy, normal, or disease-related remains a difficult but important goal in medicine: We are entering an era of dementia care that will be based upon the identification of potentially modifiable risk factors and early disease markers and the application of new disease-specific diagnostic tools and treatment modalities. Literature data showed, for example, that older persons

TABLE 1 Epidemiological and Social Impact of Dementia, Stroke, and TBI

| Disease                | Prevalence       | Annual Cost (euro)/Year |
|------------------------|------------------|-------------------------|
| Dementia               | 5 million people | 55 billion              |
| Traumatic brain injury | 700,000          | 3 billion               |
| Stroke                 | 1 million people | 22 billion              |

Source: Data from Olsen et al. [1].

can develop demonstrable cognitive impairment (“mild cognitive impairment,” MCI; [4]), especially memory deficits without crossing the threshold for dementia, but that these patients have an increasing risk of developing dementia, especially Alzheimer disease [5]. We expect that pharmacological approaches will become increasingly integrated with behavioral, genetic, and neuroimaging methods to investigate not only disease processes but also the normal and preclinical individual differences that underlie successful—or unsuccessful—aging. These future directions share an important feature with the current focus of the field: a shift from the dismal characterization of aging as an inevitable process of brain damage and decline to the concept (emerging from cognitive neuroscience) that aging can be successful associated with gains and not only with the losses. It is not necessarily a unidirectional process but rather a complex phenomenon characterized by reorganization, optimization, and enduring functional plasticity that can enable the maintenance of a productive and happy life.

#### 10.14.1.2 Trauma

Traumatic brain injury is another leading cause of disability, and survivors often suffer cognitive, mood, and behavioral disorders. TBI is an insult to the brain that leads to temporary or permanent impairments of cognitive abilities and physical functioning. TBI results principally from vehicular incidents, falls, acts of violence, and sports injuries and is more than twice as likely to occur in men as in women. The estimated incidence in U.S. rate is 100 per 100,000 persons, with 52,000 annual deaths. The highest incidence is among persons aged 15–24 years and 75 years or older, with a less striking peak in incidence in children aged 5 years or younger [6]. Since TBI may result in lifelong impairment of physical, cognitive, and psychosocial functioning and prevalence is estimated at 2.5–6.5 million individuals, it is a disorder of major public health significance. Mild TBI is significantly underdiagnosed, and the likely social burden is therefore even greater. Given the large toll of TBI and absence of a cure, prevention is of paramount importance. More recently, a hospitalized incidence rate of 229 per 100,000 was calculated for England for TBI in 2001–2002 [7]. Again, significant local variation was noted (91–419 per 100,000 across health authorities). In the United Kingdom, “serious” TBI is estimated to have an incidence rate of 52 per 100,000, while an incidence of 12 per 100,000 was reported in Australia for “severe” brain injury [8].

Research in traumatic brain injury has shown that the primary traumatic insult sets in training a cascade of events in the brain that leads to secondary injury, and that this secondary injury can be exacerbated by systemic insults such as hypoxia and shock [9]. Strategies to minimize both secondary insults and the evolution of secondary damage in the acute phase, while maximizing plasticity in the following course, are essential goals for those patients, but pharmacological studies in this field are lacking. The same can be said for long-term cognitive impairment deriving from a previous TBI, a condition affecting a significant percentage of TBI survivors.

#### 10.14.1.3 Stroke

Stroke is a vascular disorder characterized by the sudden death of brain cells due to a reduced or blocked supply of blood. The symptoms depend on the site of the

stroke, but they can include motor, speech deficits (aphasia), visuospatial deficits (including neglect), cognitive decline, and dementia. The incidence of stroke is reaching pandemic proportions: Stroke is the third leading cause of death and one of the leading causes of adult disability in North America, Europe, and Asia [10–12]. Each year across the world, 5.5 million people die as result of a stroke. A further 15 million people survive but are disabled and face the prospect of a later, even more serious stroke [13]. Costs of care, which have to be met by either the individual or the state, can also prove crippling [14].

A number of well-designed randomized stroke trials and case series have now been reported in the literature to evaluate the safety and efficacy of pharmacologic therapy for the treatment of acute ischemic stroke, but there are few data on long-term cognitive outcomes and possible treatments after first-ever stroke. Literature data showed that recurrent stroke significantly contributes to global cognitive decline after a first-ever stroke. Furthermore, studies explained that stroke prevention would be important in reducing dementia related to stroke (e.g., hypertension treatments; [15]). There is a growing interest in the latter because patients with only mild vascular cognitive impairment and no dementia are at increased risk of cognitive deterioration and should have more opportunities for treatment and prevention [16]. Further investigation of these issues may help to understand mechanisms underlying stroke-related cognitive decline and assist in planning interventions to prevent dementia related to stroke, and to ameliorate existing cognitive deficits.

## 10.14.2 SELECTING POPULATION FOR STUDY

### 10.14.2.1 Common Criteria

**Diagnostic Accuracy** Before starting a clinical pharmacological trial, clear classification of the diseases and well-recognized diagnostic criteria are necessary to realize the selection of the study population. This is relevant not only for scientific reasons (standardization and comparability between data collected by several scientific groups) but also for practical aspects (e.g., without a clear stadiation of disease, it is unthinkable to lay down different therapeutic options). A detailed anamnesis as well as physical examination at presentation are necessary for the overall evaluation of the single subject; the employment of consensus criteria for the diagnosis is essential for the group analysis comprehension. Actually, consensus criteria are well defined in dementia (Table 2 cites the most recent clinical criteria). Unlike dementia, cognitive and behavioral sequelae in stroke and TBI recognize only clinical classifications of the specific symptoms. Nevertheless, attributing single individuals to the classic syndrome categories is not easy, due to the complexity of the underlying brain damage and the existence of clinical variants. For example, aphasia, the loss or impairment of language caused by damage to several discrete cognitive systems, is one of the most devastating cognitive sequelae of stroke. Well-defined classic aphasic profiles (anomia, Broca's, conduction, Wernicke's, and transcortical) are frequent when patients with only single lesions are considered [24], whereas global and nonclassified aphasias account for 50% of cases admitted to acute stroke units, especially among patients with previous strokes [25]. A difficult to ascertain proportion of aphasic individuals cannot easily be assigned to the classic

**TABLE 2 Recent Clinical Criteria in Dementia**

| Type of Dementia        | Criteria                                                                                                                                                                                                                                                                       |

| Dementia with Lewy body | The Consortium for DLB diagnostic criteria [19, 20]                                                                                                                                                                                                                            |
| Frontotemporal dementia | Frontotemporal lobar degeneration: a consensus on clinical diagnostic criteria [21]<br>Report of the Work Group on Frontotemporal Dementia and Pick's Disease [22]                                                                                                             |
| Vascular dementia       | The National Institute of Neurologic Disorders and Stroke and the Association Internationale pour la Recherche et l'Enseignement en Neuroscience (NINDS-AIREN) diagnostic criteria [23]                                                                                        |

*Note:* The clinical diagnosis should rely on criteria that have been proposed to increase the reliability and accuracy of the diagnosis. The accuracy of these diagnostic criteria varies as a function of the dementia.

syndrome categories, whereas others display atypical clinicoradiological correlations (e.g., Wernicke's aphasia associated with frontal lobe lesions), in part, a result of the idiosyncratic brain organization of language networks [26]. Indeed, other right-handed individuals show no aphasia despite having large lesions in the left hemisphere because in such cases language is innately lateralized to the right hemisphere [27]. However, functional imaging [functional magnetic resonance imaging (MRI)], mapping language brain areas, may currently theoretically provide means to improve the diagnostic accuracy by clinicians [28, 29].

In any case, it is now recommended submitting patient to baseline imaging evaluation before beginning trial [computed tomography (CT) or magnetic resonance imaging (MRI), within 6–12 months]. This is important to confirm the original diagnosis and order to exclude other concomitant pathologies (e.g., vascular impairment for degenerative dementia, brain tumor).

**Severity Criteria** Another relevant aspect to consider when planning a trial is the stadiation of disease that includes both temporal dimension and severity. In pharmacological trials stadiation is important because different phases of illness require different pharmacological approaches. For example, this is true for the treatment of AD: Literature data showed that cholinesterase inhibitors for AD treatment are useful in the mild-to-moderate phase and ineffective in the severe stage. On the contrary, memantine, an *N*-methyl-D-aspartate (NMDA) antagonist, is approved for the treatment of moderate to severe AD. Predefined severity criteria should be made explicit in future trials to ensure transparency with regard to comparability and general applicability of results.

**Cultural and Educational Background** Cultural and educational background of the population under study is another relevant characteristic to hold in consideration. Really, cognitive and behavioral measures are particularly vulnerable to the effect of culture, language, and education. The relevance of some domains may

vary between cultures; functional disability, for example, may be less important in cultural contexts where independence and autonomy in activities of daily living are not part of the older person's role [30]. Similarly, memory impairment is not regarded as important in all cultures [31]. Moreover, the recruited subjects must have the same range of years in age and in school attendance. The age and school attendance setting is an essential requisite for making a comparison between different group performances on assessment tools.

**Baseline Safety Evaluation** Regardless of the drug that we want to try, it is also essential to assess adverse effects of treatment in order to determine the risk–benefit ratio. For this reason, it is well advised to have a safety assessment that at least includes laboratory examinations (hematology and urinalysis) and an electrocardiogram (ECG). Further clinical or instrumental evaluations before starting and during trial are established in accordance with the preliminary safety data of the drug to try.

#### 10.14.2.2 Particular Criteria

**Population with Dementia** In patients with dementia some aspects are typical, and they must be kept in mind before starting the clinical trial. The power of clinical trials in dementia is significantly reduced by diagnostic inaccuracy; therefore, there is a tension between requirements for diagnostic accuracy and the necessity for clinical trial results to be generally applicable to the clinical population that might subsequently receive the intervention.

First, it is well recognized that diagnostic accuracy and the detection of treatment effects may be easier to attain in moderate than in mild dementia, but the potential benefits of disease modification are likely to be greatest in the early or prodromal stages. Earlier intervention with disease-modifying therapies is likely to be more effective when there is a lower burden of amyloid and hyperphosphorylated tau and may truncate the devastating effects of secondary events due to inflammatory, oxidation, excitotoxicity, and apoptosis. Also for this reason revised research criteria for AD [National Institute of Neurologic, Communicative Disorders and Stroke–Alzheimer Disease and Related Disorders Association (NINCDS-ADRDA) research criteria; [5]] are now available. These new criteria would allow diagnosis when symptoms first appear, before full-blown dementia, thus supporting earlier intervention at the prodromal stage. They are centered on a clinical core of early and significant episodic memory impairment, and they stipulate that there must also be at least one or more abnormal biomarkers [among structural neuroimaging with MRI, molecular neuroimaging with positron emission tomography (PET), and cerebrospinal fluid analysis of amyloid  $\beta$  or tau proteins]. However, these criteria require significant expertise, technical skills, and financial resources to allow the comprehensive assessment of MRI, PET, and cerebrospinal fluid, and this diagnostic framework may not yet be feasible in all memory clinics and certainly not in most epidemiological studies and all clinical trials: The research criteria will need to be adapted for use in standard clinical settings.

The appearance of these criteria, however, could overcome problems encountered in clinical trials targeting MCI population, where the clinical heterogeneity of patients with this diagnosis makes the demonstration of clinical effects of a drug very difficult.

A second aspect to consider is the coexistence of several pathologies in these patients given their old age. Indeed, dementia onset is most often situated in old age (subjects who are 65 years old or more), and it is common knowledge that age is an independent risk factor for other pathologies (hypertension, diabetes, depression, etc.). Therefore, it would be necessary to exclude those conditions that may adversely affect the cognitive domain and/or giving safety problems. However, it is important to avoid a hyperselection of the study population in order to obtain a group of subjects similar to the general patient population, that is, patients seen in everyday clinical practice. This is also important to avoid insurmountable difficulties in recruitment.

Another point to consider is the common presence in dementia of behavioral and psychological symptoms [Behavioral and Psychological Symptoms of Dementia (BPSD) or neuropsychiatric symptoms; [32]]. These disturbances are distressing, present major difficulties for caregivers, and accelerate nursing home placement [33]. For these reasons antipsychotic drugs are commonly prescribed to many people with dementia (up to 45%) in residential or nursing homes but also at home, often for prolonged periods. However, studies reported that antipsychotics have a negative impact on cognition in patients with dementia [34, 35]. Even though it would be appropriate to exclude patients treated with these drugs from clinical trials, also in this case it is important to avoid a population hyperselection in order to reproduce as much as possible the real clinical situation in everyday practice. Therefore, you can evaluate whether to include patients in some specific cases: when the patient assumes a low dose of benzodiazepines with hypnotic purpose or when he has been in steady therapy with antidepressant for at least 6 months. Furthermore, it is possible to consider in some specific trials the sporadic use of low doses of neuroleptics (e.g., haloperidol).

Approaching dementia, another critical aspect must be well known: the mixed dementia. Mixed dementia, a combination of definite AD and vascular encephalopathy, is a controversial but important issue to consider given the frequency of this condition in the oldest patients. In particular, it is unclear how many vascular lacunar lesions are compatible with a diagnosis of AD (generally it is considered only one), taking into account that isolated leukoariosis is not considered an exclusion criteria for the diagnosis of neurodegenerative diseases. In the future, it could be useful to include into pharmacological trials also patients with mixed dementia.

### ***Population with Cognitive and Behavioral Deficits after TBI and Stroke***

Different than in dementia, several cognitive and behavioral clinical situations can occur following TBI or stroke, depending on the degree and type of brain injury. The variability of pretraumatic and prestroke brain function further adds elements to the clinical complexity. For example, although some brain structures are more vulnerable in TBI than others, the vast heterogeneity of the TBI patients is likely

to cause high variability in the therapeutic response to any agent. Moreover, a certain cognitive symptom may have a variable biochemical background. For example, apathy and poor initiation may arise from deficits in the dopaminergic, serotonergic, noradrenergic, or cholinergic systems or from an imbalance between these systems. At the clinical level, however, the manifestations may be very similar.

Therefore, in order to evaluate the efficacy of a pharmacological treatment in these patients, it is important to choose the population using stringent and accurate multicriteria. These criteria can be both clinical (e.g., clinical presentation at the neurological examination: neglect, aphasia, etc.) and founded on neuroimaging findings (injury level established by CT or MRI examination). Functional imaging, in particular, may theoretically provide means to evaluate the basis for treatment interventions [36], but for practical and economical reasons it seems unrealistic that, at an individual level and at larger scale, we could effectively use such tools for treatment decisions in the foreseeable future.

Another important point is that, since the damage can occur at any age, age is an important prognostic factor, and the recovery can be different between several patients, it is necessary that patients recruited for the trial are similar not only in the demographic characteristics (age, sex, and education) but also as far as premorbid conditions are concerned (e.g., it is necessary to exclude preexisting psychiatric or substance abuse problems, poor general health). The same can be said for comorbidities (such as chronic pain, depression, substance abuse, life stress, unemployment, and protracted litigation). The use of poorly matched experimental and control groups increases the likelihood that neuropsychological group differences will reflect premorbid group differences rather than the effect of damage postinjury. Moreover, it is of primary importance the good knowledge of TBI clinical details (e.g., duration of posttraumatic amnesia, coma duration, patient level at the Glasgow Coma Scale). Clearly, according to previous cited common criteria, another relevant aspect to consider is the stadiation of disease: temporal dimension postinjury and severity of the pathology at the time of the enrollment. The temporal dimension postinjury is relevant: The overall effect size for the influence of mild TBI on neuropsychological functioning, for example, in the *postacute* phase (more than 3 months postinjury) is very different than in the *acute* phase. Indeed, in a meta-analysis on neuropsychological outcome following TBI, Schretlen and Shapiro [37] concluded that mild TBI results in clear decrements in cognitive functioning that resolve in 1–3 months. In contrast, they illustrated that patients with moderate or severe brain injuries show clear evidence of early recovery but they are at risk for frank deficits more than 2 years after injury. Moreover, studies of spontaneous recovery in poststroke aphasia have shown that the greatest improvement occurs in the first 2 or 3 months, with a discernible but less evident improvement in the following months, and most patients reaching a plateau after 1 year [38]. If the stability of cognitive sequelae is ascertained, TBI and stroke survivors can be candidates to cross-over studies and not only to classical prospective clinical trial. This is not possible in dementia due to the progressive nature of the disease.

To evaluate the severity of TBI pathology at the time of the enrollment, specific scales are actually available to establish a global cognitive evaluation of the patients. They are also useful to provide follow-up and comparison of the patients [e.g., Rancho Los Amigos (RLA) Levels of Cognitive Functional Scale for TBI].

### 10.14.3 ENDPOINT SELECTION AND ASSESSMENT TOOLS FOR EFFICACY AND SAFETY EVALUATION

#### 10.14.3.1 Efficacy Evaluation

Dementia, stroke, and TBI are multifactor disorders that negatively impact cognitive, behavioral, and functional abilities. Complete and accurate evaluation of the efficacy of treatments is crucial, but the heterogeneity of symptoms makes uniform assessment difficult. Due to the complex nature of these diseases, it is crucial to design assessment procedures that accurately track disease progression across a wide variety of symptom domains. Although a number of outcome measures have been developed for this purpose, it is suitable to use the diagnostic tools that have sensibility, specificity, and relevancy enough to test modifications of estimated characteristics (primary and secondary endpoints). Generally, primary outcome measures assess key pathology domains (such as cognition, function, global impression, and quality of life in dementia), while secondary endpoint measures assess other meaningful and measurable domains, which may constitute appropriate targets for interventions (e.g., caregiver outcomes, behavioral measures, activity of daily living).

These assessment tools must be based on reliable and validated scales and scores and must be usable in many settings. Ideally, the administration of the instrument should be brief; however, many of the measurement tools used in clinical research take too much time to administer to be employed in clinical settings.

**Dementia** The goals of treatments in this field can be to prevent dementia emerging in patients with MCI, or, in those with established dementia, to evaluate improvement and stability versus deterioration. The outcome measures used to evaluate efficacy of dementia treatments should be sensitive to both improvement and decline and have minimal floor and ceiling effect [39]. The primary outcomes include key domains of dementia: cognition, function, global impression, and/or quality of life. Secondary measures assess behavioral ratings and other outcomes such as nursing home placement, caregiver burden, and others.

Table 3 shows the principal primary and secondary outcome measures used to evaluate efficacy in dementia treatments. For MCI patients, one of the primary outcome measures should be the conversion to dementia, that is, how much a drug is able to reduce the absolute and relative risk of conversion. However, this is a critical primary endpoint to evaluate, due to difficulties in establishing when the individual patient exactly passes the threshold of dementia (it basically depends from loss of independence in everyday life), and to the necessity of planning a long-term study to catch enough cases of conversion to dementia (at least 2 years).

#### 10.14.3.2 Cognitive Tools

The cognitive tools should provide an assessment of multiple cognitive functions that are affected by dementia (memory, orientation, language, frontal abilities, praxis, and others), plus a measure of global cognitive decline. The Alzheimer's Disease Assessment Scale–Cognitive subscale (ADAS-Cog) is the de facto standard primary outcome neuropsychological measure for AD trials [40]. It measures several

**TABLE 3 Primary and Secondary Outcomes Used to Evaluate Efficacy in Dementia Treatments (see text for further details)**

| Outcome                               | Scale                                                                                                                                                                                                                                                                                                                                    |

cognitive domains, including memory, language, and praxis. Total scores range from 0 to 70, with scores greater than 40 indicating severe impairment and a score of 10–25 indicating mild impairment. Many regulatory authorities recognize a four-point change on the ADAS-Cog at 6 months as indicating a clinically important difference [41–44]. Interestingly, the ADAS-Cog scale has the advantage of having parallel forms that avoid learning as a confounding factor. Unfortunately, it has limitations that are worth noting. The first of these is important when comparing results in different kinds of dementia. Since the ADAS-Cog is an assessment designed for AD, other dementias require the use of further neuropsychological instruments to assess the cognitive domain particularly affected in that specific type of disease. In patients with frontotemporal dementia, for example, frontal abilities that are specifically involved should be investigated (e.g., with the Frontal Assessment Battery [45]); in patients with Lewy body dementia, visuospatial deficits and cognitive fluctuations should be taken into consideration (for visuospatial deficits, several tests exist to evaluate visuoperceptive or visuospatial abilities, for example, some subtests of the Birmingham Object Recognition Test and the Benton Line Orientation Test, respectively; For the latter, short forms are also available [46]; cognitive fluctuations should be evaluated with specific questionnaires, such as the DLB fluctuation scale by Ferman et al. [47]).

The ADAS-Cog takes 30–45 minutes to administer; therefore it is widely used only by researchers. On the contrary, Mini-Mental State Examination (MMSE; [48]) is a brief cognitive screening tool that only takes 5–15 minute to administer. Therefore, it is used both in research and clinical settings.

As previously noted, the measures should be sensitive to disease progression over time and useful for a broad range of severity. Another limitation of ADAS-Cog is that there is a floor effect in severe AD patients [49]. For this reason, this scale is

not generally used to evaluate the cognitive changes in advanced patients, and the Severe Impairment Battery (SIB; [50–52]) is currently the most accredited instrument for tracking progression in severely demented patients [53]. The SIB includes six subscales (attention, orientation, language, memory, visual perception, and construction) and a brief assessment of social skills, praxis, and response to name. Total score ranges from 1 to 100, with a score of 63 or less being considered “very severely impaired”; this battery provides accurate assessment in patients with MMSE scores of 13 or less [54]. Like the ADAS-Cog, the original SIB is a long tool to be administered to the patient (it takes approximately 30 minutes). For this reason, a short form of the Severe Impairment Battery (SIB-S) has been developed that only takes 10–15 minutes to administer, making it more appropriate for the use in clinical pharmacological trials in patients with very severe dementia, while it maintains the attributes of the original SIB [55].

### 10.14.3.3 Outcome Measures of Function

Outcome measures of function are other important data to collect in order to demonstrate the efficacy of a drug in clinical pharmacological trials. Loss of functioning in complex tasks of everyday life is a hallmark feature of dementing illness: In fact, current clinical diagnostic criteria for dementia [17, 18] require documentation of cognitive decline as well as loss of competence in either social or occupational domains. Furthermore, measures of function allow clinicians to assess the need for personal and institutional care, and to design individually tailored interventions, so that a demented individual receives sufficient help while avoiding unnecessary assistance that may lessen patient self-esteem, increase caregiver burden, and accelerate functional deterioration. The ability to perform activities of daily living (ADLs) has a significant impact on the patient, caregiver, and society. Among the functional disability scales based on patient or informant response, we can distinguish generic tools.

Generic scales are designed to measure function regardless of the person’s specific medical history: With these scales, the disability of a patient with dementia can be compared with the disability of a patient with arthritis, for example. This type of tool evaluates basic ADLs (BADLs) and/or instrumental ADLs (IADLs). IADLs include activities that concern the ability to adapt to the environment: Some of these activities (such as telephone usage, financial management, and shopping) are particularly dependent on cognitive functioning, and often serve as earlier predictors of poor outcome; this subset of IADLs is known as advanced cognitive IADL [56]. The most popular generic BADL scale is the Katz ADL scale [57]: This measure of basic functioning requires an observer to rate the patient’s ability in bathing, dressing, going to the toilet, transferring, maintaining continence, and feeding. The most commonly used IADL scale is the Lawton IADL scale [58].

This last one includes eight items: telephoning, shopping, meal preparation, housekeeping, laundry, transportation, medications, and handling finances. A problem with the Katz IADL is that the original version of this scale uses all items for women and only five tasks for men (three items are removed for men to avoid tasks that men did not usually perform because of societal norms associated with the division of labor in household management: But these norms are changing in the last decades). A low performance in IADL scales is associated with mild

dementia, while ADL deficits characterize more severe dementia [59]. Although, measuring ability to perform ADLs and IADLs is important when assessing the therapeutic efficacy of a drug, these scales are very poorly sensitive to change, and these generic scales have been criticized for a relative insensitivity to functional losses due to cognitive impairment [60]. Therefore, alternative tools should be identified, such as more detailed functional scales or other performance instruments.

The most popular specific informant-based scales are the Blessed scale [61], the Nurses' Observation Scale for Geriatric Patients [62] (it includes a subscale specifically designed to assess IADLs, but this last one contains only five items), and the Alzheimer's disease activities of daily living international scale (ADL-IS) [63]. The ADL-IS was launched to develop an ADL scale aimed to measure pharmacological response in AD patients [63]; it was carefully developed in a 10-year period and covers a large sample of ADLs. It shows high correlations with measures of cognitive functions and stage of dementia, thus appearing a promising tool also for clinical setting. However, clinical experience with this scale is still limited. It must be added that the use of informant reports is appealing because it can allow comprehensive and longitudinal evaluations but has potential disadvantages: The source of information is filtered through an observer, and it may contain distortions based on the personal needs and opinions of the informant [64]. For this reason, in the last years, some performance measures of everyday functioning have been proposed to assess demented patients.

Performance measures are tools in which an individual is asked to perform an activity and is evaluated in a formal manner on that performance with standardized criteria (counting, timing, observation of the need for assistance, and appropriateness or completeness of the task). These measures have been used in medical rehabilitation for diagnosis and to demonstrate therapeutic progress, and have shown to predict survival, hospitalization, use of assistance, long-term-care, and nursing home placement [65–69]. The main advantage to this approach is that it directly measures ability, thus eliminating faulty perceptions. Moreover, with performance measures it is possible to take into account a large variability of the ability to perform a task, thus increasing the sensitivity of the tool [70]. Other claimed advantages are good patient acceptability and good interrater reliability [68, 71–73]. Examples are the ADL Situational Test (AST; [74]), the Physical Performance test (PPT; [72]), the Structured Assessment of Independent Living Skills (SAILS; [73]), the Direct Assessment of Functional Abilities (DAFA; [75]), the Everyday Problems Test for the Cognitively Challenged Elderly (EPCCE; [76]), and the Direct Assessment of Functional Status (DAFS; [71]). In the AST [74], evaluation is limited to one BADL (dressing) and three IADL (meal preparation, telephoning, and purchasing), each ADL item broken down into subtasks. For each item there are two scores: the time required to complete each ADL task and a performance score derived from the level of assistance needed by the subject to complete the task.

As far as the PPT [72] is concerned, this tool has been proposed to evaluate a general geriatric population rather than patients affected by dementia. The test includes some motor activities, three BADLs (eating, dressing, and walking), and writing a sentence. Therefore, IADLs are not evaluated in the PPT.

The DAFS [71] features mainly IADL skills (communication abilities, transportation, financial skills, shopping skills), along with two BADL skills (eating and

dressing/grooming skills), and time orientation. Performance is rated as correct or incorrect. The DAFS, which represents an interesting tool, but it explores only four IADL skills and does not define the degree of dependence of the patient.

The SAILS [73] includes a subset of BADL (dressing, eating) and IADL (meal preparation, telephoning, and money-related skills), as well as fine and gross motor tasks, and high-order abilities (communication, social interaction, and orientation). Each item includes five subtasks. Each subtask is scored from “unable” to “normal,” with an intermediate level of disability, with both time (on timed tasks) and accuracy (in all tasks) contributing to the score.

The DAFA [75] is a direct measure of IADLs conceived to be compared with the Pfeffer Functional Activities Questionnaire (PFAQ; [77]). Ten items are adapted to explore seven functional domains: money management, shopping, hobbies, meal preparation, awareness, reading, and transportation. Items on the DAFA and PFAQ are both evaluated by using an integer score from 0 (independent functioning) to 3 (dependent functioning).

Finally, the EPCCE [76] has been specifically designed to provide an objective measure of problem solving with respect to cognitively demanding tasks encountered in daily livings. The patient is shown 16 stimuli and asked to solve two problems related to each stimulus. Each item is scored right or wrong. The authors propose the EPCCE as a complement to other performance measures (e.g., the DAFS). These performance instruments, for example, the DAFS, represent interesting tools, but it must be recognized that these instruments could show some limitation in terms of applicability because of different sociocultural backgrounds and temporal bias (the amount of time required to administer the scales).

Our group has developed a new direct performance measure for very mild to moderate patients with dementia: the Functional Living Skills Assessment (FLSA; [78]). Eight areas of interest are evaluated (resources, consumer skills, public transportation, time management, leisure, telephone skills, self-care, and health). Performance is scored according to completeness and level of assistance. We propose its use when a high sensibility to different levels of functional impairment is needed, as evaluation of treatment efficacy, diagnosis of dementia in the very initial phase, and identification of relatively intact functional areas to plan cognitive rehabilitation.

#### 10.14.3.4 Global and Quality-of-Life Measures

Global measures are one of the most important data used in clinical pharmacological trials. Global assessment scales assess whether treatment effects are clinically meaningful and whether a given agent leads to a change, and they appear to be one of the principal modality to detect changes in mild cognitive impairment patients. The global scales encompass two distinct categories: first, the clinician’s interview-based global severity scales, and, second, the clinician’s interview-based global change scales [79]. The Clinical Dementia Rating (CDR; [80]) and the related CDR-sum of boxes (CDR-SB), the Global Deterioration Scale (GDS; [81]), and the Functional Assessment Staging (FASTM; [82]) procedure are the global severity scales most often used in clinical trials. These measures are clearly useful in subject categorization in treatment trials (they are relatively free of many of the sociocultural biases inherent in psychometric descriptors and psychobehavioral measures).

They can also be used to demonstrate therapeutic efficacy in terms of the general progression of the dementia process and have also proven to be useful in sensitively assessing pharmacotherapeutic effects in AD treatment trials.

On the other hand, the most popular clinician's interview-based global change scales are the Clinician's Interview-Based Impression of Change (CIBIC; [83]) and the Clinical Global Impressions of Change (CGIC; [84]). With the CIBIC the clinician assesses four areas of patient functioning (general, cognitive, behavioral, and ADLs) by interviewing the patient. Another version of this scale is also available: the Clinician's Interview-Based Impression of Change Plus Caregiver Input (CIBIC-Plus; [85]), which is much more elaborate and includes information derived from caregiver input. In both versions, disease severity is assessed at baseline, and the rate of change from baseline is assessed at each follow-up examination. Score ranges from 1 to 7, where a score of 1 indicates marked improvement, a score of 4 indicates no change, and a score of 7 indicates marked worsening. The CIBIC-Plus procedures require an independent clinician assessment and can provide independent, comprehensive evidence of therapeutic efficacy. The CIBIC-Plus procedures may also be useful in sensitively assessing efficacy in prevention trials (e.g., MCI therapeutic trials, and perhaps in future trials with people referring subjective cognitive complaints).

The CGIC assesses cognitive, behavioral, social, and daily functioning domains, allows for caregiver input, and provides a minimal number of sample probes to guide clinicians in their assessments. Although CIBIC and CGIC are useful global measures, the lack of structure of global assessment reduces the interrater reliability, and it can be difficult to compare these measures across drug studies [84]. Assessment terms, such as "minimal improvement," are not well defined, and the rating of change by the clinician is a subjective measure that can be prone to biases (e.g., the clinician's perception of what constitutes change; sources of information about the patient; how information is recorded; the tests used to assess cognitive functioning; how the change is rated) [83, 86].

Dementia is one of the main causes of decreased quality of life (the degree of need satisfaction within the physical, psychological, social, activity, material, and structural area) [87] among older adults. Quality of life is recognized as an abstract and broad concept encompassing physical well-being, perceptions of well-being, satisfaction, and sense of self-worth. Actually, a substantial number of researchers agree that measuring quality of life is just as important as measuring cognition, disease severity, symptom response, behavioral disturbance, functional abilities, caregiver burden, and resource utilization [88]. Currently, the consensus group for measuring treatment benefits in dementia [89] have indicated that an improvement in quality of life could be an acceptable alternative to global improvement and have identified a number of other meaningful and measurable domains that may constitute appropriate targets for interventions (caregiver outcomes, including psychological consequences and time spent in delivering care, BPSD, quality of life, activities of daily living, global assessment, health utility, and health care costs). Furthermore, quality of life is mentioned as one of the primary outcomes of interest in dementia drug trials in a recent Cochrane update on cholinesterase inhibitors for AD [90].

However, quality-of-life scales are used as outcome measure in only 4.4% of all dementia/MCI-related randomized controlled trials [91]. Quality-of-life measures

cover a range of domains: physical status, functional ability including role functioning, social and community interactions, economic status, psychological status, well-being, somatic sensation, and life satisfaction [92, 93]. The most frequent quality-of-life measures applied in pharmacological trials in dementia or MCI are the Quality-of-Life–Alzheimer Disease Scale (QOL-AD), the patient-rated scale according to Blau (PRB), the Late-Stage Dementia scale (QUALID), and the Goal Attainment Scaling (GAS). Other currently used scales are the Dementia Care Mapping (DCM), the Alzheimer Disease Related Quality-of-Life scale (ADRQL), the Dementia Quality-of-Life scale (D-QoL), the psychosocial domain of the Functional Limitation Profile (FLP), and the European Quality-of-Life scale (Euro-QoL) (for the review of these tools, see [94]). Rating of quality of life in dementia trials, three methods are generally used: self-rating (patient-reported outcomes), proxy rating, and proxy observation scales. Patient-reported outcomes (including measures of subjective symptom report, health-related quality of life, and treatment satisfaction) are unique indicators of disease activity, complementary to established outcome measures [95]. Persons with MCI and mild to moderately severe dementia can be considered good informants of their own subjective states. At more severe stages proxy measures or direct observation may be preferred. The disadvantage of proxy ratings is that they represent a subjective measure, passed throughout the filter of the caregiver's own expectations, mood, burden of care, and the specific relationship with the person being rated [96–98]. In case a patient-reported outcome is impossible, observational evaluation by an uninvolved professional caregiver is the best alternative [96].

#### 10.14.3.5 Measures of Neuropsychiatric and Behavioral Changes

Clinicians are now aware that neuropsychiatric symptoms (also known as BPSD) are very common and diverse, and that scores on specific symptom clusters, such as measures of affect, apathy, and psychosis, may be more meaningful than an overall score [99]. BPSDs are distressing, present major difficulties for caregivers, and accelerate nursing home placement. These concepts need to be further developed to facilitate valid measurement of treatment effects on specific symptoms or domains. The measure of neuropsychiatric symptoms and behavioral changes most commonly used in dementia trials is the Neuropsychiatric Inventory (NPI; [100]), which assesses 10 common BPSD areas (e.g., delusions, irritability, disinhibition, agitation, sleep disorders) through an interview with the patient's caregiver. The frequency and severity of each behavior is measured, as well as the resulting caregiver distress. Each behavioral domain score ranges from 0 to 12, with a total NPI range of 0–120 (a score of less than 20 indicates mild disturbance; a score ranging from 20 to 50 indicates moderate disturbance; and a score superior to 50 indicates severe disturbance). The NPI takes approximately 10–15 minutes to administer; therefore, it is used both in research and clinical settings. A subscale of the Alzheimer's Disease Assessment Scale (ADAS-non-Cog; [40]) and the behavioral pathology in Alzheimer's disease rating scale (BEHAVE-AD; [101]) are other global neuropsychiatric measures used in AD trials. The ADAS-non-Cog assesses 10 domains (e.g., hallucinations, delusions, depression, power of concentration) and the score range is from 0 to 50 (maximum of deficits). The BEHAVE-AD is a good measure in clinical pharmacological trials to follow up the efficacy of behavioral

drug treatments, taking into account behavioral changes independent from cognitive deficit.

Depression is a relevant psychiatric symptom in dementia, and it may deserve a specific evaluation: the Cornell Geriatric Scale, for example, is a useful scale specifically conceived to detect depression in patients affected by dementia [102].

Because specific neuropsychiatric symptoms vary in prevalence between the different forms of dementia, in clinical trials recruiting non-AD dementia patients, other instruments conceived to evaluate particular neuropsychiatric and behavioral areas according to the dementia type can be selected between the different options offered by the dementia literature.

#### 10.14.3.6 Other Measures: Outcomes Specific to Caregivers

Measures of caregiver-related outcomes are various and are useful measures as endpoints for AD and related disorders studies. In clinical trials burden and time used to assist the patient represent the most extensively examined outcomes specific to caregivers, followed by other caregiver-specific variables (such as psychological well-being, health care costs, and satisfaction with treatment) and other caregiver-dependent outcomes (institutionalization, proxy survey of interview).

Burden outcome is generally reported using the Neuropsychiatric Inventory Distress rating (NPI-D; [103]) or more global measures of burden included in the Caregiver Burden Inventory (CBI; [104]), the Screen for Caregiver Burden (SCB; [105]), and the Caregivers Stress Scale (CSS; [106]). The NPI-D measures distress in response to 10 behaviors (e.g., delusions, agitation, apathy, disinhibition, sleep disorders) exhibited by the patient.

The CBI, SCB, and CSS are measures based on a conceptual model of stress of caregivers of patients with AD. The CBI is a 24-item, multidimensional 5-subscale (e.g., it measures time, dependence burden, and developmental burden) instrument to evaluate the impact of providing care to AD patients on family members' life. The SCB is a 25-item assessment of subjective and objective burdens that has been validated against a theoretical model of caregiver stress. The CSS is a 15-domain assessment that targets caregiver's primary stressors (e.g., cognitive and behavioral symptoms), secondary role strains (e.g., family conflict), secondary intrapsychic strains (e.g., role captivity, loss of self), and mediators (e.g., management of situation, expressive support). Other burden instruments include the Relatives' Stress Scale [107], which measures caregivers' personal distress, life upset, and negative feelings associated with the caregiving role, and the Cognitive Subscale of the Poulshock and Deimling tool [108], which assesses distress responses to care recipient cognitive symptoms.

Another outcome specific to caregivers is the "time use": caregivers' time spent assisting patients to perform basic or instrumental activities of daily living. Generally, the active time used by informal caregivers is examined, and the estimations of passive care time is reported (time providing supervision but not engaging in a task per se), and of paid care time. Measures of time use includes the Allocation of Caregiver Time Survey [109] and the Caregiver Activity Time Survey [110]. Both measures assess the amount of time spent assisting the patient in activities of daily living. Similarly, the Instrumental Activities of Daily Living Scale-Plus [57], the Physical Self-Maintenance Scale Plus [111], and the Resource Utilization in Demen-

tia questionnaire [112] generate caregiver estimates of the time spent providing such instrumental activities of daily living and self-care assistance.

Although caregiver outcomes generally represent secondary endpoints in AD and related disorders, drug development, with little time and effort information derived from such instruments, could be considerably improved. In order to implement and enrich the quality and interpretability of dementia clinical research with caregiver-specific outcomes, some recommendations are useful to remember. According to Lingler et al. [113], we suggest that investigators should specify entry criteria for caregiver study participants and should collect basic caregiver sociodemographic data (caregiver sociodemographic characteristics—sex, relationship to patient, and age, years caring for the patient, primary or secondary caregiver status, caregiver marital status if a child, co-residence with the patient and other relatives, caregiver ethnicity, income, physical, and mental health status, level of social support). This will aid in the interpretation of data about drug effects on caregiver measures and data about proxy-dependent patient effects. It will also facilitate the identification of variables influencing such effects, and it will allow researchers to investigate not only whether the benefits of antidementia drugs extend to caregivers, but also to what type of caregiver (e.g., spouses or children) and under what circumstances.

#### 10.14.3.7 New and Future Measures

In the past two decades much progress has been made in refining our understanding of the neurobiology and clinical phenomenology of dementia, particularly in Alzheimer's dementia (see new research criteria for Alzheimer's disease [5]. Actually, several "candidate" biomarkers for diagnosis, severity, progression, or prediction of response are recognized (e.g., structural brain changes visible on MRI with early and extensive involvement of the medial temporal lobe in AD, molecular neuroimaging changes seen with PET with hypometabolism or hypoperfusion in specific areas, and changes in cerebrospinal fluid biomarkers). Volumetric neuroimaging, which seems particularly promising as a measure of progression, and markers of oxidative stress may also become useful. Biomarkers may be informative indicators of the mechanism of action of novel treatments or may help identify potential responders (possible strategies to facilitate work in this area in the future include stratification of study populations to identify predictors of response such as known or putative biomarkers, e.g., Apolipoprotein E—APOE—isoform ApoE- $\epsilon$ 4), but it would be considered as supplementary data to collect and not a proxy for clinically significant measures of treatment response.

***Patients with Cognitive and Behavioral Deficits after TBI and Stroke*** Currently, poor level of scientific evidence in treating the cognitive and behavioral deficits due to TBI is available. Future studies are necessary, and, in order to gather scientific evidence, selecting appropriate and reliable outcome measures is a critical issue. An important obstacle in scientific studies is the problem of how to measure cognition and behavior. It is well known that victims of TBI may show fairly good test performance, yet their everyday life is severely restricted or vice versa. In addition, pronounced fluctuation in daily functioning is a common sequel of TBI, reflecting the low cognitive reserve of the injured brain. The Functional Independence

Measurement (FIM) [114], a widely used index of rehabilitation outcome, measures the level of assistance that an individual requires to perform basic life activities. It is an 18-item, 7-level scale that rates the ability of a person to perform independently in self-care, sphincter control, transfers, locomotion, communication, and social activity. The total score is obtained by summing the partial scores, and it ranges from 18 (maximally dependent) to 126 (maximally independent). Two motor and cognitive subscales can be obtained by summing the 13 motor items (range 13–91) and the 5 cognitive items (range 5–35). The Rancho Los Amigos (RLA) Levels of Cognitive Functional Scale is another valid tool to measure global outcome in cognitive sequelae of TBI [115]. This scale was developed to use in the planning of treatment, tracking of recovery, and classifying outcome levels in TBI. There are 8 classification levels, ranging from no response (level I) to confused and agitated (level IV) to purposeful and appropriate (level VIII). It is an easy and simple to perform tool for the global cognitive evaluation of the TBI patients and an appropriate and valid scale as it can both provide follow-up and comparison of the patients.

Several cognitive and behavioral clinical situations can occur following stroke, depending on the degree and type of brain injury. We will consider in the text only poststroke aphasia as an example of cognitive sequela. While speech-language therapy actually remains the mainstay treatment of aphasia, there have been some attempts to introduce the use of pharmacological agents (piracetam, drugs acting on catecholamine systems—bromocriptine, dexamfetamine—and on the cholinergic system—donepezil—as therapeutic strategies in aphasia and other stroke sequelae (e.g., spatial neglect).

Currently, there is unanimous consensus that evaluation of aphasic deficits should be comprehensive to allow the planning of rational therapies [116]. However, there is less agreement regarding the language assessment methodology with debated problems about the different levels of analysis that should be implemented to formally assess language impairment. Some researchers [116, 117] recommend evaluation of groups of aphasic patients using standardized batteries. These batteries examine oral language, reading, and writing and combine the information gathered from different language subtests that assess spontaneous speech, comprehension, repetition, and naming to obtain a graphic profile of performance (e.g., Boston Diagnostic Aphasia Examination; [118]), overall scores of aphasia severity (e.g., Western Aphasia Battery, WAB; [119]), or measures of communicative ability (e.g., Porch Index of Communicative Abilities, PICA; [120]). The estimation of the initial aphasia severity and its clinical profile using standardized assessment batteries usually couple with mapping of lesion size. The overall score of these batteries are increasingly being used as primary outcome measures to estimate changes in the global level of performance after pharmacological treatments [121, 122].

The alternative position to evaluate aphasia is the neuropsychological approach. This approach examines the nature of both normal and abnormal language functioning in terms of current information-processing models. One of the assessment tools based on neuropsychological point of view is the Psycholinguistic Assessment of Language Processing in Aphasia (PALPA; [123]). The PALPA is useful for identifying the different clusters of linguistic impairment as well as the residual areas of strength in the aphasic patient. However, administration of the PALPA or

similar batteries is not always feasible because they are time consuming and not applicable to patients with severe aphasia. In recent years, there has been a growing convergence on the usefulness of both these two assessment approaches: The surface symptoms of aphasia and its global severity are better recognized using standardized aphasia batteries such as the WAB or PICA, whereas evaluations using the cognitive neuropsychological approach and tools such as the PALPA more appropriately assess the nature of language deficits [124].

Like in dementia, given that aphasia and cognitive-behavioral sequelae of TBI negatively affect quality of life, there has been increasing interest in developing reliable and valid assessment instruments in this field (e.g., Stroke and Aphasia Quality of Life Scale-39; [125]). Future studies also need to include psychiatric comorbidity as a predictive factor of outcome in these diseases because depression, anxiety, and social withdrawal can have a negative impact on rehabilitation, potential benefits of drugs treatment, and psychosocial functioning.

#### **10.14.3.8 Safety Evaluation**

Safety evaluation does not depart from the normal pharmacological trial procedures: Assessment of safety included reports of all possible adverse events, laboratory examinations (chemistry, hematology, and urinalysis), and vital sign measurements (electrocardiogram). Especially in the population affected by dementia, given the old age, it is important to monitor laboratory findings (renal and hepatic function, etc.) and possible cardiac adverse events by repeating electrocardiogram.

### **10.14.4 DURATION OF STUDY AND POSSIBLE BIAS IN TRIALS ON COGNITIVE IMPAIRMENT**

#### **10.14.4.1 Duration**

When performing pharmacological trials for cognitive disturbances, it is necessary to study the patient for a long time in order to detect changes. Recently, Cortes et al. [125], trying to determine the best duration of follow-up necessary to demonstrate the impact of new drugs in dementia, showed that changes undergone by AD patients under cholinesterase inhibitors after 6 months are not adequate to demonstrate the effect of a new treatment. The authors propose that an 18-month trial appear to have the potential to demonstrate clearly the effect of a new drug.

Even if previous randomized controlled trials were of limited duration (often 24 weeks) in order to contain costs and to not loose too many patients, and changes were statistically significant in some cases at 6 months, it is natural to think such a time span is far shorter than the duration of the disease. Therefore, the duration of a randomized controlled study should be at least of 9 or 12 months, with planned evaluations, in our opinion, every 3 months. In addition, it is possible to consider from the beginning an open extension of the randomized trial to obtain further data on patient evolution. Sure, a careful planning of the power of the study (i.e., of the number of patients necessary to demonstrate a treatment effect, calculated by taking into account previous data about the amplitude of the effect of existing drugs for cognitive deficits) is necessary, also taking into consideration the possibility to loose patients at the last follow-up evaluations.

#### 10.14.4.2 Possible Bias

A bias is a systematic error that alters the results of a study. We will have a bias when the population of treated patients is different from the control population, according to a characteristic that can change results in primary or secondary efficacy measures. To correctly evaluate drug efficacy, the two populations (treated patients and controls) must be identical in all their characteristics, with the exception of the experimental treatment. Possible confounders in studies on cognitive impairment may be, for example, age, education, severity of the disease, initial severity of trauma for TBI, lesion location for cognitive sequelae of stroke, comorbidity, or treatment with other drugs. The best way to avoid systematic bias is to perform an accurate randomization of subjects included in the study; randomization must follow the general rules, particularly it must be performed by a center that is external to centers involved in the study. Good randomization avoids selection bias. Another important system to avoid bias is to maintain the double-blind condition; this is not always possible, however, particularly when the drug has frequent and easily detected side effects (this was the case for interferon in multiple sclerosis trials). Sometimes it can be appropriate to perform stratification of the studied population according to main possible confounders before randomization: This is important also to identify subpopulations of patients who better respond to therapy. At the statistical level, it is indicated to perform analysis by covariating for different factors (e.g., treatment with other drugs to avoid execution bias, comorbidity, age, sex, education, center, and severity).

As in all drug studies, the intention to treat analysis allows maintaining advantages assured by randomization, and it avoids the introduction of systematic errors due to reduced compliance (which can be particularly problematic in cognitively impaired patients), that is, exclusion bias.

To avoid bias, it is also necessary to diversify the sources to recruit patients and controls. Actually, all pharmacological trials are multicentric; generally, centers of different countries are involved. This also allows to recruit a sufficient number of subjects for the study: Calculation of the study power is very important to avoid underscoring drug efficacy due to recruitment of an insufficient patient number. On the other hand, when considering standard statistical significance ( $p = 0.05$ ), we will find a casual association (and not an association due to treatment) once every 20 times. Therefore, it is necessary to limit the number of comparisons, which is the number of primary and secondary endpoints.

Other bias can derive from some deficiency of instruments used to evaluate efficacy. For example, measures of caregiver burden do not take into account some important variables, such as caregiver education, social status, relationship with the patient. (Is he/she a family member or a professional caregiver? Does he/she live with the patient?) Functional scales based on informant reports may be influenced by the same variables. Some cognitive instruments may not have parallel forms to avoid learning bias. Another bias can be represented by the interpretation bias: This arises when different stakeholders assign their individual values to the interpretation of the final results of randomized controlled trials. This can be a frequent bias in the particular domain of trials on diseases causing cognitive impairment, where really effective and satisfying treatments are lacking.

### 10.14.5 CONCLUSION

The field of drug trials in medical situations leading to cognitive impairment is a fascinating one. The population of patients who can potentially benefit from therapy is enormous. Actually, treatments available for AD are of limited efficacy, and they do not succeed in stopping cognitive deterioration and loss of function, or to significantly reduce caregiver and social burden. In other forms of dementia (with the exception of dementia with Lewy bodies, for which limited data indicate some efficacy of cholinesterase inhibitors) there is no treatment. Nearly the same can be said for long-term cognitive sequelae of TBI and stroke.

We need the pharmaceutical industry to invest its energy and financial resources in trials aimed at improving this sad situation. However, in order not to waste resources, it is necessary to plan very careful drug trials.

## 10.15.1 INTRODUCTION

Globalization increasingly characterizes the pharmaceutical industry. We see mergers and acquisitions within industry, rapid international information sharing, and emerging centers for drug discovery. With this, we see more urgency for international regulatory approval and marketing of pharmaceutical compounds. However, regulatory approval in a new region is generally not a simple matter of reciprocity. Practitioners and regulatory agencies have long been concerned with ethnic differences that may affect the optimal use of a medication in a new region, even if it is well understood in the original region. Agencies have understandable concerns about defining the indication, dose selection, product labeling, safety, tolerability, and monitoring of the medication in the new region. “Bridging studies” are one important mechanism for addressing these questions.

### 10.15.1.1 Are Ethnic Factors Real?

As an American working in Honolulu, Hawaii, arguably one of the world’s major cross roads for Eastern and Western cultural exchange, I have had the opportunity to participate in discussions regarding clinical pharmacology development programs with people worldwide. In these discussions, I hear two distinct schools of thought regarding “ethnic differences.”

One school maintains that ethnic differences are real and important considerations in evaluating new medications. For example, some see individuals composing Japanese society as unique and different from those in other societies, thus foreign data must be viewed with great caution. Support for this view comes from review of the historic and cultural differences between Japanese and Western societies, including differences in diet, average weight, expected life span, social homogeneity, and epidemiological patterns of disease. In addition, Japanese practitioners typically

utilized considerably lower doses of medications than their Western colleagues, even when using the same medication for the same indication. Data from controlled studies illustrating substantially different pharmacokinetic profiles in Japanese versus Caucasians for certain compounds, and differences in adverse event profiles in Japanese versus Caucasians for certain medications are cited to add scientific support to this perspective.

The other school asserts that there is no such thing as “ethnic differences.” This school maintains that “under the skin” all the world’s peoples are essentially the same, and that apparent ethnic differences can be explained on the basis of identifiable variables or individual differences. For example, Japanese have traditionally been smaller and lighter than Westerners and many apparent pharmacokinetic ethnic differences disappear once the profiles are adjusted for weight or percent body fat. Other differences can be largely explained by identifiable factors such as heterogeneity in hepatic cytochromes or other metabolizing enzymes, or known food effects and nutritional/dietary differences. This view is supported by data from controlled trials showing that individual intraethnic differences in pharmacokinetic profiles for many compounds are often greater than interethnic differences.

Which school is correct? In this chapter, we will discuss these issues and then revisit this question.

#### **10.15.1.2 What Are “Bridging Studies”?**

When considering two regions with ethnic differences, bridging studies are performed to facilitate approval of a medication in the new region after it has already been studied or approved in another region. A bridging study is defined as: “A supplemental study performed in the new region to provide pharmacodynamic or clinical data on efficacy, safety, dosage and dose regimen in the new region that will allow extrapolation of the foreign clinical data to the new region. Such studies could include additional pharmacokinetic information” [1].

The concept of a “bridge” is a useful metaphor. Physical bridges have long enabled people to travel and share goods and services across rivers and other natural barriers. Similarly, a bridging study provides data to members of the new jurisdiction, enabling them to interpret and apply data from the original jurisdiction. Especially if the results allow the new region to believe the drug will behave similarly in both regions, or at least reasonably similarly with a dose adjustment, the study creates a bridge allowing data from the first region to be used to support approval and labeling in the new region.

In their simplest form, bridging studies are clinical pharmacology studies done in healthy individuals or patients to compare the pharmacokinetic (PK) profile, safety and tolerability of single or multiple doses in subjects representing the new region, compared with subjects representing the original region. Such studies may be performed in either or both regions and are usually conducted in a relatively small number of participants, who may be “healthy” and “normal.” These studies are generally modeled after phase I studies performed in the United States and primarily determine if a dose adjustment is appropriate in the new region.

In the larger context, additional studies performed in the new region confirming pharmacokinetics and/or the efficacy, safety, and tolerability are also considered bridging studies if their design is based on data from foreign studies and their

purpose is to confirm or clarify the drug's behavior in the new population compared with the reference population. These studies are generally performed within the new region and enroll the target patient population. Their design is similar to phase II or phase III studies performed in the United States.

### 10.15.2 WHY DO BRIDGING STUDIES?

From a business standpoint, it is about saving time and money. The bridge allows a large body of existing safety and efficacy data to be used that would otherwise have to be re-created, allowing pivotal efficacy and safety studies in the new region to be smaller and shorter than they would be otherwise.

The key variable is the dose. Should the dose in the new region be the same, higher, or lower? Coupled closely with identifying the appropriate dose, product labeling and safety monitoring may be different in a new region, reflecting both the pharmacodynamic (PD) effects, definition of disease and identification of the target population, and the priorities and medical practices of the new region.

In this section, we will be mainly discussing the United States, the European Union (EU), and Japan, with primary attention to medications studied or approved in the United States and the European Union being considered for approval in Japan. To better understand the background for bridging studies, it may be helpful to review the cultural context for medical practice in Japan and the traditional Japanese approach to pharmacological research.

#### 10.15.2.1 Traditional Practice of Medicine in Japan and the United States

The practice of medicine in Japan has traditionally been quite different from that in the United States. Medical practice in the United States has long incorporated a fee for service system with multiple third-party payers, a competitive marketplace for drug pricing, and a physician–patient relationship based on considerable patient autonomy and expectation of information, second opinions, and informed consent.

Not so in Japan. Rihito Kimura, a Japanese bioethicist, summarizes as follows:

In the long tradition of Japanese medical practice, the Confucian notion of *jin* (benevolence) has been one of the most important ethical elements; medicine itself is known as *jinjyutsu* (the art of *jin*). Physicians, as conduits of *jin*, were required to act with benevolence toward their patients, and were responsible for the welfare of patients in a fiduciary (trust) relationship (Kimura, 1991a). It was obligatory to use medicine, a gift of benevolence, for the good of others even without payment. Physicians fulfilled their responsibility toward their patients and the patients' family members by acting in a paternalistic and authoritative way; the Japanese, nurtured in the Confucian ethos to respect law, order, authority, and social status, acquiesced without murmur to the superior knowledge of the physician. [2]

Kimura further notes:

It is important to note that owing to the character of Japanese society and its distinctive historical understanding of medicine and the role and responsibilities of the physician, it was not until the 1960s that the bioethical and sociolegal concerns about the practice

of medicine began to be deliberately reflected in Japanese society, and only during the 1980s that the notions of autonomy and rights in medicine, and of bioethics in general, became gradually influential. [2]

In addition to these cultural factors and relationship patterns, Japanese medical practice also often incorporated acupuncture and herbal medications. A universal health insurance covered most medical services and medication prices were standardized centrally.

#### 10.15.2.2 Pharmaceutical Development in Japan

The traditional approach to pharmaceutical development in Japan reflected their cultural and dynamics of health care delivery in general. Trials were generally performed under the direction of a chief investigator who wrote the protocol and reviewed the data. It was not until 1980 that the Pharmaceutical Affairs Law (PAL) included an explicit clause regulating clinical trials, including the sponsor's obligation to submit a clinical trial plan, and the minister's authority to instruct sponsors to modify the trials to avoid possible health hazards.

Even still, investigators were allowed to enroll subjects with oral rather than written consent, the discussion about possible adverse events was generally abbreviated (by Western standards), protocols were not routinely reviewed by independent ethics review boards, sponsors and auditors were not allowed access to the original source documents to establish data validity, accountability for investigational products at the trial site was informal, and reporting of adverse events was essentially up to the investigator. Studies were usually done without much if any support from clinical research coordinators, research nurses, and data management staff.

These practices changed in 1998 when the Japanese regulations were revised to meet the standards of the International Conference on Harmonisation (ICH) on good clinical practices (GCP) regulations, reflecting pharmaceutical development practices in Europe and the United States.

For cultural reasons, incorporation of the new regulations was particularly difficult regarding obtaining written informed consent, and enrollment of subjects decreased dramatically for several years. Japanese people were not accustomed to making a written contract for their daily activities, especially regarding health care. Physicians were accustomed to making patient care decisions, and many patients were more comfortable letting physicians do whatever they thought was right rather than being informed fully and being asked to make a decision themselves. In particular, Japanese people are sensitive about possible side effects of drugs. A full description of the major undesirable possibilities is not usual in daily medical practice in Japan, thus the tendency is to refrain from study participation after seeing these in written form, even though the risk is small.

Obtaining informed consent presented a dilemma for Japanese researchers. Although they recognized the importance, obtaining consent is not common in daily medical practice and contradicts the traditional doctor–patient relationships deeply rooted in the culture.

Furthermore, study participation often lacked incentives. With universal health insurance coverage, study participation did not necessarily provide services otherwise unavailable and instead required more frequent visits, procedures, and

observations than normal treatment. Stipend payments for study participation have only been recently introduced. In general, there were negative perceptions regarding study participation, rather than seeing study participation as an opportunity to contribute to society and thus an honorable duty, such as donating blood.

#### 10.15.2.3 Safety Versus Efficacy

Both safety and efficacy are important everywhere. But traditionally, there is a different cultural emphasis on safety versus efficacy in Japan compared with the United States. While Americans want safe medications, the cultural bias also insists “give me something that works,” with high interest in efficacy. If there are potential adverse effects, most individuals are willing to weigh these risks (once properly advised) against the expected benefit.

In Japan, it is almost the opposite. While they want effective medications, both providers and patients highly desire to avoid anything that could make them worse. As a cultural practice, they are generally willing to use low doses or less efficacious medications if such will also offer a safer approach.

#### 10.15.2.4 Market Factors

Of necessity, economic considerations are major factors in drug development, particularly regarding bridging studies. The largest market for pharmaceutical products is the United States, followed by the European Union (when considered collectively), then Japan, with Japan as second largest when considering individual nations. To illustrate, in 2002, the global market for sales of pharmaceutical products was approximately \$401 billion. Sales are markedly disproportional to population. U.S. sales accounted for over 50% of the world's pharmaceutical sales, of about \$204 billion, and continues to grow at 12% per year. The European Union followed the United States with combined sales of about \$91 billion, with Japan at \$47 billion. Thus these three jurisdictions account for less than 15% of the world's population, yet about 85% of the world's pharmaceutical sales.

Active drug discovery is ongoing in all three jurisdictions, and all three have and continue to produce important compounds. Historically, the European Union invested the most in pharmaceutical research and development, a leadership role that continued through 1990. Growth in the U.S. pharmaceutical industry was such that U.S. investment exceeded Europe in the early 1990s and has continued to grow rapidly. In 2004 research input by U.S. pharmaceuticals nearly matched the investments of Europe and Japan combined.

Each jurisdiction has its own approach to patent protection, marketing, distribution, and pricing. For example, U.S. pharmaceutical companies generally base pricing on market considerations. In Japan, prices have been established under the oversight of the Ministry of Health, Labor, and Welfare (MHLW), with downward adjustments applied, on the average, every 2 years. Even considering these differences, if a pharmaceutical company has a product that is commercially successful in one jurisdiction, there is usually sufficient potential for financial gain to interest industry in offering the compound in the other jurisdictions.

Market factors interface with political structures and regulatory practices and affect product development. During the 1980s and 1990s, it took a U.S.

pharmaceutical company 10 years, on average, to develop and launch a new product, whereas it required 15–17 years for the Japanese counterparts. Partially for this reason, of the 178 new chemical entities launched worldwide between 1999 and 2003, just 47 were launched in Japan. On the other hand, drugs discovered in Japan tended to be rapidly acquired and successfully launched by Western companies. Examples include Pravachol, Crestor, and Aricept, discovered, respectively, by Sankyo, Shionogi, and Eisai laboratories yet marketed outside of Japan by Bristol Meyers Squibb, AstraZeneca, and Pfizer.

Market factors are mentioned here because they are such powerful considerations, although an adequate discussion of this topic is beyond the scope of this chapter.

#### 10.15.2.5 Social and Political Factors

Collective social opinion is a significant factor in the pharmaceutical industry, influencing regulation, pricing strategies, and standards for determining what is “generally safe and well tolerated.” Social influences are particularly important in bridging studies and reflect a continuation of the usual perspectives of one’s own culture and the natural comfort of seeing and doing things in ways that are familiar. It takes substantial effort to understand perspectives and traditions that are different from your own. As will be discussed in more detail below, cultural factors are significant considerations in the practice of medicine in general and the role of pharmaceuticals in particular. Thus it is understandable that the regulatory agencies in each jurisdiction will operate with primary concern for their own population, in ways which generally represent local medical and business practices. These concerns and practices vary from one country to another. Successful global pharmaceutical development strategies require appreciation for these political factors.

The agencies in each jurisdiction and the approval process for new compounds operate within this milieu and change over time. The milestones for the U.S. Food and Drug Administration (FDA) include a long list of laws and regulations. Historically, most were “political” responses to problems within the industry [3]. Recently, the emphasis has been on increased efficiency.

Historical development in Japan was somewhat similar, with a recent emphasis on greater efficiency. Japan introduced a revised Pharmaceutical Affairs Law (PAL) in 2002, with compliance effective by 2005, with organizational and regulatory changes in product registration, industry standards, bridging studies, clinical trials labeling, advertising, product classification, and intellectual property. Restructuring under the revised PAL includes the creation of the Pharmaceutical and Medical Devices Agency (PMDA), combining the Organization for Pharmaceutical Safety and Research (OPSR), the Pharmaceutical and Medical Device Center (PMDEC), and the Japan Association for the Advancement of Medical Equipment (JAAME). The purpose of the PMDA is to expedite what had historically been a slow review process. The PMDA revised systems and regulations involving the import, marketing, and contract manufacturing requirements of non-Japanese pharmaceutical companies and signaled an intent to gradually increase the acceptance of new drug application (NDA) submissions featuring bridging studies.

Political factors and the structure of each jurisdiction’s regulatory agencies are also topics beyond the scope of this chapter. They are introduced here out of

recognition for their significance and as a transition to the discussion of regulatory guidance.

### 10.15.3 REGULATORY GUIDANCE: ICH AND E5

Bridging studies would not be possible without consensus regulatory guidance to allow data from studies done in one jurisdiction to be accepted in another. Consensus at an appropriate level of detail on issues this important is not easily achieved. Despite recognition of the substantial benefits to all concerned, consensus guidelines required diligent effort for nearly a decade before they were agreed, adopted, and utilized.

The regulatory guidance currently utilized is the effort of the ICH. The history is briefly summarized below, with attention to the topic (E5) describing use of foreign data.

#### 10.15.3.1 ICH History

The importance of independent evaluation of medicinal products before they are allowed on the market was realized at different times in different regions. In the United States, the role of the FDA in reviewing medications was markedly increased following a tragic mistake in the formulation of a sulfanilamide syrup in 1937. Japan began requiring all medicinal products to be registered for sale starting in the 1950s. Response to the thalidomide tragedy of the 1960s expanded regulatory oversight in Europe.

The different regulatory systems were based on the same fundamental obligations to evaluate the quality, safety, and efficacy of the pharmaceutical products, yet the detailed technical requirements diverged over time to such an extent that industry found it necessary to duplicate many time-consuming and expensive test procedures in order to market new products internationally.

By the late 1980s, the urgent need to rationalize and harmonize regulation in an increasingly global marketplace was impelled by concerns over the rising costs of health care, including pharmaceutical R&D, in juxtaposition to the need to meet the public expectation that there should be a minimum of delay in making safe and efficacious new treatments available to patients in need.

Harmonization of regulatory requirements was pioneered by the European Community, in the 1980s, as the European Community (now the European Union) moved toward the development of a single market for pharmaceuticals. The success achieved in Europe demonstrated that harmonization was feasible. At the same time there were bilateral discussions between Europe, Japan, and the United States on possibilities for harmonization.

The birth of the ICH took place at a meeting in April 1990. Representatives of the regulatory agencies and industry associations of Europe, Japan, and the United States met, primarily, to plan an international conference. The ICH Steering Committee, which was established at that meeting, has since met at least twice a year, with the location rotating between the three regions. ICH work groups have met frequently, and six ICH meetings have been held, most recently in November 2003 in Osaka, Japan. Although the scope of the ICH topics has expanded over time, the

fundamental goals are still generally consistent with the early goals, as expressed in a statement by the ICH Steering Committee from October, 1990:

The Parties cosponsoring this Conference, represented at the 2nd Steering Committee Meeting in Tokyo, 23–24 October 1990 re-affirmed their commitment to increased international harmonization, aimed at ensuring that good quality, safe and effective medicines are developed and registered in the most efficient and cost-effective manner. These activities are pursued in the interest of the consumer and public health, to prevent unnecessary duplication of clinical trials in humans and to minimize the use of animal testing without compromising the regulatory obligations of safety and effectiveness.

ICH Guidelines cover a variety of topics, generally arranged as:

- Quality Topics (e.g., Q7, on Good Manufacturing Practices and Q8 on Pharmaceutical Development)
- Safety Topics (e.g., S2 discussing genotoxicity studies, and S5 addressing reproductive toxicity)
- Efficacy Topics relating to studies in human subjects (e.g., E6 on good clinical practices)
- Multidisciplinary Topics, which do not fit uniquely into the above categories (e.g., M1: Medical Terminology).

### 10.15.3.2 E5 Guidelines

Of special relevance for bridging studies, ICH Efficacy Topic E5 discusses Ethnic Factors in the Acceptability of Foreign Clinical Data. The current document was recommended for adoption by the ICH Steering Committee on February 5, 1998, approved by the EU in March, 1998, published in the U.S. *Federal Register* in June 1998, and adopted by the MHLW in Japan in August 1998 [1].

Early experience in all ICH regions indicated the need for some clarification, and a Questions and Answers document was issued in November 2003. This was adopted by the European Union in November 2003, by Japan in February 2004, and by the United States in June 2004. The bridging studies discussed in this chapter were conducted within the regulatory environmental matrix described in these two documents. Although classified by ICH as an “efficacy” topic, the E5 guidelines are equally concerned with issues of patient safety.

The perspective of this author is that E5 comprises a particularly key component of ICH, providing the essential mechanism for the success of the ICH effort in achieving its goals. All topics are important. However, if data cannot be shared from one jurisdiction to the other, the pharmaceutical sponsors are essentially back where they started: duplicating the investigational program in a new region.

**E5 Objectives** The objectives of E5 are:

- To describe the characteristics of foreign clinical data that will facilitate their extrapolation to different populations and support their acceptance as a basis for registration of a medicine in a new region.

- To describe regulatory strategies that minimize duplication of clinical data and facilitate acceptance of foreign clinical data in the new region.
- To describe the use of bridging studies, when necessary, to allow extrapolation of foreign clinical data to a new region.
- To describe development strategies capable of characterizing ethnic factor influences on safety, efficacy, dosage, and dose regimen.

The guidelines further state “All regions acknowledge the desirability of utilizing foreign clinical data. . . . However, concern that ethnic differences may affect the medication’s safety, efficacy, dosage and dose regimen in the new region has limited the willingness to rely on foreign clinical data,” and thus explains the reason why there was so much duplication of the research program. The guidelines are based on the assumption that many medicines will have comparable characteristics and effects across regions, although there is acknowledgment that ethnic differences may affect the safety, efficacy, dosage, or dose regimen.

E5 “is based on the premise that it is not necessary to repeat the entire clinical drug development program in the new region.” It is also “not intended to alter the data requirements for registration in the new region; it seeks to recommend when these data requirements may be satisfied with foreign clinical data,” noting that “additional studies conducted in any region may be required by the new region to complete the clinical data package.”

**Regional Requirements** The three ICH regions have developed a basic consensus on the fundamentals of appropriate study conduct, summarized as good clinical practices (E6). Still, the regions vary in what constitutes an approvable clinical data package. At a minimum, studies need to provide data that contain adequate characterization of pharmacokinetics, pharmacodynamics, dose response, efficacy, and safety. Once these are established, further clinical trials should be performed according to GCP with appropriate choice of controls and endpoints using medical and diagnostic definitions acceptable to the new region. In particular, the pharmacodynamic endpoints for safety, tolerability, and efficacy must be performed either in the new foreign region or in a population representative of the new region.

Several ICH guidelines address these aspects of program design and provide guidance for a complete clinical data package. These include GCPs (E6), evaluation of dose–response (E4), adequacy of safety data (E1 and E2), conduct of studies in the elderly (E7), conduct of studies in a pediatric population (E11), reporting of study results (E3), general considerations for clinical trials (E8), statistical considerations (E9), and choice of control groups (E10). Guidelines are also emerging regarding specific therapeutic areas (e.g., hypertension, E12A) and clinical safety issues (e.g., QT/QTc interval prolongation for non-antiarrhythmic drugs, E14).

**Ethnic Factors** Within E5, “ethnic factors are factors relating to races or large populations grouped according to common traits and customs.” The guidance specifically notes that ethnic factors go beyond racial factors per se. The focus of attention for ethnic factors includes diet and lifestyle considerations with implications for the expected safety and efficacy of the medication in the region. For example, the Japanese authorities are more concerned with the effects of a medication within

Japan than the effects of the medication when taken by Japanese individuals within the United States.

Ethnic factors are broadly classified as Extrinsic and Intrinsic.

**Extrinsic Factors** Extrinsic factors are associated with the environment and culture in which a person resides and are more behaviorally than genetically derived. Examples include diet, use of tobacco and alcohol, exposure to pollution and sun-shine, socioeconomic status, medical practice, compliance with prescribed medica-tions, and practices in clinical trials design and conduct.

**Intrinsic Factors** Intrinsic factors apply more to the genetic features of the indi-vidual and the collective subpopulation of individuals within a region, including the physical aspects of genetics plus the lifestyle of the region. Examples include genetic polymorphism, age, gender, height, weight, lean body mass, body composition, and organ dysfunction. Table 1 illustrates intrinsic and extrinsic ethnic factors as defined in E5.

**Sensitivity to Ethnic Factors** Ethnic sensitivity is compound specific, depending on its pharmacologic class, indication, and the usual age and gender of the target patient population. No single factor is predictive of the relative sensitivity, but the following properties as a whole are generally indicative.

Examples of properties making a compound less sensitive to ethnic factors include:

- Linear pharmacokinetics
- A flat pharmacodynamic curve for both efficacy and safety

TABLE 1 Classification of Intrinsic and Extrinsic Ethnic Factors

| INTRINSIC                                   |                                           | EXTRINSIC                        |
|---------------------------------------------|-------------------------------------------|----------------------------------|
| Genetic                                     | Physiological and pathological conditions | Environmental                    |
| Gender                                      | Age (children-elderly)                    | Climate<br>Sunlight<br>Pollution |
| Height                                      | Liver                                     | <b>Culture</b>                   |
| Bodyweight                                  | Kidney                                    | Socioeconomic factors            |
|                                             | Cardiovascular functions                  | Educational status               |
| ADME                                        |                                           | Language                         |
| Receptor sensitivity                        |                                           | Medical practice                 |
| Race                                        |                                           | Disease definition/Diagnostic    |
| Genetic polymorphism of the drug metabolism |                                           | Therapeutic approach             |
|                                             |                                           | Drug compliance                  |
| Genetic diseases                            | Diseases                                  | Smoking                          |
|                                             |                                           | Alcohol                          |
|                                             |                                           | Food habits                      |
|                                             |                                           | Stress                           |
|                                             |                                           | Regulatory practice/GCP          |
|                                             |                                           | Methodology/Endpoints            |

- A wide therapeutic dose range
- Minimal metabolism or metabolism distributed among multiple pathways
- High bioavailability, that is, less susceptibility to dietary absorption effects
- Low potential for protein binding
- Little potential for drug–drug, drug–diet, and drug–disease interactions
- Nonsystemic mode of action
- Little potential for inappropriate use and abuse

The opposite properties make a compound more sensitive to ethnic factors, especially:

- Metabolism by enzymes known to show genetic polymorphism
- Administration as a prodrug, with potential for ethnically variable enzymatic conversion
- Low bioavailability, with more susceptibility to dietary absorption effects

***Bridging Data Package*** E5 specifies that the complete clinical data package intended for registration contain clinical data that fulfill the regulatory requirements of the new region and contain pharmacokinetic data relevant to the population of the new region. Use of a bridging study allows inclusion of selected information from the original region, including pharmacokinetic, dose–response, and pharmacodynamic data, with appropriate extrapolation to the population of the new region based on the results of the bridging study.

***Global Development Strategies*** Sponsors are increasingly interested in concurrent international development, and use of ICH guidelines allow data to be used across the three major jurisdictions. Thus we are seeing Japanese–Caucasian bridging studies with a clinical pharmacology focus performed concurrently with phase II studies in the United States and European Union, with the expectation that phases II and III studies will be performed in Japan concurrently with the phase III program in the United States.

### 10.15.3.3 Implications for Non-ICH Jurisdictions

This may be all well and fine for Japan, the European Union, and the United States. How about the rest of the world? The ICH regions account for approximately 85% of global pharmaceutical sales, but less than 15% of the global population. The non-ICH regions contain some of the most dynamic and changing pharmaceutical markets. These regions are also seeking innovative and better quality medicines, are also interested in benefiting from the medicines developed within the ICH regions, and are also attempting to develop world class drug/biological regulatory systems.

Long recognizing these global implications, the ICH has made efforts to involve stakeholders with similar needs and related interests from other regions. For example, the ICH Steering Committee statement of July 1997 included language that “the widespread adoption and use of ICH guidelines ... is essential if the long-term

benefit of international harmonization in terms of quicker access to effective new medicines, is to be available to patients throughout the world.”

In 1999, the ICH steering committee created a Global Cooperation Group (GCG) subcommittee to share information and harmonization practices with other nations. Participants include Canada and the World Health Organization (WHO), representing 180 countries.

Harmonization initiatives are also being coordinated on a regional basis by the following organizations:

- Asia-Pacific Economic Cooperation (APEC)
- Association of Southeast Asian Nations (ASEAN)
- Gulf Cooperation Countries (GCC)
- Pan American Network on Drug Regulatory Harmonization (PANDRH)
- South African Development Community (SADC)

These agencies are participants or interested observers in the ICH process and adopt or incorporate ICH guidelines in their regions where applicable. Thus ICH guidelines, or guidelines similar to ICH, may facilitate global availability of new compounds, global development of new compounds, and globalization of clinical research.

#### **10.15.4 ETHNIC PHARMACEUTICAL SAFETY ISSUES: PHARMACOKINETICS**

Pharmacology is a science. The ethnic, historical, and regulatory issues primarily provide a context for understanding protocol design and the regulatory approval process. The heart and soul of the clinical trials is to provide scientific data according to recognized practices that answer the most important questions regarding the behavior and effects of a specific compound following human exposure.

Sections 4 and 5 provide an overview of pharmacokinetics (PK), that is, the absorption, distribution, metabolism, and elimination (ADME) of the subject compound and the pharmacodynamic (PD) considerations and experience of bridging studies. Only selected examples are cited here, in the interest of illustrating ethnic issues relevant to planning bridging studies.

##### **10.15.4.1 ADME: Absorption**

This discussion of absorption will focus primarily on the gastrointestinal tract. For our purposes, intravenous, intramuscular, and subcutaneous routes largely bypass the absorption process. There may be ethnic differences in absorption of transdermal medications, as these may vary with skin type, including racial differences in skin thickness, barrier function, and transepidermal water loss. In terms of ethnic differences, intraocular, intravaginal, intrarectal, and other routes of administration have not received extensive investigation.

Absorption from the gut is a passive process for many medications. In this case, ethnic differences in absorption would not be expected, and none have been demonstrated. However, a number of medications are actively metabolized within

the intestinal membranes or absorbed via transport proteins. At last three major enzymes systems are involved with drug absorption across the intestinal membrane, CYP (especially CYP 3A4), the multidrug resistance proteins (MDR1-5) including P-glycoprotein (MDR-1), and the organic anion transporting polypeptide (OATP) family, which transport a large array of structurally divergent drugs [4]. While their relevance for ethnic differences at the population level have yet to be defined, individual heterogeneity and single nucleotide polymorphism (SNP) variation have been identified for a number of these transport proteins. Undoubtedly, other transport proteins have yet to be defined.

The bridging studies done with Japanese to date have shown several compounds, such as risedronate and rosuvastatin, with a higher time to maximum concentration ( $T_{\max}$ ) and area under the curve (AUC) yet a similar half-life ( $T_{1/2}$ ). These observations remain after adjustment for weight, gender, percent body fat, and related individual factors, suggesting the ADME difference is primarily one of increased absorption rather than differences in distribution, metabolism, or elimination. Bridging studies have documented these observations, even though the precise mechanism remains to be elucidated.

#### 10.15.4.2 ADME: Distribution

Insofar as a medication's distribution varies throughout body compartments, generally lipophilic medications would be expected to show a difference in the volume of distribution, with ethnic effects reflecting the population's typical percent body fat versus lean body mass. In Japan, obesity is defined as a body mass index (BMI) of greater than 25, whereas in the United States an individual is considered "overweight" with BMI 27–30 and "obese" when the BMI is over 30. This may partially account for the greater effect of diazepam in Asians than in Caucasians.

Some ethnic differences in protein binding have been described. The two major drug-binding proteins in blood plasma are albumin and  $\alpha_1$ -acid glycoprotein (AGP). Albumin has a relatively low drug affinity, but a high binding capacity with three major binding sites and the ability to bind acids, bases, and neutral compounds. Conversely, AGP has a high drug affinity but low capacity. AGP binds many basic psychotropic compounds, including haloperidol, chlorpromazine, and fluvoxamine. The structures of albumin and AGP are genetically determined, with polymorphic variations across racial groups in several studies. In general, evidence indicates that Caucasians (especially those of European origin) have higher levels of AGP than Asians and blacks, although albumin levels are similar.

Finally, ethnic differences in transport proteins such as P-glycoprotein and the OATP enzyme systems may account for differences in intracellular concentration within the liver, kidney, brain, and other tissues.

#### 10.15.4.3 ADME: Metabolism

A substantial body of literature exists regarding heterogeneity of metabolizing enzymes, particularly the hepatic cytochrome P450 (CYP) enzyme families. Considering the wide range of intraethnic mutant alleles, some authorities may argue that these approach "individual" factors. Nonetheless, the incidence of certain genotypes shows ethnic patterns and must be considered when discussing ethnic differences.

Wider application of genotyping has clarified our understanding while adding considerable complexity, as we have identified multiple mutant genotypes with similar phenotypical function. As the CYP system is also involved with detoxification or metabolism of a wide range of dietary components and environmental toxins, implications for risk of certain cancers in various ethnic populations may be as important clinically as the implications for drug metabolism and remains an area of active research.

Overall, enzymes in the CYP 2 superfamily show far greater heterogeneity than CYP 1 and CYP 3. In addition to the allele heterogeneity, some studies also show considerable individual and ethnic differences in enzyme content and activity [5–7]. Selected CYP enzyme systems with ethnic relevance for drug metabolism are considered next.

**CYP 1A1, 1A2, and 1B1** CYP 1A2 substrates include caffeine, theophylline, and tacrine. Four types of CYP 1A1 and three types of CYP 1B1 polymorphisms have been described, with distinct incidence patterns in Japanese compared with Caucasians [8], and may play a role in cancer risk. CYP 1A2 polymorphisms vary in the Chinese population, with some more similar to Japanese and some more similar to Caucasians [9]. Additional CYP 1A2 polymorphisms have been identified and shown to have variable incidence in Taiwanese, Caucasian, and African American populations. However, the functional differences of these variants is fairly small, and relevance for dose selection has not been established [10, 11].

**CYP 2C9** CYP 2C9 is a major enzyme, accounting for about 20% of the total P450 enzyme pool in both Japanese and Caucasians. Substrates include many nonsteroid anti-inflammatory medications, glipizide, losartan, and S-warfarin. There is large interindividual variability in 2C9 content and considerable intraethnic variation in both population. Some mutant alleles are shared in both populations and some are unique to each population [12].

CYP 2C9 is polymorphic, with six major allele variants. The different alleles vary in ethnic distribution between Asian, Caucasian, and African populations, and different alleles vary in their metabolic activity for common substrates.

**CYP 2C19** CYP 2C19 substrates include omeprazole and phenytoin. Along with CYP 2D6, CYP 2C19 contributes to the metabolism of selective serotonin reuptake inhibitors, tricyclic antidepressants, and a variety of other psychotropic medications.

**CYP 2D6** CYP 2D6 substrates include codeine and other opiate medications,  $\beta$  blockers, and antidysrhythmic medications such as flecainide and propafenone. CYP 2D6 also contributes significantly to the metabolism of tricyclic antidepressants, selective serotonin reuptake inhibitors, and other psychotropic medications such as haloperidol and thioridazine.

**CYP 2E1** The classic pharmacological substrate for CYP 2E1 is chlorzoxazone, although 2E1 is also a metabolic pathway for *p*-nitrophenol, ethanol, and dimethylnitrosamine. Unlike most of the other CYP enzymes, 2E1 metabolism has a tendency to activate substrates into more toxic metabolites, such as acetaminophen,

ethanol, carbon tetrachloride, thioacetamide, and the N-nitroso compounds found in red meat and processed meats. Thus a higher level of 2E1 activity may increase the risk of alcoholic liver injury and various malignancies [13–15].

A comparison of 39 Japanese and 45 Caucasians showed three types of polymorphisms, with seven genotypes found in the Japanese and four in the Caucasians [7a]. Although little difference in metabolic activity was found between the ethnic groups with one probe substrate despite the genotype heterogeneity, there is a typical difference between Japanese and Caucasians in the metabolism of chlorzoxazone, with lower clearance for the Japanese even after adjusting for differences in body weight, suggesting a lower level of catalytic activity in Japanese [4].

**CYP 3A4 and 3A5** CYP 3A4 is present in the intestinal brush border as well as hepatocytes and is the major “workhorse” for drug metabolism, that is, the major metabolic pathway for as many as 60% of our currently known pharmaceutical compounds. This lack of substrate specificity also lends itself to a large number of drug and diet interactions [16]. Individual 3A4 content and activity varies widely, with up to 40-fold individual content variation and up to 11-fold individual variability in midazolam oral clearance [5, 17]. More than 30 SNP variations have been identified, which vary in ethnic distribution between Japanese, Caucasian, and African American subjects. Despite this variety, allele frequency is low (<5%) and appears as heterozygous with the wild type. None of the alleles have been associated with clinically significant differences in drug metabolism, especially regarding interethnic comparisons [18].

CYP 3A5 is a coenzyme for many 3A4 substrates. CYP 3A5 is also polymorphically expressed with varying ethnic distribution, but the functional significance has not been established [19].

As we learn more about individual intraethnic differences in content and activity, allele function, and diet interactions, ethnic differences previously reported in CYP 3A4 activity may be partly due to individual differences in studies with small sample sizes and/or dietary factors [6, 20].

**Non-CYP Metabolic Enzymes** A number of enzymes other than the CYP system are also important in drug metabolism and demonstrate ethnic heterogeneity. The intra- and interethnic genotype variation is not always linked with phenotype expression, and this remains an area of active inquiry. Selected examples include:

- Aldehyde dehydrogenase (ALDH) is primarily significant for metabolism of ethanol, especially ALDH2. An atypical allele, ALDH2(2) results in accumulation of acetaldehyde with histamine release and flushing. Approximately 30% of Asians are ALDH deficient [21].
- *N*-acetyltransferases (NAT) demonstrate polymorphism and ethnic variation and are involved with metabolism of environmental carcinogens and a number of arylamine and hydrazine drugs [22]. As expected, SNP and allele analysis show substantial heterogeneity, both within Japanese and within Caucasians [23].
- Thiopurine *S*-methyltransferase (TPMT) is responsible for the metabolism of thiopurine medications such as azathioprine. Patients with deficient TPMT

activity are at high risk for toxicity and can be successfully treated with 10- to 15-fold lower dose. Mutant alleles vary in their ethnic distribution [24].

- Glucuronosyltransferase (UGT) enzymes catalyze the transfer of glucuronic acid to alcohols, carboxylic acids, amines, and free sulfhydryl groups. Twenty-four distinct UGT genes have been identified, with significant ethnic variation in Caucasian, Asian, and African populations [25].

#### 10.15.4.4 ADME: Elimination

The major routes of elimination are hepatic and renal. Ethnic differences in hepatic function are primarily metabolic. To my knowledge, no ethnic differences in post-hepatocyte biliary elimination have been described.

Renal clearance is the net effect of glomerular filtration, tubular secretion, and tubular reabsorption. Glomerular filtration and tubular reabsorption are largely passive processes, where ethnic differences have not been described. However, tubular secretion is an energy-requiring active process, and ethnic differences could possibly result from genetic heterogeneity in this process although they are particularly compound specific. For example, renal clearance for morphine and metabolites morphine-3-glucoronide and morphine-6-glucoronide are higher in Chinese than Caucasians, primarily due to tubular secretion. However, other medications that undergo tubular secretion have not shown ethnic differences, such as furosemide and procainamide.

#### 10.15.4.5 ADME: Dietary Factors

Most of the ADME factors described above are primarily genetically determined. But diet can have a significant influence on how these enzymes function, which may exaggerate or introduce new ethnic differences.

As a context, the “traditional diet” in Japan is quite different from most regions within the United States. Despite globalization, certain generalities still apply:

- Source of complex carbohydrates: Japanese consume more rice, and Americans more wheat, corn, and potatoes.
- Source of protein: Japanese consume more fish and soy products, Americans more beef and dairy products.
- Sources of fat: Japanese consume less fat overall, and the fat consumed is more likely to be from fish and vegetable sources. Americans consume more fat overall, and a higher percent is saturated fat from red meat and other animal sources.
- Typical vegetables and fruits vary between Japan and the United States, in addition to the seasonal variations in both regions.
- Common food preparation techniques and preferred sauces, flavorings, dressings, and spices are typically quite different.

Macronutrient differences may have some affect on drug absorption, as will physiological changes in the fed versus the fasted state such as gastric pH, gastric and intestinal motility, pancreatic and biliary secretion, drug adherence to dietary

fiber, passive drug absorption along with meal uptake, and the like. However, we should draw particular attention to the vegetables, fruits, herbs, and spices. Consumption of these items often varies by culture or region, and many fruits, vegetables, and herbs have been shown to have isoflavones or other compounds that can affect drug absorption, metabolism, or both.

One well-known example is grapefruit and grapefruit juice, which contain isoflavones that significantly inhibit CYP 3A4 in both the intestinal wall and the liver. For medications metabolized by 3A4, grapefruit intake reduces metabolism in the gut, thus increasing absorption and the  $C_{\max}$ . Grapefruit also prolongs the  $T_{1/2}$  by inhibiting hepatic metabolism. Both mechanisms contribute to a higher AUC. These effects persist at least 24 hours after dietary exposure. This grapefruit effect has presumably been present throughout human biological history, even though it was only defined in the 1990s [26]. This effect apparently applies across all ethnic groups, yet some would classify this as an “ethnic factor” as grapefruit consumption varies by region and subpopulation.

Herbal products can interact with prescription medications. St. John’s wort (hyperforin and quercetin) is commonly used as an antidepressant and has been shown to be a potent inducer of CYP 3A4 and P-glycoprotein, although it may inhibit other CYP enzymes [27]. St. John’s wort has been shown to lower the plasma concentration (and/or the pharmacological effect) of a number of drugs including alprazolam, amitriptyline, cyclosporine, digoxin, fexofenadine, indinavir, irinotecan, methadone, nevirapine, simvastatin, tacrolimus, theophylline, warfarin, phenprocoumon, and oral contraceptives, with interactions that may cause a variety of adverse clinical effects [28].

Other herbs, spices, and “natural medications” have significant effects on CYP enzymes. Ginkgo biloba (Ginkgo) can exert potent inhibition on 1A2, 2C9, and 2C19, with less inhibition of 2D6 [29]. A variety of spices, herbal and black teas, and soybean products were tested for their in vitro inhibition of CYP enzymes. All were found to inhibit 3A4 mechanisms to a variable extent, and 26 showed significant inhibition of 2C9, 2C19, or 2D6. Examples of products tested include black tea, herbal tea mixtures, sage, thyme, cloves, goldenseal, and seven soybean varieties [30]. Similar inhibition of CYP 1A2, 2C9, 2C19, 2D6, and 3A4 was noted by herbal extracts of devil’s claw root (*Harpagophytum procumbens*), feverfew herb (*Tanacetum parthenium*), fo-ti root (*Polygonum multiflorum*), kava-kava root (*Piper methysticum*), peppermint oil (*Mentha piperita*), eucalyptus oil (*Eucalyptus globules*), red clover blossom (*Trifolium pretense*), garlic (allicin), and evening primrose oil (cis-linoleic acid) [29, 31]. Gallic acid, a plant phenol found in wines and teas, can inhibit CYP 3A4 under certain conditions [32].

In general, a wide variety of clinically significant adverse events have been documented from herb–drug interactions, through a combination of pharmacokinetic and pharmacodynamic mechanisms [33]. To the extent that herbal use characterizes an ethnic group in a particular region, herbal use can be considered an ethnic factor.

Diet components may also affect transport proteins. Grapefruit, orange, and apple juice have been shown to inhibit human OATP activity, with reduced oral drug bioavailability [34]. Another study of 20 naturally occurring flavonoids and some of their corresponding glycosides demonstrated significant inhibition of OATP drug uptake, indicating the potential for drug interactions [35].

P-glycoprotein is also inhibited by a wide variety of dietary and herbal compounds, including capsaicin (in chili peppers), curcumin (in turmeric), [6]-gingerol (in ginger), and resveratrol (in grapes) [36]. Eight dietary flavonoids commonly present in fruits, vegetables, and plant-derived beverages have been shown to inhibit P-glycoprotein [37, 38]. Citrus (rutaceous) herbs are often used in traditional Japanese medicine and cuisine and contain compounds known as monoterpenoids. A number of these have been shown to be potent P-gp inhibitors [39].

Even food preparation preferences can affect drug pharmacokinetics. Charcoal-broiled and smoked foods contain polycyclic aromatic hydrocarbons formed during their preparation, which can induce intestinal CYP 1A [40].

Much of the research in this area is fairly recent and more remains. We are likely to define new transport proteins, new receptors, and new dietary influences on the pharmacokinetic or pharmacodynamic effects of drugs.

#### 10.15.4.6 ADME: Multiple Mechanisms

Certain compounds will be influenced by combinations of the above factors. Before we complete our discussion about ethnic factors in pharmacokinetics, let us use warfarin, one of the world's most widely prescribed anticoagulant medications, as an example. Although effective at reducing the incidence of thromboembolic disease in common clinical settings, there is a greater than 10-fold interpatient variability in the dose required, necessitating careful monitoring and dose adjustment for each patient.

Warfarin exists as optical S and R isomers. S-warfarin has three to five times more anticoagulant potency than its optical congener. Warfarin is well absorbed orally, although delayed in the presence of food. Absorption through the bowel as well as target intracellular concentrations may be affected by P-glycoprotein. Once absorbed, warfarin is highly protein bound, mainly to albumin. Warfarin is primarily metabolized by CYP 2C9, with minor activity by CYP 1A2 and CYP 3A, and elimination of inactive metabolites in the urine and the stool.

As discussed previously, CYP 2C9 enzymes show marked phenotypical and genotypical variability in various ethnic groups worldwide, with multiple alleles demonstrating considerable differences in rates of S-warfarin metabolism. Multiple variants have also been described in the promoter, exonic, intronic, and 3'-untranslated regions of CYP 2C9.

A wide variety and a large number of medications have reported interactions with warfarin, including azole, macrolide and quinolone antibiotics, nonsteroidal anti-inflammatory drugs, selective serotonin reuptake inhibitors, omeprazole, lipid-lowering agents, amiodarone, and fluorouracil.

Interactions with a wide variety of food and herbal medications have also been described, including vitamin K intake, green tea, danshen, fish oil, soy milk, ginseng, and quilinggao.

While there are wide interindividual differences, Asians in general tend to achieve therapeutic benefit at lower warfarin doses than Caucasians. When assessing "what are the ethnic effects," studies have compared Caucasian with Asian subjects matched by CYP 2C9 allele variants and still found unexplained differences. Likewise, interethnic differences were present with or without consideration of CYP 2C9

coding region variants, suggesting other genetic, dietary, or environmental influences [41, 42].

In this case a simple explanation for ethnic differences remains elusive. Even accounting for the genetic heterogeneity in the primary metabolic pathway, multiple mechanisms appear to be involved. Undefined genetic factors, general dietary patterns, and other environmental influences are all ethnic factors, both intrinsic and extrinsic.

### 10.15.5 ETHNIC PHARMACEUTICAL SAFETY AND EFFICACY ISSUES: PHARMACODYNAMICS

As we discussed earlier, safety and tolerability are as important, if not more important than efficacy. Once the PK profile is understood and necessary dose adjustments taken into consideration, we are prepared to assess efficacy, safety, and tolerability of the selected doses.

Pharmacodynamic effects are often about the same in Japan as elsewhere but need to be evaluated in the context of the dose and related PK characteristics. Consider risedronate sodium as an example, approved in Japan in 2002 for the treatment of osteoporosis with use of a bridging strategy. The dose was set at 2.5 mg/day in Japan, compared with 5 mg/day in the United States and the European Union because of a PK finding that a 2.5-mg dose in Japanese produced a similar AUC to a 5-mg dose in Caucasians. In addition, the efficacy of 2.5 mg/day in Japan regarding the effect on bone density was comparable to the benefit of 5 mg/day in the United States and the European Union. The main difference in the PK was increased absorption. Although these findings primarily involve the PK profile, note that confirmation of the same PD effect at the lower yet equivalent dose was necessary for dose labeling.

The same was observed with rosuvastatin calcium, for the treatment of hypercholesterolemia. Interestingly, this compound was discovered by Shionogi in Japan but developed by AstraZeneca in the United States and the European Union, with subsequent bridging studies leading to approval in Japan. Rosuvastatin received U.S. approval in August 2003 compared with approval in Japan in December 2004. Japanese and other Asian subjects showed increased absorption, with  $C_{\max}$  about twice as high as Caucasians at the same doses. Efficacy at the lower doses paralleled the PK profile. Thus labeling in the United States is from 5 to 40 mg/day with a recommended starting dose of 10 mg/day, compared with labeling in Japan of 2.5 to 20 mg/day with a recommended starting dose of 5 mg/day.

In other cases, for reasons not always well understood, the PD effects and adverse event profile may differ in Japan from the United States and the European Union. Eletriptan hydrobromide, for the treatment of migraine headaches, is another medication approved based on a bridging strategy. The maximal doses were set at 40 mg/day in Japan, compared with 80 mg/day in the European Union, after the bridging study demonstrated higher rates of adverse events such as nausea and somnolence in the Japanese at 80 mg/day, although the  $C_{\max}$  and AUC of single doses were lower in the Japanese than the foreign population. Likewise, sildenafil citrate is recommended at 50 mg, ranging from 25 to 100 mg in the United States and the European Union, but limited to 25–50 mg in Japan as the 100-mg dose caused increased

adverse events (e.g., abnormal vision) in Japanese subjects but added no further effectiveness.

After allowance for ADME profiles, one possible mechanism for different PD responses is ethnic differences in the target receptor. Ethnic heterogeneity has been described for some important receptors. Selected examples include:

- Three functional  $\beta$ -adrenergic receptor polymorphisms have been described with clinical relevance to several disease, including asthma, hypertension, congestive heart failure, cystic fibrosis, and obesity, as well as response to  $\beta$ -agonist therapy such as salbutamol or  $\beta$ -blocker therapy such as propranolol. Distribution of these alleles varies in Caucasian, black, and Asian populations, providing at least a partial explanation for their different clinical responses to therapy [43–46].
- The effects of serotonin-related gene polymorphisms on central nervous system (CNS) serotonergic function vary as a function of both ethnicity and gender [47] and may affect response to therapy.
- The mu opioid receptor gene (OPRM1) has several known variations, with different distribution patterns in Caucasian, Asian, and black populations [48]. Ethnic variations in receptor function contribute to differences in the response to morphine [49], have been associated with methamphetamine psychosis [50], and may affect patterns of opiate addiction [51].

Receptor heterogeneity is an area of active investigation, and ethnic patterns are likely to be defined with relevance for numerous clinical domains [52].

### 10.15.6 BRIDGING STUDY DESIGN

Genetically determined metabolizing enzymes, transport proteins, and receptors are significant intrinsic ethnic factors. Diet is one of the major extrinsic ethnic factors. The data cited above show some reasons to believe drugs may behave differently in different populations or new regions. With the regulatory and physiological context as above, let us turn our attention to bridging study design.

For simplicity of discussion, this section will use a scenario where the bridging goes from the European Union or the United States to Japan, that is, where a compound is approved in the European Union or the United States, or a significant body of data exist in one of these jurisdictions and the compound is well on its way to regulatory approval, and Japan is the new jurisdiction of interest. In the first 5 years of E5 guideline implementation, this has been the most common scenario. Presumably, the same general principles would work when bridging from Japan to the United States or the European Union or bridging from an ICH jurisdiction to a non-ICH jurisdiction.

The comments that follow in this section and the next are based on experience between 1998 and 2005. Requirements for data acceptability are inherently a “moving target,” as we accrue experience with bridging programs in the context of emerging scientific data, medical practice changes, and political realities. In Japan, the Organization for Pharmaceutical Safety and Research (OPSR) offers consultative guidance to sponsors planning a bridging program, and sponsors are generally well advised to seek guidance prospectively.

### 10.15.6.1 Candidate Compound

As expected, the ADME characteristics as well as the intended clinical application of the candidate compound will determine the bridging strategy. The sponsor must assess the potential for intrinsic and ethnic effects based on the criteria discussed above.

### 10.15.6.2 Basic Study Design

The successful bridging study programs to date have often utilized a phase I style clinical pharmacology study to establish the dose selection, most commonly in normal healthy individuals, followed by patient-based longer term Phase II or Phase III style studies demonstrating safety and efficacy within the new jurisdiction. In the case of applying for registration in Japan, the safety and efficacy studies for successful NDAs so far have been performed in Japan. Utilizing ethnic Japanese populations residing out of Japan to demonstrate safety and efficacy has been problematical. As per the examples discussed above, we do not yet know all the variables and mechanisms affecting a compound's PK profile or PD effects. These considerations make it understandable to perform certain safety and efficacy studies within the new target region.

Study design needs to comply with good clinical practices and related ICH guidelines, with ethical principles consistent with the most current internationally recognized standard, currently the Declaration of Helsinki.

Single-dose PK/PD studies ordinarily include a range of at least two or three doses; the usual dose administered in the jurisdiction of reference and one or more lower or higher doses to clarify dose selection in the new jurisdiction. For compounds where single-dose kinetics do not reliably predict steady-state kinetics, a multiple-dose study (again, with a range of doses administered) will likely be advised in the new ethnic group. Pharmacokinetics may need to be confirmed in a patient population if the pivotal PK study was performed in healthy individuals.

The phase II/III efficacy studies may or may not employ a placebo, versus a range of two or three active doses or an already approved active comparator. Dose selection for these studies is based on the bridging ADME data. If the doses selected are lower for the Japanese than commonly used in the United States or the European Union, pharmacodynamic efficacy endpoints need to be confirmed as well as the safety and tolerability at the lower doses selected.

***Variables Affecting ADME Study Data*** As major decisions regarding the phase II/III program will depend on the pharmacokinetic profile, the reference PK study needs to be carefully designed.

A host of variables may affect ADME study data, some of which can be foreseen and anticipated, others are more subtle. Such variables are especially relevant when considering the decision to use historical data for comparison versus concurrent controls, and when considering whether to perform a study at one center or two. At some level, these variables may affect study conduct, data capture, or the regulatory agency's perception of data quality.

Examples include:

- Staff experience, training, and expertise
- Characteristics of the local population from which subjects are recruited
- Procedures for obtaining and documenting informed consent
- Overall GCP compliance
- Temperature, humidity, mold, lighting, ventilation, and other internal environmental variables within the study unit
- Staffing and work flow regarding study procedure performance
- Work habits and involvement of the principal investigator
- Interpretation and application of the protocol
- Source documentation data capture
- Methods and style for inquiry and documentation of adverse events
- Specimen processing and handling
- Calibration and maintenance of scales, centrifuges, and related devices
- Diet and beverages provided while confined, including food preparation techniques
- Interpretation and application of study restrictions
- Medical monitor approval of protocol deviations
- Quality and completeness of the regulatory file
- Monitoring and audit team findings, reports, and interaction with study staff
- Local lab methodology differences and reported ranges of normal
- Unexpected external events (e.g., local electrical power surges or failure, and storms, earthquakes, or other natural disasters)

Bridging PK studies have been successfully performed utilizing a one-protocol, two-center approach [53]. Some studies require placement at multiple centers for timely completion. Nevertheless, for the reasons listed above and many others, combining or comparing data across centers may involve unexpected findings or subtle differences. If unexpected findings occur—are they the result of ethnic differences or study conduct variables? Unexplained findings may require repeating the study under more rigorously controlled conditions.

***Caucasian ADME Data: Historical or Direct Comparison?*** The fundamental assumptions of bridging strategies involve use of historical data gathered in a foreign region, with assessment for applicability to the new region.

Partially for this reason, the use of historical Caucasian data seems like an efficient and cost-saving approach when planning the ADME study. However, if the new data show unexpected differences, it may be difficult to tell if this is due to “real” ethnic differences or the results of differences in study design, conduct, or other nonethnic variables. Considering the pivotal nature of the PK profile for the rest of the bridging program, it is generally preferable to plan the PK study with concurrent enrollment of subjects from both ethnic groups.

#### 10.15.6.3 Subject Population

***Definition of “Japanese”*** Intuitively, defining “Japanese” seems like a simple issue, but it is not. Every ethnic group contains a certain amount of heterogeneity.

Japan is no exception, that is, sumo wrestlers and geisha may both have unquestioned Japanese genealogy. Ancient migration patterns produced different subpopulations in regions spreading from the Kyushu District (Okinawa and other islands in the south) to Hokkaido (northern islands), and immigration within the past century or so has introduced many Korean, Chinese, and others to Japan. How many generations does it take for descendents of such individuals to become “Japanese?” Conversely, if an individual is born and raised in Japan, with a pedigree of pure Japanese parents, grandparents, and great-grandparents, does he or she cease to be “Japanese” as soon as he leaves the confines of Japan’s airspace?

Even more debatable is how many generations can pass after leaving Japan before an individual is no longer considered “Japanese.” Generational terms for Japanese are as follows, each assuming that the pedigree is pure Japanese ethnicity:

- Issei (first generation, subject was born in Japan)
- Nissei (second generation, subject born elsewhere but parents born in Japan)
- Sansei (third generation, subject and one or both parents born elsewhere but grandparents born in Japan)

My Japanese colleagues who perform phase I studies in Japan report that if a subject in Japan chooses to participate in a clinical pharmacology study conducted in one of their units in Japan, there is relatively little requirement to document Japanese ethnicity. Yet for many studies, if that same subject wishes to participate in a clinical study in Honolulu, we must document Japanese birth and citizenship by passport or visa, and fill a three-generation genealogy tree documenting that both parents and all four grandparents are Japanese and were born in Japan.

The stricter standard for “foreign data” is understandable, in that “Japanese” citizens born, raised, and living in Japan represent the population of interest to the MHLW—regardless of exact ethnic pedigree or regional origin. Subjects out of Japan may or may not represent their population, and it is important to know that the subjects enrolled as “Japanese” meet acceptable criteria. Consequently, virtually all bridging studies performed outside of Japan involving Japanese subjects require at least a “four grandparents” rule, that all four grandparents are known to be of Japanese ethnicity. This allows Issei, Nissei, and Sansei participants, but not those of mixed Japanese/non-Japanese descent.

Depending on the goals of the study, some protocols limit Japanese enrollment to Issei (with documentation of a three-generation genealogy chart), sometimes with a requirement that the subject has been outside of Japan for a limited time, for example, no longer than 5 or 10 years. Additionally, many protocols also inquire regarding dietary patterns and lifestyle, discussed in further detail below.

**Definition of “Caucasian”** Likewise, defining “Caucasian” may seem to be simple, but it is not. When we have asked sponsors for their definitions, responses vary considerably, including one to the effect “anyone with blonde hair, light skin, and blue or green eyes!” Fortunately, most sponsors include more geographically based definitions. Of course, many non-Caucasians are born or raised in Europe. However, without quibbling about ancient migration patterns or attempts to nar-

rowly define genetic origins, we deal with a reasonable sense of what it means to be of “European” origin genetically, that is, the people characteristically and traditionally known as English, German, French, Italian, Russian, and so forth. Specific protocols may or may not include those of the Middle East or North African descent, partially depending on the population in which the majority of clinical pharmacology data were originally generated: If performed in Europe the definition of “Caucasian” tends to reflect the participants of the original studies; if performed in the United States the definition of “Caucasian” is generally more broadly defined.

The Guidance for Industry Regarding Collection of Race and Ethnicity Data in Clinical Trials published by the U.S. FDA, January 2003, includes guidance for clinical trials conducted outside of the United States and recognizes racial designations of:

- American Indian or Alaska Native
- Asian
- Black, of African heritage
- Native Hawaiian or Other Pacific Islander
- White

The guidance also includes ethnic categories of “Hispanic or Latino” or “Not Hispanic or Latino.” Per this guidance document, the racial category “white” can reflect origins in Europe, the Middle East, or North Africa, and the category “Asian” can reflect origins from areas ranging from India to Japan.

**Healthy Normal Versus Patient Population** Most bridging studies follow the model established in the original jurisdiction and are most commonly performed in normal healthy volunteers. The exception usually involves medications with significant potential toxicities, with ethical constraints limiting exposure in healthy individuals who will not be receiving any direct medical benefit. Precedents exist for performing PK studies in patients as well as healthy volunteers, for measuring the PK profile in patients as part of a study to demonstrate efficacy, and for confirming the PK in patient studies as well as performing a PK study in healthy volunteers.

**Male and Female Participants** Unless the subject compound was intended exclusively for a female population (e.g., oral contraceptives), pharmacokinetic studies were traditionally performed in healthy male volunteers in all jurisdictions. Current regulatory guidance favors inclusion of female subjects, as long as there are appropriate measures to minimize the risk of in utero fetal exposure to an investigational drug. Bridging studies follow this same trend.

“Adequate” contraceptive measures vary with the protocol. Oral or injected hormonal contraception is generally allowed except when concerns exist regarding direct or indirect drug interactions. Requiring surgical sterilization or postmenopausal status often introduces an age difference between the male and female participants. Intrauterine devices are not commonly used. Abstinence or various forms of “double-barrier” contraception are increasingly allowed. Regardless of the method of conception, enrollment of women of child-bearing potential requires negative tests for pregnancy at the initial screening visit and again shortly prior to dose administration.

**Age** What is the difference between an 18-year old and a 20-year old? Not much, from a clinical pharmacology perspective. But this is an important distinction from a regulatory standpoint. In most of the United States, an 18-year old is legally an adult and has the autonomy and legal authority to sign his or her own informed consent. In Japan, this occurs at age 20. Consequently, many bridging studies define the lower age limit as 20 rather than 18.

The upper age limit is increasingly flexible. Through the 1990s many studies used age 45 as the upper limit for normal healthy studies. As the average population age increases—a trend occurring in Japan as well as the United States—there is growing interest in the inclusion of more mature participants, particularly for compounds whose clinical applications will largely apply to an elderly population.

Bridging studies will typically follow the trends established in the original jurisdiction, and more commonly include individuals up to age 50 or 55 in their “normal healthy” population, and sometimes to age 65. The trend established in the original jurisdiction is also followed for compounds that will be almost exclusively used by an elderly population, and bridging studies have been performed with a lower age limit of 50.

At the other end of the spectrum, pediatric trials have their own unique issues, including the requirement for the parent/guardian to sign the informed consent and for the participant to sign an age appropriate document indicating his or her assent. Bridging studies may also include a pediatric population. As of 2003 two compounds for pediatrics use were approved in Japan utilizing bridging studies: Palivizumab (for the treatment of respiratory syncytial virus in pediatrics) and oseltamivir phosphate for pediatric influenza infection. The pediatrics approval of oseltamivir followed the approval for use in adults at higher doses.

**Weight** Historically, the Japanese population has been smaller and lighter than the American population, and weight differences account for some of the differences in typical doses administered. Ideally, bridging studies will reflect the populations in both jurisdictions, and yet still provide comparable data. In a study enrolling concurrent Japanese and Caucasian participants, we ordinarily see a reasonable range for body mass index (BMI) applicable to both populations. Perceptions of appropriate body weight vary: In Japan a BMI over 25 is considered obese, whereas in the United States obesity is a BMI over 30. To better represent the Japanese population, the lower limit is often around 18, especially if the study enrolls female participants. To better represent the Caucasian population, the upper limit is often 27 or 29. Within these ranges, weight-adjusted pharmacokinetics can be determined.

#### 10.15.6.4 Diet and Food Effects

**Japanese Versus Western Diet** Paradoxically, as globalization progresses, diets worldwide are both increasingly diverse and increasingly similar. On a short tour of a major city in Japan, one observes Japanese consuming coffee, hamburgers and fries from American-based “fast food” outlets, and Americans have a growing taste for sushi, miso soup, and saimin. Both populations enjoy pizza and pasta.

Despite this globalization, we have discussed the significant differences between the traditional Japanese diet and the traditional American diet, and many generali-

ties still apply when we look at the overall population. To illustrate, I believe most international travelers would agree that menu choices in a typical local restaurant in Japan look quite different from menu choices in a typical local restaurant in America!

Do these differences affect a compound's pharmacokinetics? Data discussed previously regarding diet effects on metabolizing enzymes and transport proteins indicates it is prudent to assume "yes" until proven otherwise. Such effects may be related to specific diet contents and effects on pharmacologically related enzymes, beyond the usual fed versus fasted effects.

For this reason, establishing an appropriate diet for bridging study requires considerable attention. If differences exist, are they dietary or genetic? We have seen some studies structured where the Caucasians consume a typical "Western" diet, to match the conditions of the original studies, and the Japanese participants consume a more typical "Japanese" diet to match the conditions expected in Japan. Other studies require that all subjects consume the same diet, which may be Western, Japanese, or selected from common denominator food items shared by both cultures. Priorities vary with the compound, any known food effects, and the mechanics of absorption.

If a specific diet is not defined in the protocol, it may be prudent to provide a sample menu along with other study data when submitted for approval.

**Fed/Fasted Studies** Taking a medication with a meal may have no effect or may increase or decrease absorption. For compliance and optimal labeling, this is an important question for orally administered medications.

At this time, the OPSR has not defined a Japanese equivalent of the FDA's standard "high-fat" breakfast to evaluate food effects. Although other specific diet items may be of scientific interest, when it comes to regulatory submission, a high-fat meal conforming to the FDA's guidance is the place to start when assessing the effects of taking a medication fed versus fasted.

#### 10.15.6.5 Restrictions

The approach to study restrictions varies with the compound, the intended clinical application, and the conditions under which data were generated in the original jurisdiction. Often, sponsors will retain certain study restrictions from the original PK studies when they are planning bridging studies so the data will be more easily compared, even though subsequent experience has shown that the original design was overly conservative.

Common restrictions include the following examples.

**Concomitant Medications** Unless a drug interaction is the goal of the study, concomitant medications are usually restricted for anywhere from 1 to 2 weeks, or up to 5 half lives, whichever is longer. Medications known to inhibit or induce the metabolic enzyme pathways of the study compound are generally prohibited for a longer period of time. Both over-the-counter and prescription medications are commonly cited, and usually herbal products and nutritional supplements are limited or prohibited. Certain exceptions often apply, such as acetaminophen or continued use of oral contraceptives.

**Smoking and Use of Tobacco Products** Nicotine may not have a direct effect on the metabolism of the study drug but is well known to affect blood pressure and heart rate, and the occurrence of nicotine withdrawals during a clinical trial skews the adverse events profile. However, smoking up to 10 cigarettes a day is still quite common in a young Japanese population, and the exclusion of smokers may cause recruitment delays.

A compromise measure is to limit cigarette consumption to a total of 10 cigarettes a day and to prohibit smoking for 2 hours before vital signs or electrocardiograms are obtained.

**Caffeine/Xanthine Products** Intake of caffeinated food and beverages is nearly ubiquitous in both Japanese and Caucasian participants. Again, there may or may not be direct effects on the ADME profile, but there may be effects on urine output and vital signs, and caffeine withdrawal headaches and related symptoms affect the adverse events. Additionally, different forms and quantities consumed by different subjects adds another variable that could complicate data analysis.

For these reasons, use of xanthine-containing products is often excluded during a confinement period, and typically for 48–72 hours prior to the first dose and sometimes through the entire course of the study, even if there are outpatient visits following the confinement. However, use is so common and xanthines are contained in so many different products that it is difficult to get through a large study, especially with cross-over periods, multiple confinements, or multiple follow-up exams, without one or more subjects violating these conditions. So as to not have an unacceptable number of protocol deviations, or lose subjects prior to study completion, it is prudent to limit these restrictions or include language in the protocol such that a medical monitor may allow participation if the quantity consumed is deemed too small to have a clinically or pharmacologically significant effect.

**Exercise** At least in Hawaii, most young healthy study participants are quite active physically. While most medical authorities support an individual program of appropriate regular aerobic exercise, vigorous exercise while enrolled in a clinical pharmacology study introduces variables in cardiac output, renal and hepatic blood flow, hydration, and other circulation changes that can affect ADME data [54]. These are especially problematic if there are marked subject-to-subject differences in the intensity or duration of the exercise, especially if the subjects baseline level of fitness are dissimilar. Vigorous exercise can also cause elevation of creatinine phosphokinase (CPK), aspartate aminotransferase (AST), and other enzymes, which may raise unnecessary questions about the compounds potential to cause myositis, rhabdomyolysis, or cardiac or hepatic toxicity.

For these and related reasons, most bridging studies collecting ADME data limit or prohibit vigorous exercise during critical portions of the study conduct, and often for 48–72 hours before the first dose. When dealing with a young healthy population, it is also advisable to obtain a chemistry panel including CPK and AST at admission or prior to dose in addition to screening, to clarify exercise versus pharmacological effects if elevations are observed postdose exposure.

## 10.15.7 BRIDGING STUDY CONDUCT

### 10.15.7.1 Recruitment

If the study unit is located in an area with a large Caucasian population, recruitment of Caucasian subjects is about the same as recruiting for any other phase I study. Or sometimes easier, if the study compound is already approved by the FDA or there is a large body of safety data in Caucasians with dose exposure similar to the study of interest and the risk of significant adverse events is small.

Recruiting Caucasian subjects in Japan is limited by the available local Caucasian population, and performing bridging studies in Japan reflect the timelines and cost structure for other clinical pharmacology studies.

Recruiting Japanese participants outside of Japan is primarily limited by the local population of eligible Japanese subjects. Yet a sizeable population alone does not necessarily assure that they are willing to be study participants. Study participation is still viewed with considerable suspicion by many Japanese. When recruiting Issei participants, cultural biases exist against exposure to medications with unknown risks, as well as known adverse events even if the risks are small. Overcoming this bias requires establishing trust, credibility, and considerable discussion, a process usually facilitated with the assistance of Issei Japanese staff members and prior study participants.

As with any “special population” study, the narrower the population is defined the more difficult it is to recruit. Limiting the Japanese participants to Issei (versus four grandparents, allowing Sansei participants), restricting BMI to less than 25, prohibiting smokers, and restricting the upper age to 45 narrows the pool of eligible candidates, especially if the Issei subjects have a time restriction on how long they have been out of Japan. Inclusion/exclusion criteria allowing both male and female participants, but requiring the females to be Issei, out of Japan less than 5 years, under age 45, and of non-child-bearing potential means that for practical purposes, the study will only enroll male subjects.

“Matching” Japanese and Caucasian subjects by one or more criteria also complicates the recruitment process. Matching subjects by sex, weight, or age may increase the confidence in pharmacokinetic analysis but must be weighed against the greater time and expense required for recruitment.

### 10.15.7.2 Informed Consent

ICH and GCP standards require that the consent be truly “informed,” with the subject’s signature only after adequate discussion whereby the study staff is confident the subject truly understands the nature of the study, including its attendant risks, goals, benefits, procedures, and restrictions. The major concern with bridging study is language: If recruiting Sansei subjects who grew up with English as their primary language (for studies performed at American centers), obtaining informed consent is much the same as for English-speaking Caucasian subjects.

However, if the protocol requires Issei subjects, especially with a fairly short time restriction out of Japan, one cannot necessarily assume that a discussion in English and use of an English language consent is adequate. While Issei candidates may be conversationally fluent in English, the medical and legal terms in many consent

documents are not necessarily familiar to them, yet they may not want to admit they are uncertain about the meaning. At times, I have found this to be the case even when dealing with university students who attend classes conducted in English and read textbooks written in English. As mentioned earlier, informed consents are not a familiar item in Japanese culture, and signing a document listing possible risks in detail is uncomfortable for many Japanese.

For these reasons, it is usually advantageous to provide an informed consent document in Japanese, and utilize staff fluent in Japanese to facilitate the discussion. This means obtaining approval and maintaining two versions of the consent: one in English and one in Japanese. The institutional review board (IRB) must approve the Japanese translation and often require that the translation be performed by their own staff. Japanese sponsors often request that this translation be submitted to them for their review and approval before it is utilized. Maintaining dual-language informed consents adds time and cost, and needs to be considered in advance.

### **10.15.7.3 GCP Practices**

Good clinical practices are well specified elsewhere, especially ICH Section E6, and will not be discussed here other than to note that bridging studies must be compliant with these guidelines. Were it not for these consensus guidelines, bridging studies as we know them could not even be performed. Study planning and conduct compliance with these guidelines is what allows data from bridging studies to be acceptable when submitted to the new jurisdiction. Their importance cannot be overstated.

### **10.15.7.4 Adverse Events**

Definition and documentation requirements for adverse event collection and reporting are specified in the good clinical practices. Bridging studies follow these guidelines the same as other studies. There are two particular challenges: language and culture.

As explained when discussing the informed consent process, Japanese participants may not be familiar with English medical terminology even if fluent in ordinary conversation. And, as with all subjects, they may only understand and explain their symptoms using informal, colloquial terms with which they are familiar. If Issei subjects are enrolled, it is advisable to utilize staff fluent in Japanese to inquire regarding adverse events and translate their results.

Related to this, participant's use of concomitant medications from Japan often requires a search for drug names or components that can be coded for Western regulatory agencies.

Japanese culture generally downplays spontaneous adverse event reporting, as many feel that there is some level of shame associated with experiencing an adverse event. This makes active inquiry even more important. At a minimum, the "expected" adverse events would have been listed in the informed consent, and subjects should be made to feel comfortable describing these should they occur. A private environment with supportive staff fluent in Japanese should inquire at regular intervals regarding adverse events in general, make sure they are adequately characterized and "translated" into codeable terms, and continue follow-up until resolved.

### 10.15.7.5 Documentation

Documentation again follows GCP guidelines, generally utilizing source documents and separate case report forms (CRFs). The standard approach to “document everything” is especially important for bridging studies. Free-form progress notes and explanatory notes to file are important items even with excellent source documents, particularly for any protocol deviations or events out of the norm.

American study centers will generally utilize English language source documents. It is advisable to capture data using metric units for weights, measures, and temperature as much as possible. CRFs may be written or electronic. They will be in English if the study center uses English-speaking staff for data entry, but good CRFs will have already defined how the data will be coded in Japanese for their own NDA submission.

### 10.15.7.6 Monitoring and Audits

As the pharmaceutical industry becomes increasingly globalized, monitoring and audits are often shared between staff in Japan, the United States, and the European Union. These processes also follow GCPs. Adequate monitoring and detailed audits, with observation of study conduct and data verification, is a feature distinguishing ICH-compliant studies from clinical trials performed prior to ICH implementation.

Because bridging studies are pivotal by nature, most are audited, and may well be audited by more than one team. Bridging studies are also subject to audits from the regulatory agencies in both jurisdictions.

## 10.15.8 BRIDGING STUDY EXPERIENCE

Since the E5 guidelines were adopted in 1998, industry has responded by implementing bridging strategies and submitting NDAs utilizing bridging data. Starting with 3.2% in 1999, use of bridging studies increased steadily. In 2003, 25% of NDAs approved in Japan were based on a bridging strategy. Dr. Kato reported at the ICH Sixth International Conference on Harmonization (Osaka, Japan, November 2003) that at least 67 submissions had involved the application of the E5 guideline. Of course, this number does not include the bridging studies performed from 1998 to 2003 for development programs for which the NDA had not been submitted.

The experience of these early bridging studies remains instructive. We will cite examples of success and illustrate challenges encountered.

### 10.15.8.1 Examples of Success

The first bridging study for which I was the principal investigator was performed in July 1998, shortly after the E5 guidelines were adopted. We studied the single- and multiple-dose pharmacokinetic profiles of oseltamivir phosphate (Tamiflu), an antiviral product to treat acute influenza infection, in 24 healthy young males—12 Japanese and 12 Caucasians. The Japanese were all Issei. The data showed that

pharmacokinetics were similar in both populations and no safety issues were observed. These data allowed the sponsor to implement a clinical trial program in Japan to demonstrate safety and efficacy during the 1998–1999 and 1999–2000 influenza seasons, and this product was approved in Japan in 2000 with the bridging study allowing use of safety and efficacy data generated in the United States and the European Union coupled with data from the studies in Japan. Early approval and introduction into clinical use has potentially saved many lives in Japan, which would have been otherwise lost to influenza. Early approval would not have been possible without the use of bridging data.

A recent review selected 26 total NDAs approved in Japan from 1999 to 2003 based on a bridging strategy. This list only included new drugs. Target clinical domains vary considerably and include cancer, viral infections, diabetes, osteoporosis, rheumatoid arthritis, migraine headache, age-related macular degeneration, glaucoma, Parkinson's disease, renal transplant rejection, allergic rhinitis, erectile dysfunction, and *Helicobacter pylori* eradication. Six of these compounds start at lower doses or limit the highest dose. Others have differences in labeling. Examples have been cited previously in this chapter.

The bridging strategy for these compounds typically included an ADME study coupled with one or more phase II/III safety and efficacy studies performed in Japan, with their design based on foreign data and the results of the ADME study. The ADME study enrolled healthy subjects in 12 of these 26 cases, healthy subjects plus patients in 4 cases, and 5 cases used an independent ADME study plus measuring the PK in their efficacy trials.

The bridging strategy “worked” in terms of the goal to save time and money. Measuring the clinical development period from the time when a phase II/III efficacy and safety study began in Japan to the time of NDA submission, the median time for NDAs using a bridging strategy was 32 months versus 56 months for compounds without a bridging strategy, a savings of 24 months [55].

### 10.15.8.2 Challenges

Discussion at the ICH Sixth International Conference on Harmonisation also included some of the challenges and difficulties encountered with some bridging programs. All concerned recognized there was some misunderstanding and confusion regarding the E5 guidelines. Attempts to clarify included a Questions and Answers document approved in November 2003, based on actual experience.

In short, issues included differences of opinion between industry and the MHLW on what constituted intrinsic and extrinsic differences, assessment of a compound's “ethnic sensitivity,” how to interpret GCP compliance, definitions of disease and medical practice in defining patient populations, criteria for evaluating risk–benefit ratio if disease incidence varied between regions, labeling for multiple indications once bridging established efficacy for the primary indication, criteria for determining if foreign data met regulatory requirements for acceptability, and mutually acceptable surrogate endpoints when assessing efficacy. Still, industry felt that the E5 guidance overall saved them time and money in their development program.

### 10.15.9 SUMMARY AND FUTURE DIRECTIONS

Again we ask the question: “Do bridging studies work?” The examples provided illustrate that the answer to this is “yes,” that bridging studies have allowed use of existing data with an abbreviated and streamlined drug development program in the new jurisdiction, saving both time and money in NDA approval.

Do bridging studies always work? No, not all have produced the expected outcome for the resources invested.

Let us come back to the question posed at the beginning of this chapter: Are “ethnic differences” real?

My answer to this is “yes,” at least for certain compounds. Some compounds have similar properties across all ethnic groups studied, and individual intraethnic variation is greater than interethnic variation. Yet for other compounds, we see characteristic pharmacokinetic or pharmacodynamic differences in one ethnic group that are quite distinct from our observations in other ethnic groups. In some cases, we have defined one or more mechanisms that account for these findings. In other cases, there are multiple mechanisms, or we do not have a clear explanation for all of our findings. We may not be able to distinguish the particular contribution of genetics versus diet, environment, lifestyle, medical practice, or the interaction of these factors within a region, all cumulatively considered “ethnic differences.” Yet we know that certain medications need to be used differently in one region than another.

As we continue our investigations, it is prudent to respect the unique culture and traditions of each jurisdiction. While we are answering scientific questions, it is prudent to design our studies with awareness of the historical, social, political, and medical context affecting the respective regulatory agencies.

### **10.16.1 INTRODUCTION**

Although our recognition of viruses as the etiologic agents of infectious disease only dates from the early years of the twentieth century, it is interesting to note that vaccines against smallpox and rabies were introduced much earlier. In the case of smallpox the procedure referred to as *variolation*, in which skin lesions from infected individuals were administered to those without lesions, dates back to the late Middle Ages [1]. Despite this, the observation by Jenner in 1798 that milkmaids continuously exposed to cows infected with cowpox were largely resistant to endemic

smallpox is rightly regarded as the origin of modern vaccination practice. Rabies vaccines, consisting of formolized suspensions of infected animal brain material and introduced in the late nineteenth century, were highly reactogenic but were used as recently as the 1960s when they were replaced by vaccines prepared from viruses grown in cell culture [2].

Most viral vaccines in use today were developed as a consequence of our ability to cultivate viruses in embryonated eggs (from the 1930s) or cell cultures (the 1950s and 1960s) and so fulfill the second of Koch's postulates for establishment of the etiology of an infectious disease. Until their discontinuation for general use in the early 1980s, vaccines against smallpox were prepared from vaccinia virus grown on the skin of calves, a procedure that would now be completely unacceptable. In vitro cultivation of bacteria was first achieved in the late nineteenth century, and many highly effective bacterial vaccines used today (notably those for the prevention of tetanus and diphtheria) were available by the 1920s. For other significant human viruses, such as hepatitis B, C, and the human papilloma viruses, the second of Koch's postulates has never been fulfilled; until the late 1980s the antigens that comprise the active ingredients of hepatitis B vaccines were actually prepared from chronic hepatitis B carriers. Fortunately, over the past 15 years hepatitis B vaccines have been prepared by the application of molecular techniques and are far more acceptable from the standpoint of safety and at the same time much less expensive. Molecular technology has allowed the realization of preventive vaccines against human papilloma viruses [3]. However, despite much effort and an urgent need, vaccines against hepatitis C (HCV) or the human immunodeficiency virus (HIV) seem much further away. For other reasons, urgently needed vaccines against herpes simplex and cytomegaloviruses, both of which can be grown in cell culture, are still unavailable, and the same could have been said until recently of rotaviruses.

### 10.16.2 RECENT TRENDS IN HUMAN VACCINE MANUFACTURE

Greater concerns about safety over the past 30 years have increased the costs of viral vaccine development to the point where all but a handful of very large multinational companies have the resources to fully comply with all the steps necessary for registration in the two major regulatory jurisdictions, the Food and Drug Administration (FDA) and the European Union. These costs have been largely driven by the willingness of U.S. courts to grant extraordinary damages against manufacturers for claims, some inspired by negligence but others due to historical gaps in our knowledge at the time of the original product registration. Examples of the latter will be given below. Until the last 20 years human viral and bacterial vaccines were prepared in Western countries by about 30–40 medium to large sized companies and a comparable number of state-run institutions or statutory corporations. The *state serum institutes* of several European countries were founded early in the twentieth century and are good examples of the latter. Their existence followed advances in microbial cultivation and the identification of blood groups around the turn of the twentieth century and the consequent development of vaccines and serum therapies, largely for use within the same country. Similar institutions had a

prominent role in the countries of the former Soviet Bloc, with their strong emphasis on immunization and public health planning. In several countries of the developing world similar institutes undertook vaccine manufacture under the aegis of colonial powers, as exemplified by the various Pasteur Institutes of some Francophone countries of Africa and Asia. The importance of these institutes in the provision of biologics was greatly enhanced by two world wars. In Australia, for example, the Commonwealth Serum Laboratories (now CSL Ltd) was instituted by the government of the day in 1917 for the express purpose of supplying smallpox vaccine for use by the Australian army in World War I in response to a likely shortfall in supply from manufacturers in the United Kingdom. CSL Ltd has greatly expanded its range of vaccines and other biologics since 1917 but is no longer a government-owned institution. As with comparable organizations, nearly all of its output, until comparatively recently, was reserved for use within Australia. The *raison d'être* for their survival over almost a century has been based primarily on perceptions of national interest!

Over the past 20–30 years most small manufacturers of human vaccines have either disappeared and/or have been subsumed by or developed strategic alliances with four giant multinational companies (*Bigpharma*). Only Bigpharma has the resources to undertake the complete development of human vaccines from early research to final clinical application, although, for many vaccines, early research relating to proof of concept is frequently undertaken by smaller start-up companies—often in association with research institutes. Because of the international nature of their operations, vaccine manufacture and accreditation of existing vaccines by Bigpharma may be carried out in more than one country. The cornerstone of modern manufacture has been the emergence of rigidly enforced international codes of good manufacturing and laboratory practice (GMP and GLP). Most countries with only limited capacity to manufacture human viral vaccines may, nevertheless, impose regulatory conditions for efficacy, safety, and standardization that are relevant to local needs. In practice, because of the sheer cost and complexity of manufacture, requirements for registration by the federal drug authority in the United States and the European Union [often with guidelines set by the World Health Organization (WHO)] remain points of reference for most national regulatory authorities.

### 10.16.3 EVENTS OVER 60 YEARS THAT HAVE CONTRIBUTED TO CHANGES TO REGULATORY ENVIRONMENT FOR DEVELOPMENT OF HUMAN VIRAL VACCINES

1. *Contamination of Yellow Fever Vaccine by Hepatitis B by Serum Preservatives (1940s)* The development of live vaccines against yellow fever and, in particular, the introduction of the egg-grown attenuated 17D strain by Theiler's group at the Rockefeller Institute just prior to World War II was a major achievement in human medicine. By April 1942 some 7 million doses had been administered to the U.S. Armed Forces alone, using vaccines prepared by the Rockefeller Institute. Yellow fever viruses are highly labile, and thermostability was conferred by the addition of human serum to the vaccine, at a time when nothing was known of the etiology of

the hepatitis B virus. By December 1942 over 50,000 cases of hepatitis and 84 deaths were recognized from infection arising from contaminated lots, representing some 2.5 million administered doses. The involvement of human serum was quickly recognized, despite the absence of definitive tests (which only became available in the 1970s), and the problem was overcome by elimination of the serum from the vaccine [4].

2. *Cutter Incident: Release of Inactivated Poliomyelitis Vaccines (IPV) Containing Residual Amounts of Live Poliovirus (1955)* Soon after the commencement of programs for the mass immunization of children in the United States, a batch of IPV, prepared by Cutter Laboratories in California, was released and subsequently shown to be responsible for poliomyelitis in 79 vaccinated children, 105 family members, and 20 community members [5]. Despite the overwhelming success of the immunization program, the *Cutter incident* and the investigations that followed provided the catalyst for the introduction of powerful national agencies for the registration of vaccines.

3. *Contamination of Early Batches of IPV by Simian Virus 40 (SV<sub>40</sub>)* Between 1955 and 1963 successive batches of IPV prepared in primary monkey kidney cultures were shown, retrospectively, to have been contaminated with SV<sub>40</sub>, a commensal of certain species of monkeys and referred to as the vacuolating agent from the cytopathic effect produced after inoculation to certain cell lines. In the United States alone, it was estimated that 10–30 million individuals were inoculated with contaminated vaccines. Because SV<sub>40</sub> virus is a member of the family Papovaviridae, members of which are oncogenic for several animal species, concerns were expressed about long-term risks to vaccine recipients. Some 30 years later and, after comprehensive epidemiological studies in the United States and Europe, the balance of evidence indicates no causal relationship between the receipt of contaminated vaccine and cancer [6].

4. *Enhancement of Pathogenicity in Infants Receiving Experimental Formalin-Inactivated Respiratory Syncytial Virus (RSV) Vaccine* Respiratory syncytial virus is the most significant respiratory pathogen of the neonatal child for which a vaccine is urgently required. In a traditional approach to control, a formalin-inactivated vaccine was administered parenterally to infants in 1968 at the Children's Hospital in Washington, D.C. Results of the study indicated that not only was the vaccine unprotective but recipients who were subsequently subjected to natural challenge experienced enhanced immunopathology in the form of Arthus-type hypersensitivity reactions [7]. These results have had profound consequences for the development of effective vaccines against RSV, and most efforts since have been directed toward the use of intranasally administered live attenuated vaccines. Experimental vaccines for use in neonatal children present unusual difficulties both in immunologic terms and from an ethical standpoint. Despite considerable progress, vaccines against RSV are still unavailable almost 40 years after the Washington study.

5. *Molecular Instability of Oral Poliomyelitis Vaccines (OPVs): Recognition of Vaccine-Associated Paralysis (1970s)* Oral poliomyelitis Vaccines have been crucial for the elimination of poliomyelitis from all but a few regions of a very small number of countries, under programs sponsored by the WHO in recent years [8].

These vaccines were developed in the early 1960s at a time virtually nothing was known as to the genetic stability of their live virus components. Molecular techniques developed over the past 20 years now indicate instability for some of these viruses following human passage, which is associated with reversion to neurovirulence [9]. If molecular evidence for instability had been available in the 1960s, OPVs would almost certainly not have been licensed and there would have been little prospect of eliminating poliomyelitis from the world some 40 years later. IPV's can only be afforded in developed countries where they have largely replaced OPVs in order to overcome concerns associated with instability.

6. *Association between Guillain-Barré Syndrome (GBS) and Receipt of Swine Influenza Vaccine (1976–1977)* In 1976 following the death of a soldier at Fort Dix, New Jersey, after infection with an H1N1 (swine) virus with apparent antigenic similarities to the agent responsible for the 1918–1919 pandemic, a decision was made to offer the entire U.S. population specially prepared monovalent vaccines. The program was curtailed after an association was recognized that resulted in the attribution of 8–10 excess cases of GBS per million during the first 6 weeks after administration of the A/swine vaccine [10]. For reasons unknown, the incidence of GBS in subsequent vaccines has been much lower, and egg-grown inactivated vaccines remain the principal public health measure for the prevention of influenza.

7. *Possible Association between Intussusception and Administration of Oral Rotavirus Vaccines (1999)* A quadrivalent reassortant simian rotavirus vaccine was licensed in 1998 for manufacture and distribution by Wyeth Laboratories and approved by the FDA after extensive testing in several countries. The vaccine was prepared for administration to infants in 3 doses at 2, 4, and 6 months. Within 12 months, subsequent evaluation of U.S. clinical data suggested a small increase in the frequency of intussusception in infants who received the vaccine, especially after the first dose [11]. Despite an urgent public health need for effective preventive measures against rotaviruses and developmental research programs extending over many years that were largely publicly funded, the vaccine was withdrawn. Fortunately, a reassortant vaccine of bovine origin and prepared by Merck was approved by the FDA in 2006, which, it is hoped, will have an impact on neonatal rotavirus infections, especially in the developing world [12].

8. *Association between Intranasal Administration of Inactivated Influenza Vaccine and Bell's Palsy (2000)* An influenza vaccine was prepared by a Swiss company (Berna Biotech) in which vaccine surface antigens were incorporated into carrier liposomes. The heat-labile *Escherichia coli* enterotoxin, a powerful mucosal adjuvant, was incorporated into the formulation. After its introduction in Switzerland, the risk of Bell's palsy was increased by a factor of 19 among those who received the vaccine intranasally. An increase did not occur in recipients who received the vaccine by parenteral injection [13]. These adverse events were not detected in prelicensure trials and the vaccine has since been withdrawn.

The list is incomplete but these events have profoundly affected the regulatory environment and have been accompanied over the same time by a vast increase in our understanding of viral replication and pathogenesis, with flow-on consequences

for product liability. Consequent advances over the period have also occurred in vaccine safety testing and in the development of models for vaccine evaluation in test populations that allow the power of a study to be estimated well in advance of its commencement. We now have a vastly increased array of standardized tests, both biological and molecular for estimating (1) the active ingredient(s) of a vaccine, (2) the presence of known adventitious contaminants, and (3) the likely toxicological consequences of its use in humans. However, the need still exists for extensive and costly clinical testing in a climate where ethical constraints on the use of volunteers for clinical trials have been greatly increased in the years immediately before and after the Declaration of Helsinki in 1964 [14]. Many trials that were conducted on earlier vaccines would be simply disallowed these days by institutional review boards, which place strong emphasis on need to provide comprehensive information on the nature of a trial to each volunteer at the point of entry. They also require to be adequately briefed concerning inducements, financial and otherwise, that are provided to volunteers. Overall, the manufacture of viral vaccines and other biologics has become commercially unattractive for all but a handful of very large manufacturers. As a consequence, the role of governments in sponsoring and meeting the costs of developing new vaccines has increased greatly.

Many highly successful vaccines for the prevention of measles, poliomyelitis, rubella, mumps, and yellow fever were developed in a much less stringent regulatory environment, and it is arguable whether many would have been registered today. The situation with OPVs has already been discussed but, to take another example, measles vaccines were first developed in the early 1960s at a time when very little was known about subacute sclerosing panencephalomyelitis (SSPE), a rare and unpredictable immunologic complication of measles associated with chronic neural infection. Effective vaccines against measles consist of live virus preparations and, if SSPE had been widely recognized at the time, the onus would have been placed on vaccine developers to prove that mass administration was not associated with SSPE. Given that there are still no satisfactory *in vitro* markers for SSPE, this would have been an impossible task and measles vaccines would probably never have become available.

Over the same period and in a very different regulatory environment, the countries of the former Soviet Bloc have made enormous and often unrecognized contributions to vaccinology. Nowhere was this more evident than in the adoption of OPV for the prevention of poliomyelitis in Western countries in the early 1960s, following the conduct of very large field trials under the direction of Smorodintsev and his colleagues in the former Leningrad [15]. The recent reemergence of childhood infectious diseases, such as diphtheria, in former Soviet countries is ample testimony to the success of former state-sponsored programs, many of which have not been maintained over the past 10–15 years. [16].

#### **10.16.4 EXPANDED PROGRAMS FOR USE OF VACCINES IN DEVELOPING COUNTRIES**

The global program sponsored by the WHO for the elimination of smallpox between the mid-1960s and the early 1980s is widely regarded as perhaps the greatest medical achievement of the twentieth century. Its success has removed the need for smallpox

vaccination—often associated with unacceptable adverse reactions—and delivered significant economic benefits, mainly to the developed world, by eliminating the need to maintain vaccination programs.

Because of the success of that program, several initiatives have commenced over the past 20 years for the elimination of pediatric viral diseases, using vaccines widely used in Western countries. These programs have been supported by philanthropic organizations, such as the Gates and Rockefeller Foundations, usually in close collaboration with the WHO. Mention has already been made of programs for the elimination of poliomyelitis by the strategic use of OPV. Another program is concerned with immunization against measles, a cause of high mortality in developing countries especially in association with malnutrition. Logistical problems in this and similar programs arise from difficulties in vaccine delivery due to poor infrastructure and problems in maintenance of the *cold chain*. Protective responses to the vaccine may be diminished by the presence of maternal antibody that is associated with high levels of measles endemicity. Here, the window of opportunity to vaccinate a child after the decline of maternal antibody but before natural exposure to the virus is often relatively narrow. It should be remembered that the use of combination measles–mumps–rubella vaccines in infants was only possible in developed countries by the elimination of endemic measles by earlier vaccination programs! Reservoirs of measles, poliomyelitis, and other preventable pediatric viruses are much more widespread, and these viruses are responsible for much higher rates of sub-clinical disease than smallpox viruses. Vaccination programs against these viruses will, therefore, need to be maintained until well after the elimination of reported clinical disease.

### 10.16.5 CLINICAL STUDIES NECESSARY FOR DEVELOPMENT OF NEW VACCINES

Figure 1 provides an indication of the cost and time scale of any program for the development and registration of a hypothetical new vaccine for the prevention of a specific viral disease. The entire process is broadly divided into four phases of

**FIGURE 1** Vaccine development process.

variable length and complexity, which relate to the virus itself, its pathogenicity, and technical impediments that may stand in the way of evaluating its effectiveness as a preventive measure. For the registration of many vaccines, data from phases II and III or II and IV trials are considered as single categories by regulators. These studies involve the participation of increasing numbers of volunteers in clinical trials and are the most expensive part of the registration process. They are generally beyond the resources of most small-to medium-sized manufacturers and research institutes and can only be undertaken by BigPharma to achieve near-simultaneous registration in many countries.

Before clinical studies can commence, a dossier of preclinical study results, and the proposed protocols for human studies are submitted to the regulatory agencies. For the FDA, an investigational new drug (IND) application is made. Clinical trials are classified as phase I, II, III, or IV, depending on the stage of clinical development of a vaccine. Phase I studies are *first-in-human* studies in which the drug is administered to small numbers of healthy volunteers to determine safety and tolerability, as well as pharmacological activity. Results can also provide information as to appropriate dose ranges for future studies. If there is a high possibility of toxic side effects, then the drug may be only administered to the patients for whom it is primarily intended. Therapeutic vaccines against HIV and hepatitis C could be examples of such an approach. Phase I studies are usually conducted in purpose-built facilities that allow close monitoring of patients.

The principal purpose of a phase II study is to determine vaccine efficacy in small groups of the targeted patients, although safety data is also collected. A range of doses is generally used to determine the maximum tolerated dose and the therapeutic range. Phase III studies are conducted in large groups of patients if phase II studies indicate that the drug is safe and has potential clinical benefit. Efficacy data continues to be collected in phase III studies, together with data on the incidence and nature of adverse effects. Phase IIIb studies may be undertaken while the application for licensing is being assessed to provide further safety and/or efficacy data (periapproval studies).

Once approval for marketing is granted, phase IV studies are conducted to determine efficacy in the typical clinical setting (using inclusion/exclusion criteria less stringent than those in the protocols for the phase III studies). Postmarketing surveillance is conducted to track adverse effects and studies comparing the new drug to existing therapies, or its role in combination therapy, may be conducted as part of phase IV studies.

### 10.16.6 THE FUTURE

The advent of recombinant deoxyribonucleic acid (DNA), together with the emergence of HIV and, more recently, HCV viruses as major human pathogens have given new impetus over the past 20 years to technologies associated with viral vaccine development. Ironically, the very success of commonly used vaccines for the prevention of poliomyelitis, rubella, mumps, and yellow fever was a major reason for a diminution of interest in vaccine technology from the mid-1960s to the early 1980s. Both HIV and HCV have been targets for an unprecedented increase in research funding on vaccines in recent years. However, for several technical reasons

not discussed here, vaccines are still unavailable against either agent, either for preventive or therapeutic use.

In recent years great changes have occurred in most countries following the acceptance by governments and other public bodies of the need to maintain vaccination programs as a basic human right. These changes have been accompanied by commensurate improvements to vaccine production, which should have resulted in improved efficiencies and lower costs and a reduction in the time and cost required for the registration of new vaccines. Unfortunately, this has not been the case. Regulatory agencies are increasingly able to fast-track approvals for new products for use in situations of immediate need, such as for the development of avian influenza vaccines, that make use of newer molecular and older technologies. However, the majority of new vaccines are only approved many years after an etiology has been established for a previously unrecognized disease or a novel approach has been put forward as an alternative to a new vaccine. Contemporary examples of these delays include (1) live attenuated vaccines against influenza, which were first proposed in the 1970s and achieved registration for restricted use by the FDA in 2002 and (2) rotavirus vaccines, referred to above, in 2006—some 33 years after an etiology was established! Costs associated with bringing a new vaccine to the community are reported to be \$US500–900 million, although BigPharma often avoid disclosing specific details, citing commercial sensitivities. National regulatory agencies are highly risk averse and are responsible for ensuring the quality, efficacy, safety, and timely availability for vaccines for the community, through a uniform system of regulatory controls. They are involved in all aspects of vaccine development from initial discovery to postapproval surveillance for adverse effects in close consultation with vaccine developers. The reasons for their increased involvement are historic and have been outlined above. However, it is fair to state that many developers of highly successful pediatric viral vaccines would have experienced great difficulties in achieving registration today. It is also highly problematic whether the manufacture of such vaccines in the current regulatory environment would be profitable, even allowing for the economies of scale enjoyed by BigPharma.

While the prevention of viral diseases by vaccination has been a singular triumph for medical science, many challenges still exist. Quite apart from HIV and HCV, vaccines are still unavailable for the prevention of most respiratory virus infections, and improvements to existing influenza vaccines are universally regarded as a matter of urgency. Vaccines are also unavailable for the prevention of all human (but not veterinary) herpesvirus infections, again despite an urgent need. Much work needs to be done to expand the number of adjuvants to improve the performance of existing and future vaccines (at present only alum is acceptable), despite the formidable problems that have been encountered over the past 20 years in this area. It would be a great pity if the constraints referred to above gave rise to a diminution in the forces of innovation that have been responsible for so many improvements to public health over the past century.

The randomized controlled trial (RCT) is one of the simplest, most powerful, and revolutionary tools of research. In essence, the RCT is a comparison of two or more interventions in which people are allocated at random to a treatment group. Randomization is a method of eliminating bias in the way that treatments are allocated to patients, but it does not guarantee that the characteristics of the groups will be completely balanced; in that if imbalance occurs it will have occurred by chance rather than by the introduction of some systematic bias. Some factors are known in advance to be important risk factors associated with the outcome of the patient. Imbalance in these prognostic variables could have a marked effect on the results of a trial and on their credibility. However, if the randomization is performed fairly, then any difference between groups is due to chance, but the groups might differ in a way that might affect their response to treatment (this is a question of clinical importance rather than statistical significance). While it is possible to modify the statistical analysis to take account of any differences between groups at baseline, it is better to control the problem at the design stage.

There are four classes of randomization procedure: complete (simple) randomization, restricted randomization, covariate-adaptive randomization, and response-adaptive randomization. The simplest randomization procedure is complete randomization with equal allocation and does not depend on prognostic factors or previous treatment assignments. Restricted randomization is used when it is desired to have equal numbers of patients assigned to each treatment group. Covariate-adaptive randomization is used to achieve similar numbers of patients in each treatment group and also to ensure that patient groups are similar with respect to prognostic factors such as age or gender. In response-adaptive randomization the treatment assignments depend upon previous patient responses to treatment. These different approaches to generating the random sequence will be discussed in detail in Sections 11.2–11.4.

## 11.1 PATIENT REGISTRATION

In a randomized controlled trial patients are identified for entry to the trial and, if they are eligible and consent to trial entry, they are then randomized to one of the study treatments. For a patient to be included into a clinical trial the following steps are necessary:

- Patient identification and recruitment
- Confirmation of eligibility
- Agreement to randomize
- Informed patient consent

- Formal entry to trial
- Treatment assignment
- Completion of relevant documentation
- Commencement of treatment

### **11.1.1 Patient Identification and Recruitment**

How potentially eligible patients are to be identified and how and where they are to be approached should be outlined in the study protocol. The study design team should have made these decisions so as to ensure that the study population will be as representative as possible of the particular disease area under investigation to ensure the generalizability of the results. All appropriate patients should be logged even if they are ineligible or missed so that a full record of potential recruits is obtained. This can then be used as a check that systematic selection bias of patients into the trial had not occurred. The recruitment process should be outlined fully and could consist of a script for the recruitment officer to follow.

### **11.1.2 Confirmation of Eligibility**

Eligibility criteria should be agreed upon before recruitment begins and should be recorded in the study protocol. The recruitment officer should check that a potential participant satisfies the eligibility criteria before asking them to consent to the trial. If the patient is recruited and then subsequently found to be ineligible, this should be logged and the decision whether to include them in an intention-to-treat analysis, or exclude them from analysis according to some consistent algorithm, made at a later date. Postrandomization exclusions unrelated to noncompliance, withdrawal, or losses to follow up occur when patients are inappropriately randomized into a clinical trial [1]. These patients can be removed from both study arms without risking bias. The number of patients randomized but not included in the primary analysis should be clearly stated along with the reasons for exclusion.

### **11.1.3 Agreement to Randomize**

It is vitally important that the patient understand the concept of randomization and agree to accept the outcome of the treatment assignment. The recruitment officer will have to explain this very carefully and be satisfied that the patient has a good understanding of the process. Patients may have a preference for one treatment over another, and it is sometimes desirable to record this as it can help to better understand subsequent noncompliance. However, the recruitment officer must be assured that this preference is not so strong that the patient will then not comply with the allocated treatment. In this situation patients are uncertain about the treatment choices and therefore should not agree to be randomized. This concept also applies to any clinician who has a strong treatment preference or who is unwilling to randomize the patients. There are study designs that allow treatment allocation according to either patient or collaborator preference, which may be adopted in order to increase recruitment especially in surgical trials.

### 11.1.4 Informed Patient Consent

There is a strong ethical and legal requirement to obtain informed consent to a randomized control trial before the patient is randomized. Therefore, it is important that the recruitment officer ensures that the patient fully understand the purpose of the study as well as agreeing to the randomization process. A well-designed patient information leaflet will describe these concepts. It should also outline what patient involvement is expected for the duration of the study (medication to take or surgery to be undertaken, clinics to attend, questionnaires to be filled in, etc.) and what steps should be taken if, at any time, the patient wishes to withdraw from the study. Patients are usually ineligible if they cannot give informed consent. For example, they cannot understand English (if there are no translations available) or they have mental health problems. Such exclusions would be stipulated in the protocol.

### 11.1.5 Formal Entry to Trial

If all the previous steps have been taken and a patient is identified as being eligible for entry to the trial, then it is necessary at this stage to record some basic demographic details about that patient. The patient's name and address can now be logged for entry into the study database. If any important prognostic factors have been identified and are to be used in the randomization process, the values should be recorded on a designated pro-forma prior to randomization. The patient might be allocated a study number at this stage (or this might be allocated at the time of randomization) if randomization is done by an external randomization service.

### 11.1.6 Treatment Assignment

Adequate concealment of treatment allocation is widely recognized to be of paramount importance to the scientific validity of any clinical trial [2]. As such, randomization should not be performed by the recruitment staff. Randomization may be performed by staff in the central study office or by an independent trials center offering this service. It is common to use either a randomization list or computer program to do this, and the process involves either sending paper forms to the randomization center for manual data entry and treatment allocation, by telephoning an automated system, or using a Web-based randomization system. Treatment allocation by sealed opaque envelopes is not recommended as this method has been shown not to be tamper-proof (e.g., envelopes have been observed to have been opened out of sequence; and there has been evidence that envelopes have been opened in advance to seek prior knowledge of treatment assignment).

Some common study scenarios are as follows:

(a) *Multicenter Trial with Central Study Office* If the trial design requires immediate treatment assignment (or randomization outside normal working hours), then it is preferable to use an automated telephone randomization service often referred to as an IVR (interactive voice response) system. A benefit of this system is that a full audit of the randomization process is automatically created. The date and time

of randomization is logged, along with at least one patient identifier so that treatment allocations can be proven to be fair and unbiased. IVR systems also help to maintain blinding since there is no staff involvement and no need for code break envelopes. It is necessary, however, to ensure that backup procedures are documented in case of very occasional system failure. It is now routine that these systems can be configured and maintained relatively cheaply, with minimal denial of service achieved for affordable cost.

This system may be backed up by IWR (interactive web response) systems, which may help overcome language difficulties (e.g., understanding of written English can often be easier than listening to a voice over the telephone). The person performing the randomization also has more time to read and digest instructions, and helpful tips can also be included on the page. It is also possible to construct multilingual Web or telephone systems. The use of an IWR system offers further benefits as it is possible to extend the system to include real-time reporting (giving up-to-date information about recruitment, randomization, and patient status). Some recent trials have also used this technology for the collection of electronic patient-reported outcome data [3].

If randomization is required only within normal working hours, then treatment assignments can be read off the randomization list and given to the recruitment officer over the telephone. Ideally, a small, customized computer program would be used to store the list and output the next treatment assignment as required to minimize breaking allocation concealment. If sufficient funds are available, then an automated system is preferred as this does not rely on someone being available to answer the telephone.

If patients are screened first and then only considered for randomization later, for example, after responding appropriately to a screening questionnaire, then an automated system may not be necessary and a computerized randomization system may be written into the trial management program. If the code is kept secure, then this would offer all the benefits of an automated telephone response system without the expense.

The randomization scheme itself could consist of an allocation list constructed from permuted blocks or might incorporate a program using minimization if important prognostic variables had been identified.

(b) *Double-blind Trial of Drug Therapy* For this type of trial design the pharmacist preparing the drugs needs to have access to the treatment allocation. While the randomization lists continue to be created by the study office or the trials unit performing the randomization, the treatment allocation should now also include a corresponding drug treatment identifier that will be used to label the drug. These lists are then sent to the pharmacy where the drugs are prepared and packaged according to the list. Treatment unblinding can be performed by the pharmacy and/or the central randomization service.

When a patient is randomized into the trial, the recruitment officer telephones the automated service. The patient is allocated a treatment allocation number, which is known to be in stock at that site. If the randomization algorithm uses random permuted blocks, then the allocated treatment will simply be the next available one on the list for that site. If a minimization algorithm is being used, then the allocation will be the next available pack of the appropriate drug type. The randomization center must be aware at all times of the current stock levels at each site and an early

warning system can be written into the IVR system to alert the pharmacy when stocks are low.

(c) *Single-Center Trial* For a single-center trial there are several possible solutions. The randomization can be performed by an independent person who is not involved with the trial; a small local computer program that incorporates a full audit trail can be written to perform the randomization; or a central randomizing service may be used if funds permit.

### 11.1.7 Completion of Relevant Documentation

At this stage in the study the following documentation should be available:

- A log sheet of all patients identified as appropriate for the study
- Ineligibility forms for those not eligible
- Eligibility forms for those considered eligible for entry to the study (with the study number)
- A consent form appropriately signed and dated (with the study number)
- A baseline data form containing basic demographic data (with the study number), previous medical history, relevant information about their clinical condition, and any baseline questionnaires (such as SF36, EQ-5D)
- (*Optional*) A randomization form containing the values for any prognostic factors, the treatment allocation code, and the study number

Any forms should be piloted before the study commences and committed to final printing only after this has proved successful. Consideration must be given as to where these forms are to be stored, and for what length of time, as any patient identifiable material should be kept in a secure environment.

### 11.1.8 Commencement of Treatment

Treatment should commence as soon as possible after randomization; so in a multitherapy trial each randomization should take place only when the patient is ready to receive that treatment. In a drug therapy trial each dispatch of study treatment requires rigorous control, and batch numbers should be checked and recorded. It is not sufficient to record only the drug pack allocated at randomization; the actual drug pack received should also be recorded.

## 11.2 GENERATING THE RANDOM SEQUENCE

In Sections 11.2.1–11.5 a description of each randomization method including advantages and disadvantages is given. This outlines the resources required, ease of use of method, allocation concealment, and predictability of the method.

In most clinical trials the complete list of participants is not available at the start of the trial, and patients will be recruited and randomized one at a time as they are identified. For both single-center and multicenter trials it is preferable that the randomization is performed by an independent organization or a central study

office to ensure that the randomization is carried out according to the required specification.

### 11.2.1 Simple Randomization

With simple randomization each patient has a known chance, usually equal, of being given each treatment, and the treatment to be given cannot be predicted in advance. The simplest method is tossing a coin, but one can also use random tables, or a random-number generator in a calculator or computer. Table 1 gives an example of a table of random digits that were generated by computer (see Appendix I for the code). To randomize a patient, (a) choose an arbitrary starting point in the list and (b) work along the rows assigning treatments by using the numbers on the list.

**Example** For *two* treatments assume the digits 0–4 correspond to treatment A and digits 5–9 correspond to treatment B. Therefore the top row of Table 1 would produce the following treatment assignments:

|   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 5 | 5 | 6 | 3 | 1 | 3 | 9 | 1 | 1 | 4 | 5 | 5 | 4 | 8 | 1 | 0 | 7 | 3 | 4 | 8 | 3 | 4 | 7 |
| B | B | B | A | A | A | B | A | A | A | B | B | A | B | A | A | B | A | A | B | A | A | B |

For *three* treatments assume the digits 1–3 correspond to treatment A, digits 4–6 correspond to treatment B, and digits 7–9 correspond to treatment C. Ignore 0 (ignoring a digit has no effect on the inherent “randomness” of the sequence). The top row of Table 1 would then produce the following treatment assignments:

|   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 5 | 5 | 6 | 3 | 1 | 3 | 9 | 1 | 1 | 4 | 5 | 5 | 4 | 8 | 1 | 0 | 7 | 3 | 4 | 8 | 3 | 4 | 7 |
| B | B | B | A | A | A | C | A | A | B | B | B | B | C | A | — | C | A | B | C | A | B | C |

For *four* treatments assume the digits 1–2 correspond to treatment A, digits 3–4 correspond to treatment B, digits 5–6 correspond to treatment C, and digits 7–8 correspond to treatment D. Ignore 0 and 9. The top row of Table 1 would then produce the following treatment assignments:

|   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 5 | 5 | 6 | 3 | 1 | 3 | 9 | 1 | 1 | 4 | 5 | 5 | 4 | 8 | 1 | 0 | 7 | 3 | 4 | 8 | 3 | 4 | 7 |
| C | C | C | B | A | B | — | A | A | B | C | C | B | D | A | — | D | B | B | D | B | B | D |

The list should be produced before the start of the trial and should be large enough to complete the trial.

#### Advantages of This Method

- Each patient assignment is completely unpredictable; and, if the numbers are large enough (say  $\geq 500$ ), then probability theory allows us to be confident that the numbers in each treatment group will be similar.
- The method is very straightforward and easy to implement.

#### Disadvantages of This Method

- Table 2 illustrates the difference in treatment numbers that may occur in a two-treatment trial with probability at least 0.05 and at least 0.01. The probability of  $\geq 10\%$  overall imbalance between treatment groups is also shown.

TABLE 1 Table of Random Numbers

|   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 5 | 5 | 6 | 3 | 1 | 3 | 9 | 1 | 1 | 4 | 5 | 5 | 4 | 8 | 1 | 0 | 7 | 3 | 4 | 8 | 3 | 4 | 7 | 9 | 3 |
| 5 | 3 | 0 | 6 | 0 | 0 | 5 | 2 | 5 | 2 | 3 | 8 | 3 | 5 | 4 | 8 | 7 | 1 | 6 | 0 | 9 | 8 | 0 | 3 | 6 |

| 500                      | 104 in any group              | 98 in any group         | 0.004                                             |
| 1000                     | 220 in any group              | 213 in any group        | 0.001                                             |

- For three or four treatments, Tables 3 and 4 show the probability of no patients being allocated to one of the treatment groups, and the probability of  $\geq 10\%$  overall imbalance between treatment groups is also shown.
- There is also no guarantee that the groups are similar with respect to important prognostic factors, and for small to medium sized trials they are unlikely to be balanced. Therefore, in practice, some sort of restricted randomization is almost always used.

### 11.2.2 Restricted Randomization

Restricted randomization is used to balance treatment assignments assigned to each treatment group. Three possible approaches are described here.

**Random Permuted Blocks** A list of allocations is prepared before the start of the trial to be assigned in sequence order. This method is used to keep numbers in each treatment group closely balanced at all times, so there is a greater chance of balance whenever recruitment ends (which may be early). Blocks are made up of all possible permutations of treatment assignments. Therefore block sizes that are multiples of the number of treatments are easier to manage.

For two treatments, blocks of an even size would be used. It is unusual to use a block size as small as 2 as this makes guessing easier, but for a small trial with few patients it may be justified. The random numbers in Table 1 can be used to produce the randomization list.

*Example: Two Treatments, Block Size 2* Let 0–4 correspond to block AB and 5–9 correspond to block BA. The top row of Table 1 would then produce the following treatment assignments:

|    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| 5  | 5  | 6  | 3  | 1  | 3  | 9  | 1  | 1  | 4  | 5  | 5  | 4  | 8  | 1  |
| BA | BA | BA | AB | AB | AB | BA | AB | AB | AB | BA | BA | AB | BA | AB |

*Example: Three Treatments, Block Size 3* Let 1 correspond to block ABC, 2 to block ACB, 3 to block BAC, 4 to block BCA, 5 to block CAB, and 6 to block CBA. Ignore 0 and 7–9. The top row of Table 1 would then produce the following treatment assignments:

|     |     |     |     |     |     |   |     |     |     |     |
|-----|-----|-----|-----|-----|-----|---|-----|-----|-----|-----|
| 5   | 5   | 6   | 3   | 1   | 3   | 9 | 1   | 1   | 4   | 5   |
| CAB | CAB | CBA | BAC | ABC | BAC | — | ABC | ABC | BCA | CAB |

*Example: Two Treatments, Block Size 4* Let 1 correspond to block AABB, 2 to block ABAB, 3 to block ABBA, 4 to block BBAA, 5 to block BABA, and 6 to block BAAB. Ignore 0 and 7–9. The top row of Table 1 would then produce the following treatment assignments:

|      |      |      |      |      |      |   |      |      |      |
|------|------|------|------|------|------|---|------|------|------|
| 5    | 5    | 6    | 3    | 1    | 3    | 9 | 1    | 1    | 4    |
| BABA | BABA | BAAB | ABBA | AABB | ABBA | — | AABB | AABB | BBAA |

It is also common practice to make the second block the mirror image of the first block, for example, Block 1 (A B A B) becomes Block 2 (B A B A). Producing a list of randomly ordered numbers is easily done within Microsoft Access. To randomly order the numbers 0–19 first create a table, say called TblRandom20, with one field in it (called ID) and add the data values 0–19 into this table. Then create a query with the following SQL (Structured Query Language) syntax:

```
SELECT TblRandom20.ID
FROM TblRandom20
ORDER BY Rnd([ID]);
```

Each time this query is opened in the datasheet view it will produce the numbers 0–19 in a random order. For 20 digits the number of possible permutations (and therefore the number of differently ordered blocks) are:

$$20! = 20 \times 19 \times 18 \times \cdots \times 3 \times 2 \times 1 = 2432902008176640000$$

This can be used by a computer program (see Appendix II) to produce a list of random permutations as illustrated in Table 5, which can then be used to produce the randomization list.

**Example: Two Treatments, Block Size 20** Let 0–9 correspond to treatment A and 10–19 to treatment B.

The top row of Table 5 would then produce block 1:

|   |    |    |   |   |    |   |   |    |    |    |    |   |   |    |   |    |   |   |    |
|---|----|----|---|---|----|---|---|----|----|----|----|---|---|----|---|----|---|---|----|
| 9 | 18 | 17 | 5 | 3 | 10 | 2 | 4 | 11 | 13 | 12 | 14 | 6 | 7 | 15 | 0 | 19 | 8 | 1 | 16 |
| A | B  | B  | A | A | B  | A | A | B  | B  | B  | B  | A | A | B  | A | B  | A | A | B  |

And the second row would produce block 2:

|   |   |    |    |   |    |   |    |    |   |   |    |   |    |   |    |   |    |   |    |
|---|---|----|----|---|----|---|----|----|---|---|----|---|----|---|----|---|----|---|----|
| 4 | 1 | 15 | 10 | 5 | 14 | 3 | 18 | 17 | 9 | 0 | 19 | 2 | 12 | 6 | 11 | 8 | 13 | 7 | 16 |
| A | A | B  | B  | A | B  | A | B  | B  | A | A | B  | A | B  | A | B  | A | B  | A | B  |

When using a fixed block size, it is possible that the block size may be guessed (resulting in allocation concealment being subverted). If the block size has been correctly guessed, then the last assignment in each block could be predicted with certainty, and potentially half the treatments in a block might be guessed. Varying the block length can be used to prevent this occurring. Implementing a variable-block length design is most easily done by a computer program. The program given in Appendix III was used to produce a list of treatment assignments for a study design with two treatments and random block sizes of 4 and 6 for an intended study population of 200 patients. The output from this program was stored in a table that, when read sequentially, gave the following treatment allocation schedule (assigning treatment A to 0 and treatment B to 1):

B A B A B A A A B B A A A B B B A B B A B A B A B A B B A A B  
 A B A B A A A B B A B A B B A A B A A B B A A B B B A B A B A  
 A B A A A B B B A A B A B B A B B A B B A B A A A B A B A A A  
 B B B A A A B B B A B B B A A B B A A A B A B B A A B A B A B  
 B A A B B A B B A A B A B B A A B A B A A A B B B B A A A A B  
 A B B B A A B A B B A B B A B A A B A A B A B B A B B A A A B  
 B A B A A B B B A A B A A B A B B A A B A B B B A A A B A B B  
 A A B A B A B B A B A B A A A B B A A A B B A

### Advantages of This Method

- The list can be prepared in advance and will ensure roughly equal numbers in each treatment group even if recruitment stops early.

TABLE 5 Random Permutations of 20 Numbers (0–19)

|    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |

| 17 | 2  | 3  | 6  | 14 | 12 | 11 | 8  | 19 | 0  | 18 | 16 | 15 | 13 | 4  | 10 | 7  | 9  | 1  | 5  |
| 18 | 2  | 11 | 9  | 3  | 5  | 10 | 12 | 16 | 4  | 19 | 0  | 7  | 8  | 1  | 13 | 15 | 6  | 17 | 14 |
| 5  | 10 | 12 | 19 | 0  | 18 | 15 | 17 | 2  | 14 | 3  | 1  | 9  | 8  | 13 | 7  | 11 | 4  | 16 | 6  |
| 13 | 6  | 18 | 14 | 3  | 19 | 0  | 8  | 9  | 10 | 7  | 16 | 17 | 4  | 2  | 15 | 11 | 5  | 12 | 1  |
| 18 | 9  | 17 | 6  | 2  | 8  | 3  | 16 | 10 | 5  | 11 | 12 | 4  | 7  | 15 | 1  | 0  | 19 | 13 | 14 |
| 16 | 18 | 13 | 4  | 10 | 12 | 14 | 3  | 9  | 0  | 19 | 17 | 2  | 11 | 15 | 5  | 7  | 6  | 8  | 1  |
| 7  | 13 | 9  | 8  | 19 | 0  | 6  | 12 | 2  | 10 | 11 | 1  | 15 | 16 | 5  | 17 | 3  | 18 | 14 | 4  |
| 3  | 5  | 14 | 4  | 11 | 9  | 12 | 15 | 13 | 8  | 18 | 2  | 1  | 16 | 7  | 17 | 6  | 10 | 0  | 19 |
| 14 | 16 | 15 | 18 | 12 | 17 | 5  | 11 | 7  | 10 | 2  | 6  | 1  | 13 | 0  | 19 | 8  | 9  | 3  | 4  |
| 11 | 6  | 10 | 14 | 5  | 13 | 9  | 15 | 17 | 1  | 12 | 2  | 7  | 18 | 3  | 19 | 0  | 16 | 8  | 4  |
| 2  | 3  | 16 | 7  | 12 | 5  | 13 | 4  | 14 | 6  | 19 | 0  | 18 | 15 | 17 | 1  | 9  | 10 | 11 | 8  |
| 8  | 12 | 2  | 9  | 15 | 13 | 14 | 5  | 16 | 18 | 3  | 17 | 4  | 19 | 0  | 6  | 7  | 1  | 10 | 11 |
| 12 | 6  | 5  | 13 | 3  | 19 | 0  | 2  | 7  | 9  | 11 | 18 | 10 | 4  | 15 | 8  | 17 | 1  | 14 | 16 |
| 9  | 12 | 8  | 5  | 14 | 19 | 0  | 7  | 6  | 11 | 4  | 10 | 13 | 18 | 1  | 15 | 2  | 17 | 16 | 3  |
| 8  | 14 | 4  | 16 | 13 | 17 | 7  | 19 | 0  | 12 | 5  | 11 | 10 | 15 | 18 | 3  | 9  | 2  | 6  | 1  |
| 14 | 12 | 13 | 19 | 0  | 18 | 10 | 5  | 15 | 8  | 6  | 4  | 17 | 11 | 16 | 9  | 7  | 2  | 3  | 1  |

### Disadvantages of This Method

- The smaller the block size, the greater the risk of predicting the next treatment assignment.
- Also, this method does not attempt to balance prognostic factors.

**The Biased Coin Method** Although blocking has been widely used, it may not be necessary to enforce such strict equality. To prevent major inequalities in treatment numbers, the biased coin design [4] can be used. This fairly simple method limits selection bias and maintains groups of roughly equal size. When a patient is to be randomized the probability of assignment to the treatment group with the least patients so far is assigned a probability  $p > \frac{1}{2}$ . If the two treatment groups are equal, then the probability  $p = \frac{1}{2}$ . Efron favored  $p = \frac{2}{3}$  and maintained that although  $p = \frac{3}{4}$  will maintain stricter balance, there is a greater chance of predicting the next allocation when there is an inequality. For a trial with  $N = 100$ , an inequality of 45:55 is not excessive but is extremely unlikely to occur with  $p = \frac{2}{3}$  [5].

*Example: Two Treatments,  $p = \frac{2}{3}$*  Let 1–6 correspond to assignment to the treatment with least patients, 7–9 to assignment to the treatment with most patients, and ignore 0.

If treatment numbers are equal, use simple randomization: Let 0–4 correspond to treatment A and 5–9 to treatment B. The top row of Table 1 would then produce the following treatment assignments:

|    |   |    |   |    |   |    |   |    |   |    |   |    |   |   |   |   |   |   |    |   |
|----|---|----|---|----|---|----|---|----|---|----|---|----|---|---|---|---|---|---|----|---|
| 5  | 5 | 6  | 3 | 1  | 3 | 9  | 1 | 1  | 4 | 5  | 5 | 4  | 8 | 1 | 0 | 7 | 3 | 4 | 8  | 3 |
| B* | A | B* | A | A* | B | B* | A | A* | B | B* | A | A* | A | B | — | A | B | B | B* | A |

where \* indicates simple randomization has been used.

To keep the allocation process as “random” as possible and to minimize the risk of prediction, it is possible to use a combination of methods. For example, use simple randomization unless the treatment imbalance exceeds some specified limit and then introduce a biased coin method to address the imbalance.

**Urn Method** Using Efron’s design, the bias of the coin,  $p$ , is a constant whatever the degree of imbalance. Wei [6] developed an adaptive biased coin method where the probability of assignment depends upon the magnitude of imbalance and number of patients treated.

For the urn design, assume an urn contains an equal number of balls of two types, A and B. When a patient is randomized, a ball is drawn and replaced. If the ball is type A, then the patient receives treatment A, and type B balls are added to the urn. If the ball is type B, then the patient receives treatment B, and type A balls are added to the urn. So the probability of assignment to the treatment with fewer numbers is increased.

The urn design is designated as UD ( $\alpha, \beta$ ) with  $\alpha$  being the number of balls of each type in the urn at the start and  $\beta$  being the number of balls added to the urn after each allocation. The simplest model has one ball of each type in the urn initially ( $\alpha = 1$ ), and one ball of the opposite type is added to the urn following each treatment allocation ( $\beta = 1$ ).

The program listed in Appendix IV was used to produce the following randomization list:

B A A A B B A A B B B A B B B A A B B B B A B A B  
A B A B A A B A A A A A B B A A B A A B B A A B B

### Advantages of These Methods

- The biased coin and urn designs control the likelihood of treatment imbalance without imposing strict balance. Therefore, they are less predictable than blocked designs and less susceptible to selection bias.

### Disadvantages of These Methods

- These methods are slightly more complex, requiring that totals of previous assignments are kept in order to calculate the probabilities to be used for the current assignment. This is best done with the aid of a computer program.
- Does not attempt to balance prognostic factors.

## 11.3 COVARIATE-ADAPTIVE RANDOMIZATION

In any clinical trial it is often desirable not only to achieve similar numbers of patients in each treatment group but also to ensure that patient groups are similar with respect to important prognostic factors such as age or gender. When using simple randomization or blocks, there is a chance that the treatment groups will differ with respect to important prognostic variables. Stratifying the randomization by the prognostic factors will reduce this imbalance. This will ensure that roughly equal numbers of patients will be allocated within each stratum to each of the treatment options either by simple randomization or by using permuted blocks. However, stratified randomization becomes unworkable as the number of prognostic factors increases because the number of strata required can quickly exceed the number of patients in the trial (see next section).

### 11.3.1 Stratification

Each combination of prognostic factors represents one stratum within the allocation list, and lists of random allocations are drawn up for each stratum. Multiple strata can become unmanageable and may lead to empty cells (the number of cells are the product of all the levels of the prognostic factors), therefore this method may not be suitable for small trials with several factors. The maximum desirable number of strata is unknown but according to Therneau [7] the number of strata in a two-treatment trial should be

$$\text{No. of strata} < \frac{N}{\text{block size}} \quad \text{and maybe} \quad \text{No. of strata} < \frac{N}{\text{block size} \times 2}$$

Imbalance between treatment groups can occur if there are strata with incomplete randomized blocks, and there is a possibility of overall treatment imbalance even

though each stratum has more or less equal numbers in each treatment. Retrospective balancing by means of an analysis involving covariates can take care of possible imbalances, but balancing provides a more efficient comparison of treatments and trials in which the prognostic factors balanced are far more convincing than sophisticated analysis alone.

International Conference on Harmonisation (ICH) Guideline E9 [8] recommends stratifying by center and recognizes that balancing by prognostic variables may sometimes be valuable, having greater potential benefits in small trials. If stratifying by center is not possible, the Committee for Proprietary Medicinal Products (CPMP) [9] recommend stratifying by country or region. However, if there are a large number of strata compared to the number of patients, there is no guarantee of balance at site level and no guarantee of treatment balance.

### 11.3.2 Random Permuted Blocks within Strata

The most commonly used method of stratification is to categorize patients into several types (or strata) and then to allocate patients within strata using permuted blocks. The block size within each stratum will normally need to be somewhat smaller than for unstratified random permuted blocks, since the number of patients within a given stratum may be quite small. The smaller the size of the trial and the larger the number of strata, the smaller the block size should be. However, blocks of size 2 should be avoided if there is any chance that an investigator could predict the next assignment.

**Example** In a recent study to investigate whether vaginal progesterone gel is effective in preventing preterm delivery in twin pregnancy (before 34 weeks of pregnancy), patients were randomized either to daily vaginal progesterone gel 90 mg or to placebo. The chorionicity of the pregnancy (monochorionic or dichorionic) was considered to be of major prognostic importance and was therefore included as a stratification factor along with the center. There were 6 recruiting centers that produced 12 ( $6 \times 2$ ) strata consisting of all combinations of center and chorionicity.

Before the trial started, a randomization list would be produced for each of the patient strata using the method described in Section 11.2.2. In this example a block size of 4 could be used, or a mix of block sizes 2 and 4, or 4 and 6, to prevent predictability of assignment. Table 6 shows the randomization lists for 240 patients using the output from the random permuted blocks of sizes 4 and 6 given in Section 11.2.2.

As patients enter the trial, they are identified as belonging to one stratum. Each patient is then allocated the next available treatment assignment from the corresponding randomization list. For example, if the first patient was from Center 1 and had monochorionicity, she would be allocated to treatment B. If the second patient was from Center 5 and had dichorionicity, she would be allocated to treatment A.

Some studies will have just one major prognostic factor for stratified randomization while others may have several. However, using too many strata increases the number of lists required and so increases the administrative burden. Another problem with having too many strata is the possibility of empty cells or cells with very few patients. Table 7 illustrates the characteristics of the first 136 patients randomized by showing their distribution across the 12 strata.

**TABLE 6** Example of Random Permuted Blocks within Strata for a Trial in Twin Pregnancies<sup>a</sup>

| Center       | 1 | 2 | 3 | 4 | 5 | 6 | 1 | 2 | 3 | 4 | 5 | 6 |
|--------------|---|---|---|---|---|---|---|---|---|---|---|---|
| Chorionicity | M | M | M | M | M | M | D | D | D | D | D | D |
|              | B | B | A | B | B | B | A | B | A | B | A | A |
|              | A | A | B | A | B | B | B | A | B | B | B | B |
|              | B | B | A | A | A | A | A | B | A | A | B | A |
|              | A | A | B | B | B | B | B | A | B | A | A | B |
|              | B | B | B | A | A | B | B | A | B | A | A | B |
|              | A | A | A | A | A | A | A | A | A | B | B | A |
|              | A | B | A | A | B | A | A | B | B | B | A | B |
|              | A | B | B | B | B | A | B | B | B | A | B | A |
|              | B | A | A | B | A | B | B | B | A | B | B | B |
|              | B | A | A | B | B | B | A | B | B | A | B | A |
|              | A | B | B | A | A | A | B | A | A | A | A | A |
|              | A | A | B | A | A | A | B | A | A | B | A | A |
|              | A | B | A | B | A | A | A | A | B | B | A | B |
|              | B | A | A | A | B | B | A | A | A | B | B | B |
|              | B | B | B | B | B | A | B | B | A | A | A | A |
|              | B | A | B | B | B | B | A | A | B | A | B | A |
|              | A | A | B | A | A | B | B | B | A | B | B | A |
|              | B | A | A | B | A | A | B | B | B | A | A | B |
|              | B | B | B | B | A | A | A | B | B | A | A | B |
|              | A | B | A | A | B | B | A | A | A | B | B | A |

<sup>a</sup>M = Monochorionic, D = Dichorionic; A = Intervention; B = Control.**TABLE 7** Distribution of Patients across Strata in a Twin Pregnancy Trial

| Center No.    |    |   |    |    |    |    |
|---------------|----|---|----|----|----|----|
|               | 1  | 2 | 3  | 4  | 5  | 6  |
| Chorionicity  |    |   |    |    |    |    |
| Monochorionic | 4  | 1 | 5  | 5  | 2  | 2  |
| Dichorionic   | 33 | 8 | 17 | 13 | 32 | 14 |

Such an uneven distribution of patients across strata is typical and may possibly lead to imbalance. For a small trial with even more strata it is obvious that the chance of empty cells is even greater. In multicenter trials “center” is very often included as a stratifying variable as it is in this example. Indeed, this is recommended by the ICH Guidelines [8] and the Food and Drug Administration (FDA). However, for a trial involving a large number of centers this could lead to a very large number of strata. Therefore, in these cases it is worth considering using center as a minimization factor. This also reduces predictability of the next treatment allocation as centers are unaware of the characteristics of patients recruited by other centers. Overstratification can be particularly evident in small trials, but at the same time the possibility of serious imbalance is greater in small trials without stratification. An alternative approach would be to use minimization.

#### Advantages of this method

- Randomization lists can be made up before the trial starts.
- Treatment allocation is unpredictable as long as the block size is kept secret.

- Allows for interaction between variables (treatment groups are balanced across *combinations* of prognostic factors).

### Disadvantages of This Method

- The number of strata can quickly become large compared to the number of patients especially if center is one of the stratifying variables.
- When stratifying by center, it is desirable to keep the block size to a minimum as there is a risk of severe imbalance resulting from the cumulative effect of imbalance within each stratum. Recruitment officers do not need to know that blocked assignment is being used, and they should never be made aware of the block size.

### 11.3.3 Minimization

Minimization was first described by Taves in 1974 [10] and Pocock and Simon in 1975 [11] and aims to ensure treatment arms are balanced with respect to predefined patient factors as well as for the number of patients in each group. Minimization can be used when it is really important to achieve close similarity between treatment groups for several variables as it ensures balance between groups for several prognostic factors, even in small samples. Simulations show that minimization provides better balanced treatment groups when compared with restricted or unrestricted randomization, and it can incorporate more prognostic factors than stratified randomization methods such as permuted blocks within strata. Some more computationally complex methods may result in an even better performance. The loss in power resulting from treatment groups of unequal size is not likely to compromise a trial, but a serious imbalance in treatment groups with regard to a factor of prognostic importance can have severe consequences. Adjustment should always be made for minimization factors in the analysis (e.g., analysis of covariance).

**Example** For a hypothetical trial with two treatments, intervention and control, assume there are three prognostic factors: sex (male or female), age (<40, 40–60 or >60), and previous surgery (yes or no). A minimization program was prepared and 10 hypothetical patients randomized. Table 8 demonstrates how minimization works by considering the treatment assignment of the next patient. If the 11th patient considered is male, aged 45, and has had previous surgery, the decision to allocate to the treatment or control group can be made by comparing the totals in these categories for both treatments and allocating the patient to the treatment group that gives most balance overall with a high degree of probability. Using Taves' method, the patient would always (i.e., with 100% probability) be assigned to the treatment group that gives best balance, and the allocation is said to be deterministic as no random factor has actually been used.

Pocock and Simon [11] defined a more general method where treatment assignment depends on three functions: the amount of variation among assignments for any given factor level, a measure of the total imbalance in treatment numbers and assignment probabilities to the  $k$  arms of the trial  $\{p_i\}$  (where  $p_1$  is the probability of assignment to the arm that would lead to the least overall imbalance). Total imbalance is usually calculated by taking the sum of the individual imbalances, but

**TABLE 8 Example of How Minimization Works Using Hypothetical Trial Data**

| Prognostic Factor | Intervention | Control |
|-------------------|--------------|---------|
| Sex               |              |         |
| Male              | 4            | 3       |
| Female            | 1            | 2       |
| Age group         |              |         |
| <40               | 2            | 2       |
| 40–60             | 1            | 1       |
| >60               | 2            | 2       |
| Previous surgery  |              |         |
| Yes               | 2            | 4       |
| No                | 3            | 1       |

a weighted sum can be used if some factors are considered more important than others. If  $p_1 = 1$ , the assignment is deterministic (as in Taves) and goes automatically to the treatment with least overall imbalance, but the  $\{p_i\}$  can also be chosen to decrease the predictability of assignment. Table 8 provides a demonstration of how the range method works in practice.

If the 11th patient has factors: Male, Age 45, Yes, Has had previous surgery:

#### **Taves' Minimization**

Total in intervention group  $4 + 1 + 2 = 7$

Total in control group  $3 + 1 + 4 = 8$

The patient is allocated to the group with the lowest marginal totals.

Therefore the 11th patient is allocated to the intervention group because  $7 < 8$ .

#### **Pocock and Simon's Range Method** (Using Unweighted Sum and $p_1 = 1$ )

If allocated to intervention group, total imbalance is  $|(4 + 1) - 3| + |(1 + 1) - 1| + |(2 + 1) - 4| = 4$

If allocated to control group, total imbalance is  $|4 - (3 + 1)| + |1 - (1 + 1)| + |2 - (4 + 1)| = 4$

The patient is allocated to the group that would lead to less overall imbalance. However, in this case the groups are equal. Therefore, simple randomization would be used to allocate a treatment to the 11th patient.

Although minimization does not ensure balance between combinations of factors, it does consider frequently occurring combinations of subcategories indirectly since they tend to work together, giving them a greater chance of being equally distributed than if they were independent.

This method cannot be implemented simply by preparing a randomization list since it is necessary to keep a record of all patient factors and allocations to date, as in Table 8. The easiest way to keep track is to have a custom-designed program (there are some generic minimization programs available). Alternatively, many clinical trials units and commercial companies sell minimization services, and the use of these can help to eliminate allocation or investigator bias.

### Advantages of the Method

- Balances treatment assignment across several prognostic factors simultaneously and across treatment groups overall.
- There is increased credibility by presenting data where prognostic variables are closely balanced within each treatment group [12].
- Planning to use minimization is a good discipline for making trialists think about prognostic factors before a study starts and for helping ensure adherence to the protocol as the trial progresses [13].

### Disadvantages of the Method

- For these dynamic allocation methods assignment lists cannot be prepared in advance.
- Although balance in the whole trial will be good, balance in a subgroup may not be. This is because minimization regards all the factors as independent (no interaction).
- If  $p = 1$ , then the assignment is deterministic, but if no investigator can predict the assignment, this may not be relevant. Decreasing the probability value can lead to treatment imbalance, so there is a need to select that  $p$  that strikes a balance between minimizing imbalance and avoiding predictability of assignment. There is a counter argument that states that even with  $p = 1$  it would still be possible for any individual to be allocated to any treatment; this is determined by the order in which they are recruited to the study, in effect by chance. The random element in the assignment arises because the factors of the next patient come from a random distribution.
- It may be more difficult to administer than other methods especially when the number of prognostic factors increases.
- A computer program may be necessary to perform the randomization and, this has potential implications for cost, programming error, system failure, and training. If a well-tested generic program is not available, it is important to use simulations to check that the method is working correctly before starting the trial.

ICH E9 recognizes that dynamic allocation procedures such as minimization can achieve balance across a number of factors simultaneously but recommend avoiding fully deterministic assignment. The ICH guidelines state that deterministic allocation procedures should be avoided, and an appropriate element of randomization should be incorporated, and that details of the randomization that facilitate predictability should not be contained in the protocol. Minimization may be used with a biased coin in favor of the winner with a suggested value of 0.8. Further extensions to the method include using combinations of factors, or some factors may be weighted more heavily if they are considered to be more important. However, minimization does consider frequently occurring combinations of subcategories indirectly since they tend to work together giving them a greater chance of being equally distributed than if they were independent [10]. The CPMP states that not only does balancing protect against chance imbalance but it also increases the statistical power for small trials and increases the power and credibility of subgroup analyses.

### 11.3.4 Minimization Compared with Simple Randomization

For varying trial sizes, the imbalance that might occur following simple randomization was simulated using the characteristics of the first 3000 participants recruited to a UK multicenter trial evaluating two interventions for the secondary prevention of bone fractures as the population. Key prognostic factors for this trial were sex, age group, presenting fracture, and time since fracture. The trial size was varied from small (100 patients) to large (2000 patients). Imbalance was deemed to occur if the percent of participants in any of the prognostic categories varied by more than 10% between trial groups. The rate of imbalance decreased nonlinearly with trial size. Small trials ( $N \leq 100$ ) regularly displayed imbalance (over 80% of occasions), but in trials of 1000 participants or more, imbalance rarely occurred. Minimization ensured that balance was obtained on all occasions. There is, therefore, evidence of a trade-off between trial size and the need for minimization. Minimization is particularly useful for small to medium sized trials, but simple randomization may suffice when the trial is large. However, even large trials are small at the time of interim analysis and when producing reports for committees such as the Data and Safety Monitoring Committee (DSMC), so there is an argument that we should always use minimization.

### 11.3.5 Other Constrained Methods

Extensions to the minimization method include Atkinson's method, which uses optimum design theory [14]. Here the probability of allocation to the under-represented treatment responds to increasing imbalance rather than just being an arbitrary value. Klotz's method [15] addresses the question of a trade-off between uncertainty and imbalance. His method is similar to that of Pocock and Simon but is more computationally intensive and describes a function for calculating optimal treatment randomization probabilities. Titterton proposes a similar method [16] that involves minimizing a quadratic criterion subject to a balance constraint. The method aims to compromise between unpredictability of assignment and good stratification balance and claims to be simpler than Klotz's method. Signorini and co-workers outlined a dynamic balancing method [17] described as an easily implemented method that balances treatment allocations both within strata and across the trial as a whole. The method keeps a tally of total treatment allocations across all strata. Simulations have been used to demonstrate that the major imbalances that are possible with other schemes do not occur using this method, and the potential for selection bias is much reduced.

However, within the United Kingdom, these methods are very seldom used [18], and the results of a recent survey of trialists conducted by our group was to keep the method of randomization as simple as possible. When selecting a method, one must only balance on scientifically justifiable factors. If a stratified method can cope, then this is the method of choice; if there are too many factors, then use a dynamic method. Predictability may be an important factor as there is a risk of selection bias if the recruitment officer can guess the next allocation. Dynamic techniques help to make the allocation less predictable.

## 11.4 RESPONSE-ADAPTIVE METHODS

As a trial progresses, it may become evident that one treatment is performing better than the other. It may be possible to make use of this information by varying the allocation ratio to ensure more patients are allocated to the apparently better treatment. In the “play-the-winner” rule of Wei and Durham [19] the probability of assignment varies according to the success of the treatments. Initially, they conceptualize an urn containing equal numbers of balls representing the two treatments, A and B. A ball is drawn and replaced and the next patient is allocated to that treatment. If a treatment produces a successful outcome, then a ball of that type is added to the urn. If a treatment produces a nonfavorable outcome, then a ball of the other type is added to the urn. Therefore the probability of assignment is skewed to favor the treatment performing “better”.

This adaptive approach to treatment assignment results in a substantial reduction of patients on an inferior treatment compared to a conventional randomized trial. However, this design is not often used as the analysis of such designs is problematic. It is recommended that assignment procedures be simple, objective, and foolproof, and this is difficult to achieve with an adaptive design.

## 11.5 SPECIAL-CASE SCENARIOS

### 11.5.1 Unequal Randomization

In the majority of trials patients are randomized equally between the experimental and control groups. Sometimes it is preferable to favor the experimental treatment where anecdotal evidence suggests there may be a great health benefit, and patients may be reluctant to have only a 50% chance of receiving the new treatment. Such unequal allocation schemes may help to improve recruitment. It should be cautioned, however, that if the experimental treatment is harmful, unequal randomization in this situation may subject more patients to a harmful treatment.

If research costs between the treatments differ, it may be more cost effective to randomize more patients to the cheaper treatment. However, economic reasons are not the only criterion for selecting unequal randomization ratios, and in some cases it may even be preferable to favor the more expensive treatment. For example, when evaluating the learning curve for a new surgical intervention, more patients may be randomized to the experimental (or expensive) treatment [20]. For many trials there is a substantial amount of previous experience relating to the control treatment, and there is more to be learnt about the new treatment [5].

When experimental treatments differ in their costs, then for a given statistical power, unequal randomization will produce the least-cost trial. Unequal randomization is unnecessary if there is no cost difference between the treatments. However, it may be possible to alter the randomization ratio as the trial proceeds if large cost differences become apparent. If unbalanced allocation is used, it is generally justified on the grounds of ethics or cost. Randomization ratios of 2:1 or 3:2 do not greatly alter the statistical properties of a trial, but loss of power appears to be substantial for a ratio of 3:1 or more extreme [5]. The chance of obtaining a statistically significant difference between the two treatments is not significantly

reduced, as long as the chosen ratio is less extreme than 70:30 [21]. Formulas exist to adjust standard sample size estimates to accommodate for unequal randomization [22].

### 11.5.2 Cluster Randomization

A cluster-randomized trial is one in which clusters of individuals, rather than individuals themselves, are randomized to different treatment groups. Cluster-randomized trials have become particularly widespread in the evaluation of non-therapeutic interventions such as lifestyle modification or educational programs. The units of randomization range from relatively small clusters such as families to entire communities such as neighbourhoods, hospitals, or medical practices. In a trial to investigate if training in a certain consultation procedure is effective, then some physicians would receive training and others would not. The patients being seen by a physician would form a cluster. If the individual patients were randomized, then they may have to be seen by another physician as it would prove difficult for the physician to switch consultation practice between patients and contamination could occur.

The clusters are often decided in advance and randomized before the intervention is applied. However, the subjects themselves are sometimes not identified at the time of randomization, and so the randomization will not balance the prognostic factors as in individual randomization. The purpose of randomization in cluster trials is to try and balance the confounding factors associated with the cluster [23]. Cluster unit characteristics will balance as the number of clusters increases, and so the patient characteristics will balance as a result. The methods described in Sections 11.2–11.4 can all be used to allocate clusters.

The design and conduct of cluster-randomized trials requires special considerations [24]. They are often more complex to design, require more participants, and require more complex analyses than individually randomized trials. Cluster randomization is less efficient in a statistical sense than randomizing individuals to treatment groups [25] because the responses of individuals within a cluster tend to be more similar than responses of individuals in different clusters. The theory of experimental design assumes that the experimental unit that is randomized is also the unit of analysis, and this is not necessarily the case in a cluster randomization trial. Analyses that do not take the clustering into account may report significance when none exists. Increasing the number of clusters enhances power more efficiently than increasing the number of subjects within a cluster.

#### **Advantages of This Method**

- Cluster randomization is often used for practical or ethical reasons when patient randomization is not possible.
- Clustering helps to avoid contamination.

#### **Disadvantages of This Method**

- Loss of statistical efficiency
- Need to recruit more participants

## 11.6 SUMMARY

In conclusion, the most important factors when choosing a randomization method are the size of the trial, practicality of the method, maintaining the blind, and reducing predictability. Smaller trials may require some form of restricted allocation to maintain balance, whereas simple randomization may suffice for large trials. Keeping the randomization method as simple as possible will reduce time, cost, and programming errors.

If the number of important prognostic factors and layers within these is sufficiently small, then the preferred method of randomization, recommended by ICH, is permuted blocks of varying random length within strata. This method eliminates the problem of predictability and at the same time balances across combinations of factors, whereas minimization only balances over single factors. If the number of prognostic factors is large, then minimization can be used to provide treatment balance as well as balance over these factors. However, only those factors known to affect outcome should be considered.

Web-based systems may become more widely used in the future, but there are some problems to be overcome, including access to the Internet, speed and reliability of access, and the lack of willingness in trial centers to adopt new technologies.

## APPENDIX I

Visual Basic for Applications (VBA) code to produce a table of 2500 random numbers.

```
Private Function GenerateList()
    Dim Num As Integer
    Dim MyValue
    Dim Numbers(25) As Integer
    Dim intI As Integer

    Open "random.txt" For Output As #1 ' Open file.
    For Num = 1 To 100

        For intI = 0 To 24
            Randomize ' Initialize random-number
            generator.
            MyValue = Int((10 * Rnd)) ' Generate random
            value between 0 and 9.
            Numbers(intI) = MyValue
        Next

        Print #1, Numbers(0); " "; Numbers(1); " ";
        Numbers(2); " "; Numbers(3); " "; Numbers(4); " ";
        Numbers(5); " "; Numbers(6); " "; Numbers(7); " ";
```

```

Numbers(8); " "; Numbers(9); " "; Numbers(10);
" "; Numbers(11); " "; Numbers(12); " ";
Numbers(13); " "; Numbers(14); " "; Numbers(15);
" "; Numbers(16); " "; Numbers(17); " ";
Numbers(18); " "; Numbers(19); " "; Numbers(20);
" "; Numbers(21); " "; Numbers(22); " ";
Numbers(23); " "; Numbers(24);
Print #1,

Next Num
Close #1

End Function

```

## APPENDIX II

Visual Basic for Applications (VBA) code to produce a table of 100 permutations of 20 numbers (0–19).

```

Private Function Permutations()
    Dim Num As Integer
    Dim intI As Integer
    Dim db As Database
    Dim rst As Recordset
    Dim rstAdd As Recordset

    Set db = CurrentDb
    Set rstAdd = db.OpenRecordset("TblPermute20")

    For Num = 1 To 100
        rstAdd.AddNew
        Set rst = db.OpenRecordset("QrySort20")
        For intI = 0 To 19
            rstAdd(intI) = rst!ID
            rst.MoveNext
        Next intI
        rstAdd.Update
    Next Num

    rst.Close
    rstAdd.Close

    MsgBox "Done!", vbOKOnly

End Function

```

**APPENDIX III**

Visual Basic for Applications (VBA) code to produce a table of approximately 200 treatment allocations in random blocks of 2 and 4.

```

Private Function Blocks()
    Dim db As Database
    Dim arrBlock() As Integer
    Dim intBlock As Integer
    Dim intBlockSize As Integer
    Dim intCount As Integer
    Dim intResult As Integer
    Dim strInsert As String

    Set db = CurrentDb

    For intBlock = 1 To 45
        Randomize

        If (Rnd > 0.5) Then
            intBlockSize = 6
        Else
            intBlockSize = 4
        End If

        ReDim arrBlock(intBlockSize - 1)

        For intCount = LBound(arrBlock) To UBound(arrBlock)
            arrBlock(intCount) = 0
        Next

        intCount = 1
        While intCount <= intBlockSize / 2
            intResult = Int((intBlockSize - 1 + 1) * Rnd + 1)
            If arrBlock(intResult - 1) <> 1 Then
                arrBlock(intResult - 1) = 1
                intCount = intCount + 1
            End If
        Wend

        For intCount = LBound(arrBlock) To UBound(arrBlock)
            strInsert = "INSERT INTO TblAllocate(Treatment)
            VALUES(" & arrBlock(intCount) & ")"
            db.Execute strInsert
        Next
    Next
End Function

```

## APPENDIX IV

Visual Basic for Applications (VBA) code to produce a table of 50 treatment allocations using the Urn method.

```
Private Function Urn()
    Dim db As Database
    Dim strInsert, Treat As String
    Dim Num, x As Integer

### **12.1 INTRODUCTION**

A randomized controlled trial is a study in which subjects are allocated at random to receive one of two possible interventions. The outcomes measured are events or quantifiable changes that are present or absent following the proposed interventions. These outcomes are known as endpoints. In general, one of the interventions chosen is a standard of comparison: the control. The control intervention can be a drug or procedure with no known clinical effect: a placebo. Alternatively, the

**FIGURE 1** Structure of randomized controlled trials.

control can be a therapeutic measure that is currently the accepted treatment or intervention for a disease process. The other group is the experimental intervention or trial drug (Fig. 1).

Randomization refers to the random allocation of the subjects to one of the intervention groups. Therefore, the allocation of patients is not determined by the clinical investigators or the subjects within the study. The random allocation of subjects to the treatment arms of the study ensures that the demographics of the subjects are likely to remain similar. Randomization also removes investigator bias in the allocation of patients to the various treatment arms. Hence, randomization reduces the risk of imbalance between the subjects receiving the trialled intervention or drug and those receiving the standard intervention or placebo drug. This balancing of prognostic factors between the two groups increases the likelihood that any observed difference is attributable solely to the proposed treatment.

A number of different endpoints can be employed to quantify the response to a trialled intervention. Endpoints can vary from laboratory-measured responses, such as changes in cell-signaling molecules or histological changes, known as biomarkers, through to clinical responses. Ideally, randomized controlled trials should have one primary objective, asking one specific question and one primary outcome or endpoint. Both the primary objective and endpoints should be well defined and easily measured. A quantifiable objective endpoint is superior to a subjective one. Many randomized controlled trials will also have secondary objectives and endpoints. In general, conclusions drawn from these secondary objectives should be regarded as tentative since the study may lack the power to address them.

A randomized controlled trial (RCT) should answer a clinical need (Fig. 2). Any intervention studied should be feasible in clinical practice and remain a viable treat-

**FIGURE 2** Issues in designing a randomized controlled trial.

ment following the results of the study. The disease process in question should be of a serious nature or impact upon a significant proportion of the population. There must be preliminary evidence (from phase I and phase II trials) that the trial intervention has a promise of efficacy. However, there also needs to be a genuine uncertainty regarding the efficacy of the new proposed treatment over the standard treatment or placebo treatment, known as equipoise. The design of the RCT should be robust and proper administration of the study is essential. Standardized reporting of the results of any RCT, combined with valid statistical analyses allows data from multiple RCTs to be compared for a more precise estimate of the effects of a treatment.

In practice other study methodologies have been used to answer the same clinical questions tackled by RCTs. This chapter will examine these methods and discuss their potential flaws.

## 12.2 UNCONTROLLED TRIALS

In some circumstances it may not be possible to conduct randomized controlled trials. This may be due to ethical problems (e.g., examining the effect of cessation of smoking and the risk of lung cancer), financial considerations, or, as occurs frequently in surgical practice, problems in recruiting adequate numbers of patients. In these scenarios, uncontrolled trials may give important clinical information. Uncontrolled studies are essentially observational trials where the effect of an intervention is assessed on a population of patients (a cohort) over a period of time. In uncontrolled trials, there is no control group and hence all endpoints are essen-

tially qualitative (in respect to the patient's initial symptom or disease status). In drug therapy, uncontrolled trials may be a useful bridging step from translating in vitro and in vivo evidence of drug efficacy into a clinical setting. Hence, the results from uncontrolled clinical trials may be used to rationalize and plan subsequent RCTs of the same intervention. In particular, uncontrolled clinical trials can provide important safety and tolerability data in the setting of drug trials.

Surgery is one field where the RCT has suffered a notable decline [1–4]. In one report, less than 40% of the published hypotheses involving surgical operations for gastrointestinal surgery could have been answered successfully by an RCT [5]. The main problems encountered included accrual of patients due to a low disease incidence and patient preference. For example, the mastectomy versus lumpectomy RCT for breast cancer suffered from significant poor accrual into the latter treatment group [6]. In such circumstances a noncontrolled cohort study may be the only means of evaluating the efficacy of a surgical intervention.

Uncontrolled trials are also useful for chronic conditions when compared to placebo controlled RCTs. In this group of patients long-term follow-up during RCTs is plagued by poor patient adherence to treatment regimens, especially in the placebo control group. There are also ethical considerations in administering a nontherapeutic drug for long periods to patients with chronic illness, which is severely restricting their quality of life. In such scenarios patients taking their preferred (and therapeutic) treatments are more likely to comply with the trial, and hence longer-term follow-up can be achieved with minimal loss of patients recruited to the trial. Uncontrolled observational studies can also recruit larger numbers of patients with fewer inclusion and exclusion criteria than RCTs. One criticism of RCTs is that they often recruit relatively small numbers of patients (in comparison to the disease burden) who are then treated and monitored under conditions that do not reflect everyday practice [7, 8].

### 12.3 PROBLEMS WITH UNCONTROLLED TRIALS

While we have discussed the clinical pressures that necessitate the undertaking of noncontrolled trials, there are major disadvantages in this type of study and assessing the reliability of the evidence reported. The lack of a control group makes it impossible to compare any new treatment with no treatment or with the “gold standard” of treatment currently adopted with any particular disorder. An example would include a hypothetical series of laparoscopic hernia repairs reported by surgeon A, which reveals a low recurrence rate, a high rate of same-day discharge, and a high level of patient satisfaction following the procedure. With no control group, we cannot compare this treatment with the current standard method of treating hernias (i.e., an open repair). As a result, although the results may indicate that laparoscopic surgery is a viable technique in dealing with hernias, we cannot assess if it is more efficacious than the currently adopted treatment regimen. In the field of testing new drugs, this may have important implications since many new drugs available on the market would incur significantly greater costs if their use was to be adopted universally, when compared to cheaper and better established medication.

Furthermore, with the lack of a control, any observed effect of drug or intervention is subject to systematic error or bias within the study. This bias may arise from

subject selection, outcome measurement, or other confounding factors. For example, in the case of a new drug treatment for insomnia, the patients selected may be well-motivated individuals who, in addition to taking the new trial drugs, have also instituted other measurements to ease stress and hence improve their ability to sleep at night. The investigator is clearly aware that all individuals assessed following the drug treatment have received the trial drug and this may affect their data collection. In studies where qualitative assessments are to be used (such as the quality of sleep overnight), this observer bias is likely to be of particular importance. Finally, the placebo effect of the new drug has not been accounted for. The placebo effect is a well-recognized response of patients to new treatments or drugs. The fact that these patients with insomnia have been selected to trial a new and potentially efficacious medication may in itself help to ease their symptoms, even if the trial drug had no pharmaceutical action at all.

Uncontrolled trials can be a useful adjunct in determining drug tolerance and acceptability in phase I and phase II clinical trials. However, results from these trials, however encouraging, should be interpreted with caution pending control group studies.

## 12.4 HISTORICAL CONTROLS

It is possible to compare outcome from new treatments in trials with data from previous studies examining alternative treatments or no treatment. Hence, the control group is named a historical control (Fig. 3). A major advantage in using

**FIGURE 3** Structure of historical control trials.

historical controls is that the studies are easier to perform, with fewer patients and shorter study period duration than studies that use concurrent controls. The treatment of diabetes mellitus with insulin, chemotherapy for childhood leukemia, and vitamin B<sub>12</sub> therapy for pernicious anemia all represent major medical advances that have been instituted as a result of data obtained from historical controls [9–12].

Historical controls may also be instituted for conditions that are sufficiently rare to result in a low rate of accrual of eligible patients for concurrent control studies. By comparing data from historical controls, it may be possible to evaluate new treatments in a much shorter time period than would otherwise be possible. In areas where financial considerations may be a limiting factor, historical control groups are an attractive proposition since they avoid the need to recruit control groups and randomization for treatment allocation. In doing so, historical controls reduce the need of support personnel required and cost.

The final argument for historical controls is an ethical one. In general, RCTs compare a newer and presumed better drug with standard therapy. If no effective established therapy exists for a particular condition, it may be argued that ethically all patients should receive the new treatment. For example, if comparing insulin treatment for the treatment of diabetes when compared to no treatment at all, those patients allocated to the control arm of an RCT would be denied a life-saving treatment.

## **12.5 PROBLEMS WITH HISTORICAL CONTROLS**

The major drawback to using historical controls is that many factors may change in the time period from accrual of data from historical controls to the implementation of the new drug or intervention in the intervention subjects. These differences may reflect the continuous improvement of medical care, changes in the demographics of patients referred, changes in referral patterns (such as earlier referral due to increased awareness of a particular condition), and improvements in epidemiological factors (better diet, increased exercise). For the intervention group, the increased monitoring and attention will also have a strong placebo effect, which will not be adequately controlled for among the historical controls.

In the setting of cancer drug trials, for example, the use of historical controls relies on the assumption that the survival rate among the controls would be the same as that among the control group in a concurrent RCT. The factors discussed in the preceding paragraph suggest that this may not be true. These confounding factors can be minimized if the data from the historical controls is from patients who were all treated at the same institution. This would ensure that referral patterns, medical care, nursing care, and other support would be as similar as possible to the intervention group [10]. It is probable, however, that some differences will inevitably exist between the control and intervention group.

Another potential flaw in the use of historical controls is that for most trialled treatments there are restrictions on which patients are selected for the intervention group. For example, in the case of chemotherapy agents the patients with worst prognosis may be excluded from the trial since they may be least likely to benefit

from the therapy. These exclusion criteria cannot be applied to the historical controls. Since exclusion and inclusion criteria cannot be adequately controlled for in the historical group, this invalidates any comparison between them.

Due to the overall improvements in medical and nursing care over the time interval separating intervention groups from their historical controls, there is a tendency for historical control trials to overemphasize the magnitude of any particular intervention. For example, the use of anticoagulant therapy following acute myocardial infarction using data from historical controls revealed a 54% reduction in mortality [13]. Subsequent concurrent RCTs showed a 21% reduction in mortality. This discrepancy occurred in spite of broad database consisting of 18 studies and 9000 patients in all. While it may not be possible to eliminate this “historical error,” it is possible to give an approximation as to the degree of error for a historically controlled study. This may be achieved by portioning the period of control entry into different intervals. The results obtained between those groups can be then compared to the overall outcome. If a significant reduction in the benefit from a new intervention is observed across the different groups, then the degree of error due to changes in clinical practice is significant (Fig. 4).

In a study by Diehl and Perry the survival times and disease-free survival times of historical controls from chemotherapy trials were compared with those from control groups derived from matched RCTs [9]. The RCTs were matched for location of disease, stage, and follow-up. This study showed that 42% of studies varied by more than 10 percentage points, 21% varied by more than 20 percentage points, and 5%

**FIGURE 4** Schematic representation from error occurring in historically controlled trials.

varied by more than 30 percentage points. It also revealed that even for institutions that had both a historical control and randomized control group, there were still significant differences between survival and disease-free survival. In summary, although historical controls offer certain advantages over RCTs in terms of simplicity, speed, and cost, they cannot be used to reliably control treatment studies.

## 12.6 CONCURRENT NONRANDOMIZED CONTROLLED TRIALS

In certain scenarios a nonrandomized design may be applicable. Nonrandomized trials still include a control and intervention group. However, allocation of patients to control or treatment arms is determined by the investigator or the patient themselves (Fig. 5). There are numerous valid reasons for the use of nonrandomized controlled trials in clinical practice. Surgery is an area where the conduction of RCTs is especially problematic. These relate to the difficulty in patients allowing themselves to be randomized. Patients who may be eligible for randomization may withhold consent to be randomized. This may be due to the fact that the new treatment under trial may be less cumbersome, less traumatic, or less disfiguring than the standard therapeutic procedure. Patients undergoing surgery will need to coordinate the timing of their procedure and recovery time around their employment and hence may be unwilling to be randomized into a treatment arm that would cause more disruption for them.

A similar circumstance can be envisaged in a hypothetical chemotherapy trial comparing an intravenous chemotherapy regime, with one using orally administered medication. The former treatment arm will necessitate the positioning of

**FIGURE 5** Structure of nonrandomized concurrent control trials.

intravenous cannulae and a visit to a hospital daycare unit, while the oral preparation may be taken at home. Many patients would prefer the less inconvenient option, particularly if the oral preparation is the newer and perceived (if only by the patients) more effective treatment for their cancer.

For certain diseases, the population of patients may be too small to accrue sufficient numbers for an effective RCT. In such situations, every patient is valuable, and hence the investigators may allow individuals to choose their treatment in order to accumulate sufficient numbers of patients. Finally, there may be ethical considerations that make randomization unfeasible. For example, in the case of the hypothetical orally administered chemotherapy agent discussed above, patients with extensive carcinomatosis and a poor prognosis, randomization into the standard treatment arm will have a significant impact on their remaining quality of life. It may be a better option to allow patients to choose their treatment, which, in turn, may result in better compliance among those patients who have chosen to be in the treatment arm examining standard therapy.

The perceived disadvantages in losing randomization has been challenged by Abel and Koch [14]. The argument for randomization is that it leads to comparable and balanced groups and so allows comparison of the new treatment arm of the study with the standard treatment or placebo arm. Having ensured that baseline characteristics have been eliminated by randomization, any differences in effect are attributable to the interventions applied. However, this assumption is inaccurate as it does not take into account the many variables that may affect outcome following allocation to treatment or control groups. Figure 6 summarizes the causes of differ-

**FIGURE 6** Pyramid of possible reasons for differences observed between treatment in clinical trials and the effect of randomization on eliminating errors. (Adapted from Abel and Koch [14].)

ences between control and treatment groups and which ones are eliminated by randomization. It is clear that there are still many more confounding factors that may alter the findings of a study erroneously.

Blinding is a concept in which patients and physicians are unaware of which treatment arm the patient has been assigned. Blinding prevents patients from overstating the benefits of a new medication in order to build rapport or please their attending doctor. It also prevents physicians from introducing observer bias when recording and interpreting the results of a tested intervention. Another stated disadvantage to nonrandomized controlled trials is that blinding is not possible. While randomization is essential for blinding of patients, it is not a prerequisite for blinding of treatment evaluation.

Nonrandomized controlled studies are a response to a clinical need to evaluate a new therapy, where the applicability of a conventional RCT is in doubt. A comparison of 30 randomized and nonrandomized controlled studies comparing treatment with no treatment found no influence of randomization on the mean observed treatment effect [15]. Other studies, however, have shown that the magnitude of effect observed may vary with randomization [16–19] for both medical and surgical clinical trials. In summary, while nonrandomized controlled trials can probably reliably predict a treatment effect, the magnitude of the effect may vary from that observed in RCTs.

## **12.7 PROBLEMS WITH CONCURRENT NONRANDOMIZED CONTROLLED TRIALS**

While the loss of the traditional advantages of randomization do not necessarily excessively penalize a nonrandomized study, there are other benefits from randomization that are now discussed. Figure 6 demonstrates that there are many other points of error that are not eliminated by randomization; however, randomization of the population study group does at least remove one tier of possible error in that prognostic factors, both known and unknown are balanced between intervention and comparison groups.

In the conduct of clinical trials, nonconsent bias is removed. For example, in our hypothetical orally administered chemotherapy agent, it may be that patients who are not willing to travel to the hospital for the intravenous standard treatment are those too frail or immobile to make such repeated journeys. In such circumstances, the true benefit of the new oral agent may not be fully appreciated due to the confounding factors of age and general fragility affecting long-term survival of the intervention arm. In addition, it would be relatively easy for an investigator to sway a patient's decision making by recommending one intervention over another. In this manner, patients with the smallest disease burden or better prognosis may be chosen for the trial arm, which would of course affect the validity of the study.

Randomized controlled trials require a significant support framework to administer treatment to patients and for appropriate supervision and data collection. In this manner, randomization compels the investigator to plan the conduct of the trial and introduce written protocols. While this is not a direct advantage of randomization, it is an advantage offered by the RCT trial framework. A second indirect benefit from introducing an RCT is that in many cases multicenter trials are required

due to a number of reasons, such as ensuring adequate recruitment of patients, and pooling of financial resources. By using a multicenter framework, many of the differences between the deliveries of patient care between centers is diluted. In this manner, the population group of the RCT is more representative of the population of patients with the disease out in the community.

The implementation of an RCT may have other beneficial effects within the trial center. RCTs may be a learning experience for clinicians in the planning, data collection, and analysis of trials. The RCT teaches a methodological approach to implementing trial therapies. The skills learnt from this can be used in the critical evaluation of other published evidence by clinicians and can directly cross over to the daily ward management of patients. The written protocols for RCTs will stipulate the manner in which the trial intervention is administered and how it is monitored. These trial tests need to run along the normal administration of care. As a result, this requires medical and nursing staff reevaluate the patient pathway through their unit. This may frequently be an opportunity to further improve the delivery of care, even for nontrial patients.

In conclusion, the pitfalls of not randomizing controlled studies are illustrated by a trial of vitamin C in patients with advanced colorectal cancer [20]. One hundred patients with terminal colorectal cancer were given high-dose vitamin C. The survival of these patients was then compared with 1000 control patients who received no vitamin C. The study found that the mean survival time in the vitamin C patients was 4.2 times greater than those in the control group. Despite these results, two further RCTs using the same inclusion and exclusion criteria as the previous study found no survival benefit from vitamin C therapy, with no differences in symptoms, performance status, appetite, or weight loss [21].

## 12.8 IS RANDOMIZATION FEASIBLE?

The final point to consider in this analysis is how applicable is randomization in providing the best medical care to patients. Earlier in this chapter the technical considerations on why randomization is not always feasible in practice were discussed. These may include poor patient recruitment due to dislike of one of the intervention options, for example, the mastectomy versus lumpectomy RCT [6], where patients preferred the less disfiguring operation over a mastectomy. Trials evaluating treatments for chronic illness may also suffer from low recruitment rates and high dropout rates, due to failure to comply with less effective medication or medication with greater side effects. It is possible to minimize these issues using the randomized discontinuation design [22]. The purpose behind these study designs is to select a subset of enrolled patients who are relatively homogenous with respect to their prognostic factors and randomize only this subgroup to treatment or intervention. These patients may be selected by their ability to tolerate medication without excessive side effects or their ability to comply with treatment regimens.

In chemotherapy trials, it is common for patients to deviate from their randomized treatment during follow-up. This is often due to worsening of their disease, which requires rescue medication, either in addition to their trial medication or in place of it. In such cases, the additional medication plays a major confounding factor since the rescue medication will doubtless contribute to outcome differences

between the intervention and control arms. In scientific and statistical terms, the best approach to this problem is to avoid making any changes to medication once the patient has been enrolled and randomized, however, this would be unethical. Excluding patients from the trial outcome analysis would also mask a proportion of patients who may not be responding to the trial therapy and hence may give a false impression of the true efficacy of the drug under evaluation. In addition, any synergistic effect of trial drug plus rescue medication combination would be lost.

Finally, there are ethical issues in the process of randomization of patients in clinical trials. In the Declaration of Helsinki it states that a subject may be enrolled in an RCT if there is genuine uncertainty (equipoise) about which treatment (standard or trial treatment) would benefit the patient [23]. New drug treatments undergo extensive preclinical, phase II and phase III testing before entering RCTs. This laborious evaluation process occurs as a result of huge expenditure on the part of pharmaceutical companies, who would only pursue such clinical testing if there was clear and dramatic evidence of the trial drug offering significant benefits over standard treatment. Doubtless, the principal investigator will be familiar with the evidence. In light of these observations, how much uncertainty is there that the new trial drug is no better than the control drug that patients will receive? The counter-argument to this observation concerns whether it is ethical to leave a patient's treatment to chance, or should he or she receive the best treatment available according to the knowledge of the day?

Another important ethical issue when considering RCTs is what to do if the trialled treatment is significantly worse or better than the standard treatment for a particular condition, during the trial period. There is provision for calling RCTs to a halt in either circumstance, but at what point would it be ethical to intervene? The azidothymidine (AZT) study was a double-blind randomized controlled study evaluating the efficacy of AZT in patients with AIDS (acquired immune deficiency syndrome) [24]. The study was terminated early before full recruitment of patients had occurred, when 19 patients receiving placebo had died and only one patient receiving AZT. The study confirmed the efficacy of AZT in the management of AIDS, but 19 patients who had been randomized to the study were unable to benefit from the new treatment.

Ultimately, the physician has a duty to provide the optimum care for his or her patient, but what if this means breaking the study protocol? The first RCT in Britain in the 1940s was assessing streptomycin in the treatment of tuberculosis. During the conduct of the trial, one of the senior research council members contracted tuberculosis and received supplies of streptomycin outside of the trial. This example highlights the fact that clinical judgment can be at conflict with the rigid protocols of RCTs.

The ethical issues touched upon do not, however, preclude the use of RCTs or nullify their usefulness in modern medicine. Sensitivity to these issues is important to the principle investigator in these trials and can be used to optimize study design. With regard to the subject of equipoise, there are numerous examples of RCTs where the trialled drug treatment has been found to be ineffective. In such circumstances, had it not been for the unbiased data collection afforded by RCTs, the ineffectual experimental treatment would be that chosen by many clinicians, having been seduced by the wealth of preclinical data supporting the efficacy of the drug. There is a subtle distinction between theoretical equipoise, as defined by the

Helsinki declaration, and clinical equipoise. Clinical equipoise is best defined as a lack of consensus among the medical community over which treatment is the most effective. Hence, although a new drug treatment is theoretically more efficacious (supported by preclinical and phase I/II data), it is still not actually proven to be so.

Most RCTs compare new treatments with standard treatments and hence are powered to pick a 5–10% improvement in efficacy. For this reason, examples such as the AZT treatment in AIDS, where a new effective treatment was compared with the standard (i.e., no treatment or placebo), are rare. In such circumstances, a well-designed and monitored RCT can be stopped and the efficacious new drug offered to all trial participants and the disease population. The AZT trial is a good example of an RCT that was well monitored by a central oversight group that intervened suitably when it became clear that the AZT treatment should be available to all participants. Although an RCT may not be appropriate or applicable to all clinical scenarios, where possible it can provide unbiased assessment of new drugs or treatments.

The technical details of randomization are discussed elsewhere in this book. In this chapter the phenomenon of “code breaking” (deciphering the allocation sequence) will be briefly touched upon. Investigators rarely document code breaking, but in anonymous questionnaires, there have been investigators who admit to sabotaging randomization codes [25]. Awareness that investigators may actively attempt to unravel the allocation sequence is important in the design of clinical trials, and hence robust steps must be taken to ensure that this not occur. RCTs may frequently alienate the clinicians involved by frustrating their clinical inclinations, and allocation deciphering is an attempt to provide the perceived best care for their patient. It is unlikely that investigators are attempting to deliberately sabotage the results of the trial. As we have seen, randomization, when possible, offers key advantages and credibility to the results of a clinical trial. It is essential then that the word *randomization* is not used in vain, and concealment of allocation codes is essential in the planning of any RCT.

## 12.9 CONCLUSION

Randomized controlled trials are the best statistical method of evaluating one treatment over another. In general, a well-conducted and monitored RCT provides an unbiased, balanced, and reliable method of determining the efficacy of new drugs or devices. Figure 7 is a schematic illustration of the level of evidence provided by different trial methodology. RCTs also carry with them important logistic and ethical issues, which must be thoroughly addressed before commencing the trial. A review of phase III RCTs evaluating chemotherapy agents observed that the methods used were satisfactory in 67.5% of cases, but 30% of authors were not respecting fundamental ethical principles [26]. In certain circumstances, RCTs may not be possible, in which case recourse to alternative trial designs may be necessary, but this must be with realization that the level of evidence provided will be diminished.

Green and Raley reported that a well-designed clinical trial should incorporate a proper randomization procedure allocating patients to treatment groups in an unbiased manner with a sample size large enough to provide adequate statistical

**FIGURE 7** Schematic representation of the tiers of evidence provided by different trial methodology. (Reproduced with permission from Lyman and Kudere [28].)

power [27]. In addition simple endpoints are required and an intention-to-treat analysis that includes all individuals randomized to the treatment groups regardless of whether or not they completed treatment. Results should be presented clearly with a confidence interval that quantifies uncertainty. A final point to consider is the quality of trial results reporting. Well-reported and designed controlled trials can have their results combined to produce a more precise estimate of the effects of treatment.

### 13.1 INTRODUCTION

Cross-over designs refer to clinical trials where patients sequentially receive several of the compared treatments, instead of receiving only one of them as in the classical parallel-arm designs. Each subject hence acts as his (her) own control. The main purpose of such a design is thus to perform within-subject comparison of treatment effects instead of between-subject comparisons, which increases efficiency. As a consequence, a cross-over trial usually requires less patients than a parallel-arm design.

The simplest cross-over design is the two-treatment two-period cross-over design, also referred to as the AB/BA design, since patients receive either treatment A followed by treatment B or treatment B followed by treatment A. A schematic representation of the AB/BA design is given Figure 1. As depicted in Figure 1, patients included in an AB/BA cross-over trial are randomized between each *group* (or sequence)  $A \rightarrow B$  or  $B \rightarrow A$ . After a potential *run-in* period where subjects are given neither A nor B, the *first period* (period 1 on the figure) begins with the administration of one of the two treatments, according to the randomization group. During the run-in period, baseline measurements can be performed. Between the two treatment periods, a *wash-out* period is generally used to remove any residual effects of the treatment received in the first period. As for the run-in period, neither A nor B is administered during the wash-out period. Then, patients switch to the treatment they did not receive yet.

Provided the disease condition of subjects is similar at the beginning of each treatment period, the cross-over design is intuitively appealing to compare treatments. Indeed, each patient will serve as his (her) own control. However, the effect of the first treatment received may persist during the second treatment period, leading to the so-called *carry-over* effect of the treatment. Several considerations on both the use of two-stage designs to cope with carry-over and the low power of the test for carry-over have generated a large literature on cross-over designs [1–6] and somewhat contradictory guidelines from regulatory agencies [7, 8]. More recently, three textbooks dedicated to cross-over trials have been published, where details and discussion regarding cross-over trials may be found [9–11].

In this chapter, we will review the main issues concerning the use and analysis of cross-over designs. We will focus on the AB/BA design and more particularly on the analysis of such trials. More complex design will be mentioned later. Another type of cross-over design can be frequently encountered, for example, in malignant diseases. It is basically a parallel-arm design where patients who fail to respond to the

**FIGURE 1** Representation of an AB/BA cross-over trial.

first treatment they were assigned to are switched to the other one. These treatment cross-overs are planned for ethical reasons in order to give each patient a chance to receive the “superior” treatment, and the main analysis relies on comparing the initial treatments only. This type of cross-over design will thus not be considered in this chapter.

## 13.2 MAIN ISSUES

### 13.2.1 Advantages

The cross-over design is intuitively well suited to compare treatments as all, or at least some, are administered to each subject. Nevertheless, the main advantage of cross-over trials is that inference on treatment effect is based on within-subject information, each subject being used as his (her) own control. Between-subject variability is eliminated, which leads to increased efficiency. In general, fewer patients, and sometimes much fewer, will be required to obtain the same precision in estimation than classical parallel designs. Cross-over trials thus may save considerable resources.

Another advantage of cross-over trials is their acceptability. As all subjects know they will receive the superior treatment at some point, their willingness to participate may increase, as well as their compliance.

### 13.2.2 Disadvantages

The principal disadvantages of cross-over trials stem from carry-over. Carry-over is defined as the persistence of the effect of the treatment received in a period into the subsequent periods. In the presence of carry-over, the outcome measured after the second treatment will be also affected by the first treatment, which is likely to bias the estimate of the treatment effect. For example, a drug agent may physiologically persist during the next period. The first treatment could also change permanently the condition of the patient, for example, by curing him (her). If the first case can be corrected by using an appropriate wash-out period between treatment periods, the second will preclude using a cross-over design. This is the case of acute infections, for instance. Carry-over has focused most concerns toward cross-over trials, and some approaches have dealt with removing carry-over, or at least accounting for it, as will be seen below. The best approach is, however, to design the study in order to avoid carry-over. Another problem related to carry-over is treatment-by-period interaction, that is, when the treatment effect is not the same in all treatment periods. As will be seen in the following, treatment-by-period interaction cannot be separated from carry-over in the AB/BA design, but both can be estimated separately in more complex designs.

Dropouts can also be more problematic in cross-over trials than in parallel-group trials, as patients who do not participate to the second study period do not provide any information on the treatment effect. This is the case for patients who die during the study.

Cross-over trials can also be used in particular situations of stable diseases, where the patient condition will not be permanently modified by the treatment.

Other less important disadvantages of cross-over trials are that all patients will receive the inferior treatment (at some point). Moreover, the duration of participation to cross-over trials is longer, due to the several period design particularly for high-order cross-over designs. This can cause some inconvenience to patients and decrease their willingness to participate.

At last, it should be underlined that cross-over trials are more complex to analyze than parallel-group designs.

### 13.2.3 Should Cross-Over Trials Be Used and When?

As already seen, cross-over trials are obviously not adapted to all situations. As each patient receives each treatment sequentially, a cross-over trial cannot be reasonably considered in diseases where patients have a nonnegligible probability of dying or considerably deteriorating during the trial period. Cross-over trials can also not be used if one of the treatments is supposed to have a permanent, for instance, curative, effect. Moreover, carry-over leads to biased estimates of treatment effect. Therefore, the Biometric and Epidemiology Methodology Advisory Committee (BEMAC) of the Food and Drug Administration (FDA) recommended during the 1970s that cross-over trials should be avoided as much as possible. One should prefer completely randomized designs where the estimate of treatment effect is unbiased, without any modeling assumption [7].

Since then, considerable research has been published on the design and analysis of cross-over trials. In contrast to this recommendation, several authors have published in defense of cross-over trials, at least in certain cases [5]. Actually, cross-over trials may be very useful but require more careful planning than parallel-group trials, as it is important to avoid carry-over [8, 11]. They should be used only in the appropriate disease settings and when dropouts are also expected to be small. For instance, it is well suited for chronic diseases such as hypertension or chronic renal failure. When planning a cross-over trial, everything should be done to avoid carry-over. This will not arise from a particular modeling strategy but from design only. It is therefore of primary importance to plan sufficient wash-out periods [11]. Additionally, random and balanced allocation to each group is advisable, with adjustment for period effect in the analysis. At last, baseline measurements may be used to increase precision. A satisfactory use of cross-over trials can also be found in demonstrating the bioequivalence of two formulations of the same drug. This is particularly the case in trials involving healthy volunteers, where carry-over is likely to be properly eliminated using an adequate wash-out period.

## 13.3 ANALYSIS OF AB/BA DESIGN

Even for the apparently simple AB/BA design, analysis of cross-over designs has generated a wide literature in the last three decades. The main reason has to do with carry-over. This section introduces the most common methods used for analysis of cross-over designs and sketches the implications of the use of these methods. More details may be found in dedicated monographs [9, 11] or in the issue of *Statistical Methods in Medical Research* dedicated to cross-over trials (1994, volume 4, issue 3).

To simplify the notations and the comparison between the different methods reviewed here, we propose to use the general model formulation for the cross-over design with a continuous outcome. Such a model has been very commonly used in the cross-over literature [1, 12–14]. Let us then note  $Y_{ijk}$  as the outcome measure of the  $j$ th subject within the  $i$ th treatment group (or sequence) at the  $k$ th period. For the AB/BA design,  $i = 1, 2; j = 1, \dots, n_i; k = 1, 2$ . The model for  $Y_{ijk}$  we consider is

$$Y_{ijk} = \mu + \pi_k + \tau_l + \eta_k \lambda_i + s_{ij} + \varepsilon_{ijk} \quad (1)$$

where  $l = 1$  if  $i = k$  and  $2$  if  $i \neq k$ , and  $\eta_k = 0$  if  $k = 1$  and  $1$  if  $k = 2$ .

In this model,  $\mu$  is the overall mean,  $\pi_k$  is the period effect,  $\tau_l$  the treatment effect and  $\lambda_i$  the first-order carry-over effect. The subject effect is represented by  $s_{ij}$  and may be regarded as a fixed or a random effect. We will adopt the latter formulation and consider that the  $s_{ij}$  are normally and independently distributed with mean 0 and variance  $\sigma_s^2$ . The within-patient errors  $\varepsilon_{ijk}$  are also assumed to be normally distributed, with mean 0 and variance  $\sigma^2$ , and both independent from each other and from the  $s_{ij}$ . We will note  $\rho$ , the correlation between observations on the same patient, which is  $\rho = \sigma_s^2 / (\sigma_s^2 + \sigma^2)$ . In this model, the whole variance of observations is  $\sigma_T^2 = \sigma_s^2 + \sigma^2$ , which can also be rewritten as  $\sigma^2 / (1 - \rho)$ . Table 1 presents the expected cell means for model (1). This model explicitly assumes that the only effects are due to treatments or periods and that they do not vary from a patient to another. It also assumes that the total variability can be split into a between-subject and a within-subject variability, that are both equal for all patients. It is thus clearly not the only possible model for the data. Freeman presents the same model with baseline measurements corresponding to a third period noted  $k = 0$  [14].

Let us note the treatment difference, or treatment effect,  $\tau = \tau_2 - \tau_1$ , the carry-over difference  $\lambda = \lambda_2 - \lambda_1$ , thereafter referred as carry-over for simplicity, and the period effect between periods 2 and 1,  $\pi = \pi_2 - \pi_1$ . Let  $y_{ijk}$  denote the observation of the random variable  $Y_{ijk}$  thereafter.

### 13.3.1 Basic Analysis

The basic analysis of the AB/BA cross-over design overlooks any period or carry-over effect. As each patient in a cross-over trial acts as its own control, the natural idea is to use within-patient differences. The basic analysis consists in computing for each patient the difference in outcome between both treatments, which is called the cross-over difference. Suppose that we use treatment A as a control for B, the cross-over difference will be  $Y_{1j2} - Y_{1j1}$  for a patient of group 1 and  $Y_{2j1} - Y_{2j2}$  for a patient

TABLE 1 Expected Cell Means for the Two-Period Cross-Over Model

| Randomization Group |               | Period                 |                                    |
|---------------------|---------------|------------------------|------------------------------------|
|                     |               | First Treatment (1)    | Second Treatment (2)               |
| 1                   | Treatment     | A                      | B                                  |
|                     | Expected mean | $\mu + \pi_1 + \tau_1$ | $\mu + \pi_2 + \tau_2 + \lambda_1$ |
| 2                   | Treatment     | B                      | A                                  |
|                     | Expected mean | $\mu + \pi_1 + \tau_2$ | $\mu + \pi_2 + \tau_1 + \lambda_2$ |

of group 2, as treatment B is given in the second period in group 1 and in the first period in group 2. Once these cross-over differences are calculated, the analysis is carried-out ignoring the distinction between both groups. This is equivalent to comparing the outcomes obtained with treatment A to the outcomes obtained with treatment B using an appropriate paired test statistic, irrespective of the randomization group. The parametric approach relies on the matched paired  $t$  test, while the nonparametric approach is based on Wilcoxon's signed rank test. This is illustrated on the example displayed in Table 2. These data have been used by Grieve [15] and come from a study carried out by CIBA-GEIGY to assess the effectiveness of transdermal nitroglycerine patches in the prophylaxis of angina in general practice [16]. A total of 63 patients were randomized between either 3-week treatment with placebo (PL) followed by transdermal nitroglycerine (TN) (group 1, PL  $\rightarrow$  TN) or vice-versa (group 2, TN  $\rightarrow$  PL). The main endpoint was the weekly anginal attack rate during the third week of treatment.

**TABLE 2 Weekly Anginal Attack Rates in Transdermal Nitroglycerine Trial**

| Group 1 |          |          |                       | Group 2 |          |          |                       |
|---------|----------|----------|-----------------------|---------|----------|----------|-----------------------|
| Patient | Period 1 | Period 2 | Cross-Over Difference | Patient | Period 1 | Period 2 | Cross-Over Difference |
| 19      | 3        | 10       | 7                     | 20      | 12       | 16       | -4                    |

| 147     | 17       | 7        | -10                   | 127     | 1        | 0        | 1                     |
| 150     | 12       | 5        | -7                    | 130     | 41       | 36       | 5                     |
| 201     | 4        | 5        | 1                     | 145     | 10       | 24       | -14                   |
| 209     | 0        | 1        | 1                     | 148     | 9        | 18       | -9                    |
| 211     | 7        | 0        | -7                    | 149     | 4        | 13       | -9                    |
| 233     | 11       | 0        | -11                   | 210     | 8        | 1        | 7                     |
| 236     | 18       | 7        | -11                   | 234     | 5        | 7        | -2                    |
|         |          |          |                       | 235     | 0        | 9        | -9                    |

In the example, the cross-over differences are displayed for each patient. Their mean would produce the basic estimator of the treatment effect. Numerically, we obtain  $\hat{\tau}^b = -3.651$ , with standard error 0.70. Using a  $t$  test, the observed  $t$  statistics is  $-5.188$  with 62 degrees of freedom, leading to a  $P$  value of  $2.5 \times 10^{-6}$  (for a two-sided test). The 95% confidence interval (CI) of the treatment effect is  $-5.058$  to  $-2.244$ .

This is a simple way to analyze cross-over trials. It is, however, only valid under particular conditions. Actually, from model (1), the cross-over differences will have expectation  $\tau + \lambda_1 + \pi$  in group 1 and  $\tau - \lambda_2 - \pi$  in group 2. With  $n_1$  patients in group 1 and  $n_2$  patients in group 2, the basic estimator has expectation  $\tau + \pi(n_1 - n_2)/(n_1 + n_2) + (n_1\lambda_1 - n_2\lambda_2)/(n_1 + n_2)$ . It is unbiased when there is no period effect, that is, no global time trend and no carry-over. However, for an unbalanced design, a period effect is sufficient to produce a biased estimator. Moreover, and even more seriously, a period effect would also result in an inflated variance of the estimator, as deterministic variations would have been attributed to random variation. Senn lists three other factors affecting the value of this basic analysis, namely a treatment by period interaction, patient by treatment interaction, and patient by period interaction [11]. Of these factors, carry-over and period by treatment interactions have been regarded as the major problems with cross-over trials.

### 13.3.2 Adjustment for Period Effect

Hills and Armitage [4] used a stratified analysis to adjust for a period effect. They still use within-patient differences but take the unweighted average of the estimator of the treatment effect obtained in each group. This defines a new estimator of the treatment effect,  $\hat{\tau}^c = \{(\bar{Y}_{1,2} - \bar{Y}_{1,1}) + (\bar{Y}_{2,1} - \bar{Y}_{2,2})\}/2$ , where the subscript “.” indicates averaging with respect to the corresponding index. This method thus combines some of the cell means of Table 1. Under the assumptions of model (1), this estimator has variance  $\sigma^2(1/n_1 + 1/n_2)/2$ , where  $\sigma^2$  is the within-subject variance. For a balanced trial where  $n_1 = n_2 = n$ , this variance reduces to  $\sigma^2/n$ . In such a case, the estimate is equal to the basic estimate, but with a different estimate of the variance. Actually, the within-subject variance  $\sigma^2$  is half the variance of a cross-over difference, which may be estimated by pooling the two within-groups sum of squares and dividing the sum by the appropriate  $n_1 + n_2 - 2$  degrees of freedom. This allows to calculate a  $t$  statistic, which also has  $n_1 + n_2 - 2$  degrees of freedom. This can be illustrated on the preceding example, with useful cell means presented Table 3.

For the two randomization groups, we obtain means equal to  $-3.839$  and  $-3.469$ , respectively, and estimated variances  $S_1 = 26.740$  and  $S_2 = 36.451$ . The estimate of the treatment effect is thus simply  $\hat{\tau}^c = -3.654$ , and the pooled variance estimate

**TABLE 3 Cell Means for Transdermal Nitroglycerine Trial Data**

| Randomization Group |           | Period 1 | Period 2 | Difference TN – PL |
|---------------------|-----------|----------|----------|--------------------|
| 1                   | Treatment | PL       | TN       |                    |
|                     | Cell mean | 8.065    | 4.226    | –3.839             |
| 2                   | Treatment | TN       | PL       |                    |
|                     | Cell mean | 6.344    | 9.813    | –3.469             |

$$2\hat{\sigma}^2 = \frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2} = 31.675$$

Hence, the within-subject variance is  $\hat{\sigma}^2 = 15.837$ , the estimated standard error of  $\hat{\tau}^c$  is 0.709, and the resulting  $t$  statistic is  $-5.152$  with 61 degrees of freedom. The corresponding  $P$  value is  $2.9 \times 10^{-6}$ . These results are very close to those obtained with the basic estimator.

This estimator is the one recommended by Senn [11]. It also corresponds to the standard weighted least-squares estimate of the treatment effect in model (1) [17]. Freeman referred to it as the CROS estimator [14], and the term was subsequently used in several reviews [11, 18]. We will thus use this terminology thereafter.

### 13.3.3 Model-Based Analysis

The alternative is to fit directly model (1) to the data. Note that, up to now, we did not consider baselines. Whether to allow separate variation for groups and patients within groups or not does not modify the estimate of treatment effect but allows to estimate a carry-over effect. The detailed analysis of variance (ANOVA) table for model (1) with fixed group, period, and treatment effects and random patient effect nested in group is not straightforward and is not detailed here. It can be found in the textbook by Jones and Kenward [9].

Numerical values for the ANOVA table together with the fixed effects estimate are presented in Table 4 for the weekly angina attack data. Using this model, the treatment effect estimator is identical to the CROS estimate presented above. The model also allows to test for carry-over or period effects, although the latter is generally of minor interest in a cross-over trial. We will detail the test of carry-over effect later. Results suggest a strong evidence for a reduction of angina attacks, about three or four per week. More precisely, the 95% confidence interval of the treatment effect is estimated at  $-5.072$  to  $-2.235$ . Moreover, there seems to be little evidence of a carry-over (group) effect nor a period effect. For purpose of comparison, note that model (1) uses a different parameterization than that used in Grieve [15], the effects estimated being minus twice the ones he chose to parameterize the model. Also note that the group effect is half the carry-over effect  $\lambda$ . The results of Table 4 perfectly match those presented by Grieve [15].

Another parameterization leading to exactly the same model would be to replace the group effect by a treatment-by-period interaction. The model used is obviously unable to attribute the difference of treatment effect in the second period to a

| Contrast        | Mean                             | Variance                                          |
|-----------------|----------------------------------|---------------------------------------------------|
| $\hat{\tau}^c$  | $\tau - \frac{\hat{\lambda}}{2}$ | $\frac{m\sigma^2}{2}$                             |
| $\hat{\lambda}$ | $\lambda$                        | $2m\sigma^2 \left( \frac{1+\rho}{1-\rho} \right)$ |
| $\hat{\tau}^p$  | $\tau$                           | $m\sigma^2 \left( \frac{1}{1-\rho} \right)$       |

carry-over [as parameterized in model (1) formulation] or to an interaction between treatment and period. Both can thus not be separated using the observed data.

Let us consider two additional contrasts:

$$\hat{\lambda} = (\bar{Y}_{2.1} + \bar{Y}_{2.2}) - (\bar{Y}_{1.1} + \bar{Y}_{1.2}) \quad \text{and} \quad \hat{\tau}^p = \bar{Y}_{2.1} - \bar{Y}_{1.1}$$

where  $\hat{\lambda}$  is the difference between the two groups, and has expectation  $\lambda$ , of which it is the weighted least-squares estimate. The contrast  $\hat{\tau}^p$  is simply the between-patient contrast for treatment effect using the first period data only. They are linked to the CROS estimator by  $\hat{\tau}^p = \hat{\lambda}/2 + \hat{\tau}^c$ . These three contrasts have a Gaussian distribution, with respective mean and variance given in Table 5, where  $m$  denotes  $(n_1 + n_2)/(n_1 - n_2)$ .

It appears in Table 5 that the CROS estimator is biased in the presence of carry-over, except if the carry-over is the same after each treatment ( $\lambda_1 = \lambda_2$ ), which does not seem much more plausible than the absence of any carry-over in practice. An unbiased estimator of  $\tau$  would be obtained using  $\hat{\tau}^p$  instead, but this would imply discarding all data recorded during the second period. This analysis has been referred to as PAR (for parallel, as no cross-over data are used). Consequently, the variance of such an estimator would be at least twice that of the CROS estimator. The contrast  $\hat{\lambda}$  provides an estimate and test for the carry-over effect. Given the variance of  $\hat{\lambda}$  as compared to that of the test of treatment effect (based either on CROS or PAR), it is clear that the test for carry-over will not be very powerful. This is, however, the basis for the general two-stage strategy proposed by Grizzle [12].

### 13.3.4 Two-Stage Analysis

Initially proposed by Grizzle [12], a two-stage approach has been recommended for many years and was commonly used for analysis. This approach begins with a formal test for carry-over, usually at a 10% level, given the limited power of this test. If no evidence of a carry-over effect is brought by this test, the treatment effect is estimated from within-patient differences using the CROS estimator. However, if the test for carry-over is considered as significant, a between-patient estimator is used instead. This estimator is the one referred as PAR above and only used the first period of the trial. Since it cannot be known in advance which test will be used,

some authors have advised the trial should always be adequately powered for the PAR analysis [1]. At first sight, this design was considered ingenious and regarded as the method of choice. Freeman conducted a thorough analysis of the two-stage design as a whole and showed that it had highly inflated type I error rates, mainly because the test for carry-over and the PAR test are not independent [14]. While some work was more recently published in defense of this procedure [5], main monographs on cross-over trials do not recommend it anymore [9–11].

For the weekly anginal attack rates of the transdermal nitroglycerin data, no significant evidence of carry-over was found at the 0.10 level. We would thus simply use the CROS analysis and conclude at a significant reduction of the weekly anginal attack rate with nitroglycerin. The estimated rate reduction would be 3.654 per week (95%CI 2.235–5.072). For comparison, if a more liberal level was used for the test of carry-over, say 0.30 for instance, the PAR analysis would be preferred. The estimated anginal attack reduction would be 1.721 per week (95%CI –5.056 to +1.615), and we would have concluded to a nonsignificant anginal attack rate reduction ( $P = 0.306$ ). Although the CROS analysis yields here a treatment effect estimate very close to the basic estimate, this two-stage procedure leads to a clearly different conclusion.

Freedman showed that if CROS behaved badly for carry-over effects departing from zero, substantial carry-over making it almost certain that spurious treatment differences would be reported [14]. The two-stage procedure had possibly highly inflated type I error rates, even in the case of absence of carry-over. For example, if  $\rho = 0.6$ , and using a 0.1 level for the test of carry-over effect and a 0.05 level for the second stage test, the actual type I error rates of the two-stage procedure would range from 0.085 in case of no carry-over effect up to 0.5 for increased carry-over effect (though it has been argued that high carry-over difference values may be quite unrealistic in case of no treatment effect). Nevertheless, the two-stage procedure always has increased significance level. On the contrary, in case of no cross-over, the two-stage procedure shows a better power than PAR, but purchased at the expense of increased type I error rates. These properties are explained by the joint distribution of the three contrasts  $(\hat{\tau}^c, \hat{\lambda}, \hat{\tau}^p)$ . If  $\hat{\lambda}$  and  $\hat{\tau}^c$  are independent, the correlation between  $\hat{\lambda}$  and  $\hat{\tau}^p$  is  $\sqrt{(1+\rho)/2}$ , which can be remarkably high, for example, about 0.866 if the within-patient variability  $\sigma^2$  is equal to the between-patient variability  $\sigma_s^2$ . The tests based on PAR and the test for carry-over are thus not independent. Actually, Senn showed that the conditional error of PAR given a significant test for carry-over at the 0.1 level lies between 0.25 and 0.5, depending on the balance between within-subject and between-subject variability [19]. On the contrary, the type I error rate of the CROS analysis is 0.05 when the test for carry-over is nonsignificant. The global type I error of the whole procedure thus lies between  $0.9 \times 0.05 + 0.1 \times 0.25 = 0.07$  and  $0.9 \times 0.05 + 0.1 \times 0.5 = 0.095$ .

Another particular property of the two-stage design pointed out by Freeman is that its performance does not increase when the sample size increases [14]. This makes worthless the proposal of some authors that the trial should be adequately powered for the carry-over test (see, e.g., Brown [1]). Actually, as results of the first stage test are more likely to yield reliable conclusions, results of the second stage will be all the more sensitive to small carry-over values. The overall performance thus worsens as sample size increases, with inflated type I error rates. For example, with  $\rho = 0.6$  and a 0.1 level for the test of carry-over effect and a 0.05 level for the

second stage test, an actual type I error rate of 0.5 occurs at  $\lambda = 1.25\sigma$  when  $n (= n_1 = n_2)$  is about 20,  $\lambda = \sigma$  when  $n$  is about 30 and  $\lambda = 0.55\sigma$  when  $n = 100$ . At last, it should be noted that if  $\hat{\tau}^c$  is a biased estimator of  $\tau$ , with bias depending on carry-over  $\lambda$ ,  $\hat{\tau}^c$  even unbiased, is correlated to  $\hat{\lambda}$ , the estimate of  $\lambda$ .

Based on these considerations, both Senn [11, 19] and Jones and Kenward [9] recommend not using the two-stage procedure. They advise the best should be done to remove carry-over, using, for instance, adequate wash-out periods. Then, a sensible analysis can be performed by CROS. Freeman would recommend the use of a Bayesian approach [15, 20, 21].

### 13.3.5 Carry-Over

As seen in Section 13.3.3, carry-over and treatment-by-period interaction cannot be estimated separately using the observed data. Thus, carry-over or treatment-by-period interaction is rather a modeling point of view [14]. If carry-over cannot be ruled out by design, then it may be preferable to perform a parallel-group trial [11, 14]. On the contrary, if a treatment-by-period interaction is suspected, any form of trial is questionable, as estimating an absolute difference between treatments is meaningless.

Of note, both may also exist in parallel-group trials. For example, in a trial comparing an experimental treatment to a standard treatment of a chronic disease, patients allocated to the experimental group may have received the standard treatment in the past, and carry-over could occur in the same way as in a cross-over trial if a (run-in) wash-out period is not planned. Conversely, one may also imagine that some patients already treated by the standard therapy and allocated to the control group may have developed some form of resistance to this treatment, which would amplify the difference between treatment arms.

Different approaches concerning carry-over may be found in the literature on cross-over trials. For instance, Senn recommends to design the trial at best to avoid carry-over and then to not consider further this issue [6, 11, 22]. Willan and Pater would also likely use a CROS analysis, but in cases where between-subject variability exceeds within-subject variability and the carry-over effect is small [13]. This would be consistent with the point of view of Poloniecki and Pearce, who argue that, since the test for carry-over has a low power, it will allow to detect only large values of carry-over [23].

### 13.3.6 Use of Baselines

Carry-over has been the focus of much concern in preceding sections. Baseline measurements may be used to add information and eliminate parameters such as carry-over from the contrasts of interest. Baselines may be intended as genuine baseline measurements of the outcome (i.e., before treatment) or more generally as other covariates. Additionally, baselines may be measured at several time points, as during a run-in period, before the first treatment period, at the end of the wash-out period, or even at the end of a second wash-out period after the last treatment period [9–11]. For example, the formulation for model (1) used in Freeman only considers baseline measurements during a run-in period [14]. Such a situation can be treated in practice in the same way as for genuine covariates. In both cases, if

the response is related to the covariate (or baseline measurement), the between-subject residual variance may be sensibly reduced by adjusting for the covariate in the model. This is the same as for parallel group trials. Considering two or more baselines requires a modification of the way data are to be analyzed [9]. Several approaches have been proposed to incorporate baseline measurements into the analysis. They differ with regard to the assumptions that may be made or not [9, 11, 24]:

- Is the period effect applicable to a baseline measurement equal to the one applying to the following outcome measurement?
- Does carry-over also apply to baseline measurements and, if so, is it the same as carry-over for the subsequent treatment?
- Do the observations on the same subject have a uniform covariance structure?

To summarize, it has been shown that incorporating baselines can reduce the variance of the treatment effect estimate, as expected, and Kenward and Jones showed how to consider these baselines without assuming a particular covariance structure for the measurements [24]. They also showed that if information from baseline could increase the power of the test for carry-over, it remained unlikely that it would be increased up to the power of the test for direct treatment effect. The methods are not detailed here but can be found in appropriate references [9, 24].

### 13.3.7 Bayesian Analysis

The reader unfamiliar with Bayesian analysis should perhaps read first the introduction to Bayesian methods in health science by Spiegelhalter et al. [25]. A first Bayesian analysis of the  $2 \times 2$  cross-over trial as used for bioequivalence assessment was proposed by Selwyn et al. [26] Grieve and co-workers have proposed a Bayesian approach to the analysis of the AB/BA cross-over design, which has been extended to incorporate baseline measurements and to other cross-over designs [15, 20, 21, 27]. According to Freeman, this is the only satisfactory analysis of the two-period two-treatment cross-over design [14]. We here present a brief summary of this approach.

The assumed model is model (1). Grieve considers a joint uninformative prior distribution for the model parameters [20]. Let us note  $p(\tau, \lambda, \sigma^2, \rho)$  the prior distribution of model parameters of interest (for simplicity, the period effect is not explicitated here). The prior distribution has the form [28]

$$p(\tau, \lambda, \sigma^2, \rho) \propto \frac{1}{\sigma^2(1+\rho)}$$

Noting  $Y$  the observed data, the following posterior distributions are obtained for the location parameters  $\tau, \lambda$  given the observations and the second-order parameters  $\sigma^2, \rho$  are obtained from standard properties of the normal distribution as:

$$\begin{aligned}
p(\tau|\lambda, \sigma^2, \rho, Y) &= N\left(\hat{\tau}^c + \frac{\lambda}{2}; \frac{m\sigma^2}{2}\right) \\
p(\tau|\sigma^2, \rho, Y) &= N\left(\hat{\tau}^p; \frac{m\sigma^2}{1-\rho}\right) \\
p(\lambda|\sigma^2, \rho, Y) &= N\left(\hat{\lambda}; 2m\sigma^2 \frac{1+\rho}{1-\rho}\right) \\
p(\tau, \lambda|\sigma^2, \rho, Y) &= N\left(\begin{matrix} \hat{\tau}^p \\ \hat{\lambda} \end{matrix}; \frac{m\sigma^2}{1-\rho}\right) \begin{bmatrix} 1 & 1+\rho \\ 1+\rho & 2(1+\rho) \end{bmatrix}
\end{aligned}$$

Unconditional distributions are computed by reparameterizing the model with  $\sigma_1^2 = \sigma^2 + 2\sigma_s^2 = \sigma^2(1-\rho)(1+\rho)$  and  $\sigma^2$  instead of  $\sigma^2$  and  $\rho$ . They depend on the sum of squares associated with residual error (SSE) and with subject within group (SSS) of the ANOVA table. The following posterior distributions are obtained:

$$p(\lambda|Y) = t\left(\hat{\lambda}; \frac{2mSSS}{n_1 + n_2 - 2}; n_1 + n_2 - 2\right) \quad (2)$$

$$p(\tau|\lambda, Y) = t\left(\hat{\tau}^c + \frac{\lambda}{2}; \frac{mSSE}{2(n_1 + n_2 - 2)}; n_1 + n_2 - 2\right) \quad (3)$$

where  $t(\mu, \theta, \nu)$  denotes the noncentral and scaled  $t$  distribution with  $\nu$  degrees of freedom, location parameter  $\mu$  and scale parameter  $\theta^{1/2}$ . The integral necessary to obtain the posterior density of  $\tau$  unconditional on  $\lambda$  is intractable, but the following approximation was derived by Grieve:

$$p(\tau|Y) \approx t\left(\hat{\tau}^p; \frac{m\phi}{2\nu}; \nu\right) \quad (4)$$

where

$$\begin{aligned}
\nu &= \frac{(SSE + SSS)^2 (n_1 + n_2 - 6)}{SSE^2 + SSS^2} + 4 \\
\phi &= \frac{(\phi - 2)(SSE + SSS)}{n_1 + n_2 - 4}
\end{aligned}$$

Grieve shows how to additionally take the constraint  $\rho > 0$  into account in this analysis [15, 20]. However, if negative correlations between different measurements on a same patient were expected, a cross-over design would unlikely be conducted. Additionally, the implied modifications only make little difference, so that these refinements are not further considered here.

The results of a Bayesian analysis of the transermal nitroglycerin trial are displayed in Figure 2. As shown in Grieve, the posterior distribution  $P(\tau < 0|\lambda = 0, Y)$  and  $P(\tau < 0|Y)$  differ markedly [15]. For example,  $P(\tau < 0|Y) = 0.85$ , whereas  $P(\tau < 0|\lambda = 0, Y) > 0.9999$ . Note that despite the modified parameterization, these

**FIGURE 2** Posterior marginal distribution of  $\lambda$  and  $\tau$  for transdermal nitroglycerin trial data.

values are identical to Grieve's analyses. Recall that the  $P$  value associated to a (frequentist) test of carry-over is 0.198, thus not supporting a model with a carry-over effect in the nitroglycerin trial data. On the contrary, the posterior density of  $\lambda$  seems rather in favour of a carry-over, with  $P(\lambda > 0|Y) = 0.90$ .

Results of the example well illustrate that a model without carry-over, noted  $M_0$ , and a model with carry-over,  $M_1$ , can lead to different conclusions. Grieve proposed a Bayesian approach of differentiating between the models  $M_0$  and  $M_1$ , using a prior specification allowing to incorporate information on prior belief on carry-over [20]. The proposed method models the set up as a mixture of  $M_0$  and  $M_1$ , and then uses a Bayes factor. The posterior probability of each of  $M_0$  and  $M_1$  can be written as

$$P(M_i|Y) = P(Y|M_i) \frac{P(M_i)}{P(Y)} \quad i = 0, 1$$

Noting the Bayes factor

$$B_{01} = \frac{P(M_0|Y)P(M_1)}{P(M_0)P(M_1|Y)} = \frac{P(Y|M_0)}{P(Y|M_1)}$$

and the prior odds on  $M_0$ ,  $\kappa = P(M_0)/P(M_1)$ , the posterior probability of the two models are

$$P(M_0|Y) = \frac{\kappa B_{01}}{1 + \kappa B_{01}} \quad \text{and} \quad P(M_1|Y) = \frac{1}{1 + \kappa B_{01}}$$

Inference on the treatment effect can then use the mixture posterior distribution

$$p(\tau|Y) = \frac{\kappa B_{01}}{1 + \kappa B_{01}} p(\tau|M_0, Y) + \frac{1}{1 + \kappa B_{01}} p(\tau|M_1, Y)$$

Where  $p(\tau|M_0, Y)$  and  $p(\tau|M_1, Y)$  are given by Equations (3) and (4), respectively. The Bayes factor  $B_{01}$  can be calculated following Spiegelhalter and Smith as [29]:

$$B_{01} = \sqrt{\frac{3}{2m}} \left( 1 + \frac{F_\lambda}{n_1 + n_2 - 2} \right)^{(n_1 + n_2)/2}$$

where  $F_\lambda$  is the  $F$ -test statistic for assessing significance of carry-over effect  $\lambda$ . The value of  $\kappa$  one chooses represents his (her) prior belief in carry-over. A value of  $\kappa = 1$  indicates indifference to the choice of a model.

A graph of posterior treatment effect as a function of prior belief in carry-over can be plotted. It represents either the posterior mean and the 95% highest posterior density (HPD) interval or either  $P(\tau < 0|Y)$  or  $P(\tau > 0|Y)$  according to model parameterization against  $P(M_1) = (1 + \kappa)^{-1}$ . Both are given in Figure 3.

Figure 3 displays some of the possible summaries of the posterior distribution of  $\tau$  according to the prior belief in carry-over for the example data. These are the posterior mean with 95% HPD interval and the probability of a benefit of transdermal nitroglycerin in the prevention of anginal attacks,  $P(\tau < 0|Y)$ . Details on the interpretation of such graphs are well described in the works of Grieve [15, 20, 27]. Briefly, the results show here that the conclusions strongly depend on the prior belief in carry-over, but it has been pointed out that it should be due to the relatively small value of  $B_{01}$  (2.052, in the present case) [20].

**FIGURE 3** Relationship between posterior inference on treatment effect  $\tau$  and prior belief in a carry-over effect (expressed as probability of a model with carry-over) for the weekly anginal attack rates.

The main advantage of Bayesian analysis of a cross-over trial is that it allows to stand in between the options of CROS and PAR analyses of a classical two-stage design. Several extensions of this technique have been considered but not reviewed here. Notably, it has been developed to consider baseline measurements [27] or nonuniform covariance matrices [30]. The use of informative priors has also been outlined [15].

## 13.4 OTHER ENDPOINTS

Analysis of AB/BA cross-over trials has generated a wide literature for normally distributed outcomes, as summarized in Section 13.3. We review here some methods for other situations.

### 13.4.1 Nonparametric Analyses

Model (1) and  $t$  tests rely on the assumption that the outcome measurements  $Y_{ijk}$  are normally distributed random variables. In some cases, however, such an assumption is clearly unverified. A first approach is to perform some variance stabilizing transformation, for example, taking the logarithm of data, in order to obtain a distribution closer to a normal distribution. Another choice is to prefer a nonparametric analysis that does not rely on a particular distribution for data. Nonparametric analyses are also well suited for ordinal variables with more than 4 or 5 classes. An excellent review of nonparametric analyses of cross-over trials is given by Tudor and Koch [31].

If a nonparametric analysis is found better adapted, the basic analysis described in Section 13.3.1 can be very simply carried out using a nonparametric test based on ranks such as Wilcoxon signed rank-sum test or a sign test, instead of the paired  $t$  test. This corresponds to test whether cross-over differences obtained for each patients are centered around zero.

Several nonparametric methods accounting for a period effect are also available [11]. Koch, in an important study on nonparametric analysis of cross-over trials proposed to use a Wilcoxon rank-sum test (or equivalently a Mann–Whitney U test) to compare period differences across groups [32]. Contrary to the basic analysis, the period differences are constructed for each patient, that is,  $Y_{ij2} - Y_{ij1}$ , whatever  $i$  is. A nonparametric test for equality of the distribution of period differences across both groups is then performed. A significant difference results in the conclusion that the average period difference is not the same in both group, which would imply a treatment effect. An estimator of this treatment effect can be obtained using Hodges–Lehman estimator, and 95% confidence limits may also be computed [33]. Senn has underlined the parallel between such a procedure and the CROS estimator of Hills–Armitage [11].

A more general procedure was also proposed by Koch that resembles the two-stage design discussed in previous sections [9, 31, 32]. In case of a significant test for treatment effect, as described above, a similar nonparametric test for carry-over is performed. Contrary to Grizzle’s two-stage procedure, this test is not carried out first but has a supportive role in a second stage, in order to address the concerns

regarding the classical two-stage procedure [11, 14]. A test of period effect given no carry-over can also be performed.

Nonparametric methods have been extended to account for multiple centers or strata, or baseline measurements. For further reading, see Tudor and Koch [31] or Jones and Kenward [9].

### 13.4.2 Binary or Categorical Data

For binary data, analysis has long relied on more or less appropriate methods for contingency tables, with the exception of the Mainland–Gart test. More recent works share the common feature to use an explicit model [34–37] while former methods often relied on implicit models [38]. We briefly present here some of the possible approaches to the analysis of binary AB/BA cross-over data, as well as their extension to count data.

**Mainland–Gart Test** The Mainland–Gart test examines the association between the period and group for patient preference [39, 40]. Subjects are classified according to their group into three categories: those who responded to treatment in period 1 and not in period 2, whose response is noted (1,0); those who responded to treatment in period 2 but not in period 1, that is, response (0,1); and those who had identical response after each period, noted (1,1) or (0,0) and who exhibited no preference. An example is given Table 6.

Under the null hypothesis, the preference (i.e., response in period 1 or in period 2) should only reflect the period effect. Ignoring patients who exhibited no preference such as in McNemar’s test, that is, ignoring the counts  $b$  and  $e$  in Table 6, a difference between treatment should lead to an association between group and the category of response (1,0) or (0,1). Such an association can be tested using any test for unpaired proportions, such as Fisher’s exact test or a chi-square test with or without continuity correction.

One of the disadvantages of such a procedure is that the number of subjects actually contributing to the test procedure may be small, as observations with the same response to both treatments are simply discarded. On the contrary, the Mainland–Gart test does not depend on the randomization of subjects into groups [9]. A test relying on randomization, but exploiting all information, was subsequently proposed by Prescott [41]. It will not be detailed here.

**Model-Based Methods** As shown for continuous outcomes, cross-over trials rely on within-subject information for the comparison of treatments. As a consequence, they result in correlated observations. Methods for modeling correlated binary data, although theory exists for many years, have long suffered from unavailability in statistical software packages. Recent advances in this domain have led to a rapid

**TABLE 6 Contingency Table for Mainland–Gart Test**

| Randomization Group | Overall Response |                |       |
|---------------------|------------------|----------------|-------|
|                     | (1,0)            | (1,1) or (0,0) | (0,1) |
| 1                   | $a$              | $b$            | $c$   |
| 2                   | $d$              | $e$            | $f$   |

diffusion of new methods for analysis of clustered binary data in the last years [34].

Contrary to the case of a linear model such as (1) for normally distributed data, the effect of a covariate on binary correlated data may have two different interpretations. The marginal effect corresponds to the average difference between two populations defined by differing covariate values, whereas the subject-specific or conditional effect corresponds to the expected difference for a same subject under different covariate values. These effect interpretations correspond to different possible models, namely the marginal or population-averaged model and the marginal or subject-specific model [34, 36, 42, 43]. Actually, for a linear model as (1), the outcome and the linear combination of covariates are on the same scale, so that parameters in both modeling approaches have the same interpretation, the difference lying in the error structure. For binary data, where a generalized model with a nonlinear link function relating the linear combination of covariates to the probability of response has to be used, both models cannot have the same interpretation anymore [36, 38].

Let us briefly detail these models and summarize their condition of use for AB/BA cross-over data. Paralleling model (1), a marginal logistic model can be expressed as

$$\text{logit } P(Y_{ijk} = 1) = \log \left[ \frac{P(Y_{ijk} = 1)}{P(Y_{ijk} = 0)} \right] = \mu + \pi_j + \delta_k \tau_l \quad (5)$$

where  $\pi_j$ ,  $\delta_k$ , and  $\tau_l$  have the same definition as for Equation (1). Other choices for the link function, such as a probit, for instance, are possible. Subject effect does not appear explicitly in model (5). Rather, dependence among observations from the same subject is accounted for via a robust covariance matrix. Model parameters are only related to the whole population, and estimates will be similar to classical logistic regression. The difference will lie in the standard errors of the parameter estimates. Several approaches have been proposed for model inference, one of the most popular being the generalized estimating equations (GEE) approach of Liang and Zeger [44]. These population-averaged models have been favored for practical computational aspects and availability in standard statistical software packages [38]. However, they are best adapted to assess the effects of cluster-level, that is, subject level in the case of cross-over trial data, covariates [36].

A conditional model can be written in a form even closer to model (1), as

$$\text{logit } P(Y_{ijk} = 1) = \mu + s_{ij} + \pi_j + \delta_k \tau_l \quad (6)$$

with  $s_{ij}$  denoting the effect associated with subject  $ij$ . As for model (1), observations are assumed independent conditionally of the subject effect, and the subject effect can be considered as either fixed or random. Two approaches to conditional modeling can thus be considered in practice. The conditional likelihood approach eliminates the subject effect [45] and corresponds to the Mainland–Gart test for the AB/BA design [38]. The other approach assumes a particular distribution for the subject effect, usually a normal distribution, which leads to a generalized linear mixed model (GLMM). This is the closest approach to model (1). In a conditional model, the covariate effects are measured conditionally on the subject effect  $s_{ij}$ . Thus,

regression parameters corresponding to covariates that do not change within subject may suffer from interpretation problems when using a conditional likelihood approach, as such effects are actually not observable [42, 43]. Conversely, GLMMs are based on both within-subject and between-subject comparisons, at the cost of distributional assumptions for the subject effects [36, 42]. For cross-over trials, however, where treatment effect estimation relies on inference about individual differences, conditional models are particularly well suited [36]. It must be noted that GLMMs have been long unavailable for use in routine practice, as major statistical packages did not offer this type of model. This was due in particular to the intractable likelihood function leading to very computer-intensive algorithms involving numerical integration. More recently, there has been a large development of methods, making the use of these models easier, though it still remains a topic of current research.

**Categorical Data** For categorical data, the same types of model as described above for binary data exist. More detailed can be found in appropriate references [9, 38, 46].

### 13.4.3 Censored Endpoints

Few works in the literature have concerned the analysis of censored endpoints in cross-over trials [47–49]. At first, cross-over trials and censored data may seem not to fit with each other because one usually thinks of survival. However, a cross-over may be adapted if the treatments are aimed for recurrent events, such as infection or headache. Another domain could be measures of some form of endurance [49].

For a single duration response, France et al. [48] have proposed to use a Cox proportional hazards model stratified by patient [50]. Such a model cannot incorporate a group effect and thus explicitly does not address carry-over. A further analysis of the same example by Bristol proposed to use a group effect without stratification [51]. Both methods led, however, to very different results. Another approach used a parametric log-linear model for a Weibull process [49, 52]. The results showed that a stratified model should be preferred to an unstratified model with period effect.

A markedly different approach was adopted by Feingold and Gillespie [47]. It used an additive model instead of the proportional hazards model of France et al. [48], which was additionally based on the usual methods for complete (uncensored) data. Two tests were considered, namely the Wilcoxon test, which only applies to two-period designs, and a more general but less powerful score transformation procedure. It was shown that these methods were more powerful than that of France et al. [48].

Multiple duration responses were only considered by Lindsey, through the log-linear model evoked above [49].

## 13.5 POWER AND SAMPLE SIZE CONSIDERATIONS

It is sometimes stated that cross-over trials require half the sample size of a parallel-arm trial to demonstrate a given (direct) treatment effect because each patient

receives both treatments. Recent work based on a review of published cross-over studies has shown that a parallel design is expected to need between 4 and 10 times more subjects than a cross-over design in order to achieve the same power, leading to costs between 2 and 5 times higher [53]. In this section, we give sample size equations for a two-period two-treatment cross-over trial with a continuous outcome. We then provide some discussion on the comparative efficiency of cross-over and parallel trials. We place ourselves in the situation where there is no carry-over and analysis is performed using ANOVA in model (1) or, equivalently, CROS.

### 13.5.1 Sample Size

Sample size is usually computed to ensure the trial will have sufficient power against a given alternative hypothesis. Under this alternative, both treatments A and B have different direct effects and the treatment effect  $\tau = \tau_2 - \tau_1$  is supposed equal to  $\Delta$ . This value is often referred as the minimal clinically relevant difference or the expected treatment effect. Sample size for cross-over trials are computed using usual methodology for the test of the null hypothesis  $\tau = 0$ . Let  $\alpha$  and  $\beta$  denote the type I and II error rates, that is, the probability of rejecting the null hypothesis when it is actually true and the probability of not rejecting the null hypothesis when the alternative is actually true, respectively. These error rates are usually fixed by convention at 0.05 for  $\alpha$  and 0.10 or 0.20 for  $\beta$  [54], though some different values can be sometimes found, such as lower  $\beta$  or  $\alpha = 0.025$  for one-sided tests. Moreover, the type II error rate is more frequently expressed using its counterpart  $1 - \beta$ , called power, which is the probability of rejecting the null hypothesis when there is actually a treatment effect. The null hypothesis can be rejected when  $\hat{\tau}^c > 0$  or  $\hat{\tau}^c < 0$  by a sufficient amount. Here, we consider the case when both chances of rejecting the null hypothesis are taken into account, which is referred to as a two-tailed or two-sided test.

As noted above, the null hypothesis of no treatment effect can be tested using  $\hat{\tau}^c$ . Recalling Table 1 for a balanced cross-over trial, that is, when  $n = n_1 = n_2$ ,  $\hat{\tau}^c$  has variance  $\sigma^2/n$ , and expectation 0 under the null hypothesis and  $\Delta$  under the alternative. Assuming the within-subject variance  $\sigma^2$  is known,  $\hat{\tau}^c$  has a normal distribution and usual sample size for Gaussian variables can be used [9, 11, 54]:

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2 \sigma^2}{\Delta^2} \quad (7)$$

where  $z_{1-\gamma}$  denotes the  $(1 - \gamma)$  quantile of the standard normal distribution.

If  $\sigma^2$  is unknown, it has to be estimated from the trial's data, and  $\hat{\tau}^c$  has a Student distribution. One could use appropriate modification of Equation (7) using the noncentral  $t$  distribution. As an approximation, a correction factor  $1/4 z_{1-\alpha/2}$  may be added to  $n$ , which improves the approximation of Equation (7) [54]:

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2 \sigma^2}{\Delta^2} + \frac{z_{1-\alpha/2}}{4} \quad (8)$$

To use Equation (7) or (8) in practice, one has to choose a value for  $\Delta$  but also to obtain an a priori estimate for  $\sigma^2$ . This is naturally also the case when planning

any type of trial, and such values are usually chosen using existing trials or studies in the domain considered. However, for cross-over trials, it might be a little more difficult to obtain a value for  $\sigma^2$ , as it represents the within-subject variance only. It may be worth noting that  $\sigma^2$  is half the variance of cross-over (or within-subject) differences, which may be more easily obtained using prior published information, for instance. The within-subject variance is also  $(1-\rho)\sigma_T^2$ , where  $\sigma_T^2$  is the total variance of an observation.

As an example, consider the transdermal nitroglycerin trial used for illustration throughout this chapter. Suppose it was considered at the planning stage that a mean diminution of two attacks per week would be clinically relevant and that the within-subject variance was not known, but that in prior early phase studies where patients received transdermal nitroglycerin the within-subject before–after differences had variance of about 30. A value of  $\sigma^2 = 15$  would then seem reasonable. With  $\Delta = -2$  and, for example,  $\alpha = 0.05$  and  $\beta = 0.20$ , formula (8) would lead to

$$n = \frac{(1.96 + 0.84)^2 \times 15}{4} + \frac{1.96}{4} = 29.89$$

By rounding up to 30, it would then be decided to recruit 30 patients in each group.

Sample size for cross-over trials in other situations, such as an equivalence or a noninferiority trial, or for bioequivalence, have been considered in detail in the review of Julious for normally distributed data [54]. A method for binary endpoints is given in Ezzet and Whitehead [46].

### 13.5.2 Efficiency of Cross-Over Versus Parallel-Group Design

A complete review of efficiency considerations for cross-over and parallel designs is given in Chapter 9 of Senn [11]. We sketch here some of these issues.

Consider a cross-over trial where  $n$  patients are randomly assigned to each of the sequences AB and BA and a parallel-group trial where  $p$  patients are randomly assigned to treatment by A and  $p$  patients are randomly assigned to treatment by B. As considered higher, the estimate of treatment effect in the cross-over trial is  $\hat{\tau}^c$ , which has variance  $\sigma^2/n$ . Conversely, the estimate of treatment effect in the parallel design is analogous of  $\hat{\tau}^p$ , as all data will be recorded in a single (first) period. From Table 5, replacing  $n_1$  and  $n_2$  by  $p$ , the variance of the estimator of treatment effect in this design is  $2\sigma^2/[p(1-\rho)] = 2\sigma_T^2/p$ . To obtain equal variance estimates, it is then necessary to recruit  $p = 2n/(1-\rho)$  patients per arm in the parallel-group trial. In the variance component model (1),  $\rho \geq 0$ , so that  $p$  will always be larger than  $n$ , even in the case where between-subject variance is negligible as compared to within-patient variance. This is because the parallel-group design is also subject to within-subject variation, which is often overlooked, as remarked by Senn [11]. Once again, if the variance component model does not hold and negative values of  $\rho$  are expected, it is anyway most improbable that a cross-over trial would be considered at all.

For choosing, whenever possible, between a parallel and a cross-over design, one may also take the duration of the trial into account, and not only the sample size. This should account for the two treatment periods of the cross-over trial but also for the

possible run-in and wash-out periods. Senn shows that when there is no run-in nor wash-out, the cross-over trial duration is always shorter than that of a parallel trial [11]. With no run-in but a wash-out duration equal to treatment period duration, the cross-over trial is shorter as soon as  $1/(1 - \rho) > 3/2$ , which is the case when between-subject variation is at least half the within-subject variation, a reasonable situation in practice. For more general cases, the reader may directly refer to Senn [11].

## 13.6 MORE COMPLICATED DESIGNS

There has been some work done toward finding the optimal design for a particular situation [9]. In particular, designs for two treatments but with more than two periods, have been studied, as a way of estimating carry-over and treatment-by-period interactions. Cross-over trials for more than two treatments, and usually at least three periods, have also been considered.

### 13.6.1 Higher Order Designs for Two Treatments

The main limitation of the AB/BA design without baseline measurements is that carry-over effects, treatment-by-period interaction, and group effects cannot be separated. Higher order designs, under specific and possibly disputable assumptions, may allow estimation of carry-over or treatment-by-period interactions.

Several assumptions or models for carry-over have been considered to examine design optimality. Some are, for example, the *simple carry-over* model, where the carry-over lasts exactly for one period and only depends on the last treatment, or the *steady-state carry-over* model, where the carry-over also lasts exactly for one period but treatment does not induce carry-over into itself.

Assuming either model, there have been numerous works on “optimality” for a wide range of cross-over designs with more groups and two periods (e.g., AB/AA/BA/BB) or with more periods (e.g., ABB/BAA) or both, such as ABA/BAB/AAB/BBA or AABB/BBAA/ABBA/BAAB [55–58]. The choice between these designs is not easy. Generally, increasing the number of periods increases the precision of the estimation of carry-over effects, but this gain is not always more efficient in terms of costs than including more patients. If the major cost is recruitment, then it has been advised to keep patients as many periods as is practical and ethical [9].

However, a greater number of periods may also lead to consider issues such as second-order carry-over or treatment-by-carry-over interactions. Overall, if a particular design should be recommended, the AABB/BBAA/ABBA/BAAB or the ABB/BAA designs would have the favor of Jones and Kenward [9].

These approaches, and particularly the assumptions concerning carry-over, have been quite sharply criticized [2, 11]. Some authors thus do not recommend multiperiod cross-over trials to be conducted except if prior knowledge on carry-over supports the underlying assumptions.

### 13.6.2 Designs for Three or More Treatments

Cross-over designs have been extended to compare more than two treatments. In practice, such designs have been preferred in situations where intervals between

treatments were short (e.g., some days). They have been quite popular in early phase I trials, with treatments also intended as several doses of the same drug.

Planning of such trials often relies on choosing sequences that form a Latin square. An example of such a design for four treatments (A, B, C, and D) may be the one displayed in Table 7, where patients would be randomly assigned in equal number to each of the four groups.

This Latin square ensures that every subject receives all four treatments, and each treatment occurs only once in each group. Moreover, the example given Table 7 also ensures that each ordered pair of treatments (e.g., A followed by B) occurs once and only once. The literature refers to these Latin squares as balanced. The efficiency of Latin square designs is the highest possible if the Latin square is balanced. As an example, the Latin square given in Table 8 is not balanced because treatment A is followed by treatment B more than once.

These designs are also most efficient if the simple carry-over model holds. Alternative models for other carry-over situations are considered in Jones and Donev [59].

Additionally, to achieve balance, it may be desirable that each treatment be followed by each other exactly once. This is not always possible in a simple Latin square, and sets of orthogonal Latin squares have been used for this purpose. Often, very few patients are included in each group. An example of a complete set of orthogonal Latin squares is presented in Table 9.

Such designs show the advantage of being balanced over all preceding treatments, so they are balanced for all first-order, second-order, and so on carry-over effects. Conversely, they may require much more subjects. For instance, using the design given in Table 9 implies including multiples of 12 subjects. Moreover, having an increased number of groups, they have a higher probability of a sequence being incorrectly administered to a patient. Williams showed that balance could be achieved by using a particular Latin square for an even number of treatments and

**TABLE 7** Balanced Latin Square Design for Four Treatments

| Group | Period |   |   |   |
|-------|--------|---|---|---|
|       | 1      | 2 | 3 | 4 |
| 1     | A      | D | B | C |
| 2     | B      | A | C | D |
| 3     | C      | B | D | A |
| 4     | D      | C | A | B |

**TABLE 8** Another Latin Square Design for Four Treatments

| Group | Period |   |   |   |
|-------|--------|---|---|---|
|       | 1      | 2 | 3 | 4 |
| 1     | A      | B | C | D |
| 2     | B      | C | D | A |
| 3     | C      | D | A | B |
| 4     | D      | A | B | C |

**TABLE 9** Orthogonal Latin Squares Design for Four Treatments

| Group | Period |   |   |   |
|-------|--------|---|---|---|
|       | 1      | 2 | 3 | 4 |
| 1     | A      | B | C | D |
| 2     | B      | A | D | C |
| 3     | C      | D | A | B |
| 4     | D      | C | B | A |
| 5     | A      | D | B | C |
| 6     | B      | C | A | B |
| 7     | C      | B | D | A |
| 8     | D      | A | C | B |
| 9     | A      | C | D | B |
| 10    | B      | D | C | A |
| 11    | C      | A | B | D |
| 12    | D      | B | A | C |

two particular squares for an odd number of treatments [60, 61]. Such designs require less subjects than using complete sets of orthogonal squares.

All these designs have the same number of treatments and periods. Sometimes, more treatments are investigated than can be reasonably given to a single patient. Some designs thus may have less periods than treatments. Conversely, to better estimate carry-over effects, more periods than treatments could be necessary, as in the two-treatment case. Details on both types of designs can be found, for example, in Jones and Kenward [9]. Briefly, in the situation where the number of treatments is greater than the number of periods, the simplest method is to delete periods from a full set of orthogonal Latin squares [62, 63]. Another popular method is the balanced incomplete block design, where each treatment is replicated the same number of times, and each pair of treatments occurs in the same block the same number of times [63]. These designs are, however, not balanced for carry-over, as each treatment does not follow every other with the same frequency. More precisions can be found in cross-over textbooks [9, 11].

### 13.7 SUMMARY

Cross-over trials are trials where subjects subsequently receive all the treatments being compared (or at least some of them). Between the treatment periods, wash-out periods are used to avoid a residual or carry-over effect of a treatment into the next period. The estimate of treatment effect being based on within-subject rather than between-subject information, cross-over trials are usually more efficient, but they can only be used in situations where treatments will not durably modify patient conditions.

Although the use of complex models for cross-over trials was long limited by availability in common statistical software packages, all analyses presented here can be easily performed using standard software such as SAS (SAS Institute Inc., Cary, NC) or R (The R Foundation for Statistical Computing, Vienna, Austria).

### **14.1.1 BIOMARKER DEFINITION AND CRITERIA**

Biomarkers are valuable tools for drug development that provide greater accuracy or more complete information regarding drug performance and/or disease progression. Developments in genomics, genetics, proteomics, and imaging have highlighted the importance of biomarkers as useful clinical indicators. The Biomarkers Definitions Working Group [1], sponsored by the National Institutes of Health, has defined a biomarker as:

A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.

In most cases, a biomarker should satisfy two criteria: (1) be associated with the biological mechanisms involved within a disease or treatment of a disease and (2) have the potential to correlate statistically with clinical outcomes. This broad definition means that a vast array of tests falls within this scope, spanning methods as varied as measurements of serum troponins and cardiac computed tomography. It is also important to clarify that most biomarkers are *not* surrogate endpoints. Under regulatory agency definitions, surrogate endpoints are findings or measurements that may be substituted for disease endpoints in clinical trials to evaluate the safety or effectiveness of a medical therapy for treating disease. These well-defined and accepted biomarkers represent a small subcategory of the biomarker world.

While there are different categories of biomarkers, three categories are most relevant to this discussion: target, mechanism, and outcome. Although a biomarker used in any stage of drug development may be from the target, mechanism, or outcome categories, in general, target biomarkers are more often part of discovery applications and outcome biomarkers are more likely to be seen in clinical situations. Qualification and acceptance of biomarkers, in applications paralleling the test's ultimate use and in cost-effective manners that minimize the possibility of patient harm, also are key considerations [2]. The primary goals of incorporating biomarkers into a drug development program, either clinically or preclinically, are to make better informed decisions earlier, more accurately, and to reduce the overall cost of drug development. The basic strategy is to define the critical question to be answered and then employ an appropriate biomarker in a relevant biological system that will answer that question as early as possible. When the purpose of the biomarker is to confirm hitting the putative therapeutic target, it then is possible to assess the relevance of the presumed pathophysiological mechanism and if altering this mechanism will affect clinical status.

Strategies for incorporating new biomarkers into clinical practice form the basis for translational medicine. One of the most tangible problems that scientists have been facing in recent years is finding biomarkers that are predictive, or "translate well," from animal or *in silico* models to humans. For example, inhibiting an enzyme in animal models may have a dramatic effect in the animal, whereas inhibiting the same enzyme in humans may have very limited or no clinical impact. The reasons for lack of correlation are many and varied: (1) the therapy can impact the biomarker chosen, but the parameter is irrelevant to the disease, (2) the biomarker may be indicative of the disease but not reflect clinically important effects of the treatment, and (3) a drug may work in humans through several different pathways not reflected in animal models. It is important to remember that a drug or other intervention should treat the disease, not a biomarker. Proper biomarker progress requires close dialog between biomarker scientists and practicing physicians, and this ideally can be accomplished under the banner of translational medicine.

The cost and duration of clinical trials are two of the primary drivers of biomarker research. Improving the understanding of a new drug's effects also is fundamental in using biomarkers within the pharmaceutical industry and for current regulatory focus on improving the success rates in drug development. Development of new therapeutic agents is estimated to cost between \$800 million [3] and \$1.7 billion [4] and requires 7–12 years. Reducing the high attrition rate of drugs by selecting better molecules, and being able to make decisions on compound viability earlier, have tremendous potential for reducing the high costs of bringing new

therapeutic agents to patients. The poor success rate for many compounds makes this an especially attractive goal. Attrition rates in phase II clinical research programs are as high as 55% [5] to 90% [6], with lack of efficacy as the primary cause. Thus, biomarkers that accurately predict human efficacy at the preclinical or phase I clinical trial stages are particularly valuable in reducing costs and increasing confidence in the compound. Similarly, biomarkers of chronic disease progression/resolution would substantially enhance clinical trial design and characterization of research efforts in diseases such as rheumatoid arthritis, type II diabetes, Alzheimer's disease, and Parkinson's disease.

Although many think of *omics* (proteomics, genomics, metabonomics, etc.) when the term *biomarkers* is used, many biomarkers are less exotic or "high-tech" and yet have contributed significantly to our understanding of disease processes. In 1733, Stephen Hales first measured blood pressure [7], and subsequent to this initial measurement, many investigators found blood pressure to be elevated in some disorders and reduced in others. Over many years, blood pressure was proven to have such clear clinical utility and predictivity to warrant acceptance as a surrogate for many forms of cardiovascular disease. Upon first description, however, blood pressure characterization was a new tool with unknown real potential. Although now deeply ingrained in medical practice, blood pressure initially presented a situation akin to the current status of C-reactive protein (CRP). The utility and significance of CRP [8, 9] are yet to be defined for inflammation and other diseases and only will be understood after more clinical experience is gained.

Although CRP is becoming a standard marker for inflammation, in the absence of known sources of inflammation, CRP is associated with the pathogenic inflammatory process in several diseases such as rheumatoid arthritis. Clearly, CRP and other newly discovered biomarkers need to stand the test of time in large clinical trials and long-term population studies. In addition, a biomarker like CRP must be reliably and conveniently measured. Clinical laboratories must be able to reproduce the measure, and national standards must be established so that consistent interpretation of measures from different laboratories can be achieved [10]. As the significance of inflammation has been identified in a variety of diseases, other inflammatory biomarkers are also the subject of current research interest. Lind [11] has described fibrinogen, leukocyte count, interleukin-6, tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), immunoglobulins, cell-adhesion molecules, complement, serum amyloid A, phospholipase-A2, and neopterin as other biomarkers of inflammation that might be useful in predicting coronary diseases. Like blood pressure, if these biomarkers prove important in mediating disease processes, they also will be targets for drugs that block their action, and thereby reduce the risk for disease.

### 14.1.2 BIOMARKERS AND DECISION MAKING

Biomarkers constitute a rational approach that, at its most optimal, reflects both the biology of the disease and the effect of the drug candidate. Proper incorporation of biomarkers in drug development strategy enables the concept of "fail fast, fail early," allowing early identification of the extremely high proportion of compounds that fail during drug development. In addition to minimizing human exposure to drugs unlikely to be effective or with safety concerns, substantial cost savings can

be achieved by shifting resources to those molecules most likely to become effective new medicines. A properly selected and characterized biomarker also facilitates the choice of the proper critical path toward approval and can differentiate the new product from approved drugs in a competitive marketplace. The challenge, therefore, is to identify relevant biomarkers early enough to implement them for “go, no-go” decisions at critical stages of the development process.

Traditional clinical trial endpoints, such as morbidity and mortality, often require extended time frames and may be difficult to evaluate. Imaging-based biomarkers are providing objective endpoints that may be confidently evaluated in a reasonable time frame. Imaging techniques tend to be expensive but can be cost effective when used in well-defined situations where subjective assessment has been the only approach available. Examples of therapeutic areas where imaging is reshaping clinical trial design include Alzheimer’s disease, pain, and osteoarthritis. In affected joints, as well as in tissues expressing specific receptors, magnetic resonance imaging (MRI), computed tomography (CT), and position emission tomography (PET) imaging are delivering new information to clinicians and researchers. These biomarker technologies are rapidly developing, requiring close collaboration between basic researchers and physicians treating patients.

Biomarker development forms one of the cornerstones of a new working paradigm in the pharmaceutical industry by increasing the importance of linking diagnostic technologies with the use of drugs. The position of the Food and Drug Administration (FDA) is rather clear on this. Biomarkers are crucial to generate safe and efficacious drugs and are essential for deciding what patients should receive which treatment. It appears likely that development of pharmaceuticals also will drive the development of biomarkers as diagnostic probes for clinical decisions and stratification of patients. Preclinical biomarkers are essential to identifying compounds with the greatest potential for therapeutic intervention. Work at this stage of the process has tight controls of environmental conditions, diet, and genetics of the laboratory animals and provides access to tissues that cannot be collected during normal clinical trials. These studies provide opportunities for high-content data gathering using functional genomics, proteomics, metabonomics, simulations, computational methods/informatics, analytical technologies, and interventions. Results from the preclinical studies then can be distilled and used in the clinical phases of the most promising compounds.

In early-stage clinical trials, the use of suitable biomarkers should be incorporated to assist in demonstrating proof of concept (POC) and to identify appropriate dosage regimens for safe and efficacious clinical trials. Assessing which subpopulations are most likely to benefit from a new treatment can help in the planning of subsequent efficacy clinical trials. Although this approach may appear to be straightforward, integrating biomarkers can involve several practical problems and pitfalls. Clinical observations in a given patient may serve multiple purposes, with implications for the way in which the observed characteristics are documented, validated, interpreted, and used.

Aside from their use in diagnosis and prognosis, biomarkers currently have applications in drug discovery and development, aiding in formulating dosing and in guiding pharmacokinetic/pharmacodynamic (PK/PD) indices, and assisting in determining efficacy. These PK/PD indices are important factors in determining efficacious doses, particularly for evaluation in early-phase clinical trials. A deter-

mination of efficacy using biomarkers serves an important and cost-effective role in lieu of traditional large-scale clinical trials with standard clinical endpoints. Another important area that is well served by biomarkers is drug safety and the characterization of toxicity. Safety biomarkers can ensure exclusion of high-risk patients before treatment is administered, and monitor the need for early withdrawal of treatment before adverse side effects are manifested. These biomarkers also can be critical for assessing the relevance of preclinical findings and preventing or monitoring for their occurrence in humans.

### 14.1.3 LIFE CYCLE OF BIOMARKER

Biomarkers do not come to preclinical or clinical practice fully formed, fully validated, applicable across all patient populations, and with the guidance as to when to use or not use the particular marker. The tests are introduced poorly characterized with limited directions for understanding their limitations, potential, and applicability, much like an infant enters the life cycle. With care and further research, over time the biomarker can become a powerful tool to be utilized in drug development or patient care. In addition to the biological component of the biomarker requiring nurturing, the testing platform utilized to measure this biomarker usually does not exist as a point of care device that can be administered at the bedside. Rather, it is usually and necessarily by definition in the early stages, an untried, unreliable, and briefly tested platform that will be appropriately labeled “exploratory.”

To illustrate the life cycle of a biomarker, it can be viewed from late maturity, the stage at which most individuals outside of the research laboratory will first encounter the test, working backwards to inception. At its most mature stage, an accepted biomarker is commonly referred to as “validated,” meaning the biology is solid and the testing platform is reliable. But for the purpose of making what sort of decision? The term *validated* also conjures quite varied images in the minds of different people, with the same assay’s robustness assumed to be greater as one ascends each step on the management ladder. Currently, the concept of “fit-for-purpose” is gaining acceptance in the pharmaceutical industry to provide more precise terminology and recognizing that the requirements for a biomarker when screening compounds is fundamentally different than when deciding to escalate doses in a clinical trial. Earlier in this chapter the different classifications of biomarkers were described (target, mechanism, outcome), in addition to the decisions that can be made with the information the biomarker provides and the types of testing platforms that can be utilized. Since the nature of questions asked in different situations varies greatly, the real answer for when a given biomarker is appropriate lies in whether it can be expected to reliably provide the information necessary to confidently make a decision. The risks and benefits to be weighed when conducting *in vitro* testing of a chemical library using high-throughput screening are very different than determining whether to recommend angioplasty or choosing between orally active compounds acting through Factor Xa inhibition versus coumarin therapy.

Determining a biomarker to be fit-for-purpose in the indication for which it is to be used is a more precise designator of the confidence in the combination of the

biology, platform, patient population, and the proposed action. This approach also takes into account that the magnitude of a decision can be substantially different even when the underlying questions are similar. For example, the acceptable false-positive/false-negative rates for a biomarker may be higher when one is prioritizing a large number of early-stage molecules than when determining whether to cancel research on a potential therapeutic target for which only one or two candidate compounds have been identified.

The degree of testing also can be affected by knowledge of similar drugs in the same class or current clinical practice. A biomarker supporting a new statin compound with a safety profile comparable to the marketed products is unlikely to require the same degree of characterization as a biomarker for drugs with a completely new indication (i.e., neovascularization). The potential of a biomarker to provide actionable information is directly proportional to its maturity, fitness for the intended purpose, and the gravity of the decision to be made using this information.

The development of a new biomarker minimally takes 6–9 months and can span many years (Fig. 1). Testing and building confidence in the biology can strengthen or wane, and the testing platform can improve by becoming smaller, more portable, and more widely available. In many ways, a biomarker goes through phases similar to the development of a child. The life cycle of a biomarker can be viewed as progressing from infant to toddler, then to child, preteen, adolescent, young adult, independent individual, and finally a mature person. The progression of blood pressure as a biomarker through these stages is illustrated below.

**FIGURE 1** Life cycle of a biomarker: exploration, demonstration, characterization, and surrogacy.

In 1913, Janeway published a well-documented study where blood pressure was measured via sphygmomanometer in a large group of patients [12]. This study was made possible because of the blood pressure cuff developed by Scipione Riva-Rocci [13] and a large relevant patient population (~8000) examined over nearly a 10-year period. Janeway noted that 11% of the patients had systolic blood pressures over 160 mmHg, and this group of patients survived for only 4–5 years after being identified with the condition he named “hypertensive cardiovascular disease” [12]. The underlying physiology of hypertension was poorly understood at this time, and therapy options largely were limited to rest and reduced salt intake. Extensive research efforts in multiple laboratories led researchers in numerous directions, but it was not until 1939 that the renin–angiotensin–aldosterone system (RAAS) became the coherent focus of primary research [14]. Much more bench research and clinical findings, in addition to a consensus opinion of the community, led to the National High Blood Pressure Education Program Task Force I (NHLBI/NIH); *Report to the Hypertension Information and Education Advisory Committee* in 1973, and the report of the Joint National Committee (JNC I) on *Detection, Evaluation, and Treatment of High Blood Pressure* [15, 16]. These reports address reference ranges for the biomarker of blood pressure, compare recommended therapies and pharmaceutical interventions, and in the most recent release discuss patient stratification. This developing application and acceptance of blood pressure as a biomarker beyond its original use demonstrates its increasing maturity to the current status as one of the very few accepted surrogate biomarkers by both clinical practitioners and regulatory agencies. The life cycle of blood pressure is nearly 100 years and continues to grow as knowledge in the field accumulates and scientific and medical confidence in the biomarker increases.

Further illustrating that biomarkers are not a new concept, and their progression through various stages of development/acceptance, can be seen in routine medical practice. The likely tests performed at an annual physical examination include several biomarkers that have changed over the years, as has the clinical confidence in using them to make decisions. Among the tests administered will be body weight, diastolic/systolic blood pressure, heart rate, and serum lipid profile to provide an initial diagnosis of cardiovascular health. If any of these tests are skewed or abnormal, additional biomarker measurements would be initiated. Electrocardiogram (EKG), stress tests, troponins, CRP, and a host of other tests can characterize the presence or absence of heart disease, as well as inform the physician on appropriate therapy. Tests/biomarkers such as glucose, glycated hemoglobin, and alanine aminotransferase (ALT) provide information on other possible clinically important alterations and diseases that may indirectly impact cardiovascular health. Among these biomarkers, some can be considered “adolescent” (CRP) as “young adult” (prostate-specific antigen), “independent individual” (troponin, stress test, body mass index, glycated hemoglobin), and “mature person” (blood pressure, EKG, lipid profile, glucose, ALT).

The two initial reports on hypertension mentioned above can be considered the forerunners of biomarker initiatives currently underway as consortia between the pharmaceutical industry and the FDA, International Life Sciences Institute/Health and Environmental Sciences Institute (ILSI/HESI), and National Institutes of Health (NIH). The driver for these present-day programs clearly is the economics of drug development. The process of drug development has grown significantly in

cost at the same time as the number of drugs submitted and approved per year has steadily decreased. The decline has resulted from a wide range of causes from the complexity of new disease targets, multifactorial diseases, increased regulatory requirements, and higher expectations of drug safety. As the acute causes of mortality and morbidity have been addressed by the medical community, the population now is experiencing the ill effects of more chronic diseases, and novel therapeutic targets and methods have become necessary. Many of these new therapeutic areas are still in need of predictive animal models for early-stage testing, as well as more comprehensive tools for defining the condition. Due to the greater uncertainty in these areas, the compound attrition rates have been higher. Inefficiencies in the drug development process and marketing expenses also have contributed to the increases in drug development costs. The marketplace also has a substantial impact on whether a new drug, even if approved, will actually be distributed to patients. A compound that cannot be sufficiently differentiated from similar approved molecules in terms of safety, efficacy, or cost, is unlikely to be included in the formularies of large insurers or become an approved course of treatment in countries with publicly funded health care systems. Biomarkers can be used to establish differentiation in class and this use will likely increase.

In the early-attrition paradigm designed to identify nonviable compounds at the first possible stage of development, many new biomarkers are being utilized by the pharmaceutical industry to achieve the cost-containment goals. These biomarkers are only sufficiently characterized to be considered a discovery tool and are generally limited to uses that prioritize similar early-stage molecules. Nevertheless, the tests are valuable for proving viability or proof of nonviability of a therapeutic target or class of compounds. These biomarkers most often are mechanism of action or safety markers. In contrast, disease-related outcome biomarkers can be difficult to validate in the absence of sizable efforts like the one for hypertension. Without additional research involving multiple clinical situations, possibly necessitating consortia to share resources, very few biomarkers currently being developed will mature past the point in their life cycle where they are used for internal decision making during pharmaceutical testing.

Biomarkers are seen as among the most promising tools for reducing the cost of developing drugs and ensuring that the appropriate patient populations are treated. Proper use of these tests can improve the quality and quantity of mechanistic information obtained at each step of the drug development process, allow better understanding of other results and the factors relevant to their interpretation, aid in the allocation of scarce resources, and provide clearer indications of a molecule's activity or potential safety liabilities. Clearly there is a wide spectrum of technologies encompassing biomarkers, with individuals from many specialties involved in the field with varying degrees of success. There also are numerous considerations to keep in mind when selecting a biomarker, and which must be balanced against each other, to ensure the test developed will meet the intended goal and actually be used. Among the critical biomarker parameters to be defined are:

- Nature of the biomarker's use (activity, efficacy, safety, differentiation)
- Throughput, capacity, and turn-around time requirements
- Reproducibility, sources of physiologic variation, and sensitivity
- Sample requirements and practicality of collection from the patients or pre-clinical species being evaluated

- Stability of parameter and compatibility with the study design
- Safety considerations in collecting and/or processing sample
- Existence of similar assay or approach that can be modified to the situation
- Time frame in which an appropriate method needs to be developed
- Defining how the biomarker adds value

Biomarkers of pharmacological or therapeutic activity and safety can be critical indicators of an early compound's activity and safety. This is especially important as drug development costs rise and the number of new compounds registered decreases. Appropriate selection and application of biomarkers can allow companies to terminate nonviable programs earlier, and reallocate resources to compounds with the highest probability of helping patients. Biomarkers also can be important for small companies in highlighting a new chemical entity's attractiveness and potential when looking for partnerships or licensing opportunities with big pharmaceutical companies.

#### 14.1.4 DRUG SAFETY

Biomarkers in drug safety can be key determinants in expediting decisions and may foretell the survival of a molecule, or even an entire program. Serious effects seen in preclinical testing, particularly at low multiples of presumed efficacious exposure, necessitate either a biomarker that allows safe progression or discontinuation of the compound. Many drug safety biomarkers are clinical pathology parameters, with long histories and years of clinical use. Alanine aminotransferase (ALT), troponins, urea nitrogen, bile acids, creatinine, electrolytes, and a host of other tests allow monitoring of tissue injury and have good correlations between humans and pre-clinical species. Safety departments within the pharmaceutical industry also are actively developing new biomarkers using the older platforms, as well as the technologies of proteomics, genomics, and metabonomics.

Discovering, developing, validating, and utilizing safety biomarkers present a variety of challenges in advancing pharmaceutical compounds. Safety has implications at all stages of the drug development process and carries significant relevance for clinical trial design and regulatory approval. Since the purpose of preclinical toxicology testing is to assist in defining relevant safety concerns for the clinical trials, biomarkers developed and evaluated in these experiments can be adapted for studies conducted in healthy volunteers and patients. Acceptable tests for the adverse effects seen in the preclinical testing that can be used in healthy human volunteers or patients are essential for safely advancing a compound into clinical trials. This connection between drug safety and clinical groups is one of the most important aspects of translational medicine.

Early identification of safety concerns, or indications that they will not be an issue, allows more effective prioritization and resource allocation. It also is often necessary to work backwards from a phenotype (liver injury, vasculitis, renal damage, etc.) caused by an unknown mechanism to a specific parameter, or group of markers, that caused the injury. The “wealth of opportunities and potential mechanisms” can be the most difficult and valuable aspect of the problem. In

contrast to many activity/efficacy biomarkers, biomarkers of specific tissue damage often can be applicable for monitoring toxicity of a range of molecules acting via a variety of mechanisms, but on the same tissue or subset of tissues.

Often even more challenging to manage are effects seen in preclinical species for which the clinical significance is unknown. Vasculitis has been an issue for a variety of therapeutic targets [antivirals, phosphodiesterase inhibitors, endothelin antagonists, norepinephrine reuptake inhibitors]. In these instances effects seen in animals may or may not be predictive of human risk, with the further complication that no good measures of the injury exist for monitoring in clinical trials. A biomarker panel capable of clearly monitoring vascular injury and early changes would allow compounds to be safely tested in human volunteers and patients, as well as having significant value in improving clinical practice related to vasculitis.

Identification, development, and validation of a safety biomarker follow approaches very similar to that required for efficacy assays. These include:

- Based on relevant parameters, with a foundation in a known mechanism.
- Coordinated engagement across departments (discovery, clinical, pharmacokinetics and drug metabolism, safety/toxicology) to optimize acceptance.
- Confidence in the test's performance that it can be used to make decisions.
- Use technology to efficiently demonstrate role in the toxicity, while remembering that the platforms are the tools and not the goal.
- Keep in mind that the question to be answered/characterized may be tissue rather than specific enzyme based—do not limit options.
- Comparative biology may be important in determining if the toxicity is relevant for human volunteers/patients or unique to the preclinical species.
- Good science is essential, as is the ability to show why the assay should be accepted as premonitory or able to detect changes before serious and irreversible injury has occurred.
- Ability to translate from preclinical to clinical application, as well as reverse engineering clinical tests, is critical for acceptance when entering new areas.

In many instances it is possible to utilize an efficacy biomarker to predict undesirable effects, particularly in areas such as anticoagulants. Thrombin inhibitors, low-molecular-weight heparins, Factor Xa inhibitors, and vitamin K antagonists are valuable therapeutic agents. Since most of these molecules at high doses exhibit only minimal toxicity other than those mediated through the same pathways as their pharmacologic methods of action (bruising, internal bleeding, etc.), the same assays that predict their activity can be used to assess toxicity. Tests such as ecarin clotting time, activated partial thromboplastin time, prothrombin time, and Factor Xa activity all represent useful safety and efficacy biomarkers. Since these assays show considerable translatability across species, and are already within the repertoire of most hospital laboratories, their acceptance by clinicians and regulatory agencies is enhanced. An added benefit for the development of drugs for which toxicity is generally limited to exaggerated pharmacology is that frequently early indications of efficacy and maximum tolerated doses can more accurately be estimated in phase I clinical trials than for most other compounds.

Additionally, it is highly desirable to have a biomarker that precedes overt tissue injury. Many of the oldest and most accepted biomarkers of toxicity represent leakage of cellular components and therefore only are seen at significant levels after at least minimal damage to an organ system has occurred.

In many instances, significant corporate overhead is automatically assumed whenever the situation requires a safety biomarker. Concerns are frequently voiced regarding regulatory agency acceptance, interpretation of new tests, and clinical practice. While at Pfizer, two of the authors of this chapter (MRB and RR) were among the scientists who advanced and advocated the “fit-for-purpose” approach (Bleavins and Rahbari, personal communication). Careful consideration of the decisions to be made for the test results, nature of the toxicity, and population being evaluated are all critical. However, open discussion across toxicology and clinical departments, as well as early engagement of the relevant regulatory agencies has been productive. It has been our experience that if the science is solid, and the rationale for use of the biomarker as part of the compound development strategy is well communicated, the physicians involved with the clinical trials and the regulatory agency reviewers will feel comfortable with the monitoring, and compound development is expedited.

#### 14.1.5 EFFICACY

One of the most important areas in drug development for the application of biomarkers is defining and characterizing efficacy in clinical trials. As previously described, few validated biomarkers of disease efficacy and even fewer surrogate endpoints currently exist. Nevertheless, biomarkers are increasingly being incorporated into clinical trials in various therapeutic areas, often at early stages (e.g., phase I, phase IIa), and sometimes relying on advanced technologies such as genomic, proteomic, or imaging analyses. At this stage of drug development, there is a strong desire to have very quick assurances of hitting the target and a justification for continued development of the compound. In the later phases of development, especially after the initial proof of concept has been established, the more established measures of efficacy (“gold standard”) may be employed.

Initially seen as an extension of the mantra of “fail fast, fail early” that was widely adopted by large pharmaceutical companies in the 1990s in preclinical development programs, the value of biomarker use in clinical development is increasingly being recognized for more than just identifying potential drug failures at an earlier stage. Integration of a drug’s molecular response profile in animal disease models with clinical response enables better drug development decisions and efficiency. The current drug development paradigm is being reshaped by patient stratification using biomarker profiles.

An example of a clinical efficacy biomarker is an individual’s BCR-ABL tyrosine kinase genotype. Characterization of the chromosomal rearrangement creating this abnormal protein, and the multiple subsequent mutations that can occur, are used to identify patients with chronic myeloid leukemia who are likely to respond to the drug, imatinib mesylate (Gleevec), which inhibits this kinase [17]. Additionally, imatinib also is an inhibitor of the C-KIT tyrosine kinase. Based on convincing clinical biomarker data, the U.S. FDA approved the use of imatinib to treat BCR-

ABL-positive chronic myeloid leukemia and gastrointestinal stromal tumors associated with activating mutations in C-KIT.

An additional well-characterized example is the anticancer drug trastuzumab (Herceptin), which achieved global sales in excess of \$1.3 billion despite being efficacious in only a subset of patients [18]. Herceptin is an antibody that targets the HER2 receptor protein. Amplification of the human epidermal growth factor receptor (*HER*)2 (ErbB2) gene in approximately 25–30% of patients with breast cancer results in elevated expression of HER2. The clinical response rate to treatment with Herceptin is high at 35% in patients with overexpression of HER2-while the drug is ineffective in patients who do not have increased protein levels. Therefore, clinical genotyping of breast cancer patients to identify HER2-positive cancers and determine a patient's suitability for Herceptin therapy is now commonly practiced. This approach maximizes the drug's use in patients who will benefit from the drug, while minimizing the exposure and cost to other patients of potential toxicity when those individuals are unlikely to respond. Although not a perfect biomarker, HER2 expression is a valuable tool for the oncologist, and additional research is being conducted to refine the predictivity of this measure, either by alternative tests or better characterization of key variables.

Efficacy biomarkers are, of course, not limited to genotypes and can be based on gene expression patterns, individual proteins or proteomic patterns, metabolomics, imaging, histology, physicians' clinical observations, or patients' self-reported observations (e.g., pain intensity). Thus, an efficacy biomarker is not defined by technology but by its reliable and predictive correlation to a differential response in patient subpopulations. It should be noted that rarely is the genomic or other molecular biomarker profile used alone to determine the drug therapy and dosage regimen. Many other factors such as age, body weight, concurrent diseases, and concomitant medications need to be considered as well, and the ultimate decision has to be made by physicians who are cognizant of all of these factors as they apply to the individual patient and his/her biomarker profile. The biomarker offers a valuable tool for enhancing and supplementing existing options, and "individualizing" the patient's treatment.

Interindividual differences in drug absorption, distribution, metabolism, and excretion (ADME) are known to be associated with differential efficacy or toxicity responses to many compounds. Genetic polymorphisms in drug metabolizing enzymes (DMEs) are a major cause of this substantial variability among individuals. This is especially important for drugs with narrow therapeutic windows that undergo extensive biotransformation to pharmacologically inactive metabolite(s) by one or more polymorphic drug metabolizing enzymes. Poor metabolizers (PMs) are typically at increased risk of adverse drug reactions, while ultra-rapid metabolizers may not be able to achieve therapeutic exposures when the parent compound is the active form. Prodrugs requiring metabolic activation by a polymorphic enzyme to an active metabolite also may have reduced efficacy or higher incidences of treatment failure in PMs. Three clinically important cytochrome P450s (CYP2D6, CYP2C9, CYP2C19) collectively are involved in the metabolism of approximately 40% of marketed drugs [19], and have a large number of functionally significant genetic polymorphisms. One example of an efficacy failure in PMs of CYP2D6 pertains to codeine, a central analgesic and cough suppressant that is metabolized to its pharmacologically active metabolite, morphine, by CYP2D6. The analgesic

effects of codeine are dramatically reduced in CYP2D6 PMs [20], whereas subjects who have multiple copies of the *CYP2D6* gene, so-called ultra-rapid metabolizers (UMs), have an increased analgesic response to normal doses of codeine, and in some cases, experience severe toxicity [21].

For the past several decades, pharmaceutical sponsors and clinical investigators have been conducting clinical pharmacology studies to evaluate the effects of genetic polymorphisms in DMEs using subpopulations of extensive and PMs (and UMs where appropriate). In some situations, this has led to postapproval labeling changes as new information in specific populations has become available. Several recent examples include the addition of deoxyribonucleic acid (DNA)-based DME biomarkers to the labeling of 6-mercaptopurine (Purinethol), azathioprine (Imuran), and irinotecan (Camptosar) [22].

More recently, regulatory agencies have recognized that pharmacogenomic testing has evolved to the point that regulatory policies and guidance are required. In January 2005, the FDA approved the first clinical diagnostic test, Roche's AmpliChip for the rapid genotyping of *CYP2D6* and *CYP2C19* variants. To encourage more extensive sharing of genomic data, increase understanding on how and when to use this type of information, and determine opportunities for genomic studies to expedite drug development, the FDA published its *Guidance for Industry: Pharmacogenomic Data Submissions* in March 2005 [23].

Whether intended to improve efficacy or to avoid toxicity, biomarkers for selecting appropriate patients to enroll in clinical trials are becoming increasingly prospective rather than retrospective. Historically, as mentioned above, stratification has occurred after market approval when variation in the drug's effects has become better understood and could be correlated to results of a biomarker assay or diagnostic test. For example, the clinical utility of the kinase inhibitor gefitinib (Iressa) was defined after the drug failed to show efficacy in an unselected population of patients with lung cancer. The drug was, however, associated with marked responses in a small subset of patients with non-small-cell lung carcinoma [24]. There are several other examples where a nonstratified approach to drug therapy failed because of poor efficacy or unacceptable toxicity, and subsequent patient stratification based on biomarkers restored drug efficacy in a subset of patients. Human immune deficiency virus (HIV) treatment regimens are based on matching therapies to the viral strain present in the patient in consideration of resistance-conferring mutations, and antibiotics are matched to specific resistant infections. The anticancer drug irinotecan (Camptosar) has been associated with severe toxicity (diarrhea and leukopenia) in patients with a genetic variant of the UDP-glucuronosyltransferase 1A1 enzyme (UGT1A1) [25]. An FDA-approved diagnostic test based on the UGT1A1 biomarker is now available to identify patients potentially at higher risk for developing toxicity [26].

From a drug development perspective, lessons learned from these retrospective applications of biomarkers are increasingly leading to more prospective incorporation of safety and efficacy biomarkers into clinical trials. By enriching patient populations in clinical trials with likely responders, and excluding patients at greater risk of developing toxicity, drug development risks are reduced at the same time as the sample size necessary to demonstrate efficacy is reduced. Most importantly for diseases with traditional long-term endpoints such as survival, efficacy biomarkers allow for shortened endpoint observation times. In chronic and slowly progressive

diseases (arthritis, Alzheimer's disease, diabetes, lysosomal storage diseases), biomarkers can be evaluated after several weeks/months of drug treatment versus years for traditional clinical endpoints. The escalating cost of drug development and poor survival of drug candidates in phase II are causing pharmaceutical companies to reevaluate programs for chronic diseases for which there are no predictive biomarkers of efficacy. This is an even more critical concern for biotechnology and emerging pharmaceutical companies, reliant on venture capital or other short-term financing, for which it is not financially feasible to conduct multiyear clinical trials with compounds of unknown activity. Demonstrating proof-of-concept in trials of shorter duration by employing efficacy biomarkers can make the difference between continuing to pursue a new molecular target and/or molecular entity and eliminating a research program due to poor clinical promise. Indeed, the use of biomarkers has become common practice in phase IIa first-in-patient and even in some phase I first-in-human trials. This approach has the potential to provide useful information to validate preclinical disease models, assist in dose and biomarker selection to take forward into larger late-stage clinical trials, as well as excite management and investors with early "hints" of efficacy. However, the complexity and cost of early clinical trials involving biomarkers increases, and one should be careful that "more information" does not quickly become "too much information." Particularly for molecular profiling or multivariant biomarker strategies, the amount of data generated even for relatively small patient sample sizes can be enormous, and may require sophisticated and time-consuming data analysis and interpretation. For novel biomarkers, data on the normal variation in baseline (predose) levels may be limited, and a preliminary "survey" study may be necessary to define normal ranges. Unless the biomarker incorporated into the study design is decision making for the compound's future, biomarkers are rarely useful when they result in equivocal findings.

It is apparent that the increasing use of efficacy biomarkers will continue to make important contributions to clinical drug development by lowering late-stage failure rates, improving decision making and the efficiency of clinical trials, improving patient care, and paving the way toward personalized medicine.

#### **14.1.6 PATIENT STRATIFICATION**

In traditional clinical trial designs, patients with a particular condition were enrolled in clinical trials assuming a near homogenous group (Fig. 2), with random selection to prevent bias. The goal of random sampling employed in traditional drug development was to ensure the general population was well represented. In reality, the groups were heterogeneous with respect to stage of disease, drug metabolizing capabilities, environmental conditions (e.g., diet, smoking status, lifestyle), concurrent or previous medication exposures, and often even underlying cause of the symptomology. By using biomarkers to better characterize the biological makeup of the participants in clinical trials, drug developers are streamlining the testing process. The most obvious and often quoted use of patient stratification is to select only patients who would be expected to respond to a particular investigational new drug based on the mechanism of action of the drug. The drug's statistically significant benefits, in this targeted subset of patients, could be shown in a smaller and shorter clinical trial than those needed for randomly selected patients. Under some

**FIGURE 2** Traditional treatment approaches often assume a relatively homogeneous patient population, with limited differentiation of individuals before administration of a new drug.

circumstances, stratification of responders could also be performed retrospectively on the data collected to demonstrate efficacy of a compound in a subpopulation. While generally not acceptable for registration, retrospective findings can be important for identifying potential new therapeutic applications and redirecting programs (e.g., Neurontin for neuropathic pain, Rogaine for hair growth, Viagra for erectile dysfunction).

Minimally, stratification can speed approval for drug candidates intended for a subset of patients while leaving the door open for further testing and market expansion in the more heterogeneous population of patients. Maximally, it can unmask a useful therapeutic agent that would be lost in the noise generated by the nonresponders in the study, as described above for trastuzumab and gefitinib.

Since the challenge of testing new drugs in chronic diseases is one of the most difficult aspects of tackling these devastating conditions, an example in this area seems appropriate. Alzheimer's disease (AD) is a major health care concern that will only become more pressing as the baby-boomer generation ages. However, clinical studies for AD are difficult due to the generally slow progression of the disease, subjective nature of diagnostic tests, and limited ability of the affected individuals to actively participate in their care. Selecting early-onset AD patients may provide advantages in studying this disease because their symptomology presents with faster progression. Clinical trials could be shorter, thereby providing a quicker determination on a new molecule's efficacy. Unfortunately, this approach also has some rather severe limitations. Initial clinical trials still need to be many months in duration to demonstrate a compound's activity, and the early-onset form of AD may or may not effectively predict effects in the much larger population developing AD later in life. Far more valuable to identifying new therapies for AD would be a biomarker that accurately predicts disease progression or resolution in weeks or months. A biomarker of this type would revolutionize clinical trial design and allow significantly more new chemical entities to be tested for activity. It also would provide desperately needed information on the relevance of animal models,

further increasing the speed and productivity of basic research into this disease. AD is at the forefront of biomarker development for neurodegenerative diseases, and several promising candidate biomarkers have emerged in recent years, including isoprotanes, tau, A $\beta$ , homocysteine, apolipoprotein E genotype, and several others [27]. Imaging technologies such as resting glucose PET and volumetric MRI are also being investigated as biomarkers for AD.

The focus of pharmacogenetics is to identify the molecular causes of differential therapeutic response across patient populations. It is generally appreciated that patients and their disease show significant variations in response to a given treatment based on their genetic background in addition to the better recognized environmental causes. Advances in understanding the mechanisms underlying diseases, as well as drug response, are increasingly creating opportunities to match the right patients with the right therapies that are more likely to be effective and safe. At the extreme of patient matching is personalized medicine (Fig. 3). Currently, there are few examples of patient matching to therapies for which some form of biomarkers are available to indicate that a given patient is likely to show a response to a specific therapy. In addition to the BCR-ABL example described above, for the chemokine receptor 5 (CCR5) antagonist anti-HIV drug Maraviroc, prospective stratification based on CCR5 and HIV-1 genotyping results was included in the new drug application (NDA) submission. These data also were key components in the successful registration of the compound in 2007.

Patient stratification strengthens traditional medicine by associating an individual patient with a specific therapy. Patient stratification is already practiced in several contexts, though often after first-line empirical treatment proves unsatisfactory because of poor efficacy or intolerable toxicity. Examples can be seen in antibiotics that are matched to specific resistant infections, or the often protracted process of selecting the appropriate medicine for patients with schizophrenia. Biomarkers enable the progression from empirical therapy to stratification therapy, linking patient subsets with therapies that have an increased likelihood of success. In breast cancer, patients with different levels of receptor tyrosine kinase HER2 expression characterize not only their cancer type but even their candidacy for receiving treatment. Similarly, HIV therapies that are tailored to the viral variant

**FIGURE 3** Personalized medicine utilizes a diagnostic test/biomarker to optimize therapeutic decision making.

present and oncology treatment regimes prioritize agents based on histological and molecular tests. In the absence of a biomarker, patient stratification may not be possible. For instance, the lack of accepted biomarkers in depression that are reflective of disease status or progression often results in patients receiving several different therapies to identify one that leads to a satisfactory response. At present the treatment for depression remains limited to empirical, trial-and-error therapy.

Patient's stratification has considerable economic impact on the model of the pharmaceutical industry and society. By identifying the populations most likely to benefit from a new therapy, drug development costs can be reduced at the same time as treatment of people unlikely to respond is minimized. Exposure to drugs that do not address a patient's underlying disease is minimized, thereby also reducing the likelihood of adverse events in those for whom the compound does not provide help. Overall, the risk–benefit assessment is substantively refined when the potential for adverse drug–drug interactions is reduced, and the process enhanced when biomarker data enabling patient stratification are available. Patient compliance also will be improved as treatment becomes more closely linked with disease resolution in a higher proportion of the individuals treated. Ultimately, better targeting of specific disease and responsive patient through biomarkers can reshape clinical practice by providing clinicians with new opportunities for better patient care.

### 14.2.1 INTRODUCTION

Biomarkers are being used increasingly in clinical drug development by research-based pharmaceutical and biotechnology companies. Examples of their application to the development of new medicines to treat chronic disorders will be discussed in two central nervous system (CNS) diseases: multiple sclerosis (MS) and Alzheimer disease (AD). Combined, these two neurological disorders are creating great suffering to the affected patients and their families and represent a public health burden to societies. MS and AD are common and devastating neurological diseases for which pathophysiological processes leading to inflammation and neurodegeneration are thought to begin long before early clinical symptoms emerge and thus can be detected. For many years, AD and MS have been considered as two completely different diseases with no common features, MS being characterized by diffuse inflammation and demyelination, inflammation resulting in sclerotic scars (MS plaques) during healing [1], and AD clinically characterized by an insidious and progressive loss of memory and cognitive abilities, with *definite* diagnosis requiring pathological confirmation of amyloid plaques and neurofibrillary tangles associated with brain atrophy resulting from neuronal and synaptic loss [2–4].

Despite substantial progress, existing therapeutic interventions are only moderately effective in improving clinical symptoms, and research efforts are focusing on the development of disease-modifying therapies to impede disease progression. There is a widely shared perception that biomarkers are critical to identify the presymptomatic phase of the disease and to allow the development of these new therapies, since limitations in animal models and inadequate understanding of the pathophysiology still persist [U.S. Food and Drug Administration (FDA) Critical Path Initiative, European Medicines Agency (EMA) Innovative Medicine Initiative].

In recent years, transcriptomics and neuroproteomics analyses as well as genetic association studies have revealed that AD and MS pathophysiologies share common features of inflammation and neurodegeneration [1, 5–8] and also glucose metabolism impairment [9]. One of the main challenges in improving care of MS and AD patients resides in the poor performance of clinical diagnostic criteria that, in their current state, do not allow MS or AD diagnosis before the appearance of characteristic clinical symptoms but instead many years after the neurodegenerative and inflammatory processes have been started (Figure 1). Consequently, the diagnosis is made and the therapy is initiated when the disease process has reached irreversible steps, rendering the impact of potential disease-modifying therapies almost negligible in terms of clinical benefit. As basic molecular events in the initiation and progression of the diseases are still poorly understood, a rather long gap between disease onset and diagnosis remains. In addition, MS and AD show a high degree of individual variability in severity and clinical course, highlighting the existence of disease subtypes that current diagnostic criteria do not allow differentiation and which could necessitate different treatments.

A large panel of clinical biomarkers is beginning to be used in early drug development to determine whether the drug is reaching and affecting the appropriate molecular target in humans, allowing comparisons with preclinical data and providing measurable endpoints that predict desired or undesired clinical effects. The ultimate goal of this approach is to increase the success rate in the confirmatory stage of clinical development. Noninvasive neuroimaging techniques, particularly magnetic reso-

**FIGURE 1** Different stages of MS and AD related to time frame and window for therapeutic intervention. MCI: mild cognitive impairment; CIS: clinically isolated syndrome.

nance and positron emission tomography (PET), are promising methods applied to clinical trials to assess potential therapeutic mechanisms in MS and AD, in addition to molecular biomarkers emerging from genomics and proteomics research.

In this chapter, molecular and neuroimaging biomarkers are reviewed in parallel for MS and AD, focusing on inflammatory and neurodegenerative common features and highlighting unique biomarkers specific to each condition. Possible applications of biomarkers in clinical development are also discussed.

Very intensive research efforts in genetic research in these two multifactorial and genetically complex disorders have led to the identification of a number of genetic risk factors associated with disease, such as apolipoprotein E (ApoE) polymorphism in sporadic AD, amyloid precursor protein (APP), presenilin 1 (PSEN1) and presenilin 2 (PSEN2) mutations in familial forms of AD, and human leukocyte antigen (HLA) locus in MS. None of the biological indicators tentatively associated with the disorders has demonstrated enough sensitivity and specificity to allow their use as symptomatic or presymptomatic diagnostic tools.

This well-known limitation to diagnose MS and AD patients in a clinical course window between disease onset and clinical manifestation is undoubtedly linked to the absence of cure for these neurological disorders. Analysis of the clinical success rate from first-in-man to registration is showing that CNS compounds have one of the lowest success rates compared to other therapeutic areas, the lack of efficacy being the major cause of attrition in the clinic and accounting for approximately 30% of failures, with high failure rates in phases II and III trials [10] (Figure 2).

Different approaches have been proposed to reduce attrition in drug development, starting from the earliest stages of discovery. These include getting very strong

**FIGURE 2** Success rates from first-in-man to registration. The overall success rate is 11%. However, if the analysis is carried out by the therapeutic areas, big differences emerge. The data are from the ten biggest drug companies during 1991–2000. (The companies are AstraZeneca, Bristol-Myers Squibb, Eli Lilly, F. Hoffman-LaRoche, GlaxoWellcome Johnson & Johnson, Novartis, Pfizer, Pharmacia, Schering-Plough, and SmithKline Beecham; data were obtained by Datamonitor in the Pharmaceutical Benchmarking Study.) evidence for proof of mechanism with modulation of target involved in relevant disease pathways, eliminating compounds with poor toxicity profiles, and using appropriate animal models for efficacy testing in preclinical studies. It is interesting to note that CNS pharmacological research, one of the areas with the highest attrition rate, is also the area where animal models are very poor predictors of human pathophysiology for AD as well as for MS.

In this context, clinical biomarkers have emerged as a critical tool to help define disease and to determine pharmacological response [11–13]. Biomarker research is intensively focusing on diagnostic biomarkers to track disease at its initiation or when only mild symptoms occur, as disease-modifying therapies could more effectively slow down the disease process if prescribed early. Intensive biomarker research is also conducted on prognostic and predictive biomarkers to evaluate disease severity, progression rate, and patients at risk who would most benefit from novel treatments to anticipate efficacy and/or safety of symptomatic and/or disease-modifying neurotherapies [14, 15].

#### 14.2.1.1 Working Definitions

The National Institutes of Health Biomarkers Definitions Working Group has agreed on the classification of biomarkers allowing a clear distinction between biomarkers and clinical endpoints [16], with surrogate endpoints being a subset of biomarkers:

*Biological Marker = Biomarker* A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention.

*Surrogate Endpoint* A biomarker that is intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm

or lack of benefit or harm) based on epidemiological, therapeutic, pathophysiological, or other scientific evidence.

**Clinical Endpoint** A characteristic or variable that reflects how a patient feels, functions, or survives.

The optimal biomarker should identify a universal and fundamental feature of the pathophysiology of the disease and should be validated in patients who have developed the disease, such as in neuropathologically confirmed patients for AD or in morphologically characterized MS patients with demyelination, inflammation, gliosis, and axonal damage. The optimal biomarker should also be independent of the clinical symptoms, have high specificity and sensitivity, and possess specific technical characteristics, such as being noninvasive, allowing repeated measurements, and being easy to test and inexpensive. A combination of biomarkers may be necessary to achieve all/most of these components.

### 14.2.2 WHEN TO USE BIOMARKERS

#### 14.2.2.1 Diagnosing AD and MS and Biomarkers to Identify Disease: Diagnostic Biomarkers

**Diagnosing AD in Clinical Practice** Over the last two decades, a wealth of evidence has supported the amyloid hypothesis in AD, with a central role attributed to the accumulation and deposition of fibrillar  $\beta$ -amyloid driving neurodegeneration and cognitive decline and leading to dementia [17–19]. Advances in understanding the neurobiology of the normal aging brain as well as the mechanisms of AD have allowed increasing agreement between clinical (antimortem) and autopsy (postmortem) diagnoses in demented aged individuals.

The diagnosis of AD is currently based on clinical criteria [2–4]. According to the NINCDS-ADRDA criteria [4], the diagnosis of AD is classified as probable, possible, or definite. Definite AD depends on the observation of amyloid neuritic plaques and neurofibrillary tangles at neuropathological examination. The diagnoses of probable and possible AD rely on proper clinical information. Probable AD is defined by progressive memory decline associated with impairment of at least one additional cognitive function, such as language, visuospatial, or executive abilities, in the absence of other brain or systemic diseases that may cause cognitive decline. The diagnosis of possible AD admits the occurrence of an atypical clinical course, such as plateaus, or the presence of a concomitant clinical abnormality capable of producing cognitive impairment but not considered by the clinician to be sufficient to produce dementia.

Although being essentially based on exclusion, the diagnostic criteria of probable AD displays good sensitivity (81%), although with lower specificity (70%), in relation to the gold-standard pathological diagnosis, and appropriate clinical follow-up substantially increases this diagnostic accuracy [20]. Disease duration is typically 8–10 years but ranges from 2 to 25 years.

Some ancillary tests have been found to increase the diagnostic accuracy of AD. Hence, atrophy of the hippocampus and of the entorhinal cortex, indicated either by volumetric analysis [21–23] or by visual inspection [24, 25], on magnetic resonance imaging (MRI) and PET scan showing decreased metabolic rates in posterior temporoparietal, posterior cingulate, and prefrontal cortices [26, 27], increased levels

of total and hyperphosphorylated tau and reduced concentrations of amyloid beta ( $A\beta$ ) in the cerebrospinal fluid (CSF) [28, 29], and high  $A\beta_{42}$  plasma levels [30] have all repeatedly shown to improve the clinical diagnosis of AD. Moreover, the presence of one or two copies of the  $\epsilon 4$  allele of the *APOE* gene also increases diagnostic specificity [31, 32].

**Diagnosing MS in Clinical Practice** MS is the most frequent chronic inflammatory demyelinating disorder of the CNS, and its diagnosis is based on the demonstration of a temporal and spatial dissemination of inflammatory lesions in the CNS. This demonstration is obtained on a clinical basis and also using surrogate outcome measures like brain and spinal cord MRI and CSF examination. A recent revision of diagnostic criteria has been performed by a panel of experts [33], with recent modifications [34]. This is further complicated by the lack of existence of a definite histopathological diagnosis, like in AD, and by the relatively low number of autopsic cases so far analyzed. These criteria are universally accepted, but their validity and concordance among different examiners are yet to be established. On MRI, findings of multifocal lesions of various ages, especially those involving the periventricular white matter, the brainstem, the cerebellum, and the white matter of the spinal cord, support the diagnosis, and the appearance of gadolinium-enhancing lesions on MRI indicates sites of active inflammation and rupture of the blood–brain barrier. CSF analysis supports the diagnosis if it shows an increased intrathecal synthesis of immunoglobulins which are not present in the serum—so-called oligoclonal band (OB) positivity at the isoelectrofocusing. In the absence of gold standard for the diagnosis of MS, it is difficult to give specific accuracy features of MRI and CSF OB methods. There is a considerable clinical heterogeneity of the disease, for which there are essentially two different modes of presentation. The most common is the relapsing–remitting (RR), which occurs in about 85% of the patients, and it is characterized by the occurrence of episodes of neurological manifestations followed by complete or partial recovery. About 80% of RR patients develop a secondary progressive (SP) course, with or without superimposed relapses at a certain time after the onset: nearly 50% within 10 years and more than 80% within 25 years from the onset [35], while the remaining 20% are fully functional after 15 years of disease and are defined as benign cases. Ten to 15% of patients are affected by the primary progressive (PP) form, which is characterized by a progressive accumulation of irreversible disability since the disease onset. In MS, between 55 and 65% of patients experience cognitive decline as revealed by neuropsychological test battery, which is more frequent and severe in patients with the progressive phase [36–39] and in association with the *APOE4* genotype in severe cases of cognitive impairment [40]. The cognitive decline resembles the pattern seen in subcortical dementias, and it is clinically characterized by slow information processing, impaired memory retrieval, deficient problem solving, and personality and mood disturbances as a consequence of the disruption of the white matter connections between the frontal lobes and the subcortical structures.

#### 14.2.2.2 Identifying Risk of Developing MS and AD: Presymptomatic Biomarkers

Many studies have suggested that pathological processes occurring in MS and AD begin long before the onset of clinical symptoms. For instance, in relation to AD, neuropathological studies have demonstrated that a large proportion of cognitively

**FIGURE 3** Biomarkers in AD and MS. The goal of the next generation of biomarkers is to allow a shift in the detection of disease stages at earlier stages: from symptomatic AD or MS to presymptomatic MCI or CIS to asymptomatic, as indicated by the dotted line arrows for each biomarker subtype making disease-modifying therapies effective in preventing disease or slowing down its progression.

normal elderly individuals have amyloid plaques when autopsy is performed [41, 42]. These presymptomatic phases have been characterized as clinically isolated syndrome (CIS) for MS, which is defined as the occurrence of a first acute episode of neurological worsening due to a single white matter lesion and usually happens in about 85% of patients [43] and mild cognitive impairment (MCI) for AD [44]. The identification of these early disease stages are critically important for the development of disease-modifying therapies designed to slow the underlying progression of the disease, therapies likely to be the most valuable for patients with mild symptoms or asymptomatic patients. The development and validation of biological markers, neuroimaging tests, and other objective indicators of preclinical AD and preclinical MS are regarded as the most important research areas to aid in identifying individuals at high risk for developing symptomatic AD or MS [45–47] (see Figure 3).

### Neuroimaging Biomarkers

**Structural Imaging: Conventional and Nonconventional Biomarkers** Structural neuroimaging techniques, especially MRI, have been intensely investigated as diagnostic tools to identify patients in the very early stages of AD or in individuals with MCI, who are at high risk of conversion to AD. Great attention has been focused to medial temporal lobe structures, especially the hippocampus and the entorhinal cortex, since these areas are known to be the first to be affected in AD [48]. Some studies have shown that direct (volume of the structures) or indirect measures (such as volume of the temporal horn of the lateral ventricle) of medial temporal lobe involvement, particularly when longitudinal information is available, may be useful as indicators of increased risk of progression from MCI to dementia [49–51]. Even the assessment of medial temporal lobe atrophy by visual rating has been shown to be a significant independent predictor of conversion from MCI, especially when memory is impaired, to AD [52].

In a longitudinal study in which patients with MCI and cognitively normal controls were followed over two years, longitudinal hippocampal volume losses were

associated with increasing hyperphosphorylated tau and decreasing A $\beta$ <sub>42</sub> CSF levels, suggesting that the increasing atrophy over time of the hippocampal formation might be related to underlying pathological abnormalities that occur in AD [50].

In another study, in which amnesic MCI patients and normal controls were submitted to serial MRI, two quantitative MRI measures, namely whole-brain and ventricle atrophy rates, obtained 1–2 years before baseline were associated with an increased likelihood of conversion from MCI to AD. The combination of these two atrophy rates with cross-sectional hippocampal volume at baseline provided additional predictive information regarding conversion from MCI to AD. Nonetheless, some degree of overlap between converters and nonconverters was observed, indicating that these measures cannot be used as definite prognostic indicators for individual patients [49].

An additional MRI-based method evaluated in prospective studies of MCI is voxel-based morphometry (VBM). In two recent studies using this technique, MCI patients who converted to AD on follow-up (from 18 to 24 months) showed significant reductions in gray matter density in brain regions known to be affected early by AD pathology, such as the hippocampus and posterior cingulate, and also in other neocortical areas in the frontal, temporal, and parietal lobes [53, 54]. MRI spectroscopy seems to be another promising tool for early diagnosis of AD (in the MCI stage), although the studies published so far were all cross-sectional [55, 56].

As previously stated, CIS is considered to be the presymptomatic phase of MS. From a clinical point of view, according to a large database of patients affected by CIS, 52% presented with long-tract symptoms, 18% with an optic neuritis, 9% with a brainstem syndrome, and 21% with multifocal abnormalities [57]. By definition, the CIS phase evolves into MS if there is a demonstration of dissemination in time of inflammatory lesions. Differently from the past when the occurrence of a second clinical relapse resulted in a diagnosis of clinically definite MS [58], the recent McDonald criteria [33] with further revisions [34] consider that the presence of a gadolinium-enhanced lesion on an MRI done at least 3 months after the first episode or a new T2 lesion confirmed on two MRI scans done no less than 3 months apart is sufficient to demonstrate a dissemination in time of lesions and hence a diagnosis of MS. As regards to the sensitivity, specificity, and accuracy of the McDonald criteria in predicting the 3-year conversion to MS, Dalton et al. [59] found sensitivity, specificity, and accuracy of 83%, while Tintore et al. [60] reported respectively figures of 74, 86, and 80%. Therefore, conventional MRI is considered to be extremely important in making MS diagnosis and in helping to reduce the latency between the disease onset and the clinical diagnosis. However, conventional MRI techniques, namely the assessment of the number of T2 lesions, T1 lesions, and gadolinium-enhancing lesions, are of limited value for prognosis in the early phases of the disorder, while nonconventional MRI techniques are more useful.

We can distinguish among different techniques which can be used in the assessment and prognosis of CIS patients. It is now known that brains of MS patients show early axonal pathology that correlates with immune cell damage [61] and that even in a classical neuroinflammatory disorder like MS there is an unexpected collateral damage to neurons, which however do not represent the target of the immune attack, which is the myelin sheet. It is speculated that the extent and size of irreversible axonal loss in CIS patients are predictive of the long-term disability, and the measurement of progressive brain atrophy is a marker of irreversible tissue damage [62].

Dalton et al. [63] performed a longitudinal 3-year follow-up study on 55 CIS patients and demonstrated that patients who progressed into MS (53% of the total) developed more important gray matter atrophy than patients without MS diagnosis. Interestingly enough, the white matter volume did not change over time in both converters and nonconverters, and the number of T2 lesions was moderately correlated with atrophy measures, showing that they are less sensitive and less indicated to longitudinal changes. Another study [64] found a decrease in the normalized brain parenchymal volume and percentage brain volume change of CIS patients. Magnetization transfer (MT) and diffusion-weighted (DW) MRI has the potential to detect and quantify the extent of tissue damage present in the brain and cervical cord, which is not visible by using other techniques. A low MT ratio can be detected in normal-appearing white matter and brain tissue of CIS patients, but it is still unclear whether it can be used as a measure of disability prediction, as only one study found that the measure was predictive of subsequent disease progression [65], while others did not [66, 67].

Proton magnetic resonance spectroscopy can add information on the biochemical nature of changes in the CNS. It has been used in a recent study including 96 patients with CIS who have been tested within 6 months of their clinical episode [68], and high myoinositol and creatine levels have been found in the white matter of diseased patients. It is interesting to notice that a lower ratio of *N*-acetylaspartate and creatine and a lower brain parenchymal fraction have been found in patients with CIS without cognitive impairment versus patients affected by CIS and cognitive impairment, possibly suggesting a more severe axonal loss in the latter group.

Another interesting research area is represented by the MRI of the optic nerve as a model of damage and recovery in demyelination. The best model of demyelination is represented by CIS patients who experience a retrobulbar optic neuritis in which there is a visual loss which is determined by a demyelination of the optic nerve.

**Functional Imaging** As functional neuroimaging methods, particularly functional MRI (fMRI) and PET, became more widely available in recent years, they have been increasingly investigated as potential biomarkers for preclinical or very early AD and MS diagnosis.

In MCI, fMRI studies assessing the risk of conversion to AD are still scarce. However, a recent study in which two carriers of a *PSEN1* mutation were scanned (one presenting subtle memory problems on comprehensive neuropsychological testing and another with amnesic MCI), significant differences related to the pattern of brain activation during an episodic memory task were observed in both subjects in comparison to healthy controls [69]. It is noteworthy that the very mild symptomatic carrier was 20 years old, almost 30 years younger than the mean age of clinical manifestation of the disease in the family. This observation supports further investigation of fMRI as a possible biomarker in very early AD. Moreover, fMRI may also be viewed as a promising tool for monitoring the neurochemical and brain function changes induced by pharmacological agents [70].

PET scan, especially using fluoro-2-deoxy-*d*-glucose (FDG), has proven to be an efficient method for early diagnosis of AD, even prior to the MCI stage. Indeed, in a 3-year longitudinal study enrolling 48 cognitively healthy elderly, from whom 11 declined to MCI, De Leon et al. [71] found that reductions in the metabolic rate in the entorhinal cortex at baseline accurately predicted this conversion. Moreover,

among those subjects who declined, baseline metabolism anticipated the emergence of memory deficits as well as of hippocampal and temporal neocortex hypometabolism. Reduced metabolic rates in additional brain regions, such as the temporoparietal cortex, posterior cingulate, and prefrontal areas, have also shown to be good predictors of conversion from MCI to AD [72–74]. FDG PET was found to be superior to neuropsychological testing as an indicator of subsequent global cognitive decline in patients with MCI [53], although some degree of heterogeneity in the patterns of brain glucose metabolism reduction has been reported in these individuals, a feature that probably will have to be taken into account in future studies [75].

Perhaps the most promising neuroimaging method for very early AD diagnosis is the amyloid PET tracer named Pittsburgh Compound-B [(11)C-PIB], which has been shown to detect in vivo amyloid plaques in the brain of patients with mild AD [76]. Subsequent studies found an inverse correlation between in vivo amyloid load and the concentration of A $\beta$ <sub>42</sub> in the CSF in AD [77], a positive correlation between whole-brain atrophy rates and whole-brain and regional (11)C-PIB uptake [78] and a negative correlation between amyloid load in the parietal cortex and the performance in a verbal memory test [79]. More interesting and promising, though, is the finding of elevated (11)C-PIB uptake in some nondemented individuals, suggesting that it may turn out to be a sensitive method for detection of preclinical AD in MCI or even in totally asymptomatic individuals [80]. On the other hand, the observation of a relatively stable (11)C-PIB uptake in mild AD patients after a 2-year follow-up suggests that amyloid deposition in the brain tissue reaches a plateau by the early stages of the disease and thus the method may not be ideal for tracking amyloid reduction induced by future treatments [79].

As regards to MS, fMRI studies on CIS patients are extremely useful in assessing the cortical reorganization and plasticity secondary to lesions in the CNS. A 1-year follow-up study of patients with a CIS found that those who developed clinically definite MS had a different response on motor tasks at fMRI than those who did not convert [81]; more specifically, the nonconverters had more substantial activations in the contralateral primary somatomotor cortex, supplementary motor area, ipsilateral paracentral lobule, and cerebellar hemisphere, while MS patients who converted had a more widespread recruitment of additional areas not involved in motor response.

**Predisposition Biomarkers: Susceptibility Genes and Modifiers** Genetic epidemiology studies have demonstrated that genetic factors are clearly involved in the etiology of AD and MS [82–85]. Despite the fact that only about 25% of AD is familial (FAD), tremendous progress has been made in understanding the etiology of AD by dissecting the molecular genetics of the disease. Mutations in the A $\beta$  precursor protein ( $\beta$ APP) coding gene, *PSEN1* [86], and *PSEN2* are associated with early-onset familial AD (EOFAD). Mutations in these genes result in altered processing of  $\beta$ APP and the relative overproduction of all forms of the  $\beta$ -amyloid peptide or specific overproduction of isoforms ending at residue 42. The relative proportion of EOFAD patients carrying mutations are 10–15% for *APP*, 20–70% for *PSEN1*, and <1% for *PSEN2* [82–84, 87]. Other genes are causing EOFAD as kindreds with autosomal dominant FAD with no known mutations in *PSEN1*, *PSEN2*, or *APP* have been described [88]. About 1–6% of all AD cases are early onset (<60 years) and about 60% of early-onset AD is familial, with 13% appearing

to be inherited in an autosomal dominant manner [82, 89]. Therefore, the EOFAD group comprises less than 2% of all AD cases [90].

Despite the application of the same molecular tools to MS, identification of specific or definitive MS genes has failed. Association of MS with HLA haplotype within the major histocompatibility complex (MHC) on chromosome 6, extending over a long interval containing over 200 genes, has consistently been reported by several independent studies for more than three decades [91, 92]. However, the vast majority of MS patients do not share the same haplotype, the strength of association is declining from Northern to Southern Europe, and calculations suggest that the MHC could explain between 17 and 62% of the genetic etiology of MS [93]. Genetic data reject a single-locus model of MS susceptibility but suggest that MS depends on independent or epistatic effects of several genes, with a small contribution of each of them. As efforts in genetic research are pursued, it is likely that a limited number of genetic profiles determined by genetic variants in different genes can clearly identify MS patients and be used for presymptomatic diagnosis and selection criteria for treatment. In the meantime, apart from the HLA haplotype, no genetic biomarker can contribute to MS diagnosis in the early stage of the disease.

Several studies have found an increased frequency of the *HLA-A2* allele in patients with EOAD and others have demonstrated an association between the *A2* allele and an earlier age of onset of AD [94], with *HLA-A2* homozygotes having an onset of AD 5 years earlier, on average, than either *A2* heterozygotes or those without *A2*, reflecting a gene dosage effect independent of *APOE4* status. It has been suggested that the *HLA-A2* allele may have a role in regulating an immune response in the pathogenesis of AD or that there may be a responsible gene in close linkage to *A2* [94].

The *APOE4* (Cys112Arg) variant of apolipoprotein E is associated with increased risk for late-onset AD (LOAD, after age 60) in a dose-dependent fashion [95, 96]. The *APOE4* allele, by unknown mechanisms, appears to affect age of onset by shifting the onset curve toward an earlier age [97]. Estimates of the total contribution of *APOE* to the variance in onset of LOAD vary widely. As the inheritance of one or more *APOE4* alleles is not deterministic for AD and the mechanism by which inheritance of one or more *APOE4* alleles causes AD is unidentified, the usefulness of *APOE* genotyping in clinical diagnosis and risk assessment remains unclear [98]. *APOE* genotyping may have an adjunct role in the diagnosis of AD because a large proportion of demented individuals with *APOE4* alleles have been found to have neuropathological confirmation of AD at autopsy [31, 32, 99, 100]. Increased risk of LOAD associated with the *APOE4* allele has also been shown in African-Americans [101] and Caribbean Hispanics [102]. In a segregation analysis of LOAD families, Daw et al. [103] found evidence that, in addition to *APOE*, four additional loci make a contribution to the variance in age at onset of LOAD similar to or greater in magnitude than that made by *APOE* alone, with one locus making a contribution several times greater than that of *APOE*. Their results suggested that several genes not yet localized to that time may play a larger role than does *APOE* in LOAD.

No result indicates that homozygosity or heterozygosity for *APOE4* allele causes a greater risk of developing MS, but there are several studies which found an association between the allele *APOE4* and a faster disease progression and also two longitudinal studies which found a relationship between the allele and the progression rate. A recent meta-analysis confirmed such data [104].

Numerous candidate gene studies have been conducted both in MS and AD to identify additional disease modifiers. Some positive findings have been reported, but modestly significant associations were observed, suggesting that the studied genetic variants have only modest effects on risk/protection, age at onset, and disease duration. This observation reinforces the existence of not yet identified additional putative functional variants and demonstrates that none of the investigated single variants taken alone contributed substantially to the development of AD or MS in the respective studied samples. Among the analyzed genes, the following can be cited: *UBQLN1* [105], *APBB2* [106], *TNF alpha* [107], *LRP1*, *ACE*, *A2M*, *BLMH*, *DLST*, *TNFRSF6*, *NOS3*, *PSEN1*, *PSEN2*, *BCHE*, *APBB1*, *ESR1*, *CTSD*, *MTHFR*, and *IL1A* [108]. Croes et al. [109] argued against using genetic testing for AD as a diagnostic tool, suggesting that the contribution of genetic testing to clinical diagnosis is small and does not counterbalance the problems associated either with interpretation or with secondary effects on family members. In contrast to the utility of *APOE* testing as an adjunct diagnostic test in individuals with dementia, there is general agreement that *APOE* testing should not be used for predictive testing for AD in asymptomatic persons.

**Soluble Biomarkers: Analysis of Body Fluids** Biological analyses of body fluids such as CSF, blood, and urine samples have the potential to deliver important biomarkers in the clinic due to the accessibility of these biological materials. However, lumbar puncture is a relatively invasive procedure and repeated collection of CSF needs to be restricted, representing a limitation for its use in the clinical setting and also as a potential surrogate marker in clinical trials. Blood–brain barrier damage, both in MS and AD, allows relatively large amounts of CSF to be absorbed in the blood every day [110], but the main challenge resides in the relevance of brain leakage proteins likely to be present in CSF and/or plasma in poor to very poor levels in comparison to abundant proteins such as albumin. This is due to the fact that peripheral blood represents a traffic compartment for both regulatory and effector lymphomonuclear cells, and it is very unlikely that the processes occurring in the CNS would be reflected and paralleled in the peripheral circulation [111]. Moreover, soluble molecules, which could play a relevant role in the ethiopathogenesis of MS and AD, act in an autocrine or paracrine fashion, which typically show a short half-life [112].

**Common Features between MS and AD** CSF levels of protein tau (total tau) have been shown to be significantly increased in patients with AD, with elevations of two- to threefold CSF total tau, but weak correlations present with changes in cognitive scores [113, 114]. In MS, increased total tau levels in patients with active disease compared to clinically nonactive states indicate axonal pathology in active disease [115], and the report was confirmed in a second study [116]. The association of tau concentrations with AD suggests that the protein could be related to cognitive dysfunction in MS. Over the last 20 years, several studies have confirmed the association of MS with the HLA complex, the most polymorphic gene cluster known in humans with >200 genes, but the MS-associated DR2 haplotype, also known as HLA-DRB1\*1501-DQA1\*0102-DQB1\*0602, extends over a long interval containing multiple genes [93]. Most recent studies based on linkage disequilibrium analysis with highly dense single-nucleotide polymorphism (SNP) maps have demonstrated

that it is the HLA class II genotype patterns that determine susceptibility and resistance to MS, this pattern of susceptibility strongly supporting an autoimmune etiology for MS [117, 118]. *HLA-A2* allele association with earlier age of AD onset has been reported with an additive effect of *HLA-A2* and *APOE4* demonstrating a 3-year shift [94, 119]. Although sensitivity is high, poor specificity limits the diagnostic value of these biomarkers.

**Specific Features of AD**  $A\beta$  is recognized as a normal product of cellular metabolism throughout life and circulates as a soluble peptide in biological fluids. The most reproduced finding is the decrease of CSF  $A\beta_{1-42}$  levels [28, 120, 121] in association with higher levels of total tau in the CSF of AD patients in comparison with the CSF of controls while CSF  $A\beta_{1-40}$  levels (or  $A\beta_{total}$ ) are not different from age-matched controls. The high positive likelihood ratio indicates that combined biomarker tests are useful in confirming the diagnosis of AD, but the low negative likelihood ratio indicates that a negative test result cannot rule out the disease [122]. Changes in CSF biomarkers occur early in the course of AD in most patients. No consistent correlation of  $A\beta_{1-40}$  or  $A\beta_{1-42}$  plasma concentrations with CSF levels has been observed [123]. Based on CSF levels of  $A\beta_{42}$ , tau, and ubiquitin, subgroups presenting different clinical profiles can be distinguished; these different subgroups may benefit from different therapeutic drugs [124].

Analysis of the different CSF phosphorylated tau isoform (p-tau 181, 199, 231, 235, 396, and 404) levels revealed that CSF tau-199 (phosphorylation at serine 199) is significantly increased in AD patients compared to non-AD subjects, exceeding both sensitivity and specificity over 85% as a sole biomarker for AD [125], but with many of the non-AD tauopathy and degenerative dementias also showing increased tau-199 levels. Cross-sectional studies examining three p-tau species as diagnostic measures (tau-181, tau-199, and tau-231) have revealed that tau-231 may have a greater specificity to AD [126]. The observed correlations between levels of CSF phosphorylated tau and hippocampal atrophy are independent of disease duration and severity, suggesting that CSF phosphorylated tau levels may reflect neuronal damage in AD [127].

Combining CSF tau and CSF  $A\beta_{1-42}$  levels improves specificity, allowing differentiation between AD, normal aging, and vascular dementia [128]. Other biological markers such as CSF levels of neurotransmitters, cytokines, or superoxide dismutase were shown to have less diagnostic value [129].

**Specific Features of MS** As regards biomarkers related to the inflammatory phase, it is well known that the detection in the CSF of an intrathecal antibody production, namely the presence of two or more oligoclonal IgG bands (OB) detected by separation of CSF proteins, while not demonstrable in corresponding serum, is supportive of a diagnosis of MS. Several studies suggest that CSF analysis increases diagnostic sensitivity, though perhaps at the cost of specificity and accuracy [130]. However, findings in one large study of PPMS [131] have led to a recommendation to revise the CSF criteria for this population of patients, and it is no longer a requirement for diagnosis [34]. MS patients with and without CSF bands may be clinically indistinguishable but may represent two immunologically distinct populations [132].

Other components of the immune system, and mostly cytokine and chemokine blood levels, have been extensively studied as potential biomarkers with

disappointing results, with only few studies trying to test more than one potential biomarker at the same time in the same subjects [133].

Given the recent evidence that axonal loss occurs in MS since the early stages of the disease, there is a current strong interest in the identification and analysis of biomarkers which reflect the axonal damage, which can be divided into cytoskeleton markers, membrane markers, and other axonal markers [134]. Several studies have shown that concentration of light-chain neurofilament (NfL), one of the major axonal cytoskeleton proteins, is increased in CSF of patients with MS [135], with peak concentrations during relapses. In addition, the correlation of NfL and heavy-chain neurofilament (NfH) autoantibody indices with surrogate markers for atrophy on MRI suggests a relation with disease progression [136]. Combining CSF markers (tau and NfH) can increase sensitivity in predicting the conversion from CIS to MS (40% compared with 34% for MRI), which could be further increased to 60% if CSF and MRI criteria were combined [137]. Similarly, the combination of tau and NfH showed higher specificity (94%) than MRI (82%). The only marker related to neuronal damage that has shown promising results in peripheral blood is 24S-hydroxycholesterol [138], with concentrations decreased in serum of patients with MS, especially if affected by the primary progressive form of MS. Additional markers of axonal loss which have been tested are the ApoE levels, the 14–3–3 protein, and the neuron-specific enolase with, however, conflicting results.

### **14.2.3 CLINICAL DEVELOPMENT APPLICATION: DRUG EFFICACY AND SAFETY**

#### **14.2.3.1 Using Biomarkers to Select Patient Subgroups**

Biomarkers may be applied to drug development in a number of distinct ways [129]. First, additional diagnostic measures in clinically identified populations are provided (high specificity and sensitivity are therefore required). Second, new biomarkers of presymptomatic disease are very important for population enrichment strategies and confirmation of efficacy during the assessment of novel disease-modifying therapies. Third, biomarkers can help to establish a differential therapeutic approach and to treat individuals selectively according to their pathophysiological/genetic subtype and disease status (Table 1). In clinical development, the most important benefit offered by biomarkers is to limit investigational drugs to high-risk groups, who would gain the most of novel therapies and/or in which efficacy is most likely to be observed. Heterogeneity in the patient population can be limited by subgrouping patients according to these additional biomarker criteria. In the absence of subgrouping patients, dilution effect on efficacy may lead to no statistically significant results and arrest of drug development of molecule even if the molecule may be valuable for some patient subgroups. Enrichment trial designs using the same methodology as in cancer drug development can be extremely valuable strategy, especially for unprecedented targets [139]. The improved accuracy in diagnosis with additional diagnostic measurements can lead to better chance of success in proof-of-principle/proof-of-concept (POP/POC) studies, allowing us to concentrate our efforts on successful POP/POC studies to continue to late-phase clinical development and, therefore, to speed up the testing of novel treatments. The reduction in

**TABLE 1 Different Types of Biomarkers**

|                              |                                                                                                                                                                                                                                   |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Predisposition biomarkers    | To use in families where risk of developing disease is high and/or age dependent, such as in AD families with mutations in APP, PSEN1, PSEN2, the penetrance may not be 100%.                                                     |
| Screening biomarkers         | To be used for screening in high-risk presymptomatic populations—mutations in APP, PSEN1, and PSEN2 are too rare to justify the effort and expense, and ApoE is not sufficiently strong to be used in presymptomatic populations. |
| Diagnosis biomarkers         | Neuroimaging biomarkers and oligoclonal bands for MS. In AD, neuroimaging biomarkers are the most promising, ApoE being used as an adjunct.                                                                                       |
| Therapy selection biomarkers | To use to define targeted populations where disease-modifying therapies have been efficacious (targeted therapies).                                                                                                               |
| Prognosis biomarkers         | Once diagnosis is performed, markers defining disease severity and/or rate of progression.                                                                                                                                        |
| Predictive biomarkers        | To anticipate efficacy and/or safety of symptomatic and/or disease-modifying neurotherapies.                                                                                                                                      |

sample size estimates is also very important: Enrollment of fewer subjects is needed if using neuroimaging and soluble biomarkers rather than when using cognitive measurements (for AD) or clinical criteria (for MS) [39, 140].

From a broader clinical standpoint, redefining disease is the challenge of future medicine. Because of heterogeneity in MS and in AD, subtyping patients by genetic, clinical, neuroradiological, and neuroimmunological parameters will be necessary, and biomarkers will be extremely important contributors to the subtyping algorithm.

#### **14.2.3.2 Predicting Changes in Response to Therapy and Disease Course: Predictive Biomarkers**

As new targets have emerged from genomics, it has been put forward that insufficient target validation has caused the increase in failure rates of drug development programs. As a consequence, experimental medicine groups frequently develop and validate biomarkers to enable them to test if the pharmacology can be safely expressed in humans and if the pharmacological activity provides sufficient efficacy and differentiation in the disease indication [141].

A number of strategic considerations are addressed in the course of drug development and questions frequently emerge: Why and how to use biomarkers in clinical drug development? With rare exceptions, biomarkers cannot substitute primary endpoints in drug registration trials and, by definition, a surrogate can only approximate the gold standard. Biomarkers may be applied to drug development in a number of distinct ways [129]. If deployed as early as possible, biomarkers can contribute to the development of three phases of the clinical plan: (1) to confirm if the drug is hitting the target; (2) to test if hitting the target alters the pathophysiological mechanism of disease (POP/POC); and (3) to test if altering the mechanism affects clinical status [142].

Consequently, classes of biomarkers differ not only for each therapeutic area but also according to their objectives. In risk reduction, specific biomarkers may be developed for selecting drug dose, for selecting patient population, for assessing early efficacy, or for predicting toxicity, making some biomarkers suited for one

role and inappropriate for another. Specificity and sensitivity required will depend on the application. Clearly, they are add-ons to facilitate decision making and not a substitute for clinical endpoints requested by regulatory authorities (FDA or EMEA) [143].

Development and validation of biomarkers can be cost effective in drug development programs, aiming for high-risk unprecedented targets (such as biologicals) coming from genomics discoveries and carrying increased risk in early development, as well as in chronic diseases and in pre-phase II studies to separate more quickly and cheaply than traditional phase II studies. In these instances, biomarker studies contribute not necessarily to go–no go drug development decisions but rather to gaining confidence in a novel compound and promoting it for further development, keeping in mind that validation and reliability of biomarkers are frequently difficult points and that safety and efficacy biomarker data are to be weighed against “traditional” safety and efficacy data. In parallel, for the measurement of disease severity, observations of changes in biomarker with disease progression are to be observed in longitudinal studies (high specificity not specially required in this case).

#### 14.2.4 CONCLUSION

The development and validation of diagnostic and predictive biomarkers in diseases with usually extended asymptomatic phases, like MS and AD, are particularly challenging and can take a long time as their validation is by necessity often linked to long-term clinical outcomes. Nonetheless, such biomarkers could have a big impact on health care by facilitating the assessment of new drugs that prevent costly chronic progressive disease [144]. Progress in identifying diagnostic biomarkers has been rate limited due to incomplete understanding of the pathogenesis of these disorders despite the advances in the identification of genes associated with inherited risk. Biomarkers for AD are far from reaching clinical practice while MRI and CSF OB bands are the only validated biomarkers currently used in MS. Yet, if validated diagnostic biomarkers as well as disease-modifying treatments with ability to slow down the disease progression became available—as the first A $\beta$  modulators in AD and interferons in MS—patients would highly benefit from management of the early disease stage.

Biological and neuroimaging biomarkers with strong potential are currently being used in early drug development programs to allow for the exploration of pharmacodynamic effects of targeted therapeutics and to aid early diagnosis, alone or in combination, but require additional validation to be considered for their ability to reveal effect of investigational drugs [11, 12, 145]. CSF A $\beta$  and tau are biological markers of AD pathophysiology, and their measures may have potential clinical utility in the future diagnosis of AD. They might be combined with neuroimaging techniques, and the PET scan with (11)C-PIB tracer is perhaps the most promising candidate [77]. Combinations of biomarkers hold great promise: For example, tau and NfH are valuable biomarkers for axonal damage in CIS patients. Predicting conversion from CIS to MS can be improved if CSF markers are combined with MRI [137]. However, soluble biological biomarkers show considerable variance, with significant overlap between values obtained in disease groups and controls for AD or MS. Meta-analyses of previous studies comparing these markers need to demonstrate similar findings. For most biomarkers, the differences are not sensitive

and specific enough for discrimination between disease and control groups or prediction of disease outcome in individual patients. Few studies on specific markers for neurodegeneration in body fluids have been done. The studies have typically included only small numbers of patients, and, more importantly for monitoring of neurological decline, follow-up needs to be performed on longer time periods. Validation of biomarkers requires longitudinal studies to collect data on disease progression and on neuropathology, especially for AD.

The search for biomarkers in MS and AD has just started and is already yielding promising results. Intensive research efforts are currently being accomplished using mass spectrometry-based proteomics as well as other promising technologies to provide a deep coverage of the body fluid proteomes. In the immediate future, emerging biomarkers for MS and AD are more likely to be used in clinical trials than in clinical practice, but undoubtedly, some of them will bring interesting diagnostic and prognostic tools to molecular medicine [146].

The fundamental lesson to be understood by doctors is that when they stray from the traditional concepts of medicine—saving lives, healing, and ameliorating pain and suffering—they enter into a territory that is fraught with danger, not only for their patients, but also for the morality of medicine as a profession.

 Editors of *Military Medical Ethics*, Volume 2, 2003,  
 in memory of Sheldon H. Harris, Ph.D.

## 15.1 BACKGROUND

### 15.1.1 Development of Human Research Guidelines

Adherence to the highest ethical and moral standards is important not only for routine clinical practice but also for all research involving human subjects. In the United States, the Food and Drug Administration (FDA) regulates the evaluation of medications and biomedical devices and has the sole responsibility of approval for their commercial sale for use in humans. The Office of Human Research Protections (OHRP) oversees the regulation of federally funded human research [1, 2]. The primary oversight authority of investigators, however, is the responsibility of the institutional review board (IRB) or institutional ethics committee (IEC). The delegation of oversight responsibility to the IRB was made in recognition of the regional and institutional variations that exist in ethical and treatment standards of care [3]. The geographic proximity of the IRB/IEC to the location of the research facilitates timely direct communication between the regulatory body and the investigator. However, there is a growing move toward regional or community review boards, as well as a move toward independent review boards. Open communication between investigators and the IRB/IEC is critical for the timely performance of

audits, reviews, notifications, and amendments and ultimately provides improved safety and welfare for the research participants.

### 15.1.2 History and Landmark Doctrines

The history of IRBs/IECs has not been without significant challenges and problems, however. Prior to the early to mid-twentieth century, human research was governed by individual conscience, professional bodies, societal norms, and government customs of the time [4]. The earliest known legal requirement pertaining to informing human subjects of medical experimentation was the Berlin Code of 1900 [5]. The United States made some initial efforts toward forming human research guidelines and ethics in the early 1900s with studies such as the U.S. Army's Yellow Fever Project; but, unfortunately, most physicians and scientists either knew little of these guidelines or refused to adhere to such strict rules [5, 6].

Formalization of human research standards came as a reaction to the atrocities committed by Nazi medical researchers found during the Nuremberg Military Tribunal [7]. In addition, it is estimated that several hundred thousand deaths occurred from the Japanese biomedical, biological, and chemical warfare experimentation on involuntary subjects from the mid-1920s until 1945 [8]. The atrocities of forced human testing performed by Nazi and Japanese scientists on prisoners and civilians during World War II resulted in a global outcry and the establishment of a variety of ethical guidelines for research involving human subjects. In 1953, the Department of Defense instituted the first directive for an official process for conducting human-use research, called the Wilson Memorandum, which unfortunately, was kept mostly secret [6]. The National Institutes of Health attempted to establish policies for approving research studies on humans, but no consensus could be reached as to which human-use research projects should be subject to regulation [9]. A more substantial and formal systematic protection of human subjects in medical research remained dormant for many years.

In 1964, the World Medical Association issued the Declaration of Helsinki, a groundbreaking treatise for international research protections. The Declaration of Helsinki continues to be followed today and has been revised periodically, most recently in 2000 during the 52nd World Medical Association General Assembly in Edinburgh, Scotland [10]. However, the United States did not formulate human research regulations until after Henry Beecher published his ethics paper in 1966 [11] outlining some of the unethical human research projects being conducted in the United States, which sparked the U.S. Congress to pass the National Research Act in 1974 [12]. The National Research Act established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which is best known for formulating the links between ethical principles and human research practices in the Belmont Report of 1979. This legislation formally required the establishment of IRBs to oversee all federally funded research activities [12, 13]. The Belmont Report (available at <http://www.hhs.gov/ohrp/humansubjects/guidance/belmont.htm>) articulates the three main ethical principles upon which all IRBs should operate: respect for persons, beneficence, and justice [13]. Various international and federal regulations that govern human subject research require the oversight of research by an IRB or its equivalent (e.g., ethics committees, institutional ethics committees, health research ethics committees, etc.).

## 15.2 DEFINITIONS

### 15.2.1 Institutional Review Board

An independent group, committee, or similar such entity consisting of a combination of medical/scientific and nonmedical/nonscientific members that is formally organized to oversee biomedical research involving human subjects at an institution. An IRB's primary objective is to protect the rights, safety, and welfare of human subjects participating in biomedical research [14].

### 15.2.2 Ethics Committee

Essentially equivalent to an IRB but usually uses the name ethics committee (EC) or human research ethics committees (HREC) in countries outside the United States. Each country sets specific minimum requirements for the composition of ECs as guided by the International Conference on Harmonisation (ICH) E6 Good Clinical Practice (GCP) guidelines [15].

### 15.2.3 Data Monitoring Safety Boards

An independent, objective group that is charged with monitoring the safety of clinical trials. Clinical trials that are evaluating new drugs, biologics, or devices are required by 21 CFR § 312.50 and 21 CFR § 312.56 to monitor their studies [16]. Data monitoring safety boards (DSMBs) are an additional group that may perform a monitoring function [17]. Although DSMB composition may vary from place to place and country to country, they should be composed of scientists, clinicians, biostatisticians, and bioethicists who have the expertise necessary to be able to evaluate independently an objective safety analysis of the clinical trial [18].

### 15.2.4 Assurances

Documents for acknowledging compliance by an institution of mandated federal policies for human subject research and for the protection of research subjects. Assurances are a written commitment obtained through the Office of Human Research Protections (OHRP) that must be approved before federal funding can be awarded. The most common type of assurance accepted by OHRP is the Federalwide Assurance (FWA). All organizations participating in federal research that have an IRB must obtain an assurance and a written agreement between IRBs and/or organizations outlining their relationships and commitments to the recognized assurance [19].

### 15.2.5 Human Research

A systematic investigation conducted by an investigator involving living individuals or identifiable information of the human subjects that is conducted in a manner that is designed to contribute new knowledge. All research activities that fall under the regulation of Title 45 CFR part 46 are required to abide by IRB/IEC oversight [3].

### 15.2.6 Informed Consent

The process by which human subjects are informed of all aspects of a research study including potential risks and benefits that may influence the subject's decision on whether or not to volunteer to participate in the study. The informed consent document must be reviewed and approved by the IRB/IEC. In the event that a research subject is not legally competent to consent, as in the case with a minor or a person who lacks mental capacity (such as a person in a coma), the law normally allows a third person, typically a family member, to consent on the person's behalf. Check the requirements of the jurisdiction you are in to determine whether it is appropriate and the procedure to be followed. Care should be taken to ensure the IRB/IEC is acting in the best interests of the research subjects. In at least one instance an IRB was cited for erroneously putting the interests of investigators over the interests of subjects [20]. Informed consent may be oral or written depending on the risk level. More than minimal risk studies typically require formal written consent. Documentation of informed consent is done through a document that is signed and dated [15].

### 15.2.7 Institution

Any medical or dental entity or facility, public or private, where clinical trials can be conducted.

### 15.2.8 IRB Registration

Registration is required by any IRB/IEC that reviews U.S. federally supported human research or any institution that is subject to the Common Rule [3]. IRBs/IECs must be registered with OHRP before they may be designated on an FWA. IRBs/IECs that are registered are listed on the OHRP website at <http://ohrp.cit.nih.gov/search/asearch.asp#ASUR>. An OHRP assurance is also required.

## 15.3 GLOBAL NATURE OF RESEARCH REVIEW: INTERNATIONAL COMMITTEE ON HARMONISATION AND GOOD CLINICAL PRACTICE

All human subject research, regardless of the country in which the research is taking place, should be conducted under the International Conference on Harmonisation (ICH), E6 Good Clinical Practice (GCP) guidance (available at <http://www.fda.gov/cder/guidance/959fnl.pdf>). The International Conference on Harmonisation of Technical Requirements for the Registration of Pharmaceuticals for Human Use grew out of a meeting hosted by the European Federation of Pharmaceutical Industries and Associations in Brussels in 1990 that brought together the regulatory authorities and pharmaceutical industries in the European Union, United States, and Japan to discuss joint regulation of the pharmaceutical industry. The early intent of the ICH was to establish an international process for the development and regulation of new medical products in a more efficient manner.

The ICH has continued to expand its guidance through harmonization of therapeutic advances, technical developments, and other specific medical products based

on scientific consensus and the protection of public health and individual safety on an international perspective. The World Health Organization (WHO) has endorsed these ICH GCP international standards as well as the Declaration of Helsinki and the Council for International Organizations of Medical Sciences (CIOMS) International Ethical Guidelines for Biomedical Research Involving Human Subjects as the ethical and scientific standards for conducting biomedical human subject research [21]. These guidelines are intended to help facilitate biomedical research and clinical trials worldwide. The Office for Human Research Protections has been working on compiling an international listing of countries that have laws, regulations, or guidelines to cover human research. The 2005 international compilation listing includes 72 countries with links to standards and international organizations (available at <http://www.hhs.gov/ohrp/international/HSPCompilation.pdf>).

## **15.4 COMPOSITION, ROLES, AND ACTIVITIES OF INSTITUTIONAL REVIEW BOARD/INSTITUTIONAL ETHICS COMMITTEE**

### **15.4.1 Composition**

The composition of an IRB/IEC will vary but should consist of a reasonable number of members with qualifications and expertise in a variety of aspects so as to ensure the rights, safety, and welfare of subjects involved in research are protected. In the United States, 45 CFR § 46.107 strongly encourages diversity, not only as to race, creed, sex, and national origin, but also professional and social experience [3]. If a vulnerable population, such as prisoners are used, there must be someone on the committee representing their interests (45 CFR § 46.304). Minimum requirements: at least five members, at least one member who is from a nonscientific background, and at least one member who is independent of the site or institution. Both genders must be represented, including making quorum, which must be at least 50% of the primary membership (45 CFR § 46.108) [14]. Many institutions are moving to a two-tiered system that adds a scientific review component step before the protocol is presented to the IRB/IEC. The scientific review is intended to aid in promoting research excellence. This two-step system is intended to help streamline the IRB/IEC review process by having a scientific review by experts on the subject matter first address the study design aspects of the protocol, which then allows the IRB/IEC to focus on the human use issues. However, the IRB/IEC still needs to review the report from the scientific review as well as review the protocol as a whole in the human use context.

### **15.4.2 Oversight**

The main goals of an IRB/IEC are to ensure that the rights of the research subject especially in regards to privacy and informed consent are maintained, that investigators conduct their research in a professional and ethical manner, and that the potential benefits of the study outcomes outweigh the potential risks to the patient. IRBs/IECs are also tasked with the responsibilities to ensure that the studies that fall under their purview are methodologically sound in their design, whereby the objectives of the research will provide meaningful data and the risks and benefits

for study involvement are suitable for human participation. If an institution uses a scientific review committee, the findings from the scientific review should be reviewed by the IRB/IEC. These roles for the IRB are not exclusive to the initial protocol approval but are continuous throughout the duration of the study and for at least 3 years after the study has completed, and even longer for pharmaceutical clinical trials according to 45 CFR § 46.115 [3].

### 15.4.3 Informed Consent

The informed consent process and documentation is a critical element the IRB/IEC must review. The information contained within the informed consent document must be at a language level appropriate for the study population (usually sixth grade level) and may need to be made available in more than one language in order to support all participants. The information must be clear to the potential volunteer so that the decision of whether to participate can be made freely by the subject. When the research involves a medical product such as a device or pharmaceutical, an adequate summary of the product must be communicated to the potential subject that includes the safety information and clinical experience or the product. Any compensation for subject participation should be contained in the informed consent document as well. Compensation may not be at a level that is seen as improper inducement to participate in the research. The process of recruiting the potential subjects as well as a description of the informed consent process must be approved by the IRB/IEC in order to reduce potential coercion.

### 15.4.4 Other Concerns

There are other important concerns that an IRB/IEC must also consider for each research protocol such as legal issues and intellectual property rights. Members of the IRB must remember that research protocols may contain sensitive or proprietary information. It is imperative that members of the IRBs/IECs respect the confidentiality of the research protocols. “Products of human ingenuity” such as a new medication or device should be considered intellectual property as guided by *Diamond v. Chakrabarty*, 447 U.S. 303, 1980, [22, 23]. The IRB will also be assessing a number of other issues as outlined in Table 1, all in accordance with respect for persons, beneficence, and justice [24].

## 15.5 TYPES OF IRB REVIEWS

### 15.5.1 Initiating Clinical Trial and Types of IRBs/IECs

Before starting any human research or clinical trial, an investigator must attain written approval from his or her IRB/IEC prior to initiation of the study. This approval process includes approval of informed consent forms, advertisements, and other written documents as well as specific procedures, data collection, analysis, and storage. When an institution does not have an IRB/IEC, there are independent IRBs/IECs that can be contracted to serve as an IRB/IEC to review research under your institution’s OHRP accepted assurance. For multicenter clinical trials, central IRBs/IECs can be used [25]. Clinical trials that fall under the investigative new drug

**TABLE 1 Overview of Basic Items in an IRB Review**

| Purpose of Study                            | Background, Summary, and Aims                                                                                                              |
|---------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------|
| Sponsor                                     | The name of the organization that takes the responsibility for and initiates a clinical trial. It may be a private or public organization. |
| Investigator                                | Qualifications, financial disclosures, conflicts of interest.                                                                              |
| Study population                            | Inclusion/exclusion criteria, subject recruitment, appropriateness of subject selection, advertisement.                                    |
| Scientific design                           | Objectives, design description adequate to answer question, research procedures.                                                           |
| Informed consent                            | Written documentation of process is essential.                                                                                             |
| Potential risks and discomforts to subjects | Risk relative to alternatives, risk–benefit analysis.                                                                                      |
| Confidentiality                             | Are procedures adequate to protect the privacy and confidentiality of the subject?                                                         |
| Data oversight                              | Stopping rules, data monitoring board.                                                                                                     |
| Data analysis                               | Appropriate data analysis and statistical analysis.                                                                                        |
| Compensation and costs                      | Is compensation or reimbursement of subject reasonable?                                                                                    |
| Other                                       | Depending on the type of clinical trial, other checks may be considered by the IRB.                                                        |

(IND) regulations must be approved by an IRB/IEC. Central IRBs/IECs help facilitate the IRB/IEC process by reducing redundancy in effort, and for small institutions, can provide a more diverse perspective for reviewing the research protocol. Centralized IRBs/IECs are consistent with 21 CFR § 56.114 that provides for institutions involved in multi-institutional studies and joint reviews. Centralized IRBs/IECs can be used by institutions in whole or in part for the review of a multi-center clinical trial [25]. In addition, if there is a registered IRB/IEC in your geographic region, you can negotiate having them conduct reviews for your institution, or an institution may also consider establishing its own IRB/IEC.

In all cases in which research is conducted using funds from the U.S. government each institution must obtain its own assurance that is accepted by OHRP (45 CFR § 46.103). Regardless of the type of review system, there are a number of elements in common that must be addressed in the protocol submission (Table 1). Local IRBs/IECs have the flexibility to specify the format and detailed content required for the review as long as the information meets federal requirements. The type of review a protocol receives is up to the IRB/IEC, not the investigator. It is prudent for an investigator to discuss a potential protocol with the IRB/IEC for guidance before submitting a protocol. However, the IRB/IEC or its properly established subcommittee must review the protocol before deciding which type of review is most appropriate. This is normally determined by local guidelines.

### 15.5.2 Exempted Review

Certain types of research can be exempted from the full detailed review of the IRB. The research must meet all of the criteria in 45 CFR § 46.101(b) (1-6) and involve no greater than minimal risk to be eligible for exempted review (e.g., retrospective review of last 100 abdominal CT studies) (Table 2). The IRB typically does not conduct continuing reviews of exempted protocols, but the investigator will be

**TABLE 2 Exempted Research Criteria as Found in 45 CFR§ 46.101 (b)**

| Category                                                                                                                                                                                                                        | Conditions                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| (1) Research conducted in established or commonly accepted educational settings, involving normal educational practices, such as:                                                                                               | (a) Research on regular and special education instructional strategies;<br>OR<br>(b) Research on the effectiveness of or the comparison among instructional techniques, curricula, or classroom management methods.                                                                                                                                                                                                                                                                                                                                                                                                         |
| (2) Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures or observation of public behavior, if:                                              | (a) Information obtained is recorded in such a manner that human subjects cannot be identified, directly or through identifiers linked to the subjects;<br>AND<br>(b) Any disclosure of the human subjects' responses outside the research would not reasonably place the subjects at risk of criminal or civil liability or be damaging to the subject's financial standing, employability, or reputation;<br>AND<br>(c) Subjects are not under the age of 18 or members of a vulnerable class, including prisoners, pregnant women, individuals who are mentally disabled or economically or educationally disadvantaged. |
| NOTE: all three conditions must apply.                                                                                                                                                                                          | (a) The human subjects are elected or appointed public officials or candidates for public office;<br>OR<br>(b) Federal statutes(s) require(s) without exception that the confidentiality of the personally identifiable information will be maintained throughout the research and thereafter.                                                                                                                                                                                                                                                                                                                              |
| (3) Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures, or observation of public behavior that is not exempt under paragraph (2) above if: | (a) These sources are publicly available;<br>OR<br>(b) If the information is recorded by the investigator in such a manner that subjects cannot be identified, directly or through identifiers linked to the subjects.                                                                                                                                                                                                                                                                                                                                                                                                      |
| (4) Research, involving the collection or study of existing data, documents, records, pathological specimens, or diagnostic specimens, if:                                                                                      | (a) Public benefit or service programs;<br>OR<br>(b) Procedures for obtaining benefits or services under those programs;<br>OR<br>(c) Possible changes in or alternatives to those programs or procedures;<br>OR<br>(d) Possible changes in methods or levels of payment for benefits or services under those programs.                                                                                                                                                                                                                                                                                                     |
| (5) Research and demonstration projects which are conducted by or subject to the approval of department or agency heads, and which are designed to study, evaluate, or otherwise examine:                                       | (a) Wholesome foods without additives are consumed;<br>OR<br>(b) If a food is consumed that contains a food ingredient at or below the level <b>and</b> for a use found to be safe, <b>or</b> agricultural chemical or environmental contaminant at or below the level found to be safe, by the Food and Drug Administration or approved by the Environmental Protection Agency or the Food Safety and Inspection Service of the USDA.                                                                                                                                                                                      |
| (6) Taste and food quality evaluation and consumer acceptance studies, if:                                                                                                                                                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |

*Note:* In order to qualify for exemption, all of a project's activities must qualify as one or more categories from the left column. (To qualify for a category, a project must meet the conditions to the right of the category). The IRB/IEC makes the decision regarding exempted status. This is presented as a guideline only.  
*Source:* Adapted from Ref. [3].

required to complete an annual report. The investigator is also still bound by all the federal ethical requirements and regulations for good clinical practice (GCP) [15]. Informed consent is typically not required by law for exempted protocols, however, the sponsor or local IRB/IEC may require it. In the United States, the Health Insurance Portability and Accountability Act (HIPAA) authorization or waiver may also be needed. The IRB/IEC will make the determination as to which protocols fit exempted review status and the human use requirements for the investigator.

### **15.5.3 Expedited Review (45 CFR § 46.110)**

Certain kinds of research can be conducted through an expedited review process. Protocols that may be subject to expedited review need to have certain characteristics that may include: (1) must be no more than minimal risk; (2) may be exempted research; (3) must fit within the categories outlined by federal regulations 45 CFR § 46.110; (4) may be a review of minor revisions for a previously approved research study; and (5) may still require informed consent. The local IRB/IEC has the authority to make the decision for expedited reviews, not the investigator.

### **15.5.4 Full Review**

Most prospective studies and some retrospective studies will require a full review. Consult with the local IRB/IEC when in doubt. The review must be conducted at a convened IRB meeting that has a quorum of at least half of its primary members. The IRB must determine that all of the federal requirements specified in 45 CFR § 46.111 and 21 CFR § 56.111 are satisfied [3, 14]. A protocol must receive the approval of the majority of the IRB members present at the meeting to be approved. The IRB must inform the investigators and the institution in writing of its decision to approve, modify, or disapprove the research. Most protocols go through at least one round of revisions prior to final approval.

### **15.5.5 Continuing/Annual Review**

Continuing reviews of each protocol will occur at intervals appropriate for the degree of risk, but must not be less than once a year. If 365 days elapse without continuing review (or a shorter period of time specified by the IRB), the study is suspended [26]. There is NO grace period. The purpose of the continuing review is to review the progress of the entire study, not just the changes to it. The review process not only protects the study subjects, but also exists to make sure enrollment is being done reasonably, and that the study is being conducted as outline by the research protocol. Studies with higher risk levels are reviewed more frequently (e.g., every 3 months or after every 3 subjects). The IRB/IEC will make the determination for the frequency, plus the IRB/IEC has the authority to change the frequency of the reviews based on what it considers appropriate for the safety of the subjects and the integrity of the study.

The IRB/IEC reviews all amendment requests by the investigator/sponsor. The amendments must not deviate significantly from the original proposal and need to be critically evaluated for potential risk to the subjects and to scientific validity of the study design.

## 15.6 ADVERSE EVENTS

Adverse events are taken very seriously by IRBs/IECs. Serious and unexpected adverse events must be reported expediently to the IRB [24]. A serious event is considered to be any experience that results in death or a life-threatening situation where the subject is admitted to the hospital or the outcome is a persistent or significant disability, incapacity, or congenital anomaly in a progeny. An unexpected event is any adverse experience not consistent with the current description of the IRB-approved protocol and informed consent form. Not all adverse events need to be evaluated individually by the IRB/IEC or DSMB. Events that are not significant or not clinically meaningful to the safety of the subjects should be documented, but normally do not require special review [24]. The IRB/IEC and/or DSMB will review protocols at least annually to assess the protocol for safety and documentation. Sometimes, unexpected frequencies of adverse events may cause the IRB/IEC or DSMB to either require a modification to the risk–benefit section of the protocol and informed consent document, or in rare cases, terminate the study.

## 15.7 IRB RECORDKEEPING AND ADMINISTRATIVE ACTIONS

### 15.7.1 Information That Must Be Retained and Duration

Institutional review boards are required to maintain accurate records of every protocol and investigator under their authority [1]. In the United States, the FDA requires IRBs/IECs to maintain accurate records of all research activities of the institution and store them for at least 3 years after completion or termination of a protocol [1]. The international guidelines similarly recommend the same careful documentation and 3-year minimum storage of records [27]. Some sponsored clinical trials and institutions may keep their research records longer.

### 15.7.2 Training and Credentials

The main functions of the IRB/IEC are to thoroughly review each research protocol, perform continuing reviews, and review adverse events. The breadth of an IRB/IEC's responsibilities is truly great and even includes the responsibility for ensuring that investigators have adequate training to perform the research procedures and have the necessary credentials to adequately care for the participants. In addition, the members of the IRB/IEC need to have periodic continuing education and training for their roles in the IRB/IEC process.

### 15.7.3 Privacy and Confidentiality

One additional aspect of the IRB/IEC's responsibility that cannot be overlooked concerns the protection of the participants' privacy and confidentiality rights. The IRB/IEC must assure that the investigators maintain the participants' privacy in all aspects of the research protocol. In the United States, there are added security requirements (HIPAA), which went into effect April 14, 2003 [28]. Table 3 outlines the protected health information.

**TABLE 3 Health Information Protected by 45 CFR§ 164.514(b)**

|                                                                   |                                                                      |
|-------------------------------------------------------------------|----------------------------------------------------------------------|
| Names                                                             | Biometric identifiers                                                |
| Dates that directly relate to an individual                       | Persons over the age of 89                                           |
| Telephone numbers                                                 | Fax numbers                                                          |
| Medical record number                                             | Social Security number                                               |
| Health plan beneficiary number                                    | Electronic e-mail address                                            |
| Certificate/license numbers                                       | Account numbers                                                      |
| Web universal resource locators (URLs)                            | Internet protocol (IP) address                                       |
| Full-face photograph                                              | Geocodes                                                             |
| Any copyrighted/unique identifying number, characteristic or code | Geographic subdivisions smaller than a state (some exceptions apply) |

*Source:* Adapted from 45 CFR § 164.514(b) [29].

The IRBs/IECs must also make sure the intellectual property rights of each protocol and the investigators are protected as well. IRB/IEC research protocols are considered confidential material for the participants and the investigators and must be kept in a secure or locked file. Each institution must also maintain accurate and adequate files and databases of their research that are kept secure.

## **15.8 INVESTIGATOR RESPONSIBILITIES**

### **15.8.1 Principal Investigator**

Investigators that participate in human research have a variety of responsibilities that include qualifications and expectations, study design and performance, and communication with research stakeholders. The principle investigator, or PI, has the ultimate responsibility to ensure that all investigators (i.e., associate investigators) and staff on the study have the appropriate qualifications to perform their roles within the study design. The PI bears the primary responsibility for study adherence to regulatory and ethical standards and the integrity of both the scientific and clinical aspects of the research.

### **15.8.2 Qualifications and Training**

A primary responsibility of any investigator is that he or she has the adequate education, training, and experience to participate in the proposed research. If an investigator is a novice, it is generally expected that additional experience under the tutelage of an expert is obtained prior to the individual's performance of the task independently. If a formal certification process exists for that procedure or task, the investigator is expected to have obtained that certification. Furthermore, it is expected that investigators adhere to the laws, regulations, and ethics of the country and locality that pertain to the tasks or research that are being performed. Financial disclosure is required when the investigator has a monetary relationship with sponsors. This is to avoid possible conflicts of interest in the clinical trial [30].

In addition to being qualified to perform their roles within a project, all investigators must also receive proper human research protections training. This can be

achieved various ways such as via a traditional classroom instruction, interactive CD ROM program, or Web-based tutorial. In special cases, if an IRB/IEC feels that a researcher has not met full qualifications to participate in research, the IRB/IEC can require additional training or the involvement of a more senior investigator to oversee the work and mentor the less seasoned investigator [26]. The investigators' responsibilities, regardless of the type of study or type of scientific or medical discipline, are based on the ICH and GCP documents. In the United States, in addition to human research protection training, investigators should be given a copy of the Belmont Report (<http://www.hhs.gov/ohrp/humansubjects/guidance/belmont.htm>) as an ethical guide.

### **15.8.3 Study Design and Performance**

Investigators are responsible for designing studies that have not only scientific merit but also do not unduly jeopardize the well-being of the participants. Accordingly, human research studies must be designed such that the study can be validated or replicated, the study participants are not exposed to unnecessary risks, and the benefits of the research outweigh the risks to the individuals volunteering their time for the research. The investigator and the IRB should note that "a poorly designed human research protocol is unethical" [31, p. 109]. Inherent to this concept is that the study design includes proper surveillance methods for detecting potential risks and/or qualified individuals to identify abnormalities.

### **15.8.4 Logistical Support and Budgetary Planning**

Prior to the performance of the study, the investigators must ensure that there is adequate logistical support (e.g., personnel, equipment, space, etc.) and funding for the performance of the proposed study. Should resources lapse (e.g., key investigator leaves the institution or funding abruptly be terminated) during the conduct of a study, it is the responsibility of the investigators to notify the IRB and potentially suspend or amend the protocol to more modest goals should the resource not be replenished.

### **15.8.5 Study Security and Maintenance**

Investigators are responsible for the integrity of the data, the human subject recruitment, informed consent process, and maintenance not only of the regulatory documentation but also of subject data files. Investigators are also responsible for maintenance of subject privacy and confidentiality, which includes development of the processes for the assurance of these elements. It is common practice for the secure storage of study records and materials. Secure storage of research documents is usually required to be no less than 2 years following FDA market application approval or discontinuation (21 CFR § 312.62) [16], but some sponsors and institutions require much longer storage periods, so investigators are responsible for finding out specific requirements. The records that must be maintained by the investigator are: investigational drug disposition, dates, quantities of drugs given, unused supplies, case histories, all recorded observations, supporting data, signed informed consent documents, progress notes, and any other pertinent medical records or data

collected for the trial (21 CFR § 312.62) [16]. These recordkeeping requirements may also be required by the institution. Investigators have the responsibility to ensure that records for the research study are being properly completed and maintained.

### 15.8.6 Communication with Stakeholders

Investigators are expected to communicate honestly, openly, and freely with not only the subjects but also the IRB/IEC or other outside regulatory (e.g., FDA) or interested bodies (e.g., sponsor or funding agency)—that is all persons with a “stake” in the research. Investigators, thus, are responsible not only for the preparation of the research proposal document but also for the presentation and defense of the proposed study to the IRB/IEC and any other applicable regulatory committee. A clinical study which entails the use of chest X rays, for example, typically must also receive approval from the institution’s radiation safety committee. Investigators also have a responsibility to maintain the communication with the IRB/IEC and other stakeholders even after the study has been initially approved.

**New Findings** Investigators are expected to notify the IRB/IEC of any new findings such as unanticipated risks or benefits. There is a similar expectation that subjects also be notified. Investigators are expected to incorporate their new information into the study and request amendment to the study design or documentation (e.g., informed consent documentation) in accordance to the new information. Note that this pertains not only to new information that the investigator may have learned from the specific research undertaken but also from the reported literature or available information from studies performed by other investigators. If the study is an investigational new drug trial, the pharmaceutical company (i.e., sponsor) typically provides regular updates on new findings, namely serious adverse events, that arise from all sites such that individual sites can benefit from the experience of other investigators. In response to any new study finding, investigators have the responsibility of determining if the protocol needs amendment and the responsibility of filing the appropriate regulatory paperwork for protocol amendment.

**Amendment Requests and Protocol Deviation Reporting** Any changes or amendment requests to the protocol require IRB/IEC approval. If, after the fact, a deviation for the protocol is noted, the deviation must be documented and explained to the IRB/IEC and the sponsor of the study. Deviations are considered protocol violations and are taken seriously by an IRB/IEC. Deviations made for patient safety may be done prior to IRB/IEC approval but must be reported and an amendment request made immediately to the IRB/IEC, the sponsor, and any regulatory authorities, or the trial may be suspended [15]. The protection of the human subject is the primary responsibility of the investigator. The investigator must not coerce subjects into volunteering for trials, and the investigator must be careful to fully disclose the potential risks and benefits to the subjects prior to enrollment (45 CFR § 46.116) [3]. Only investigators on the IRB/IEC-approved protocol are allowed to administer investigation drugs and with disposing of or returning unused supplies to the sponsor.

**Complying with Audits** Investigators also are responsible of complying with regulatory audits, which can be performed as a scheduled audit or impromptu inspection by the IRB or on occasion, the FDA or other regulatory body. IRBs/IECs are required to review human subject research no less than annually. In studies associated with higher risk, IRBs/IECs may choose to review the protocol more frequently. In any case, the investigators are responsible for adhering to these regulatory responsibilities which typically include an interview with an IRB/IEC representative, a reporting of study progress, and preparation of data files for review.

**Safety and Data Safety Monitoring Boards** Investigators must also report regularly to the sponsor any data or information specified by the agreement between the sponsor and investigator for the conduction of the trial. Types of reports are IRB/IEC approvals and rosters, progress reports, safety reports, and final reports. In addition, the investigators may be monitored by study monitors that are supplied by the sponsor, in addition to any monitoring requirement made by the IRB/IEC. DSMBs are growing in use by IRBs/IECs. However, there is some confusion and overlap of responsibilities between the IRBs/IECs and the DSMBs because the FDA requirements (21 CFR § 312.66) for reporting unanticipated problems are vague [16]. The overall goal should be to adequately protect the research participants through a process that can reliably detect harm to participants and then respond quickly and appropriately to the particular instances [32]. DSMBs are meant to help the research process, but more standardization of roles and adverse event reporting need to be established on an international basis [32]. Nonetheless, investigators must comply with approved protocol procedures and safety regulations. Noncompliance by investigators such as failure to report changes in the protocol, failure to report safety problems, or misuse of informed consent documents may result in the IRB/IEC halting the protocol and investigating the issues [26]. Serious lapses or continued lapses by the investigator may lead to termination of the protocol. IRBs/IECs want to ensure that the research being performed with human subjects is being done in a manner that protects the rights and welfare of the participants. Similarly, sponsors and researchers hope to bring safe and beneficial health care products, techniques, and devices to clinical practice.

## 15.9 SUMMARY

Institutional review boards or institutional ethics committees are an essential part of the clinical trial system. IRBs/IECs should help the researchers conduct research in an ethical manner that protects the rights and welfare of the human participants. There are many international regulations and guidelines such as the ICH/GCP that help guide IRBs/IECs in clinical trials. These boards are in place because of the atrocities that have occurred in past medical research, especially during World War II. This chapter presented an overview of the IRB/IEC process along with resources for researchers who want to be involved in clinical trial research. The bottom line is to perform clinical research that is safe and ethical to the human participant such that new knowledge can be gained for the advancement of health care.

### **16.1 INTRODUCTION**

On the face of it, the number of subjects required for a clinical trial is obtained from a mechanical application of a formula. A number representing the trial size pops out after presumed values of efficacy and variance, and specified levels of false-

positive and false-negative rates are plugged into the formula. However, arriving at a well-planned trial size is much more than a routine calculation. Because the derivations of formulas for different analysis methods are amply and adequately covered in the literature, they will be kept to a minimum here. The emphasis instead will be on the many challenges that arise when practical aspects of the size of a trial are considered. For purposes of keeping the focus on certain practical aspects, the chapter will be limited to randomized trials comparing two treatments and unless stated otherwise, a 1:1 allocation ratio.

Scientific, strategic, operational, and ethical deliberations exert a push and pull on the appropriate number of subjects needed for a trial. The tension this creates is described later in the section. Section 16.2 will give a limited overview of the technical details. In Sections 16.3 and 16.4 methods to avoid certain pitfalls will be described. Section 16.5 will briefly discuss noninferiority/equivalence testing and unequal allocation.

The minimum inputs to trial size (better known as sample size) assessment are the presumed values of efficacy and variability, the type I error (false-positive) rate or  $\alpha$  and the type II error (false-negative) rate or  $\beta$ . Power is  $1 - \beta$ , or in words, the probability of obtaining a statistically significant result assuming the presumed value of efficacy to be true. When power is held fixed, the number of subjects and  $\alpha$  have an inverse relationship. Determining the sample size at fixed power is equivalent to determining the power at fixed sample size. Typically, for confirmatory phase III trials, the one-sided  $\alpha$  is set at 0.025 and  $\beta$  at either 0.1 or 0.2. The fact that  $\alpha$  is chosen to be less than  $\beta$  is a reflection of how we, the clinical trials community, including regulatory bodies such as the U.S. Food and Drug Administration (FDA), are more concerned about the risk of declaring an ineffective treatment effective than we are of the risk of failing to declare an effective treatment effective. We have agreed to reach our conclusions by risking on average, for every 40 trials, no more than 1 false positive or no more than 4–8 false negatives.

The presumed value of efficacy used in sample size calculations is stated under the alternative hypothesis for the primary variable (also referred to as the response or outcome variable or endpoint). Its complement, the null hypothesis, states that the presumed value of efficacy is 0—that is, the efficacy of the experimental treatment is no different from control. (But see noninferiority/equivalence testing in Section 16.5 for different formulations of the null and alternative hypotheses.) For example, for a trial comparing cholesterol-lowering drugs, the null hypothesis may state that the average low-density lipoprotein, LDL or “bad cholesterol,” in the two groups is the same, and the alternative may state that the experimental treatment, compared to the control, lowers the average LDL by 15 mg/dL.

We now get into how the scientific, strategic, operational, and ethical matters exert a push and pull on how many subjects are appropriate for addressing the trial’s objectives.

### 16.1.1 Challenges Faced in Practice

**Scientific** Let  $\Delta$  denote the presumed value of efficacy. (For our cholesterol example, we would write  $\Delta = 15$  mg/dL.) Since the sample size formula relies heavily on the value specified for efficacy (the sample size is a function of  $\Delta^2$ ), it is important

to investigate where  $\Delta$  came from. In assessing its reliability, the following sorts of questions need to be investigated.

1. Did  $\Delta$  come from an earlier trial conducted by the same institution/sponsor? If so, how is the trial being planned different from the earlier one? Was the earlier one a small-sized trial conducted in a few centers? Will the upcoming trial include a more heterogeneous population? Are there differences in the lengths of follow-up between the two trials? Is the control group the same?
2. If  $\Delta$  was provided to a statistician by a clinician, what was their source of information?
3. Was  $\Delta$  inferred from a published article that reported results on a recently approved treatment with a similar mechanism of action?
4. Could medical advances in the field influence the magnitude of  $\Delta$  estimated from earlier trials? For example, organ transplant patients receive immunosuppressants to weaken the body's immune system to prevent it from attacking the transplanted organ. Advances in surgical methods for organ transplant may influence  $\Delta$  independent of the drug effect.
5. If  $\Delta$  was obtained from a peer-reviewed journal article, then taking that  $\Delta$  at face value will likely be an optimistic value. Positive trials tend to get published, whereas negative trials tend not to. If we had results from positive and negative trials, then our presumed value of efficacy would weigh the evidence from all trials. Overlooking the fact that negative results get censored leads to an overly favorable  $\Delta$ .

All things considered, if  $\Delta$  seems optimistic, it would be advisable to err on the side of being conservative. Even in the simple case of  $\Delta$  defined as the difference in means, the statistician, if only as a watchdog, has an important role to play in checking whether the disparate bits of information contribute a well-inferred assessment of the presumed value of efficacy.

If the primary variable is instead time to some event (e.g., time to heart attack in our cholesterol-lowering example), then other challenges are present. Here  $\Delta$  is the ratio of hazards, a concept generally not readily understood by nonstatisticians when adjustments to it are made depending on the subject accrual rate, the follow-up duration, nonproportional hazards, censoring due to loss to follow-up, and competing risks. For such an endpoint the statistician needs to be even more involved in carefully projecting the number of events and in ensuring that  $\Delta$  has been carefully selected.

Some of the same questions also arise when choosing a value for the variance. Let  $s^2$  denote the estimate of variability to be used in sample size calculations that is associated with the estimate of  $\Delta$ . Often in a covariate-adjusted analysis  $s^2$  is obtained by conditioning on marginal totals (e.g., the number of subjects per center). The estimate is valid only when there is no interaction between treatment and the stratification factor. When interaction exists, the estimated treatment effect is biased and the estimated variance is an underestimate (Section 16.3).

Additionally,  $s^2$  obtained from an earlier trial does not represent, in the statistical repeated sampling sense, an estimate of variability for the upcoming trial. No two trials are ever conducted under identical conditions subject only to random variation. For instance, the inclusion/exclusion criteria or the centers may be different or

the definition of the disease may have been refined over time. It is more appropriate, therefore, to refer to  $s^2$  as a “guesstimate” of the true variance. The estimate–guesstimate delineation is a reminder that the upcoming trial will not be identical, except for random variation, to the completed one from which  $s^2$  was calculated. This realization prepares us for questioning or challenging our assumptions while the trial is ongoing and possibly even reestimating the sample size from interim trial data.

Values of  $\Delta$  and  $s^2$  that get plugged into the sample size formula often assume compliance to the protocol. But the assumption of compliance itself is one to guard against. As Efron [1] notes: “There could not be worse experimental animals on earth than human beings; they complain, they go on vacations, they take things they are not supposed to take, they lead incredibly complicated lives, and, sometimes, they do not take their medicine.” Too often little attention is paid at the *planning* stage about the consequences of protocol deviations on the power of the trial. Standard sample size formulas do not automatically adjust for imperfect compliance. When subjects prematurely terminate from the trial, their efficacy assessment at the final visit will be missing. If the intention is to analyze per the intent-to-treat principle—a principle that mandates inclusion of all randomized subjects—then the results depend on the imputation method. Careful planning of sample size should acknowledge the pervasiveness of missing data, make realistic projections on the proportion likely to be missing, and calculate the sample size consistent with the proposed imputation method.

Other challenges to sample size calculation arise when subjects midstream change their trial conduct. In blinded trials with long-term follow-up, some subjects may modify their behavior after they become unblinded to the blinded treatment. Unblinding can occur when subjects are able to infer the treatment administered by monitoring the trajectories of their outcomes. Upon becoming unblinded, subjects may then, for example, start taking prohibited study medications, thus confounding the causal assessment of efficacy. Adjusting for such a deviation in the sample size is difficult. The combination of even slightly unrealistic values for  $\Delta$  and  $s^2$ , and deviations from protocol procedures can drastically impact the chance of achieving the trial’s objectives. Section 16.3 discusses this in more detail.

**Strategic** The size of a trial is generally governed by its primary objective. Sometimes, however, trialists have strategic objectives in mind that go beyond the trial’s primary objective. These concern finding expeditious ways to license a drug or terminate the trial early for futility. This situation is best described with some examples. (1) Suppose a sponsor is initiating its phase II trial around the time news on the approval status of its competitor’s drug is forthcoming. The sponsor adopts the following strategy. If the competitor receives approval, then the sponsor will amend the protocol to add another cohort of subjects who would be randomized to the competitor’s newly approved drug or to the sponsor’s experimental treatment. Results from the additional cohort would facilitate planning of the sponsor’s phase III trials by giving them an “early read” of the efficacy of their experimental treatment relative to the newly approved one. If the competitor does not receive approval, then the trial size remains unchanged. (2) In a phase II trial with long-term follow-up, if enrollment turns out to be much slower than expected, the sponsor may no longer wish to wait for trial completion. Instead the sponsor may decide to test for superiority (or noninferiority) on a surrogate endpoint that is measured before the primary clinical endpoint, while continuing enrollment. If superiority (or noninferi-

ority) is established, then enrollment and follow-up for evaluation of the clinical endpoint continues, otherwise the trial terminates for futility. Because the trial may be underpowered with interim data, the sponsor may choose to lower the threshold for demonstration of its objective on the surrogate endpoint.

Such strategic objectives can influence the trial's size, but they may not get written into the trial protocol, particularly when the sponsor's thinking is still evolving at the time of initiating the trial.

**Operational** Trials can be very expensive, especially late-phase trials. The National Heart, Lung, Blood Institute–funded Coronary Drug Project Trial, designed to assess lipid-influencing regimens, randomized 8341 subjects and was reported to cost \$42 million [2], amounting to an average cost of approximately \$5000 per subject. In 2010 this amount is about \$11,000 per subject after adjusting for inflation, a cost by no means out of the ordinary for a typical trial. More expensive trials, particularly those sponsored by nascent pharmaceutical or biotechnology companies, may simply not get off the ground. (The possibility of joint sponsorship with institutions or larger companies is not always viable.) The solution, however, is not necessarily to reduce drastically the trial size because that would also lower the chance of success. Indeed, the failure to demonstrate success has been attributed to an inadequate number of subjects [3]. As aptly put by Lachin [4]: “Clinical trials with inadequate sample size are thus doomed to failure before they begin and serve only to confuse the issue of determining the most effective therapy for a given condition.” A trial that has failed to demonstrate efficacy because it was not sufficiently sized, may simply not get repeated, risking termination of not just the trial but the development of a potentially important therapy. Innovative alternatives to reducing the trial cost need to be considered without substantially compromising statistical power.

**Ethical** If trials could be done on plots of land, many of the challenges noted above would not arise. There would be full adherence to the protocol and ample data, none of it missing. But ethical concerns with human participation bring the size of trials into glare. Trials with mortality or irreversible morbidity as the primary variable lend themselves to extra scrutiny if they are too small or too large. Small-sized trials have a low probability of success and a high probability of equivocal results, whereas excessively large trials expose more subjects than necessary to at least one suboptimal or detrimental therapy. Ethical concerns sharply bring to focus the point that subjects are, after all, volunteers who provide data to help trialists decide fairly conclusively whether or not the experimental treatment (a) can proceed to the next stage for further testing or (b) is safe and effective for licensure.

## 16.2 STATISTICAL METHODS FOR DETERMINING TRIAL SIZE

In this section an outline of the methods for calculating the sample size for different analysis methods will be described. The methods will be described in some detail for differences in means and proportions, but sketched for the time-to-event endpoint. The level of detail in this section is intended to provide a basic understanding. For an in-depth understanding the references in this section and the next should be consulted. The excellent paper by Lachin [4] belongs to the “must read” category.

### 16.2.1 Difference in Means

Let  $Z_\alpha$  and  $Z_\beta$  denote the  $\alpha$  and  $\beta$  percentiles of the normal distribution, respectively. Power is mathematically expressed as

$$1 - \beta = P(Z > Z_{1-\alpha} | \Delta) \quad (1)$$

Un-normalizing the  $Z$  test gives

$$1 - \beta = P\left(\frac{\hat{\Delta}}{\sqrt{\text{Var}(\hat{\Delta})}} > Z_{1-\alpha} | \Delta\right) \quad (2)$$

where  $\hat{\Delta}$  is the estimated treatment effect and where  $\text{Var}(\hat{\Delta}) = 4\sigma^2/N$ , with  $\sigma^2$  denoting the variance of each observation and  $N$  denoting the *total* trial size. The above equation simplifies to

$$1 - \beta = P\left(Z > \frac{Z_{1-\alpha}\sqrt{\text{Var}(\hat{\Delta})} - \Delta}{\sqrt{\text{Var}(\hat{\Delta})}}\right) \quad (3)$$

If the two treatments are identical (i.e.,  $\Delta = 0$ ), then regardless of the size of the trial, power equals the false-positive rate  $\alpha$ . From (3)

$$Z_\beta = \frac{Z_{1-\alpha}\sqrt{\text{Var}(\hat{\Delta})} - \Delta}{\sqrt{\text{Var}(\hat{\Delta})}}$$

We almost always choose power to exceed 50%, so  $Z_\beta$  is negative. Noting that  $-Z_\beta = Z_{1-\beta}$  we solve for  $N$  to get the total sample size:

$$N = \frac{4\sigma^2 (Z_{1-\alpha} + Z_{1-\beta})^2}{\Delta^2} \quad (4)$$

For  $\alpha = 0.025$  it is simpler to remember the total sample size as  $N = 42/(\text{signal-to-noise ratio})^2$  for 90% power or  $N = 32/(\text{signal-to-noise ratio})^2$  for 80% power where  $\Delta/\sigma$  denotes the “signal-to-noise ratio.” When testing on the difference scale a trial with 90% power requires about 30% more subjects than a trial with 80% power (and  $\alpha = 0.025$ ).

The sample size calculation relies on the  $Z$  test, which assumes that the variance is known. The data are analyzed, however, using the  $t$  test instead, which is like the  $Z$  test, except that the variance is estimated from the data. There is very little loss in power caused by the discrepancy in using one statistic ( $Z$  test) for calculating power and another ( $t$  test) for analyzing data. The  $Z$  and  $t$  tests make assumptions that (a) the variances associated with each treatment are equal, and (b) the data are normally distributed. Do violations of any, or both, of these assumptions make the sample size formula unreliable? There may be some loss in power due to violations of assumptions but (4) is still reliable. The  $t$  test is remarkably robust to violations in assumptions. Posten, Yeh and Owen [5] study robustness when the equal variance

assumption is violated. A powerful conclusion they reach in the case of normal data and a sample size of 15 per group is that “no matter how much  $\sigma_1^2$  varies from  $\sigma_2^2$ , the true significance level [of the  $t$  test] is within 0.01 units of the desired level  $\alpha = 0.05$ .” Heeren and D’Agostino [6] demonstrate the robustness of the  $t$  test for data on 3, 4, or 5-point ordinal scales. Aside from invoking normality to analytically calculate power, power may also be empirically calculated by simulating data under the alternative for the type of nonnormal data at hand (e.g., ordinal or skewed data).

Some investigators [7] have argued that the sample size calculated by the above method is “really large.” They say that this method “permits an illogical interpretation that tempts investigators and plagues readers. The large sample size can lead one to declare an unimportant difference important.” What they mean by this is that an unimportant but statistically significant difference in means may be interpreted as clinically meaningful. It would be inappropriate to conclude, as the authors assume readers are wont to do, that a statistically significant result is clinically meaningful. They instead advocate the following sample size that was proposed by Feinstein [8]:

$$N \geq \frac{4\sigma^2 Z_{1-\alpha}^2}{\Delta^2} \quad (5)$$

According to them power is not the issue—instead one needs to pick an “intellectually honest”  $\Delta$  before data collection and then draw inferences by reference to  $\Delta$  and 0. The following explains their recommendation (wherein positive values of  $\Delta$  signify improvement, LL and UL denote the lower and upper confidence limits around  $\hat{\Delta}$ ):

If  $\hat{\Delta} > \Delta$  and  $LL > 0$ , conclude an important difference.

If  $\hat{\Delta} < \Delta$  and  $LL < 0$ , concede the null.

If  $\hat{\Delta} < \Delta$  but  $LL > 0$  and  $UL > \Delta$ , conclude an important difference may exist.

If  $LL > 0$  and  $UL < \Delta$ , conclude result is unimportant even though statistically significant.

Their approach, however, is not feasible. First, as an inequality (5) does not indicate how large  $N$  should be relative to  $4\sigma^2 Z_{1-\alpha}^2 / \Delta^2$ . Second, power is paramount, although the authors do not believe in it. In the end it is necessary to know what chance of success a sponsor has of meeting the trial’s objectives. For example, with  $\Delta = \sigma = 1$ , an  $N$  equal to  $4\sigma^2 Z_{1-\alpha}^2 / \Delta^2$  would require 16 subjects ( $\alpha = 0.025$ ). The power of declaring that  $\hat{\Delta}$  is statistically significantly different from 0 is approximately 50%; the power of declaring that an important difference exists (as they have defined it) would be even less. Why would a sponsor undertake a trial that has less than a 50% chance of finding an important difference? Third, presupposing an “intellectually honest”  $\Delta$  belies the reality that proposing a carefully thought-through  $\Delta$  may involve the weighing of evidence from fragmentary and conflicting data. It would be unrealistic to expect a sponsor, a regulatory agency, or a committee advising the agency to all agree on the same value of  $\Delta$ . If clinical rather than statistical significance is of interest, then it would be better to power the trial so that the LL

exceeds the clinically important difference. However, the power required for a clinically important difference would result in an even *larger* sample size than (4).

### 16.2.2 Differences in Means Adjusted for Baseline Data

When baseline data on the same endpoint are available, variability can be reduced by taking the change from baseline or by fitting an analysis of covariance (ANCOVA) model. Under standard assumptions ANCOVA improves variability by nearly  $1 - r^2$  [9] and  $0.5(1 + r)$  [10] compared to the unadjusted and change from baseline models, respectively, where  $r$ , which takes values between  $-1$  and  $1$  [11], denotes the correlation of the baseline and posttreatment data. (For pre/post data,  $r$  usually takes values between  $0$  and  $1$ .) The sample size for the ANCOVA model is obtained as  $N_{\text{adj}} = N(1 - r^2)$  where  $N$  is as shown in (4). Since ANCOVA results in a smaller variance than change from baseline, there is no reason to continue to use change from baseline as the endpoint.

### 16.2.3 Difference in Proportions

A simple method for calculating the sample size for comparing the difference in proportions makes use of the fact that the proportions are approximately normally distributed. The derivation proceeds along the same lines as for the difference in means with one important distinction explained below.

The null and alternative hypotheses are:  $H_0: p_1 - p_2 = 0$  and  $H_1: p_1 - p_2 = \Delta$ , where  $p_1$  and  $p_2$  denote population proportions. The estimate of the treatment effect is  $\hat{\Delta} = \hat{p}_1 - \hat{p}_2$ . The important distinction is that there are two formulas for the variance of  $\hat{\Delta}$  that feature in the sample size formula: one under the null hypothesis and the other under the alternative. We start by rewriting (2) as

$$1 - \beta = P\left(\frac{\hat{\Delta}}{\sqrt{\text{Var}_{H_0}(\hat{\Delta})}} > Z_{1-\alpha} | \Delta\right)$$

where the variance under the null is  $\text{Var}_{H_0}(\hat{\Delta}) = (4/N) \bar{p}(1 - \bar{p})$  and  $\bar{p} = (p_1 + p_2)/2$  is the average of the proportions specified under the alternative. Recognizing that power is calculated under the alternative, this can be reexpressed as

$$1 - \beta = P\left(Z > \frac{Z_{1-\alpha} \sqrt{\text{Var}_{H_0}(\hat{\Delta})} - \Delta}{\sqrt{\text{Var}_{H_1}(\hat{\Delta})}}\right) \quad (6)$$

where the variance under the alternative is

$$\text{Var}_{H_1}(\hat{\Delta}) = \frac{2}{N} \{p_1(1 - p_1) + p_2(1 - p_2)\}$$

The total sample size derived from (6) is

$$N = \frac{[Z_{1-\alpha} \sqrt{4\bar{p}(1 - \bar{p})} + Z_{1-\beta} \sqrt{2p_1(1 - p_1) + 2p_2(1 - p_2)}]^2}{\Delta^2} \quad (7)$$

Noting that  $\text{Var}_{H_0}(\hat{\Delta}) \geq \text{Var}_{H_1}(\hat{\Delta})$  a more conservative sample size formula is obtained by replacing  $\text{Var}_{H_1}(\hat{\Delta})$  in (6) with  $\text{Var}_{H_0}(\hat{\Delta})$  giving

$$N = \frac{4\bar{p}(1-\bar{p})(Z_{1-\alpha} + Z_{1-\beta})^2}{\Delta^2} \quad (8)$$

Formulas (7) and (8) yield approximate but not exact power. This is because the difference in proportions has a discrete distribution that is only approximately normal. Adjustments have been proposed so that power of the test gets closer to the stated value of  $1 - \beta$  [12]. The formula implemented in the sample size software nQuery Advisor [13] is the one proposed by Fleiss, Tytun, and Ury [14]; their formula is

$$N' = N + \frac{4}{|p_1 - p_2|} \quad (9)$$

where  $N$  is shown in (7).

When either proportion is expected to be very small ( $\leq 0.05$ ) or very large ( $\geq 0.95$ ), Fisher's or Barnard's [15] exact test is used for analysis because tests that rely on the normal approximation are less reliable. The sample size calculation should then reflect the power of the exact test and not one based on the normal approximation. It is beyond the level of technical detail intended for this chapter to describe the exact methods, but the interested reader is referred to [16]. Gordon [17] provides an excellent review of the sample size methods for comparing proportions.

#### 16.2.4 Time to Event

Instead of analyzing data on a binary scale, the time to the occurrence of the event (i.e., time to event) is often a more powerful analysis [18]. The sample size calculation is sketched for one of the more commonly used time-to-event test statistics, the log-rank test [19].

The concept of a hazard is central in time to event analysis. Loosely put, the hazard at time  $t$  is the instantaneous risk that the event will occur at time  $t$ . A large portion of the sample size literature rests on the assumption that the hazard of an event at any given time for one treatment group is proportional to the hazard at that time for the other treatment group. The assumption of proportional hazards enables the derivation of the sample size formula for the log-rank statistic, although once the data become available, the log-rank test remains valid even if that assumption is unmet.

The null and alternative hypotheses are:  $H_0: \lambda_1(t)/\lambda_2(t) = 1$  and  $H_1: \lambda_1(t)/\lambda_2(t) = \Delta$ , where  $\lambda(t)$  denotes the hazard of an event at time  $t$  for an individual. On a log scale we test  $H_0: \log_e \lambda_1(t) - \log_e \lambda_2(t) = 0$  against  $H_1: \log_e \lambda_1(t) - \log_e \lambda_2(t) = \log_e \Delta$ . For large samples, the log-rank statistic has an approximate normal distribution with mean  $\log_e \Delta$  and, under a 1:1 allocation ratio, variance  $4/d$ . Following the same steps in this section in going from Equations (1)–(3), we see that the variance of the log-rank statistic can also be written as  $(Z_{1-\alpha} + Z_{1-\beta})^2/(\log_e \Delta)^2$ . Therefore, the

number of events required to achieve power  $1 - \beta$  at a type I error rate of  $\alpha$  is  $d = [4(Z_{1-\alpha} + Z_{1-\beta})^2] / (\log_e \Delta)^2$ .

The required number of subjects is obtained from  $N = d/P(\text{event})$  where  $P(\text{event})$  is the probability of the event and is a function of efficacy, the accrual rate, and follow-up period. For randomized trials  $P(\text{event})$  is the average of  $P(\text{event in group 1})$  and  $P(\text{event in group 2})$ . To obtain this probability for each treatment group, let  $a$  denote the accrual period,  $f$  denote the follow-up period going from the end of accrual to a fixed period (in the same time unit), and assume that enrollment occurs at a uniform rate. Then it can be shown that  $P(\text{event in group } i)$  equals

$$1 - 1/6 \{P_i(T > f) + 4P_i(T > 0.5a + f) + P_i(T > a + f)\} \quad (10)$$

for  $i = 1, 2$  [20]. In the equation above,  $T$  is a random variable denoting the time to event, and the notation  $P_i(T > x)$  denotes the probability that the time to event in group  $i$  exceeds  $x$ . When enrollment is simultaneous,  $a = 0$ , and  $P(\text{event in group } i)$  simplifies to  $1 - P_i(T > f)$ . When enrollment is staggered  $P_i(T > f)$ ,  $P_i(T > 0.5a + f)$ , and  $P_i(T > a + f)$  are all decreased as the accrual period increases, and (10) shows how this increases the probability of the occurrence of an event.

Often a terminal event such as death or irreversible morbidity is the “event” in time-to-event trials. (Such trials also get the most media attention.) It is therefore important to understand the concept of hazards, the derivation of the formula, and the assumptions that the formula depends upon beyond the silhouette presented above. A highly accessible account of the sample size derivation is in Collett [20]. Other useful references include George and Desu [21], Schoenfeld [22], and Lachin and Foulkes [23]. A novel method to calculate the sample size that does not make any of the restrictive assumptions is discussed in Section 16.3.

## 16.3 REALISTIC ASSESSMENT OF TRIAL SIZE

PhRMA (the Pharmaceutical Research and Manufacturers of America) says that of drugs completing Phase II trials, about 50% fail in Phase III, often for lack of efficacy (quoted in [24]). But Temple [24] points out that phase II trials are meant to demonstrate efficacy, so it is startling that the phase III failure rate is as high as 50%. It may well be that when sizing phase III trials misjudgments in  $\Delta$  or  $s^2$  contribute to the high failure rate. This section will discuss the sensitivity of the sample size to various assumptions regarding  $\Delta$ ,  $s^2$ , and protocol compliance.

### 16.3.1 Misspecification of Rates

A simple hypothetical example is presented to help understand better why the sample size (or, equivalently, power) is so sensitive to the initial assumptions. Table 1 displays the sample sizes for 80 and 90% power for testing  $H_0: p_1 - p_2 = 0$  against  $H_1: p_1 - p_2 = 0.07$ . As explained in Section 16.2, to calculate the sample size or power we also need the presumed population proportions. Suppose we believe that  $p_1 = 0.12$  and  $p_2 = 0.05$  are the true population proportions. Table 1 shows that we need a total of 552 subjects to have 80% power and 720 subjects for 90% power. If in reality the population proportions are instead  $p_1 = 0.13$  and  $p_2 = 0.06$ , a slight change from our

**TABLE 1 Sample Sizes under Various Assumptions ( $\alpha = 0.025$ )**

|                   |      |      |      |      |
|-------------------|------|------|------|------|
| $p_1$             | 0.12 | 0.13 | 0.14 | 0.13 |
| $p_2$             | 0.05 | 0.06 | 0.07 | 0.07 |
| $p_1 - p_2$       | 0.07 | 0.07 | 0.07 | 0.06 |
| $N$ (power = 80%) | 552  | 606  | 656  | 848  |
| $N$ (power = 90%) | 720  | 790  | 860  | 1114 |

Note: Samples sizes obtained from nQuery Advisor Version 5.0 or equivalently from (9).

| Stratum | Social Class and Gender | Treatment A |             |                  | Treatment 2 |             |                  |
|---------|-------------------------|-------------|-------------|------------------|-------------|-------------|------------------|
|         |                         | $n_A$       | $\bar{y}_A$ | $\hat{\sigma}_A$ | $n_B$       | $\bar{y}_B$ | $\hat{\sigma}_B$ |
| 1       | Low, female             | 41          | 1.38        | 0.22             | 40          | 1.36        | 0.28             |
| 2       | Low, male               | 41          | 1.26        | 0.25             | 38          | 1.28        | 0.19             |
| 3       | Medium, female          | 33          | 1.51        | 0.31             | 35          | 1.41        | 0.27             |
| 4       | Medium, male            | 45          | 1.46        | 0.28             | 46          | 1.39        | 0.33             |
| 5       | High, female            | 18          | 1.61        | 0.34             | 20          | 1.51        | 0.41             |
| 6       | High, male              | 23          | 1.59        | 0.46             | 23          | 1.44        | 0.30             |

Source: From Fleiss [25].

assumptions although the difference of 0.07 is maintained, we need 606 and 790 subjects for 80 and 90% power, respectively. The sample size increases even though  $\Delta$  is unchanged because  $\text{Var}(\hat{\Delta})$  increases. The next column shows a similar increase in sample sizes (656 and 860 subjects for 80 and 90% power) for a similar increase in the proportions. The last column shows how significant the impact can be if both the proportions and the difference in proportions are slightly off target. For  $p_1 = 0.13$  and  $p_2 = 0.07$  we need 848 and 1114 subjects, respectively, for 80 and 90%. (Note that in each case the sample size for 90% power is roughly 30% more than the sample size for 80% power.)

### 16.3.2 Misrepresentation of Estimate of Treatment Effect and Variance

Consider the data in Table 2 on 403 subjects displayed by social class and gender for two treatments [25]. We assume the data were obtained from a trial that employed the method of simple (permuted block) randomization. Further assume that the design of the upcoming trial is similar to the completed one. When data become available for the upcoming trial, the analysis will adjust for the six stratification factors to reduce variability. Although the data in Table 2 suggest that there is no evidence of treatment by stratum (social class or gender) interaction, we will assume for the sake of illustration that such an interaction exists. We use this information to estimate the variability of  $\hat{\Delta}$ .

It is common to estimate the treatment effect as  $\hat{\Delta} \sum_{i=1}^6 w_i \hat{\Delta}_i / (\sum_{i=1}^6 w_i)$  where  $\hat{\Delta}_i$  is the estimated effect for the  $i$ th stratification level, and where  $w_i$  is a weight that is a function of the number of subjects in each cell in the  $i$ th stratum. For example, for  $i = 1$ ,  $\hat{\Delta}_1 = 1.38 - 1.36 \equiv 0.2$  and  $w_1 = 41 \times 40 / (41 + 40) \equiv 20.25$ . When interaction exists, which is another way of saying that  $\Delta_i$ 's are not all equal, then  $\hat{\Delta}$

is biased [26]. The reason  $\hat{\Delta}$  is biased is because the weights,  $w_i$ 's, are treated as fixed constants, whereas according to the trial design the weights are random. (If randomization was stratified within each stratum, then  $\hat{\Delta}$  is unbiased [27]). Moreover, the pooled estimate of variance is as an underestimate. The pooled variance estimate,  $s^2$ , is calculated as a weighted average of the variance in each cell in Table 2:

$$\left\{ \frac{(41-1) \times 0.22^2 + (40-1) \times 0.28^2 + \dots}{+(23-1) \times 0.30^2} \right\} / (40 + 39 + \dots + 22) = 0.0883$$

Typically, this is the value of  $s^2$  that gets plugged in (4) to calculate the sample size. This variance is known as the conditional variance where the condition is the observed number of subjects in each of the 12 cells. Because  $\hat{\Delta} = \sum_{i=1}^6 w_i \hat{\Delta}_i / (\sum_{i=1}^6 w_i)$  is biased when interaction exists, the unweighted and unbiased estimate of the treatment effect may be preferred. Accordingly, we need to use the appropriate variance formula. It has been shown that [26] the unconditional variance is

$$\text{Var}(\hat{\Delta}) \approx \frac{4}{N} \left( \sigma^2 + \frac{K}{2} \right)$$

where  $K = \sum_i \pi_i \{(\mu_{Ai} - \mu_A)^2 + (\mu_{Bi} - \mu_B)^2\}$ ;  $\pi_i$  denotes the proportion of subjects who belong to the  $i$ th stratification level ( $i = 1, 2, \dots, 6$ ),  $\mu_{Ai}$  and  $\mu_{Bi}$  denote the population means of treatments A and B for the  $i$ th strata with  $\mu_A = \sum \pi_i \mu_{Ai}$  and  $\mu_B = \sum \pi_i \mu_{Bi}$  denoting the population means. The unconditional variance adds  $K/2$  to the pooled variance  $\sigma^2$  to free the conditional variance from requiring inferences limited to fixed cell sizes. Just as the data in Table 2 provided an estimate of  $\sigma^2$ , so too we use the data to estimate  $\pi_i$ ,  $\mu_{Ai}$ ,  $\mu_{Bi}$ ,  $\mu_A$ , and  $\mu_B$ . For example, the estimate of the proportion of subjects who belong to the "medium, female" level,  $\pi_3$ , is  $68/403 = 0.17$  and the estimates of  $\mu_{A3}$  and  $\mu_{B3}$  are 1.51 and 1.41, respectively. Substituting estimates for population parameters, we get  $K/2 = 0.0065$ , so the pooled estimate of variance goes from 0.0883 to  $0.0883 + 0.0065 = 0.0968$ .

The sample size formula corresponding to the unconditional variance becomes

$$N = \frac{(4\sigma^2 + 2K)(Z_{1-\alpha} + Z_{1-\beta})^2}{\Delta^2} \quad (11)$$

Using the conventional sample size formula (4) gives a total sample size  $N$  of 772 subjects to achieve 80% power, whereas (11) requires 964 subjects to achieve the same power, an increase of 25%. Put another way, the power that will be achieved with 772 subjects is 70% and not, as claimed, 80%. The tradition of using an unconditional variance for sample size is common in survey sampling but not, however, in the clinical trials literature. [Because the population proportions are known in survey sampling, the unconditional variance expression is different from (11)]. For survey sampling the unconditional variance has been recommended by none other than Deming [28] who says that it is the "formula which one will use at the planning stage."

### 16.3.3 Sensitivity to Projected Number of Events

A large vaccines trial was designed to reduce the burden of illness due to herpes zoster in a population at least 60 years of age with a minimum of 6 months of follow-up [29]. Approximately 38,000 subjects included in the analysis received either an investigational vaccine or placebo, in a 1:1, randomized, double-blind manner. Although the primary analysis variable for the trial was the relative reduction in the herpes zoster burden of illness score, we will consider the relative reduction in the proportion of subjects with herpes zoster.

There were a total of 957 confirmed cases of herpes zoster included in the analysis, 315 among vaccine recipients and 642 among placebo recipients. The relative risk is 0.49 and the 95% confidence interval (CI) is (0.43, 0.56). Because the interval excludes 1, the result is statistically significant. (In fact, since the upper limit is much below 1, the investigational vaccine substantially reduced the rate of herpes zoster.) Table 3 shows the observed result in the first row and hypothetical ones in the next two rows. Comparing the first and second rows, we see that width of the CI is the same even though  $N$  in the second row is less by 28,000 subjects. The massive reduction in sample size has no effect on the width of the interval because the variance of ratios of estimates of event rates is driven by the number of events (and only trivially by the total sample size). Comparing the second row with the third, we see that  $N$  is the same but the number of cases are halved and that this only slightly increases the width of the interval. Although the reduction in number of cases from 957 to 450 is large, the result is, in effect, unchanged. This is because the relative risk  $Z$  values for both are very large, raising questions whether the trial was overpowered. An interim analysis allowing for early termination upon demonstration of a significant reduction in herpes zoster cases may have markedly reduced the trial size. Indeed, if mortality were the outcome variable, an interim analysis would be mandatory so that the trial not enroll more subjects than necessary.

### 16.3.4 Deviations from Assumptions and from Protocol Procedures

Here we consider sample size assessment when the outcome variable is binary or time to some event and when there is loss to follow-up, noncompliance, “drop-in,” nonproportional, or nonconstant hazards. (Drop-in refers to subjects changing their randomized treatment in violation of protocol procedures.) For binary outcomes Lakatos [30] has presented a method for calculating the sample size under such realistic conditions. His method uses a Markov model for adjusting the proportions,  $p_1$  and  $p_2$ , for losses due to noncompliance, drop-in, and so forth. Each treatment group is modeled separately. In Lakatos’ Markov model, a transition matrix is

**TABLE 3** Number of Cases of Herpes Zoster,<sup>a</sup> Relative Risk Estimates and 95% CI

| Sample Size        | Vaccine | Placebo | Relative Risk | 95% CI       |
|--------------------|---------|---------|---------------|--------------|
| $N \approx 38,000$ | 315     | 642     | 0.49          | (0.43, 0.56) |
| $N^* = 10,000$     | 315     | 642     | 0.49          | (0.43, 0.56) |
| $N^* = 10,000$     | 150     | 300     | 0.50          | (0.41, 0.61) |

*Note:* The number randomized to each group is roughly  $N/2$ . The first row shows real data, the next two rows (indicated by  $N^*$ ) show hypothetical data.

<sup>a</sup>From [29].

created for each time interval (the length of the time interval is user specified). The rows and columns of the transition matrices are states subjects belong to and will transition to with probabilities that are also specified by the user. Typical examples of states that subjects belong to include: a loss to follow-up state (no further information available for that subject), an event state (subject has had the event), an at-risk state for a subject who is a complier (subject is at risk of experiencing the event assuming compliance), and an at-risk state for a subject who is a noncomplier (subject is at risk of experiencing the event assuming noncompliance). Needless to say, subjects would transition from at-risk states to the same or other states, but not from a loss to follow-up or an event state to an at-risk state. At the beginning of the trial the probability of belonging to the at-risk state is 1 for compliers and is 0 for all other states. At the end of the trial the probability of belonging to any particular state is the Markov process, obtained as the product of the transition matrices. The adjusted proportions,  $p_1$  and  $p_2$ , obtained from the Markov process for the end of the trial get plugged in the sample size formula.

Lakatos compares the sample size for the SHEP (systolic hypertension in the elderly program) trial calculated the traditional unadjusted way and upon application of the Markov model. The outcome variable for the trial was fatal or nonfatal stroke. Subjects were to be followed for a minimum of 4 years. The experimental treatment was assumed to lower the rate of stroke relative to control by 40%. Without adjusting for losses, noncompliance, and drop-ins the control and treatment rates were assumed to be 0.0775 and 0.0471, respectively. Application of (9) results in a sample size of 2784 to achieve 90% power ( $\alpha = 0.025$ ). After making reasonable adjustments for noncompliance, losses to follow-up, and the like, the Markov model gave rates of 0.0677 and 0.0463. With these rates, the required sample size is 5116.

Lakatos later [31] extended his method for the log-rank statistic enabling calculation of the sample size under unrestrictive conditions. Unlike other methods in the literature, Lakatos' method does not rely on the assumption of proportional hazards. Indeed, the advantage of this method is that it can accommodate any arbitrary pattern of data projected for the future. The difference in sample sizes calculated with and without adjustments for loss to follow-up, noncompliance, and drop-in for nonproportional hazards data is striking. For example, in Table 2 of Lakatos [30], assuming constant recruitment the sample size to achieve 90% power is 4397 ( $\alpha = 0.025$ ). For the same constant recruitment assumption but adjusting for a lag effect (i.e., a certain type of nonproportional hazard), modest loss to follow-up, noncompliance, and drop-in rates the required sample size is 8009.

These examples exemplify the point that trialists should pay careful consideration at the planning stage of the impact on power when rates are misspecified or when protocol compliance is less than perfect.

## 16.4 SAMPLE SIZE REESTIMATION

Methods have been proposed to estimate the variance while the blinded trial is still ongoing to allow for reestimation of the sample size. One option is to break the treatment code after data on some fraction of subjects has become available

and estimate the variance. However, because this step unblinds the trial, it has to be done with much forethought. One has to be concerned about protecting the integrity of trial results at its scheduled termination due to interim unblinding. Here we discuss a method proposed for continuous outcome variables that does not require breaking the blind [32, 33]. To apply the method it suffices to know the enrollment order and randomization block size. The method is simple to apply and works reasonably well for small randomization block sizes when compared to its unblinded counterpart. It works as follows. At an interim stage we have data on the outcome variable for, say,  $\tilde{N}$  subjects. Suppose the randomization block size is  $n$  and there are  $k$  blocks, so that  $\tilde{N} = nk$ . Denote the data on the outcome variable as

$$Y_{11}, Y_{21}, \dots, Y_{n1} | Y_{12}, Y_{22}, \dots, Y_{n2} | \dots | Y_{1k}, Y_{2k}, \dots, Y_{nk}$$

The data structure written this way means that of the first set of observations,  $Y_{11}, Y_{21}, \dots, Y_{n1}$ , half of those belong to one treatment group and the other half to the other treatment group. Of the second set of  $n$  observations,  $Y_{12}, Y_{22}, \dots, Y_{n2}$ , half belong to one group and half belong to the other, and so on until the last set  $Y_{1k}, Y_{2k}, \dots, Y_{nk}$ .

Take the sum of the  $Y$ 's within each set. For the  $j$ th set denote this sum by  $T_j$ . The blinded variance estimator is (variance of  $T_j$ )/block size or:

$$\tilde{\sigma}^2 = \frac{1}{n} \frac{\sum_{j=1}^k (T_j - \bar{T})^2}{k-1} \quad (12)$$

This blinded variance estimator is unbiased and achieves minimum variance—that is, the variation in  $\tilde{\sigma}^2$  is smallest—when  $k$  equals the number of treatments. The following example demonstrates how the method works.

Normally distributed data of size 20 with seed 1234 were generated in SAS version 8.2 with mean 0 and variance 1 for group 1 and mean 2 and variance 1 for group 2. If the means are equal, then blinded data estimation of variability would amount to unblinded estimation. For this reason the means chosen were sufficiently different. The data are shown in Table 4. Assume the randomization block size is 2. Data that belonged to the blocks were taken to be those generated sequentially by SAS for the chosen seed. The first two observations, one from each group, were assigned to block 1, the next two to block 2, and so on. The unblinded estimates of the variances of the data in groups 1 and 2 are 1.19 and 1.81, respectively. Since they are estimating the same variance, we take their average, 1.24, as the unblinded variance estimate. From (12) the blinded variance estimate is 1.28, a result similar to the unblinded estimate. As the block size gets larger, the performance of the blinded variance estimator is less impressive. For normally distributed data, the ratio of the standard deviation of the blinded variance estimator relative to its unblinded counterpart is  $\sqrt{n(\tilde{N}-2)/(\tilde{N}-n)}$ ; for  $n = 2$  the ratio equals  $\sqrt{2}$  [32]. This method based on block sums has been extended to estimate the variance after adjusting for covariates [33]. Other simple methods are also available for estimating the within-group variance [34, 35]. These methods depend, however, on guessing the true treatment effect and are limited to two-treatment trials.

**TABLE 4 Blinded Variance Reestimation Example**

| Block | Group 1 | Group 2 | Block Sum |
|-------|---------|---------|-----------|
| 1     | 0.277   | 3.462   | 3.74      |
| 2     | 0.299   | 0.293   | 0.59      |
| 3     | 0.895   | 1.396   | 2.29      |
| 4     | 0.591   | 2.857   | 3.45      |
| 5     | -0.331  | 2.874   | 2.54      |
| 6     | -1.839  | 1.990   | 0.15      |
| 7     | -1.261  | 1.321   | 0.06      |
| 8     | 0.902   | 0.867   | 1.77      |
| 9     | -0.701  | 1.378   | 0.68      |
| 10    | -0.829  | 3.049   | 2.22      |
| 11    | -1.21   | 0.141   | -0.98     |
| 12    | 0.657   | 4.126   | 4.78      |
| 13    | -1.487  | 4.192   | 2.71      |
| 14    | -1.409  | 1.880   | 0.47      |
| 15    | 0.648   | 1.491   | 2.14      |
| 16    | 1.246   | 2.351   | 3.60      |
| 17    | -1.072  | 2.978   | 1.91      |
| 18    | -0.067  | 1.913   | 1.85      |
| 19    | 0.925   | 2.208   | 3.13      |
| 20    | -2.490  | 1.393   | -1.10     |

Note: Group 1 is  $N(0, 1)$  and group 2 is  $N(2, 1)$ . Data generated in SAS (version 8.2) using seed 1234. The unblinded pooled variance is 1.24, the blinded variance, for block size 2, is 1.28.

## 16.5 POINTS TO CONSIDER WHEN PLANNING SIZE OF TRIAL

The topics discussed above will be summarized in this section after briefly discussing noninferiority/equivalence trials and unequal allocation.

### 16.5.1 Noninferiority/Equivalence Trials

When the control is a marketed product, it is not uncommon to design a noninferiority trial in which the objective is to demonstrate that the experimental treatment is not inferior to control. For example, a sponsor may wish to demonstrate that the once-a-day dosing regimen of its experimental treatment is not inferior to the twice-a-day dosing regimen of an approved drug. The critical issue is the choice of a “margin” that defines noninferiority. For superiority trials, the margin is unambiguously defined to be 0; in other words, to establish superiority, the objective is to demonstrate that  $\hat{\Delta}$  is statistically significantly different from 0. For noninferiority trials the objective is to demonstrate that  $\hat{\Delta}$  is statistically significantly different from some margin  $\delta$ . For example, to demonstrate whether the experimental treatment is not inferior to a marketed control, the sponsor may wish to test whether the difference (experimental minus control) in the proportion of subjects surviving at the end of the trial is greater than  $\delta = -10\%$ . A regulatory agency, such as the FDA, may consider it more appropriate if instead  $\delta = -5\%$ . The choice of  $\delta = -5\%$  is a more difficult objective to meet than  $\delta = -10\%$  and requires a larger sample size.

Equivalence trials involve a lower and an upper margin,  $(\delta_L, \delta_U)$ . An example of an equivalence trial is a vaccine lot consistency trial whose goal is to demonstrate

that the vaccine lots (as assessed, e.g., by the titer values obtained in a clinical trial across the different vaccine lots) are equivalent.

The null hypothesis for noninferiority is  $H_0: \Delta \leq \delta$  and for equivalence is  $H_0: \Delta \leq \delta_L$  or  $H_0: \Delta \geq \delta_U$  with alternative hypotheses, respectively,  $H_1: \Delta > \delta$  and  $H_1: \delta_L < \Delta < \delta_U$ . The sample size derivation for two-treatment noninferiority/equivalence trials is conceptually similar to that for superiority. However, since the sample size is calculated under the alternative hypothesis, a value of  $\Delta$  needs to be specified. In some equivalence trials it has been common to let  $\Delta = 0$ ; this is often a mistake. For vaccine lot consistency (or equivalence) trials, it is demonstrated why the  $\Delta = 0$  assumption may lead to a severely underpowered trial [36]. Following the steps in Section 16.2 for calculating the sample size for noninferiority/equivalence will make evident why the choice of the margin(s) influences the trial size. In particular, the closer the margin(s) is to 0, the larger the sample size. Before planning the size of a noninferiority or equivalence trial, the sponsor needs to be confident in its choice of margin(s). Useful references for determining the sample size in noninferiority/equivalence settings include Farrington and Manning [37] and Nam [38].

### 16.5.2 Unequal Allocation

Although the variance is minimized when the allocation to the two treatments is equal, in large placebo-controlled trials it is not uncommon to allocate more subjects to the experimental treatment. Such allocation provides more safety data for the experimental treatment in subjects who are representative of the population to be treated. In small- to midsized dose-ranging trials where the objective is often to compare increasing doses of the drug to control, it is statistically preferable to allocate more subjects to control, yet it is not uncommon to allocate an equal number of subjects to each group. Such an allocation provides more data on various doses of the drug at a stage in the drug's development when there is little prior evidence of its dose-ranging activity or efficacy. In the large or the dose-ranging trial pragmatism was elevated over statistical idealism. Before determining the sample size, first an allocation ratio deemed to be pragmatically (but not necessarily statistically) appropriate should be determined.

## 16.6 CONCLUSION

In conclusion, the gist of the chapter can be organized around a few assertions. Determining the number of subjects needed is much more than a calculation. Unfortunately, too often the sample size assessment is done mechanically. The inputs to the sample size formula require carefully combining pieces of information. This is where collaboration between statisticians and nonstatisticians is most important. In general, the presumed values of efficacy and variance should be on the conservative side. The impact of missing data should be considered upfront. As stated by Lavori [39]: "Do not expect nature to be kind . . . Many power calculations are based on expected causal differences (what would happen under complete control), and not on expected practical differences (when uncontrolled extra treatments or undelivered study treatments intervene)." It is very helpful to calculate sample sizes under various values of presumed efficacy and variance after adjusting those values by the

intended imputation method for missing data expected in the trial. When the trial is ongoing, examine the blinded data for noncompliance. The impact of disproportionate noncompliance should be assessed. If possible, estimate the variance without breaking the blind after applying the imputation method that was stated in the trial protocol. If the blinded variance estimate is very different from the assumed variance, then recalculate the power of the trial and evaluate the options. Monitor the number of events for time-to-event or relative risk analyses, recalling that the variance is a function of the number of events not the total number of subjects. It will be informative to compare the total number of events observed during the blinded portion with the number that was projected in the sample size calculation.

The calculation of the size of a trial, like any other learning process, is iterative, and not a one-step solution. A more reliable sample size will be obtained if the factors that influence it are given due attention and subject to debate, the assumptions challenged, the blinded data evaluated than if the calculation is performed mechanically.

### **17.1 INTRODUCTION**

Treatment recommendations in guidelines are mainly based on the results of randomized controlled trials (RCTs) [1]. Results of RCTs should provide the closest possible approximation to the truth. Bias-reducing safeguards (e.g., concealments of randomization and blinding) are important because their omission can exaggerate a treatment effect by 20–45% relative to the true treatment effect [2]. Overestimation in this order may be important since most RCTs seek to detect treatment

**TABLE 1** Quality of Different Allocation Methods<sup>a</sup>

| Allocation by | Constant Probability | Equal Probability | Independent Probability |
|---------------|----------------------|-------------------|-------------------------|
| Randomization | Yes                  | Yes               | Yes                     |

effects of moderate size of about 20–35% [3]. For this reason, moderate degrees of bias can lead to important distortions in treatment effect estimates; and authorities [4] encourage the use of RCT methodology and researchers conducting systematic reviews of RCTs. In systematic reviews heterogeneity in trial results are often explained by the possibility of differences in trial methodology. Sometimes the effect size is weight based on the methodology used in the RCT [5]. Such corrections are problematic since a trial that is not double blinded must per se not be of inferior quality than a trial in which only data collectors and outcome assessors were blinded or even where an open trial methodology was used.

Often only wordings without common sense such as double blind were used without exactly reporting who was blinded and who was not. Despite efforts to improve the reporting of RCTs, such as the Consolidated Standards of Reporting Trials (CONSORT), studies have documented in a low number concealment of randomization and blinding [2, 6].

Most researchers appreciate the meaning of blinding, but beyond general appreciation there is confusion. Terms such as single blind, double blind, and triple blind mean different things to different people (Fig. 1) [7]. Moreover, many medical researchers confuse the term blinding with allocation concealment. Allocation concealment is primarily used to prevent selection bias and to protect an assignment sequence before and until allocation. In contrast, blinding refers to keeping persons (participants, investigators, and data assessors) unaware of the allocated treatment or therapy, so that they are not influenced psychologically or physically by that knowledge. In well-blinded trials one can have more certainty that any differential effect between groups is due to the treatment rather than the subjects' or researchers' bias [8].

About 44–93% of publications of randomized controlled trials lack a clear description of allocation concealment [9]. This is really a poor rate since a clear description without quantitative information needs no additional trial effort and inadequate information exaggerates the treatment effect [6].

There is agreement that the allocation should be performed by chance, but randomization is not always used as it should be. There are still other allocation procedures in use (Table 1), such as allocation by alternation, by birthday, and by initials. These methods do not fulfill all three criteria: constant, equal, and independent probability [10].

## 17.2 NEED FOR PLACEBO

In contrast to several other study types, randomized controlled trials always have a control group. Having control patients who are completely without treatment does

(A)

(B)

(C)

**FIGURE 1** An exact description of who is blinded when is preferable to stating the trial was “single” (A), “double” (B), or (C) “triple” blinded. In the pictures the author is (A) “single”, (B) “double”, and (C) “triple” blinded.

not allow to decipher whether any response improvement in the treatment group is due to therapy or due to the fact of being treated in some way. Even if therapy is irrelevant to the patients condition, the patient’s attitude to his or her illness and indeed the illness itself may be improved by a feeling that something is being done to improve his or her condition [11].

Gribbin [12] argues that many patients could be effectively treated by placebo, especially by the use of attractive pills and a convincing statement by the physician as to their value. Hence, in any randomized drug trial versus untreated controls, it is worth considering giving the latter a placebo. The use of a placebo allows to eliminate the “placebo effect” from the therapeutic comparison. For this reason placebos are commonly used now in many disease trials.

The decision whether some standard active drug therapy should be a control and the new drug is given as an add-on is an entirely separate issue. One basic principle is that patients cannot ethically be assigned to only a placebo if there exists an alternative standard therapy of established efficacy [11]. The problem is that in many areas of medicine the standard therapy was never tested by sound evidence-based trials. Without supportive evidence the physician has to rely on clinical experience and opinion in deciding whether it is ethical to withhold what has become accepted as standard therapy.

Sometimes two active components should be compared. In this scenario often a “double-dummy” method is used. For example, if we want to compare two medicines, one presented as a blue tablet and one as a red capsule, we could also supply blue placebo tablets and red placebo capsules. Both patient groups have to take one blue tablet and one red capsule [13].

Placebos are used to make patients’ and observers’ attitudes to the trial as similar as possible in treatment and control groups. Under many circumstances the use of placebos is a prerequisite to perform a double-blinded trial.

### 17.3 FEATURES OF PLACEBO

Placebos have to be identical in all respects to the active drug, except that the active drug is absent. This means for oral placebos that they are not distinguishable by color, size, shape, taste, or texture. For oral therapy there are several modes of application available: capsules, tablets, or liquids. Since many active drugs have a distinctive taste, the use of capsules is most often feasible.

When using liquids for oral therapy or for injections, in addition to the color the viscosity and the potential to generate foam by shaking should also be considered. For example, liquids containing protein generate foam but buffer solutions do not. In this case, the ideal placebo will contain also an inactive protein in low concentrations such as human albumin. Some clinicians are very clever in breaking the code; they not only shake or identify the drugs by taste and smell but even photometers were used to determine differences between active drug and placebo. For such reasons it is sometimes very difficult to guarantee blinding.

### 17.4 CODING AND RANDOMIZATION

Double-blinded randomized trials require most careful organization in the allocation of treatments. The allocation to different treatments should have similar probabilities (see above and Table 1).

Before the generation of a randomization list is performed, principal considerations have to be made. Should the randomization list be generated by simple

random permutation or is there a need for stratification in the trial. In some trials, for example, stratification for different operations and age are useful. To allocate approximately the same number of patients to the placebo and the treatment group in each center, a block randomization is often used. This means, for example, in a trial with 100 patients it could have a block size of 20 patients randomizing 10 placebo patients and 10 treatment patients to one center. If one block is assigned, the next block will be used by the individual study center.

Another topic to be discussed is the use of an unequal randomization to placebo and treatment group. Driven by the enthusiasm for a new treatment, sometimes more patients were randomized to the treatment group, even though it would involve some loss of statistical efficiency [14]. Thus randomization in a 2:1 or 3:1 ratio for the new:standard treatment is a realistic consideration; however, there is an even greater loss in statistical power in the 3:1 approach.

There are several methods for the generation of randomization lists available. A detailed description of which method was used is given in Table 2. In general, the preparation of random lists and drug packages should be performed by persons not otherwise involved in conducting the trial. Most times random lists are generated by the study statistician. In all cases it is important to have a simple coding system linking the drug packages to the randomization list. Each package must have a unique trial code number that is also written on the randomization list and patient record form to safeguard a traceable link between, patients, packs, and the list.

Today, more and more central computers are used for randomization and for distribution and allocation of medication packages to the different study centers over a interface with the telephone (interactive voice response, IVR) or the Internet (interactive Web response, IWR). These methods led to significant savings in the amount of medication needed, but also to an increased risk of breaking the code [15]. A deduction from the dispensing order is in some cases possible. An example of such a situation is given by McEntegart et al. [15]. Four packs—two of each group—were delivered to the site in a trial with two treatments (A and B) stratified by gender. The first two patients randomized into the study were male (numbers

**TABLE 2 Generation of Randomization Lists and Allocation Concealment<sup>a</sup>**

| Method        | Adequate Descriptions                                                                                                   | Inadequate, Incomplete Descriptions                                                                                                                             |
|---------------|-------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Computer      | Random lists generated by a computer were used by the physician to sequentially allocate the patients to a treatment.   | Just mentioning the use of a computer is not enough information. Further details should be given since computers are rarely involved in the allocation process. |
| Envelopes     | For allocation serially numbered, sealed and opaque envelopes were used.                                                | Allocation was done by the use of opaque envelopes                                                                                                              |
| Vehicles      | Vehicles were indistinguishable, sequentially numbered, and sequentially administered without knowledge of the content. | For allocation indistinguishable vehicles were used.                                                                                                            |
| Pharmacy unit | Drug preparations from the pharmacy unit, using indistinguishable vials and content were used.                          | Allocation was performed by the pharmacist.                                                                                                                     |

<sup>a</sup>Criteria for adequate description of allocation concealment were taken in part from Schulz [34].

001 and 002). They were assigned to treatments A and B. The next patient, a female, was assigned to treatment A, as defined by the random list and received a matching pack, which was in this example number 004. From this numbering can be concluded that pack 003 must contain different medication from pack 004 because 003 was not given to the patient. Since pack 003 and 004 are different from each other also 001 and 002 must be different from each other.

Another problem is called pack separation, which occurs when the medication is supplied or used in a different ratio to the one used for packaging. More packs from one type will be left, for example, due to a higher withdrawal rate on active treatment. Repeated resupply of packs with equal numbers of packs will allow a division of packs into two distinct groups (one group with more and one with fewer packs), which allows assumptions on their difference. This clearly demonstrates also that sophisticated blinding and drug supply procedures with IVR and IWR technology are susceptible to bias unblinding.

To overcome these problems two strategies are possible. In the first approach the number of delivered packs in each block is increased, but then a part of the drug savings obtained by the individual delivery of packs is lost. Another approach is a double randomization [15]. In this case packs are randomly shuffled around so that there is no longer any association between the order in the file and the pack numbers. This method probably increases the complexity of labeling and distribution, and care has to be taken that no confusion occurs.

## 17.5 BLINDING MORE THAN PATIENTS AND PHYSICIANS

For the term *blinding* sometimes the synonym *masking* is used but blinding is used more often. Blinding, however, is used to reduce bias, but it is not always easy to obtain. Before an *open (nonblinded) trial* is performed, the question should be asked as to who can be blinded of the persons involved in the trial. A list of the individual groups is defined in Table 3 in accordance with Montori et al. [16].

*Single-blind trials* (where either only the investigator or the patient is blind to the allocation) are most times preferable to *open trials*. In *double-blinded trials* it

**TABLE 3 Individual Groups That Could Be Blinded**

| Group                 | Definition <sup>a</sup>                                                                                                                                                                 |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Participants          | Individuals who are randomly assigned to the interventions under evaluation.                                                                                                            |
| Health care providers | The physicians, nurses, or other personnel that actually care for the participants during the study period and/or administer the interventions.                                         |
| Data collectors       | The individuals who actually collect data for the study outcomes. Data collection could include a quality-of-life questionnaire, talking and/or recording a blood pressure measurement. |
| Outcome assessors     | The individuals who ultimately decide if a patient has suffered the outcome of interest.                                                                                                |
| Data analysts         | The individual who conducts the data analysis.                                                                                                                                          |
| Manuscript writers    | The individuals who write alternative versions of the manuscript before breaking the randomization code.                                                                                |

<sup>a</sup>Definitions were taken from Montori et al. [16].

is implicated that the assessment of patient outcome is done without knowing the treatment received [13]. Such blind assessment of outcome can often also be achieved in trials that are open. For example, pathological findings can be assessed by someone else who was not involved in running the trial. Blinded assessment of patient outcome is also valuable in epidemiological studies, such as cohort studies. In diagnostic tests and other trials, persons evaluating the performance of those performing the test should be unaware of the true diagnosis. Or in studies for the evaluation of the reproducibility of a measurement technique, the observers should be unaware of previous measurements on the same individuals [13].

One particular advantage of double-blind trials is that they allow the objective evaluation of side effects, both by the patient and by the physician. For instance, side effects (usually minor effects such as headache, fatigue, nausea) were reported by patients on placebo. This enables to correct for the overreporting of side effects on active therapy to get an unbiased estimate of adverse reactions attributed to the treatment itself [11].

Beyond the widely used term *double blinding* sometimes the term *triple blinding* is also used. This term usually means a double-blind trial that also maintains a blinded data analysis [11], but this is not always the case. Some people think it denotes that investigators and assessors as well as the participants are all unaware of the assignment.

Since there is some confusion on the use of the terminology *single blind*, *double blind*, and *triple blind* in the report of trials, clear statements should be given on who was blinded at what part of the study (Fig. 1). In general, the quality of the reports of concealment and blinding is poor (Table 4), but there seems to be an improvement in the reports from 2002 to 2004, although the studies from Montori et al. [16] and from Devereaux et al. [2] did not use identical criteria for trial selection. Montori et al. [16] analyzed RCT reports from five leading journals, and Devereaux et al. [2] used reports from internal medicine patients. Poor reporting does not mean automatically poor conduction of the trials. Some authors stated that they performed concealing randomization and blinding in adequate ways [2]. From this observation it can be concluded that readers should not assume at least in general that bias-reducing procedures not reported in RCTs did not occur.

However, on average, randomized trials that have not used appropriate levels of blinding show larger treatment effects than blinded studies [17]. In parallel,

**TABLE 4 Reporting Allocation Concealment and Blinding in Randomized Trials<sup>a</sup>**

<sup>a</sup>Information given on allocation concealment and blinding in randomized controlled trials. n.a. = not assessed in the study.

diagnostic test performance is often overestimated when the reference test is interpreted with knowledge of the test results [18]. Quantification of the blinding bias by adjusting the results for a single trial or a meta-analysis of several trials for trial quality is problematic. However, without quantification blinding makes it difficult to bias results intentionally or unintentionally and so helps to ensure the credibility of study results [13].

Beyond the blinding of participants, health care providers, data collectors, outcome assessors, and data analysts (Table 3) some trialists postulate even the blinding of writers [19]. In this approach two or more manuscripts were prepared before the code of the trial is broken. In one manuscript the test drug is significantly better than placebo and in the other there is no benefit of the new treatment. In my opinion this approach is too much directed by statistical rigidity, aside of clinical reality. There should be a clear hypothesis published in advance for the primary outcome of the trial, but the manuscripts will differ gradually. For example, the new treatment can be statistically better than the standard, as assumed beforehand, or even better at a lower significance level, or unchanged or even significantly adverse. However, hardly anyone would write five different manuscripts and interpretations of the results in advance.

## 17.6 BLINDING TRIALS OTHER THAN ORAL DRUG COMPARISONS

Blinding in oral drug trials is most times the easiest part, but it can be also more complex, for example, in the comparison of repetitive applications with a single application. In this case multiple placebo applications are needed to safeguard blinding.

Placebo injections present a greater practical and ethical problem than oral placebos. Additionally, subcutaneous and peripheral injections, for instance, are more easily accepted than more invasive procedures such as insertions of central venous lines.

The problem of blinding is most prominent in surgical trials. Blinding of surgeons is in most cases impossible, and a placebo operation (sham operation) will be in most cases unethical, but it is under some circumstances possible. In a trial by Freed et al. [20] patients received a sham surgery by drilling holes in the skull without penetration of the dura mater. This trial was accepted by the local ethics committee and published in the *New England Journal of Medicine*. A sham treatment such as this one is probably not possible in a lot of other centers. This example demonstrates that ethical considerations may be influenced by local and cultural differences.

Even if blinding of the surgeon is impossible, very elegant designs were used to reduce bias in surgical trials. For instance, in several trials comparing laparoscopic cholecystectomy with conventional surgery, an improved outcome for the new technique was reported [21]. Expectation bias was excluded for the first time in a randomized controlled trial from Majeed et al. [22] comparing laparoscopic and small-incision cholecystectomy. In this trial identical wound dressings in both groups were used so that nurses and trial personnel were blinded to the type of operation. Investigators found no difference between the groups with regard to hospital stay, time back to work, and time to full activity. In this case blinding has destroyed the illusion of a significant improvement by the use of laparoscopy.

**FIGURE 2** Need for blinding: In parallel with the decrease of objectivity from “hard” endpoints to “soft” endpoints, the influence of expectation increases. Blinding is more important for the assessment of outcomes with high expectation influence.

## 17.7 WAIVING BLINDNESS

Ethical considerations often rule out a double-blind trial design. As already mentioned, in most cases of surgical trials it would be unethical to subject a control group to incisions under anesthesia, mimicking genuine surgery. But, except for the surgeon, all others involved in the trial can be blinded (Table 3).

For some treatments it is totally impossible to arrange a double-blind design. For instance, the evaluation of cytotoxic drugs in cancer therapy is often not double blinded because of complicated dose schedules, the likelihood of serious side effects, and dose modifications to suit each patient’s needs. All these points make it necessary for the treating physician to know the patient’s therapy [11].

It should be considered how serious the bias might be without blinding. In general, for more subjective endpoints a double-blind design is more important than for more objective ones such as mortality (Fig. 2). In each trial organizers have to weigh the pros and cons when planning the trial and writing the trial protocol. Both, ethical and practical problems with blinding have to be considered.

## 17.8 SAFETY MECHANISMS: BREAKING CODE IN CASE OF EMERGENCY

In the case of an emergency a rapid decoding must be possible. For this reason the sponsor and investigators at the different centers must be immediately able to break the code of each individual patient. For this event in most randomized, blinded trials envelopes are prepared for decoding. With each drug package an opaque, sealed, unique coded envelope is delivered to the responsible physician that allows decoding. An additional set of envelopes are left with the sponsor. Another method is the preparation of lists that allow one to scratch off the number code to identify the drug assigned to the participant. In no case should the entire randomization list be transferred to the investigator, which would allow decoding all patients in the trial. Decoding should be allowed only when necessary for the care of the individual patient. Each time the code is broken, the reasons why, the date, and person who broke the code should be recorded. The condition of envelopes will be checked at

each monitoring visit. At the end of the trial the envelopes will be collected, inspected, and mentioned in the final study report [23].

## 17.9 ASSESSMENT OF BLINDING AND EXPECTATION

Ideally, investigators state in the report if blinding was successful. The success of blinding can be easily determined by asking participants, health care providers, data collectors, and outcome assessors to guess which intervention was provided. Table 5 demonstrates an example from a randomized, placebo-controlled trial. Patients were nicely blinded, but health care providers and data collectors were not. In this trial [24, 25] the study drug was G-CSF (granulocyte colony-stimulating factor), which increases the number of granulocytes. Unblinding was probably performed by the knowledge of the leukocyte count. Furthermore, in our trial there was no change over time in the different groups of persons asked. Others have found a change over time, so a repeated measurement of blinding is favored by them [26].

In general, the number of trials providing evidence on the success of blinding is poor. In a analysis by Fergusson et al. [27] it was shown that only 8% (15 of 191 trials) provided qualitative or quantitative information about blinding. Only in 5 of these 15 trials was blinding successful, and only two presented qualitative data. Due to the poor information given, the reporting of randomized controlled trials in regard to this topic should be improved.

In surgery, independent of the treatment, whether the new test drug or placebo is applied, patients believed that the disease will be cured and symptoms reduced by the operation (Table 6). Surgeons had a much more realistic expectation knowing the current literature and their own results. Positive expectations by the patient have a strong influence on the outcome as demonstrated by Koller et al. [28]. Furthermore, a comparison of patients included in the randomized controlled trial and patients treated under routine conditions in the same institution demonstrated an improved outcome of the patients under trial conditions [29]. This observation is not new but often neglected at the time of interpretation of trial efficacy data and extrapolation in regard to clinical efficiency in routine.

In many trials participants showed a strong tendency to believe they had been assigned to the active intervention (Table 6). Expectation can be analyzed also with questionnaires. In our G-CSF trial [24, 25] 68/75 patients thought immediately before the operation that they got the active substance and not the placebo. This belief may be influenced by the time of asking (beginning or end of the trial) and

**TABLE 5** Guess of Treatment (Blindness) of Patients, Surgeons, Ward Assistants, and Data Collectors at Day 3 after Operation (and at Discharge)<sup>a</sup>

| Group           | Correct Guess (%) | Phi Coefficient | <i>P</i> value  |
|-----------------|-------------------|-----------------|-----------------|
| Patients        | 41 (50)           | −0.16 (0.10)    | 0.155 (0.37)    |
| Surgeons        | 73 (73)           | 0.46 (0.49)     | <0.001 (<0.001) |
| Ward assistants | 67 (76)           | 0.33 (0.54)     | <0.005 (<0.001) |
| Data collectors | 73 (76)           | 0.46 (0.54)     | <0.001 (<0.001) |

<sup>a</sup>Blinding was evaluated in a randomized controlled trial with filgrastim prophylaxis versus placebo in patients with increased risk (ASA class 3 and 4) for an adverse outcome after colorectal cancer surgery [24, 25]. Most patients guessed (68/75) that they received the active study drug and not the placebo. *P* values were determined with the Chi-square test.

<sup>a</sup>Expectation of patients and surgeons was evaluated in a randomized controlled trial with filgrastim prophylaxis versus placebo in patients with increased risk (ASA class 3 and 4) for an adverse outcome after colorectal cancer surgery. *P* values were determined with the Chi-square test.

by repeated asking itself to guess what treatment they got. Differentiated outcome analysis of blinded and unblinded patients revealed that correct guess of treatment by the study personnel had no influence on patients' outcomes in all major end-points like: quality of life, the McPeck recovery index, length of stay, mortality, complication rate, and re-operation rate.

Expectation bias can be further reduced by using different persons for study coordination and psychometric rating [30]. Since during the trial patients become increasingly familiar and comfortable with the staff and trial office, this often triggers a therapeutic response to the patients [31].

To reduce expectation effects in randomized trials with psychotropic drugs, often a placebo run-in phase is included, which is a single-blind placebo period that lasts about 7–14 days. The placebo run-in phase occurs before randomization, and all study-eligible subjects are given the placebo treatment and are withdrawn most times from any psychoactive drugs during this interval. Responders to the placebo in this preliminary phase were excluded from the trial to reduce expectation and to increase the size of the treatment effect. A recent meta-analysis showed that trials with a placebo run-in phase and elimination of the placebo responders before randomization tended to result in a larger drug effect size, but without statistical significance [32].

Another approach to reduce expectation is to orientate patient expectations with educational statements. This may include statements about the possibility of the study drug working as intended; they may get a placebo and consequently may not improve, and they may receive admonitions to report the actual symptoms honestly without attempting to “help” in accentuating the positive [30]. For instance, site personnel would read the educational statement to the patient during the consent and review it at each succeeding visit. Information about these complex interactions between patients and staff is also important and will further reduce expectation.

## 17.10 INDICES FOR ASSESSMENT OF BLINDING

The success of blinding can be assessed not only by questionnaires but also by validated indices that are available [8, 33]. In the simple and easy-to-calculate index of

James et al. [8] the value increases from 0 to 1 with the success of blinding, while 0.0 is the complete lack of blinding, and 1.0 perfect blinding. In contrast to this index the more complex index of Bang et al. [33] includes also the important opinion of uncertainty. The index is scaled to an interval of  $-1$  to  $1$ ;  $1$  being completely lack of blinding,  $0$  being consistent with perfect blinding, and  $-1$  indicating opposite guessing, which may be related to unblinding.

It is the decision of the persons responsible for the particular trial to use a score or questionnaire. They should be aware that these tools can help to assess the rate of unblinding and the potential influence on the outcome.

### 17.11 BREAKING CODE AT END OF TRIAL

Before the code is broken, all parameters and endpoints listed in the trial protocol should be determined and saved in a log file. This procedure should guarantee as much as possible blindness of data collectors, outcome assessors, and data analysis. At that time point when all steps of data analysis were performed without group comparison, it is time to break the code. Unblinding is a milestone in randomized controlled trials and is for this reason often performed as a ceremonial act.

When the whole trial is completed and the results are interpreted, then it is desirable to inform investigators of each patient treatment. This allows one to get feedback from the experience of the investigators and understanding of the treatments. This procedure allows further the improvement of future trials. Some patients also want to know to which treatment group they were assigned. At this time the information should be accessible for them.

### 17.12 CONCLUSION

There is no uniform methodology for all randomized controlled blinded trials. The need for blinding is increasing in parallel with the decrease of objectivity from “hard” endpoints to “soft” endpoints as the influence of expectation increases. Blinding is more important for the assessment of outcomes with high expectation influence. Ethical and practical problems with blinding have to be considered early in trial development. Reducing bias by blinding is also possible in trials where health care providers (e.g., surgeons) cannot be blinded; but data collectors, outcome assessors, and data analysts can effectively be blinded. Some critical questions to be asked are listed in the Appendix. The success of blinding can be determined at various time points by asking participants, health care providers, data collectors, and outcome assessors to guess which intervention was provided. Blinding can be also assessed by the use of a scoring system. The decision of which system of quantification is used is not so important, but the trial report should include a clear statement of how randomization and allocation were performed and who was at which time point blinded. Following the general consideration mentioned here, bias can be reduced and the plausibility of trial results can be increased.

## APPENDIX CRITICAL QUESTIONS FOR BLINDED, PLACEBO-CONTROLLED RANDOMIZED TRIALS

| Item                     | Questions to Be Answered                                                                                                                                                                    |
|--------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Use of placebo           | What is the current standard for the treatment of the specific disease under investigation?<br>Is the use of a placebo ethically sound?                                                     |
| Preparing the placebo    | Which pharmaceutical form is the best to hide the identity of the drug in regard to smell, taste, color, and structure?<br>Is the placebo identical to the active medication?               |
| Coding and randomization | Which method is used for coding and randomization?                                                                                                                                          |
| Blinding                 | Does the study allow to blind: participants, health care providers, data collectors, outcome assessors, data analysts?<br>Does the blinding result in any harm or undo risk to the patient? |
| Breaking the code        | Which safety mechanisms are provided to break the code in an emergency?                                                                                                                     |
| Testing blinding         | Should the study include a test of blinding of the different individuals involved in the trial?                                                                                             |
| Reporting                | Is the generation of the randomization code, allocation process, and blinding adequately described?                                                                                         |

### **18.1 INTRODUCTION**

A vast majority of clinical trials are designed to scientifically assess the efficacy, safety, effectiveness, or usefulness of a given medical procedure, most often a therapeutic intervention (drug treatment, surgery, physical therapy, etc.) and sometimes a diagnostic test or a prognostic marker. Such clinical trials challenge a small

segment of actual or upcoming medical practice. Their goal is to improve the welfare of the enrolled patients, which represents a determinant condition for the acceptance of new medical techniques. Proper conduct of clinical research is necessary to ensure the scientific validity of such claims for improvement. However, besides this important body of medically oriented trials, one can identify a minority of clinical experiments not strictly directed toward the improvement of the participants condition. Such trials are typically aimed at studying a given scientific question, which is to be tested during a clinical investigation, however, without therapeutic purpose. Depending on the type of question, one may distinguish between clinical studies in *physiology*, which address normal functions of the organism, *pathophysiology*, dealing with disease mechanisms, and *pharmacology*, oriented toward characterization of drug properties in humans. This chapter is devoted to the latter type of trials. Clinical pharmacology trials play an important role both in drug development and in optimization of patient care, and their specific methodological characteristics will be reviewed.

### 18.1.1 Ethical Issues in Human Pharmacology Trials

Even if scientific progress has indirect repercussions beneficial for patient care, clinical trials in pharmacology are most often without clear benefit to the subjects included. Those subjects may be either healthy volunteers or patients presenting with a given condition to investigate, such as renal or hepatic insufficiency susceptible to alter the disposition of a drug. Even in the latter case, the drug tested is generally given without medical indication (e.g., a single dose of an antibiotic may be given to hemodialysis patients not currently suffering from infection). This has definite ethical implications [1]:

- Obtaining a fully informed consent is absolutely necessary, and the inclusion of subjects not able to understand extensively the study conditions is unacceptable (while it may be considered feasible to some extent in therapeutically oriented trials).
- Not the slightest foreseeable risk is acceptable for study participants (while an expectedly favorable benefit–risk ratio is required in therapeutic trials, even when potentially hazardous treatments are administered).
- Study subjects will usually receive significant financial compensation for their participation (which is usually not the case in therapeutic trials).
- No pressure is to be exerted on the candidates to stimulate their participation in the study, making it problematic to include economically disadvantaged people, who may depend too strongly on financial compensation, or collaborators of the investigator, bound by professional dependency.
- Insofar as altruistic motivations play some role in the decision of subjects to participate in a trial, the investigators have a moral responsibility of exploiting the study results with the best consideration to public health.
- Eventually, particular attention must be paid to psychological and relational aspects of the study: Most people will not easily accept unnecessary medical investigations and drug treatments, even with compensation. Participating subjects may experience irrational concerns and anxiety or unpleasant feelings of

“hiring one’s body.” Thus, it is important that investigators in clinical pharmacology be capable of psychological attention, receptive attitude, recognition of valuable motivations, and thankfulness toward study subjects.

A detailed discussion of ethical issues raised by the inclusion of healthy volunteers in clinical trials will be found elsewhere in this textbook (see Chapters 24.1 and 24.2). It is worth noting that the ethical standards applied to the conduct of human pharmacology trials have changed over the time and do not apply equally all over the world. The preferential involvement of prisoners as study subjects had been advocated for centuries; it culminated under the Nazi regime in Germany, and it was still practiced in the United States up to the 1970s [2]. It is now considered incompatible with human rights. The systematic inclusion of homeless people is still current practice in some places. Similarly, numerous academic centers would regularly ask their employees to participate in clinical investigations requiring healthy subjects. On the other hand, the importance of financial aspects in pharmacological research becomes of increasing public awareness. For-profit contract research organizations (CROs) play nowadays a leading role in the conduct of phase I trials, a vast majority of them being exclusively supported by industrial sponsors. In addition, the general trust of western populations in pharmaceutical companies is decreasing [3]. In this changing world, a strong commitment is required from investigators to apply rigorous ethical standards and protect human pharmacology research from any suspicion of implication in postmodern forms of slavery.

### **18.1.2 Roles and Importance of Clinical Pharmacology in Drug Development**

Clinical pharmacologists working in pharmaceutical companies are traditionally in charge of phase I trials, mostly devoted to the characterization of the pharmacological profile of new compounds. Issues related to the organization and performance of phase I trials are discussed elsewhere in this textbook (see Chapter 9.2). However, human pharmacology studies cannot be merely equated with phase I trials. Pharmacological questions are to be investigated at every step of drug development [4]. Pharmacokinetic analyses are increasingly included in phase II and III trials. Many drug interaction studies are conducted during phase IV. Moreover, it is often only after the commercialization of a drug that the suitability of therapeutic drug monitoring (TDM) for dosage individualization is examined, justifying further pharmacological assessments. In other instances, a biomarker useful for patient follow-up is identified and requires proper pharmacodynamic validation before large-scale evaluation and implementation.

The pharmacological characterization of new drugs has been considered by many authors as not entirely satisfactory at the time of product registration. Numerous drugs have been launched at suboptimal dosage, either too high or (less frequently) too low, because of a poor description of their dose–response relationship. A systematic analysis of 499 new prescription drugs approved by the Food and Drug Administration (FDA) over 20 years revealed that dosage changes had occurred in 73 of the drugs over the following years, the vast majority of which were decreases in dosage due to safety reasons [5]. Similar findings were reported in Europe [6]. Recommended dosing schedules happen to prove inadequate, either globally or in

specific subgroups of patients. For example, while most intravenous  $\beta$ -lactam antibiotics should probably be proposed as 24-hour infusions [7], they are still prescribed as injections on a t.i.d. (three times a day) or q.i.d. (four times a day) basis. Significant drug interactions frequently remain unknown at launch time, which may cause serious adverse outcomes in patients and even the withdrawal of products from the market [8, 9]. This is also the case for pharmacogenetic influences, which should receive more consideration [10]. Lastly, treatment monitoring and dosage adaptation issues are paid insufficient attention from drug developers, preventing the patients from obtaining the best possible benefit from new drugs until rational individualization strategies have been elaborated. Typical examples can be found in HIV (human immunodeficiency virus) treatment with protease and reverse transcriptase inhibitors [11], immunosuppression [12], and probably cancer treatment with new signal transduction inhibitors.

Clinical pharmacology has much to bring to drug development not only during the clinical phases I–IV but may even complement or replace some parts of the preclinical development. The sensitivity of drug assay methods is continuously increasing, with accelerator mass spectrometry techniques currently enabling determination of minute concentrations of radiolabeled compounds in biological fluids [13]. The administration of tiny amounts of new drug candidates to human volunteers, well below efficacy and toxicity dose thresholds, has been advocated for screening purposes, before the initiation of costly preclinical pharmacology and toxicology programs. This so-called phase-zero approach puts emphasis on the human pharmacokinetic profile as a relevant criterion for early drug development decisions [14]. It must be recalled that less than one in five drug candidates entering phase I eventually reach the market; this attrition plays a significant role in increasing the global costs of pharmaceutical research [15]. Clinical pharmacologists employed in the pharmaceutical industry are those who regularly bring the elements leading to a decision to kill a drug candidate during development. An earlier acquisition of such elements might therefore allow significant savings in research expenditures.

Finally, clinical pharmacology is still a science under development, and presently unknown concepts probably remain to be discovered. The whole story of cytochrome P450 enzymes has occupied many scientists since the 1970s, with numerous clinical trials devoted to elucidate their metabolic roles, genetic variations, and modulation by interacting drugs [16]. More recently, drug transporters went into scrutiny and justified a further amount of clinical investigations, which are still currently underway [17]. Other mechanisms of drug disposition are still poorly characterized and deserve definite research efforts (e.g., degradation pathways for peptide products). Advances in biopharmacy and new drug delivery techniques raise further issues that require to be tested at the clinical level. Pharmacodynamic mechanisms, besides their detailed dissection through *in vitro* experiments, also warrant to be better described through clinical experiments. Much remains to be discovered, too, in the field of adverse effect causation. Pharmacogenetics and ethnopharmacology represent further areas for intensive scientific exploration. Such “knowledge-oriented” research has been traditionally ascribed to academic groups, in opposition to “product-oriented” development. It is, however, important that both types of research conform to similar quality standards. Noticeably, a part of the scientific findings produced by universities lead to patent protection and industrial develop-

ment. Conversely, phase I trials devoted to a specific product development can identify new pharmacological concepts and produce generalizable findings. Thus, not only is clinical pharmacology important for drug development, but drug development itself invigorates clinical pharmacology in various scientific aspects.

### 18.1.3 Classical Study Questions and Designs in Clinical Pharmacology

Clinical pharmacology aims to describe, explain, and predict the fate and the effects of drugs in the human organism and to provide scientific foundations for the rational use of drugs in therapeutics. It relies on established knowledge in physiology and pathophysiology, and it uses specific methodological approaches to derive useful conclusions from clinical measurements, obtained during drug administration trials designed for that purpose. The general concepts governing clinical pharmacology can be found in dedicated textbooks [18, 19], and only their practical investigation through human trials will be covered here.

**Main Types of Study Questions** Traditionally, the scientific questions addressed during clinical pharmacology studies have been classified into two main groups:

- *Pharmacokinetic* (PK) issues are those dealing with the fate of a drug in the human organism, that is, *absorption* from administration site, *distribution*, *metabolism*, and *excretion* (metabolism and excretion are regarded together as *elimination*, and distribution and elimination are referred to collectively as *disposition*) [19]. The variables to be measured in a pharmacokinetic trial are mainly circulating concentrations or excreted amounts of the drug and/or its metabolites.
- *Pharmacodynamic* (PD) issues are those related to the effects of a drug on the human organism, that is, dose and time dependency of the response, effect modulation over repeated administration, such as *sensitization* or *tolerance*, and interference with other endogenous or exogenous agents, such as *synergism* or *antagonism*. The variables to be assessed during a pharmacodynamic trial are biological effect markers, or *biomarkers*.

During the past decade, the advantages of simultaneously addressing both groups of questions in clinical pharmacology trials have been recognized. Such *pharmacokinetic–pharmacodynamic* (PKPD) studies are increasingly performed [20]. They require an elaborated methodology for the analysis of their results, which take specifically into account the mechanisms of translation of concentration profiles into effects, as they can be observed clinically [21].

**Usual Study Objectives** The aim of a clinical pharmacology study can be a mere *description* of the average trends that characterize dose–concentration (PK), or dose–response or concentration–response (PD) relationships. However, many investigators will also propose an *interpretation* of study observations, with reference to a theoretical model (e.g., compartmental modeling in PK trials, or  $E_{\max}$  modeling in PD trials). This approach provides clinical estimates of a set of parameters describing the drug PK, PD, or PKPD profile, according to the model chosen. Those parameters can then be used to explain or predict the influence of *specific factors* on the

pharmacological profile. The type of factors entering into consideration delineate another way to classify clinical pharmacology investigations, based on the comparisons planned in the study protocol:

- *Dose–range trials* investigate the influence of the dose administered on drug PK descriptors (e.g., pharmacokinetic *linearity* issues), or PD or PKPD profile (*dose–response* issues).
- *Demographic characteristics trials* examine the influence of gender, age, race, or body weight on a drug PK, PD, or PKPD parameters. This basic approach is applied, for example, to the display of results in most PK trials.
- *Drug formulation trials* examine how the route of administration and galenical conditioning of an active ingredient influences its PK, PD, or PKPD profile. *Bioavailability* and *bioequivalence* trials enter into this category, the latter being oriented toward the demonstration of an acceptable degree of similitude between two different formulations of a given pharmacological agent, for example, an original and a generic brand (which raises specific statistical issues).
- *Food effect trials* investigate the influence of food intake, mainly on the PK parameters of the study drug.
- *Pregnancy trials* aim to determine how childbearing alters the pharmacological profile of a drug. Some investigations also include an evaluation of the transplacental passage of the drug agent to the fetus (e.g., through measure of the drug in cord blood at delivery). The secretion of a drug agent into breast milk can be determined in women subjects during *lactation*.
- *Drug interaction trials* examine the modifications induced by a specific co-medication in the PK, PD, or PKPD characteristics of a given drug.
- *Organ insufficiency trials* assess the impact of a given degree of failure affecting a given physiological system on the PK, PD, or PKPD profile of a drug. While most such trials investigate alterations of drug disposition in subjects suffering from kidney or liver failure, other types of *drug–disease interaction* are sometimes conducted. Drug *dializability* studies are to be cited here as well.
- *Pharmacogenetic trials* try to demonstrate the influence of specific individual genetic traits on the pharmacological profile of a given drug; among classical examples for such investigations are those addressing genetic polymorphisms of cytochrome P450 enzymes or drug receptors.

The combination of those study objectives with the PK, PD, or PKPD principal aims outlines a general typology of human pharmacology trials. Not infrequently, several objectives are combined in a single trial (it is, however, recommended to hierarchize the study questions, and to predefine one or a few main questions for confirmatory analysis, while keeping an exploratory status for all other comparisons).

***Classes of Study Designs*** A further axis for study classification relies on the *trial design*. While many variations can be imagined with regard to the questions addressed and the context of the study, trials can be roughly classified into one of the following main categories:

- *Sample-rich trials* correspond to the classical pharmacological experiments in human subjects, as they were performed by innumerable investigators over more than one century. Such trials continue to be required for new drug registration and represent the most straightforward way to bring answers to well-defined scientific questions of clinical pharmacology [22]. Traditionally, they include a limited number of subjects (between 5 and 50), while each subject provides a large amount of data (repeated concentration and/or effect measurements).
- (a) *Single-dose trials* apply PK and/or PD measurements to the follow-up of one drug administration. Such trials are often built up in *cross-over*, that is, the study subjects receive several single doses (using different dose levels, formulations, interacting medications, etc.) according to a given sequence, the administrations being separated by wash-out periods. This design enables the subtraction of difficult-to-control individual determinants of drug exposure and response, which cancel out during within-subject comparisons. Ideally, the sequence would be randomized to minimize confounding influences such as time-related trends. However, during early development of new products, a *dose-rising sequence* is often preferable for safety reasons; the inclusion of interspersed placebo periods allows randomization and blinding. Placebo control and blinding are usually considered of little relevance in PK trials but are recommended in principle when PD measurements are performed, to evaluate and subtract the baseline response profile observed after a zero dose of the test drug. Factors such as demographic or genetic characteristics can only be tested according to a *parallel* design.
- (b) *Repeated-dose trials* imply a prolonged period of observation and therefore often follow a parallel design. Such trials with *longitudinal* follow-up and analysis are necessary to observe time-related trends in exposure and response, for example, concentration accumulation, autoinduction of metabolism, or tolerance to drug effects. Sometimes, a *transversal* snapshot over one dosing interval is considered sufficient to assess some aspects of the drug PK or PD profile in patients treated on the long term.
- *Population trials* have been proposed since about the last three decades and rely upon data analysis techniques based on pharmacostatistical modeling. Such techniques allow for the estimation of pharmacologically relevant PK and PD parameters from observations drawn in sparse sample conditions, that is, when a large number of subjects provide few data each. Observations can thus be collected on a large scale directly among the target population of patients receiving the treatment, under less stringent study conditions than in classical trials. Population modeling techniques can accommodate varying dosing levels and schedules, unbalanced designs, and fragmentary data. They enable the estimation of both the mean values and the variability of PK and PD parameters among the population. Moreover, the influence of demographic factors, genetic markers, food effects, organ insufficiency, and co-medication can be assessed, provided that the trial population covers a sufficient range of individual differences. While subject heterogeneity is considered as a nuisance in traditional sample-rich trials, it is rather an advantage in population trials. Thus, population approaches have received much attention from both drug

developers and registration authorities [23], and they contribute currently to extend the scope of pharmacological characterization of drugs throughout their clinical development [24–26].

## 18.2 PHARMACOKINETIC CHARACTERIZATION OF DRUGS

During clinical PK trials, drug assay techniques are applied to a series of biological samples to determine the concentration profile that develops following drug administration; the results are analyzed to describe the fate of the drug, and possibly its derivatives, in the organism. This analysis, interpreted with reference to the classical laws governing the absorption and disposition of drugs, provides estimates of the *pharmacokinetic parameters* that characterize the drug studied. Such parameters represent specific values appearing in the pharmacokinetic equations used to model the drug PK profile. The parameter values are specific not only for a given drug but also for a given type of individual in a given condition. Many pharmacokinetic investigations will include a search for important factors that influence the parameters to a clinically significant extent. Knowing a drug PK profile is a prerequisite for designing rational therapeutic regimens and individualization strategies.

### 18.2.1 Drug Assay Methods

**Key Steps of Drug Assay** A PK trial has to rely on efficient and valid laboratory methods. The measurement of drugs and their metabolites in plasma, urine, or other fluids is most often achieved using chromatographic methods. Without entering into details of analytical chemistry, we just summarize here the main steps of a drug assay:

- *Preanalytical processing* covers the operations done on the sample between its collection and assay. Blood will usually be separated into either plasma or serum by centrifugation, with or without anticoagulant, respectively (although certain assay methods are developed specifically for whole blood). For poorly stable compounds, the sample may have to be added with preservatives (pH or oxidation modifiers, chelators, or enzyme inhibitors). In general, a series of samples will be stored under refrigeration until analysis. The influence of storage conditions on sample stability must be checked. Not infrequently, the samples will have to be sent frozen (e.g., on carbonic ice) to a distant lab. Preanalytical processing can be a source of serious bias in PK results: The tested drug may undergo spontaneous degradation or adsorption on the walls of sample tubes, or additives such as anticoagulants may interfere with the assay. Another important issue is *sample labeling*, which has to be thoroughly designed and organized to avoid any confusion between samples. A proper sample label should indicate the study name, the study site, the patient identification number, and the date and time of its collection; it must survive in storage conditions. All sequential tubes used in preanalytical processing must be labeled, working conditions must be organized to minimize the risk of confusion, and the technicians must be taught to “always read the tube they hold.”

- *Extraction* is often necessary to avoid slandering of analytical devices by protein-rich fluids. Protein denaturation, for example, by trichloroacetic acid, followed by centrifugation is often sufficient. *Solid-phase extraction* on micro-columns or *liquid-phase extraction* in an organic solvent may achieve a rough preliminary separation and compensate for variations in the sample matrix (e.g., urine concentration). It is important to check the degree of completeness of extraction through recovery experiments at various concentration levels. *Microdialysis* or *ultracentrifugation* techniques will enable the specific extraction of the unbound moiety of a drug in plasma or serum and the determination of free circulating drug concentrations. Such techniques are delicate to implement and highly sensitive to preanalytical processing conditions.
- *Separation* represents the central step in a chromatographic assay. It may be achieved in liquid phase, with a solvent eluting the components of the sample extract along a solid column under high pressure (*high-performance liquid chromatography*, HPLC) or in gaseous phase along a tiny capillary tube (*gas chromatography*, GC). Numerous choices are available to optimize the separation process, which depends on the relative physicochemical affinity of the analytes for the mobile and fixed phases. It is frequently possible to develop a method enabling the simultaneous separation of a drug and its metabolites, or of several drugs in a single run. On the other hand, different components of the sample happen to come out of the separation column at the same time, which represents an important risk of interference when nondiscriminative detection methods are used.
- *Detection* of the analytes at the exit of the separation column enables their quantification. Traditional HPLC methods use spectrometric, fluorimetric, or amperometric detection, with a modest discriminative power. More recently, mass spectrometry methods have been implemented, enabling detection of both high specificity and sensitivity, and thus decreasing the requirements on separation. *Gas chromatography and liquid chromatography with mass spectrometry* (GCMS and LCMS) assays have imposed a new standard on PK analytical methods, while both increasing the sensitivity and specificity of drug determination and decreasing sample processing time. The addition of ion fragmentation and mass spectrum analysis of fragments adds a further degree of specificity; it even enables the qualitative identification of chemical components in the sample, with reference to a database of fragmentation spectra.
- *Quantification* uses the signal issued by the detection apparatus. It usually consists of integrating the electronic signal over the duration of the peak corresponding to the analyte of interest. The value is then transformed into a concentration level according to a calibration curve. Many choices are available for the calibration method and may significantly impact on the performance of the assay (curve shape, regression method, coverage of the dynamic range by calibrators). It is frequently recommended to use an *internal standard*, that is, a chemical compound different from the analyte, which is added in fixed amount into the sample before extraction and separation, and detected and quantified on its own. Normalizing the measurement signal of the analyte by the signal of the internal standard will compensate for variations in the whole assay process and can significantly improve its reproducibility.

- *Quality control* determines the acceptance of a series of results. It is usually done by including a few *internal control* samples of known concentration and checking whether their results lie in a predefined acceptance range (e.g.,  $\pm 10\%$ ). In case of problematic precision, one may decide to perform all measurements in duplicate or triplicate. For drug measurements widely performed, programs of *external quality control* may be available, with one center sending samples of undisclosed concentration to all participating labs, receiving the results and analyzing the respective performance of each lab. If only one lab performs a given drug assay, it can be a good idea to provide *blinded duplicates*, that is, to separate certain study samples into two tubes and send one with a coded label.

Other analytical methods are used as well in clinical PK besides chromatographic assays and can be roughly described according to similar steps. For example, biotech products are often poorly characterized at the molecular level, as they represent a mixture of numerous chemical species (e.g., proteins with different stages of glycosylation). For such types of drugs, immunoassays are often preferable, with antibodies ensuring the step of analyte separation; the detection is ensured by radioactivity counting (*radioimmunoassay*, RIA), enzymatic reactions followed by spectrometry (*enzyme immunoassay*, EIA), or *fluorescence polarization* (FPIA). One frequent problem is the cross-reactivity of drug metabolites, either active or inactive, or other sample constituents with the assay method. Another interesting family of separation techniques uses a preparation of drug receptors instead of antibodies: such *receptor assays* are able to specifically measure the sum of chemical species showing affinity for the pharmacological drug target. Going one further step in the direction of pharmacodynamics, *bioassay* techniques directly measure the pharmacological activity contained in the sample (e.g., inhibition of bacterial growth by antibiotics). Such assay methods are often of high relevance, however, of limited performance.

**Elements of Assay Validation** Whatever the assay technique considered for a PK trial, it must be set up methodically, and its performance and reliability must be controlled in a preliminary validation step, before it can be applied to study samples. The elements to be collected during this step have been listed in the recommendations published following the Washington Conference on Analytical Methods Validation [27], considered as a basic document for good laboratory practice in the field of PK assay methodology. Similar elements are mentioned in the Q2 guideline of the International Conference on Harmonisation (ICH), which, however formally, address pharmaceutical quality control rather than PK determinations [28]. Briefly, the following pieces of information are required to characterize the performance of an assay method:

- *Accuracy* is the extent to which results generated by the method agree with the “true value.” It is usually determined by assaying control samples of known concentration (e.g., serum spiked with precise amounts of the analyte). Accuracy is expressed as a *relative bias*, which should not depart statistically from zero.
- *Precision* is the extent to which the individual results of multiple measurements of a series of standards agree together. It is expressed as a *coefficient of varia-*

tion. Intraassay (also termed *repeatability*), interassay and possibly interlab (also termed *reproducibility*) components of variability can be identified using appropriate tests.

- *Sensitivity* is given by the *limit of detection*, that is, the point at which a measured signal is significantly larger than the background noise (signals from blank samples), allowing to conclude that some analyte is definitely present in the sample; and by the *limit of quantification*, that is, the minimum concentration that allows precise measurement. The latter limit, together with the upper level of concentrations still measurable with linearity and precision, define the *dynamic range* of the analytical method.
- *Linearity* is the ability of the assay to elicit results that are (either directly or by means of a given mathematical transformation), proportional to the concentration of analyte in the samples within a given range. It can be determined by serial dilutions of a highly concentrated sample.
- *Specificity* (or *selectivity*) is the ability of the assay to measure unequivocally an analyte in the presence of chemical interferences, such as drug excipients, degradation products, co-medications, impurities, or other components of the sample matrix. Its assessment requires extensive search for cross-reactive substances.
- *Robustness* is the resistance of the assay methods toward changes in technical conditions of operation (e.g., temperature, processing time, batch of reactants, etc.).
- Finally, the period of assay validation is a suitable time to check *sample stability* issues under various collection and storage conditions (type of tubes, matrix effects, and length and temperature of storage).

### 18.2.2 Sample-Rich Trials

In traditional pharmacokinetic experiments, a panel of individuals are administered one or several standard doses of the drug studied and provide a series of blood samples (and possibly urine collections) for the determination of drug concentrations [29]. Practical aspects of subject selection, drug administration, sample collection, and data analysis are presented in this section.

**Selection of Subjects** Many PK trials are performed in healthy young volunteers, considered as reference subjects for the assessment of PK parameters of a given drug in “normal conditions.” Any departure from normality would raise a risk of biased evaluation of the drug PK profile. Therefore, rather stringent inclusion criteria are usually applied to ensure that the study population will actually correspond to this goal. The list below enumerates inclusion criteria frequently applied in PK study protocols on healthy subjects.

- As a principle, both male and female subjects should be included so that the results reflect possible sex-related differences and avoid selection bias [30]. Exceptions are for treatments indicated only in either gender or expected to seriously interfere with reproduction (impact on menstrual cycle, potential for teratogenic activity). Pregnant women should not be included, as pregnancy

significantly influences the absorption and disposition of numerous drugs [31]. Contraceptive use is usually permitted, however, potential interaction of the study drug with contraceptive agents should be taken into account. A pregnancy test may be included in lab screen.

- “Young volunteers” are usually considered between 18 and 45 years. Beyond age 30, a progressive decline of many physiological functions by roughly 1% per year is reported in the average population [19]. It probably results less from programmed physiologic changes than from a trivial increase in the probability of facing sequels of diseases and traumas. In any case, there must be some predefined cutoff to avoid significant impact of such changes on the PK study results.
- Significant underweight or overweight subjects should be avoided as well. Usual weight limits range between 55 and 95 kg for men and from 45 to 80 kg for women, with a body mass index (BMI, i.e., body weight divided by squared height) between 18 and 28 kg/m<sup>2</sup>.
- The medical history and physical examination should not reveal “significant findings,” that is, any condition susceptible to bias the evaluation of normal PK parameters or to impair the safety of exposure to the study drug. A history of severe drug allergy or atopic condition is frequently considered as an exclusion criterion, as are hypertension, cardiac disease history, or significant electrocardiographic abnormalities (including prolonged QT interval).
- Routine laboratory tests should be ordered (blood count, electrolytes, proteins, kidney, and liver tests), and subjects having clinically significant laboratory abnormalities should not be included. Noticeably, athletic young men can have rather high serum creatinine values without any renal impairment due to abundant production by the muscular mass. Gilbert’s syndrome (a rather frequent condition with increased total and unconjugated bilirubin on fasting, due to impaired glucuroconjugation) can be accepted if the study drug is not a substrate for glucuroconjugation reactions.
- Urine drug screens for common street drugs are usually requested, to refuse candidate volunteers with current substance use disorder, in which unwanted interactions might happen. The existence of false-positive results for those tests is to be remembered (e.g., poppy seed bread consumption producing positive opiate screen).
- In general, there should be no limitation of race in PK studies. However, it is to be remembered that ethnic factors play a definite role in drug disposition, mainly because the frequency of genetic polymorphisms affecting drug metabolism or transport varies between the different populations across the world (e.g., higher number of CYP2C19-poor metabolizers in Asians, of CYP2D6 ultrarapid metabolizers in Ethiopians [32]). Genotyping of the study subjects for important pharmacogenetic polymorphisms is increasingly requested in PK trials and is now recommended by registration authorities to explore the influence of given genes on the PK profile of new drugs.
- The use of any medication is to be forbidden 2 weeks prior to study drug administration and during the follow-up, including aspirin or other over-the-counter preparations. The use of long half-life drugs with induction or inhibition

potential may affect drug metabolism even more durably (e.g., phenobarbital, amiodarone). Acetaminophen may be permitted before and during the study as a rescue medication with investigator permission.

- The subjects must generally be asked not to consume quinine or grapefruit beverages, as they inhibit CYP2D6 and CYP3A4/5, respectively. Tobacco smoking or exposure to hydrocarbons induce CYP1A2, and alcohol abuse induces CYP2E1. More generally, the study subjects should be asked to refrain from excessive food consumption, prolonged fasting, strenuous exercise, dehydration, and blood donation before and during the whole study period.
- Finally, ability to understand the study conditions, willingness to participate, provision of written informed consent, and appropriate compliance toward study restrictions represent obvious inclusion criteria.

**Dose Determination** The pharmacokinetic literature reveals a striking contrast between the marked attention devoted to analytical and mathematical aspects of the exploitation of biological samples and the poor consideration given to the pharmaceutical aspects of drug administration. A recent literature survey reported that the assessment of doses actually administered was mentioned only in a small minority of pharmacokinetic trials published in clinical pharmacology journals, while about one quarter of those trials met criteria indicating a theoretical relevance for such an assessment [33]. No mention of procedures for actual dose assessment is found in the recommendations of registration authorities for the performance of pharmacokinetic studies. However, current pharmacopeia requirements set acceptance criteria to  $\pm 10\%$  around the nominal strength for the pharmaceutical quality control of most manufactured drugs; moreover, analytical methods used in quality control are usually not identical to assays used for pharmacokinetic determinations, which can quantify similar drug amounts fairly differently (especially when based on immunological reactivity and/or applied to complex agents or biologicals); salt factors may be neglected; and finally, the preparation of solutions for infusion introduces a supplementary risk of dilution errors, leakage, residues, adsorption on syringes or lines, or inaccuracy in infusion rate and volume. All those factors can be expected to introduce significant bias in the determination of pharmacokinetic or pharmacodynamic parameters if the calculations rely upon the labeled dose instead of the best estimate of the dose actually administered. The following pragmatic steps are thus recommended to implement actual dose assessment when necessary in pharmacological trials involving human subjects:

- While dose determination is certainly not necessary in all kinds of trials, the question of the relevance of such assessment should be raised for each study at the time of protocol elaboration. Various criteria should suggest investigators to plan such procedures in a given trial: use of intravenous injections or infusions, experimental drug manufactured on a small scale, especially peptides, proteins, or other complex agents (e.g., phytopharmaceuticals), immunologically based analytical methods (e.g., RIA or EIA), parallel-group design with qualitatively different treatment assigned to each group, and estimation of a drug absolute clearance, volume, or effective dose parameters (the calculation of which include a dose term).

- For trials using a ready-for-use drug formulation, such as an oral tablet, a global evaluation of the average actual dose present in the trial drug is usually sufficient. Pharmaceutical quality controls should be checked, and their results should be used if they indicate any significant departure from the nominal dose of the formulation. The identity and actual titer of the substance used to prepare the calibrators for drug assay in biological fluids should be checked as well (taking a possible salt factor into account). For complex preparations such as biological agents, one may consider determining actual dose amounts using the assay method developed for plasma samples.
- For trials using a drug in solution, typically for intravenous infusion, the actual dose delivered to each study subject should be assessed individually. First, the volume of solution actually infused will be carefully measured and recorded (use the indications given by an electronic pump after a preliminary validation of its flow rate; alternatively, weight precisely the solution vials or bags connected with lines before and after drug administration, and divide the difference by the specific gravity of the solution measured on a sample). Second, the concentration of active drug in the infusion solution will be determined using the assay applied to plasma samples (which must have been validated for aqueous matrix). Whenever feasible, prepare more infusion solution than required, and retain samples from each treatment at the outlet of the line (after postinfusion weighting).
- The differences between assigned dose levels and the amounts actually administered should be reported, and the cause for significant departures should be elucidated. Attention should be paid to the accuracy and precision of the measurement and assay methods used for dose assessment, to avoid the unnecessary introduction of variability in PK or PD calculations (the reproducibility should be reported as standard deviation or coefficient of variation).
- Whatever the approach, the procedures applied to actual dose assessment should be described in study reports and publications, and the results used in the calculation of PK or PD parameters.

In PK experiments, it is important to properly standardize the conditions of drug administration. Unless specified by the protocol, oral dose intake should occur on an empty stomach, hence the subjects are to remain fasted over several hours before. A predefined amount of water is to be given with the oral dose. Even the posture of the subjects should be standardized, as gastrointestinal absorption, hepatic first pass, and renal excretions are influenced by body position. Similarly, the site of a subcutaneous drug injection is to be standardized across the whole trial. Further precautions are necessary for topical drug administration. Finally, it is important to hold a comprehensive drug accountability throughout the study, and to preserve all drug containers and packages until the end of the study.

**Sample Collection** Study protocols of PK trials usually define a series of sequential sampling times. The goal is to cover with sufficient thoroughness the concentration curves to be described. Ideally, the duration of PK follow-up should last over at least three to four half-lives of the drug. Sampling should be more frequent immediately after drug administration and around the peak time or immediately

after infusion cessation; thereafter, the samples can be separated by larger time intervals. However, the terminal phase is often the most relevant part of the PK profile to be described, as it determines effect duration and accumulation.

Several pragmatic recommendations deserve to be mentioned with regard to sample collection:

- Prepare a gallery of sampling tubes with appropriate labels, along with a worksheet to be filled in during the experiment. The worksheet comprises a sample record log (Fig. 1). Ensure that the labels correspond to worksheet designations for each tube and that consistent designation rules apply to all subsequent procedures.
- Record on the worksheet the precise clock time of drug administration(s) and blood samplings. While the protocol defines relative sampling time after dose administration, it is convenient to write down on the worksheet the absolute times scheduled for sampling (which depend on the actual dosage time). In case of an infusion, the worksheet will mention start and end times, infusion flow rate, weight of the pouch before and after infusion, and collection of a retain sample.
- For repetitive blood samplings, it is suitable that the subjects are equipped with a venous cannula with cap and lateral valve. Large forearm veins are best suited to draw blood (avoid antecubital and dorsal hand veins for subjects convenience). In case of a drug infusion, use different venous accesses for drug administration and blood sampling, as sampling through the same line has every chance to contaminate the samples with the infusion solution (which is about 1000 times more concentrated).
- Before drawing samples, discard 0.5 mL of blood (to flush the cannula dead volume); immediately after sampling, recap properly the cannula and rinse it with 2 mL normal saline through the lateral plug. Normal saline is sufficient to main the permeability of venous access over several hours; anticoagulants are unnecessary and may only cause problems (interference with assays, sensitization). Tell the subjects to ask for supplemental rinsing in case of blood reflux observable in the tip of the cannula.
- When collecting a blood sample takes a significant amount of time, record the midsample time on the worksheet and mention this difficulty in a remark. Whatever the system used for blood collection, drawing blood gently rather than trying to pull it out with a strong suction pressure will always do it better. Blood collection may be facilitated by warming the arm bearing the cannula (as a cold skin associated with increased venous tone and decreased blood flux through superficial veins). If it is impossible to obtain blood, report the problem and keep the empty tube in the series.
- If urine collections are scheduled in the study protocol, record precisely each micturition time, and measure the total collection volume before taking samples (it is advisable to weight precisely the recipient and subtract the tare; as urine density varies between 1000 and 1030 g/L, the measurement error is not expected to exceed 3%, which is often more precise than direct measurement of the volume in a column). Offer the subjects a quiet place and ask them to empty their bladder as completely as possible. Ensure sufficient provision of water

**FIGURE 1** Example of worksheet for sample recording over one period in a PK trial, where 30 subjects received twice 20 mg of fluoxetine orally (Prozac versus generic) at 2-month interval.

over the investigation. Calculate the duration of each collection as the difference between end of collection time and initial micturition time; recall that the initial urine does not belong to the collection and is to be discarded. If a subject needs to urinate before the scheduled collection end, save that urine in the container. If a subject forgets to give his or her urine, ask for an evaluation of the missing volume and record the deviation on the worksheet.

- Process the sample tubes as soon as possible and store them in structured racks and boxes, at the appropriate temperature. It makes sense to dispatch the plasma or serum of each blood sample into two tubes, so as to obtain two parallel collections, including one for backup. Ensure that the storage conditions are respected up to sending the samples to the lab. Temperature “spy” recorders may help in monitoring the storage conditions. Refrigerators should be connected to an alarm system to prevent unrecognized malfunction.
- Have all samples shipped to the laboratory, along with the list of tubes. The study samples will most often need to be shipped frozen on dry ice, and packaging issues are of critical importance. The lab should immediately check the completeness of the sample series. If possible, all samples of one subject should be analyzed on the same day.

**Description of PK Results** Once the lab has produced measurement data for the series of samples, after careful quality check, the first step is to produce graphics of *individual time–concentration profiles* (Fig. 2). Not infrequently, the graphics will identify remaining errors in data handling or suspect data points requiring reanalysis. The actual sampling times are to be used to draw individual PK curves. In most situations, the use of a log *Y* scale is advisable, as it will linearize the exponential components of the time–concentration relationship and indicate the most suitable model to describe the data. The issue of results below quantification limit (BQL) has been abundantly discussed in the literature, and many authors have issued recommendations on that specific question. When sufficient amounts of data are

**FIGURE 2** Individual graphic of raw data in a PK trial, where 30 subjects received 20 mg of fluoxetine orally (generic formulation). A log *Y* scale is used. Observe several delayed samples, one suspect point at 6 hours, the fairly log-linear shape of the terminal phase, the decrease in relative measurement precision at low concentration levels, and the presence of one slow eliminator among the subjects.

available (e.g., in Fig. 2), the best solution is to merely drop such data points from individual curves and calculations. For the calculation of means and during population analyses, a simple approach is to equate the first BQL point to half the value of the quantification limit, drop all subsequent points, and force the residual error to include at least the range between zero and the quantification limit. This will somewhat correct a selection bias of data points, which would otherwise lead to overrepresentation of higher values over BQL, and thus to overestimation of terminal half-life.

In a second step, an *average time–concentration profile* can be computed and plotted (Fig. 3). It is highly recommended to compute geometric means with corresponding coefficients of variation and to plot them along a log Y scale (see Appendix ). Several average curves can be compared on a common graph when the PK experiment involves different doses, formulations, co-medications or subgroups of subjects (according to gender, age, genotype, clinical condition, etc.).

Most sample-rich PK trials will apply a “two-step” approach in data analysis, that is, the characteristic values describing the PK profile are first calculated for each subject individually, and then submitted to statistical tests. The classical descriptors of PK profile curves are as follows:

- The *maximum concentration* ( $C_{\max}$ ) corresponds to the highest observed value in the curve. This descriptor is of significance mainly for drugs administered through an extravascular route (oral, subcutaneous, etc.). It is clearly dose dependent, and it represents for some drugs the best predictor of pharmacodynamic efficacy.

**FIGURE 3** Individual graphic of average data in a PK trial, where 30 subjects received 20mg of fluoxetine orally (generic formulation). A log Y scale with geometric mean and standard deviations is used. Based on the graphic of individual values (Fig. 2), the characterization of average curve appears appropriate up to 96 hours after dose. Observe the relative homogeneity of the dispersion, however, slightly increasing toward low concentration levels.

- The *time of maximum concentration* ( $t_{\max}$ ) is merely the time corresponding to the observation of  $C_{\max}$ . It is affected by both the rate of absorption and the rate of disposition of the drug, according to the pharmaceutical formulation studied. It is usually determined with less precision than other PK descriptors, due to the sparse distribution of sampling times and to the sensitivity of the concentration plateau to slight measurement errors.
- The *rate constant of the terminal phase* ( $\lambda_z$ ) is the absolute value of the slope of log-transformed concentration values versus time (only natural logarithms must be used). It is computed by linear regression over the terminal part of the curve, including all points that appear sufficiently well aligned on the graph (e.g., in Fig. 1, the data points would be included beyond 10 hours after dose intake). Various algorithms have been devised to select formally the points to be included, but visual inspection is often sufficient. When a drug is given at different doses, the quantification limit of the assay often restricts the possibility of estimating  $\lambda_z$  at the lowest doses, producing artificially high  $\lambda_z$  values; this must be differentiated from the case of true PK nonlinearity, where increase in dosage actually slows down drug elimination.
- A distribution phase is sometimes identifiable on the log concentration versus time curve, translating into a steeper initial segment; this is mainly the case after intravenous drug injection. A *rate constant of the initial phase* ( $\lambda_1$ ) can be computed in such situations.
- After administration of an intravenous bolus dose, a *concentration at time zero* ( $C_{(0)}$ ) can be back-extrapolated as the intercept of the log-linear regression line fitted over the points of the initial phase.
- The *area under the curve* (AUC) is the most important descriptor to calculate after single-dose administration. It is estimated by numerical integration over all segments of the concentration curve. It is dose dependent, and it represents for many drugs the best exposure marker correlated with pharmacodynamic efficacy. The *trapezoidal rule* is often used to calculate AUC segments: if a concentration  $C_i$  is measured on time  $t_i$ , followed by a concentration  $C_j$  on time  $t_j$ , the corresponding segment has the area

$$\text{AUC}_{i-j} = (t_j - t_i) \left[ \frac{1}{2} (C_j + C_i) \right]$$

During the decay phase, especially when samples are taken at sparse intervals, the trapezoidal rule tends to overestimate segment areas, as their upper boundary is in fact curvilinear; using the *log-trapezoidal rule* is thus considered as preferable:

$$\text{AUC}_{i-j} = (t_j - t_i) \left[ \frac{C_i - C_j}{\log(C_i) - \log(C_j)} \right]$$

The sum of all segments is then calculated from the first to the last observed concentration ( $\text{AUC}_{\text{last}}$ ). However, this sum still underestimates the true AUC, and it must be complemented with extrapolations. An extrapolation between dosage time and the first measured concentration will use  $C_{(0)}$  for the estimation

of the first segment area in case of an intravenous bolus injection; for other routes of administration, the concentration at dosage time can be considered to be zero, and the first segment of AUC can be equated to a triangle having an area of  $AUC_{0-1} = 0.5C_1/t_1$ . At the other end of the time–concentration curve, an extrapolation of the AUC toward infinity can be based on the last measurable point ( $C_{last}$ ) and the rate constant of the terminal phase:

$$AUC_{last-\infty} = \frac{C_{last}}{\lambda_z}$$

Some authors recommend to replace the observed  $C_{last}$  by a fitted value based on all points of the terminal phase. Both extrapolations  $AUC_{0-1}$  and  $AUC_{last-\infty}$  are added to the sum of segments to compute  $AUC_{0-\infty}$ , the best available estimate of total AUC. As the extrapolations represent the least robust part of AUC estimation, it is often required that they do not represent more than 10% of the total AUC, to ensure an accurate estimation of the concentration exposure. In repeated dose trials, when concentrations are followed over a dosing interval at steady state (i.e., once accumulation is complete), no extrapolation to infinity must be applied, as the AUC limited to one dosing interval is equivalent to the AUC to infinity, which would have been observed after a single dose.

- The *area under the first moment curve* (AUMC) is another descriptor of PK curves used sometimes. The first moment curve is the curve of concentration values multiplied by corresponding sampling times. Its integration can be interpreted as an exposure marker assigning bonus to concentration levels according to their duration. The trapezoidal rule for AUMC estimation is

$$AUMC_{i-j} = (t_j - t_i) \left( \frac{t_i C_j + t_j C_i}{2} \right)$$

A log-trapezoidal rule has also been proposed but it is far more complicated and rarely used. The estimation of AUMC has also to be extrapolated toward infinity:

$$AUMC_{last-\infty} = \frac{t_{last} C_{last}}{\lambda_z} + \frac{C_{last}}{\lambda_z^2}$$

As this descriptor weights concentrations by sampling times, the percent extrapolated is often fairly high, which limits the confidence that can be placed on AUMC estimation.

**Noncompartmental PK Parameters** Once the descriptors mentioned above have been computed for each individual PK curve, they can serve to estimate various dose-independent parameters, taking into account the actual dose administered ( $D$ ), the administration route, and the study design [34]. The following PK parameters are usually calculated:

- The *terminal half-life* is taken as the inverse of the rate constant of the terminal phase multiplied by the natural logarithm of 2 (i.e., 0.69):

$$t_{1/2z} = \frac{\log(2)}{\lambda_z}$$

In case of intravenous injection or rapid extravascular absorption,  $t_{1/2z}$  reflects the drug *elimination half-life*; however, for slow-absorption formulation, it may reflect the *absorption half-life*, which becomes the factor limiting drug disposition. Similarly, the terminal half-life of a drug metabolite measured in blood can reflect the kinetics of either its formation or its elimination. When an initial log-linear segment can be identified on the time–concentration curve, its rate constant can be used to estimate the *initial half-life*, which most often represents a *distribution half-life*.

- The *total drug clearance* is calculated as the ratio of the dose over the resulting AUC:

$$CL = \frac{D}{AUC}$$

Notice that after extravascular administration, this formula gives the *apparent clearance* ( $CL/F$ ) rather than the absolute clearance, as the concentration exposure results only from the fraction of the dose able to reach the circulation, which is the *bioavailability* ( $F$ ). When urinary determinations are performed, the amount of drug excreted into the urine ( $A_e$ ), which may require extrapolation toward infinity, can be used to determine the *renal clearance* of the drug:

$$CL_R = \frac{A_e}{AUC}$$

The *fraction of dose undergoing renal excretion* is calculated as the ration  $A_e/D$ . When a drug metabolite is measured in plasma or serum, the AUC of this metabolite is usually presented along with its half-life. However, to determine the fraction of the dose eliminated through the corresponding metabolic pathway requires that the absolute clearance of the metabolite is evaluated after intravenous administration of the metabolite itself. Alternatively, the fraction of the dose recovered in urine as metabolite can provide some indication. Otherwise, the metabolite AUC cannot be assigned a precise meaning, as it results from both the drug transformation into metabolite and the disposition kinetics of the metabolite, which are unidentifiable.

Finally, it is to be recalled that any estimation of a drug clearance refers always to a specific medium where drug concentrations are measured: for most drugs, the plasma clearance will significantly differ from the whole blood clearance. By default, total plasma is considered as the reference medium. There is growing interest for the determination of free drug concentrations in the plasma; for drugs highly bound to plasma carriers (albumin,  $\alpha$ -1-glycoprotein, lipoproteins, etc.), as free concentrations are very low, *free drug clearance* can

reach impressive values, especially in case of high liver extraction ratio, when the metabolic activity of the liver is able to displace the binding equilibrium in plasma during blood transit through the liver. Free drug concentrations are considered to be more tightly related to pharmacodynamic activity than total plasma levels.

- The determination of the *absolute bioavailability* of an extravascular formulation requires to compare the AUC after its administration with the AUC after intravenous injection of the active ingredient, accounting for possible dose differences:

$$F_{\text{extravascular}} = \frac{\text{AUC}_{\text{extravascular}} D_{\text{intravenous}}}{\text{AUC}_{\text{intravenous}} D_{\text{extravascular}}}$$

When two extravascular formulations are compared, this formula gives the *relative bioavailability* of one formulation with respect to the other (taken as reference). This is the key parameter estimated in bioequivalence trials.

- Finally, several types of *volume of distribution* can be defined. The *volume of the terminal phase* is simply derived from the total clearance and the terminal constant rate:

$$V_z = \frac{\text{CL}}{\lambda_z}$$

Notice that after extravascular administration, this formula gives the *apparent terminal volume* ( $V_z/F$ ) rather than the absolute one. After intravenous bolus injection, an *initial* or *central volume* can be deduced from the concentration extrapolated at time zero:

$$V_1 = \frac{D}{C_{(0)}}$$

When an AUMC value has been estimated after intravenous injection, it can be used to calculate the *mean residence time*:  $\text{MRT} = \text{AUMC}/\text{AUC}$ , a weighted estimator of the average duration of sojourn of drug molecules in the organism before their elimination. After intravenous infusion, the ratio  $\text{AUMC}/\text{AUC}$  is equal to the MRT plus one half the infusion duration. After extravascular administration, it is equal to the MRT plus the *mean absorption time* (MAT), which can thus be determined only by comparison with the intravenous administration. Knowing the MRT of a drug enables one to calculate its *volume at steady state* (i.e., when concentrations in the different compartments are at equilibrium):

$$V_{\text{ss}} = (\text{CL})(\text{MRT})$$

Like clearances, volumes of distribution always refer to a given measurement medium, and for agents highly bound to plasma carriers, the distribution volume of the free moiety can exceed many times that of the total plasma drug.

**Pharmacokinetic Modeling** Beyond the basic calculations outlined above, many more sophisticated calculations can be devoted to the analysis of PK data, depending on the study aims and conditions. A detailed description of all possible approaches is beyond the scope of this chapter [19]. Briefly, the models that are regularly applied belong to the following classes:

- *Exponential models* use nonlinear regression techniques to fit the data with a general equation, usually a sum of exponential terms; for example, a two-exponential concentration curve after intravenous injection will be described according to the equation:

$$y = Ae^{-\alpha t} + Be^{-\beta t}$$

As PK data are characterized by noticeable heteroscedasticity (i.e., heterogeneity in variability), the issue of appropriate weighting schemes for the regression is of relevance. The coefficients estimated ( $A$ ,  $\alpha$ ,  $B$ ,  $\beta$ , termed PK *macroconstants*) enable the calculation of classical PK parameters ( $\lambda_1$ ,  $\lambda_z$ , CL,  $V_1$ ,  $V_z$ ). Notice that the model equation can also be built up using directly clearance and volume parameters. Parameter values estimated this way not infrequently show fair differences with their noncompartmental counterparts (with the exception of CL, which is the most robust regarding estimation methods). Exponential models are ideally suited to draw continuous curves across the data points and calculate various simple extrapolations (e.g., dose repetition).

- *Compartmental models* aim to fit the data with a set of differential equations. The equations characteristically describe the evolution of drug amounts throughout body compartments. For example, the bicompartmental disposition of a drug after intravenous injection will be described according to the set of differential equations:

$$\frac{dY_1}{dt} = k_{21}Y_2 - k_{12}Y_1 - k_{10}Y_1$$

$$\frac{dY_2}{dt} = k_{12}Y_1 - k_{21}Y_2$$

where  $Y_1$  is the amount of drug in the central compartment (related to the concentration through the volume  $V_1$  of this compartment), and  $Y_2$  the amount of drug in the peripheral compartment. The coefficients ( $k_{12}$ ,  $k_{21}$ ,  $k_{10}$ ,  $V_1$ , termed PK *microconstants*) enable as well the derivation of macroconstants and classical PK parameters. Compartmental models can accommodate a wider spectrum of conditions, such as time-varying infusion rates, first-pass effect and enterohepatic cycle, multiple metabolites production, or situations where some PK processes are nonlinear, for example, saturable elimination pathways following Michaelis–Menten kinetics. The results are more susceptible to be interpreted mechanistically and can be used in simulations where PK mechanisms are selectively modified (e.g., prediction of the effects of a change in formulation or organ function).

- *Physiological models* try to incorporate physiological variables, such as anatomical volumes of tissues and organs, or circulation flow rates. While those models are mainly used in animal experiments, they can be useful in selected clinical situations, such as the determination of drug kinetics through an organ, either natural or artificial (e.g., renal replacement machines), especially when it is accessible to measurement (e.g., cerebral imaging of drug distribution into the brain).

While the basic PK calculations described above can be achieved using a simple spreadsheet, fitting exponential, compartmental, or physiological models requires specific computer facilities. Numerous pieces of software are available to perform such advanced PK data analyses, most of them being represented on the Internet (see, e.g., the online catalog maintained by Bourne [35]). Among such programs, WinNonLin and Kinetica currently experience a high level of recognition among pharmacokineticists. In addition, several computer packages for general statistics have now implemented specific routines for PK data analysis (e.g., S-Plus, R, and Stata). Nowadays, the limiting factor for a sound exploitation of PK data using computer resources is only the degree of knowledge and experience required from users.

**Statistical Analysis of PK Results** Once the PK parameters have been deduced from the raw concentration data, they are ready for description, analysis, and comparisons according to the study objectives and design. It is standard practice to compare PK parameters rather than the concentration results themselves. Many specialized PK computer programs incorporate statistical tools to perform tests on the parameter estimates that have been calculated. Alternatively, the parameters may be copied into a standard statistical computer package.

If the main study objective is a mere *description* of a drug PK profile, the importance will be put on the summary table of PK parameters. Several choices are available for statistical description. The calculation of geometric means and associated percent variations should be encouraged, as it is often the most appropriate alternative (see Appendix). Nevertheless, arithmetic means and standard deviations are still often encountered. When parameter values appear to follow an irregular distribution pattern, nonparametric descriptors should be preferred (i.e., median and interquartile range). The descriptive presentation of PK results is often complemented with some statistical comparisons of the parameters according to various factors, such as gender, age, or the genotype regarding given polymorphisms. Such tests must be viewed as *exploratory*, that is, the *P* values have only an indicative interest, and no Bonferroni-like correction is applied for multiple testing.

When a PK trial is built up toward the assessment of a given hypothesis, the main study objective must be specified in terms of one or a few PK parameters to be tested regarding the influence of relevant factors, and *confirmatory* statistical tests must be predefined in the protocol. A preference should be given to parametric tests after preliminary log transformation of the parameters. For example, in a metabolic interaction study following a cross-over design, the effect of a given treatment on the log of the clearance of the tested drug is to be assessed through an analysis of variance; in a renal failure study including patients with various degrees of renal impairment, the correlation of the log of the clearance of the tested drug with the log of the glomerular filtration rate is to be evaluated. When the distribution of PK

parameters departs significantly from a log-normal, nonparametric tests should be applied instead.

A particular case is represented by *bioequivalence* trials, which are intended to establish the absence of clinically relevant difference between two formulations of the same agent. In this situation, it is not sufficient to show an absence of statistically significant differences. The ratio of the parameters of interest ( $AUC$ ,  $C_{\max}$ ,  $T_{\max}$ ) between both formulations is to be calculated in each study subject, and the bioequivalence can be claimed only if the statistical confidence interval at the 90% level around the geometric average of this ratio lies entirely inside a predefined range. Registration authorities set this range between 0.8 and 1.25 for  $AUC$  and  $C_{\max}$  and between 0.7 and 1.4 for  $T_{\max}$  [36, 37]. This is roughly equivalent to performing two one-sided  $t$  tests, and to conclude that the probabilities that the “true” ratio lies either below the lower limit or above the upper limit are less than 5% each [38]. A similar approach can be used to establish the absence of influence of food or of a potentially interacting drug on the PK profile of a given agent. Another investigation oriented toward showing an absence of difference is the assessment of PK linearity, usually performed by comparing dose-corrected  $AUC$  values. Here again, all the statistical calculations are to be done on log-transformed values (as suggested by the asymmetrical acceptance range for the confidence interval around the ratio of parameters of interest).

### 18.2.3 Population PK Studies

Population PK studies differ in many aspects from the classical sample-rich trials, while their general aims remain similar, namely to characterize the absorption and disposition profile of drugs in humans. They must rely as well on efficient, reliable, and validated analytical methods. Their importance is increasingly recognized in both academic circles and registration authorities, and they are progressively invading drug development [39]. They are not aimed to replace, but rather to complement, the small-sized trials performed during early drug development in healthy volunteers. They can be easily engrafted, indeed, on other types of studies, such as phase II or phase III therapeutic trials.

***Specificities of Population PK Study Protocols*** While classical PK trials mainly derive from the tradition of physiological experimentation, population PK studies owe something to epidemiological concerns: drug characteristics should be established from observations gathered in field conditions, where the drug is employed for therapeutic purposes. This explains substantial differences in study protocols and data analysis techniques [40].

The *study subjects* will thus preferably be representative patients having to receive the drug for a medical condition, rather than healthy subjects selected according to strict normality criteria. This does not mean that population approaches cannot be used in phase I trials: They can indeed, only with less relevance. Subject heterogeneity, which is considered as a nuisance in experimental trials, is regarded in population studies as a valuable opportunity to assess the variability of PK parameters and to identify determinant factors affecting their value. A condition, however, is to carefully record what the relevant subject characteristics are (gender, age, body weight, medication, morbidity, renal and liver function tests, genotype results for

polymorphic enzymes or transporters, etc.), so that they can be used as explanatory *covariates* during data analysis.

Population *study designs* are also less stringent: While healthy subjects are able to undergo intensive investigations, involving numerous blood samplings over a short time, medical patients should not be exposed to cumbersome study protocols. Specific population data analysis techniques can accommodate sparse-sample designs. Therefore, instead of obtaining a lot of measures in a restricted group of subjects, population studies will tend to include a larger number of patients (several dozen at least), with each patient providing only a limited number of observations (usually between 3 and 12). This makes, for instance, population studies represent the only way to address pharmacokinetic issues in pediatrics. Moreover, neither the dosing regimen nor the blood sampling schedule need to be rigorously standardized, as population techniques will accommodate unevenness in doses, intervals, blood sampling times, and even administration routes. So the study patients may take their drug and undergo venipuncture on convenient times (this may be initially accepted with perplexity by health professionals, who often associate clinical research with the requirement for strict timetables). Of prime importance is, however, the thorough recording of all actual dosing and sampling times. Dose determination issues need also to be considered (see above). In addition, compliance may represent a noteworthy problem, while it is rarely an issue in classical PK experiments. Compliance determination using electronic devices may thus be suitable in some population PK trials.

This flexibility makes population PK studies relatively easy to append to a variety of clinical trials. In particular, phase II and phase III therapeutic trials may clearly benefit from this kind of extension (which can be applied only to a subgroup of patients, e.g., those in the hospital). This will help to assess concentration–efficacy and concentration–toxicity relationships in the target patient population, to uncover causes of treatment failure or toxicity, to design dosing adaptation strategies for specific patient subgroups, and to optimize rationally the medical utilization of new drugs. A further step will be to pool the PK data gathered during all phase I, II, and III trials of a new drug into a large database, and run a systematic population analysis with proper exploration strategies and confirmation cycles, which will extract all clinically relevant knowledge from concentration data. This has been achieved for some newly developed drugs; however, it represents nonnegligible technical requirements and expenses, in terms of data management, computer facilities, and specialist time [24].

In summary, population PK studies are remarkably flexible toward patient inclusion criteria, drug administration, and sampling time schedules, but this implies that each blood sample tube comes associated with a set of carefully recorded clinical data. The data to record vary from one study to another, and the following tentative list is only indicative:

- Patient identity and unique number in the study
- Study group and investigation center, when relevant
- Usual dosing regimen regarding the study drug
- Last dose administered, along with precise dosing time and other relevant details (e.g., route, formulation, infusion rate, compliance assessments, etc.)

Accurate sampling time

Demographic covariates, such as gender, age, body weight, height, and ethnicity  
Scores of organ insufficiency (heart, kidney, liver), global functional scores (in chronic disease patients)

Biochemical markers of organ function, such as typically creatinine or bilirubin  
Concentration of plasma carriers (albumin,  $\alpha_1$ -acid glycoprotein), for drugs highly bound

Genotype results regarding relevant polymorphisms susceptible to affect drug disposition (whenever tested, which is increasingly the case)

Concomitant medications, to be classified at the end of data collection according to their potential for interaction with the study drug (e.g., inhibitors of inducers of a given cytochrome P540 isoenzyme)

**Analysis of Population PK Data** The analysis of a set of observations collected during a population PK study represents a nontrivial assignment. It requires both specific computer facilities and specialized skills [40]. An analysis will include in a single run the PK data obtained in all study subjects. The system will fit them with a family of PK models, based on a common equation (or system of equations), with variable parameters allowed to take different values between each subject.

Formally, if we call  $f$  the common equation, without specifying it, the model for the  $j$ th concentration value observed in the  $i$ th subject will correspond to the general expression:

$$y_{ij} = f(x_{ij}, \phi_i) + \varepsilon_{ij}$$

where the  $x_{ij}$  are the *fixed effects* that apply to sample  $y_{ij}$ , such as dose and relative sampling time, the  $\phi_i$  are the *individual PK parameters* values that characterize subject  $i$ , and  $\varepsilon_{ij}$  is a *residual error* (i.e., the difference between model prediction and actual observation). The errors  $\varepsilon_{ij}$  are assumed to be randomly distributed around zero with a variance  $\Sigma$ , which quantifies the residual or *intrasubject* variability, a mixture of measurement errors, biological oscillations, and model misfit. More complex error structures may be used, for example, involving both addition and multiplication of error terms and necessitating to define  $\Sigma$  as a matrix of variance components. This model for observations is complemented with a second layer of models, which express the variability of the subjects PK parameters and their dependency toward individual factors:

$$\phi_i = g(z_i, \theta) + \eta_i$$

where the  $z_i$  are the *covariates* characterizing subject  $i$  (which may even vary along time:  $z_{ij}$ ), the  $\theta$  are the average *population PK parameters* including constants that correlate individual parameter values with covariates, and  $\eta_i$  is a *random effect* affecting the parameter value in subject  $i$  (i.e., the difference between its “actual” value and the value predicted equation  $g$ ). The random effects  $\eta_i$  are distributed around zero with a variance  $\Omega$ , which quantifies the unexplained *intersubject* variability, while equation  $g$  captures the part of variability that is explained by the covariates. Here again, additive and multiplicative random effect models may be

used. Moreover, there may exist some degree of correlation between the random effects affecting various PK parameters, necessitating to define  $\Omega$  as a variance–covariance matrix.

Thus, fitting a population model represents a problem of hierarchical, or *mixed-effect* regression, which involves the presence of two levels of errors (a third level is sometimes introduced, leading to distinguish between intersubject, interoccasion, and residual variability terms). The individual PK parameters  $\phi_i$  cannot be directly measured and represent latent variables. In general, the mathematical expressions for the functions  $f$  and  $g$  above are not reducible to linear equations. The population PK parameters to be found are not only the values of the constants  $\theta$  but also the components of the variance matrices  $\Sigma$  and  $\Omega$  (hence the designation of *pharmacostatistical model*). Their estimation requires one to decide on appropriate fitting criteria and to apply efficient numerical algorithms. Many choices must be done regarding the equations  $f$  and  $g$ , the inclusion of influent covariates among the available  $z_i$ , and the acceptability of various underlying assumptions. That is why a series of sequential models are usually adapted to a given set of population PK data, requiring the adoption of appropriate decision rules, and giving utmost importance to a rational and clinically guided model building strategy.

Several software tools have been developed for this type of calculations [35]. NonMEM, developed by L. B. Sheiner and S. L. Beal at UCSF, remains the most widely accepted program in the field. While depending on a whole set of assumptions often difficult to validate, it provides a highly flexible framework for population data analysis, which can accommodate a unrivaled variety of study conditions. Several computer tools have been devised to facilitate NonMEM operation, lacking notably from user-friendliness (Wings, PDx-POP, Xpose). Other tools are currently available for population PK analysis, which use different algorithms and will suit a more restricted range of study problems (WinNonMix, P-Pharm, Kinetica, WinBUGS, Monolix, PopKinetics, USC\*Pack, etc.). Extension modules for population PK analysis are also available in all-purpose statistical packages (NLME for R and S-Plus, NLMIX for SAS, etc.).

Without going into much detail, we just summarize here the main concrete steps of a population data analysis [40]:

- The preparation of the data set may take a while, as stringent requirements of the computer program must be followed. The drug measurement results must be entered in a structured way, along with all corresponding clinical data (subject identification, dosing schedule, sampling times, and covariate values). Automatized extraction from a database is tricky to set up and requires careful checking.
- The simplest possible population model, chosen according to preliminary knowledge of the drug PK profile, should be adapted initially, without including any covariate. The resulting set of population PK parameters will serve as a baseline for further model building.
- A set of decision rules for the acceptance of refined models should be chosen. It is usual to consider indices of goodness-of-fit such as the improvement in log-likelihood or Akaike information criterion, diagnostic graphics such as scatter-plots of predictions versus observations or of residuals versus predictions (taking

both the individual and the population predictions), and commonsense arguments such as the clinical relevance of refinements introduced in the model.

- Usually, model building will begin with the search of an appropriate structural PK model, that is, deciding on the number of exponentials or compartments. The measurement of metabolites or urinary excretion may further complicate the problem. A second issue is the choice of the most appropriate error model, both for intraindividual and interindividual variability. Thereafter, the sequential inclusion of covariates will be tested. *Covariate selection* may be valuably assisted by graphical explorations, showing possible trends between individual parameter estimates and known subject characteristics. It is important as well to be aware of the meaning of each sophistication proposed for the model and to judge its clinical pertinence. Covariate centering is usually recommended; for example, when testing a dependency of distribution volume toward body weight (BW), the expression

$$V = \theta_1 + \theta_2 \frac{BW - 70}{70} + \eta_V$$

will be more satisfactory than

$$V = \theta_1 + \theta_2(BW) + \eta_V$$

As in the first case,  $\theta_1$  represents the volume of a typical 70-kg individual and  $\theta_2$  the change predicted a doubling in body weight, while in the second case, no particular meaning can be attributed to  $\theta_1$  and  $\theta_2$ . Moreover, convergence issues are better dealt with using the first type of expression.

- Once the final model is established, it must undergo a formal validation. Internal validation will be based on careful examination of diagnostic graphics, standard errors and cross-correlations of each parameter, sequential removal of each covariate to test its marginal significance level, estimation of the lack of fit, and the like. Whenever possible, external validation on a different set of data is recommended. Overparametrization is often an issue, and the principle of parsimony should be kept in mind during data modeling.
- The equations and population parameters of the final model should be presented, along with the model building history. A graphical representation of the model is often useful to show the typical concentration curve expected in an average subject receiving a usual dosage; a 90% prediction interval should ideally be drawn around the typical curve, using either simulations or error propagation calculations. Sophisticated visual predictive check techniques are increasingly recommended.

### 18.3 PHARMACOKINETIC–PHARMACODYNAMIC EVALUATIONS

Most drugs induce measurable effects, which mediate their therapeutic efficacy, and at least in part the adverse reactions that they can cause. Ultimately, human pharmacology trials aim to describe, explain, and predict not so much the concentration

profile than the effect profile of pharmaceutical agents, taking into account the administration scheme and the clinical characteristics of recipients. It is suitable that clinical pharmacodynamic trials include drug concentration measurements whenever possible, as the pharmacokinetic phase of drug action in humans represents usually the major source of variability in pharmacological response [19]. PKPD trials thus tend to break down the analysis of dose–response relationships into the sequential assessment of dose–concentration (PK) and concentration–response (PD) relationships. This section presents some considerations on the latter part of the work.

### 18.3.1 Pharmacodynamic Variables

Whereas a single type of data is encountered in PK modeling, namely drug concentration measures, PD trials happen to deal with a variety of response modalities. The global aims of both PK and PD investigations in humans remain, however, to record the profile of the respective variables along time. Hence many methodological considerations discussed above for PK studies apply similarly to PD and PKPD trials: necessity to develop and validate accurate, sensitive, specific, and reproducible measurement methods, importance of dose determination, accurate recording of dosage and measurement times, choice of an appropriate study design with respect to the scientific questions addressed, rational approaches for data description, interpretation and modeling, and the like.

All kinds of clinical, physiological, or biochemical measures can be employed as PD variables, as soon as they are shown to change in response to a given drug treatment. Their clinical relevance may, however, vary considerably. Certain variables correspond themselves directly to the *clinically relevant outcome* of a treatment, for example, the level of pain after administration of an analgesic. Other variables are used as *surrogate markers* for treatment outcome, based on sufficient preliminary evidence showing that they play a significant role in the pathophysiology of the disease under treatment and that their correction correlates with clinical improvement in the patient, for example, the levels of viremia and CD4-positive lymphocytes in chronic HIV infection. The evidence allowing a marker to be recognized as a valid surrogate for clinical outcome may be difficult to establish. For example, it has taken decades to confirm that blood pressure or plasma cholesterol levels, beyond their predictive potential regarding the occurrence of cardiovascular diseases, were amenable to pharmacological correction with an actual benefit for the patients; a famous counterexample is the case of ventricular arrhythmia, a condition apparently improved by antiarrhythmic agents, however, at the expense of increased patient mortality. Finally, mere *biomarkers* reflecting drug action are frequently measured during PKPD trials, however, without claim for a strong predictive value with regard to clinical outcome. Such markers may, however, help to understand the clinical pharmacology of new agents, to build up rational dosage strategies, and to develop useful treatment monitoring methods. Noticeably enough, some biomarkers are so tightly correlated with circulating drug concentrations that they can even be used for PK assessments: for example, circulating angiotensin-converting-enzyme (ACE) activity closely reflects blood concentration of ACE inhibitors.

The pharmacometric characteristics of PD variables are important to take into account when designing a PKPD trial. Whenever possible, *graded response markers* are preferable to accurately assess concentration–response relationships using

regression techniques and formal PKPD modeling. This kind of measures are therefore most frequently encountered in clinical pharmacology studies and include, for example, biochemical markers (e.g., glucose, lipids, electrolytes, hormones, cytokines, coagulation tests, etc.) and functional variables (e.g., electrocardiographic or electroencephalographic variables, spirometric flows, psychometric tests, etc.). The measurement of subjective symptoms can also be performed using continuous variables: This is the principal merit of *visual analog scales* (VAS), such as those used to assess pain or sleepiness. The subjects are presented with a 100-mm horizontal line printed on a paper, labeled with “none at all” on the left end and “worst imaginable” on the right end. They are instructed to place a mark on the line to report the intensity or quality of the sensation being experienced. The distance between the left end and the mark is recorded precisely and provides a suitable quantification of the subjective response. Symptoms and clinical signs may also be recorded using validated scores, typically on a 1–4 scale corresponding to clear definitions, for example, for the assessment of tolerability and adverse events (1, mild; 2, moderate; 3, severe; 4, life threatening). Such *ordinal variables* deserve a different treatment during data analysis. Formal validation is not less important for scoring methods than for graded response markers, however, slightly different approaches are used, including test–retest and interinvestigator concordance assessments. Lastly, *binary variables* can intervene in PD studies, such as typically success/failure assessment, for example, for infection cure.

Most effect variables measured during PD and PKPD trials are less precise and less specific than PK measurements, thus making effect profiles more irregular and noisy than concentration profiles. Evaluating the *signal-to-noise ratio* of a response marker is one of the objectives of the procedure of validation and may help to choose the most efficient measure among several available ones. Highly variable markers further increase the requirement for appropriate data analysis approaches, able to deal with imprecision and to extract pharmacologically pertinent trends. The choice of an appropriate *scale* for marker measurement is of importance, as it may dramatically influence data analysis and results interpretation (e.g., expressing the response to antacids as a change in either pH or  $H^+$  concentration in gastric juice). Frequently, PD response measures start from a certain *baseline level* that is to be thoroughly assessed before drug administration. Moreover, the level of the response variable may display systematic *fluctuations* even in the absence of an active substance, for example, due to cyclic modifications (circadian, circannual), spontaneous disease evolution, psychological influences, and the like. Therefore, PD and PKPD trials will often include a placebo arm, while this is useless in purely PK trials. Effect variables may also be distinguished according to their degree of *reactivity* or inertia. Some markers quickly respond to drug exposure and return to baseline thereafter, while others integrate the response over prolonged times. A striking example can be found in osteoporosis treatment: A marked response to bone resorption inhibitors can be recorded over a few hours in healthy volunteers while following specific bone resorption markers such as plasma or urine collagen degradation products; on the other hand, a radiological follow-up of bone density in patients takes years to reveal significant changes in this marker, which seems, however, better correlated with the fracture risk. In addition, the sensitivity of a response variable may decrease over time, due to a *tolerance* phenomenon, such as a decrease in number and/or excitability of cell receptors (e.g., with opioids), or the induction of physiological

counteraction mechanisms (e.g., with  $\alpha$ -blocker antihypertensives). Inversely, some responses display a phenomenon of *sensitization*, meaning an increase in amplitude over prolonged exposure (e.g., drug addiction or allergy). Appropriate PKPD models are thus required to account for such time-related changes in concentration–response relationships. Finally, the description of a drug effect over fairly long time periods may necessitate to take into account the proper kinetics of pathophysiological events that characterize the disease and that modulate its response to treatment. Such *disease evolution modeling* represents an important research area, leading clinical pharmacology to meet the traditional questions of therapeutics.

### 18.3.2 Concentration–Response Relationships

**Pharmacodynamic Data Description** Effect measurement results gathered during sample-rich trials can first be described using simple calculations fairly similar to those developed for PK data description (see above). This basic approach will be useful to summarize the results, apply statistical comparisons, and reveal important trends. The following calculations are applicable even when the effect curve shows some retardation compared with the concentration curve, provided the effect has been followed over a sufficiently long time to capture the major part of its development and resolution:

- The *maximum effect observed* ( $E_{\max}$ ) corresponds to the highest marker value in the curve.
- The *time of maximum effect* ( $t_{E_{\max}}$ ) is merely the time corresponding to the observation of  $E_{\max}$ . It is rarely determined with good precision, as it is measured on effect plateau.
- The *area under the effect curve* (AUEC) can be estimated by numerical integration over all segments of the effect curve. The *trapezoidal rule* is generally used to calculate AUEC segments. As it is exceptional that a model is proposed to fit the terminal part of the effect curve, no extrapolation to infinity is usually added to the sum of AUEC segments.
- Even if some usefulness could be imagined for an area under the moment of the effect curve, no such calculations are usually performed.

When sufficient amounts of data are available, those PD descriptors can be submitted to simple statistical tests to assess the effects of dose, demographic factors, medical condition, co-medication, or genotype and to explore their correlation with the elementary PK descriptors. Among various questions in consideration, the identification of the best PK predictor for the effect is of relevance: For example, among the antibiotics, one can distinguish agents with an efficacy depending on peak concentration (e.g., aminoglycosides), on the time of concentrations exceeding a threshold (e.g., penicillins), or on the AUC (e.g., macrolides) [41]. When different effects depend on diverse PK descriptors, manipulating the dosing regimen will help to enhance the specificity of the treatment for a given effect. This is a way to optimize the efficacy/toxicity ratio for anticancer agents, for example. Finally, such basic explorations are useful as an orientation for appropriate model selection in further PKPD analyses.

**Pharmacokinetic–Pharmacodynamic Models** The simplest representation of the dependency between circulating drug concentrations and effect levels postulates merely an instantaneous correlation between both variables. This view characterizes the *immediate PKPD models*, where the development and the resolution of the effect are directly driven by the shape of the PK curve. In the situations satisfying the assumption of immediacy, a simple correlation analysis between simultaneous effect and concentration measures is sufficient to describe the effect profile. Only exceptionally is a *linear* correlation appropriate for an accurate description. In most conditions, the level of response tends rather to increase proportionally to the logarithm of the circulating concentration, making relative concentration changes more accurately predict the effect level than absolute concentration values. *Log-linear* relationships are thus sometimes used in immediate PD models to relate an effect to a circulating drug concentration. This model is, however, not entirely satisfactory, as it predicts negative effects at very small concentration values. Moreover, in many pharmacological situations, the effect is observed to saturate at the highest values of concentration. Thus, a hyperbolic equation derived from the receptor theory is most often used to describe clinical concentration–effect relationships. This is the  $E_{\max}$  model relating an effect  $E$  to the drug concentration  $C$ :

$$E = E_0 + \frac{E_{\max}C}{EC_{50} + C}$$

where  $E_0$  is the baseline response level predicted for a zero concentration,  $E_{\max}$  the maximal increase in response predicted at infinite concentration, and  $EC_{50}$  the concentration associated with one-half of the asymptotic maximal effect. This expression corresponds to a sigmoid curve when represented on a log  $X$  axis. Inhibition of a response variable may require subtraction of the right-sided term from the baseline  $E_0$ . The value of  $E_{\max}$  is traditionally considered to reflect the *efficacy* of the drug, while  $EC_{50}$  expresses its *potency*. These parameters can serve to compare various drugs among a pharmacological class. For a given drug, different  $EC_{50}$  values characterize various types of responses (e.g., therapeutic and adverse effects), which may help to assess the *therapeutic margin* and define a suitable therapeutic range. Notice that the parameters of the clinical  $E_{\max}$  model have little to do with their counterparts found during in vitro pharmacological experiments. A supplemental coefficient of steepness  $\gamma$  may be added in the concentration–response curve, giving *Hill's* or *sigmoid  $E_{\max}$  model* (initially developed to describe the affinity of oxygen for hemoglobin):

$$E = E_0 + \frac{E_{\max}C^{\gamma}}{EC_{50}^{\gamma} + C^{\gamma}}$$

Further PD models have been developed to account for less usual shapes of concentration–effect curves.

For binary response variables, a convenient description of the PK dependency uses the *logistic regression* model, which associates to each concentration level  $C$  a probability  $\pi(E)$  of successful achievement of the effect:

$$\pi(E) = \frac{e^{\alpha + \beta C}}{1 + e^{\alpha + \beta C}}$$

where the logit of  $\alpha$  gives the baseline probability in the absence of drug, and  $\beta$  indicates the log of the odds associated with a unit increase in concentration. A less sophisticated model sometimes used for binary responses is the step function curve, characterized by a single threshold concentration value, above which the effect is assumed to be achieved (e.g., the minimum inhibitory concentration for antibiotics).

Not infrequently, the expansion of the PD curve does not parallel the PK curve, and the effect appears with retardation, while still depending on the circulating concentration profile. In such situations, a concentration–effect scatterplot will not reveal a steady correlation but rather separate lines over the periods of concentration ascent and descent, respectively. Such a looping appearance of the concentration–effect curve calls for the application of *hysteresis PKPD models*. Several approaches have been devised to handle this phenomenon in modeling. The *link model* derives from the compartment theory and assumes that the circulating drug distributes in an effect compartment, where it induces the effect through an immediate relation as shown above [42]. Thus, the drug concentration at effect site is constructed as a latent variable. The retardation between plasma concentration and effect curves is explained by the time constant that determines drug accumulation and persistence in this peripheral effect compartment (this is in fact the rate constant of elimination from this compartment,  $k_{e0}$ ). This model is in accordance with physiological concepts, with receptors sometimes actually located in peripheral tissues, or receptors themselves found to progressively accumulate and slowly release ligands. Another class of models deserving mention are the *indirect models* [43]. These models, based on a compartmental approach, consider the effect marker as an endogenous substance, which is produced and eliminated with its proper kinetics. The drug administered is assumed to act either on the production or on the elimination rate of the endogenous marker, either to stimulate or to inhibit the process, through one of the direct concentration–effect relationships introduced above. While the drug concentration is supposed to influence immediately the rate of change of the endogenous marker, the resulting absolute marker level integrates this response over time with a definite inertia, thus accounting for the retardation between concentration and response curves. This model finds physiological justifications for a series of drugs known to act through second messengers, sometimes amenable to measurement (e.g., oral anticoagulants, which inhibit the synthesis of coagulation factors having specific turnover rates). It can also be applied to other situations where the turnover of a latent endogenous marker is nothing but a virtual representation.

A number of sophisticated PKPD models have been developed to describe more complex dose–concentration–effect relationships [44]. The production of a virtual antagonistic metabolite can be invoked to describe a phenomenon of tolerance, which is characterized by an antihysteresis loop. Feedback stimulation or inhibition loops can be added, either on PK or on PD processes. Further intermediary effect compartments can be designed. A complex interplay between the drug and living

pharmacological targets (e.g., viruses, cancer cells) can be modeled. Nonlinearity in PKPD models explain the schedule dependency shown by some drugs, meaning that the effect of a given total amount of drugs strongly depends on the way it is administered over time. Even paradoxical responses can be accounted for, with different administration schemes resulting in opposite effects (e.g., gonadotrophin-releasing-hormone analogs, which stimulate ovulation and hormone production when given in pulses but achieve a so-called chemical castration when released slowly from a depot formulation [45]).

### 18.3.3 Design and Analysis of PKPD Trials

As outlined above, PKPD studies are much more versatile than traditional PK trials due to the variety of measurable response markers, each of them having its own clinical relevance, pharmacometric properties, and endogenous profile. Hence PKPD study protocols have to be somewhat creative, but care must be given to have them produce good science anyway. The following recommendations deserve consideration for the design, execution, and analysis of PKPD trials:

- Precise study objectives should always be defined in advance, and one or a few of them should be specified as primary. The study design should be decided in accordance with the study aims, with consideration for preliminary knowledge of the characteristics of the drug tested. PKPD trials may involve single or multiple dosages, parallel or cross-over designs, and sample-rich or sparse-sample measurement schedules.
- The inclusion of a *placebo* arm is often useful in PKPD trials to assess the evolution of response markers in the absence of pharmacological agents. For trials testing an experimental treatment, the inclusion of a *verum* arm, that is, a reference treatment of known impact on the response markers, may be useful as positive control.
- A restricted choice of effect variables should be done, based on a selection of the most appropriate response markers. When a large number of response markers are available, the selection should be oriented to minimize the redundancy and to mainly retain variables that complement each other. For example, a rapidly reactive variable will be chosen along with a slowly integrative one. Marker measurement methods should undergo formal validation. A preliminary pilot study may be useful to check the feasibility of the methods before undertaking a large-scale trial.
- Whenever possible, basic robust descriptors should be calculated separately on both PK and PD results data, before initiating any formal PKPD modeling. In rich-sample trials, the questions corresponding to main study objectives are frequently addressed only with reference to such simple descriptors, while the fitting of a formal PKPD model is left among the secondary objectives. Individual and average response curves should be graphed for all study variables.
- In sparse-sample trials, population approaches are perfectly suited for data analysis and may work even better in this context than in purely PK trials. Most

computer facilities developed for this purpose allow the inclusion of both concentration and effect data, even though it makes the problem technically more demanding. *Population PKPD analysis* represents probably the best available tool for a rational exploitation of the results of human pharmacology trials [46]. Sometimes, only the PK data deserve a population analysis, while the PD data and PKPD associations are merely analyzed by simple statistical approaches applied to basic descriptors outlined above (e.g., AUEC), which can be correlated to the individual PK parameters produced by the population analysis. Another alternative is to first fit the data from the PK part, then fix all PK parameters, and then rerun the population analysis to estimate the PD parameters.

## 18.4 CONCLUSION

Clinical pharmacologists have the task to gather, produce and summarize relevant knowledge on the pharmacological profile of therapeutic drugs in order to optimize their medical utilization. Rational dosing regimens must be established, and consistent recommendations for dosage individualization must be issued. Many choices are to be discussed during early clinical drug development: selection of the best candidate among a family of compounds, route of administration, pharmaceutical formulation, dose level and dosing frequency, duration of treatment, dosage adaptation strategies (according to body weight, age, organ failure, coexistent diseases, interacting drugs or pharmacogenetic tests), requirement for some form of monitoring based on either biomarkers or drug concentrations, and the like. The answers to such questions should ideally be found before a candidate drug enters into large phase III confirmatory trials, where it should be ready for use as in clinical practice [4]. Considering all those questions, and the number of effect variables susceptible to be examined, one may envision vast drug development projects with hundreds of studies to explore any imaginable combination of choices. However, this is neither feasible nor really suitable. The aim of early clinical drug development is to find the most efficient pathway reaching the optimal combination of choices, across the tortuous hills and valleys of a multidimensional space of possible decisions. This requires to arrange a series of efficient, small-sized clinical experiments, each of them being designed according to the results of the previous ones. Exploration–confirmation cycles are continued until sufficient information has been obtained to devise rational dosing and monitoring recommendations. PKPD modeling and simulation represent highly valuable tools to improve this process [47, 48]. This effort does not end up at authorization to market. It is to be continued not only by drug manufacturers but also by academic researchers taking up the responsibility to raise critical questions and to challenge the therapeutic tools, so that the patients and the public obtain the best service from the drugs they buy. This is how clinical drug development definitely resembles the art of “response surface analysis,” to quote Sheiner [4] referring to an elegant theoretical framework developed in engineering [49]. This amazing vision must not be restricted to the sole domain of clinical pharmacology applied to drug development but will probably prove relevant in many conditions where human trials are planned, performed, and analyzed.

## APPENDIX NOTE ON GEOMETRIC AVERAGES AND COEFFICIENTS OF VARIATION

Both drug concentration data and pharmacokinetic parameters usually follow a skewed distribution among individuals, which is best described according to a *log-normal* rather than a Gaussian statistical model. This is because most pharmacokinetic processes are governed by *first-order rates* (i.e., transfer or reaction rates are proportional to the amount of substrate available), giving importance to *relative* rather than absolute changes.

In this situation, it is not appropriate to summarize results using ordinary mean and standard deviation (SD), as the thin and tall upper tail of the distribution will drag the mean well above the bulk of typical values and increase the magnitude of SD up to exceeding the size of the mean. A more suitable summary descriptor is the *geometric mean*, which is defined as the  $n$ th root of the product of  $n$  individual values. Practically, it is obtained by transforming the individual values into logarithms, computing the usual (arithmetic) mean of log transforms, and calculating back the antilog of this mean. For example, the three values 80, 100, and 125 correspond to a geometric mean of 100.

Computing the SD of those log-transformed data, and then taking its antilog, provides an estimate of the relative spread of log-normally distributed values: It can be interpreted as the typical factor either multiplying or dividing the geometric mean, which encompasses about two thirds of the data. For our three values 80, 100, and 125, this “geometric SD” represents a factor of 1.25. (Remember that the classical SD around an arithmetic mean is the typical difference either added to or subtracted from the mean, which encompasses about two thirds of a set of data that follow a Gaussian distribution). It may be more convenient to express this relative spread as a *percentage of variability*, by simply subtracting 1 from the geometric SD and multiplying by 100. In our example, this leads to a value of 25%. This value is higher than the “arithmetic” coefficient of variation, defined as the (arithmetic) SD divided by the mean (which would give  $22.6/101.7 = 22\%$  in our example). Nevertheless, it is sometimes called a *geometric coefficient of variation* (a more proper denomination would be the “coefficient of variation of the multiplicative model”). A more exact estimate for this coefficient can be calculated as the square root of the antilog of the variance of log-transformed data minus one (giving  $\sqrt{0.051} = 22.6\%$  in our example) [50].

For graphic purposes, it is recommended to represent geometric means associated with error bars showing their multiplication and division by the corresponding geometric SD. This is the easiest way to compute error bars that appear symmetric along a log Y axis (Fig. 3). Likewise, when parametric statistical tests are to be used for treatment or group comparisons on log-normally distributed data, a preliminary log transformation of the data is clearly indicated. Subsequently, it is possible to translate a difference between average log values back into a ratio of relative change. Study factors are thus assumed to impact multiplicatively rather than additively on the variables of interest, which they do most of the time (e.g., an enzyme inhibitor will be said to increase the concentrations of an interacting drug by a given percentage, rather than by a fixed amount in milligrams/liter). While this log-transform approach is standard practice in clinical pharmacokinetics, it would probably be suitable in many other areas of data analysis for clinical research.

## 19.1 INTRODUCTION

This chapter describes modeling and simulation (M&S) applied to clinical drug development within a pharmaceutical company. In that context, M&S serves the two goals of drug development: learning and confirming [1].

From the learning perspective, M&S is a tool to learn how the drug works. M&S helps us design and interpret clinical trials, the learning experiences of clinical drug development. M&S is also a framework for representing what we learn in the precise language of mathematics.

For confirming, M&S provides a rigorous context in which to make statistical judgments about relationships, such as whether increases in dose are significantly associated with increases in response.

As you can see from the previous paragraphs, it is conventional to use the phrase “modeling and simulation” as a singular noun. But modeling and simulation are different things. Let us begin with a separate consideration of each. We will then discuss some general notions about how models are built and briefly introduce Bayesian methodology, which plays a large role in M&S. Then we will pause to outline how the remainder of the chapter describes M&S in clinical drug development.

### 19.1.1 What Is a Model?

A model is a way of predicting outputs from inputs.

For example, consider a model to predict the steady-state concentration  $C_{ss}$  obtained by infusing a drug at rate  $R$  into a subject who has clearance  $CL$ :

$$C_{ss} = \frac{R}{CL} \quad (1)$$

The output is  $C_{ss}$  and the inputs are  $R$  and  $CL$ . Note that different inputs may play different roles. The infusion rate is at the discretion of the experimenter (physician, pharmacologist, . . .). The clearance is a characteristic of the subject and drug. Both might be called variables, or we might refer to the clearance, which may be unknown, as a parameter.

Now consider the systolic blood pressures at baseline, the start of the trial, among patients enrolled in a clinical trial for an antihypertensive drug. The protocol will specify some severity of hypertension for included patients, but there will still be variability among patients at baseline. We use the language of probability to create a model for such variability. Suppose the average baseline blood pressure among all eligible patients is  $\mu$  and the variance is  $\sigma^2$ . It is often the case that a collection of blood pressures follows a bell-shaped curve that we might characterize as a normal probability distribution. We then say the output—baseline blood pressure  $B$ —is predicted from the inputs— $\mu$  and  $\sigma^2$ —according to the Normal probability model:

$$B \sim N(\mu, \sigma^2) \quad (2)$$

In (2),  $B$  is called a random variable;  $\mu$  and  $\sigma^2$  are both considered parameters. Note that to represent a random variable as an output from its distributional model we use  $\sim$  instead of  $=$ .

Imagine observing steady-state concentrations by taking blood samples and assaying them. Even if model (1) is reasonable, and even if we know  $CL$  as well as  $R$ , our observed concentration will probably not exactly equal  $C_{ss}$  because of measurement error and because of physiological fluctuations that render the model incomplete. We account for this discrepancy by introducing a new variable, usually denoted  $\varepsilon$ , called the residual error. It is modeled as a random variable, analogous to the baseline blood pressures (2), and we often use the same Normal probability model. We usually assume a mean of zero for residual errors, so the only input is the variance,  $\sigma^2$ . We then expand (1) to

$$C_{ss} = \frac{R}{CL} + \varepsilon \quad (3)$$

$$\varepsilon \sim N(0, \sigma^2) \quad (4)$$

Note that in (3)  $\varepsilon$  plays the role of an input, but in (4) it plays the role of an output. Chaining models together in this way gives modeling great power while maintaining conceptual simplicity.

Suppose we administer a single intravenous bolus dose  $D$  of a drug at time 0, and suppose the systemic circulation behaves as if it is a single well-mixed compartment. Then the systemic concentration  $C$  of drug may be predicted as a function of the inputs dose ( $D$ ), time post dose ( $t$ ), clearance ( $CL$ ), and compartmental volume ( $V$ ) as

$$C(t) = D \exp\left(\frac{-CL t}{V}\right) \quad (5)$$

Models with time as one of the inputs play a very important role in clinical trials (and throughout science), so it is common to highlight the input time by using it as an argument in a representation of the output as a function, as  $C(t)$  in (5).

The one-compartment model (5) is somewhat special because we can write the dependence of concentration on time algebraically. Frequently, models with time as input can only be expressed by describing how the rate of change of the output

depends on time and other inputs, that is, as a differential equation. A differential equation corresponding to (5) is

$$\frac{dC}{dt} = -\left(\frac{CL}{V}\right)C \quad C(0) = D \quad (6)$$

The algebraic representation (5) is the solution to the differential equation (6). But often no algebraic solution can be found, and we must solve the differential equation numerically, which takes us to simulation.

### 19.1.2 What Is Simulation?

Simulation is the act of computing values of the output for given values of the input. In (1), if we plug in values for  $R$  and  $CL$  and compute the resulting value of  $C_{ss}$ , we have accomplished a very simple simulation.

Usually, however, simulation refers to repeating such calculations many times for different values of the inputs to see how changes in the inputs translate into changes in the outputs. The three most common situations are:

1. One of the inputs is time, and the computations are done to see how the output evolves as time progresses.
2. One or more of the inputs is a random variable, and the computations are done to see how the output varies due to the random process(es) represented by the random variable(s).
3. Both 1 and 2 together.

### 19.1.3 Model Building

Models seldom spring fully formed from the heads of modelers, at least if “fully formed” includes specification of the values of the model’s parameters. Usually, the parameters must be estimated by fitting the model to data. Often the structure of the model (e.g., algebraic functions, differential equations, or probability distribution) and the inputs that best predict the outputs are determined partly if not wholly by fitting different models to the data and choosing the one that seems best, a process called model building.

Fitting the model to data means selecting parameter values of the model to minimize some measure of discrepancy or maximize some measure of similarity between observed values of the output variable (the data) and predictions of the output variable from the model. The sum of squared differences between data and predictions is a measure of discrepancy; minimizing it yields a least-squares fit. A common similarity measure is the likelihood, which, as its name implies, quantifies how probable the observed data are according to the model; maximizing it yields a maximum-likelihood fit.

The more complex the model the better the fit in terms of least squares or likelihood. To decide when to stop building, called model selection, criteria may be used that penalize models for being too complex, both for the aesthetic appeal of parsimony and because theory shows that these criteria effectively home in on the best model. Two such criteria are the Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) [2].

### 19.1.4 Bayesian Methods

In the Bayesian approach to modeling, parameters are considered random variables not unknown constants. A parameter's probability distribution represents our uncertainty regarding its value. To learn is to reduce that uncertainty, corresponding to a reduction in the variance of the parameter's probability distribution. At the start of a new learning step, the probability distribution is called the prior. When we acquire new data and thereby learn something about the parameter, the updated probability distribution is called the posterior. This process of updating our knowledge, called Bayesian inference, is accomplished via Bayes rule, a mathematical formula. Berry [3] provides an introduction to Bayesian methods and their application in clinical trials.

### 19.1.5 What Lies Ahead

The remainder of this chapter will describe types of M&S used in clinical drug development and types of clinical trials that strongly depend on M&S. Each section will begin with a statement of purpose for the type of M&S covered or for the use of M&S in the clinical trial.

The sections will frequently cross reference one another. Curly braces { } will denote section number cross references, whereas square brackets [ ] will denote bibliographical citations and parentheses ( ) will denote equation numbers.

Although the chapter's parts must be sequentially ordered in a print medium such as this, there is no perfect sequencing of the material. Figure 1 displays one possible configuration of the dependencies among the sections.

**FIGURE 1** Dependencies among chapter sections.

The heart of the chapter is {19.2.4}, which covers dose–exposure–response (DER) modeling, the fundamental clinical characterization of how a drug works and how M&S helps determine what dose to give to which patients. {19.1.1}–{19.2.3} provide the fundamentals of M&S needed to understand how DER models are built and used. {19.2.5}–{19.2.6} introduce exciting new areas of biological modeling that support DER modeling with mechanistic underpinnings. {19.2.7} describes methods for characterizing higher level disease progression. Within the process of drug development, an important application of models is to support decision making; {19.2.8}–{19.2.9} cover that. Finally {19.3} showcases five types of clinical trials whose design and interpretation benefit from M&S; they are presented roughly in the order they might appear in a drug development program.

## 19.2 TYPES OF MODELING AND SIMULATION

### 19.2.1 Regression Models

**Purpose:** *To infer how one variable may be predicted empirically from one or more others using independent observations of those variables in a sample of subjects.*

One variable, such as blood pressure (BP) at the end of a hypertensive trial, is the output, called the response; and one or more others, such as baseline blood pressure, treatment, dose, age, and sex, are inputs, called predictors. The goal of relating the response to the predictors may be learning—for example, to devise a rule to predict future observations of the response—or confirming—for example, to test if one or more of the predictors, such as treatment, is statistically significant. The model is fitted to data comprising one record per subject, each record containing observations of the response and the predictors, with records from different subjects considered independent.

Instead of being derived from any scientific theory, the form of a regression model is selected as a compromise between mathematical convenience and the empirical representation of the data's shape. Often a linear model (7) suffices because relationships tend to be approximately linear over limited ranges of the data.

Simple linear regression has one continuous response, for example, BP, that depends on a continuous predictor, for example, dose, and residual error:

$$\text{BP}_i = \beta_0 + \beta_1 \text{dose}_i + \varepsilon_i \quad (7)$$

$$\varepsilon_i \sim N(0, \sigma^2) \quad (8)$$

where  $\beta_0$ ,  $\beta_1$ , and  $\sigma^2$  are parameters that are estimated by fitting the model to data and where the subscript  $i$  indexes the data, that is, here the subjects. Presumably, if the drug were an antihypertensive,  $\beta_1 < 0$ .

The adjective “linear” refers to the linearity of (7) with respect to the parameters  $\beta_0$  and  $\beta_1$ , not dose. If in (7) dose were replaced by, for example, the logarithm of dose, it would still be a linear model even though a plot of  $\beta_0 + \beta_1 \log(\text{dose})$  versus dose would be curved.

If there are several predictors, such a model becomes a multiple regression model.

Nonlinear regression is when some parameters appear nonlinearly, such as

$$BP_i = \beta_0 + \frac{\beta_1 \text{dose}_i}{\beta_2 + \text{dose}_i} + \varepsilon_i \quad (9)$$

Suppose we create a new response variable,  $Y$ , by considering only whether BP dropped by 3 mmHg or not, for which we assign  $Y = 1$  or 0, respectively. Logistic regression is where the logit transformation of the probability that  $Y = 1$ , say  $p$ , is modeled linearly as

$$\text{logit}(p) = \log \left[ \frac{p}{(1-p)} \right] = \beta_0 + \beta_1 \text{dose} \quad (10)$$

Logistic regression is an example of a broader class of models called generalized linear models [4], where some function of the mean of the response is related linearly to the predictors.

A clinical outcome may be the time to some event, such as death. Regression models for such a response time are a major component of survival analysis. The chance of the event occurring in the next instant of time, given that it has not happened yet, is called the hazard. In the Cox proportional hazards model, the logarithm of the hazard is related linearly to the predictors.

Many statistics textbooks cover regression modeling. See [5] for a nontechnical introduction or [6] for a technical one.

### 19.2.2 Longitudinal Models

**Purpose:** *To infer how one variable may be predicted empirically from one or more others using observations measured at more than one time per subject in a sample of subjects.*

Whereas regression models {19.2.1} are appropriate when subjects independently contribute one observation each, longitudinal models describe multiple observations collected over time for each subject. The several observations of the same individual tend to be correlated, which must be accounted for by the model. This additional complication buys, for confirming purposes, additional precision and power, and, for learning purposes, additional insight into how the response evolves as conditions change.

Regression models generalize to longitudinal models in two ways: marginal models and mixed-effect models.

The focus of a marginal model is to predict the population's average response, generally for confirming purposes. As in generalized linear models {19.2.1}, some transformation of the average response is assumed to admit a linear structure in the predictors. The correlation structure is handled somewhat empirically using methods that are known to be robust with sufficiently large samples; see [7].

Marginal models have two main limitations. First, they require that all subjects have the same number of observations under the same design. Second, they generally are not informative about individual responses.

Mixed-effect models (MEMs) overcome these limitations. An MEM is constructed hierarchically, by chaining models together as described in {19.1.1}, starting from a model for the response of an individual. The parameters of the individuals' separate models are themselves outputs of regression-type models. This accounts for the necessary correlation structure of the data and allows the models to be fitted to data even where subjects have different numbers of observations at different times.

Let us consider an MEM generalizing (7–8) to describe a study where each subject receives successively higher doses at each of which BP is measured. Let  $BP_{ij}$  and  $dose_{ij}$  be the  $j$ th observed BP and dose for the  $i$ th subject. The MEM is

$$BP_{ij} = b_{0i} + b_{1i} dose_{ij} + \varepsilon_{ij} \quad (11)$$

$$b_{0i} = \beta_0 + \eta_{0i} \quad b_{1i} = \beta_1 + \eta_{1i} \quad (12)$$

$$\eta_{0i} \sim N(0, \omega_0^2) \quad \eta_{1i} \sim N(0, \omega_1^2) \quad \text{corr}(\eta_{0i}, \eta_{1i}) = \rho \quad (13)$$

$$\varepsilon_{ij} \sim N(0, \sigma^2) \quad (14)$$

Each subject has his or her own intercept and slope  $b_{0i}$  and  $b_{1i}$ . These inputs to model (11) are outputs of the models (12). The random variables  $\eta_{0i}$  and  $\eta_{1i}$  are called random effects. They characterize the variation among subjects of the intercepts and slopes of the BP-vs.-dose relationships, and their presence accounts for the correlations among the several  $BP_{ij}$  values for the  $i$ th subject.

Suppose we believe that some of the variation in the dependence of BP on dose is due to age. We need only make age an input to the model for  $b_{1i}$  in (12):

$$b_{1i} = \beta_1 + \beta_2 \text{age}_i + \eta_{1i} \quad (15)$$

If any of the parameters in an MEM besides the variances appears nonlinearly, then the model is called a nonlinear MEM or NLMEM, which will figure prominently in {19.2.4}.

Longitudinal models for clinical trials are reviewed in [8]. See also [9].

### 19.2.3 Exploratory Modeling and Data Mining

**Purpose:** *In large data sets, to find patterns that can be used as hypotheses to guide further experimentation or as retrospective explanations of surprising signals.*

Exploratory modeling in clinical drug development has two main applications. The first is part of the guided knowledge generation that is common to all science, when some general goals of discovery are pursued in the hopes of generating hypotheses that might be confirmed with further experimentation. Examples are mining genomic data to find potential biomarkers, or mining clinical data to find possible new indications for marketed drugs.

An alternative setting occurs when a clinical trial produces some surprising signal, such as a worrisome toxicity. Sometimes called fire-fighting, exploratory modeling then seeks to propose a plausible story for the observed results. Such a story would ultimately require confirmation, and thus this second application is really one of

hypothesis generation like the first; but if strong enough, such modeling results might be proposed as tentatively confirmatory or at least satisfactorily descriptive for, say, a regulatory submission.

The steps of exploratory modeling are (a) defining the problem, (b) exploring the data with graphical, tabular, and numerical summaries, (c) building models, and (d) validating models.

In the first two steps, the scope of potential models is clarified by learning the structure and content of the data and identifying any important substructures such as grouping in study centers, or local laboratories with different reference ranges, or time profiles of observations.

The nomenclature of data mining, derived largely from computer science, often refers to modeling as the application of various algorithms. Commonly used algorithms are listed below. To link with our view of modeling {19.1.1}, for each algorithm we identify the kind of outputs. In every case, the inputs might be anything else in the database; finding the right inputs and their relationship with the outputs is the model building {19.1.3}.

*Classification Algorithms* The output is one or more discrete variables, such as responder versus nonresponder. Methods include logistic regression {19.2.1}, rule induction, decision trees, neural networks,  $K$ -nearest neighbors, and support vector machines.

*Regression Algorithms* The output is one or more continuous variables, such as blood pressure. Methods include linear regression {19.2.1}, regression trees, and neural networks.

*Segmentation Algorithms* The output is the assignment of a patient into one of several groups, or clusters, of patients that have similar properties. Methods include clustering techniques, neural networks, and visualization methods.

*Dependency Algorithms* The output is any variable in the data set, and often outputs are inputs for other relations in a chain or network that represents associations among different variables. Methods include correlation analysis, association rules, and Bayesian networks.

Finally, after a model is built, its prediction performance is evaluated. Cross-validation, bootstrapping, and bagging are the techniques usually used. Sensitivity, specificity, positive predictive value, negative predictive value, accuracy, and receiver operating characteristic (ROC) curve are the mostly used evaluation metrics. For a comprehensive introduction to these ideas and data mining generally, see [10].

#### 19.2.4 Dose–Exposure–Response Modeling

A fundamental goal of drug development is to learn what dose of the drug to give to which patients. Most drugs reach their site of action via the systemic circulation, so drug concentrations in the blood or plasma are often more predictive of response than dose. Hence, one way of building a dose–response model is to concatenate a dose–exposure (or pharmacokinetic) model with an exposure–response (or pharmacokinetic/pharmacodynamic) model. But direct modeling of dose–response is also done. This section describes these various models.

**Dose–Response Modeling**

**Purpose:** *To characterize the relationship between dose and any measurable response.*

Dose–response modeling is regression modeling {19.2.1} or longitudinal modeling {19.2.2} with dose as input and response as output. Examples are models (7–14). Responses may be biomarkers, clinical outcomes, adverse events, or even pharmacokinetics, although the latter merits separate consideration (see below). See {19.3.4} for use of such models in dose-finding trials.

**Pharmacokinetic (PK) Modeling**

**Purpose:** *To describe measured drug concentrations as a function of dosing regimens and, usually, time.*

Pharmacokinetics is “what the body does to the drug,” as in absorption, distribution, metabolism, and elimination (ADME). Systemic drug concentrations are measured in repeated blood (or plasma) samples over time after one or multiple doses administered to healthy volunteers or patients. PK models characterize such concentrations by mathematically quantifying the ADME processes as parameters such as clearance (the flow at which the drug leaves the body), volume of distribution (the apparent volume in which the drug is distributing), half-life (the rate at which the drug is declining, once transient events in the body have taken place, a parameter that combines influences of elimination and distribution). Examples of such models are (1, 3–6).

Models (5–6) are appropriate when the PK behaves as if drug distributes within a single, well-mixed compartment. Quite often, however, the PK data require assuming the drug distributes among multiple compartments; usually two or three are adequate to describe a PK profile. All such models are referred to as compartment models.

A comprehensive reference on PK models is [11].

Ultimately, the number of compartments in the body is (at least) the number of homogeneous tissues. This is recognized by physiologically based PK (PBPK) modeling, which, in the situation of transitioning from animal studies to first-study-in-man, attempts to predict the key human pharmacokinetic parameters in advance before doing the actual experiments {19.3.1}. A PBPK model is based on literature data in human and animal models about blood flows and sizes of respective organs, and on actual compound-specific PK data in animals (e.g., the rat, mouse, dog, and less often the monkey). For animal-to-human extrapolation, the approach is extremely resource intensive and problematic, despite recent advances. In rare situations, retrospective attempts to develop PBPK models have been largely successful, for instance, for well-known drugs (oncology, morphine) or in other applications, like extrapolations from adults to children [12].

Population PK is another extension of PK modeling; see discussion below for details.

Pharmacokinetics results provide instrumental knowledge along the development of a compound and are essential for the drug submission dossier to help characterize the clinical pharmacology of the new chemical entity [13]. The classical method for data analysis initially avoids models and is therefore sometimes called “noncompartmental analysis.” Metrics of exposure to the drug like  $C_{\max}$  (the

maximum concentration value) and AUC (the area under the measured concentration time points) are determined through simple calculations. This approach, combined with cross-over experiments assessed by analysis of variance, is extremely powerful for descriptive and comparative purposes (e.g., across formulations or dosing regimens).

Quite often, the exposure metrics  $C_{\max}$  and AUC are considered as outputs in dose–response models (see discussion above). A commonly used model is the so-called power model:

$$\text{AUC} = \beta_0 \text{dose}^{\beta_1} \quad (16)$$

Of interest is whether or not  $\beta_1 = 1$ , in which case the PK is said to be dose proportional or linear. Testing whether  $\beta_1 = 1$  is a confirming role for (16).

### **Pharmacokinetic/Pharmacodynamic (PK/PD) Modeling**

**Purpose:** *To characterize the mutual variation of drug concentrations and biomarkers or clinical responses to the drug.*

Pharmacodynamics is “what the drug does to the body.” PD data comprises observations of a marker of drug effect in a subject, be it a systemic marker (e.g., a hormone or a pathway intermediate), a diagnostic assessment [e.g., a QT interval within the electrocardiogram (ECG)], a surrogate marker [e.g., HbA1c for diabetes or CD4 counts for human immunodeficiency virus (HIV)], or a clinical outcome (e.g., fractures in osteoporosis, death in oncology). Usually, the observations are repeated over time, or, for single events such as death, the time to event is relevant.

A very simple class of PK/PD models, commonly used for clinical outcomes in chronic diseases, uses the same empirical forms as dose–response models (see discussion above) but replaces the input dose with a summary measure of systemic exposure such as AUC.

The objective of PK/PD modeling is often to describe temporal delays of the PD response relative to the PK. A classical type of PK/PD modeling for this purpose is the effect-compartment model, when the drug exhibits its effect in a compartment that is not in rapid equilibrium with the systemic circulation [14]. Such a compartment may represent a real physiological space, such as the brain for anesthetics, or it may be empirically imputed solely to account for the observed delay. The drug concentration in such a compartment is an output of the PK part of the model and an input for the effect of the drug on the PD. In some cases, when the distribution to the site of action is extremely slow, the maximal effect can be achieved late after the administration of the drug, when the systemic concentrations are no longer detectable (have reached levels below the limit of assay quantification).

Another more physiological approach for accounting for delays between the time course of the drug effect relative to drug concentration is the turnover model (initially introduced as the “indirect-response model”) [15]. Under normal physiological conditions, the rate of production,  $k_{\text{in}}$ , of the marker of drug effect is equal to the rate of elimination,  $k_{\text{out}}$ ; “nothing happens”—the level of the marker remains constant at  $k_{\text{in}}/k_{\text{out}}$ . Depending on the compound and the marker, the drug effect is described as a stimulation or inhibition of the rate of production or of the rate of elimination. For instance, a single turnover model is adequate to describe, across a broad range of bisphosphonate doses, the kinetics of selected markers of bone

degradation which are inhibited by 0–80% even in healthy subjects. These markers are fast, reacting over hours/days. Bone mineral density is a slow bone marker, where changes are detectable over months/years.

It is important that the PD assessment is part of the causal chain linking the dose of drug to the ultimate clinical effect (e.g., reduction of fracture in case of a drug for osteoporosis, diminishing the risk of heart failure for a cardiovascular drug). Biomarkers are important tools to make drug development more efficient. Reacting more quickly to therapeutic interventions than clinical responses, sometimes even in healthy subjects, they may be signals to guide rapid and inexpensive decision making. The number and type of links in the causal chain will vary; for example, a biomarker may be a parallel process to the clinical effect (as shown in Fig. 2) or it may be directly in the causal chain. Nonetheless, the biomarker should clearly indicate that the drug has bound to the intended target.

In the effect-compartment model and in the turnover model, concentration serves as the stimulus to effect. In contrast, there are situations where PK and PD are intimately linked and cannot be separated, for example, monoclonal antibody kinetics [16], where the PD, the interaction of the drug with its receptor, plays an important role in the actual disposition and elimination of the drug, the PK. With such target-mediated drug disposition, further complexities arise; for example, the system may become nonlinear, with overproportional increase in AUC with dose. PK/PD models are necessary; noncompartmental approaches for PK analysis are largely insufficient.

Further mechanism-based PK/PD models have been reviewed recently [17]. These authors highlight that the principles are well known and illustrate a large amount of experience with these models in a wide variety of therapeutic areas. Much of this experience has accumulated presently in academic settings. However, experience within the pharmaceutical industry is increasing dramatically as the potential of the approaches reaches the attention of senior management and regulators.

In early-phase drug development, PK and PK/PD models are often used to predict the concentration (and response) after multiple dosing based on the first human trial after single-dose administration. Such models may be used in clinical trial simulation {19.2.8} to help in planning future studies, such as proof-of-concept studies {19.3.3}.

Since the uncertainty under such circumstances is great, one cannot expect a model to be always right, even if it is based on the most accurate quantitative data and knowledge available at this particular point. Learning in the form of ongoing revision to the model ought to occur all along the development of the compound and should incorporate insights from the development of similar pharmacological entities or different compounds addressing the same therapeutic indication.

**FIGURE 2** Causal chain.

In terms of regulatory submission, when a model is used for extrapolation, it must be validated beforehand or agreed upon with the regulators that the approach taken is convincing [18].

As an integrative tool later in development, population PK/PD modeling is more and more used for dose–exposure–response assessment [19]; see discussion below.

### **Population PK Modeling**

**Purpose:** *To explain and predict how systemic drug exposure varies among subjects.*

Population pharmacokinetics (PopPK) originated as an attempt to infer the patterns of PK response within a patient population from sparse PK data collected under routine clinical care [20]. Nonlinear mixed-effect modeling {19.2.2} was employed, according to which the parameters of compartmental PK models are themselves considered outputs of models where patient covariates (and random effects) comprise inputs. For example, clearance might depend on body size, age, and the presence of some concomitant therapy that induces a drug–drug interaction.

PopPK has evolved into a widely used tool in clinical drug development for characterizing the variability of PK in patient populations by means of nonlinear mixed-effect models [21, 22].

PopPK is valuable when “a reasonable a priori expectation exists that intersubject kinetic variation may warrant altered dosing for some subgroups in the target population” [23]. It can be used strategically to help assess a need for altered dosing, as in ethnic bridging [24]. It is also useful whenever PK understanding is needed but only sparse PK data can be collected, for example, pediatric trials [25]. Regulators frequently request a PopPK analysis as part of a submission dossier, and many drug development scientists believe that a PopPK characterization of variability is an essential component of a development program.

The steps of using PopPK for clinical trials are design, data collection, model building, model validation, and model application.

The design goal for PopPK is usually to extract useful PK information from few blood samples per patient. Optimal design methods have been implemented in software for such purposes [26].

Data collection can be problematic because the clinical sites are not always used to it. Care must be taken that dates and times of dosing and blood sampling are accurately recorded because errors in that data can lead to biased and imprecise estimates of the model’s important PK parameters.

Building the submodels that describe how the compartmental PK parameters depend on covariates is an intensively data-driven task. Optimal strategies for this step are the subject of much current research [27].

Model validation is demonstrating that the model is credible for its intended purpose. If the only purpose is quantification and explanation of variability, then validation might consist of checking stability of the parameter estimates when refitting the model to random subsets of the data [28]. Ever more frequently, concentration outputs from PopPK models are used as inputs into models for clinical responses as part of integrated dose–exposure–response models (see next section) and for clinical trial simulation {19.2.8}. To be used for such a purpose, the model should be validated by demonstrating that its predictions are consistent with observed data

(predictive checking [29]), preferably new data that was not used as part of the model building (external validation [30]).

### ***Integrated Dose–Exposure–Response Modeling***

**Purpose:** *To comprehensively describe relationships among dose, exposure, and clinical response (efficacy and safety), often by pooling data from several clinical studies.*

The clinical response (effectiveness, undesirable effects) to a specific dose of a drug varies from patient to patient. With an integrative dose–exposure–response (IDER) model, one tries to understand which factors are responsible for individually differing responses. This information is important for the safe and effective use of a drug in individual patients. For example, it can help to specify an appropriate individualized starting dose, or the best way to adjust doses for individual patients [31].

The IDER analysis is typically done in two steps: First, the relationship between dose and drug concentration in blood (exposure) is described, and factors responsible for variations in exposure are identified (such as body weight or renal function); a PopPK analysis (see above) can provide this information. Second, the PK/PD relationship between drug concentration in blood and clinical response is investigated, and factors responsible for individual differences (such as gender or ethnicity) are identified. The PK and PK/PD models are cumulatively learned throughout the drug development process. Both mechanistic models (e.g., pathway models {19.2.5} or physiological models {19.2.6}) and empirical models (e.g., regression models {19.2.1} or longitudinal models {19.2.2}) are used for the development of the IDER relationships.

An IDER model can have a powerful impact in getting the drug approved and providing guidance on dosing. An example is the development of Certican (everolimus) in combination with Neoral (cyclosporine) for prophylaxis of acute organ rejection in renal transplant recipients. Studies in about 1200 patients showed good efficacy but unsatisfactory renal function when everolimus was administered as 1.5 or 3.0 mg daily together with full dose cyclosporine [32, 33]. An IDER model [34] revealed that improved efficacy was associated with everolimus exposures above 3 ng/mL, but that efficacy did not vary with observed cyclosporine exposures. On the other hand, better renal function was associated with lower cyclosporine exposures, whereas renal function did not vary with observed everolimus exposures. The IDER model thus suggested that therapeutic drug monitoring (TDM) should be used for everolimus to ensure that everolimus exposure is above 3 ng/mL in each patient, and that cyclosporine exposure should be individually reduced using TDM. This regimen was then prospectively tested in an additional study with about 250 patients that confirmed the predicted good efficacy and renal function [35, 36].

### **19.2.5 Pathways Modeling**

**Purpose:** *To describe and quantify the dynamic behavior of biological signaling pathways.*

As discussed in {19.2.4}, clinical response to a given drug varies from patient to patient. This variability can be due to routinely collected demographic factors such as gender and race, but it can also be due to different protein and gene expression

levels, as well as mutations in relevant biological entities, such as the drug target or the drug metabolizing enzymes.

Mathematical models of signaling pathways elucidate the dynamical behavior of such relevant biological entities. In terms of target discovery and validation, such models may suggest what are the optimal ways that the system can be manipulated by drugs [37]. In targeted therapies used in oncology, such models can help elucidate possible combinations of drugs that would together achieve efficacy without interfering with the physiological function of the drugs' targets in normal tissue, thus limiting toxicity [38, 39]. In combination with molecular dynamics simulations, such models can address the role that a mutation in the drug target has in the overall clinical efficacy seen with a drug [40]. Schoeberl et al. [41] have used mathematical modeling to show that different protein expression levels from different cell lines and tissues can lead to largely different behavior of the same signaling network and thus helped to reconcile seemingly contradictory literature results.

Signaling pathways are usually modeled by a set of differential equations {19.1.1}, where the state variables are proteins or protein complexes within the signaling pathway. The kinetic parameters in the system include the Michaelis–Menten constant, turnover numbers, and rate constants of association and dissociation [42].

Development of highly predictive pathway models is difficult because such models require (1) complete characterization of the molecular interactions in the pathway and (2) numerical values for the parameters associated with the model equations. Parameter values are often determined via numerical optimization against experimentally measured quantities (model fitting, {19.1.3}). This, in turn, creates an additional complexity for models of realistic size since the number of the unknown parameters is too large as compared to the available experimental data [37]. Sensitivity analysis can determine the dominant parameters, which helps both by pointing to data that can best inform and constrain the model, as well as by suggesting possible biomarkers [43]. In addition, specialized techniques such as extended metabolic control analysis [44], determining the components that control the dynamics of signaling pathways, facilitate the extraction of the relevant pathway modules to be included in a larger disease model {19.2.7} for clinical development.

### 19.2.6 Physiological Modeling

**Purpose:** *To describe mathematical models of tissues and organs and outline possible utility in clinical drug development.*

Mathematical models of human physiology have been of interest for a long time [45]. The IUPS Physiome project (<http://www.physiome.org.nz>) represents a worldwide public domain to build a computational framework and quantitative understanding of human physiology and pathophysiology. As new data accumulates, these models have become increasingly more sophisticated and biologically plausible. Organs that have been described by such mathematical models include kidney [46], respiratory tract [47], heart [48], and even the whole human physiology [49]. Because constructing these models is complex, data intensive, and computationally expensive, such modeling efforts have been largely the subject of academic research with somewhat limited applications to human health. However, the situation appears to be changing with the accumulation of data, government funding, and establishment of consortia and collaborative efforts that pool data across different organizations.

One example for a tissue-level model that is being used to guide clinical decision making is that of cardiac electrophysiology. The last decade has been marked by the withdrawal of several medicines whose use in patients has been associated with the development of torsade de pointe (TdP), a potentially fatal polymorphic tachycardia [50]. Regulatory guidelines [51] propose the prolongation of the QT interval on the electrocardiogram as a biomarker for torsadogenic risk of a given compound. However, TdP is triggered by a dynamic combination of multiple factors, and so, in order to reduce the number of false positives and false negatives, pharmaceutical companies are looking into combining the strengths of different methodologies (both experimental and modeling) to make the best informed decision. A detailed description of the cardiac system in humans allows inclusion of experimental data on the effects of different drugs in a relatively simple manner [52] and prediction of the effect of the molecules both in reference to healthy subjects as well as high-risk individuals. It is worthwhile to note that as the models become more predictive and computation becomes cheaper, such prospective simulations can be used routinely in the drug development process and can serve as data integration tools.

### 19.2.7 Disease Progression Modeling

**Purpose:** *To improve the assessment and predictability of a drug's impact on a disease by distinguishing drug-specific properties from disease-specific properties.*

Many chronic diseases that are targets of drug development, such as Alzheimer's, diabetes, and osteoporosis, are degenerative. The durations of clinical trials may not be insignificant on the time scales of disease progression. So disease progression is a source of variability, accounting for which can improve the detection of drug effect. On the other hand, clinical trials are almost always short relative to the expected duration of a drug's use by a chronic-disease patient. So a reliable forecast of a drug's long-term impact is important for developers, prescribers, patients, and payors.

Disease progression models first quantify the evolving status of a disease absent a drug and then characterize alterations induced by the drug. This hierarchical approach facilitates clarity, extrapolation to different dose regimens, and comparison of different drugs.

Although models for different diseases might be expected to have little in common, certain simple model forms have been found practical as well as conceptually enlightening. Chan and Holford [53, 54] considered the constant progression model,

$$\frac{dS}{dt} = \alpha \quad S(t) = S_0 \quad (17)$$

where  $S(t)$  is the disease status at time  $t$ ,  $S_0$  is the initial status, and  $\alpha$  is the rate of disease progression. They cited use of such a model for Alzheimer's, Parkinson's, chronic obstructive pulmonary disease (COPD), and diabetic nephropathy.

A drug may alter  $S(t)$  by affecting  $S_0$ ,  $\alpha$ , or both. A drug effect on  $S_0$  is considered a symptomatic effect; if drug treatment stops,  $S(t)$  reverts to its original trajectory. A drug effect on  $\alpha$  is considered a protective effect; if drug treatment stops,  $S(t)$

**FIGURE 3** Untreated disease progression and symptomatic and protective drug effects.

continues on a trajectory displaced from the original at the position where treatment stopped. See Figure 3.

Post et al. [55] introduced a class of models based on the disease process being a perturbation of a turnover model {19.2.4}. The disease alters  $k_{in}$  or  $k_{out}$  in a progressive way. Symptomatic drug effects add to or multiply the perturbed  $k_{in}$  or  $k_{out}$  without affecting the process of perturbation. Protective drug effects affect the process of perturbation directly. Models of this sort were applied to type 2 diabetes in [56].

### 19.2.8 Clinical Trial Simulation

**Purpose:** *To assess the expected performance of clinical trial designs and analysis methods.*

Clinical trials often have one or both of two objectives related to the two goals of drug development {19.1}: (i) learning—estimate some characteristic of the drug's behavior, such as the maximum tolerated dose; and (ii) confirming—test some hypothesis about the drug, such as whether the drug is superior to placebo. Modelers have long studied how different experimental designs, estimates, and tests affect the accuracy and precision of such inferences [57]. When their algebra and calculus are not powerful enough to quantify these properties, modelers resort to simulating {19.1.2} their experiments on the computer, for example, [58, 59].

Holford et al. [60] identified three broad classes of questions for which simulation experiments might be useful: (1) To investigate the properties of new model-based methods, such as nonlinear mixed-effect modeling for PopPK {19.2.4} [61]. (2) To study the properties of novel trial designs, such as concentration-controlled trials [62]. (3) Applications to specific clinical trials, for example, [63, 64]. For the latter, different designs can be input to the model and the best design selected for actual implementation based on comparison of the outputs. Simulating the different designs

may cost tens of dollars; actually conducting the trial may cost millions; the small investment of model-based forethought can have a big impact.

A trial simulation model may be thought of as one large model, the key input to which is the design of a clinical trial, and the key output of which is some performance measure of the trial. However, it is useful to consider component models. Commonly, these include an integrated dose–exposure–response (IDER) model [19.2.4], a covariate distribution model, and a trial execution model [60].

The covariate distribution model describes the trial’s target patient population in terms of the distribution of relevant covariates, such as the distribution of blood pressures in (2).

The trial execution model is a computer algorithm for simulating the trial. It generates simulated patients according to the covariate distribution model who experience outcomes according to the IDER model. The trial execution model may allow deviations from the trial protocol through noncompliance, missing observations, and the like. The trial’s simulated data are statistically analyzed according to the protocol. This is done repeatedly for many simulated replications of the trial. Then the statistical outcomes of all of the trials are summarized as a performance measure that addresses the question that motivated the simulation experiment.

An excellent compendium on clinical trial simulation is [65].

### 19.2.9 Decision Analysis

**Purpose:** *To help clinical teams create, compare, and evaluate strategies for clinical development, and to achieve clarity of action in choosing among strategies in the face of uncertainty.*

Modeling and simulation is a powerful tool for decision making due to its role in knowledge integration and its ability to quantify “what-if” scenarios via trial simulation [19.2.8]. Decision analysis is a structured process designed to facilitate effective communication between decision makers and a project team (including modelers and experts), driving toward clarity of action [66, 67]. Matheson and Matheson [68] characterize six components of a decision analysis: (1) framing, (2) strategy generation, (3) meaningful, reliable information, (4) clear values and trade-offs, (5) logically correct reasoning, and (6) commitment to action. Decision quality is achieved when further improvement in each component is not worth the additional time and resources that would be required. Each of these six components is now explained:

1. *Framing* consists of understanding the key questions. A decision hierarchy is developed to distinguish between those decisions already made, those decisions that are to be made now, and those that can be settled at a later time.
2. In *strategy generation*, creative doable strategies are assembled from different alternatives associated with the decisions to be made now.
3. *Meaningful, reliable information*. An integral feature of decision-analytic thinking is to accept the existence of uncertainties and to quantify them by means of probability distributions. Probabilities over clinical (and sometimes also market) possibilities may be developed via modeling from data, but also may be carefully assessed from experts in a manner designed to reduce various biases [69].

4. *Clear values and trade-offs* are selected to allow meaningful, quantitative comparisons of strategies. For-profit companies will typically be concerned with expected (i.e., probability averaged) net present (dollar) value. However, some useful proxies may also be evaluated, and then explicitly balanced against resources (i.e., cost and time). In early-phase “proof-of-concept” trials {19.3.3}, the proxy focus is typically the chance of a correct “go/no-go” after completion of the trial. In later phase (dose finding) trials {19.3.4}, the focus shifts toward the chance for correctly choosing the best dose regimen(s). For phase III trials, the focus is the chance of correctly confirming a compound’s safety and efficacy, leading to successful registration. Beyond the clinical development of a single compound, larger decisions may be analyzed, such as allocation of resources between many development projects in a portfolio [70].
5. *Logically correct reasoning* proceeds comparing the performance of selected strategies against the chosen evaluation criteria. Typically, trial simulation and probabilistic (Bayesian) inference {19.1.4} must be used. Sensitivity analysis can also be performed and the value of information computed [67], allowing better focus on the most salient information.
6. *Commitment to action* among stakeholders is achieved by involving the right people in the above steps. This includes a planned sequence of opportunities for the decision maker to provide input into the frame, the strategies chosen for consideration, and the evaluation criteria.

Other authors might use the term “decision analysis” to refer to steps 3–5. Examples of such decision-theoretic M&S applied to clinical trial designs can be found in [71, 72]. However, the fuller decision analysis process that includes all of steps 1–6 often generates insights leading to improved strategies; teams who engage in such a systematic process frequently report that the open, guided discussion of assumptions, uncertainties, alternatives, and values along with emergent insights provide as much or more benefit compared with the mathematical model outputs.

## 19.3 M&S-BASED CLINICAL TRIALS

### 19.3.1 First-in-Man Studies

**Purpose of M&S:** *To estimate doses for first-in-man studies.*

A hallmark of a good development candidate is to have a high probability of surviving through the clinical proof-of-concept PoC study {19.3.3}, showing pharmacologically useful activity. To assess this one answers three questions: (1) Is the site of action exposed to sufficiently efficacious drug concentration for a suitable duration? (2) Do these concentrations have a suitable safety profile? (3) Can formulations that achieve these concentrations be developed? Several research and development functions generate data, each utilizing different methodologies. M&S should play a key role to fully integrate these data, anticipate doses likely to elicit pharmacological and adverse effects in humans, and then optimize the early clinical development program.

The dose for a first-in-man (FIM) study is generally determined by following international, public guidances of the International Conference on Harmonisation (ICH) E8 [73] and ICH M3 [74]. These provide the rationale for estimating a safe starting dose by specifying target organs, dose dependency, relationships to exposure, and potential reversibility in FIM trials. Further, ICH S6 [75] (for biologicals) defines the principle of relative safety exposure between test animals and humans. The no-observed-adverse-effect level (NOAEL) and the toxic dose in animals are the bases of anticipating the FIM dose, and uncertainty of estimation is accounted for by setting safety margins. The Food and Drug Administration (FDA) [76] gives guidance on the maximum recommended starting dose (MRSD) for FIM studies by  $\text{mg}/\text{m}^2$ -based scaling of Good Laboratory Practice (GLP) toxicology data with a typical 10-fold safety margin.

That said, the guidance [76] does not cover how to determine the pharmacologically active dose, that is, the lowest dose with the intended pharmacological activity, making MRSD essentially a safety secured dose. However, an MRSD far below the pharmacologically active dose requires a long dose escalation scheme, while an MRSD far exceeding the right dose range will not allow us to detect the complete dose–effect relationship [77]. In addition, the guidance-compliant approach does not necessarily fully secure the safety, as highlighted in 2006 by TGN1412, a monoclonal antibody whose MRSD was calculated by conventional approaches with a 500-fold safety margin, but six healthy volunteers were seriously injured in the FIM study.

Collectively, a rational approach is demanded to efficiently anticipate FIM doses, in addition to the guidances, following the core scientific principle that drug effects are a function of target exposure. A three-step process is practical to anticipate the human dose–response [78] (Fig. 4): (1) Experimentally, determine exposure–response relationship in preclinical (animal) studies. Blood (plasma) concentration is often considered as a surrogate to the target exposure, assuming drug distribution equilibrium between circulating blood and drug target. Summary measures such as AUC or  $C_{\text{max}}$  [19.2.4] may be used if appropriate. (2) Adjust the exposure response curve from preclinical species to human. This will involve correcting for interspecies differences (e.g., known binding affinities to blood components and/or the drug target). (3) Convert the anticipated exposure–response to dose–response in humans using

**FIGURE 4** Anticipating the first-in-man dose.

pharmacokinetic scaling, such as allometry [79] or physiologically based pharmacokinetic modeling {19.2.4} [80].

### 19.3.2 Oncology Phase I Studies

**Purpose of M&S:** *To optimally design and analyze first-in-man trials for oncology drugs.*

First-in-man trials for oncology trials differ from other therapeutic areas because oncology drugs often cannot be tested in healthy volunteers due to their toxicity at therapeutic doses. The typical design for such trials is therefore a dose escalation scheme in patients, with interim analysis and dose escalation/stopping decisions after each cohort. The primary endpoint is the occurrence of a dose-limiting toxicity (DLT), and the primary objective is the assessment of a maximally tolerated dose (MTD), corresponding to an acceptable target rate of DLTs. In order to optimally design such trials, the M&S challenge is to define decision rules for dose escalation and MTD selection (specifically, model-based rules), and to evaluate their operating characteristics through simulation.

Heuristic rules to decide upon dose escalation and MTD declaration have been proposed [81, 82], the most popular being the so-called “3+3” method, which bases decisions on whether to escalate, keep, or deescalate doses on how many DLTs are observed in the previous cohorts of size 3. Starting with the so-called continual reassessment method (CRM) [83], many model-based methods have been introduced, where decision rules and MTD selection are based on a model fitted to the available data. In its simplest form, where DLT is binary (i.e., occurrence or nonoccurrence), a model for DLT has the rate of DLTs as output and the dose as input along with parameters: rate of DLTs =  $f(\text{dose, parameters})$ . Due to the sparseness of the data (binary data from few patients), complicated models with many parameters cannot be fitted; thus, the proposed models typically have one or two parameters. An example is the two-parameter logistic function:  $\text{logit}(\text{rate of DLTs}) = \alpha + \beta \log(\text{dose})$ , where  $\text{logit}(p) = p/(1 - p)$  {19.2.1}. After each cohort, the model is fitted to the data, either through maximum likelihood {19.1.3} or using a Bayesian approach {19.1.4}. The latter has some distinct advantages since it allows to base decisions on posterior probabilities of the quantities of interest [84]. For example, one may want to specify the optimal target rate of DLTs to be in the range [0.25, 0.33]; anything beyond 0.33 would be deemed unacceptable toxicity. In a Bayesian framework, this is easily transformed to a decision rule, by choosing a dose maximizing the posterior probability of the rate of DLTs being in the interval [0.25, 0.33], while keeping the posterior probability that the rate of DLTs exceeds 0.33 below a threshold, for example, 0.05; this may be complemented with restrictions on how many dose levels to escalate.

The evaluation of operating characteristics is done through clinical trial simulation {19.2.8}. Generic features can be evaluated through the simulation of typical situations (see, e.g., [84]). However, specific trials with a unique set of prior assumptions and logistic restrictions will very often require specific simulation-based evaluation.

For a discussion of different approaches, with an emphasis on Bayesian methods, see [84] and the references given therein. For a nontechnical introduction see [85]. For references to extensions such as time-to-event and continuous outcomes, covari-

ates, combination trials, and combined safety–efficacy outcome, see references given in [84–87].

### 19.3.3 Proof-of-Concept Studies

**Purpose of M&S:** *To improve the information value of proof-of-concept trials with regard to efficacy and safety evaluation.*

Early development studies for establishing proof-of-concept (PoC) generally use small patient cohorts (typically between 10 and 20) observed for a relatively short period of time (several weeks) in a dose escalation design to evaluate early efficacy and safety signals. Cohorts are assigned, in sequence, to increasing doses until the maximum tolerated dose, generally determined in a previous study, is reached, or unacceptable safety is observed for a given cohort. A new cohort is only allowed to start once acceptable safety signals are verified for all previous doses. At the end of the study, one hopes either to determine a dose range for further exploration in phase IIb or to conclude that no PoC can be established based on the efficacy/safety trade-off.

Because of the small cohort sizes, only safety problems occurring in a relatively large percentage of patients can be reliably detected. Likewise, only relatively strong efficacy signals can be detected with reasonable statistical power using traditional pairwise hypothesis tests.

Safety and efficacy variables are often measured on a continuous scale and observed several times over the duration of the study. However, typically, the end-points for the go/no-go decision are based on a single time point (e.g., change from baseline at end of study) and on dichotomized versions of the original variables to characterize responder/nonresponder behavior. An example of the latter is the transformation of continuous liver function test measurements [e.g., alanine aminotransferase (ALT) and aspartate aminotransferase (AST)] into binary indicators of exceeding three times the upper limit of normal. There are, therefore, two types of information loss often present in PoC studies: (1) not using of all available longitudinal measurements collected in the study and (2) the dichotomization of continuous endpoints.

Safety and efficacy signal detection can be made more efficient in a variety ways: by using information external to the trial and longitudinal modeling approaches {19.2.2} to exploit all available information. Furthermore, the utility of PoC studies within the drug development program can be enhanced by incorporating the information obtained in them directly into later phase trials. Bayesian modeling techniques {19.1.4} are particularly useful in implementing these different approaches.

The key idea is to use a Bayesian mixed-effect model (typically nonlinear) {19.2.2} to characterize the longitudinal dose–response behavior of efficacy and safety variables, measured on a change from baseline scale (e.g., log of measurement divided by baseline). Preclinical or other external data can be used in the elicitation of priors for the Bayesian model. The estimated model is then used to simulate longitudinal profiles of change from baseline for different doses, which are combined with a sample of baseline values, obtained from a database of previous trials with a similar population, to produce dose–response longitudinal profiles. Dichotomization and other transformations can be applied to the simulated profiles to evaluate efficacy and safety more efficiently compared to using a single dichotomized time point. An

additional benefit of the approach is that it allows the use of external information, frequently available in pharmaceutical companies.

### 19.3.4 MCP-Mod: Unified Strategy for Dose-Finding Studies

**Purpose of M&S:** *To combine multiple comparison procedures and modeling in dose finding.*

Understanding and adequately representing the dose response (DR) profile of a compound, for both efficacy and safety, is a fundamental objective of clinical drug development. Proper understanding of this relationship has both a confirming and a learning component: confirming whether there is an overall DR effect (proof-of-concept {19.3.3}); and if so learning which doses to select for further development (dose finding). Selecting too low a dose decreases the chance of showing efficacy in later studies, while selecting too high a dose may result in tolerability or safety problems.

The analysis of dose-finding studies can be classified into two major strategies: modeling [88,89] and multiple comparison procedures (MCP) [90,91]. Dose–response (DR) modeling {19.2.4} assumes a functional relationship between dose (taken as a quantitative factor) and the response, according to a prespecified parametric model (defined in the study protocol). While this provides flexibility in investigating the effect of doses not used in the actual study, the validity of its conclusions highly depends on the correct choice of the DR model, which is typically unknown.

A multiple comparison procedure regards dose as a qualitative factor and makes very few, if any, assumptions about the underlying DR model. It can either be used for detecting an overall dose signal by means of trend tests or for the estimation of target doses by stepwise testing strategies, while preserving the overall type I error rate at a prespecified level. Such procedures are relatively robust to the underlying DR shape but are not designed for extrapolation of information beyond the observed dose levels.

MCP-Mod is a hybrid methodology combining features of MCP and modeling to provide a flexible and principled approach for designing and analyzing dose-ranging studies. Its central idea is the use of a set of candidate DR models to cover the possible shapes anticipated for the DR relationship. MCP are applied to a set of test statistics, determined optimally for the models in the candidate set, to decide which shapes give statistically significant signals. If no candidate model is statistically significant, the procedure stops and declares that no DR relationship can be established from the observed data (i.e., no proof of concept). Otherwise, out of the statistically significant models a best model is selected for dose estimation in the last stage of the procedure. The selection of the dose estimation model can be based on the minimum  $P$  value (of the candidate models) or some other relevant model selection criteria such as AIC or BIC {19.1.3}. The selected dose–response model is then employed to estimate target doses using inverse regression techniques [where the output (response) and input (dose) exchange roles] and possibly incorporating information on clinically relevant effects.

Simulation results suggest that MCP-Mod is as powerful as standard trend tests, while allowing more precise estimation of target doses than MCP, due to its modeling component [88, 92]. It is worth pointing out that this method can be seen as a

seamless design that combines proof of concept (phase Ib/IIa) with dose finding (phase IIb) into one single study.

### 19.3.5 Adaptive Trials

**Purpose of M&S:** *To determine the operating characteristics of an adaptive design, and ensure that the optimal design will be conducted.*

Adaptive designs are a relatively new type of clinical trial in which data from the trial can be used to modify some design aspect of the trial while the trial is still ongoing. This greater flexibility allows for design aspects to be modified in the case where some original trial design assumptions were incorrect, without having to wait for the conclusion of the trial. Such flexibility can save a considerable amount of development time for a novel drug. Adaptive trials can also combine what traditionally might be two separate studies into a single trial, thereby eliminating the time between the two trials. However, in order to design these trials, the decision process must be carefully thought out in advance and specified in the protocol. Often, clinical trial simulation {19.2.8} is the best way to understand and modify the operating characteristics of an adaptive trial.

Although there are many types of adaptation, one common type, sample size reestimation, is very appealing because often the parameters needed for sample size calculations are completely unknown at the beginning of the trial. Therefore, the idea is to try to estimate these needed parameters during the trial and modify the sample size accordingly. However, it has to be understood that at this interim time, the estimates for these parameters have considerable variability in them as well. Therefore, it might not be optimal to use such estimates directly, but instead use them to guide the calculation for the final sample size. A decision rule can be defined for how the sample size will be changed, and then computer simulation can be used to determine how the sample size would change under various scenarios.

Another type of adaptive design is a seamless adaptive design in which two trials are combined together. For example, a trial could be designed such that multiple doses are started in the beginning of the trial, and then the optimal dose is selected during an interim analysis. Additional patients would then only be randomized to the selected dosage group (and control), and all the data would be used at the conclusion of the trial to determine if the selected dose was indeed efficacious. If proper statistical testing procedures are in place at the end of the trial, then this type of design could cover objectives of both a phase II dose-finding study {19.3.4} and a confirmatory phase III trial.

For this type of seamless adaptive trial, simulation must also be used to determine the operating characteristics of the trial. For example, once a dose–response model {19.2.4} is assumed, and the dose selection algorithm is defined, the trial could be simulated to determine how often the selected dose would have a significant statistical test for efficacy at the conclusion of the trial (the statistical power for the trial). Another important characteristic of the trial that could be determined via simulation is the selection probabilities for each of the doses. Simulations should then be performed using different assumed dose responses, selection rules, and sample sizes to ensure that the trial has robust operating characteristics under many different scenarios.

For an introduction to adaptive trials, see [93].

## 19.4 DISCUSSION

This chapter introduces M&S in clinical drug development. Just a chapter cannot do the topic full justice, and indeed a thick book has recently been published that surveys the field [94]. The references herein provide some historical markers as well as some general introductions to specific methodologies. Readers interested in following trends would do well to monitor the journals *Clinical Pharmacology and Therapeutics*, *Journal of Pharmacokinetics and Pharmacodynamics*, *Statistics in Medicine*, and others cited in the references.

## 20.1 REASONS FOR MONITORING CLINICAL TRIAL DATA

Many traditional methods for the analysis of data assume that the data are all available contemporaneously. This reflects the setting of agricultural experimentation in which much of the methodology was developed, as data on crop yields from different fields are collected simultaneously after harvesting. In the majority of clinical trials, however, patients are recruited over a period of time, so that data accumulate gradually through the course of the trial, with data from some patients available prior to the recruitment of others. This accumulation of data makes possible the statistical analysis of some of the data collected before the trial is completed. Such analysis of data during the course of the trial is termed *monitoring*.

There are a number reasons why monitoring of clinical trial data might be considered desirable. The first is an ethical reason. In a randomized trial, randomization of subjects to receive one treatment or another is generally considered ethically acceptable provided there is *equipoise*, that is, an uncertainty as to which treatment is superior. If clear evidence was available that one treatment was of superior efficacy to the other, or that one treatment was less safe than the other, continued randomization would be considered unethical. In a single-arm trial, enrollment in the trial would be similarly considered unethical if the treatment being assessed clearly led to an unacceptable level of adverse events. Monitoring of efficacy and safety data allows the results of an ongoing trial to be regularly assessed and enables termination of the trial as soon as the results are sufficiently convincing that continued recruitment cannot be ethically defended.

The second reason for monitoring a clinical trial is administrative. As the trial progresses, it is desirable to ensure protocol compliance, check data collection procedures, and to monitor recruitment rates. The estimation of nuisance parameters (such as the unknown variance for normally distributed responses) used in power calculations can also be conducted to ensure that the trial will have a sufficient sample size before the close of recruitment.

The third reason for monitoring a clinical trial is economic. Clinical trials are expensive, and it is not in the interest of sponsors or patients to continue a trial once the results are clear. By monitoring the accumulating data, a clinical trial can be stopped as soon as sufficient data are available to justify a conclusion that an experimental treatment is superior or inferior to the control, or that the data clearly indicate that any difference is so small that continuation of the trial is futile.

In a blinded randomized trial we may consider data monitoring to be divided into three types: first, administrative monitoring of clinical trial conduct and monitoring of safety data with no monitoring of efficacy data; second, monitoring of efficacy data without unblinding of treatment allocation, for example, for the estimation of nuisance parameters; third, monitoring of efficacy data with treatment allocation unblinded to allow the estimation of the difference in efficacy between the treatments being compared. In the latter two instances, administrative and safety monitoring will most likely be conducted in addition. As will be discussed in Section 20.3, it is the third of these types of monitoring that presents the most ethical and statistical challenges. It is therefore on this type of monitoring that the majority of the chapter will be focused. Before moving on, however, the first two types of monitoring will be discussed briefly in the next section.

## 20.2 MONITORING OF CLINICAL TRIAL DATA WITHOUT UNBLINDING TREATMENT ALLOCATIONS

### 20.2.1 Administrative and Safety Data Monitoring

Monitoring of administrative data such as recruitment rates, accuracy of completion of record forms, treatment compliance, and data collection/transfer procedures is common in large clinical trials. The aim of such monitoring is to ensure that any problems in trial conduct or data collection are identified and rectified as soon as possible. Identification of incomplete record forms from a particular investigator could lead, for example, to collection of the missing data prior to the end of the trial, while observation of a lower than anticipated recruitment rate might justify the introduction of new centers in a multicenter trial. An example of a form to assess ongoing treatment compliance as part of a trial is given in Figure 1. Administrative monitoring of this kind is generally conducted without unblinding treatment allocation since treatment information is generally irrelevant. The risks of increased error rates or release of information about the performance of the study drugs that could lead to bias as discussed in Section 20.3 therefore do not arise from this sort of monitoring.

Many large trials also involve some monitoring of safety data. As discussed above, in a trial in which serious adverse events may be observed, this type of monitoring serves an important ethical function. In order to assess whether there is an excess number of adverse events in one treatment group relative to the other, it is necessary to unblind treatment allocation. In some cases, the two treatment groups are presented simply as groups A and B, without indicating which group is receiving the experimental treatment and which the control. However, it is generally easier to interpret adverse events in the light of the treatment administered, so that full unblinding is considered to be a better practice [1]. The unblinding of treatments introduces the risk of bias as discussed in Section 20.3. In order to minimize this risk, particularly in large clinical trials, the safety data may be reviewed by a *data and safety monitoring board* (DSMB) (sometimes alternatively called a *data monitoring committee*), so that only members of this committee need have access to the unblinded data. This committee decides on the basis of the unblinded data reviewed whether or not it is safe for the trial to continue and makes its recommendation to the *trial steering committee* responsible for the overall conduct of the trial. Further details of the role and function of DSMBs are given by Ellenberg et al. [2] and Whitehead [3]. Two example forms for monitoring adverse events are given in Figures 2 and 3. Figure 2 illustrates the categorizations to be used when determining adverse events and their attributability. Figure 3 shows how a case report form for serious adverse events might be structured.

As the purpose of safety monitoring is solely to recommend termination of the clinical trial if an experimental treatment is associated with too many adverse events, this type of monitoring cannot lead to a positive claim of effectiveness for the experimental treatment based on the monitored data. This means that, in contrast to the type of efficacy monitoring discussed in Section 20.3, there is no risk of a false-positive conclusion arising as a result of this monitoring; that is, the type I error rate cannot be increased. The special statistical methodology that is discussed in the rest of this chapter is therefore not required in this case.

**FIGURE 1**    Example form for monitoring treatment compliance.

**20.2.2    Monitoring for Estimation of Nuisance Parameters and Sample-Size Reviews**

Sample size calculations at the planning stage of a clinical trial often require the specification of values for unknown parameters other than the treatment effect of primary interest. These are often known as *nuisance parameters*. For example, if data are assumed to be normally distributed, the primary measure of relative treatment

**GUIDELINES FOR RECORDING OF ADVERSE EVENTS**

**NB A SERIOUS ADVERSE EVENT is defined as the following:**

- Any untoward medical occurrence that at any dose
- Results in death
  - Requires inpatient hospitalization or prolongation of existing hospitalization
  - Results in persistent or significant disability/incapacity
  - Is life threatening (at the time of the event)

**FIGURE 2** Example categorizations for adverse event monitoring.

efficacy will often be the difference in the mean response for the two treatments. Specification of the variance of the response, which is commonly assumed to be the same in the two groups, is, however, needed for calculation of the required sample size. A second example is for binary data, when the sample-size calculation depends on the average probability of success for the two groups. In practice, in such cases, the guess of the nuisance parameter required before the start of the trial may be inaccurate. This might lead to an inappropriate choice of sample size and to an underpowered or overpowered trial.

**FIGURE 3** Example form for monitoring serious adverse events.

Gould and Shi [4] proposed, as a solution to this problem, the use of an analysis of the accumulating data part way through the trial to estimate the unknown nuisance parameter in what is usually termed a *sample-size review*. A review of the method and further advances in the methodology is given by Gould [5]. The required sample size for the trial can then be obtained based on this estimate of the nuisance parameter, and the sample size for the remainder of the trial adjusted accordingly. For example, suppose a trial with a normally distributed response was initially designed with a sample size of 100 patients. An analysis could be conducted when data were available from 50 patients to calculate the unknown common variance. At this point it might be revealed that the estimated variance based on the data was larger than the value anticipated when the trial was planned, so that the trial is likely to be underpowered. Based on the estimate from the data, the required sample size might be 120 patients rather than the initial 100 planned. The second stage of the trial could then recruit a total of 70 rather than 50 patients to give this total sample size. Simulation studies have shown that such an approach is effective in maintaining the power even if the initial guess of the unknown nuisance parameter is inaccurate.

In the case of normally distributed data, as in the illustration above, the nuisance parameter that is estimated at the sample size review is the common variance. The usual pooled variance estimate is given by

$$s^2 = \frac{1}{n_{E1} + n_{C1} - 2} \left[ \sum_{j=1}^{n_{E1}} (x_{Ej} - \bar{x}_{E1})^2 + \sum_{j=1}^{n_{C1}} (x_{Cj} - \bar{x}_{C1})^2 \right] \quad (1)$$

where  $x_{E1}, \dots, x_{En_{E1}}$ , with mean  $\bar{x}_{E1}$ , are the  $n_{E1}$  observations on the experimental arm and  $x_{C1}, \dots, x_{Cn_{C1}}$ , with mean  $\bar{x}_{C1}$ , are the  $n_{C1}$  observations on the placebo arm. The calculation of this estimate requires a knowledge of which patients are in which treatment group, so that the treatment allocation must be unblinded. As explained below, this is undesirable in clinical trial monitoring as it may lead to bias through the differential treatment and interpretation of further patients in the trial.

Expression (1) for  $s^2$  can be rearranged to give

$$s^2 = \frac{1}{n_{E1} + n_{C1} - 2} \left[ (n_{E1} + n_{C1} - 1)s_0^2 - \frac{n_{E1}n_{C1}}{n_{E1} + n_{C1}} (\bar{x}_{E1} - \bar{x}_{C1})^2 \right] \quad (2)$$

where  $s_0^2$  is the overall estimate of variance, which can be calculated without breaking the blind, given by

$$s_0^2 = \frac{1}{n_{E1} + n_{C1} - 1} \left[ \sum_{j=1}^{n_{E1}} (x_{Ej} - \bar{x})^2 + \sum_{j=1}^{n_{C1}} (x_{Cj} - \bar{x})^2 \right] \quad (3)$$

with  $\bar{x}$  the overall mean.

This suggests a method for estimation of the standard deviation from blinded data. The first term in (2), depending on  $s_0^2$ , can be found from the unblinded data. An estimate of the standard deviation can thus be obtained from blinded data together with an estimate of  $(\bar{x}_{E1} - \bar{x}_{C1})$ , the treatment difference. Gould [5] suggests

using the treatment difference under which the power is calculated to give an estimate of the standard deviation on which a new sample size can be calculated. If we denote this difference by  $\delta_R$ , replacing  $(\bar{x}_{E1} - \bar{x}_{C1})$  in (2) by  $\delta_R$  gives an estimate of the variance of

$$\frac{1}{n_{E1} + n_{C1} - 2} \left[ (n_{E1} + n_{C1} - 1) s_0^2 - \frac{n_{E1} n_{C1}}{n_{E1} + n_{C1}} \delta_R^2 \right]. \quad (4)$$

If an estimate of the unknown variance is based on blinded data, the sample size reestimation procedure does not have any impact on the overall type I error rate, in contrast to the more general sequential monitoring that is discussed in the next section. The type I error rate may be inflated, however, if unblinded data are used to provide the variance estimate used for the calculation of the sample size for the second stage [6]. This gives further reason for the use of methods that do not require knowledge of treatment allocations.

### 20.3 DANGERS OF UNPLANNED CLINICAL TRIAL MONITORING

Although, for the reasons just described, monitoring of accumulating data in a clinical trial is very appealing, there are a number of dangers, particularly when considering treatment efficacy, to which careful attention should be given whenever data monitoring is considered.

The main danger is a statistical one: The conduct of multiple analyses can lead to difficulty in the interpretation of the results [7]. In particular, if significance tests comparing experimental and control treatments are performed more than once, with testing stopped as soon as a significant result is obtained, the type I error rate is inflated as explained below.

When a single significance test is conducted, it is performed in such a way that the probability of declaring the treatments to be different if in fact they are identical, that is, of making a type I error, is controlled, usually to be 5%. If the test is repeated at a number of analyses, with each test conducted at the 5% level and the procedure stopped as soon as a significant result is obtained, there is risk of a type I error at each of these analyses. The overall probability of such an error, the type I error rate, will thus be more than 5%. The effect of repeated looks conducted at the 5% level in the simplified setting of comparison of normal data with known variance was assessed by Armitage et al. [8]. They showed that in this setting while a single analysis has a type I error rate of 5% as planned, if two analyses are conducted, the overall type I error rate is increased to 8%, with this increasing to 14% if five analyses are conducted, and increasing further if the number of analyses is more than five.

The problem of type I error rate inflation means that monitoring of clinical trials cannot be conducted without the use of specialist statistical methodology to ensure the type I error rate is controlled at the nominal level. The remainder of this chapter gives descriptions and examples of such statistical methods, explaining how valid tests may be obtained. A clinical trial conducted using such methodology is called a *sequential clinical trial*, and the formal analysis of data part way through the trial is known as an *interim analysis*.

A further statistical problem, related to that of type I error inflation, is that of estimation at the end of a monitored clinical trial. Just as the type I error rate is inflated because the trial stops exactly when extreme results are obtained, so a conventional estimate obtained at the end of a sequential clinical trial will be biased because the trial stops exactly when positive results are seen at an interim analysis. Again, special statistical techniques are required to provide a valid analysis, as described below.

In addition to the statistical problems associated with the conduct of interim analyses, there are some practical problems that may make monitoring of efficacy data difficult or undesirable. In some trials the primary endpoint may be some measure, such as long-term survival, that is observed only after considerable follow-up. In this case, all patients may be treated before the primary endpoint data from even the first patients enrolled in the trial are observed. This means there is no possibility of stopping the trial as a result of interim analyses. Although there may be some advantage in monitoring the efficacy data even in this case, for example, to obtain the results of the trial more quickly, there is no potential saving in terms of trial length or sample size.

If the data observed early in a trial are not considered typical of all of the data that are likely to be observed, the results of an interim analysis may be misleading. Monitoring of efficacy data in this case is thus undesirable and should be avoided. An example might be a comparison of treatments for cancer when the primary efficacy endpoint is survival, and one treatment is expected to lead to excess early mortality, but to better long-term prognosis. If only early death data were available at an interim analysis, the long-term advantages of this treatment could be missed, and the trial halted erroneously.

The final danger associated with many data-monitoring strategies is the need to unblind the treatment allocation. If treated patients continue to be followed-up, there is a danger that knowing which treatment they are receiving may lead to a difference in the level of care for or interpretation of results from patients in the experimental treatment and control groups. This may give rise to bias in the treatment comparison. The release of interim results may also lead to reluctance among investigators to recruit patients, or reluctance among the patients themselves to consent to randomization, if there is some evidence of a treatment difference, so that equipoise is no longer considered to exist.

## **20.4 METHODOLOGY FOR SEQUENTIAL MONITORING OF UNBLINDED EFFICACY DATA**

As described above, some clinical trial monitoring, such as monitoring of adverse events for safety, or the estimation of nuisance parameters from blinded data for sample-size review may be conducted with no risk of type I error rate inflation or effect on the final analysis. The monitoring of unblinded efficacy data, with the chance to stop the trial early if a large difference between the treatments is observed, does, however, lead to an increase in the type I error and bias in the analysis unless specific statistical methods are employed. The remainder of this chapter describes such methods and illustrates how valid monitoring of efficacy data can be conducted. Most of the statistical methodology in this area has been developed for clinical trials

in which two treatment groups, often corresponding to an experimental treatment and a control treatment, are compared. It is on this type of trial that the rest of the chapter will be specifically focused.

Whitehead [9] gives a list of the four key elements that must be considered in the design and conduct of a sequential clinical trial to assess treatment difference. These are a parameter giving some measure of the advantage of the experimental treatment over the control treatment; test statistics that give information on the size of this advantage on the basis of the data observed at an interim analysis and the amount of information about the treatment difference that is given by the observed data; a stopping rule that determines, on the basis of the observed test statistic, values at an interim analysis whether the trial should continue or should stop; and a final analysis method, valid for the stopping rule used, that enables a conclusion of whether or not the experimental treatment is superior to the control and provides a  $p$  value and point estimate and confidence interval for the treatment difference at the end of the trial.

The four elements are now considered in detail. Specification of the first two, the treatment difference parameter and the test statistics, is required whether fixed sample size or sequential methods are employed, but is discussed here for completeness. The specification of the third, the stopping boundary, represents a solution to the problem of control of the type I error rate. A number of solutions to this problem have been proposed, leading to several different approaches to the way in which the stopping boundary is calculated. These are described below. Although the fourth element, the analysis, is very important in the interpretation of the results from the sequential trial, statistical methodology in this area has generally lagged behind that for the construction of stopping rules. In practice, the use of an appropriate final analysis has often been neglected, in part due to the lack of availability of suitable software. Methods for the valid analysis have been developed, however, and the analysis can now be conducted using commercially available software. The methods are described briefly below and the alternative computer programs are discussed in the next section.

#### 20.4.1 Parameterization of Treatment Difference and Test Statistics

As in a fixed sample-size trial, the first stage in the design of a sequential clinical trial is the specification of some primary measure of treatment efficacy. This measure should be chosen on the basis of clinical relevance, ease and accuracy of measurement, and familiarity to clinicians. Following the definition of the primary endpoint, an associated parameter measuring the difference between the experimental and control treatments must be chosen. This will depend on the type of data collected on the primary endpoint, the interpretability of the parameter, for example, whether a difference or a ratio is more familiar, and the precision of the resulting analysis.

For example, if the primary response is a dichotomous variable such as whether a cancer patient is in remission or not after one year, the chance of being in remission in each group can be measured by the odds of remission, and the difference between the treatment groups can be measured by the ratio of the odds in the two groups, or more commonly the logarithm of this ratio, the *log-odds ratio*. If the primary response is a continuous measure such as weight loss, a difference in true unknown mean weight loss for the two groups would be of interest. If the primary

response is the time to some event, such as death, the difference between treatment groups might be measured by the ratio of the hazards in the two groups or the logarithm of this ratio.

At each interim analysis, some test statistic measuring the difference between the experimental and control treatments based on the observed data is calculated together with a test statistic measuring the amount of information given by the observed data at that interim analysis. Whitehead [10] and Jennison and Turnbull [11] suggest using a measure of difference known as the *efficient score* statistic and a measure of information called the *observed Fisher's information*, though other pairs of statistics may also be used, such as an estimate of the treatment effect and its standard error as suggested by Jennison and Turnbull [12] or a  $p$  value for comparison of the treatments and the planned sample size, as is used in *repeated significance testing* described in the next paragraph and in the *adaptive design* approach described in more detail in the last section of this chapter.

#### 20.4.2 Repeated Significance Testing

As discussed above, if a simple significance test comparing the experimental and control treatment groups is conducted repeatedly at the 5% level until a significant result is obtained, the overall type I error rate will be increased above 5%. Armitage et al. [8] showed how the actual error rate could be calculated when the number of repeated tests is specified. Similar calculations to those performed by Armitage et al. can be used to enable repeated significance testing with overall type I error rate controlled at the 5% level. By conducting each individual test at a more stringent level, the overall type I error rate is reduced, and so may be reduced to be 5% as desired. Numerical computation may be used to calculate the required error rate for each of the repeated tests to ensure that the overall level is 5%.

Pocock [13] proposed such a repeated significance testing approach, giving tables of the nominal type I level at which each test should be conducted to give an overall type I error rate of 5 or 1% for different numbers of tests. For example, to give an overall type I error rate of 5%, if two tests are performed each should be carried out at the 2.94% level, whereas if five tests are conducted, the nominal level for each should be 1.58%.

The repeated significance tests described by Pocock [13] are assumed to all be conducted at the same nominal level so that the same critical value is used for a standardized test statistic at each of the interim analyses. In general, there is no requirement that this should be so. If, say, five interim analyses are planned, it is possible to use different nominal levels for the five significance tests and control the overall type I error rate to be 5%. An alternative pattern of significance levels was proposed by O'Brien and Fleming [14]. They constructed the repeated significance tests in such a way that the level of evidence required to reject the null hypothesis that there is no difference between the two treatments at the earlier analyses is greater than that required to reject it at later analyses. In particular, the critical value for the  $i$ th interim analysis is chosen to be  $k_1/\sqrt{i}$  for some constant  $k_1$  chosen to maintain the overall type I error rate at the desired level. This choice of nominal levels, while maintaining the overall type I error rate, makes stopping at early interim analyses almost impossible, negating some of the advantages of sequential analysis. The Pocock [13] design, on the contrary, has been criticized, for example,

by Pocock and White [15], for leading to too high a chance of early stopping. Alternative approaches have been proposed [16], although the repeated significance testing approach has been largely superseded by the more flexible spending function approach described in the next section.

### 20.4.3 Spending Function Approach

A disadvantage of the repeated significance testing approach is that the number of interim analyses and the timing of these in terms of the amount of information available at each analysis need to be specified in advance in order to calculate the critical values required to control the overall error rate. Lan and DeMets [17] introduced a more flexible approach in which neither the timing nor the number of interim analyses need be given at the design stage.

Rather than specifying the critical values at a number of interim analyses, Lan and DeMets [17] proposed that the stopping rule should be given by a *spending function* that describes how the overall type I error rate, say 5%, is spent through the course of the trial. At the design stage, the maximum amount of information that will be attained if the trial does not stop early is calculated. At each interim analysis the level of information currently available is evaluated and the *information time* calculated to be the proportion of the maximum information available from the current data. The spending function gives, as a function of this information time, the amount of type I error that is to be spent, and the hypothesis test is conducted at such a level to ensure that the overall type I error spent up to and including this interim analysis is equal to this amount.

The spending function is thus an increasing function of the information time. It takes value 0 for information time 0, that is, at the start of the trial, and value equal to the overall type I error rate for information time 1, that is, at the end of the trial. It is common to denote the information time by  $t$ , and the spending function by  $\alpha^*(t)$ . Suppose that interim analyses are taken at information times  $t_1, t_2, \dots$ . The critical values used for the hypothesis tests at each of the interim analyses are chosen so that the probability of stopping and rejecting the null hypothesis at any of the interim analyses up to and including the  $i$ th is equal to  $\alpha^*(t_i)$  if the null hypothesis is really true. Equivalently, if the null hypothesis is true, the probability of stopping and rejecting the null hypothesis at the  $i$ th interim analysis given that the trial has not stopped at an earlier interim analysis is equal to  $\alpha^*(t_i) - \alpha^*(t_{i-1})$ . The critical values to give these stopping probabilities can be calculated using a recursive numerical integration technique similar to that used by Armitage et al. [8] to evaluate error rates for repeated significance tests. A similar technique enables calculation of the probability of stopping under a specified alternative hypothesis, and this allows the maximum information level to be chosen to give a test that satisfies some power requirement. Further details of the spending function approach and the computations required to calculate the critical values and sample size are given by Jennison and Turnbull [11].

As in the repeated significance testing approach, there is considerable flexibility regarding how likely the trial is to stop at the different interim analyses within the constraint that the overall type I error rate is controlled at the desired level. In the spending function approach this flexibility is expressed in the choice of the spending function, which may be any increasing function rising from 0 to the overall type I

error rate. A number of forms for spending functions have been proposed. Lan and DeMets [17] give spending functions to give approximations to the repeated significance testing procedures of Pocock [13] and O'Brien and Fleming [14], while Kim and DeMets [18] and Hwang et al. [19] suggest possible families of spending functions.

The flexibility of the sequential stopping boundaries in terms of the form of the spending function was utilized further by Kim and DeMets [18]. They showed how two different spending functions may be used to construct tests that have different properties for positive and negative treatment differences.

The sequential approach can be extended further to give tests that have different power to detect positive and negative treatment differences. A lower power is associated with a smaller sample size. Since the sample size is no longer fixed, but is now a random variable depending on the observed data, it is possible to stop the trial earlier for certain observed treatment differences than others. In particular, the stopping rule may not be symmetric, so that different decisions may be taken for positive and negative observed differences of the same magnitude. This is valuable, for example, in a clinical trial comparing an experimental treatment with a placebo. If the experimental treatment is superior to the placebo, we desire a high probability of rejecting the null hypothesis that there is no difference, and we are willing to randomize the large number of patients required to demonstrate this. If the experimental treatment is actually inferior to the placebo, demonstrating this is of less interest. It is sufficient to show that the experimental treatment is either the same or worse than the placebo and to continue to randomize patients to discover whether the disadvantage associated with the experimental treatment is significant or not is undesirable. Whitehead [10] calls asymmetric tests of this type tests with *power requirement I*, in contrast to the more usual symmetric tests, which he calls tests with *power requirement II*. Sequential procedures with power requirement type I can also be constructed using the spending function approach [20, 21].

#### 20.4.4 Boundaries Approach

The repeated significance testing approach and the spending function approach provide a stopping rule. In each case, for each interim analysis conducted, a pair of critical values is obtained, and the trial is stopped if the test statistic lies outside of the interval defined by these two values. The critical values are said to form a *stopping boundary* and the set of intervals to form a *continuation region*. The observed values of the test statistic measuring the treatment difference at the interim analyses are said to form a *sample path*, which is compared with the stopping boundary to decide whether or not the trial should continue.

An alternative to the methods for construction of the stopping boundary described above is based on the abstract concept of continuous monitoring, in which it is imagined that the value of the test is observed at all times rather than just at the discrete times given by the interim analyses. In this case, a plot of the test statistic measuring the treatment difference against that measuring the amount of information available forms a continuous line. In the *boundaries approach*, this continuous line is compared with continuous stopping boundaries that are expressed as functions of the information level.

The boundaries approach stems from the work of Wald [22] who developed the sequential probability ratio test (SPRT), initially for the testing of armaments during World War II. In the SPRT the likelihood ratio for a simple alternative hypothesis relative to the null hypothesis is calculated at each interim analysis. The test continues so long as this likelihood ratio falls within some fixed range. Wald derived stopping limits so as to give a test with specified type I error rate and power under the assumption of continuous monitoring. The SPRT has the important optimality property that among all tests with the same type I error rate and power, the SPRT minimizes the expected sample size when either the null or alternative hypothesis holds. Although the expected sample size is minimized by the SPRT, however, the SPRT has no maximum sample size, so that it cannot be guaranteed that the sample size will be below any fixed value. This feature makes the SPRT unsuitable for many clinical trials.

Following the work of Wald [22], a number of alternative forms for boundaries that maintain the overall type I error rate have been proposed. The choice of the form of boundary in this approach is analogous to the choice of spending function in the approach described above, and, as above, trials may be designed with asymmetric (power requirement I) or symmetric (power requirement II) boundaries. Whitehead [10] describes a wide range of such tests, including approximations to the SPRT that do place a limit on the maximum sample size required. One family of boundary shapes that is particularly common in sequential clinical trials is based around the triangular test. If the efficient score statistic is plotted against the observed Fisher information, this test has straight boundaries that form a triangular-shaped continuation region. An example of a double triangular test is illustrated in the example in Section 20.6. The triangular test approximately minimizes the maximum expected sample size among all tests with the same error rates. Unlike the SPRT the triangular test has a maximum sample size. It can be shown that for a triangular test there is a high probability of stopping with a sample size below that of the equivalent fixed sample size test, so that on average the sample size will be reduced by the use of this sequential design.

The stopping boundaries obtained using the boundaries approach maintain the overall type I error rate under the assumption of continuous monitoring of the test statistic measuring the treatment difference. In practice, monitoring is necessarily discrete, even if an interim analysis is conducted after observation of every patient. This means that if the critical values from the boundaries approach are used, the type I error rate will be less than the planned level. Whitehead [10] has proposed a correction, known as the *Christmas tree correction*, to modify the continuous boundaries to allow for the discretely monitored sample path. This correction allows interim analyses to be made at any time provided that the timing is not dependent on the observed treatment difference.

#### 20.4.5 Analysis after a Sequential Trial

At the end of a sequential trial a final analysis of the data observed should be conducted. This analysis should provide a  $p$  value for testing the null hypothesis that there is no difference between the experimental treatment and the control, and a point estimate and confidence interval for the difference between the treatments,

usually as measured by the primary parameter of treatment difference discussed above.

The fact that a sequential stopping rule has been used means that many of the standard analysis methods that would be employed after a fixed sample sized trial are no longer valid. Facey and Lewis [23] reported in 1998 that a standard analysis is performed inappropriately in many sequential trials. This is hopefully now changing.

Suppose that a sequential trial stopped at some interim analysis with the upper critical value exceeded by the test statistic measuring observed treatment difference, leading to the conclusion that the experimental treatment was superior to the control treatment. The trial has stopped precisely because of the large observed value of the treatment difference. This means that standard unbiased estimates of treatment difference will, on average, overestimate the true value of the treatment difference. In a similar way, the  $p$  value from a standard analysis will, on average, be too small, that is, it will tend to overstate the evidence against the null hypothesis. Special methods of analysis are therefore required to allow for the interim analyses that have been conducted in a sequential trial.

The meaning and interpretation of the  $p$  values, point estimates, and confidence intervals obtained after a sequential clinical trial are the same as for a fixed sample size trial, but a method must be employed in their calculation that is valid for the sequential stopping rule used. A number of methods of analysis have been proposed. Most are based on an ordering of all possible data sets to reflect which are considered to provide strongest evidence against the null hypothesis being tested. Further details are given by Whitehead [10] and Jennison and Turnbull [11]. The implementation of these methods in commercially available software, as described in more detail in Section 20.5, enables the easy conduct of a valid analysis following a sequential trial.

#### 20.4.6 Monitoring and Analysis of More Than One Endpoint

In a clinical trial it may be the case that other endpoints in addition to the primary endpoint are important in the clinical assessment of a treatment. If these endpoints are only to be analyzed at the end of the study after complete data on all patients are available, then they are usually termed *secondary endpoints*. No formal monitoring of these is conducted during the trial. If, however, one or more of the endpoints can really be regarded as additional primary endpoints that are important in determining whether a study should stop or continue, then further statistical methodology is required. There are two general approaches to monitoring these *co-primary endpoints* depending on the nature of the endpoints involved.

If several endpoints are measuring a similar aspect of treatment performance, then it may be acceptable to demonstrate efficacy in a collective way across the endpoints. Combining the various endpoints together into a single global measure and then using methods already described in this chapter would then be a suitable approach. As an example, consider the therapeutic area of stroke. There is no single endpoint that is universally accepted. Outcomes of interest include the Barthel index, the modified Rankin score, the Glasgow outcome scale, and the National Institutes of Health (NIH) stroke scale. Investigators do not believe that a positive result in terms of a single one of those outcomes is sufficient. Tilley et al. [24]

describe using a global test statistic in precisely this indication and discuss the advantages and disadvantages of such an approach.

In some indications, with some endpoints, it is not clinically meaningful to combine the endpoints into a single measure. Examples include the need to demonstrate efficacy for two outcomes to gain licensing, such as in Alzheimer's disease where it is generally necessary to consider both mental and physical aspects of a patient's progress. The simultaneous monitoring of efficacy and safety responses would be another example. In these instances, the endpoints should be kept separate and the correlation between them accounted for in the design and analysis of any sequential trial. Due to the complexity of computations, most authors have concentrated on developing *bivariate* methodology, that is, for the case of two co-primary endpoints, see, for example, Jennison and Turnbull [25], Cook and Farewell [26], and Todd [27].

## 20.5 IMPLEMENTATION OF SEQUENTIAL DESIGNS

As illustrated in Section 20.4, there are a number of different approaches to the specification of a sequential design and in particular the form of a stopping rule. When considering the implementation of such methodology, the most important issues to focus upon are the reasons why it is desirable to either stop or continue the trial at an interim analysis. Reasons for stopping were outlined above and may include evidence that the experimental treatment is obviously better than the control, evidence that the experimental treatment is already obviously worse, or indication that there is little chance of showing that the experimental treatment is better than the control so that it is considered futile to continue. Reasons for continuing may include belief that a moderate advantage of the experimental treatment is likely and it is desired to estimate this magnitude carefully, or evidence that the event rate is low and more patients are needed to achieve required power. Criteria such as these will first determine the symmetry requirement that is appropriate for the study under consideration, that is, whether an asymmetric (power requirement I) or a symmetric (power requirement II) design should be considered. Once this has been established, attention turns to the specific properties of different tests within a broad category. A choice between the tests is then made based upon consideration of likely sample sizes under various possible treatment effect scenarios. The wide range of stopping rules now available allow sequential designs to be devised for testing *superiority*, *noninferiority*, *equivalence*, and even formal *safety* aspects of clinical trials. As discussed above, some more complex designs even aim to deal with both efficacy *and* safety aspects in a combined stopping rule.

The availability of appropriate designs is just one element of enabling the implementation of sequential methodology. The key requirement for widespread take-up of the techniques is access to software. There are four major commercial software packages currently available. The package PEST [28] is based on the boundaries approach. The package EaSt [29] implements the spending function approach. An addition to the package S-Plus is the S+SeqTrial module [30], which also implements the spending function approach, in this case for a family of designs based on the methodology described by Kittelson and Emerson [31]. The package AddPlan (see [www.addplan.com](http://www.addplan.com)) is based on the adaptive design approach mentioned in Section 20.7. If a study is to be a comparison of two treatments in respect of a single primary endpoint, with the objective of discovering whether one treatment is superior, non-

inferior, or equivalent to the other, then it will be possible to implement a suitable sequential method using one of the available packages.

When planning to include interim analyses in any clinical trial, the implications of introducing a stopping rule need to be thought through carefully in advance of the study. All parties involved in the production of the protocol should be consulted on the choice of clinically relevant difference, specification of an appropriate power requirement, and the selection of a suitable stopping rule. The operation of any sequential procedure should be clearly described in the statistical section of the trial protocol. Once the trial is underway, it is extremely important that the interim results of an ongoing trial are not circulated widely. Such knowledge may have an undesirable effect on the future progress of the study. Whether a treatment looks good or bad as the trial progresses will obviously affect an investigator's attitude toward the trial. For this reason, it is often the case that a DSMB may be established to consider the progress of a sequential trial as well as assess safety data as discussed in Section 20.2.

If a DSMB is appointed, one of its first duties should be to review the protocol and to scrutinize any proposed sequential stopping rule prior to the start of the trial. The procedure for undertaking the interim analyses should also be finalized in advance. The DSMB would then review results of the interim analyses as they are reported. It is usual for the board to be supplied with full, unblinded information. Ideally, the only other individual to have knowledge of the treatment comparison would be the statistician who performs the actual analyses of the accumulating data. After each interim examination of the data, the DSMB should issue a short report detailing the outcome of its deliberations. The most common outcome of a meeting is likely to be that the study should continue without modification. However, the DSMB may recommend continuation with some protocol modifications, stopping the study due to safety concerns, or stopping as a result of the formal stopping rule for efficacy having been met. An example of the form of report issued by a DSMB following a meeting is given in Figure 4.

Decision making as part of a sequential trial (whether by a DSMB or another party involved in the trial) is both important and time sensitive. A decision taken to stop a study affects both the current trial and impacts on future trials in the same therapeutic area. However, continuing a trial too long puts participants at unnecessary risk and delays dissemination of important results. The issue applies not only to monitoring efficacy data but also to reacting in a timely manner to safety problems. Wondering whether data are accurate and up-to-date makes the decision process harder. It is therefore necessary to have both timely and accurate data. Unfortunately, a trade-off exists. It takes time to ensure accuracy. One option is to establish a "fast-track" system, processing efficacy data and key safety data separately from other information. Fewer data means that they can be validated more quickly. This is a particularly important issue that requires careful thought and planning.

## **20.6 EXAMPLE: LITHIUM GAMOLENATE IN PATIENTS WITH ADVANCED PANCREATIC ADENOCARCINOMA**

The prognosis for pancreatic cancer patients is poor, with an average survival time of a matter of months from diagnosis. Chemotherapy for pancreatic cancer sufferers

Dear

The independent review committee met today to hear in confidence the results of the third interim analysis presented by the independent statistics committee, and then held discussions with representatives of the company.

We noted the incidence of severe side effects but acknowledge that this particular form of cancer is classically associated with thrombotic complications!

We were reassured to hear that centers were now treating patients more expeditiously and with greater familiarity and expertise.

Our decision as to whether to continue the trial was *not* an easy one, but we unanimously agree that the trial should continue under close monitoring and we await the next analysis (70 deaths) with interest.

#### **Other Comments**

- Would it be possible to look statistically at the first few versus the later patients treated at main centers
- For the future – the patient information sheet should tell patients that therapy may be associated with hemoglobinurea and thrombotic problems
- Regarding the proposed protocol amendment, we feel that to issue the results of the company analysis prior to the interim independent analysis was improper, and reject it. In any case such major amendments would, we believe, constitute a new trial.
- We congratulate the company on the preparation and distribution of the weekly data tables.

The independent review committee plans to meet again on June 15.

Yours sincerely

Chairman of the DSMB

**FIGURE 4** *Example letter sent from the DSMB to the Steering Committee.*

offers only very small survival benefits and is associated with considerable side effects. It was essentially felt that there was no standard treatment available. It has been found that unsaturated fatty acids (lithium gamolenate) have an antitumour effect in experimental studies, and in phase II trials few side effects of this treatment were observed. This prompted the conduct of a randomized dose-finding phase III study [32]. It was required to reach a reliable conclusion concerning the optimum dose when considering survival time from randomization.

Patients with a diagnosis of inoperable pancreatic adenocarcinoma were treated with one of three doses of the active treatment, either oral dose, or low or high intravenous doses. When the objectives of the trial were considered, it was decided that a sequential approach was appropriate. The methodology followed was the boundaries approach, as discussed in Section 20.4. The comparison employed was

between the high intravenous (IV) dose and the oral dose. The plan was to recruit patients into the study until a sufficiently large difference in the survival rate was seen between these two doses. Analyses involving the low dose IV treatment were considered secondary to this main analysis. The study was designed to have 90% power to detect a difference in median survival of 4 months between the oral dose and the high dose treatments as significant at the 5% level. The reference median survival for oral treatment was taken to be 120 days.

In evaluating the appropriate dose of the treatment, it was desirable to stop the trial as soon as there was sufficient evidence to indicate that either dose was significantly superior to the other. If there was no difference between the doses, then it was also important to distinguish this quickly. In the latter case, further development of oral dose could be justified as this is a less invasive form of the treatment than the intravenous administration. A sequential procedure that satisfies these requirements and has smaller expected sample sizes than the equivalent fixed sample test for any size of treatment difference is the double triangular test [10].

The data concerning survival times following entry into the trial were modeled as survival data, with the difference between the two treatment groups measured by the log hazard ratio. The statistic signifying the difference between the two doses seen so far was taken to be the efficient score for the log hazard ratio. This is the usual log-rank test for survival data, which will be denoted by  $Z$ . The statistic measuring the amount of information upon which the comparison was based will be denoted by  $V$ . This is the variance of  $Z$  and is approximately one quarter the number of deaths. An independent data and safety monitoring board was established to monitor the progress of the trial at the interim analyses. Figure 5 shows the outcome of five interim analyses. On the diagram the inner dotted boundaries show the Christmas tree correction for discrete looks. These form the stopping boundary, so that the trial should be stopped when one of these values is reached.

FIGURE 5 Sequential plot for the trial of lithium gamolenate.

A total of 278 patients were recruited to the trial. Of these 93 patients received oral dose, 90 patients received low dose, and 95 patients received high dose. The log-rank statistic  $Z$  crossed the boundary, which indicated that the oral dose was significantly superior to high dose, which was actually contrary to expectations. This occurred at the fourth interim analysis, and recruitment to the trial was stopped at this time. Continuing follow-up of patients already recruited when the trial stopped led to one further *overrunning* analysis, the results of which are also illustrated in Figure 5. A final analysis of the data was conducted using the computer package PEST [28]. The  $p$  value obtained was 0.03, a significant result in favor of the oral dose. Median survival after oral treatment was 129 days, while after high dose treatment it was 94 days.

## 20.7 RESPONSE-DRIVEN AND ADAPTIVE DESIGNS

In the methodology described in detail in Sections 20.4 and 20.5 and illustrated by the example, a single decision is made at each interim analysis: whether the trial should be stopped or should continue to the next interim analysis. Much more general sequential methods can be envisaged in which many aspects of a clinical trial design are reconsidered on the basis of the results from the interim analyses. Decisions could be made after each interim analysis regarding, for example, how many patients should be recruited to the next stage of the trial, whether treatment arms should be dropped from a multiarmed clinical trial, which doses should be used for the treatment of the next group of patients in a dose-finding study, or how the treatment allocation ratio might be changed to favor an apparently superior treatment, in addition to the decision of whether or not to stop the trial. Such general methods are often referred to as *response-driven*, *response-adaptive*, or *data-dependent* designs. They are also sometimes called *sequential designs* or *adaptive designs*, although increasingly these terms are reserved for the methods described in Section 20.4 and methods based on the work of Bauer and Köhne [33], which are described in the next paragraph, respectively.

A statistical approach for clinical trials that compare two treatments that allows more flexibility than the sequential methods described in Section 20.4 is the *adaptive design* approach [33]. In this approach, a  $p$  value is obtained at each interim analysis to test the null hypothesis that there is no difference between the two treatments on the basis of the new data obtained since the previous analysis. The  $p$  values from the different interim analyses are then combined by taking their product, and the value of this product is used to decide whether or not to stop the trial and whether the experimental treatment is superior to the control treatment at the end of the trial. Provided the data from the different stages of the trial are independent, any adaptation of the trial can be conducted without increasing the type I error rate. This method thus provides considerable flexibility in terms of design modification while still enabling valid inference to be drawn. It has been shown, however, that if the flexibility is not utilized, there is a slight reduction in power relative to the sequential methods described in Section 20.4 [34]. Further details of the adaptive design approach are given, together with a review of recent advances, by Posch et al. [35].

Although there has been much interest in the methodology for more general response-driven designs, there has been relative little use of such approaches in

practice. There are two main areas where such designs have been used. The first area is that of small two-arm studies that attempt to modify treatment allocation toward the treatment observed to be more effective. These methods extend the *play-the-winner* designs in which an interim analysis comparing the two treatments is made after observation of each patient, and the next patient is treated with the treatment currently observed to be most effective. A review of statistical methods for the design and analysis of such studies is given by Rosenberger [36].

The second area where response-driven designs have been used is in phase I dose-finding studies. In these studies the aim is to identify a dose that leads to an acceptably low risk of some adverse event in the trial subjects, who may be patients or healthy volunteers. Subjects are often treated in small groups, or *cohorts*, perhaps of three subjects, and the number of subjects to demonstrate the adverse event is recorded. The responses from each cohort are used to decide the dose level or levels to be used for the next cohort. Reviews of methodology for studies of this type are given by Cavalli and Sessa [37] and Whitehead et al. [38].

### **21.1 INTRODUCTION**

Mainly in response to ethical and cost concerns, it has become a common practice that clinical trials, especially phase III studies comparing the efficacy of two or more treatment agents, are monitored using the so-called *group sequential testing procedures*. In a group sequential clinical trial a set of stopping boundaries are usually specified for a test statistic at a few time points, either in terms of real calendar time or statistical information. The stopping boundaries are chosen in a way that the type I error (false-positive) and type II error (false-negative) rates are controlled at the desired levels. In the past several decades, extensive research efforts have been devoted to the determination of these stopping boundaries, resulting in a number

of popular methods such as those developed by Pocock [1], O'Brien and Fleming [2], Lan and DeMets [3], Whitehead and Stratton [4], and Jennison [5], to name a few. Jennison and Turnbull [6] and Proschan, and co-workers [7] provide excellent overview of these group sequential methods.

Statistically speaking, the primary aim of a clinical trial is to test the null hypothesis that there is no significant difference between treatment agents under investigation, while maintaining a satisfactory statistical power if certain treatment difference indeed exists. A sequential clinical trial should be terminated as soon as the monitoring test statistic, derived based on the so-termed *primary endpoint*, reaches a stopping boundary, although the Data Safety and Monitoring Board (DSMB) may recommend the trial be terminated earlier before reaching a boundary or be continued after reaching a stopping boundary, based on various reasons, such as safety concerns. Once a boundary is reached and the trial stops, a decision can then be made on whether the null hypothesis should be rejected and one treatment agent is better than the other.

When reporting clinical trial findings, it is not sufficient to simply state *rejection* or *no rejection* of the null hypothesis. Point estimates and confidence intervals, which measure the magnitude of the treatment difference, and  $P$  values, which give the strength of the trial against the null hypothesis, should also be provided as an integrated part of the trial findings. However, from a frequentist's point of view, the usual maximum-likelihood approach, which provides (asymptotically) most efficient fixed sample-size inference, yields biased estimation due to the randomness of the observed sample size and its dependence with the test statistic and is thus no longer appropriate. In fact such randomness and dependence have been long well recognized as the cause of the type I error inflation when the usual fixed-size critical values are used repeatedly at each interim analysis. Unfortunately, when it comes to inferential analysis following a sequential trial, randomness and dependence are often ignored and the usual maximum-likelihood inference is conducted.

In what follows, we summarize several popular approaches developed in the literature to construct point and interval estimation and  $P$  values with respect to the primary endpoint following the termination of a sequential phase III trial. A brief overview will also be given to methods for inference concerning a secondary endpoint. Sequential phase II clinical trials in which interim monitoring is based on a Bernoulli variable (binary outcome) will not be discussed. However, most concepts and principles described here apply analogously to analysis following a sequential phase II trial.

## 21.2 BROWNIAN MOTION PARADIGM IN SEQUENTIAL TRIALS

A phase III clinical trial is usually monitored based on a Brownian motion  $X(t)$  with drift  $\delta$ , provided that the sample size is large enough so that the test statistics can be well approximated by a Brownian motion. A Brownian motion  $X(t)$  with drift  $\delta$  satisfies several nice properties:  $X(0) = 0$ , and  $X(t) \sim N(\delta t, t)$  for  $t > 0$ . Furthermore, for any  $0 < t_1 < t_2 < \dots < t_k < \infty$ ,  $X(t_1)$ ,  $X(t_2) - X(t_1)$ ,  $\dots$ ,  $X(t_k) - X(t_{k-1})$  are mutually independent, a proposition so well termed as *independent increments*, each normally distributed as  $X(t_j) - X(t_i) \sim N(\delta(t_j - t_i), t_j - t_i)$  and  $\text{cov}(X(t_j), X(t_i)) = t_i$ , for  $i < j$ . In practice,  $t$  is usually the Fisher information and  $X(t)$  is usually a test statistic, and

the drift parameter  $\delta$  is a measure of treatment difference with  $\delta = 0$  if there is no treatment difference.

To give the readers a flavor of how such Brownian motion may be constructed, let us consider the case of comparing, with equal allocation, two normal means with known common variance. Let  $X_{1A}, \dots, X_{nA}$  be the outcomes from  $n$  subjects allocated to treatment  $A$ , and  $X_{1B}, \dots, X_{nB}$  be that to treatment  $B$ . Assume that  $X_{iA} \sim N(\mu_A, \sigma^2)$  and  $X_{iB} \sim N(\mu_B, \sigma^2)$ . The null hypothesis is  $H_0: \mu_A - \mu_B = 0$ . The standardized test statistic is  $Z_n = \sum_{i=1}^n (X_{iA} - X_{iB}) / \sqrt{2n\sigma^2}$ , which follows standard normal  $N(0, 1)$ , and a two-sided test with level of significance  $\alpha$  rejects the null hypothesis if  $|Z_n| > \Phi^{-1}(1 - \alpha/2)$ , where  $\Phi$  is the standard normal distribution. To put this into a Brownian motion framework, we redefine (after a little bit pleasant algebraic manipulation) the test statistic as

$$X = \sqrt{\frac{n}{2\sigma^2}} Z_n$$

then  $X$  resembles a Brownian motion  $X(t)$  with drift  $\delta = \mu_A - \mu_B$  and in this example the (discrete) time  $t = n/(2\sigma^2)$ .

This Brownian motion paradigm applies to the two-arm comparison of many clinical endpoints such as proportions, ordinal data, and survival rates. Whitehead [8] presented a nice review of this structure and named it a *unified theory*. See also Lan and Zucker [9] and Proschan and co-workers [7].

With this framework, a group-sequential clinical trial can be formulated as interim monitoring of a Brownian motion  $X(t)$  with drift  $\delta$  at several discrete time points  $t_1, \dots, t_K$ , where  $K$  is the prespecified number of interim and looks to be carried out during the whole course of the trial. For each look  $k$ , let  $C_k = (a_k, b_k)$  be the continuation region and  $S_k = (-\infty, a_k] \cup [b_k, \infty)$  be the stopping region, where  $a_k < 0 < b_k$  define the lower and upper boundary of the sequential test. Then the trial stops at the  $k$ th look if the  $k$ th boundary is reached first, that is, if

$$X(t_i) \in C_i, i \leq k-1 \quad X(t_k) \in S_k$$

Upon stopping at the  $k$ th interim look, we observe two statistics, the stopping time  $T = t_k$  and the position of the Brownian motion  $X(T) = X(t_k)$ . These two statistics together are sufficient for the drift parameter  $\delta$  and hence inference on  $\delta$  can be based solely on  $(T, X(T))$ . The joint distribution  $f_\delta(k, x)$  of  $(T, X(T))$  at  $(T, X(T)) = (t_k, x)$  is  $f_\delta(k, x) = f_0(k, x) \exp\{x\delta - \frac{1}{2}t_k\delta^2\}$ , where the baseline functions  $f_0(k, x)$  can be computed numerically using the following recursive formulas:

$$f_0(1, x) = \frac{1}{\sqrt{t_1}} \phi\left(\frac{x}{\sqrt{t_1}}\right)$$

and

$$f_0(k, x) = \frac{1}{\sqrt{t_k - t_{k-1}}} \int_{C_{k-1}} \phi\left(\frac{x-s}{\sqrt{t_k - t_{k-1}}}\right) f_0(k-1, s) ds \quad k = 2, \dots, K$$

where  $\phi$  is the standard normal density function. Thus, for a statistic  $h(T, X(T))$ , its expectation is given by

$$E(h(T, X(T))) = \sum_{k=1}^K \exp\left\{-\frac{1}{2}t_k\delta^2\right\} \int_{s_k} h(k, x) f_0(k, x) \exp\{x\delta\} dx \quad (1)$$

### 21.3 ESTIMATING MAGNITUDE OF TREATMENT DIFFERENCE

The maximum-likelihood estimate of  $\delta$  is  $\hat{\delta}_{\text{ML}}(T, X(T)) = X(T)/T$ , the same form as that following a fixed-size test ( $K = 1$ ). However, its statistical properties change substantially due to the randomness of  $T$  and further complication of the dependence between  $T$  and  $X(T)$ . As a consequence, many optimal properties that the estimate enjoys under fixed-size sampling vanish under sequential sampling. For instance, the maximum-likelihood estimate is no longer unbiased. When  $K = 2$ , the bias function  $b(\delta)$  can be expressed in a closed form as

$$b(\delta) = \sqrt{t_1} \left( \frac{1}{t_1} - \frac{1}{t_2} \right) \left\{ \phi\left( \frac{b_1 - \delta t_1}{\sqrt{t_1}} \right) - \phi\left( \frac{a_1 - \delta t_1}{\sqrt{t_1}} \right) \right\}$$

See Emerson [10].

A naive approach to reduce the bias is to subtract from  $\hat{\delta}_{\text{ML}}$  the maximum-likelihood estimate of the bias  $b(\delta)$ , yielding an estimate as  $\hat{\delta} = \hat{\delta}_{\text{ML}} - b(\hat{\delta}_{\text{ML}})$ . Since  $\hat{\delta}_{\text{ML}}$  is biased for  $\delta$ ,  $b(\hat{\delta}_{\text{ML}})$  may not be a good estimate for  $b(\delta)$ . Therefore, the resulting estimate  $\hat{\delta}$  may not be a good estimate for  $\delta$ . Whitehead [11] instead suggested replacing  $\delta$  in the bias function by the so-called *bias-adjusted estimate*,  $\hat{\delta}_w$ , to be solved from the equation

$$\hat{\delta}_w + b(\hat{\delta}_w) = \hat{\delta}_{\text{ML}}$$

Whitehead [11] initially proposed his bias-adjusted estimate in the context of *fully sequential tests* with parallel or triangular stopping boundaries. He presented substantial numerical evidence for both boundaries that the bias-adjusted estimate indeed has smaller bias (and mean-squared error as well!) than the maximum-likelihood estimate.

However, the idea is quite general and applicable in reducing the bias of an estimate, so long as the bias function of the estimate can be worked out. The performance of such estimate depends on the shape of the bias functions. If the bias function of the estimate is nondecreasing and can be differentiated at least twice, then the bias-adjusted estimate has uniformly smaller mean-squared error than the initial estimate; see Whitehead [11] and Liu [12].

Emerson and Fleming [13] investigated Whitehead's bias-adjusted estimate in the context of group-sequential tests and compared with an unbiased estimate constructed in their study using conditioning argument:

$$\hat{\delta}_{\text{EF}} = E\left\{ \frac{X(t_1)}{t_1} \middle| (T, X(T)) \right\}$$

This is indeed an unbiased estimate since the expectation of  $X(t_1)/t_1$  is always  $\delta$ , regardless at which stage the test stops. Although  $\hat{\delta}_{\text{EF}}$  nullifies the bias, numerical results from Emerson and Fleming [13] showed that in general it has a larger mean-squared error than Whitehead's bias-adjusted estimate, a sacrifice to be made for enforcing unbiasedness. As expected, the two estimates both have smaller bias and mean-squared error than the maximum-likelihood estimate, as considerable numerical results have shown. However, analytic results are limited, perhaps due to the complicated forms of the density functions, on the statistical properties and comparison of the two estimates.

More can be said about how the sequential sampling [resulting in the randomness of  $T$  and dependence between  $T$  and  $X(T)$ ] changes the statistical property of a parameter estimate. Under fixed-size sampling, the maximum-likelihood estimate  $\hat{\delta}_{\text{ML}}$  is the unique unbiased estimate based on the sufficient statistic  $X(T)$  ( $T$  is a constant now) and has uniformly minimum variance among the unbiased estimates, a fact attributed to the well-known Rao–Blackwell theorem. Under group-sequential sampling, however, as shown in Liu and Hall [14], there are infinitely many sufficient-statistic-based unbiased estimates and none,  $\hat{\delta}_{\text{EF}}$  particularly included, has uniformly minimum variance. Only when restricted to unbiased estimates that are independent of future stopping rules does  $\hat{\delta}_{\text{EF}}$  have uniformly minimum variance.

## 21.4 CALCULATION OF P VALUES AS EVIDENCE AGAINST NULL HYPOTHESIS

The  $P$  values in a clinical trial measure the statistical strength (evidence) against the null hypothesis that there is no difference between treatment agents. It is defined as the probability, computed under the null hypothesis, of obtaining data that yields a statistic of interest being at least as extreme as the observed value of the statistic. Thus, smaller  $P$  values correspond to more extreme data from which the statistic is computed and reflect stronger evidence against the null hypothesis.

In a fixed-size clinical trial ( $K = 1$  and  $t_1$  is a constant), the calculation and interpretation of the  $P$  values is more straightforward and much less problematic. So long as the statistic of interest is a monotone function of  $X(t_1)$ , as is true for most cases, the upper- and lower-tail  $P$  values are given by, respectively,

$$P_{\delta=0}(X(t_1) > \tilde{x}) = 1 - \Phi\left(\frac{\tilde{x}}{\sqrt{t_1}}\right) \quad P_{\delta=0}(X(t_1) < \tilde{x}) = \Phi\left(\frac{\tilde{x}}{\sqrt{t_1}}\right)$$

where  $\tilde{x}$  is the realization (observed value) of  $X(t_1)$ . Doubling the smaller of the upper- and lower-tail  $P$  values yields the two-sided  $P$  value, which, because of symmetry, is given by

$$P \text{ value} = P_{\delta=0}(|X(t_1)| > |\tilde{x}|) = 2 \left\{ 1 - \Phi\left(\frac{\tilde{x}}{\sqrt{t_1}}\right) \right\}$$

Unfortunately, the definition of a  $P$  value in a group-sequential trial is not as clear as it would be in a fixed-size trial and sometime brings considerable ambiguity and confusion to many practitioners. What does it mean by data being *extreme*? What statistic should be used in defining *extreme*? The problem comes from the fact that, instead of summarizing the data by a one-dimensional sufficient statistic  $X(t_1)$  in a fixed-size trial, we now have to summarize the data by two dependent statistics,  $T$  and  $X(T)$ , both of which contain information on the treatment difference  $\delta$ . A sample path (or data) with smaller  $T$  (earlier stopping) and larger  $X(T)$  is without doubt more extreme than a path with larger  $T$  and smaller  $X(T)$ . But what about a path with  $T$  and  $X(T)$  both smaller and a path with  $T$  and  $X(T)$  both larger? In a word, how should the points  $(T, X(T))$  in the sample space in a group-sequential trial,

$$\Omega = \{X(t_1) \in S_1\} \cup \left[ \bigcup_{k=2}^K \{X_{t_i} \in C_i, i < k, X_{t_k} \in S_k\} \right]$$

be ordered so that *being extreme* is well defined? Is there an ordering that is better than the others, statistically and/or practically?

A number of popular orderings have been proposed in the literature, most based on a one-dimensional statistic  $s(T, X(T))$  defined on the sample space  $\Omega$ . A point  $(t_i, X(t_i))$  is more extreme than another point  $(t_j, X(t_j))$  if  $s(t_i, X(t_i)) > s(t_j, X(t_j))$ . With this ordering, suppose the trial stops at stage  $k$  with  $X(t_k) = \tilde{x}$ , then the upper-tail  $P$  value is given by

$$P_{\delta=0} \{s(T, X(T)) > s(t_k, \tilde{x})\}$$

which can be computed numerically using the recurse density functions. The lower-tail  $P$  value is given accordingly, and the two-sided  $P$  value is twice the smaller of the two  $P$  values.

Roser and Tsiatis [15] defined  $s(T, X(T))$  to be the score statistic (the position of the Brownian motion)  $X(T)$ , while Chang [16] suggested using the standardized test statistic  $X(T)/\sqrt{T}$ , and Emerson and Fleming [13] investigated ordering based on the maximum-likelihood estimate  $X(T)/T$ .

The so-called *stagewise ordering* (e.g., Siegmund [17], Fairbanks and Madsen [18], and Tsiatis and co-workers [19]) is somewhat different from the above three orderings and is not based on a one-dimensional statistic. A data point  $(t_i, X(t_i))$  is more extreme than the other  $(t_j, X(t_j))$  if it reaches the upper or lower boundary earlier [ $i < j$  and  $X(t_i) > b_i$  or  $< a_i$ ]. For data points with the same information time, the one with larger value of  $X(t)$  is more extreme.

All four orderings reduce to the same one in the fixed-size setting. However, there are no deterministic results on which ordering is better than the others. Some argue that the stagewise ordering is more preferable since it yields  $P$  values in agreement with the decision from the hypothesis testing; it is less than the significance level  $\alpha$  if and only if the null hypothesis is rejected. Moreover, the stagewise ordering does not depend on the stages beyond the stopping one, making it applicable in some more flexible designs in which the information time points at which interim analysis is conducted are not specified in advance. See Jennison and Turnbull [6].

## 21.5 CONSTRUCTION OF CONFIDENCE INTERVALS

A confidence interval of  $\delta$  with level  $(1 - \alpha)$  is an interval with lower bound  $\delta_L^* = \delta_L^*(T, X(T))$  and upper bound  $\delta_U^* = \delta_U^*(T, X(T))$  such that for any  $\delta$

$$P_\delta \{\delta_L^* < \delta < \delta_U^*\} \geq 1 - \alpha$$

One approach to construct such an interval is to use an ordering of the sample space described previously for calculating  $P$  values. Let the terminal data be  $(t_k, \tilde{x})$ . Then  $\delta_L^*$  is the drift value at which the probability is half  $\alpha$  of observing data being at least as extreme as  $(t_k, \tilde{x})$ , and  $\delta_U^*$  is the drift value at which the probability is  $1 - \alpha/2$  of observing data being at least as extreme as  $(t_k, \tilde{x})$ . That is,  $\lambda(\delta_L^*; t_k, \tilde{x}) = \alpha/2$  and  $\lambda(\delta_U^*; t_k, \tilde{x}) = 1 - \alpha/2$ , where

$$\lambda(\delta; t_k, \tilde{x}) = P_\delta \{(T, X(T)) \text{ is at least as extreme as } (t_k, \tilde{x})\}$$

In order for the two equations to yield an interval, the function  $\lambda(\delta; t_k, \tilde{x})$  needs to be increasing in  $\delta$  for any given data point  $(t_k, \tilde{x})$ . With such monotonicity each equation has a unique solution and  $\delta_L^* < \delta_U^*$  holds. If the  $\lambda$  function is nondecreasing, then  $\delta_L^*$  can be set to be  $\{\delta: \lambda(\delta; t_k, \tilde{x}) = \alpha/2\}$  and  $\delta_U^*$  to be  $\{\delta: \lambda(\delta; t_k, \tilde{x}) = 1 - \alpha/2\}$ . It can be shown analytically that Emerson and Fleming's [13] ordering and the stagewise ordering both yield increasing  $\lambda$  functions; see Emerson [10] or Hall and Liu [20] for the former and Jennison and Turnbull [6, Chapter 8] for the latter. There is no analytic results on this matter for the other two orderings though limited numerical results do not seem to support the monotonicity property.

Jennison and Turnbull [6, Chapter 8] discussed several criteria for defining a good confidence interval such as agreement with the hypothesis testing results and inclusion of the maximum-likelihood estimate. They come to a conclusion that the stage-wise ordering gives a more preferable confidence interval, which, in addition, is the only feasible method to use when future information time for interim analysis is not specified.

Woodroof [21] proposed a different approach to construct a confidence interval by modifying the fixed-size procedure to take the bias into consideration. Write  $Z(\delta) = (X(T) - T\delta)/\sqrt{T}$ . In fixed-size sampling,  $Z$  is normally distributed with zero mean and unit variance and serves as a pivot to construct the usual  $(1 - \alpha)$ -level confidence interval with limits  $X(T)/T \mp \Phi^{-1}(1 - \alpha/2)/\sqrt{T}$ . In a group-sequential sampling, this pivot no longer has a standard normal distribution, so a certain adjustment is needed. A new pivot is defined as  $Z(\delta) = (Z(\delta) - \mu(\delta))/s(\delta)$  where  $\mu(\delta)$  and  $s(\delta)$  are the mean and standard deviation function of  $Z(\delta)$ , respectively. If we assume that this new pivot approximately follows a standard normal distribution, then an approximate  $(1 - \alpha)$ -level confidence interval for  $\delta$  has confidence limits being

$$\left\{ \frac{X(T)}{T} - \frac{\hat{\mu}}{\sqrt{T}} \mp \frac{\hat{s}}{\sqrt{T}} \Phi^{-1}\left(1 - \frac{\alpha}{2}\right) \right\}$$

where  $\hat{\mu}$  and  $\hat{s}$  are proper estimates of  $\mu(\delta)$  and  $s(\delta)$ , respectively, which are often obtained with  $\delta$  replaced by its maximum-likelihood estimate.

Unlike the confidence intervals based on a sample space ordering, the above pivotal method does not always guarantee the exact coverage probability of  $1 - \alpha$ . However, it works pretty well in most cases, and the coverage probability of the resulting confidence intervals are quite close to the nominal level of  $1 - \alpha$ .

We have seen applications of the orderings of the sample space to constructing confidence intervals and calculating  $P$  values. Another usage of a proper ordering of the sample space is to compute a *median-unbiased* estimate  $\hat{\delta}_M = \hat{\delta}_M(T, X(T))$  of  $\delta$  such that

$$P_{\delta}\{\hat{\delta}_M(T, X(T)) < \delta\} = P_{\delta}\{\hat{\delta}_M(T, X(T)) > \delta\} = \frac{1}{2}$$

That is, a median-unbiased estimate has equal chances to over- or underestimate the parameter. (In contrast, the usual unbiased estimates such as  $\hat{\delta}_{EF}$  are referred to as *mean-unbiased* estimates, if such distinction needs to be made.) For an ordering of sample space with monotonicity property, the corresponding median-unbiased estimate at  $(t_k, \tilde{x})$  can be found by solving for  $\delta$  the equation:

$$\frac{1}{2} = \lambda(\delta; t_k, \tilde{x}) = P_{\delta}\{(T, X(T)) \text{ is at least as extreme as } (t_k, \tilde{x})\}$$

Emerson and Fleming [13] investigated the bias and mean-squared error of the median-unbiased estimates based on certain orderings. Compared with the bias-adjusted estimate  $\hat{\delta}_w$  and the unbiased estimate  $\hat{\delta}_{EF}$ , the median-unbiased estimates in general tend to have larger bias, often coupled with larger mean-squared error as well.

## 21.6 INFERENCE CONCERNING SECONDARY ENDPOINT

Termination of a sequential clinical trial is based on the *primary endpoint*, such as patients' survival in a cancer trial. In contrast, a *secondary endpoint*, such as patients' disease-free survival or treatment  $\times$  strata interaction, refers to an endpoint whose values are also observed from each patient along with the primary endpoint but do not contribute in any way to the termination of the trial. The secondary endpoints are usually analyzed only after the trial stops, though they may be evaluated at certain interim analysis, and such evaluation plays no role in sequential monitoring of the trial.

A secondary endpoint is usually correlated with the primary endpoint since they both are observed from the same patients. Due to the correlation, the usual likelihood analysis should also be adjusted for the random stopping of the trial so that a valid inference on secondary endpoints can be made. For most trials the primary and a secondary endpoint can be put into a random-sampling framework and be (asymptotically) modeled as two correlated Brownian motions with constant (often assumed to be known) correlation and proportional information time. The first Brownian motion, as given in the previous sections, governs the stopping of the trial, and the second one summarizes the observations of the secondary endpoint with

its drift parameter usually measuring the difference in the endpoint between treatment arms. For this drift parameter, Whitehead [22] constructed a bias-adjusted estimate to reduce the bias of the maximum-likelihood estimate, and Liu and Hall [23] investigated its unbiased estimates. Certain confidence intervals are developed by Whitehead and co-workers [24] using Woodroffe's pivotal method; these confidence intervals can also be used for testing hypotheses concerning the secondary endpoints.

Not all secondary endpoints can be modeled (asymptotically) with the primary endpoint as two Brownian motion with constant correlation coefficients. Yakir and Hall [25] and Hall and Yakir [26] gave examples that do not satisfy this model. One example is that a sequential trial with staggered entry is carried out to compare the survival rate of two treatment arms based on the log-rank statistic. Upon termination of the trial, one wants to know whether treatment  $\times$  gender interaction exists. In these examples, the primary and secondary endpoints are modeled as two Gaussian processes with correlation being a function of the information time. Hall and Yakir [26] derived distributional theory and certain optimal properties to construct point estimates and confidence intervals of the parameters associated with the secondary endpoint.

The inference procedures discussed so far are parametric in nature. Chuang and Lai [27, 28] developed nonparametric methods based on a resampling technique for confidence intervals concerning both the primary and secondary endpoints.

**22.1 INTRODUCTION**

Evidence-based medicine is a cornerstone of current medical practice. Randomized controlled trials are regarded as the most robust form of evidence-based medicine. An appreciation of statistical methods is fundamental to understanding randomized trial methods and results.

A randomized controlled trial aims to provide unbiased treatment effect regarding the efficacy and safety of a medicinal product or a therapeutic procedure. The observed treatment effect, however, may represent the “true” difference between the new drug and the comparative treatment or it may not. Therefore, if the trial were repeated with all the available patients in the world, then the outcome would either be the same as the trial (a true result) or different (making the trial result a chance event, or an erroneous false result). Understanding the possible sources of erroneous results is critical in the appreciation of clinical trials. The reasons for erroneous results fall into three main categories.

- First, the trial may have been biased in some predictable fashion.
- Second, it could have been contaminated (confounded) by an unpredictable factor.
- Third, the result may simply have occurred by chance.

**22.1.1 Bias and Systematic Errors**

Bias can influence a trial by the occurrence of systematic errors that are associated with the design, conduct, analysis, and reporting of the results of a clinical trial. Bias can also make the trial-derived estimate of a treatment effect deviate from its true value [1, 2]. The most common types of bias in clinical trials are those related to subject selection and outcome measurement. For example, if the investigators are aware of which treatment a patient is receiving, it could affect the way they collect information on the outcome during the trial, or they might recruit patients in a way that could favor the new treatment, resulting in a selection bias.

In addition, exclusion of subjects from statistical analysis because of noncompliance or missing data could bias an estimate of the true benefit of a treatment, particularly if more patients were removed from analysis in one group than the other [3, 4]. Much of the advanced design strategies seek to reduce these systematic errors.

### 22.1.2 Confounding

Confounding represents the distortion of the true relationship between treatment and outcome by another factor, for example, the severity of disease [5]. Confounding occurs when an extra factor is associated with both the outcome of interest and treatment group assignment. Confounding can both obscure an existing treatment difference and create an apparent difference that does not exist.

If we divided patients into treatment groups based on inherent differences (such as mean age) at the start of a trial, then we would be very likely to find the benefit of the new treatment to be influenced by those preexisting differences. For example, if we assign only smokers to get treatment A, only nonsmokers to get treatment B, and then assess which treatment protects better against cardiovascular disease, we might find that the benefit seen with treatment B is due to the lack of smoking in this group. The effect of treatment B on cardiovascular disease development would therefore be confounded by smoking.

Randomization in conjunction with a large sample size is the most effective way to restrict such confounding, by evenly distributing both known and unknown confounding factors between treatment groups. If, before the study begins, we know which factors may confound the trial, then we can use randomization techniques that force a balance of these factors (stratified randomization). In the analysis stage of a trial, we might be able to restrict confounding using appropriate statistical techniques such as stratified analysis and regression analysis [6].

### 22.1.3 Random Error

Even if a trial has an ideal design and is conducted to minimize bias and confounding, the observed treatment effect could still be due to random error or chance [1, 2, 7]. The random error can result from sampling, biologic, or measurement variation in outcome variables. Since (given specific selection criteria) the patients in a clinical trial are only a sample of all possible available patients, the sample might yet show a chance false result compared to the overall population. This is known as a sampling error. Sampling errors can be reduced by choosing a very large group of patients. Other causes of random error are described elsewhere [2].

Statistical analyses deal with random error by providing an estimate of how likely the measured treatment effect reflects the true effect [7–9]. Statistical testing or inference involves an assessment of the probability of obtaining an observed treatment difference or more extreme difference for an outcome, assuming that there is no difference between treatments. This probability is often called the *P* value or false-positive rate. If the *P* value is less than a specified critical value (e.g., 5%), the observed difference is considered to be statistically significant. The smaller the *P* value, the stronger the evidence is for a true difference between treatments. On the other hand, if the *P* value is greater than the specified critical value, then the observed difference is regarded as not statistically significant and is considered to be potentially due to random error or chance. The traditional statistical threshold is a *P* value of 0.05 (or 5%), which means that we only accept a result when the likelihood of the conclusion being wrong is less than 1 in 20. In other words we conclude that only 1 out of a hypothetical 20 trials will show a treatment difference when in truth there is none.

Statistical estimates summarize the treatment differences for an outcome in the forms of point estimates (e.g., means or proportions) and measures of precision [e.g., confidence intervals (CIs)] [7]. A 95% CI for a treatment difference means that the range presented for the treatment effect contains (when calculated in 95 out of 100 hypothetical trials assessing the same treatment effect) the true value of treatment difference, that is, the value we would obtain if we were to use the entire available patient population is 95% likely to be contained in the 95% CI.

Finally, testing several different hypotheses with the same trial (e.g., comparing treatments with respect to different outcomes or for several smaller subpopulations within the trial population) will increase the chance of observing a statistically significant difference purely due to chance [10]. Even examining the difference between treatments at many time points (interim analyses) throughout the length of the trial could lead to a spurious result due to multiple testing [10, 11]. Therefore, the aim should be to plan a trial in such a way that the occurrence of any such errors is minimal.

## 22.2 TYPES OF DATA, SUMMARY, AND DATA PRESENTATION

### 22.2.1 Types of Data

Clinical studies compare effects of medical treatment or interventions on two or more groups of subjects. Data are collected, however, at the individual subject or patient level. Data are composed of baseline characteristics such as age, gender, height, weight, and so forth, or of disease factors such as presence of arthritis, coronary disease, or severity of a fracture, or of treatment response variables such as reduction in pain, improvement of disease, or prolongation of life. These data come from variables of different types—either continuous (or quantitative), such as age or hemoglobin levels, or they may be categorical (or qualitative), such as race or gender.

Data can be classified further into four main groups:

- Binary (categorical): for example, sex (male and female)
- Unordered (categorical): for example, race (white, black, other)
- Ordered (categorical): for example, severity (mild, moderate, severe)
- Numerical (continuous): for example, age (in years)

### 22.2.2 Data Description and Presentation

In clinical studies, data are summarized for presentation by treatment groups using frequency distributions. These present the distribution of both qualitative and quantitative data, summarizing how often each value of a data point is repeated. With quantitative data, we mostly present a grouped frequency distribution. From a frequency table we can appreciate:

- The frequency (number of cases) occurring for each category or interval—for example, number of 70-year-old patients

- The relative frequency (percentage) of the total sample in each category or interval—for example, 70-year-old patients were 10% of the overall sample
- The highest and lowest or the range of possible values from our patient groups—for example, in that group the oldest patient was 96 and the youngest patient was 25

Although a frequency table provides a detailed summary of the distribution of the data, presentation of the distribution in a graph/chart makes the message from the data more informative. The type of graph depends on the type of data. Generally, if the data are categorical, we use a bar graph or a pie chart. If the data are continuous, a histogram or frequency polygon is more appropriate. As well as for the entire study population, the frequency distributions can then be presented for each treatment group. This is a fast way of ascertaining whether there are broad similarities or differences between treatment groups. Later we can use statistical tests to ascertain whether any differences between the groups are significant.

### 22.2.3 Summarizing Quantitative Variables

Categorical variables may be expressed as percentages and compared between different groups. There is little more that can be done to describe such variables. However, for a quantitative variable we can do more than this. We have other measures with which to summarize the data (summary measures). From the frequency distribution we can calculate the location (or central tendency) that summarizes where the center of the distribution lies and we can also summarize the spread/range (or variation) of the distribution, which describes how widely the values are spread above and below the central value.

There are two measures commonly used to describe the location for the central tendency, depending on whether the distribution is even (such as age) or more biased in one direction (such as physical fitness—many more people are unfit than are Olympic athletes).

- *Mean:* The mean can be calculated by summing all the quantitative observations and divided the sum by the number of observations.
- *Median:* The median is the value that divides the distribution equally. The median is more appropriate for distributions that are skewed, such as physical fitness. When the distribution is symmetrical, the median equals the mean.

There are three measures commonly used to summarize the spread of a variable:

- *Standard deviation:* This gives the average distance of all observations from the mean. The standard deviation has an important role in statistical analysis.
- *Range:* Any data between the lowest and highest values is known as the full range of values.
- *Percentile:* This is the value below which a given percentage of the data observations occur. The most commonly used percentiles are 5 and 95%. Using these overcomes the problem of extreme data values away from the mean or median.

## 22.3 NORMAL DISTRIBUTION: SYMMETRIC FREQUENCY DISTRIBUTION

### 22.3.1 What Is a Normal Distribution?

Quantitative variables can range from very small to very large values, and, in some situations, from negative to positive values. Consider the systolic blood pressure (BP) measurements of 1000 subjects participating in a lifestyle survey. The frequency distribution of these systolic BPs is shown in Figure 1. The height of each vertical bar in this graph shows the proportion (or probability) of subjects whose systolic blood level was between the values at the base of the bar. So, if we summed the heights of all the bars in the histogram, we should find that the total of all the proportions is 1. Proportion is the same as the percentage expressed as a fraction over 100%.

The distribution of these blood pressures conforms approximately to a bell-shaped curve or normal distribution typical for common continuous biological measurements. The curve has particular mathematical properties expressed by the

Normal distribution function:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \quad \sigma > 0, -\infty < \mu < \infty, -\infty < x < \infty$$

Properties of normal distribution (curve):

The curve has a single peak at the center; this peak occurs at the mean ( $\mu$ ).

The curve is symmetrical about the mean.

The curve never touches the horizontal axis.

The total area under the curve is equal to 1.

The width or shape of the curve is described by the variance ( $\sigma^2$ ), the squared root of which is the standard deviation ( $\sigma$ ).

**FIGURE 1** Histogram and fitted normal distribution curve for systolic blood pressures from 1000 subjects.

equation shown with the curve. This distribution is one of the most important distributions in statistics and is known as the Gaussian distribution [12].

If we have enough values with smaller bars, the heights of these bars would form the bell-shaped curve shown superimposed on the chart. This curve is defined by the mean, or central value ( $\mu$ ), of 149.044 mmHg, and by its spread, or standard deviation ( $\sigma$ ), of 37.317 mmHg.

### 22.3.2 Properties of Normal Distribution

The properties of a normal distribution are illustrated in the legend of Figure 1. The standard deviation helps to describe the spread of the observations, with about 68% of all observations being captured within one standard deviation at either side of the mean and about 95% of all observations captured within two standard deviations at either side of the mean.

## 22.4 PRINCIPLES OF STATISTICAL INFERENCE

Let us suppose that it is necessary to measure the average systolic blood pressure (SBP) level of all males aged  $\geq 16$  years in the United Kingdom in 2005. For practical and financial reasons, it is not possible to directly measure the SBP of every adult male in the United Kingdom. Instead, we can conduct a survey among a subset (or “sample”) of 500 males within this population. Through statistical inference, we can measure the properties of the sample (such as the mean and standard deviation) and use these values to infer the properties of the entire UK adult male population [11–13].

Population properties are usually determined by population parameters (numerical characteristics of a population) that are fixed and usually unknown quantities, such as the mean ( $\mu$ ) and standard deviation ( $\sigma$ ) in a normal distribution  $N(\mu, \sigma^2)$  [14, 15]. The statistical properties of the sample, such as the mean ( $\bar{X}$ ) and standard deviation ( $S$ ), can be used to provide estimates of the corresponding population parameters. Conventionally, Greek letters are used to refer to population parameters, while the Roman alphabet is used to refer to sample estimates.

Two strategies that are often used to make statistical inference are [7, 13, 14]:

1. Hypothesis testing
2. Confidence intervals (CIs)

### 22.4.1 Hypothesis Testing

Statistical inference can be made by performing a hypothesis (or significance) test, which involves a series of statistical calculations [7, 12–14]. In the sample of 500 adult males, the mean SBP ( $\bar{X}$ ) was 130 mmHg, with a standard deviation ( $S$ ) of 10 mmHg. The empirical estimate for the mean SBP of this population from previous medical literature is reported as 129 mmHg (denoted by  $\mu_0$ ). So, we want to know whether there is any evidence that the mean SBP value for all adult males in the United Kingdom in 2005 ( $\mu$ ) is different from 129 mmHg ( $\mu_0$ ).

We start by stating a hypothesis that the population mean SBP for all adult men in 2005 is 129 mmHg, or  $\mu = \mu_0$  (i.e., no different to that reported in the medical literature). This is referred to as the null hypothesis and is usually written as  $H_0$ , representing a theory that has been put forward as a basis for argument [7, 12–14]. The hypothesis test is a means to assess the strength of evidence against this null hypothesis of no difference.

The alternative hypothesis, usually written as  $H_a$ , is that the mean SBP for the study population is not equal to the specified value, that is,  $\mu \neq \mu_0$ . Note that under the alternative hypothesis, the 2005 population mean could be higher or lower than the reference mean. The statistical test for the above hypotheses is usually referred to as a two-sided test.

Once the null hypothesis has been chosen, we need to calculate the probability that, if the null hypothesis is true, the observed data (or data that were more extreme) could have been obtained [7, 12–14]. To reach this probability, we need to calculate a test statistic from the sample data (e.g.,  $\bar{X}$ ,  $S$ , and  $n$  for quantitative outcomes) using an appropriate statistical method. This test statistic is then compared to the distribution (e.g., the normal distribution) implied by the null hypothesis to obtain the probability of observing our data or more extreme data.

For the SBP data, given the relatively large sample size, we can use the  $Z$  test to calculate the value of the test statistic  $Z$ . The  $Z$  test is expressed by the following formula [7, 12–14]:

$$Z = \frac{\bar{X} - \mu_0}{S/\sqrt{n}}$$

This statistic follows a normal standard distribution under the null hypothesis [7, 12–14]. For the SBP data:

- $\bar{X} = 130$  mmHg
- $S = 10$  mmHg
- $n = 500$
- $\mu_0 = 129$  mmHg

Replacing the values in the formula generates  $Z = 2.24$ . A variety of statistical methods can be used to address different study questions (e.g., comparing treatment difference in means and proportions). The choice of statistical test will depend on the types of data and hypotheses under question [7, 12–14].

Having obtained the appropriate test statistic (in our example, the  $Z$  value), the next step is to specify a significance level. This is a fixed probability of wrongly rejecting the null hypothesis,  $H_0$ , if it is in fact true. This probability is always chosen by the investigators taking into account the consequences of such an error. That is, the significance level is kept low to reduce the chance of inadvertently making a false claim. The significance level, denoted by  $\alpha$ , is usually chosen to be 0.05 (5%). The corresponding  $Z_{\alpha/2}$  is called the critical value of the  $Z$  test. The critical value for a hypothesis test is a threshold with which the value of the test statistic calculated from a sample is compared in order to determine the  $P$  value to be introduced next. For example, if  $\alpha = 0.05$ , we have  $Z_{0.05/2} = 1.96$ ; if  $\alpha = 0.01$ , we have  $Z_{0.01/2} = 2.58$ .

A  $P$  value is the probability of our result ( $Z = 2.24$  for the SBP data) or a more extreme result ( $Z < -2.24$  or  $Z > 2.24$ ) being observed, assuming that the null hypothesis is true. The exact  $P$  value in the  $Z$  test is the probability of  $Z \leq -Z_{\alpha/2}$  or  $Z \geq Z_{\alpha/2}$ , which can always be determined by calculating the area under the curve in two-sided symmetric tails from a statistical table specifically of a normal distribution [7, 14]. For the SBP data, the exact  $P$  value = 0.025.

In a practical application, we often need to determine whether the  $P$  value is smaller than a specified significance level,  $\alpha$ . This is performed by comparing the value of the test statistic with the critical value. Statistically  $P \leq \alpha$  if, and only if,  $Z = -Z_{\alpha/2}$  or  $Z = Z_{\alpha/2}$ . For the SBP data, since  $Z = 2.24 > Z_{0.05/2} = 1.96$ , we can conclude that  $P < 0.05$ . A smaller  $P$  value indicates that  $Z$  is further away from the center (i.e., the null value  $\mu - \mu_0 = 0$ ) and consequently provides stronger evidence to support the alternative hypothesis of a difference.

Although the  $P$  value measures the strength of evidence for a difference, which is largely dependent on the sample size, it does not provide the size and direction of that difference. Therefore, in a statistical report,  $P$  values should be provided together with CIs (described in detail later) for the main outcomes [7, 14].

We are now in a position to interpret the  $P$  value in relation to our data and decide whether there is sufficient evidence to reject the null hypothesis. Essentially, if  $P = \alpha$ , the prespecified significance level, then there is evidence against the null hypothesis, and we accept the alternative hypothesis stating that there is a statistically significant difference. The smaller the  $P$  value, the lower the chance of obtaining a difference as big as the one observed if the null hypothesis were true, and, therefore, the stronger the evidence against the null hypothesis. Otherwise, if  $P > \alpha$ , there is not sufficient evidence to reject the null hypothesis or there is no statistically significant difference.

For our SBP data, since  $P < 0.05$ , we can state that there is evidence to reject the null hypothesis of no difference at the 5% significance level, and, therefore, that the mean SBP for the adult male population is statistically significantly different from 129 mmHg. Furthermore, the actual  $P$  value equals 0.025, which suggests that the probability of falsely rejecting the null hypothesis is 1 in 40 if the null hypothesis is indeed true. On the other hand,  $Z_{0.005} = 2.58 > Z = 2.24$ , and  $P$  is  $> 0.01$ . Now we can state that there is no evidence to reject the null hypothesis of no difference if the significance level  $\alpha$  is chosen as 0.01.

The implementation of the above procedures for hypothesis testing with the SBP data is summarized in Table 1.

#### 22.4.2 Alpha (Type I) and Beta (Type II) Errors

When testing a hypothesis, two types of errors can occur. To explain these two types of errors, we will use the example of a randomized, double-blind, placebo-controlled clinical trial on a cholesterol-lowering drug A in middle-aged men and women considered to be at high risk for a heart attack. The primary endpoint is the reduction in the total cholesterol level at 6 months from randomization.

The null hypothesis is that there is no difference in mean cholesterol reduction level at 6 months postdose between patients receiving drug A ( $\mu_1$ ) and patients receiving a placebo ( $\mu_2$ ) ( $H_0: \mu_1 = \mu_2$ ); the alternative hypothesis is that there is a difference ( $H_a: \mu_1 \neq \mu_2$ ). If the null hypothesis is rejected when it is in fact true, then

TABLE 1 Practical Procedures for Hypothesis Testing

| Step | Procedure                                                                                                                     | Illustration with SBP <sup>a</sup> Data                                                                                                                                                                                                                                                                                               |
|------|-------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1    | Set up a null hypothesis and alternative hypothesis that is of particular interest to study.                                  | $H_0: \mu = \mu_0 (= 129)$ , i.e., population mean SBP is equal to 129 mmHg<br>$H_a: \mu \neq \mu_0$ , i.e., population mean SBP is different from 129 mmHg                                                                                                                                                                           |
| 2    | Choose a statistical method according to data type and distribution and calculate its test statistic from the data collected. | $Z = \frac{\bar{X} - \mu_0}{S/\sqrt{n}} = 2.24$<br>$\bar{X} = 130$ mmHg<br>$S = 10$ mmHg<br>$n = 500$                                                                                                                                                                                                                                 |
| 3    | Define a significance level $\alpha$ and its corresponding critical value.                                                    | $\alpha = 0.05$ and $Z_{\alpha/2} = 1.96$<br>$\alpha = 0.01$ and $Z_{\alpha/2} = 2.58$                                                                                                                                                                                                                                                |
| 4    | Determine the $P$ value by comparing the test statistic and the critical value, or calculate the exact $P$ value.             | Since $Z = 2.24 > 1.96$ , $P < 0.05$<br>Since $Z = 2.24 < 2.58$ , $P > 0.01$<br>Exact $P$ value = 0.025                                                                                                                                                                                                                               |
| 5    | Make your conclusion according to the $P$ value.                                                                              | As $0.01 < P < 0.05$ , there is evidence to reject the null hypothesis of no difference at the 5% level of significance, but there is no evidence to reject the null hypothesis at the 1% level. The $P$ value of 0.025 means that the probability of falsely rejecting the null hypothesis is 1 in 40 if the null hypothesis is true |

<sup>a</sup>SBP, systolic blood pressure.

a type I error (or false-positive result) occurs. For example, a type I error is made if the trial result suggests that drug A reduced cholesterol levels when in fact there is no difference between drug A and placebo. The chosen probability of committing a type I error is known as the significance level [7, 12–14]. As discussed above, the level of significance is denoted by  $\alpha$ . In practice,  $\alpha$  represents the consumer’s risk [2], which is often chosen to be 5% (1 in 20).

On the other hand, if the null hypothesis is not rejected when it is actually false, then a type II error (or false-negative result) occurs [7, 12–14]. For example, a type II error is made if the trial result suggests that there is no difference between drug A and placebo in lowering the cholesterol level when in fact drug A does reduce the total cholesterol. The probability of committing a type II error, denoted by  $\beta$ , is sometimes referred to as the manufacturer’s risk [2]. The power of the test is given by  $1 - \beta$ , representing the probability of correctly rejecting the null hypothesis when it is in fact false. It relates to detecting a prespecified difference.

22.4.3 Confidence Intervals

The second strategy for making statistical inference is through the use of CIs. In making inference about a population, we might want to know the likely value of the unknown population parameter [e.g., mean ( $\mu$ ), proportion]. This is estimated from the sample statistics. For example, mean ( $\bar{X}$ ), and we call  $\bar{X}$  a point estimate of  $\mu$ .

In addition, we might want to provide some measure of our uncertainty as to how close the sample mean is to the true mean. This is done by calculating a CI (or interval estimate)—a range of values that has a specified probability of containing the true population parameter being estimated. For example, a 95% CI for the mean is usually interpreted as a range of values containing the true population mean with a probability of 0.95 [2]. The formula for the  $(1 - \alpha)\%$  CI around the sample mean ( $\bar{X}$ ) corresponding to the  $Z$  test, is given by

$$\bar{X} \pm Z_{\alpha/2} \text{SE}(\bar{X})$$

where  $\text{SE}(\bar{X})$  is the standard error of  $\bar{X}$ , calculated by  $S/\sqrt{n}$ . This is a measure of the uncertainty of a single sample mean ( $\bar{X}$ ) as an estimate of the population mean [7]. This uncertainty decreases as the sample size increases. The larger the sample size, the smaller the standard error. Therefore, the narrower the interval, the more precise the point estimate.

For our SBP example, the 95% CI for the population mean ( $\mu$ ) can be calculated with the following formula:

$$\bar{X} \pm 1.96S/\sqrt{n} = 129.1\text{--}130.9\text{ mmHg}$$

This means that the interval between 129.1 and 130.9 mmHg has a 0.95 probability of containing the population mean  $\mu$ . In other words, we are 95% confident that the true population mean is between 129.1 and 130.9 mmHg, with the best estimate being 130 mmHg.

Confidence intervals can be calculated not just for a mean but also for any estimated parameter depending on the data types and statistical methods used [12, 14]. For example, one could estimate the proportion of people who smoke in a population, or the difference between the mean SBP in subjects taking an antihypertensive drug and those taking a placebo.

#### 22.4.4 Relationship between Significant Testing and Confidence Intervals

When comparing, for example, two treatments, the purpose of significance testing is to assess the evidence for a difference in some outcome between the two groups, while the CI provides a range of values around the estimated treatment effect within which the unknown population parameter is expected to be with a given level of confidence.

There is a close relationship between the results of significance testing and CIs. This can be illustrated using the previously described  $Z$  test for the SBP data analysis. If  $H_0: \mu = \mu_0$  is rejected at the  $\alpha\%$  significance level, the corresponding  $(1 - \alpha)\%$  CI will not include  $\mu_0$ . On the other hand, if  $H_0: \mu = \mu_0$  is not rejected at the  $\alpha\%$  significance level, then  $(1 - \alpha)\%$  CI will include  $\mu_0$ .

For the SBP data of adult males, the significance test shows that  $\mu$  is significantly different from  $\mu_0 (= 129 \text{ mmHg})$  at the 5% level, and the 95% CI ( $= 129.1\text{--}130.9 \text{ mmHg}$ ) did not include 129 mmHg. On the other hand, the difference between  $\mu$  and  $\mu_0$  is not significant at the 1% level; the 99% CI [ $129 \pm (2.58 \times 10)/\sqrt{500} = 128.8\text{--}131.2 \text{ mmHg}$ ] for  $\mu$  does indeed contain  $\mu_0$ . Further information about the proper use of the above two statistical methods can be found in [7, 16].

### 22.4.5 Examples

Let us assume that four randomized, double-blind, placebo-controlled trials are conducted to establish the efficacy of two weight loss drugs (A and B) against placebo, with all subjects, whether on a drug or placebo, receiving similar instructions as to diet, exercise, behavior modification, and other lifestyle changes. The primary endpoint is the weight change (in kilograms) at 2 months from baseline. The difference in the mean weight change between an active drug and placebo groups can be considered as weight reduction for the active drug against placebo. Table 2 presents the results of hypothesis tests and CIs for the four hypothetical trials. The null hypothesis for each trial is that there is no difference between the active drug treatment and placebo in mean weight change. In trial 1 of drug A, the reduction of drug A over placebo was 6 kg with only 40 subjects in each group. The *P* value of 0.074 suggests that there is no evidence against the null hypothesis of no effect of drug A at the 5% significance level. The 95% CI shows that the results of the trial are consistent with a difference ranging from a large reduction of 12.6 kg in favor of drug A to a reduction of 0.6 kg in favor of placebo.

The results for trial 2 among 400 patients, again for drug A, suggest that mean weight was again reduced by 6 kg. This trial was much larger, and the *P* value ( $P < 0.001$ ) shows strong evidence against the null hypothesis of no drug effect. The 95% CI suggests that the effect of drug A is a greater reduction in mean weight over placebo of between 3.9 and 8.1 kg. Because this trial was large, the 95% CI was narrow and the treatment effect was therefore measured more precisely. In trial 3, for drug B, the reduction in weight was 4 kg. Since the *P* value was 0.233, there was no evidence against the null hypothesis that drug B has no statistically significant benefit effect over placebo. Again this was a small trial with a wide 95% CI, ranging from a reduction of 10.6 kg to an increase of 2.6 kg for the drug B against the placebo.

The fourth trial on drug B was a large trial in which a relatively small, 2-kg reduction in mean weight was observed in the active treatment group compared with the placebo group. The *P* value (0.008) suggests that there is strong evidence against the null hypothesis of no drug effect. However, the 95% CI shows that the reduction is as little as 0.5 kg and as high as 3.5 kg. Even though this is convincing statistically, any recommendation for its use should consider the small reduction achieved alongside other benefits, disadvantages, and cost of this treatment.

Key points from the four trials are summarized in Table 3.

**TABLE 2 Point Estimate and 95% Confidence Interval (CI) for Difference in Mean Weight Change from Baseline between the Active Drug and Placebo Groups in Four Hypothetical Trials of Two Weight Reduction Drugs**

| Trial | Drug | No. of Patients per Group | Difference in Mean Weight Change from Baseline (kg) between the Active Drug and Placebo Groups | Standard Deviation of Difference | Standard Error of Difference | 95% CI for Difference | <i>P</i> value |
|-------|------|---------------------------|------------------------------------------------------------------------------------------------|----------------------------------|------------------------------|-----------------------|----------------|
| 1     | A    | 40                        | −6                                                                                             | 15                               | 3.4                          | −12.6, 0.6            | 0.074          |
| 2     | A    | 400                       | −6                                                                                             | 15                               | 1.1                          | −8.1, −3.9            | <0.001         |
| 3     | B    | 40                        | −4                                                                                             | 15                               | 3.4                          | −10.6, 2.6            | 0.233          |
| 4     | B    | 800                       | −2                                                                                             | 15                               | 0.8                          | −3.5, −0.5            | 0.008          |

**TABLE 3 Summary of Key Points from Results Described in Table 2**

| Key Points from Significance Test and CI                                                                                                                                                                         | Examples       |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------|
| In a small study, a large $P$ value does not mean that the null hypothesis is true—absence of evidence is not evidence of absence                                                                                | Trials 1 and 3 |
| A large study has a better chance of detecting a given treatment effect than a small study and is therefore more powerful                                                                                        | Trials 2 and 4 |
| A small study usually produces a CI for the treatment effect that is too wide to allow any useful conclusion                                                                                                     | Trials 1 and 3 |
| A large study usually produces a narrow CI, and therefore a precise estimate of treatment effect                                                                                                                 | Trials 2 and 4 |
| The smaller the $P$ value, the lower the chance of falsely rejecting the null hypothesis, and the stronger the evidence for rejecting the null hypothesis                                                        | Trials 2 and 4 |
| Even if the $P$ value shows a statistically significant result, it does not mean that the treatment effect is clinically significant. The clinical importance of the estimated effects should always be assessed | Trial 4        |

## 22.5 COMPARISON OF TWO MEANS

The statistical methods used to compare two means of different treatment groups depend on how the two means were obtained. Data may be obtained from paired or unpaired samples. Paired samples occur when the source of the observations in the first sample are from the same source as the observations of a second or repeat sample. For quantitative data this means that repeated observations are from the same person using a before and after treatment method. Unpaired samples occur when individual observations in one group are independent of individual observations in the other. That is to say that the groups of subjects are different.

The most commonly used statistical test for the comparison of two means is the  $t$  test. The  $t$  test compares the means of two sets of continuous variables and expresses the probability that any differences are due to the play of chance (i.e., the null hypothesis is supported), or that the differences may be “real” (i.e., the alternative hypothesis is supported). This probability is often determined by a  $t$  value. The  $t$  tests can be used to compare two sample means for both paired and unpaired data, but formulas for calculating  $t$  values are different [12, 14]. An example of a  $t$  test for unpaired data is shown in Table 4.

From Table 4, we see that the  $t$  value of 2.055 corresponds to an observed  $P$  value of 0.040. The  $P$  value is the probability of observing the difference (3.440) or even larger (e.g., absolute difference  $>3.440$ ) from the samples if the null hypothesis were true. The null hypothesis is that the difference in means of the two populations is zero. If there were no difference in systolic blood pressure between two treatment groups, there would be a small chance ( $P = 0.040$ ) that we would observe the difference we did. We can turn this around and say that it is more likely that the two treatment groups differ. We say: “The difference in means between two treatment groups is statistically significant” since the observed  $P$  value is lower than our significance threshold value of  $P = 0.05$ .

The  $t$  test can be performed equivalently by calculating a confidence interval for the difference in means. A confidence interval is a range of values within which the “true” population parameter (such as difference in two means) is likely to lie. Usually 95% confidence limits are quoted, which implies that there is 95%

**TABLE 4** Example of Comparison of Two Means from Independent Samples—*t* Test

An example calculation in a study to evaluate the effects of a treatment to reduce blood pressure are given. A randomized placebo-controlled trial comparing the effect of an antihypertensive therapy against placebo was conducted. The primary endpoint is systolic blood pressure at 6 months after randomization. The results of the two groups of patients were as follows:

Results of Blood Pressures

- In the control group of 548 patients the mean systolic blood pressure was 150.22 with a standard deviation of 27.12 mmHg
- In the treatment group of 550 patients the mean systolic blood pressure was 146.78 with a standard deviation of 28.32 mmHg

Using these data the *t* test can be calculated in the following manner:

Suppose two populations of sizes  $n_1$  and  $n_2$  have blood pressure results forming normal distributions with means  $\bar{X}_1$  and  $\bar{X}_2$  and standard deviations  $S_1$  and  $S_2$ , respectively. Then the efficacy of the treatment, as compared to placebo, can be examined by testing the following hypotheses:

$$H_0: \mu_1 = \mu_2$$

$$H_1: \mu_1 \neq \mu_2$$

The statistic (*t*) for the above test is given by

$$t = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\frac{[(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2]}{(n_1 + n_2 - 2)} \sqrt{1/n_1 + 1/n_2}}}$$

Therefore the null hypothesis can be rejected ( $H_0: \mu_1 = \mu_2$ ) at the  $\alpha$  level of significance if  $|t| \geq t(\alpha/2, n_1 + n_2 - 2)$ , where  $t(\alpha/2, n_1 + n_2 - 2)$  is the upper  $(\alpha/2)$ th percentile of the *t* distribution with  $n_1 + n_2 - 2$  degrees of freedom.

In this case, we have  $n_1 = 548$ ,  $n_2 = 550$ ,  $\bar{X}_1 = 150.22$ ,  $\bar{X}_2 = 146.78$ ,  $S_1 = 27.12$ ,  $S_2 = 28.32$ . Substituting the above sample statistics into the *t*-test formula, we obtain  $t = 2.055$ , which equates to a probability of 0.040 that the two populations are the same. The estimated difference in means together with its 95% confidence interval is 3.440 [0.156, 6.724].

As  $P = 0.040 < 0.05$  (or 95% confidence interval does not contain 0), we can say that there is a statistically significant difference in the systolic blood pressures between the two treatment groups. In other words, the drug appears to reduce systolic blood pressure compared to placebo, and the result has a low likelihood of arising by chance.

confidence in the statement that the “true” population parameter will lie somewhere between the upper and lower limits. For the Table 4 data, the estimated 95% confidence interval for the difference in means is [0.156, 6.724]. If the 95% confidence interval does not contain zero, we can say that there is a statistically significant difference in means between two populations. For Table 4 data, as the lower limit of the 95% confidence interval is greater than zero, we can say that two means are statistically significantly different.

Four key assumptions are required in the two-sample *t* test. Firstly, we assume that the two treatment group populations from which the samples are drawn are distributed normally [8, 12, 14]. Second, we assume that the variances (or standard deviations) of the two populations are equal [8, 12, 14], that is,  $\sigma_1^2 = \sigma_2^2 = \sigma^2$ . The equality of variances assumption can be formally verified with an *F* test [8, 12, 14]. We can also perform an informal check by examining the relative magnitude of the two-sample variances  $S_1^2$  and  $S_2^2$ . For example, if  $S_1^2 / S_2^2$  is considerably different

from 1, then the assumption that  $\sigma_1^2 = \sigma_2^2 = \sigma^2$  will be in doubt. In cases where  $\sigma_1^2 \neq \sigma_2^2$ , we need to use a modified  $t$  test or nonparametric method [8, 12, 14, 17]. Third, we assume that the observations in the two treatment groups are independent of each other, that is, no observation in one group is influenced by another observation in the second group [8, 12, 14, 17]. In other words, the value in one treatment group is not affected by that in another group. Finally, we assume that the two populations are homogeneous in terms of the observed and unobserved characteristics of patients (i.e., free from confounding) [7]. These characteristics might be demographics (such as age), prognosis (such as clinical history or disease severity), or baseline measurements of outcome variables.

Although we might never know the unobservable heterogeneity (differences) between two populations, we can assess whether the two populations are comparable by examining the observed summary statistics, such as means or proportions at baseline by treatment. This is why a table that summarizes the baseline information in a clinical trial by treatment group is always provided in a clinical report. If the two treatment groups are not balanced with regard to some of the predictors of outcome, covariate adjustment by means of stratification or regression modeling can be employed [1, 14, 17].

## 22.6 COMPARISON OF TWO PROPORTIONS

Quite often, we have a binary variable result or proportion to analyze from both groups. For example, in a clinical trial comparing a new treatment to reduce mortality after myocardial infarction, the primary endpoint is a binary outcome of death or survival. The numbers of subjects who die or survive in each of the two treatment groups form a  $2 \times 2$  contingency table, from which we can calculate the rate of death or proportion dead for each treatment group [9, 12, 14].

The most common approaches for comparing two proportions are the chi-squared ( $\chi^2$ ) test and the Fisher exact test. The  $\chi^2$  test involves determining the expected number of deaths in the new and standard treatment arms and then comparing these to those observed numbers. The test statistic used to assess these differences in deaths can be expressed as  $\chi^2 = \Sigma(O - E)^2/E$ , where  $O$  represents the observed frequencies and  $E$  the expected frequencies in each cell of the  $2 \times 2$  table. Under the null hypothesis,  $\chi^2$  should follow a chi-squared distribution with one degree of freedom. The Fisher exact test is a little more complex and consists of evaluating the sum of probabilities associated with the observed frequency table and all possible two-by-two tables that have the same row and column totals as the observed data [9, 12, 14]. The  $\chi^2$  test can also be used to compare more than two proportions [9, 12, 14].

When the total study size is large (say over 200), a test for the difference between two proportions also uses a normally distributed test statistic  $Z$  (known as  $Z$  test), which can be easily calculated by hand (Table 5).

The null hypothesis in Table 5 is that there is no difference between the two treatment groups in the death rate among patients after myocardial infarction. The  $P$  value ( $<0.001$ ) gives us the probability of observing the difference seen in the death rates ( $-0.028$ ) if the null hypothesis were true. As the  $P$  value is far less than 0.001, we can reject the null hypothesis and say that the difference in proportions is statistically significant.

**TABLE 5 Example of Comparison of Two Proportions—Z test**

A randomized placebo-controlled clinical trial was conducted to evaluate a cardiovascular drug on reducing mortality on patients with myocardial infarction (MI). The primary endpoint was the death after MI at 30 days after randomization. Following data were obtained from the trial:

- Group 1 (treatment) 110 deaths out of a total of 2045 patients
- Group 2 (placebo) 165 deaths out of a total of 2022 patients

Statistical inference of binary data such as death from parallel two-group trial involves testing the hypotheses regarding the difference in proportions with a yes response between the treatment and the placebo group. This can be expressed as

$$H_0: \pi_1 = \pi_2$$

$$H_a: \pi_1 \neq \pi_2$$

The statistic for the above test is given by

$$Z = \frac{\hat{p}_1 - \hat{p}_2}{\sqrt{\hat{p}_c(1 - \hat{p}_c)(1/n_1 + 1/n_2)}}$$

where  $n_1$  and  $n_2$  are the sample sizes (2045 and 2022),  $X_1$  and  $X_2$  the number of events in the two groups (110 and 165), respectively, and  $\hat{p}_1 = X_1/n_1$  ( $= 110/2045 = 0.054$ ),  $\hat{p}_2 = X_2/n_2$  ( $= 165/2022 = 0.082$ ), and  $\hat{p}_c = (X_1 + X_2)/(n_1 + n_2)$  ( $= [(110 + 165)/(2045 + 2022)] = 0.068$ ).

Therefore, the null hypothesis can be rejected ( $H_0: \pi_1 = \pi_2$ ) at the  $\alpha$  level of significance if  $|Z| \geq Z_{\alpha/2}$ , where  $Z_{\alpha/2}$  is the upper  $(\alpha/2)$ th percentile of the standard normal distribution.

In this case the  $Z = -3.548$ , which equates to a probability of  $P < 0.001$ . The estimated difference is  $-0.028$  (95% confidence interval:  $[-0.043, -0.012]$ ).

The above results suggest that patients in the treatment group have a statistically significant lower death rate than patients in the placebo group.

Alternatively, we can calculate the confidence interval for the difference between the two rates. For the Table 5 data, the observed difference is  $-0.028$  ( $-2.8\%$ ) with a 95% confidence interval  $[-4.3\%, -1.2\%]$ . From these results, we can say that there is a 95% probability that the difference that would be seen, if the entire population of all myocardial infarction patients were tested with either the new or standard treatment, would be between  $-4.3$  and  $-1.2\%$ . As the 95% confidence interval does not include zero, we can say that rate of death in the treatment group would be lower than that for standard treatment.

There is one common important assumption for the  $\chi^2$   $t$  test, the Fisher exact test, and the  $Z$  test: The two treatment groups are homogeneous in terms of the patients' characteristics (e.g., demographic information, disease-related risk factors, medical histories, and concurrent medical treatments). We can check whether the two groups are comparable by examining the observed baseline summary statistics. If the two treatment groups are not balanced with regard to some predictor(s) of outcome, logistic regression modeling could be used to adjust for these potential confounding factors [7, 9].

### 22.6.1 Assessing Size of Treatment Effect in Two-Arm Trial

In the previous sections, we have introduced different methods for assessing whether there is any evidence against the null hypothesis of no difference. In this section, we describe three commonly used measurements for assessing the size of any treatment effect for a binary outcome.

**Risk Difference** The difference in the proportion of the outcomes between two groups,  $p_1 - p_2$ , is called the risk difference. In the case of the myocardial infarction (MI) trial data, the risk difference is the risk of death between the active drug and placebo, that is,  $5.4\% - 8.2\% = -2.8\%$ . This means that the estimated absolute risk of death is 2.8% lower (about 3 in 100 MI patients) in the active drug group compared to the placebo group. Statistical inferences about the risk difference, such as point estimate and CIs, can be made by means of a  $Z$  test, as described in the last section.

**Risk Ratio** The *risk ratio* is the ratio of the risks in the active drug treatment group compared to the placebo group. The risk ratio is often abbreviated to RR, and is also sometimes called the relative risk:

$$RR = \frac{p_1}{p_2} = \frac{X_1/n_1}{X_2/n_2}$$

For the MI trial, the  $RR = 0.66$  ( $5.4\%/8.2\%$ ), meaning that the risk of death for the patients in the active drug treatment group is 66% of the risk in the placebo group. Equivalently, we could say that the drug treatment is associated with a 34% ( $100\% - 66\%$ ) reduction in mortality at 30 days.

**Odds Ratio** A third measure of treatment effect is the *odds ratio* (OR). The odds of an outcome event are calculated as the number of events divided by the number of nonevents. For example, in the active treatment arm in the MI trial, the number of deaths is 110 and the number of survivals is 1935, so the odds of death are  $110/1935 = 0.057$ . If the odds of an event are  $>1$ , the event is more likely to happen than not. In particular, the odds of an event that is certain to happen are infinite, and the odds of an impossible event are zero. The OR is calculated by dividing the odds in the active treatment group by the odds in the placebo group.

For the MI trial data, OR is calculated as  $(110 \times 1857)/(1936 \times 165) = 0.64$ , meaning that the odds of deaths after MI in the drug group is 64% of the odds in the placebo group. Clinical trials typically study treatments that reduce the proportion of patients with an event or equivalently have an  $OR < 1$ . In these cases, a percentage reduction in OR is often quoted instead of the OR itself. For the preceding OR, we can say that there is a 36% ( $100\% - 64\%$ ) reduction in the odds of deaths in the active treatment group.

## 22.7 SURVIVAL ANALYSIS

In many clinical trials, the primary outcome is not just whether an event occurs but also the time it takes for the event to occur. For example, in a cancer study comparing the relative merits of surgery and chemotherapy treatments, the outcome measured could be the time from the start of therapy to the death of the subject. In this case the event of interest is death, but in other situations it might be the end of a period spent in remission from cancer spread, relief of symptoms, or a further admission to hospital. These types of data are generally referred to as time-to-event data or survival data even when the endpoint or the event being studied is something

other than the death of a subject. The term “survival analysis” encompasses the methods and models for analyzing such data representing time free of events of interest.

22.7.1 Example: Pancreatic Cancer Trial

The death rate from pancreatic cancer is among the highest of all cancers. A randomized controlled clinical trial was conducted on 36 patients diagnosed with pancreatic cancer. The aim of this trial was to assess whether the use of a new treatment (A) could increase the survival of patients compared to the standard treatment (B). Patients were followed-up for 48 months and the primary endpoint was the time, in months, from randomization to death. Table 6 displays the survival data for the 36 patients. We will use this example to illustrate some fundamental survival analysis methods and their applications.

22.7.2 Basic Concepts in Survival Analysis

*Censoring* In survival analysis, not all subjects are involved in the study for the same length of time due to *censoring*. This term denotes when information on the outcome status of a subject stops being available. This can be because the patient is lost to follow-up (e.g., they have moved away) or stops participating in the study, or because the end of study observation period is reached without the subject having an event. Censoring is a nearly universal feature of survival data. Table 7 summarizes

TABLE 6 Survival Data for 36 Patients with Pancreatic Cancer in Trial of New Treatment versus Standard Treatment

| New Treatment             |                                             | Standard Treatment        |                                             |
|---------------------------|---------------------------------------------|---------------------------|---------------------------------------------|
| Survival Time<br>(months) | Survival Status<br>(0 = survival, 1 = dead) | Survival Time<br>(months) | Survival Status<br>(0 = survival, 1 = dead) |
| 2                         | 0                                           | 3                         | 0                                           |
| 5                         | 0                                           | 5                         | 1                                           |
| 10                        | 1                                           | 6                         | 0                                           |
| 12                        | 1                                           | 7                         | 1                                           |
| 15                        | 0                                           | 8                         | 1                                           |
| 27                        | 1                                           | 10                        | 1                                           |
| 36                        | 0                                           | 11                        | 0                                           |
| 36                        | 0                                           | 12                        | 1                                           |
| 37                        | 1                                           | 13                        | 0                                           |
| 38                        | 0                                           | 15                        | 1                                           |
| 39                        | 0                                           | 16                        | 0                                           |
| 41                        | 0                                           | 23                        | 1                                           |
| 42                        | 0                                           | 30                        | 1                                           |
| 44                        | 0                                           | 39                        | 1                                           |
| 45                        | 1                                           | 40                        | 1                                           |
| 46                        | 0                                           | 45                        | 1                                           |
| 48                        | 0                                           | 48                        | 0                                           |
| 48                        | 0                                           | 48                        | 0                                           |

**TABLE 7** Reasons for Censoring Observations in Clinical Trials

| Reason                                                                                        | Example                                                                         |
|-----------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------|
| Lost to follow-up                                                                             | Patient moved away or did not wish to continue participation.                   |
| Patient withdrawn                                                                             | Patient withdraws from the study due to side effects.                           |
| Patient has an outcome that prevents the possibility of the primary endpoint (competing risk) | Death from cancer where death from cardiac causes is the primary endpoint.      |
| Study termination                                                                             | All patients who have not died are considered censored at the end of the study. |

the main reasons for censoring that can occur in a clinical trial. Survival analysis takes into account censored data, and, therefore, uses the information available from a clinical trial more fully.

**Survival Function and Hazard Function** In survival analysis, two functions are of central interest, namely *survival function* and *hazard function* [18, 19]. The survival function,  $S(t)$ , is the probability that the survival time of an individual is greater than or equal to time  $t$ . Since  $S(t)$  is the probability of surviving (or remaining event-free) to time  $t$ ,  $1 - S(t)$  is the probability of experiencing an event by time  $t$ . Plotting a graph of probability against time produces a *survival curve*, which is a useful component in the analysis of such data.

The hazard function,  $h(t)$ , represents the instantaneous event rate at time  $t$  for an individual surviving to time  $t$  and, in the case of the pancreatic cancer trial, it represents the instantaneous death rate. With regard to numerical magnitude, the hazard is a quantity that has the form of “number of events per time unit” (or “per person-time unit” in an epidemiological study). For this reason, the hazard is sometimes interpreted as an incidence rate. To interpret the value of the hazard, we must know the unit in which time is measured.

For the pancreatic cancer trial, suppose that the hazard of death for a patient is 0.02, with time measured in months. This means that if the hazard remains constant over one month, then the death rate will be 0.02 deaths per month (or per person-months). In reality, the 36 patients contributed a total of 950 person-months and 16 deaths. Assuming that the hazard is constant over the 48-month period and across all patients, an estimate of the overall hazard is  $16/950 = 0.017$  deaths per person-months.

**Kaplan–Meier Method** The Kaplan–Meier (KM) approach estimated the proportion of individuals surviving (i.e., who have not died or had an event) by any given time in the study [18, 19]. When there is no censoring in the survival data, the KM estimator is simple and intuitive.  $S(t)$  is the probability that an event time is greater than  $t$ . Therefore, when no censoring occurs, the KM estimator,  $\hat{S}(t)$ , is the proportion of observations in the sample with event times greater than  $t$ . For example, if 50% of observations have times  $>10$ , we have  $\hat{S}(10) = 0.50$ .

The KM estimates of the survival curves by the two treatment groups for the pancreatic cancer trial data are displayed in Figure 2. The survival curve is shown in a step function: The curve is horizontal at all times at which there is no event, with a vertical drop corresponding to the change in the survival function at each time,  $t_j$ , when an event occurs.

In reports, KM curves are usually displayed in one of two ways. The curves can decrease with time from 1 (or 100%), denoting how many people survive (or remain event free). However, in general it is recommended that the increase in event rates is shown starting from 0 (or 0%) subjects, with an increasing curve ( $1 - \hat{S}[t]$ ) unless the event rate is high [20]. Placing the curves for different treatment groups on the same graph allows us to graphically review any treatment differences.

**Log-Rank Test** For the two KM curves by treatment group shown in Figure 2, the obvious question to ask is: Did the new treatment make a difference in the survival experience of the two groups? A natural approach to answering this question is to test the null hypothesis that the survival function is the same in the two groups: that is,  $H_0: S_1(t) = S_2(t)$  for all  $t$ , where 1 and 2 represent the new treatment and the standard treatment, respectively.

The above hypothesis can be assessed by performing a log-rank test equivalent to a  $\chi^2$  test [18, 19, 21]. The main purpose of this test is to calculate the number of events expected in each treatment group, and to compare this expected number of events with the observed number of events in each treatment group if the null hypothesis is true.

For the pancreatic cancer trial, the resulting  $\chi^2$  value is 5.424 [22], converted to a  $P$  value of 0.020. As  $P < 0.05$ , the log-rank test has shown a significant survival difference between the new treatment A and standard treatment B. This test readily generalizes to three or more groups, with the null hypothesis that all groups have the same survival function. If the null hypothesis is true, the test statistic has a chi-

**FIGURE 2** Kaplan–Meier survival functions by treatment group for the pancreatic cancer trial data.

squared distribution with the degrees of freedom equal to the number of groups minus 1.

**Cox Proportional-Hazards Model** The proportional-hazards model relates the hazard function to a number of covariates (such as patient's characteristics at randomization and the treatment received in a clinical trial) as follows [18, 19, 22]:

$$h_i(t) = h_0(t) \exp(b_1 x_{1i} + b_2 x_{2i} + K + b_p x_{pi}) \quad (1)$$

where  $x_{ki}$  is the value of the covariate  $x_k$  ( $k = 1, 2, \dots, p$ ) for an individual  $i$  ( $i = 1, 2, \dots, n$ ).

The equation says that the hazard for individual  $i$  at time  $t$  is the product of two factors:

- A baseline hazard function  $h_0(t)$  that is left unspecified, except that it cannot be negative.
- A linear function of a set of  $p$  fixed covariates, which is then exponentiated.

The baseline hazard function can be regarded as the hazard function for an individual whose covariates all have values of 0 and changes according to time  $t$ .

This is called a proportional-hazards model because, while the baseline hazard can constantly change over time, the hazard for any individual is assumed to be proportional to the hazard for any other individual and will depend on the individual values of covariates. To see this, let us assume that the model only has one covariate (treatment,  $x_{1i}$ ,  $x_{1i} = 0$  for standard treatment and 1 for new treatment). We first calculate the hazards for two individuals 1 and 2 according the Equation (1) and then take the ratio of the two hazards:

$$\begin{aligned} h_1(t) &= h_0(t) \exp(b_1 x_{11}) \\ h_2(t) &= h_0(t) \exp(b_1 x_{12}) \\ \frac{h_1(t)}{h_2(t)} &= \exp[b_1 (x_{11} - x_{12})] \end{aligned} \quad (2)$$

What is important about the equation is that  $h_0(t)$  is canceled out of the numerator and denominator. As a result, the ratio of hazards,  $\exp[b_1 (x_{11} - x_{12})]$ , is a constant over time or proportional.

### 22.7.3 Assessing Size of Treatment Effect in Two-Arm Trial for Survival Data

**Incidence Rate Difference and Ratio** The incidence rate is defined as the number of events divided by the number of units of time [14, 22]. By comparing the incidence rates between treatment groups, we can derive the incidence rate difference and ratios following the procedures described by Kirkwood and Sterne [14, 22]. For the pancreatic cancer trial data, the incidence rates are calculated as 0.9 and 2.9 deaths

per 100 person-months for the new treatment group and the standard treatment group, respectively. The estimates of incidence rate difference and rate ratio together with their 95% CI and  $P$  value are as follows:

- Incidence rate difference:  $-2.0$ , 95% CI  $(-3.9, -0.1)$ ,  $P = 0.034$
- Incidence rate ratio:  $0.30$ , 95% CI  $(0.08, 0.94)$ ,  $P = 0.026$

The above results suggest that the new treatment reduces deaths by 2 per 100 person-months, with a 95% CI of  $0.1$ – $3.9$  per 100 person-months, and that the incidence rate for patients in the new treatment group is only about 30% of the incidence rate for those in the standard treatment group.

Although the incidence rate uses the information on censored observations, it is based on the assumption that the hazard of an event is constant during the study period or has an exponential distribution. In the case of the pancreatic cancer trial, it means that the hazard of death is constant over the 48-month period. However, the risk of an event can change with time. To overcome this problem, the Cox model, which does not require such assumptions, can be used to derive a better measurement for the treatment effect.

**Hazard Ratio** The treatment can be simply measured as a binary covariate (1 for new treatment A and 0 for standard treatment B in the pancreatic cancer trial) and introduced into a Cox proportional-hazards model. In the pancreatic cancer trial, the estimated hazard ratio of death for patients who received treatment A to those who received standard treatment B is  $0.31$ , with 95% CI  $(0.11, 0.89)$ ,  $P = 0.030$ . This means that the new treatment is estimated to reduce the hazard of death by 69%, with 95% CI (11%, 89%) and the reduction in hazard is statistically significant at the 5% significance level. As there is only one covariate (treatment) in the Cox model, the estimated hazard ratio is called a crude or unadjusted treatment effect. The adjusted hazard ratio for the treatment will be generated if other baseline patient characteristics are introduced in the model.

## 22.8 COMMONLY USED TERMS IN CLINICAL TRIALS

**ANOVA (*Analysis of Variance*)** A statistical method for comparing several means by comparing variances. It concerns a normally distributed outcome (response) variable and a single categorical (predictor) variable representing treatments or groups. ANOVA is a special case of a linear regression model by which group means can be easily compared.

**Bias** Systematic errors associated with the inadequacies in the design, conduct, or analysis of a trial on the part of any of the participants of that trial (patients, medical personnel, trial coordinators, or researchers), or in publication of its the results, that make the estimate of a treatment effect deviate from its true value. Systematic errors are difficult to detect and cannot be analyzed statistically but can be reduced by using randomization, treatment concealment, blinding, and standardized study procedures.

**Confidence Intervals** A range of values within which the “true” population parameter (e.g., mean, proportion, treatment effect) is likely to lie. Usually, 95% confidence limits are quoted, implying that there is 95% confidence in the statement that the “true” population parameter will lie somewhere between the lower and upper limits.

**Confounding** A situation in which a variable (or factor) is related to both the study variable and the outcome so that the effect of the study variable on the outcome is distorted. For example, if a study found that coffee consumption (study variable) is associated with the risk of lung cancer (outcome), the confounding factor here would be cigarette smoking since coffee is often drunk while smoking a cigarette, which is the true risk factor for lung cancer. Thus, we can say that the apparent association of coffee drinking with lung cancer is due to confounding by cigarette smoking (confounding factor). In clinical trials, confounding occurs when a baseline characteristic (or variable) of patients is associated with the outcome, but unevenly distributed between treatment groups. As a result, the observed treatment difference from the unadjusted (univariate) analysis can be explained by the imbalanced distribution of this variable.

**Correlation Coefficient ( $r$ )** A measure of the linear association between two continuous variables. The correlation coefficient varies between  $-1.0$  and  $+1.0$ . The closer it is to 0, the weaker the association. When both variables go in the same direction (e.g., height and weight),  $r$  has a positive value between 0 and 1.0 depending on the strength of the relationship. When the variables go in opposite directions (e.g., left ventricular function and life span),  $r$  has a negative value between 0 and  $-1.0$  depending on the strength of this inverse relationship.

**Covariates** This term is generally used as an alternative to explanatory variables in regression analysis. However, more specifically refer to variables that are not of primary interest in an investigation. Covariates are often measured at baseline in clinical trials because it is believed that they are likely to affect the outcome variable and, consequently, need to be included to estimate the adjusted treatment effect.

**Descriptive/Inferential Statistics** Descriptive statistics are used to summarize and describe data collected in a study. To summarize a quantitative (continuous) variable, measures of central location (i.e., mean, median, mode) and spread (e.g., range and standard deviation) are often used, whereas frequency distributions and percentages (proportions) are usually used to summarize a qualitative variable. Inferential statistics are used to make inferences or judgments about a larger population based on the data collected from a small sample drawn from the population. A key component of inferential statistics is hypothesis testing. Examples of inferential statistical methods are  $t$  test and regression analysis.

**Endpoint** Clearly defined outcome associated with an individual subject in a clinical research. Outcomes may be based on safety, efficacy, or other study objectives (e.g., pharmacokinetic parameters). An endpoint can be quantitative (e.g., systolic blood pressure, cell count), qualitative (e.g., death, severity of disease), or time to event (e.g., time to first hospitalization from randomization).

**Hazard Ratio** In survival analysis, hazard (rate) represents instantaneous event rate (incidence rate) at a certain time for an individual who has not experienced an event at that time. Hazard ratio compares two hazards of having an event between two groups. If the hazard ratio is 2.0, then the hazard of having an event in one group is twice the hazard in the other group. The computation of the hazard ratio assumes that the ratio is consistent over time (proportional hazards assumption).

**Hypothesis Testing or Significance Testing** Statistical procedure for assessing whether an observed treatment difference was due to random error (chance) by calculating a  $P$  value using the observed sample statistics such as mean, standard deviation, and so on. The  $P$  value is the probability that the observed data or more extreme data would have occurred if the null hypothesis (i.e., no true difference) were true. If the calculated  $P$  value is a small value (like  $<0.05$ ), the null hypothesis is then rejected, and we state that there is a statistically significant difference.

**Intention-to-Treat Analysis** A method of data analysis on the basis of the intention to treat a subject (i.e., the treatment regimen a patient was assigned at randomization) rather than the actual treatment regimen he or she received. It has the consequence that subjects allocated to a treatment group should be followed up, assessed, and analyzed as members of that group regardless of their compliance to that therapy or the protocol, irrespective of whether they later crossed over to the other treatment group or not or whether they discontinued treatment.

**Kaplan–Meier Estimate and Survival Curve** A survival curve shows an estimate of the fraction of patients who survive over the follow-up period of the study without an event of interest (e.g., death). The Kaplan–Meier estimate is a simple way of computing the survival curve taking into account patients who were lost to follow-up or any other reasons for incomplete results (known as censored observations). It usually provides a staircase graph of the fraction of patients remaining free of event over time.

**Meta-Analysis** The systematic review and evaluation of the evidence from two or more independent studies asking the same clinical question to yield an overall answer to the question.

**Normal Distribution** A bell-shaped symmetric distribution for a continuous variable having highest frequency at a mean value and less frequency further away from this mean value. A normal distribution can be completely described by two parameters: mean ( $\mu$ ) and variance ( $\sigma^2$ ). In the special case of  $\mu = 0$  and  $\sigma^2 = 1$ , it is called the standard normal distribution.

**Number Needed to Treat (NNT)** This term is often used to describe how many patients would need to be given a treatment to prevent one event. It is determined from the absolute difference between one treatment and another. In a randomized study the group receiving treatment A had a death rate of 12.5%, and the group receiving treatment B had a death rate of 15.0%. Both groups are matched for size and length of follow-up. Comparing the two treatments there was an absolute risk reduction of  $15\% - 12.5\% = 2.5\%$  for treatment A. From this we can derive that the

NNT ( $= 1/0.025$ ) is 40. This means 40 patients need to be given treatment A rather than B to prevent 1 additional death.

**Odds Ratio (OR) and Risk Ratio (RR)** These terms compare the probability of having an event between two groups exposed to a risk factor or treatment. The RR is the ratio of the probability of occurrence of an event between two groups. The OR is the ratio of the ratio of patients with and without an event in each group. If the number of deaths in the treatment and control arms (both of sample size 100) of a randomized study are 50 and 25, respectively, the  $RR = (50/100) / (25/100) = 2$ . The treatment group has a twofold relative risk of dying compared with the control group. The  $OR = (50/50) / (25/75) = 3$  indicates that the odds of death in the treatment arm is threefold of the control arm.

**Per-Protocol Analysis** A method of analysis in which only the subset of subjects who complied sufficiently with the protocol are included. Protocol compliance includes exposure to treatment, availability of measurements, correct eligibility, and absence of any other major protocol violations. This approach contrasts with the more conservative and widely accepted “intention-to-treat” analysis.

**Power** The probability of rejecting the null hypothesis (e.g., no treatment difference) when it is false. It is the basis of procedures for calculating the sample size required to detect an expected treatment effect of a particular magnitude.

**Random Error** An unpredictable deviation of an observed value from a true value resulting from sampling variability. It is a reflection of the fact that the sample is smaller than the population; for larger samples, the random error is smaller, as opposed to systematic errors (bias) that keep adding up because they all go in the same direction.

**Regression Analyses** Methods of explaining or predicting outcome variables using information from explanatory variables. Regression analyses are often used in clinical trials to estimate the adjusted treatment effect taking into account differences in baseline characteristics, and in epidemiological studies to identify prognostic factors while controlling for potential confounders. Commonly used regression models include linear, logistic, and Cox regression methods.

**Risk Factor** A risk factor can be defined as anything in the environment, personal characteristics, or events that make it more or less likely one might develop a given disease, reach an adverse event or experience a change in health status. For example, raised cholesterol is a risk factor for heart attacks.

**Standard Error** A measure of the random variability of a statistic (e.g., mean, proportion, treatment effect) indicating how far the statistic is likely to be from its true value. For example, standard error of the mean (SEM) indicates uncertainty of a single sample mean ( $\bar{X}$ ) as an estimate of the population mean ( $\mu$ ). A smaller SEM implies a more reliable estimate of the population mean. Standard error can be used to calculate confidence interval of an estimated population parameter. The

smaller the standard error, therefore, the narrower the confidence interval, and more precise the point estimate of the population parameter.

**Treatment Effect** An effect attributed to a treatment in a clinical trial, often measured as the difference in a summary measure of an outcome variable between treatment groups. Commonly expressed as difference in means for a continuous outcome, a risk difference, risk ratio, or odds ratio for a binary outcome, and hazard ratio for a time-to-event outcome.

**Univariate/Multivariate Analysis** The term variate refers to the term variable. A univariate analysis examines the association between a single variable and an outcome variable (correctly called a bivariate analysis), for example, age and occurrence of stroke. In a multivariate analysis, associations between many variables are examined simultaneously. In particular, multivariate regression analysis can be used to assess the relative importance and contribution of each predictor variable to the outcome variable. For example, a multivariate logistic regression can be undertaken to identify the most important prognostic factors among several risk factors (e.g., age, sex, systolic blood pressure, and cholesterol level) that predict the occurrence of stroke.

## 22.9 CONCLUDING REMARKS

We have introduced some basic statistical approaches to dealing with different types of data and samples. To apply these methods for data analysis, there are a few basic principles we should adhere to. We first need to make the purpose of the analysis clear. For example, is the analysis to compare groups or to estimate associations? Different purposes will require different methods. Second, we need to identify the nature of the data. Are they data from paired samples or two independent samples? Third, we need to examine the characteristics of the data. Are the variables qualitative or quantitative? Symmetrically distributed or not? These properties of the data will guide to use the correct assumptions for analysis. Important as the appropriate use of statistical methods is, we must also ensure that the data are clean, accurate, meaningful, and complete and were gathered reducing any biases occurring in the design, conduct, and analysis of the clinical trial. The advice of a statistician with experience in medical research should always be sought from the design through to completion and analysis phases of a clinical trial.

23.1    PRAGMATIC AND EXPLANATORY PERSPECTIVES

In 1967 Schwartz and Lellouch published an article in the *Journal of Chronic Diseases* (the precursor to the *Journal of Clinical Epidemiology*) titled “Explanatory and pragmatic attitudes in therapeutical trials” [1]. The article was significant because it clearly distinguished, for the first time, different philosophical attitudes of clinical trialists. Since that time the article has become a classic in the field of clinical trial methodology (the 2007 edition of *Web of Science* records 421 citations), and the ensuing discussion has stimulated development of several methodological advances.

Schwartz and Lellouch argued that clinical trialists can have explanatory or pragmatic attitudes (or perspectives, or orientations) to clinical trials. These attitudes influence many aspects of trial design. In the contemporary literature, explanatory trials may be called “efficacy trials” [2, 3]. Pragmatic trials may be called “effectiveness trials” [2, 3] or “practical clinical trials” [4] or, nearly synonymously, “large simple trials” [5].

Explanatory trialists conceive of clinical trials as being clinical analogs of classic laboratory experiments. The aim is to learn of the potential effects of the specific intervention. Explanatory trials are designed to establish “proof of concept” of a new intervention [3] (Table 1).

In contrast, pragmatic trialists think of clinical trials as a mechanism for informing clinical decisions. Pragmatic trials tell us about the importance of interventions in the real world of clinical practice. They are designed to inform clinical decisions about whether to implement a particular intervention.

We need both explanatory and pragmatic trials. It would appear sensible to first conduct explanatory trials on a particular intervention and then subsequently subject the same intervention to a pragmatic trial. An exception might be where health interventions become established clinical practice before they are subject to clinical trials. Arguably, the first trials of such interventions should adopt a pragmatic approach.

Trialists rarely make explicit statements, in trial reports, about whether their intentions are explanatory or pragmatic. Many trials incorporate some features of explanatory trials and some features of pragmatic trials. This suggests that at least some trialists do not clearly think through whether their intentions are explanatory or pragmatic.

**TABLE 1    Explanatory and Pragmatic Attitudes to Clinical Trials**

| Explanatory Attitudes                                                                                            | Pragmatic Attitudes                                                                                         |
|------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------|
| Aim is to learn about effects of an intervention.                                                                | Aim is to make a decision about whether to administer an intervention.                                      |
| Interest is in any effect.                                                                                       | Interest is in clinically important effects.                                                                |
| Ascertains if an intervention <i>can</i> produce effects (proof of concept).                                     | Ascertains if an intervention <i>does</i> confer effects.                                                   |
| Used to make inferences about specific effects of narrowly defined interventions given under optimal conditions. | Used to make inferences about the real-world effects of complex interventions in routine clinical practice. |

Those trialists who explicitly adopt a particular perspective may find themselves misunderstood by reviewers of grant applications or journals. Sometimes pragmatic trials are criticized for failing to satisfy requirements that are particular to explanatory trials and vice versa. Thus it appears that the issues raised by Schwartz and Lellouch over 40 years ago are still not fully appreciated by clinical trialists.

This chapter discusses some of the consequences of the trialist's perspective (explanatory or pragmatic) for design and analysis of randomized trials. The chapter concludes by making some recommendations for the design, analysis, and reporting of randomized trials.

## 23.2 PARTICIPANTS

### 23.2.1 Inclusion and Exclusion Criteria

One of the first issues that confront trialists, when developing a trial protocol, is which patients to include in the trial.

If the intention is to learn whether the intervention *could* be effective (the explanatory perspective), then a sensible course of action would be to recruit those patients in whom effects of intervention are most likely to be apparent. Usually, this involves sampling from a carefully selected and homogenous population. Careful formulation of inclusion and exclusion criteria can ensure that only participants with characteristics likely to be associated with large treatment effects are sampled, and homogeneous sampling can ensure that the variance of outcomes is minimized. Selective, homogenous sampling maximizes the possibility of detecting effects of intervention, but it may also exclude patients who might, in the course of normal clinical practice, be offered the intervention. People with comorbidities, pregnant women, and people who do not speak the local language are typically excluded from explanatory trials.

Pragmatic trialists seek to make inferences about the effects of an intervention on the population for whom the intervention is indicated. Thus pragmatic trials typically sample broadly. Typically, they have broad inclusion criteria and few exclusion criteria. (In some trials the primary inclusion criterion is simply that the relevant clinician might choose to offer the intervention and the participant might choose to accept it. An example of such a trial is the MRC Spinal Stabilisation Trial in which the primary inclusion criterion was that “patients who were candidates for surgical stabilisation of the spine were eligible if the clinician and patient were uncertain which of the study treatment strategies was best” [6].) Pragmatic trials often sample patients under the care of many clinicians and from multiple sites [4].

Ideally, pragmatic trials would do more than sample broadly. Theoretically, at least, pragmatic trials should sample in a representative way from the population about which inferences are to be made. Random sampling is usually difficult or impossible, so there are very few examples of trials that randomly sample participants. However, a small number of studies have made explicit attempts to sample as representatively as possible. Fransen and colleagues describe how they attempted to obtain a representative sample of general medical practitioners and patients in the DIAMOND study of two protocols for management of dyspepsia in primary care [7].

### 23.2.2 Run-In Periods

In some trials, patients are not randomized at the time they are recruited into the trial. Instead, they are asked to participate in a run-in period, during which their compliance with the intervention (or, more usually, with the placebo intervention) is monitored. Only those patients who demonstrate a sufficiently high level of compliance are subsequently randomized into the trial. Thus the run-in period serves to winnow out potential participants who are unlikely to comply with the intervention specified in the trial protocol.

The use of run-in periods offers several potential benefits to explanatory trialists. First, run-in periods can reduce loss to follow-up. Second, the use of a run-in period potentially increases compliance, enabling better explanatory estimates of effects of intervention (see Section 23.6). Third, simulation studies show that when there is both a high degree of noncompliance and the run-in period gives an accurate indication of who will and will not comply with the intervention protocol, the use of a run-in period can produce modest increases in statistical efficiency [8]. (That is, slightly fewer patients would need to be recruited to a trial with a run-in period to yield the same level of statistical power as a trial without a run-in period.) However, these benefits are not guaranteed: When compliance is high or the ability to discriminate between compliant and noncompliant patients is low, the statistical efficiency of trials with run-in periods may actually be lower than in trials without a run-in period [8]. Trials with run-in periods require a longer period of participation in the trial, which could paradoxically reduce participation rates and increase rates of noncompliance and loss to follow-up. Thus, while the use of run-in periods may seem attractive to explanatory trialists, they can be counterproductive.

The use of run-in periods is much less attractive to pragmatic trialists because pragmatists are much more tolerant of noncompliance. From the pragmatic perspective, noncompliance is as much a characteristic of the intervention as it is of the patient. If patients do not comply with an intervention, then the intervention is unlikely to be of any real practical effect, regardless of its explanatory effects. Insofar as a pragmatic estimate of the effect of an intervention depends on the degree of compliance with the intervention, a pragmatic trial of the intervention should involve patients with similar levels of compliance to the population about whom inferences are to be made. This means that, theoretically at least, pragmatic trialists should seek to recruit participants with representative levels of compliance. As discussed above, pragmatic trialists have rarely made explicit efforts to sample representatively, so it may be often true that pragmatic trials do not sample patients with representative levels of compliance.

## 23.3 SAMPLE SIZE

### 23.3.1 Criteria Used to Calculate Sample Size

The classic hypothesis testing approach to sample size calculation is to calculate the sample size required to provide adequate statistical power to detect an effect of intervention while keeping the probability of falsely claiming an effect to acceptably low levels.

A fairly general form of the equation for estimating sample size in two-armed clinical trials with equally sized groups is

$$n \geq 2(z_{1-\alpha/2} + z_{1-\beta})^2 \left( \frac{SD^2}{\delta^2} \right)$$

where  $n$  is sample size per group,  $z_{1-\alpha/2}$  is the  $z$  score corresponding to the probability,  $\alpha$ , of falsely rejecting the null hypothesis,  $z_{1-\beta}$  is the  $z$  score corresponding to the probability,  $\beta$ , of falsely retaining the null hypothesis,  $SD$  is the within-group standard deviation (usually assumed to be the same for both groups), and  $\delta$  is the smallest effect worth detecting [9].

This approach to sample size calculation is widely used but, because it is built on a hypothesis testing approach to statistical inference, and because hypothesis testing is becoming increasingly regarded with suspicion by methodologists, it has been strongly criticized (see, e.g., [10]). Here discussion of issues of sample size calculation is restricted to comparison of explanatory and pragmatic approaches to sample size calculation.

The explanatory trialist might wish to detect *any* effect of intervention, no matter how small. This is because the explanatory trialist's interest is in proof of concept rather than in whether the effect of intervention is large enough to make the intervention worth implementing in clinical practice. But it is not possible to design trials to reliably detect *any* effect because the sample sizes required to detect very small effects become impossibly large. The hypothesis testing approach requires the trialist to nominate  $\delta$ , the smallest effect that is worth knowing about, and calculate the sample size required to detect effects of at least that size. This is problematic for explanatory trialists because in explanatory trials the choice of  $\delta$  seems arbitrary. Consequently, sample sizes calculated for explanatory trials seem arbitrary too.

Pragmatic trialists find the task of nominating  $\delta$  more straightforward. Pragmatic trials are intended to inform decisions about whether or not to implement an intervention, so they should be designed to reliably detect effects of intervention that are just large enough to warrant the risks, costs, discomforts, and inconveniences of intervention [11, 12]. Recently, Barrett and colleagues have developed the benefit-harm trade-off method to establish patient-focused estimates of the smallest important effect of intervention [13–15]. This method can be used to obtain empirical estimates of  $\delta$ .

Paradoxically, while pragmatic trialists may find it easier to nominate  $\delta$  than explanatory trialists, it has been argued that it is not necessary for pragmatic trialists to nominate  $\delta$  [1, 16]. The argument is as follows. The pragmatic trialist does not care about falsely rejecting the null hypothesis because, from the pragmatic trialist's perspective, if the interventions given in the two arms of the trial are equally effective, it does not matter which of the two interventions is administered in clinical practice. Insofar as pragmatic trialists do not care about falsely rejecting the null hypothesis, they should always consider that the intervention with the larger observed effect is the more effective intervention, regardless of any considerations of sampling error. This strategy results in one of three possible scenarios:

1. The two interventions have identical effects, but the trialist claims one is more effective than the other.

2. One intervention is more effective than the other, and the trialist correctly identifies the more effective intervention.
3. One intervention is more effective than the other, and the trialist incorrectly concludes the less effective intervention is the more effective one.

According to Schwartz and Lellouch [1], only the last type of error is of any concern to the pragmatic trialist. They refer to the probability of this kind of error as  $\gamma$ . As the pragmatic trialist wishes only to minimize  $\gamma$ , such studies requires only a sample size of

$$n \geq 2(z_{1-\gamma})^2 \left( \frac{SD^2}{\delta^2} \right)$$

Even if  $\gamma$  is set at just 1%, the sample size calculated in this way will be nearly one-third less than with conventional calculations that assume  $\alpha = 0.05$  and  $\beta = 0.2$ . This observation has been used to defend the conduct of small pragmatic trials [17].

As MacRae has pointed out, Schwartz and Lellouch's approach to sample size calculation for pragmatic trials should only be used when the trialist is prepared to apply an intervention that is no more effective than alternative interventions [16]. In practice, that is often not the case because competing interventions often have quite different risks, inconveniences, and costs. For example, most surgeons would be disinclined to offer spinal stabilization surgery to patients with chronic low back pain if alternatives such as an intensive rehabilitation program have similar effects because the surgery is associated with significantly greater risks, discomfort, inconvenience, and costs than rehabilitation [6].

From a pragmatic perspective, the hypothesis testing approach to sample size calculation is quite unsatisfactory. Pragmatic trials should be designed to assist clinicians and health policymakers make decisions about whether the effects of particular interventions are big enough to be worthwhile. The most useful trials are those that provide precise estimates of the effects of intervention: The more precise the estimate, the more likely it will be that the decision maker will be able to conclude that the intervention definitely is or is not worth implementing [11, 12]. In practice, the hypothesis testing approach to sample size calculation often yields estimates of treatment effects that are too imprecise to be useful for clinical decision making. (That is, confidence intervals or credible intervals are usually so broad that they include both clinically worthless and clinically worthwhile effects.) This suggests an alternative approach to sample size calculation is needed. A better approach may be to explicitly specify the precision required of estimates of effect, and then estimate the sample size required to achieve that precision [18]. Admittedly, the choice of the acceptable precision will usually be quite arbitrary.

### 23.3.2 An Even More Pragmatic Approach: Value of Information

One response to the issues outlined above is to use decision-theoretic approaches to sample size calculation. Decision-theoretic approaches are explicitly pragmatic because they seek to maximize the difference between the cost of a trial and the expected value of the results.

Willan and Pinto have described a decision theoretic approach to sample size calculation in clinical trials [19]. They take a societal perspective, although the broad approach could be modified to take other perspectives such as the perspective of a corporate entity. They estimate the expected value of a trial (the expected value of sample information), the cost of conducting the trial, and the opportunity cost of treating some patients in the trial with the inferior intervention. All three quantities (the value of sample information and the cost and opportunity costs of the trial) are functions of sample size. The optimal sample size is that which maximizes the value of the trial minus its costs. This approach will often result in radically different estimates of sample size to those obtained with traditional methods. Indeed Willan and Pinto show that in some circumstances optimal trial size is zero, and the intervention should be implemented without first conducting a randomized trial.

Willan and Pinto's [19] approach to sample size calculation is attractive because it is rational and because it does not require the trialist to go through the arbitrary exercise of nominating  $\alpha$ ,  $\beta$ , and  $\delta$ . The disadvantage is that the calculations are complex and require that the trialist nominate other difficult-to-estimate quantities such as the number of patients who would, in the future, be eligible to receive the experimental or control interventions.

### 23.3.3 Adjusting Sample Size Calculations for Noncompliance

As noted above, explanatory trialists try to minimize noncompliance with intervention. From an explanatory trialist's perspective, participants who do not receive the experimental intervention cannot provide information about the effects of that intervention. In most trials, however, some degree of noncompliance is inevitable and explanatory trialists need to decide how to deal with it.

One strategy is to omit noncompliant cases in a "per protocol analysis." If the primary analysis is to be conducted per protocol (though it is not clear that it ever should—see Section 23.6), the sample size calculations should anticipate the loss of participants due to noncompliance and apply an appropriate correction. In the simplest scenario in which similar proportions of participants are randomly excluded from two equally sized groups, the sample size should be increased by a factor of  $1/(1 - \text{anticipated proportion excluded})$ .

A better alternative is to retain all participants in the analysis and apply a correction for attenuation of the explanatory effect by noncompliance (see Section 23.6). If the primary analysis is to involve obtaining estimates of explanatory effects of intervention calculated in this way, then the sample size should be adjusted accordingly. Newcombe [20] describes a method for adjusting conventional sample size calculations when an explanatory effect of intervention is to be estimated from the difference between two means, and Sato [21] provides sample size formulas for trials in which the explanatory effect of intervention is to be estimated as a risk difference. Sommer and Zeger tabulate the relative efficiency of pragmatic and explanatory estimates of risk ratios [22].

As discussed in Section 23.2, pragmatic trialists consider that noncompliance is a nonissue. Pragmatic trialists are uninterested in the hypothetical effect that an intervention could have in the presence of complete compliance. To them the parameter of most interest is the average effect of the intervention in clinical populations. It is understood that clinical populations contain some patients who do not

comply with intervention. For this reason pragmatic trialists generally do not adjust sample size estimates for noncompliance.

## 23.4 INTERVENTIONS

### 23.4.1 Experimental Intervention

Some health interventions are constrained by tight protocols that ensure uniformity of clinical practice. More often clinical practice is highly variable. Many clinicians have quite a high degree of autonomy, and they tend to develop their own formal or informal protocols for administering particular interventions. Individual clinicians may develop idiosyncratic decision rules that are not shared by other clinicians. In some settings a particular intervention may be administered in a technically adept manner using optimal protocols by clinicians who appear competent and demonstrate empathy. In other settings the same intervention may be administered tardily, incompetently, or indifferently.

The explanatory trialist wants to know about the effects of an intervention when it is administered optimally. Consequently, explanatory trialists expend considerable effort ensuring that the intervention is administered as well as is possible. Usually, the intervention is administered by a clinician with recognized expertise, and the intervention is administered according to strict protocols. This confers an incidental advantage: It ensures that it is clear precisely what intervention has been provided in the trial, so there need be little ambiguity about precisely what sorts of intervention the trial can be used to make inferences about.

The pragmatic trialist's interest is, instead, in the effects of the intervention as it is administered in real practice. (Or, when the trial is of a *new* intervention, the pragmatic trialist's interest is in what the effects of the intervention *would be* if it was to be administered in real practice.) Seen from this perspective, there is no necessity to enforce optimal intervention in clinical trials other than with the usual mechanisms that regulate the quality of clinical care. The interventions should be applied by clinicians who are representative of the spectrum of clinicians who apply (or would apply) the intervention in clinical practice, not exclusively by expert clinicians.

Useful pragmatic estimates of the effects of an intervention may be difficult to obtain when the intervention is new and administration of the intervention is difficult. An important example is new surgical techniques. The problem arises because new surgical techniques are pioneered by surgeons who have specific expertise in that type of surgery, but with time those techniques come to be more widely used by surgeons with less specific expertise. Moreover, the techniques themselves usually evolve rapidly, so that over the months and years that follow the introduction of the technique the standard approach becomes refined. Pragmatic interest should be in the effects of the intervention some time after the introduction of the new technique, at a time when the intervention has become, or could have become, part of routine surgical practice. By that time the technique may have been greatly refined, many more surgeons (including those with less expertise in the field) may be using the technique, and good training programs may have been introduced. A trial conducted soon after the introduction of a new surgical technique might neces-

sarily involve sampling unusually gifted surgeons who are relatively unpracticed in the technique, and might involve the administration of relatively unrefined surgical methods, compared to the same trial conducted several years later. Thus, while it may be possible to conduct explanatory trials seeking proof of concept soon after the introduction of a new surgical technique, it may be impossible to obtain realistic and generalizable pragmatic estimates of effect until the surgical technique has become widely established. Only then may it become possible to observe the effects of surgeons with widely representative competence performing refined surgical techniques.

#### 23.4.2 Comparison Intervention

The choice of comparison intervention should reflect the orientation of a trial. Explanatory trialists usually aim to determine the specific effects of an intervention. To them, nonspecific effects associated with the rituals of administration of the intervention and the interactions between the clinician and patient are usually of no interest and should not be allowed to contaminate estimates of the specific effects of the intervention. It is possible to estimate the specific effects of intervention by ensuring that both the experimental and control groups experience exactly the same nonspecific effects. That is, explanatory trialists can ensure that estimates of the effects of intervention are uncontaminated by nonspecific effects by ensuring that experimental and control interventions are “equalized” [1].

Experimental and control interventions can be equalized by providing a placebo (or sham) intervention to the control group. The ideal placebo intervention is one that involves identical nonspecific rituals of administration but lacks the specific effects of the experimental intervention. Thus most phase III drug trials compare the outcomes of a group of patients given pills (or injections, or ...) containing the experimental compound with the outcomes of a group given pills that are identical in shape, size, and color but that do not contain the experimental compound. Then both the experimental and control groups experience, on average, similar nonspecific effects associated with administration of the intervention. As a consequence, estimates of the effects of the intervention (the difference in the outcomes of the two groups) are believed to be uncontaminated by these nonspecific effects.

Similar reasoning is used to justify blinding of the clinician who administers the intervention. Blinding of the clinician ensures that, on average, the clinician provides the same degree of enthusiasm and positive regard when administering both interventions [2].

There is almost universal agreement that phase III drug trials should blind both the participants (patients) and the clinician administering the intervention. In contrast, there is much more ambivalence among researchers about blinding patients and clinicians in trials of other sorts of interventions. Trials of surgical interventions, medical devices, and programs of care such as educational interventions, exercise programs, and psychological or behavioural interventions frequently do not blind patients or clinicians. No doubt this is due, at least in part, to issues of feasibility: It can be difficult to design a sham intervention that is both comparable to the experimental intervention and therapeutically inert, ethical considerations may preclude the provision of a convincing sham, and it may be difficult to blind clinicians to whether they have administered the experimental or sham intervention. But there

are also theoretical objections to the use of sham interventions: Placebo controls are important in explanatory trials but may be unnecessary, or less necessary, in pragmatic trials.

To the pragmatic trialist, nonspecific effects are a potentially important component of the total effect of an intervention. Therefore, from the pragmatic trialist's perspective, there is no need to separately estimate specific and nonspecific effects. The pragmatic trialist needs only to know the total effect (the sum of nonspecific and specific effects) of administering the intervention. It is this effect that can be anticipated when the intervention is administered to patients in clinical practice. From this perspective there is no need to equalize exposure to nonspecific factors in experimental and control groups. Instead it is more important that the control group is offered a clinically relevant alternative intervention. In Schwartz and Lellouch's terminology, the goal of the pragmatic approach is to optimize rather than equalize the control intervention [1].

More generally, pragmatic trialists need to know whether their patients will experience better outcomes if prescribed the experimental intervention than if prescribed the best available alternative intervention. In general, then, pragmatic trials should compare outcomes of participants receiving the experimental intervention with the outcomes of participants receiving the best available alternative intervention. When the best alternative intervention is minimal intervention (such as advice and support), the most useful trial is one that compares the outcome of participants given the experimental intervention with the outcomes of participants that receives minimal intervention. When the best alternative intervention is a particular program of treatment, the most useful trial is one that compares the outcome of participants given the experimental intervention with the outcome of participants that receive that program of treatment. The principle is that pragmatic trialists should conduct trials with clinically reasonable (relevant) comparison groups [4]. For this reason pragmatic trialists should seriously consider *not* conducting placebo-controlled trials [23].

This advice needs to be qualified. First, the nonspecific effects of intervention may be context-specific. For example, it may be that a particular intervention has placebo effects that manifest in the context of a particular trial (where, e.g., there may be a particularly high degree of regard paid to the patient) but not in the context of broader clinical practice. Context-specific nonspecific effects are of little interest and should be controlled for. Also, the imperative to obtain clinically relevant comparisons may be outweighed by the need to prevent bias. In clinical trials, blinding of participants and clinicians serves additional purposes, over and above controlling for nonspecific effects associated with the rituals of administration of the intervention. At least theoretically, blinding could reduce differential loss to follow-up. More importantly, whenever outcomes are measured subjectively (as they often must be in pragmatic trials) blinding of participants prevents any possibility that the effects of treatment are biased by participants anticipating the responses that they believe the researchers want to hear (the "polite-patient effect" [12]). One of the greatest advantages of blinding of assessors in trials is that it means subjective outcomes can be evaluated without fear of assessor bias ("the clinical impression can be included and given full weight in the analysis" [24]). These important considerations may cause even the most pragmatic trialist to implement placebo controls in their trials.

### 23.5 CHOICE OF OUTCOMES

Unlike pragmatic trialists, explanatory trialists are not preoccupied with the issue of whether the effects of intervention justify adoption of the intervention in clinical practice; they simply want proof of the concept that the intervention produces certain specific effects. Thus explanatory trialists often use measures of disease activity or disease severity as the primary trial outcomes or endpoints. Examples include measures of tumor size, blood pressure, biochemical markers, muscle strength, bone density, and so on.

In the clinical trials literature these sorts of outcomes are often called surrogate outcomes [25, 26]. Trials that monitor surrogate outcomes are generally considered to be less useful than trials that monitor clinical outcomes such as mortality or quality of life because, as history has shown, surrogate outcomes can provide a misleading indication of the true clinical effects of intervention on mortality or quality of life [26].

The contemporary suspicion of surrogate outcomes is underpinned by two very pragmatic ideas. First, pragmatic decisions about whether or not to implement an intervention involve weighing up all of the potential good and all of the potential harm caused by the intervention. This is more easily achieved by examining global measures of benefit and harm than by assessing the effects of the intervention on specific measures of disease activity. Second, an intervention is ultimately only of clinical benefit if it increases length of life or quality of life. For this reason, the primary outcomes of pragmatic trials should be measures of mortality (survival) or quality of life.

The assessment of mortality is relatively straightforward. A minor controversy concerns which deaths should be counted. Explanatory trialists may prefer to measure disease-specific mortality because analyses of disease-specific mortality may have more statistical power, and therefore be more able to detect effects of intervention, than analyses of all-cause mortality [27]. Pragmatic trialists are more inclined to count all deaths, regardless of their cause, rather than disease-specific mortality. All-cause mortality provides a more global measure of the effects of an intervention because it allows for the possibility that reductions in disease-specific mortality are offset by increases in other causes of mortality [28].

Measurement of quality of life is a more complex task. Quality of life can be measured with generic scales or with any of numerous disease-specific quality-of-life measures [29]. Some trialists are reluctant to measure quality of life because they believe measures of quality of life are relatively insensitive to change and may obscure real effects of intervention. But such reluctance may not always be justified. The *measure* of quality of life must be sensitive to changes in the underlying construct (the latent variable of true quality of life) but, at least from a pragmatic perspective, there need not be any requirement that the underlying construct of quality of life should be sensitive to change.

Outcome measures can be considered to lie on a spectrum. At the explanatory end are measures of disease activity, like biochemistry results, and at the pragmatic end are mortality and quality of life. Somewhere between the ends of this spectrum are outcome measures that are not formal measures of quality of life but could reasonably be expected to reflect quality of life. Examples include measures of depression, or disability, or incidence of injury, or severity of incontinence. From an

extremely pragmatic perspective these measures are really only of interest insofar as they can be used to predict quality of life or costs. Nonetheless, because it is reasonable to expect that these sorts of outcomes are likely to be important determinants of quality of life, they may provide suitable endpoints for pragmatic trials.

Policy-level decisions about whether to implement a particular intervention should be informed by cost-effectiveness (or cost-utility) analyses. For this reason pragmatic trials often measure costs of intervention. Costs to the consumer and health service providers can usually be quantified with relatively little difficulty, although costs to society may be considerably more difficult to estimate. Cost-effectiveness and cost-utility analyses are naturally pragmatic in their orientation so they should always be based on pragmatic outcomes such as quality of life.

## 23.6 ANALYSIS

### 23.6.1 Who Should Be Included in Analysis?

Even the best conducted trials experience protocol violations. For example, participants in the experimental group may fail to be given, or comply with, the experimental intervention. Participants in the control group may fail to comply with the control intervention. Participants in either group may be given co-interventions other than those specified in the protocol. People who do not satisfy the inclusion criteria may be incorrectly admitted to the trial. Outcome measures may be obtained at times other than (usually later than) specified in the protocol.

Some trialists may be tempted to identify participants who experience serious protocol violations and exclude those participants' data from the analysis (a per protocol analysis). This strategy might be particularly attractive to explanatory trialists because it might appear that excluding noncompliant participants' data from the analysis would provide a better estimate of the effect of intervention in compliant participants. However, per protocol analyses are potentially seriously biased [30]. Insofar as protocol violations are related to allocation, exclusion of randomized participants can produce imbalance in observed or unobserved baseline covariates. The potential for bias is great when the proportion of excluded participants is moderate or large. In addition, because per protocol analyses are conducted on a subsample of data, they may be underpowered. Another problem is that inference in per protocol analyses is to a relatively poorly and retrospectively defined population.

For these reasons the primary analysis of most clinical trials should be conducted on all available data from all randomized patients. More generally, the analysis should be conducted on an "intention-to-treat" basis. Different meanings are ascribed to the term intention to treat [31], but here the term is used to mean that (a) wherever possible outcome data are obtained from all trial participants (i.e., from every person who was randomized, not just those for whom the trial protocol was followed), (b) all available data (not just data from participants for whom the protocol was followed) are included in analysis, and (c) each participant's data are analyzed in the groups to which the participant was assigned (not according to treatment actually received). In short, the intention-to-treat policy is one of "ever randomised, always analysed" [32].

There may be some circumstances under which departures from an intention-to-treat policy may be reasonable. Fergusson and colleagues [33] have argued that it is reasonable to exclude from the analysis those participants who were clearly ineligible to participate in the trial at the time they were randomized (i.e., people whose inclusion in the trial was a result of the researchers' failure to follow the protocol). On the other hand, participants should not be excluded from the analysis if the information required to determine they did not meet eligibility criteria only became apparent sometime after randomization. For example, participants who were thought to have a particular diagnosis, but who were found some time after randomization to have an alternative diagnosis that would have excluded them from the trial had the alternative diagnosis been known at the time of allocation, should not be excluded from the primary analysis. These recommendations have a distinctly pragmatic flavor.

### 23.6.2 Adjustment for Noncompliance

In the preceding section it was argued that per protocol analyses should not be used to obtain explanatory estimates of the effects of intervention. The primary analysis should be by intention to treat.

The intention-to-treat approach presents little difficulty for pragmatic trialists. Pragmatic trialists understand estimates of the effects of interventions as estimates of the effect of the *intention* to provide the intervention, or of a *policy* to provide the intervention, rather than in terms of the effect of the intervention itself. More subtly, pragmatic trialists appreciate that the estimate is of the effect of the intervention when it is given in good faith to the people for whom it is thought to be appropriate, even though the intervention may sometimes, for one reason or another, actually be given to patients for whom it may be inappropriate. Similarly, effects are considered to be those measured at as close as possible to a target follow-up time, understanding that in practice the timing of this effect may be variable in practice. An intention-to-treat analysis provides estimates of effects of intervention that can be understood in these pragmatic terms.

Explanatory trialists may, however, be unsatisfied by estimates of effects of intervention based on simple intention-to-treat analyses. Explanatory trialists wish to know the effects of actually receiving an intervention, as distinct from the effects of intending to provide the intervention. This interest may stem from a desire to understand how the effects of intervention are mediated or, alternatively, from a concern about the generalizability of pragmatic estimates of effects of interventions [34, 35]. In recent years there has been a rapid development of methods that can be used to adjust intention-to-treat-based estimates of the effects of interventions to take account of protocol deviations. The focus has been on obtaining intention-to-treat-based estimates of the effects of intervention in compliant patients.

The simplest method for obtaining compliance-adjusted estimates of effects of intervention from all randomized participants applies to the situation in which participants either complied fully with the intervention or received, from the moment of allocation, the intervention they were not allocated. Newcombe has shown that, in this special case, the effect of intervention is attenuated by an amount that depends only on the frequency with which participants receive the intervention they were not allocated to [20]. The explanatory estimate of the treatment effect is the

conventional pragmatic estimate divided by an attenuation factor, which is simply the proportion of subjects in one group receiving the allocated intervention minus the proportion of subjects in the other group receiving the same intervention. The attenuation factor is always less than or equal to one, so the explanatory effect is always greater than or equal to the pragmatic effect. The validity of this estimate is contingent on the assumption that participants complied perfectly either with the allocated intervention or the alternative intervention from the time of randomization (i.e., it assumes participants did not “cross-over” some time after they had already experienced some of the effect of the allocated intervention or too late to experience some of the effect of the intervention they crossed over to). Insofar as participants cross-over after they have already experienced some of the effect of the allocated intervention, or too late to experience some of the effect of the intervention they crossed over to, this explanatory estimate will be biased upward.

Pocock and Abdallah describe a number of simple analyses they conducted to obtain explanatory estimates of the effects of intervention from a placebo-controlled trial of dexfenfluramine for obesity [36]. As they had data on the degree of compliance, they were able to regress outcome against compliance for participants in the experimental group. The regression equation was used to estimate the outcome of perfect compliers in the experimental group. An explanatory measure of the effect of the intervention could then be obtained by subtracting from this value the mean outcome for the control group. (A better approach, though one that was not possible with the data available in that trial, would be to subtract the estimated outcome of perfect compliers in the control group from the estimated outcome of perfect compliers in the experimental group.) A difficulty with this approach is that compliance may be both a determinant and an effect of outcome [37]. Comparison of outcomes of treated and control groups at the same level of compliance are potentially biased when the treatment and control conditions have different influences on compliance.

Sommer and Zeger circumvented this problem in their analysis of a trial of vitamin A supplementation on child mortality [22]. Compliance was treated as a dichotomous variable, so participants were considered to be either compliant or noncompliant. The approach was to infer virtual compliance levels in the control group by assuming that compliance levels in the control group were the same in the control and experimental groups. Unbiased estimates of the effects of intervention in compliant participants could be obtained by comparing mortality risk in the subgroup of compliant participants in the experimental group with the inferred mortality risk in the virtual subgroup of compliant participants in the control group.

Little and Rubin show that both Newcombe’s approach and Sommer and Zeger’s approach can be derived with causal models [38]. Causal modeling provides a rigorous framework for development of explanatory estimates of effects of intervention. The fundamental idea is that the explanatory effect of an intervention on any individual is the difference between the outcome that individual would have experienced with and without intervention. The obvious statistical problem is that, in a clinical trial, each individual either receives the intervention or does not. Nonetheless, given some often plausible assumptions, it is possible to estimate the average causal effect in compliant people. Causal models have been subject of active development in recent years. Bellamy and colleagues provide an introduction to the use

of causal models for obtaining explanatory estimates of effects of intervention in randomized trials [39].

There are two distinctly different ways of conceiving of explanatory effects of intervention. One possibility is to think of the explanatory effect of intervention in terms of the effect of intervention on the subpopulation of patients who comply (the conditional compliance-related treatment gain [35]). Alternatively, the explanatory effect of intervention could be thought of as the effect intervention would have had if all patients had complied with the intervention (the unconditional compliance-related treatment gain [35]). Estimation of these two quantities involves invoking different assumptions and involves different types of statistical models [39].

It goes without saying that any attempts to estimate the effects of intervention in compliant people can only be conducted if good data are available on compliance. Compliance is a complex construct that includes dimensions of consistency, intensity, and sustainability. Noncompliance may manifest as missed treatments, treatments in which the intervention was administered at an inappropriately high or low dose, or failure to continue with treatment. Unfortunately, it is often difficult to obtain good data on all these dimensions. Measurement of compliance is most often based on pill counts, patient diaries, and participants' self-reports [40], all of which may be biased. Usually, compliance data are reduced to a simple dichotomy, so that participants are classified as compliant or noncompliant.

## 23.7 REPORTING

The primary theme of this chapter has been that the design of a clinical trial should be strongly influenced by whether the intention is explanatory or pragmatic. Explanatory trials and pragmatic trials differ in the way they sample participants, administer the intervention and control interventions, measure outcomes, and analyze data. Authors of clinical trials should state explicitly, both in trial protocols and trial reports, whether their intention was explanatory or pragmatic. This will go some way to reducing misunderstandings that arise from the different intentions of trialists and readers of trial reports.

Pragmatic trialists are more interested than explanatory trialists in generalizing their findings to clinical contexts. (Perhaps a more accurate way to say this is that pragmatic trialists are more concerned that their findings can be used to make inferences about the care of individual patients.) The extent to which this is possible depends on the extent to which the characteristics of the trial participants and trial interventions resemble the participants and interventions about which inferences are to be made. Consequently, it is particularly important that reports of pragmatic trials provide detailed information about the characteristics of trial participants (patients and clinicians) and how the intervention was administered. Specific details should be provided about the strategies used to facilitate compliance with the intervention.

The conclusions of trial reports should be consistent with the design of the trial. Importantly, authors of explanatory trials should restrict their conclusions to claims about proof of concept. In the event that an explanatory trial provides evidence in support of the specific effects that were hypothesized, the conclusions should state just that. Explanatory trials should not make global claims about the effectiveness

of an intervention. Such claims should await demonstration of clinically important effects with pragmatic trials.

### 23.8 RECOMMENDATIONS

1. Clinical trials of interventions that are already in widespread practice should usually be pragmatic in orientation.
2. Run-in periods should not be used in pragmatic trials.
3. Pragmatic trials should sample participants (patients and clinicians) in as representative a way as is possible.
4. If sample size calculations for pragmatic trials are to be based on a hypothesis testing approach, they should incorporate empirical estimates of the smallest worthwhile effect of intervention, such as can be obtained with the benefit-harm trade-off method. Alternatively, sample size calculations for pragmatic trials could be based on considerations of the precision of estimates of effect, or of the value of sample information.
5. If the primary analysis of an explanatory trial is to involve adjustment of estimates for noncompliance, sample size should be adjusted accordingly.
6. Explanatory trials should blind participants and clinicians wherever possible. Pragmatic trialists should consider not blinding participants or clinicians.
7. In pragmatic trials the control group should receive the best available treatment alternative.
8. Pragmatic trials should have as endpoints either survival or measures that reflect quality of life or both.
9. The primary analysis of all trials, whether explanatory or pragmatic, should be conducted on an intention to treat basis.
10. Reports of clinical trials should explicitly indicate if the intention is to answer an explanatory or pragmatic question.
11. Pragmatic trials should provide detailed information about the characteristics of trial participants (patients and clinicians), how the intervention was administered, and the degree of compliance with the intervention.
12. Explanatory trials should not make global claims about the effectiveness of an intervention. Such claims should await demonstration of clinically important effects with pragmatic trials.

### **24.1.1 FOUNDATIONS FOR TRIAL DESIGN**

The ethics of clinical drug trialing start with the concept of the trial that is to be undertaken. The trial must aim to answer a question that has not yet been answered, thereby necessitating the need for such a trial [1]. It should not be a substitute for a marketing strategy in which investigators place patients onto expensive agents for which either the patient or the formulary (namely the list of drugs available within a specific facility) cover the real costs of the trial, while the yield from the study contributes very little to scientific/clinical knowledge and more to treatment commitment [2].

The latter group of studies have a distinct advantage for the pharmaceutical company that is sponsoring them because they represent a pool of patients who would, otherwise,

possibly not receive the medication, were it not for the conduct of the clinical trial [3]. These studies generally lack scientific validity, and investigators need to think very carefully before committing to such questionable trials. Ethics committees also need to review the content of studies to make sure that they are not merely marketing tools masquerading as clinical trials.

The design of a study should include calculations to determine the sample size necessary to allow sufficient mathematical power to achieve a reliable response with adequate scientific rigor [4].

There needs to be consideration of the size of the response expected, the right dosage needed to attract such a response, the correct comparator (be it placebo, which theoretically equates to no comparator, or a proven therapeutic agent already known to be effective in the management of the condition under review), and the potential subject “dropout rate” that needs to be accommodated to achieve the desired final sample size upon which to base the study’s analysis with adequate power [5].

It is often impossible to determine these parameters accurately as they may rely on earlier animal studies for extrapolation, and the animal data may not properly translate into human experience [6]. Alternatively, the concept may require an initial pilot study, in which far fewer subjects are involved but in which either the idea or the methodology under investigation can be tested. Such pilot studies may not truly reflect definitive data, but they will provide invaluable evidence to either support or refute the initial hypothesis [7, 8].

Pilot trials may be the only source of information upon which to base a foundation with which to ascertain indicative information to be used as the basis for calculations to determine a subsequent study that allows adequate power to truly answer the scientific question being posed. Often such pilot studies are difficult to publish as they lack the power to answer the question reliably, but their value should not be underestimated nor should the ethics of publication of such information be dismissed as they may represent the only proof of concept information [9].

The dosage of medication to be used in the trial may prove critical. Studies that have used too large a dosage cause unnecessary adverse events and hence delay or impede a drug’s development or acceptance, as was the case with topiramate, which used a dosage of 200mg in its trials [10, 11]. Conversely, the dosage that was used within the trial may be too low to achieve adequate response rate, thereby suggesting the agent to be less effective than it truly is, as was found with gabapentin [12]. Such errors have direct negative implications for the target patient population and may deny patient access to what amounts to an effective therapy because the study design was formulated on false expectations. It can be seen that innocent, but incorrect, assumptions may carry with them ethical consequences that may ultimately affect patient well-being because they affect the availability of appropriate therapeutic modalities [13].

The cost of conducting a trial has direct implications upon the adopted methodology. A crossover design is far less expensive than is a parallel arm design, and the purpose of the study must be decided. If the purpose of the study is to satisfy a regulatory requirement, then a parallel arms study design may be mandated by those regulatory authorities that are to determine the fate of the product under review [14].

The reason for reduced costs, in a crossover design, is that the subject acts as his or her own control, thereby allowing a significantly reduced sample size, as one patient serves in both arms of the trial to answer the study's question, which may effectively half the necessary sample size. This obviously reduces both the time delay and the effort it takes to recruit double the sample size and hence also reduces the need for additional investigators with inherent monitoring and infrastructure costs. Thus the purpose of the study may determine the study design, beyond any strict scientific or ethical requirements.

Where there is a need to have large numbers in a trial, then it often follows that the trial sponsors will resort to cost-cutting measures that may impact on the scientific rigor adopted for the protocol. An example of this is the use of large open-label studies to answer questions of comparative efficacy where the cost of a double-blinded methodology would be prohibitive due to the need for a "double-dummy approach" (in which both treatment A and treatment B need to have mirrored therapy with matched placebos such that the patient receives either treatment A, plus placebo, or placebo plus treatment B, thereby offering a potentially truly double-blind methodology) [15, 16]. The costs of such an approach might mean that the study would never have been feasible while the open-label design may still provide some very useful information.

The need to have large numbers recruited to a study may also translate into the inclusion of less skilled investigators, with far greater propensity for protocol violation and hence possible pollution of data. It is hoped that such potential problems do not translate into ethical expedience with insufficient external scrutiny of procedure.

It can be seen that the ethics of clinical research, and drug trialing, commence long before the first investigators are approached, the first study site is selected, or the first patient is recruited into the trial. The consideration of ethics starts with the selection of the scientific question to be asked, the capacity to answer that question, and the study design to be adopted for that purpose [17].

### **24.1.2 INVESTIGATOR SELECTION**

For an investigator to accept to be part of a clinical trial requires that the investigator be confident that he or she can fulfill the requirements of the trial. This dictates that the investigator conducts a review of the purpose of the study, the question(s) to be asked in the trial, the methodology to be adopted, the types and numbers of patients sought for inclusion (reviewing inclusion and exclusion criteria), and the feasibility of conducting the study within the constraints of his or her center, while recognizing that all conduct within the trial must adhere to good clinical practice [18].

Many international trial sponsors will conduct a feasibility study of proposed investigators, but, as these are based on personal estimations, their validity is quite suspect [19]. Despite this shortcoming, the concept that each proposed investigator should at least assess his or her capacity to adequately conduct such a trial is very appropriate.

It is inappropriate, and ethically unjustified, to nominate oneself for inclusion as a prospective investigator within a trial if it is highly doubtful that one could accom-

modate the proposed trial's needs [20]. If selected as an investigator, the study sponsor automatically accumulates direct costs: such as investigator meetings, with its transportation and accommodation costs, costs for ethics committee submissions, and infrastructure costs [21].

There are basic considerations applicable to each nominated investigator. These include having adequate knowledge of the subject matter under consideration, having the resources to conduct the trial (be it space, staff, storage facilities, or standard operating and accounting procedures), having access to an acceptable and properly constituted ethics committee, and expecting to be able to recruit adequate numbers of appropriate patients to justify inclusion [22].

Without these ingredients, the proposed investigator should exclude him or herself.

The purpose of this discussion is to demonstrate that there are unequivocal ethical obligations on the investigator even before agreeing to be part of any investigative team. These obligations are often overlooked but to do so may cause unnecessary burden to a prospective sponsor. This may cause a sponsor to think twice about underwriting future studies, if investigators failed to meet their agreed commitments.

### 24.1.3 EXTERNAL STUDY APPROVAL

Once the aims of the study have been determined, the protocol established, and investigator sites selected, the study must then be subjected to external scrutiny.

All those who are involved with the conduct of the study (namely the company initiating the trial, the sponsor, the clinical research organization that will supervise the study, and the investigators) must review all the requirements [23], which may include contractual negotiations, privacy agreements, financial incentives, and infrastructure requirements, all of which should be available to the external review process as required by the relevant committees.

Submission to review boards, be they for scientific validity or for human research ethics committee (HREC) evaluation, are usually prepared in a predetermined fashion. The purpose of the HRECs is to protect the interests of trial subjects. Some, but not all, HRECs ask for a relevant expert scientific evaluation of a proposed protocol, before deliberating on the trial, so as to ensure that it is seeking valid scientific answers within the study design. This process should ensure that the study is not simply a marketing ploy. Such appraisal also seeks to confirm the feasibility of a study, its merits, and any potential risk that may, or may not, have been identified at the time of the submission. Some HRECs rely on their own members, which might include the relevant scientific expertise to provide the necessary scientific input. In either context, the role of the HREC is less to do with the scientific value of the proposed research (for which it can rely on others), and its main function is to focus its principal deliberations on the ethics of patient involvement [24].

The HREC reviews the protocols, the reasons for the study, patient safety, access to necessary information, format, content, and language of both patient information and consent documentation, access to investigators in case of any problems, and clear evidence of lack of coercion when recruiting patients [25].

This is of particular importance when the sample population is recruited from the clinical practice of an investigator, be it in the private or public practice of medicine. Patient protection is the fundamental obligation of the HREC [25], while at the same time it should not obstruct worthwhile research that may benefit the wider community.

Clinical trials can expose research candidates to new, and often unknown, risks when consenting to be subjects for a trial. To protect patients against such risks, the sponsors are expected to take out insurance to cover those risks should they eventuate [26]. More recently, members of HRECs have also sought insurance to indemnify their membership against potential litigation consequent to any adverse events that may occur within a trial. The HREC will often seek confirmation of appropriate insurance being in place before approving any study that involves human participation.

Studies that include live subjects (human or animal) cannot proceed without ethics committee approval, and, in the case of humans, a written consent or signed surrogate consent is needed from either the patient or someone responsible. Surrogate consent is “ideally a substituted judgment made by a person responsible for healthcare decision-making for a particular patient under the relevant legislation” [27]. The situations in which such surrogate consent may be required include evaluation of therapy for certain conditions, such as treatment in stroke patients for whom the capacity to decide is no longer valid. It may also be necessary to seek surrogate consent in underage subjects for whom guardian approval is mandatory. A similar situation exists for patients who lack the intellectual capacity to comprehend what is being asked of them within the trial protocol, as is the case with intellectually handicapped patients. For these patients it is also necessary to seek guardianship board approval, so as to relegate the authority to consent for such a patient to be included within any given trial, to a “responsible other” person who will have the patient’s best interests as his or her primary concern [28].

#### 24.1.4 CONSENT PROCESS

“Consent is widely believed to affirm the autonomous decision-making rights of prospective research participants, and their capacity to protect their own interests” [27]. Once the study has been approved by the external review process, each investigator assumes responsibility for the conduct of the trial within his or her institution, be it in private or public practice. This starts with a site initiation visit in which the sponsor, or surrogate, usually a clinic, also termed contract research organization (CRO), which is specifically contracted for the task, confirms that all those at the site are fully conversant with their obligations and the procedures to be adopted within the trial and that the center has the wherewithal to conduct the study [29].

With the emergence of CROs there has also emerged an understanding that they too have unequivocal ethical obligations. The level of sophistication impacting upon CROs have developed to the point of these being umbrella organizations designed to oversee compliance of its voluntary membership [30].

The investigator(s) then approaches suitable candidates regarding their willingness to participate within the trial. Each candidate must provide informed consent, based on provision of HREC approved study information, which clearly outlines

the purpose of study, the obligations imposed on both subjects and investigators, and the potential known risks and hazards that accrue consequent to participation in the trial. Each subject must have exercised free will, devoid of the imposition of undue influence, and must have the capacity to ask any questions that may have arisen, following the reading of the study information, before signing the informed consent document [22].

This process must be conducted in an open and unbiased fashion and the written consent should be witnessed and signed by a competent adult, recognizing that the written consent may be provided by a surrogate, representing the patient's best interests. Some may allow for the lack of equipoise in the doctor–patient relationship and have the trial coordinator initiate the consent process, following which the doctor will be available to answer any outstanding questions [26, 31].

It is imperative that the investigator must still be available to answer more difficult questions (which were beyond the capacity of the trial coordinator) and that investigator should countersign the consent form and confirm its authenticity [26, 31].

This goes some way to overcome any suggestion that patients, selected from the clinical practice of an investigator, have been coerced into participating in the trial. It is far easier to refuse participation within a trial if the request comes from a research coordinator rather than the doctor, especially if the HREC-approved study information includes a passage that guarantees ongoing clinical care by the doctor, irrespective of whether the prospective subject is willing, or not, to participate in the trial [26, 31].

The consent documents must acknowledge that trials of new therapeutic agents may not have encountered all possible risks and hazards that attach to the medication under experimentation. Potential subjects must be warned of the known risks and must also be advised that no one can guarantee that the trial will provide a direct benefit for them. Where a trial compares an investigative agent to a placebo, trial subjects must understand that they may not receive the medication under review, within the trial, and may receive the equivalent of a “sugar pill.” They also need to be appraised of the risk ratio of this happening [29]. Similar advice needs to be given where differing doses of the study medication are to be given so that consent is truly informed. In short, the study protocol must be adequately described within the patient information and consent documents to clearly demonstrate that there has been no attempt to hide vital information or to give a false risk–benefit ratio [29]. The HREC has the responsibility to ensure that this has occurred and that the language used is of a sufficiently simple nature to avoid excessive use of jargon that may confuse a prospective subject. It must also be satisfied that the concepts, including the consent of information documents, are provided in a manner that is not too complicated for the average man/woman to understand [27].

Many trials of new medications adopt a blinded methodology, be it single or double blinded, and the potential subject must appreciate that he or she will not know what medication he or she will receive in a blinded study [15]. It is even more important for the subject to understand that, in the double-blinded methodology, neither the patient nor the doctor knows which medication the patient is taking during the trial. As mentioned earlier, the trial may use a placebo as the comparator. In such trials subjects will not know if they are receiving an active compound at all, in addition to the standard medications they were receiving before the trial. This

encapsulates the very essence of a randomized, placebo-controlled, double-blinded protocol. Most placebo-controlled studies do make provision for the patient to receive the experimental compound in an open-labeled, long-term safety and efficacy trial that follows the blinded study and that continues until the study medication is freely available. This must also be explained to potential trial subjects [23, 32].

Only subsequent to the free giving of informed consent, based on full disclosure, can the patient be included within the trial procedures [33]. Part of the consent process also includes provision for the withdrawal of consent, at any time throughout the study, without fear of compromising future ongoing clinical care by the doctor [33].

#### 24.1.5 CONDUCT OF TRIAL

There is usually very little latitude to alter the conduct of a trial. All requirements and expectations of a trial are set out in the HREC-approved trial protocol, which stipulates the timing and conduct of the trial visit [22]. Unfortunately, all trials that include human subjects will also include errors made by either the investigating team or the subjects themselves. Some of these errors represent only minor infringements for which a waiver may be sought from the sponsor [29]. Other errors may be so significant as to dictate immediate exclusion and withdrawal from any further trial involvement. Should a waiver be approved, then the patient can continue in the trial and allowance is made for the deviation from trial protocol requirements.

If the patient experiences a serious adverse event (SAE), such as the occurrence of something that causes hospitalization or is life-threatening, then both the HREC and the sponsor need to be advised, as soon as is possible, following the investigator having been made aware of the SAE [34]. The necessary action that is to be taken, regarding the experimental agent, is at the discretion of the investigator, although everyone needs to be advised of the action taken. Depending on the nature of the SAE, and its cause, it may be necessary to advise all patients within a trial of the SAE, and it may also be necessary to amend the patient information and informed consent documents. The HREC, itself, may insist on this action and it may go so far as to terminate the trial if its members believe that continuation of the trial is no longer ethical or in the patients' best interests. Investigators must make the same considerations, and advise the HREC accordingly, thereby demonstrating that the investigator also holds the well-being of the trial subjects as his or her primary concern for continuation of any given trial [34].

Others who are trialing the same medication—either for a similar indication or an alternatively indication—and who encounter an SAE—must also notify their appropriate authorities, such as their HREC, sponsor, or CRO. They, meaning the sponsor or CRO, must notify all other investigators who are/were trialing the same agent. Once notified of these SAEs encountered by others, it is imperative that the investigator also bring these to the attention of their HREC in the same fashion as they would have done had they personally encountered the SAE [29]. This further ensures maintenance of informed consent, should any of the SAEs have a bearing on the decision to continue a trial, be it from the perspective of the investigating team or subject.

Based on the SAE reporting, the HREC may seek clarification to determine if: the trial should continue with its currently recruited subjects; if continuation of recruitment should be allowed, if the entire process should be aborted, or if there needs to be an amendment to the current informed consent and information documents; and if the informed consent process needs to be repeated with each subject who is already within the trial to expedite their withdrawal should they choose not to face further previously unforeseen risk [29].

Depending on the nature of an adverse event, there may be need to unblind the blinded randomized data to determine whether the patient was exposed to the experimental compound and, if so exposed, the dosage of the exposure. Again this is at the discretion of the investigator, but it remains imperative that the patient's well-being must assume primal consideration [34]. This takes priority over any secondary ethical obligation that the investigator may have to the sponsor of the study to adhere to trial protocol as it relates to blinding of treatment arms.

Upon completion of the trial, the subject may either elect to continue on the study agent, if an open-label study is to follow, or choose to stop whatever it was that they were taking during the trial [23]. It must be remembered that trial subjects may not be advised of what they were taking during a double-blinded study, even after they complete that part of the trial, if not all subjects have completed the study. This is considered important to maintain mathematical integrity when analyzing the study data, but it does raise important ethical considerations as the decision to continue within the open-label arm is often based on inadequate information, in the absence of knowing what was taken during the trial. Some patients may think that they had a real benefit from the study medication when in fact they were on placebo, while others who were on the study medication may have thought they were on placebo [35]. Thus far there has not been an adequate resolution to this mathematical and ethical dilemma, which still needs to be resolved on a consensus basis.

The question of conducting an open-label study, following completion of a blinded protocol, is also of ethical importance [32]. Access to the study medication, following involvement in a blinded study, is often considered as an inherent ethical consideration, even at the time of the initial HREC approval for the blinded study to be undertaken. It is considered important to ensure that patients, who consider that they have benefited from the study medication, be allowed to continue on it until the medication is available on the market at a reasonable price, especially where a formulary exists, as is the case with the government-sponsored Pharmaceutical Benefits Scheme (PBS) in Australia [23, 36, 37].

#### **24.1.6 AFTER STUDY COMPLETION**

Responsibility for the trial consequences does not automatically stop once the last subject has completed his or her trial commitments. Insurance against the delayed expression of adverse effects is expected to be maintained long after the study has been completed and at least for one year. Ongoing support of patients, access to effective treatment, and notification of subsequent SAEs remains obligatory to ensure that patient safety is maintained [29, 34].

What is often less clear-cut is the ethical requirement to publish the findings of the study once the results become available. Current opinion supports an ethical

obligation to make the findings of any study publicly accessible, to ensure the widest dissemination of all results, be they positive or negative [38]. To satisfy this obligation, it is mandatory for journals to provide equal space for both negative and positive studies, something that is often claimed but not necessarily satisfied or realized with the current perception being that positive studies are far easier to publish than our negative studies [39, 40].

### 24.1.7 CONCLUSION

The ethics of clinical drug trials start at the time of establishing what question(s) should be asked, and answered, as a consequence of the trial. The response to these issues influences every step along the way, up to and including posttrial follow-up.

Issues that have not been canvassed within this treatise include those ethical obligations that represent the responsibility of trial subjects to adhere to their commitments to follow trial dictates. It behoves all those concerned with the conduct of the trial to recognize that trials represent a very expensive and demanding exercise that must adhere to the requirements as stipulated within the relevant protocol. Other issues, not addressed in the above analysis, include the ethical obligations that should be addressed by the company that sponsors the trial. These obligations should include the maintenance of rigorous postmarketing surveillance concerning the product being trialed, to protect against unexpected SAEs, as occurred with such medications as vigabatrin, which caused specific visual field defects that were only recognized years after the drug had come to market [41]. It may also be relevant to conduct postmarketing studies that better reflect the true use of products to see if clinical practice truly reflects what was demonstrated as a consequence of regulatory determined trials [42–44].

**24.2.1 INTRODUCTION**

“It is not enough that you should understand about applied science in order that your work may increase man’s blessings. Concern for man himself and his fate must always form the chief interest of all technical endeavors.”

—*Albert Einstein, Address to the California Institute of Technology, 1931*

“There is the more reliable safeguard provided by the presence of an intelligent, informed, conscientious, compassionate, responsible investigator.”

—*Harry Beecher, New England Journal of Medicine, 1966*

The quest for new treatments to alleviate suffering and prevent disease is indeed a very noble cause. Medical research has the potential to create huge benefits to society and enhance the professional reputation of the researchers who are responsible for these discoveries. However, a researcher must never forget that concern for the participants of human research is paramount, irrespective of how important the research outcomes are to society in general. A researcher must never knowingly seriously compromise the welfare of a research participant—“the ends must never justify the means.” According to Harry Beecher, careful training of researchers in both biomedical and ethical concerns is the key to preventing or minimizing serious mishaps. Therefore, the aim of this chapter is to educate clinical researchers in the common pitfalls of human experimentation and ways to avoid these ethical problems in pharmaceutical trials.

**24.2.2 ETHICAL DILEMMAS CENTRAL TO CONDUCT OF CLINICAL RESEARCH**

Ethics is a branch of philosophy that is concerned with answering the age-old questions about duty, honor, integrity, and justice. Research ethics is a branch of applied ethics that studies the ethical problems, dilemmas, and issues that arise in the conduct of research. Within the field of clinical trials three key ethical dilemmas often arise [1]:

1. *Good of Individual Versus Good of Society* Central to all moral theories is the need to respect and promote the rights of an individual. Natural or universal rights are those rights which are inherent in the nature of people and are not contingent on human actions or beliefs nor do they require legal enforcement by government or society. Philosophers believe that the rights to life and liberty (ability to act according to his or her own will) are the two guiding principles of natural rights. On the other hand, the promotion of social welfare of the community in general is also a central tenet in moral philosophy. Unfortunately these moral principles of respect for an individual's natural rights and the needs of society are often in conflict in the setting of clinical research. It is vitally important to use human subjects in research in order to gain valuable scientific knowledge that can benefit all of society, but this research has the potential to place individuals in harm's way and compromise their natural rights. Therefore the central ethical question in all clinical research is how best to protect the universal natural rights of an individual without compromising the scientific validity and social value of the research.

2. *Net Result of Risks Versus Benefits* In any clinical research setting with the potential to harm the participant physically or mentally, the researcher has an ethical obligation to ask the question whether the benefits of the research to the participant and/or the community in general outweigh the risks to the individual. It is normal to assess risks/benefits in terms of probability and magnitude and in the context of the underlying health status of the trial participants. For example, it would be considered unethical to conduct a research study for a medication with even a low risk of death (1%) in the setting of a non-life-threatening medical condition such as dermatitis or alopecia. However, it may be ethically acceptable to enroll terminally ill patients with grade IV astrocytoma in a trial of a new chemotherapy medication with a 1% chance of medication-induced death if this trial treatment gives them any real chance of cure. Conversely, it may be acceptable to place healthy phase I trial volunteers at significant risk of mild reversible adverse events such as headaches or nausea, but it is totally unacceptable to place them at any material risk of death or irreversible disability.

3. *Just Distribution of Benefits and Harms* All human experimentation raises the important ethical dilemma of equitable distribution of benefits and harms. The potential benefits to an individual of being involved in medical research include access to new potentially more efficacious treatments, supervision of clinical care by highly qualified medical staff with intensive monitoring, identification of secondary pathology during the trial entry examination, financial support, and improved self-esteem. Many people gain considerable benefit from knowing that their participation in research is advancing medical science, thereby helping other people in the future with the same medical condition that they are experiencing. Such altruistic motivation is a common positive psychological benefit of trial participation. Conversely, involvement in a clinical trial may create harm. The trial medication may produce physical or psychological adverse effects ranging from the relatively benign through to death. For example, if the participant is allocated to the placebo arm of a study, their involvement in research may delay or block their access to already established effective treatments. Finally, many trial designs require extensive monitoring which can be intrusive and tiresome to an individual whose quality of life may already be diminished by their underlying disease. If the benefits of participa-

tion in a trial are likely to exceed the potential risks, natural justice would dictate that any individual, regardless of their age, race, gender, religion, or financial resources, should have equal access to the trial.

### **24.2.3 PHILOSOPHICAL THEORY AND CLINICAL TRIAL ETHICS**

Philosophers have developed several different ethical theories/principles which may assist in making the morally correct decision in the field of clinical research [2]. The following discussion will summarize the main components of the three most useful theories/principles in the field of research ethics. Each of these theories/principles has its own strengths and weaknesses, making it important to not analyze a clinical research dilemma from a single philosophical point of view.

#### **24.2.3.1 Deontological Theory (Kantianism)**

Deontological theory is an approach to ethics that focuses on the rightness or wrongness of actions themselves, as opposed to the rightness or wrongness of the consequences of those actions [2]. It can be summarized succinctly as an ethical theory based on “moral duty or obligation.” The German philosopher Immanuel Kant (1724–1804) is generally considered as the father of deontological theory. Kant claimed that an action is morally wrong, irrespective of the final outcome, if it is inconsistent with the status of a person as a free and rational being [3]. The duty to promote an individual’s freedom and rationality is the guiding ethical principle of Kantianism, referred to as the categorical imperative. Stated differently, Kantianism requires an individual to treat both themselves and others as ends in themselves, never only as means to an end. All human beings have intrinsic moral dignity and we should not abuse, manipulate, harm, exploit, or deceive people in order to achieve specific goals, no matter how desirable that goal may be. Put quite simply, deontological theory can be condensed into “the ends never justify the means” and “do unto others as you would have done to yourself.”

#### **24.2.3.2 Utilitarianism**

The basic guiding principle of utilitarianism is that the morally right thing to do is to produce the best overall outcome for the most number of people. The English philosophers Jeremy Bentham (1748–1832) and John Mill (1806–1873) developed the theory of utilitarianism [4]. Mills stated that the morally correct action was the one which created the greatest balance of happiness for the greatest number of people—somewhat akin to a moral “cost–benefit” analysis. Where deontological theory prohibits placing clinical trial participants at significant personal risk for the benefit of science or the community in general, utilitarianism states that this is ethically sound provided the expected outcomes for society are favorable. Utilitarianism is a commonly used theory in medical research as investigators and institutional review boards (IRBs) are always trying to find the appropriate balance between personal risk and benefit for the trial participant versus the benefits to society in general.

### 24.2.3.3 Principlism

The term *principlism* is used to describe four standard principles outlined in the Declaration of Helsinki [5] and the Nuremberg Code [6] that govern ethically responsible research practice. These principles include respect for autonomy, non-maleficence, beneficence, and justice [7]. Principlism is not derived from a single philosophical theory, but rather combines several different philosophical perspectives [1]. For example, the right of individual freedom or autonomy is central to deontological theory while beneficence or the generation of “greater good” is a key feature of utilitarianism. As principlism borrows the best features of the available philosophical theories, it is generally considered the most applicable to resolving ethical dilemmas in medical research:

(a) *Autonomy* Autonomy is the basic human right to respect an individual’s ability to make their own decisions regarding their own health and future. If a researcher is to respect an individual’s right for self-determination, he or she must create a situation where the research subject is able to make an autonomous decision regarding participation in the research. This can only be enabled by providing adequate information about the participant’s involvement in the trial (informed consent) and avoiding undue influence or coercion. To achieve informed consent, subjects must be given adequate information regarding the research procedures that they will undergo, the risks and benefits of being involved, and alternative medical therapies of proven benefit outside the clinical trial. This information must be provided in both oral and written form in simple lay language that can be easily understood by a person with only basic language skills. Furthermore, all study participants must enter voluntarily, free from coercion or undue influence, and understand that they may withdraw at any time. The provision of excessive financial reward or the threat of withdrawal of standard medical care would be considered an unethical violation of the ethical principle of subject autonomy.

(b) *Beneficence* Beneficence refers to actions likely to promote individual well-being and/or benefit others.

(c) *Nonmaleficence* The concept of nonmaleficence is best embodied by the Latin phrase *primum non nocere* (“first do no harm”). To avoid doing harm has been a guiding principle of medical treatment since the advent of the Hippocratic oath. Medical researchers have both a moral and legal obligation to avoid “unjustified” harm to trial participants. Some harm may be justifiable provided that the benefits outweigh the negatives. All medical research must be assessed on the balanced probability of harm versus benefit according to the ethical principles of beneficence and nonmaleficence.

(d) *Justice* Justice requires that there be fair procedures and outcomes in the selection of research subjects. The burdens and benefits of research must be equally distributed to include individuals of both genders, different ages, and various racial and ethnic backgrounds, not just the easily available or vulnerable to facilitate trial recruitment. In the past researchers have targeted middle-aged white men for trials, avoiding recruitment of children and women of reproductive age. This produces an injustice as it creates an inequality in medical understanding of how a particular treatment may work (or not work) in children and women while robbing these

disadvantaged groups of the opportunity to benefit from new clinical trial treatments.

#### **24.2.4 HISTORICAL TRIGGERS FOR DEVELOPMENT OF CODES OF ETHICAL RESEARCH PRACTICE**

Clinical research using the established scientific method of hypothesis generation, observation, and experimentation has been conducted throughout the world for many centuries. However, only relatively recently have such medical experiments been placed under the scrutiny of ethical analysis and the nature of human experimentation limited by published ethical guidelines. Unfortunately many researchers have either been ignorant or intentionally subjugated these established ethical principles, often leading to disastrous consequences. Some of the best known and studied examples of human experimentation gone awry are outlined in the paragraphs below as examples of why clinical research requires enforceable ethical guidelines to protect research participants and society alike.

The Tuskegee experiment is an example of medical research that breaks almost every ethical principle [1]. In 1929 the U.S. Public Health Service commenced a study to examine the prevalence of syphilis among poor uneducated blacks and its possible mechanisms of treatment. The study confirmed that mass treatment of syphilis was feasible and desirable, but by 1932 funding for treatment was suspended due to lack of money created by the Great Depression. However, in the town with the highest prevalence of syphilis (Tuskegee, Alabama) it was decided that researchers would continue to monitor participants for the long-term complications of untreated syphilis, thereby ascertaining the natural history of the disease in African Americans [8, 9]. Participants were administered “therapy” which was known to be ineffective (mercurial ointment and spinal taps) and coerced into being involved in the research by being offered financial incentives such as provision of free medical “care” and payment of funeral expenses! The Tuskegee research participants were not told that they had syphilis but rather “bad blood” and they were not offered alternative medical treatment, despite penicillin becoming an established medical cure for syphilis as early as 1945. It was not until 1972, following considerable public outcry, that the U.S. Department of Health, Education and Welfare (DHHS) closed the study. This unfortunate experiment breaks several established ethical principles, including the right of participants to make an informed unbiased choice regarding their involvement in research (autonomy), the need to maximize individuals’ well-being while minimizing harm (beneficence, nonmaleficence), and justice [9].

Medical experiments conducted by Nazi doctors of the Dachau, Auschwitz, and Buchenwald concentration camps are one of the worst examples in history of a researchers’ subjugation of their ethical duties to research participants. These doctors were proponents of racial hygiene theory, which stated that people of non-Aryan background such as Jews were subhuman and therefore should not be afforded the same basic human rights as the Aryan people. As such, the Nazis believed that they were free to conduct experiments on concentration camp prisoners that can only be described as barbaric. These experiments included subjecting prisoners to extremes of temperature and pressure, ingestion of seawater, limb transplants

without medical need, injection of infectious agents to determine the effectiveness of new antibacterial drugs or vaccines, deliberate inflicting of skin wounds to provide an experimental model to assess new forms of wound therapy and exposure of subjects to high doses of radiation [1, 10]. In all of the experiments the aim was to gain knowledge that was helpful to the German military, not the treatment of underlying prisoner ailments. Furthermore, prisoners were not told what would happen to them, were not given the opportunity to refuse consent, and were not offered established medical treatment when complications arose. These gross violations of basic human rights and ethical principles by the Nazis during World War II were the impetus for the development of the first formal international guideline on the ethical conduct of medical research, the Nuremberg Code (1949).

There are many examples of researchers using vulnerable subjects for research to help facilitate recruitment [1]. In the 1950s New York University conducted experiments in which mentally retarded institutionalized children from Willowbrook State School were deliberately infected with hepatitis virus to enable study of the natural progression of the disease. These children's parents had unfair inducement applied by researchers to give their consent by offering to expedite admission of their children to the school if they agreed to be involved. Between 1960 and 1972 the Defense Atomic Support Agency funded a research program in which low-income, poorly educated principally black patients with cancer were administered massive doses of whole-body irradiation as a "treatment." Despite there being no scientific justification for treating a localized cancer with whole-body irradiation, this study was conducted so that the military could assess human tolerance to radiation exposure and effective methods of treatment. Finally there are multiple examples of prisoners being subjected to dangerous exposures of infectious agents and radiation in the interests of medical research. While many of these prisoners were informed of the nature of the experiments, they were coerced into involvement by incentives such as early release from prison or gifts of money and cigarettes. In the prison system, where an individual's liberties are severely limited, such coercion does not allow unbiased informed consent.

#### **24.2.5 DEVELOPMENT OF GUIDELINES FOR ETHICAL CONDUCT OF MEDICAL RESEARCH**

##### **24.2.5.1 Hippocratic Oath (Fourth Century BC)**

The Hippocratic oath is an oath taken by physicians governing the ethical practice of medicine. It is believed that the oath was written by Hippocrates, the father of medicine, in the fourth century BC. While the contents of the oath do not pertain directly to medical research, they do set down some valid ethical practices to which physicians conducting clinical trials should aspire. Two components of the oath have special relevance to the ethical practice of clinical research. First, Hippocrates outlines the need for nonmaleficence and beneficence in the phrase "I will prescribe regimes for the good of my patients according to my ability and my judgment and never do harm to anyone" and the decree to keep "myself far from all intentional ill-doing." Second, he speaks of the importance of educating the next generation of physicians. In the broadest sense, one can draw parallels between this requirement

for education and the ethical requirement for researchers to share knowledge gained during research with the general community.

#### 24.2.5.2 Nuremberg (1949)

Following the end of World War II trials of war criminals were conducted before the Nuremberg Military Tribunal in order to investigate and punish those individuals who committed crimes against humanity. Specifically, they were in response to the inhumane Nazi human experimentation carried out during the war by individuals such as Dr. Josef Mengele [2, 10]. During the trial several of the accused argued that their experiments differed little from prewar experiments and that there was no law that set the boundaries differentiating legal from illegal human experimentation. Dr. Leo Alexander then submitted to the tribunal a list of six points that defined what should be considered legitimate human medical research. These six points were adopted by the trial verdict and an additional four points were added—together making the 10-point Nuremberg Code governing ethical human experimentation [6]. The contents of the Nuremberg Code are outlined in Appendix A. In summary, the code outlines the need for ensuring participant autonomy (Articles 1 and 9), beneficence (Article 2), and nonmaleficence (Articles 3–8 and 10) during human experimentation.

While an excellent starting point in the development of guidelines to govern ethical human experimentation, the Nuremberg Code was lacking in several key areas. First, the code contained no guidelines concerning the ethical conduct of research on individuals who are unable to give informed consent (e.g., children, mentally impaired, and critically ill). Second, it totally ignored the need for maintaining participant confidentiality and the need for justice regarding individual's opportunity to engage in medical research. These deficiencies were later addressed in the Declaration of Helsinki [5].

#### 24.2.5.3 Declaration of Helsinki (1964)

The Declaration of Helsinki [5] was developed by the World Medical Association (WMA) as a set of ethical principles for physicians and other participants in medical research. It was originally adopted in 1964 in Helsinki, Finland, and has since undergone eight revisions, the latest significant revision occurring in 2000 (Appendix B). The declaration covers all of the major ethical protections outlined in the Nuremberg Code but also contains several important additions:

1. *Article 1* The declaration states that human material and identifiable human data require the same ethical protections given to individuals undergoing direct human experimentation. This means that researchers are not able to conduct experiments using human tissue/blood samples collected for a non-related purpose without the consent of the original research participant. Similarly, researchers are not able to use databases containing confidential medical details of individuals for the purposes of research without first gaining these individuals' informed consent.
2. *Articles 8 and 23–25* Here the declaration discusses restraints required for the ethical conduct of research on “vulnerable persons” such as children, the

mentally incompetent, and subjects in a dependent therapeutic doctor–patient relationship with the researcher.

3. *Article 9* The declaration states that the ethical protections set forward by the declaration cannot be reduced or eliminated by local legal or regulatory requirements but these protections should be considered universal worldwide.
4. *Article 12* Here the declaration states that due care for the environment and welfare of animals must be taken into consideration during the conduct of medical research.
5. *Article 13* There is an absolute requirement that all human research protocols should first be reviewed by an independent committee of relevant experts (ethical review committee) to ensure that the study design is scientifically robust and provides adequate protection of research participants.
6. *Article 21* This stresses the need for maintaining participant privacy and confidentiality.
7. *Article 27* Both authors and publishers of scientific journals have an obligation to honestly disclose the results of both positive and negative outcomes of human experimentation. Furthermore, any potential source of conflict of interest must be declared in all publications.
8. *Articles 29 and 30 and Associated Clarifications* Following public outcry concerning the use of a placebo in a U.S. Center for Disease Control study of the antiviral zidovudine to prevent perinatal transmission of HIV in the developing world, the declaration's provisions on acceptable "alternative care" were revised (2000). This revision held that developed-world standards of care should apply to the conduct of clinical trials in the developing world, irrespective of whether this standard of care is actually available to the public through the existing health system. While the current declaration does not expressly prohibit placebo-controlled studies, it does set out some significant limitations. Article 29 states that "the benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic, or therapeutic method exists." The declaration then goes on to state that it is acceptable to use a placebo in a research study where there is a proven alternative therapy provided that the condition being studied is a relatively minor one and the research participant will not suffer any irreversible harm and all research participants allocated to the placebo arm will later be offered the best available proven therapy at the conclusion of the study.

#### **24.2.5.4 National Research Act (1974) and Belmont Report (1979)**

Although the Nuremberg Code and Declaration of Helsinki provided excellent guidelines on what constituted the ethical practice of medical research, they did not have the power of legal mandated enforcement within individual countries. Starting in the United States, the Surgeon General (1966) and later the U.S. Food and Drug Administration (FDA) (1971) mandated prior peer review of all

human research protocols funded by the National Institutes of Health or regulated by the FDA. This in turn led to the development of the National Research Act (1974), which mandated that any government-funded medical research would first require review and a pass judgment on the acceptability of the proposed research by an independent IRB. Furthermore, the regulations set down rules which would govern the composition of these IRBs, such as a mixture of men and women, scientific and nonscientific members, as well as general community members. The composition of these boards was to ensure that they had the capacity to assess the scientific validity of the research proposal as well as that ethical principles such as distributive justice, participant safety, and autonomy were respected while blocking research with the potential for inciting moral outrage in the general community.

When the National Research Act was signed into law on the July 12, 1974, The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was formed. This commission was charged with developing guidelines that should be followed during all human medical experimentation. The results of nearly 4 years of deliberations by the commission were published in 1979 as the landmark Belmont Report [11]. As would be expected, the report focuses on the need to respect participant autonomy, the need to maximize good (beneficence), and the application of justice.

#### **24.2.5.5 CIOMS (1982)**

The Council for International Organizations and Medical Sciences (CIOMS) was formed in 1949 by the World Health Organization (WHO) and the United Nations Scientific and Cultural Organization (UNESCO) with the goal to facilitate and promote international activities in the field of the biomedical sciences. As part of this mandate, CIOMS undertook important work in the field of bioethics during the 1970s, culminating in the publication of the “International Ethical Guidelines for Biomedical Research Involving Human Subjects” in 1982. This work has since been updated in 1993 and 2002 and is available in print [12] or online via the CIOMS website (<http://www.cioms.ch/>; CIOMS 2002 guidelines). The CIOMS document consists of 21 guidelines governing the ethical conduct of human biomedical research. These guidelines are heavily based on those contained within the Declaration of Helsinki but also contain several important practical discussions on how best to implement ethical principles in the design and conduct of a research. For example, guideline 4 stresses that informed consent is a continuing process that should be conducted throughout the life of a study, not just an event at the commencement of a participant’s enrollment in a research study. The CIOMS document provides a very useful 26-point checklist that helps ensure that all the requirements of proper informed consent are met by a study [12]. Guideline 7 outlines in very practical terms what level of financial reimbursement is ethically acceptable for involvement in a trial and what would be considered unacceptable financial inducement. Appendix 1 of the CIOMS guidelines outlines the 48 individual points of discussion that need to be addressed by all research submission to a Human Research Ethics Committee/IRB to enable proper determination of the ethical merits of the proposed research.

#### **24.2.5.6 National Guidelines on Ethical Conduct of Human Research**

Most countries have their own guidelines governing what is ethically acceptable practice in the field of human experimentation. The Office of Human Research Protections, DHHS, publishes a summary of the individual regulations and legislation covering human research in 79 individual countries and two confederations (European Union and the Commonwealth of Independent States). This summary is updated regularly and can be located on the Office for Human Research Protections website [13]. While the legislation enacted in each country may differ, it should be stressed that no national ethical, legal, or regulatory requirement should be allowed to reduce or eliminate any of the protections for human subjects set forth in the Declaration of Helsinki (Article 9, 2000).

### **24.2.6 ETHICAL ISSUES IN DESIGN, CONDUCT, AND REPORTING OF MEDICAL RESEARCH**

The aim of this section is to make the reader aware of aspects of the ethical debate surrounding the design, conduct, and reporting of a clinical trial. Several issues which are discussed in previous chapters are not discussed in detail here. These include stopping a clinical trial (Chapter 20), the role of Data and Safety Monitoring Committees (DSMCs) and ethics committees (Chapter 8), and patient records and privacy (Chapter 15). It is further recognized that as the ethical debate is evolving, guidance documents and ethical codes are revised at regular intervals, and new legislative changes are under consideration. For example, at the time of this writing, the Declaration of Helsinki is being revised [5], an update of the CONSORT statement is being prepared [14], and federal legislation requiring disclosure of clinical trial results is being considered in the United States [15]. Therefore, where possible, we have provided current website addresses that direct the reader to the latest versions of the relevant documents (Table 1).

It is further noted that the ethical conduct of clinical trials extends beyond the study design, conduct, and reporting. Appropriate attention to the quality of manufacture of investigational drugs, validation of methods, and demonstration of stability underpins ethical evaluation of new drug candidates. Such considerations are now mandatory in most regulatory territories. In addition, when conducting non-clinical safety studies to support clinical trial programs, researchers must be aware of the applicable quality systems—Organisation for Economic Co-operation and Development (OECD) principles for good labor practices (GLP) [16]; GLP regulations, Code of Federal Regulations (CFR), Title 21, Part 58] [17]—and the Declaration of Helsinki, Article 12, which states that “the welfare of animals used for research must be respected” [5].

#### **24.2.6.1 Gold Standard: Randomized Clinical Trial**

A necessary, although not sufficient, condition for any experiment on human subjects is that the study is scientifically sound [18]. The principle of beneficence includes the requirement that the hypothesis being tested has scientific merit, that the design of the study adequately addresses the hypothesis, and the outcomes

**TABLE 1 Summary of Ethical Codes for Clinical Research—Web-Based Resources**

| Guidance/Ethical Code                                                                                                                                                                                              | URL or Literature Reference                                                                                                                                              |

of the study are valid. Beneficence further requires that investigators are competent to conduct the study and they seek to minimize the risks and maximize the benefits of the research [12]. The “gold standard” for determining the efficacy and safety of a new therapeutic intervention is the randomized controlled trial (RCT).

*Randomization* aims to eliminate systematic differences between treatment groups [19]. It removes any selection bias that may be introduced by those conducting the study and, ideally, balances confounding variables (some of which may be unknown) among the treatment groups, thus preventing “covariate imbalance” [20]. By diminishing the chance that baseline confounding variables differ among the treatment groups, the validity of conclusions relating the study outcomes to the intervention under investigation is enhanced. A more detailed discussion on randomization procedures is provided in Chapters 11 and 12.

*Blinding* involves the effective masking of both the investigational drug and control treatments (e.g., a placebo or comparator drug) in an attempt to ensure that all those involved in the study (i.e., trial participants and trial staff) do not alter their behavior in response to the knowledge of which treatment is being administered. In a “double-blind” trial, treatment allocation is unknown to the participant, investigator, sponsor, and trial staff, including those assessing outcome measures. Blinding thus aims to minimize potential bias in the management, treatment, and assessment of trial subjects that may otherwise occur if the treatments were known [19]. The term “single blind” refers to studies where one party (usually the subject) is blinded to treatment allocation.

The design of the RCT raises many complex ethical issues. For example, how can investigators be asked to suspend the principles of individualized patient care inherent in the Hippocratic oath and, blinded to prospective treatments, allow their patients to be randomized receive an experimental or control therapy? Further, can the use of placebo as a control be justified if currently available therapies are known to effectively treat the condition under investigation? How can a clinician condone trial-based medical procedures (e.g., the taking of biopsies) that have no therapeutic benefit for the patient? Indeed, should the roles of treating physician and clinical investigator be separated and filled by different individuals?

From the trial participant’s perspective, does an RCT—in requiring patients to delay knowledge of their treatment until the randomization code is broken—contravene the principle of autonomy that would allow individual patients to determine which treatment they receive?

Ethical frameworks for the conduct of a clinical trial, with reference to ethical codes, are briefly introduced in the following sections.

#### **24.2.6.2 Ethical Frameworks for Conduct of Clinical Trials**

The concept of uncertainty in outcome, or “equipoise,” has been invoked by many authors to resolve ethical considerations inherent in the conduct of an RCT. According to this paradigm, equipoise exists if the outcome of a trial is sufficiently uncertain such that an individual participating in the trial will not be disadvantaged; under these circumstances, enrollment in the trial is therefore considered “an equal bet in prospect” [21] and participants should not be harmed by random

allocation to a given treatment arm [22]. A trial in equipoise should, therefore, be acceptable to both Kantian and utilitarian philosophies [21], both of which seek to balance the duties and rights of the individual and society (see a brief description of each above). Thus, in the presence of true equipoise, individuals can, in theory, contribute to the wider medical knowledge at no cost to themselves [23]. The application of the concept of equipoise does, however, raise several questions. For example:

1. *From whose point of view should equipoise exist?* Options include the individual investigators, the clinical research community (“clinical equipoise,” after Freedman [24]), or the prospective patient. Many commentators would consider equipoise as essentially a characteristic of the informed, competent patient [21]. Importantly, a trial that may be considered to be in equipoise for one trial participant may not be for another [23].

2. *What degree of equipoise should exist?* Any given outcome in a clinical study is rarely an “even bet.” As a therapeutic candidate moves through the development process, a significant body of knowledge accrues, and it is unlikely sponsors would continue development unless previous nonclinical and clinical studies were favorable. Moreover, most published industry-funded trials report a positive outcome in favor of the drug candidate under investigation [22, 25]. This finding is not explained by publication bias alone and suggests that, in reality, very few industry-sponsored trials are in true equipoise. The question then becomes: At what point of “equipoise imbalance” does a trial become unethical? One study found that 50% of subjects perceived a trial to be unethical when 70% of experts favored one arm of the study; if this figure rose to 80% of experts, less than 3% of subjects thought a trial is justifiable [26].

3. *At what point is a decision regarding equipoise made?* The key decision faced by most trial participants is whether or not to consent to randomization. Equipoise in this context would mean the prospective participant perceives that agreeing to randomization gives them an equal chance of a good outcome as not participating in the trial [27].

The concept of equipoise has many critics. Some consider that the term lacks consistency, reality, and utility [28], while others maintain that it disregards the autonomy of the subject [22] and is fundamentally incoherent [29, 30]. Alternative ethical frameworks for the conduct of clinical trials have been proposed, including the “positive expected outcomes” [22]. Under this model, the trial participant would base a decision to participate in a given study on the pooled average of expected outcomes in all arms of the trial before randomization. In this context, some authors have noted that many trial participants achieve above average clinical outcomes even though the trial may have reported a negative result or the patient received a control treatment [31, 32]. Several reasons for this observation have been cited, including the cyclical nature of the disease being studied [20], the contention that clinicians who recruit to trials tend to be better clinicians [31], and the possibility that the strict protocol-driven procedures (often overseen by expert committees) provide a superior standard of care. It is emphasized, however, that improved medical care should not be offered as an inducement to participate in a clinical trial.

### 24.2.6.3 Ethical Issues in Clinical Trial Design: Study Power and Control Groups

**Study Power** The social value and scientific validity of a study are critical to the ethical conduct of clinical research. Exposure of trial participants to even minor risks cannot be justified if the study is poorly conducted or is of little scientific merit. It is often argued in this context that underpowered trials that yield outcomes that are not clear-cut have the potential to mislead and are therefore unethical. In contrast, others would maintain that, if equipoise truly exists, then there is no ethical objection per se to participating in an underpowered study [21]; the patient does not “lose out in prospect.” While this contention would seem to contravene a central tenet of ethical clinical research that demands validity and scientific rigor, there are examples where an underpowered trial may be better than no trial at all or where an underpowered trial represents a key step in the drug development process. These include studies on rare conditions, where alternative sources of data may be used to support the trial results, and early-phase studies that aim to determine estimates of efficacy and safety [33]. The authors point out that, in both cases, prospective participants should be informed of how the trial data may be used (e.g., inclusion in a subsequent meta-analysis) and that the trial may only indirectly contribute to health care benefits.

**Placebo-Controlled Trials** Significant ethical concern and debate surround the use of placebo treatments as a control in a clinical study. Some authors have invoked the concept of equipoise to argue that, if an effective treatment is available, then placebo-controlled trials are unethical because equipoise cannot exist [21]. In contrast, others have argued that methodologically sound placebo-controlled trials, where participants are not exposed to excessive risks of harm, are ethical and that equipoise in this context does not provide an adequate ethical framework [30, 34].

Article 29 of the Declaration of Helsinki (issued in October 2000) states: “The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists” [5]. This article was initially interpreted by some, in its strictest sense, to mean that the use of placebo controls was ruled out whenever an effective therapy was available. In 2002, the WMA added a note of clarification to Article 29, reaffirming “its position that extreme care must be taken in making use of a placebo-controlled trial and that in general this methodology should only be used in the absence of existing proven therapy. However, a placebo-controlled trial may be ethically acceptable, even if proven therapy is available, under the following circumstances:

- Where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic or therapeutic method; or
- Where a prophylactic, diagnostic or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm” [5].

The CIOMs guideline 11 [12] elaborates on these points, further stating that a placebo control can be used “when withholding an established effective intervention would expose subjects to, at most, temporary discomfort or delay in relief of symptoms.” Examples cited include a slightly raised blood pressure or serum cholesterol, common headache, or treatments for baldness or common cold.

In relation to the term “compelling and scientifically sound methodological reasons,” it has been argued that the use of “active controls” does pose methodological concerns [35, 36]. Such views would hold that a noninferiority or equivalence study showing no difference between a study drug and active comparator could be interpreted to mean that both were effective, both were ineffective, or the trial (for whatever reason) was simply not able to detect a difference between them. In this regard it has been noted that, in several areas of medicine, not all “known” active treatments will reliably prove to be superior to a placebo in every study. This particularly applies to analgesics, antidepressants, antianxiety drugs, antihypertensives, antiangina drugs, anti-heart failure drugs, antihistamines, and drugs for asthma prophylaxis [35]. Moreover, trials designed to demonstrate that a new drug and an active control possess similar efficacy do not provide sponsors and investigators with the same “built-in incentives for trial excellence” [19] as studies designed to show a treatment difference. It is relatively easy for poorly designed and conducted studies to fail to show a difference between treatment arms. Thus, for some therapeutic areas, it is widely considered that reliable evidence of efficacy can only be obtained by superiority trials or the internal validation of active-comparator equivalence or noninferiority trials using a placebo. In the former case, the requirement to demonstrate superior efficacy over an authorized treatment may be considered too restrictive. Moreover, an active comparator trial may expose patients to risk and fail to deliver a clear-cut answer.

Thus, if invoking this clause to justify inclusion of a placebo control, the possibility of “additional risk of serious and irreversible harm,” including the period of time a placebo treatment may be administered, needs to be carefully considered. All other ethical safeguards should apply to placebo-controlled trials including ethical and scientific review, full disclosure and informed consent, and the right to withdraw at any time. Additional strategies to minimize the risk of participants include the incorporation of predefined “stop” rules in the study protocol and the monitoring of data collected during the study by a Data Safety and Monitoring Board (Chapter 20). Where appropriate, interim analyses should be undertaken to ensure trial participants are not exposed to the placebo for any longer than necessary or to assess the likelihood that the trial will deliver a clear-cut answer. If, in the latter case, this probability is low, the trial should be terminated. Study designs that seek to address the ethical and practical issues associated with the conduct of placebo-controlled trials are described in the International Conference on Harmonisation (ICH) guideline “Choice of Control Group and Related Issues in Clinical Trials” [19], including “early escape” and “randomized withdrawal” designs.

#### **24.2.6.4 Informed Consent**

Informed consent is a central tenet of clinical research. It is fundamental to all codes of ethical clinical research. The first principle of the Nuremberg Code states that “the voluntary consent of the human subject is absolutely essential” [6]. The

Declaration of Helsinki (Articles 20–26) clearly addresses the principles of informed consent, including reference to subjects who may have a dependent relationship with their physician, subjects who are legally incompetent or physically and mentally incapable of giving consent, and subjects with a condition that renders them unable to give informed consent. In obtaining consent, clinical researchers should adhere to the requirements outlined in the ICH “Guideline for Good Clinical Practice” (Section 4.8) [37], the CIOMS guidelines 5 and 6 [12], and any additional codes published by regulatory authorities (e.g., 21 CFR 50) [38].

Consent must be voluntary and based on sufficient information about the proposed study and the implications of participation to allow potential trial participants to make an autonomous decision whether or not to enroll. The Belmont report states that “no undisclosed risks may be more than minimal” [11]. Importantly, subjects must have realistic expectations as to the study outcomes, including any potential benefit to both the individual participant and society. The language used on the informed consent documents should be “as non-technical as practical and should be understandable to the subject or the subject’s legally acceptable representative and the impartial witness, where applicable” [37]. It is important that the informed consent process continue throughout the course of the study [12].

The source of funding, financial relationships, and financial interests of the parties involved should be disclosed in line with the recommendations in the FDA guidance “Financial Relationships and Interests in Research Involving Human Subjects: Guidance for Human Subject Protection” [39] or local institutional policies. This FDA guidance further recommends that, if a potential or actual financial conflict of interest exists that could “influence the tone presentation or type of information presented during the consent process,” then a third party who has no conflict of interest should be involved in the consent process.

**Coercion and Inducement** Coercion and undue inducement are ethically unacceptable and can invalidate consent. While the issue of patient dependence is addressed in Article 23 of the Declaration of Helsinki, researchers should be alert to the fact that more subtle forms of coercion (or intimidation) can result from the position of authority held by an investigating clinician. Indeed, in one study of patients consenting to a major surgical procedure, consent was based more on the trust rather than an assessment of information provided to them [40]. All subjects should be assured that a decision whether or not to participate in the proposed clinical trial will not affect their medical care [12].

It is generally accepted that, for studies that aim to recruit patients into later phases (phases II and III trials), financial reimbursement should only compensate for direct costs of participation (such as travel to and from the clinic). Exceptions to this position may be considered in situations where administration or outcome-testing schedules cause significant inconvenience or when little or no benefit is expected to result from trial participation.

In the case of phase I trials, bioequivalence or pharmacokinetic studies, where participants receive no medical treatment that may be of benefit, a payment above out-of-pocket costs as compensation for inconvenience can be offered. However, such a payment should not be so great as to encourage participants to expose themselves to excessive risk. Moreover, payment contingent on completion of the trial

may prevent participants from leaving a study against their better judgment and could be deemed to constitute undue inducement.

Reasons for leaving a trial should be documented. In cases of withdrawal due to adverse reactions to the study drug, trial subjects should be encouraged to fully articulate all reasons for leaving the trial, and full payment should be offered. Subjects who withdraw due to personal reasons should be considered for a prorated payment. Willful noncompliance on the part of a participant, resulting in expulsion from the study, may be grounds for withholding all payment.

Any incentives offered to trial participants must be reviewed by an ethics committee before recruitment activities commence (see the Declaration of Helsinki, Article 13).

One interpretation of inducement deserves further comment. Although the benefits of participation in clinical trials have been discussed by several authors [20, 31, 32], the prospect of improved medical care cannot be offered as inducement to participate in a trial. However, application of this ethical principle in the context of (for example) teaching hospitals that service populations who may not have access to or cannot afford ongoing quality medical care presents several ethical challenges [18]. Does the prospect of access to medical care (including, e.g., transport to and from the clinic) constitute undue inducement? Does the recruitment of such individuals raise issues of distributive justice that would require the burdens and benefits of clinical research to be evenly distributed (see CIOMs guideline 12 [12])? Does participation in a trial by those seeking access to treatments not otherwise available to them constitute exploitation? In considering these issues, clinical researchers should be cognizant of the principles of justice implicit in relevant articles in the Declaration of Helsinki. In particular, Article 19 states: "Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research." It is noted here that the definition of "populations" is open to interpretation, and there are many clinical research situations where the intended benefit is directed at the wider community. Further, Article 22 states: "The subject should be informed of the right to abstain from participation in the study or to withdraw consent to participate at any time without reprisal." Lastly, in relation to posttrial access of beneficial medicines, in its clarification to Article 30 of the Declaration of Helsinki, the WMA "hereby reaffirms its position that is necessary during the study planning process to identify post-trial access by study participants to prophylactic, diagnostic and therapeutic procedures identified as beneficial in the study or access to other appropriate care." This article raises several ethical and practical issues; importantly, posttrial access arrangements should be agreed to prior to commencing the study and such arrangements require prior review by an ethics committee. For a discussion of the wider ethical issues of research in populations or communities with limited resources, the reader is referred to CIOMS guidelines 10 and 11 [12].

**Competence** Consent should be given by competent individuals with the capacity to understand the information provided to them. It is recognized that conditions for informed consent may vary with the nature of the study and the cultural and religious sensitivities of the participants and their communities. The Belmont report states: "it is necessary to adapt the presentation of the information to the subject's capacities" [11]. It is important that the ethical review process (see Chapter 11)

provides a further level of protection to the informed consent process. The ICH “Guideline for Good Clinical Practice” [37] requires that, before initiating a trial, the investigator must have obtained “written approval of the informed consent form and any other written information to be provided to subjects.” Further, consent by a subject alone is not reason enough to justify participation in the trial. The Declaration of Helsinki (Article 15) states: “The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent.”

Despite the best attempts of sponsors and investigators to clearly present information about a clinical trial to potential participants, several studies have shown that some degree of communication difficulty is inevitable [21]. For example, the concept of randomization and its justification may not be fully grasped by all individuals [29, 41], and patients who have recently received a diagnosis of a life-threatening disease may not be in a psychological state that enables them to absorb all the information provided to them [42]. In this context, provision of information should not be conducted in a manner that may cause distress; “respect for persons” does not only equate with autonomy [11, 43]. The degree of protection provided by investigators and IRB/Institutional Ethics Committees (IECs) should take into account both a patient’s capacity for self-determination and the risk of harm and degree of benefit that participation in a clinical trial may entail.

Finally, all investigators and sponsors should carefully review their patient information sheets and informed consent forms before initiating their study. Are all risks adequately disclosed? Is the language in any way coercive? Are the chances of receiving a placebo treatment or active therapy fully spelled out? Are financial conflicts of interest disclosed? On a more operational note, Good Clinical Practice (GCP) audits commonly reveal shortcomings in the informed consent process, including use of outdated forms or forms that have not been approved by the relevant ethics committee, timing of signing of the informed consent form in relation to commencement of trial procedures, and forms not appropriately signed or dated by the subject or witness.

#### **24.2.6.5 Transparent Clinical Trial Culture: Financial Disclosure, Trial Registration, and Reporting of Results**

Several related initiatives that seek to increase the transparency of the clinical trials process have arisen in response to (1) concerns that financial interests in clinical research may be placing trial participants at risk [44]; (2) the delayed disclosure or nondisclosure of trial results and publication bias [45], including selective publication [46], selective reporting [47], and inadequate reporting [48]; and (3) inappropriate authorship and ghost writing of publications [49]. There is little doubt these concerns have significant ethical implications and momentum is building on several fronts to address them.

**Financial Disclosure** Clinical researchers should be aware of and adhere to the ethical codes and guidance documents relevant to both their regulatory territories and institutional affiliations. The Declaration of Helsinki (Article 13) states: “The researcher should also submit to the (ethical review) committee, for review, information regarding the funding, sponsors, institutional affiliations, other potential conflicts of interest and incentives for subjects.”

The document “Financial Relationships and Interests in Research Involving Human Subjects: Guidance for Human Subject Protection” was released by the DHHS in 2004 to help research institutions, IRBs, and investigators identify potential and actual conflicts of interest and suggest means to eliminate or manage such conflicts with the interests with the welfare of the trial subjects in mind. This guidance document, which is based on the ethical principles described in the Belmont report (respect for persons, beneficence, and justice), poses several questions that IRB members, investigators, and researchers should consider when determining whether or not a conflict of interest exists; it then suggests several “actions to consider” in each case. Many research institutions have adopted these principles.

It should be noted that some consider that the requirement for investigators to disclose any actual or potential conflicts of interest on the informed consent documents does not go far enough to adequately protect research subjects. Indeed, there is a lack of data on how potential clinical trial participants use disclosures in their decision-making process [44]. Moreover, disclosure alone, without further safeguards, may even confer a “moral license to exaggerate” on the part of investigators that could potentially increase any bias in the study that exists as a result of a conflict of interest [43]. Some therefore propose that additional mechanisms must be found to protect subjects; in many cases, the only answer would seem to be to encourage investigators conducting a trial to divest any possible conflicts of interest.

**Registration of Clinical Trials** The participation of any subject in a clinical trial that does not contribute to the medical knowledge of the wider research community contravenes the obligations of clinical researchers. Nondisclosure or delayed disclosure of trial results may mean that the welfare and safety of trial participants could be adversely affected by subsequent clinical trial designs and ethical review processes that do not build on prior research knowledge. On a wider scale, failure to consider all available data may misdirect those responsible for health policy decisions and resource allocation. The Declaration of Helsinki includes several statements relevant to these considerations:

*Article 16* “Every medical research project involving human subjects should be preceded by careful assessment of predictable risks and burdens in comparison with foreseeable benefits to the subject or to others.

The design of all studies should be publicly available.”

*Article 11* “Medical research involving human subjects must ... be based on a thorough knowledge of the scientific literature, other relevant sources of information. ...”

*Article 19* “Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.”

Registration of clinical trials on publicly available databases represents a key mechanism to promote transparency, knowledge sharing, and the timely and accurate disclosure of clinical information. A global movement for registration of clinical trials is gaining momentum, driven by bodies such as the Ottawa Group [50, 51], WHO [52], and the International Committee of Medical Journal Editors (ICJME)

[53, 54] (see below) and the trial registries. Many trial registries currently exist, including the International Standard Randomized Controlled Trial Number (ISRCTN) register and ClinicalTrials.gov, which is administered by the National Library of Medicine. The WHO International Clinical Trials Registry Platform (ICTRP) project aims to set international standards for trial registration, ensure a minimum set of results are reported, and provide global trial identification and search capability. The ICJME policy, requiring trial registration as a prerequisite to publication, has resulted in a marked increase in the number of trials registered [15, 54].

However, registration of trial information does not currently require that trial outcomes will be disclosed and there are no international standards for reporting of clinical trial results [55]. In response, many now advocate systems to facilitate full public disclosure of published and unpublished trial results. Significantly, in the United States, both federal and state legislation are addressing such concerns. In Maine, a law that came into effect in October 2005 requires companies wishing to advertise prescription drugs to disclose trial results, including adverse effects. In addition, federal legislation currently under consideration will require reporting of results in government databases [15]. For example, the Fair Access to Clinical Trial Act of 2005 would see the ClinicalTrials.gov database expanding to include a clinical trials registry and clinical trials results.

Significant challenges to the registration of clinical trials and disclosure of results lie ahead, including agreement between the pharmaceutical industry and other stakeholders as to the minimal data set for trial registration [51], validation of the registry data, prevention of duplicate registrations, and defining and naming of interventions and the format of reporting and validation of results [15]. Nevertheless, the climate is changing. As noted by a recent ICMJE editorial, “three years ago trial registration was the exception; now it is the rule” [54].

**Publication of Clinical Trial Results** “Both authors and publishers have ethical obligations. In publication of the results of research, the investigators are obliged to preserve the accuracy of the results. Negative as well as positive results should be published or otherwise publicly available” (Declaration of Helsinki, Article 29).

In addition to the registration of trial information and initiatives under way to promote the public disclosure of trial results, several important policy and guidance documents have been developed by professional bodies to promote the quality of reporting of clinical trials in biomedical journals.

**International Committee of Medical Journal Editors** Three policy initiatives of the ICMJE, a committee representing 12 member biomedical journals, are discussed below. These include the requirement to register trials as a prerequisite to publication and requirements for authorship and disclosure of any conflicts of interest on published manuscripts. Additional information can be found in the Uniform Requirements for Manuscripts (URM) Submitted to Biomedical Journals, a set of ethical principles and recommendations developed by the ICJME to promote the accurate reporting of biomedical studies [56]. These guidelines have been adopted by many journals.

1. *Requirement to Register Trial: Prerequisite to Publication* In 2005 the ICMJE established a policy that requires information about trial design to be prospectively registered in recognized databases as a prerequisite to publication in member journals as follows [53]:

The ICMJE member journals will require, as a condition of consideration for publication, registration in a public trials registry. Trials must register at or before the onset of patient enrollment. This policy applies to any clinical trial starting enrollment after July 1, 2005. For trials that began enrollment prior to this date, the ICMJE member journals will require registration by September 13, 2005, before considering the trial for publication.

A marked increase in the number of registrations lodged with the five recognized registries was seen around the time of implementation of the policy. The largest existing registry, ClinicalTrials.gov, which registered around 30 trials per week before September 2005, received over 200 registrations per week after September 2005 [15]. The number of registrations continued to grow as many other biomedical journals embraced this policy.

Although early-phase studies (including phase 1 trials and pharmacokinetic studies) were initially excluded from this requirement [53], the ICMJE has recently adopted the WHO definition of clinical trials as “any research study that prospectively assigns human participants or groups of humans to one or more health-related interventions to evaluate the effects on health outcomes” [54]. Thus, as of July 1, 2008, all early-phase studies will require, as prerequisite to their publication, registration on a recognized database. Importantly, in addition to the five previously recognized registries, the ICMJE will now accept registration on primary registries participating in the WHO ICTRP project [54].

2. *Requirements for Authorship* The URM lists three requirements for authorship as follows [56]:

- Substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data
- Drafting the article or revising it critically for important intellectual content
- Final approval of the version to be published

Authors should meet all these conditions and no authors who fulfill these criteria should be omitted. The URM further states that “acquisition of funding, collection of data, or general supervision of the research group, alone, does not justify authorship.” While these guidelines have been widely adopted, the requirements of individual journals should be observed.

3. *Conflict of Interest* In-line with the Declaration of Helsinki (Article 27), which states, “Sources of funding, institutional affiliations and any possible conflicts of interest should be declared in the publication,” the URM requires: “When authors submit a manuscript, whether an article or a letter, they are responsible for disclosing all financial and personal relationships that might bias their work. To prevent ambiguity, authors must state explicitly whether potential conflicts do or do not exist.” Again, individual journals often have their own conflict of interest policies.

*Good Publication Practice (GPP) for Pharmaceutical Companies* The GPP guidelines set forth principles that aim to increase the transparency of the processes

involved in the publication of industry-sponsored trials, reduce publication bias, and clarify the roles of the sponsor company and academic investigators [57, 58]. The guideline includes topics such as publication standards, premature publication, duplicate publication, authorship, and the role of professional medical writers.

A further comment on the role of professional medical writers is made here. Ghost writing occurs when a professional writer controls the content of the manuscript and discloses neither their involvement nor their funding source. This is ethically unacceptable. However, working with a professional medical writer should pose no ethical concerns provided that (1) the medical writing assistance is acknowledged and (2) their source of funding is disclosed [59]. Throughout the writing of the manuscript, authors should maintain responsibility and control for the content of the publication, including key messages and data to be presented.

*CONSORT (Consolidated Standards of Reporting Trials) Statement* The CONSORT group (which comprises trialists, methodologists, and medical journal editors [60]) has developed several initiatives to improve the reporting of randomized clinical trials, including the CONSORT statement. The CONSORT statement is an evolving guideline that was originally published in 1996 [61] and revised in 2001 [48]. Following a meeting of the CONSORT group in January 2007, a further update of the CONSORT statement is due for release. The latest versions of all CONSORT documents can be found on the CONSORT group website [60].

In its current form, the CONSORT statement includes a 22-item checklist and flow diagram that is intended to improve the quality of the writing and assist in the review and evaluation of RCT reports. In particular, the checklist items encourage transparency in the reporting of the trial methods and results, which together account for 17 of the 22 items. The flow diagram depicts the number of participants progressing through the enrollment, intervention allocation, follow-up, and data analysis stages of a clinical trial, allowing the reader to evaluate the basis of any analysis undertaken. Although the main CONSORT statement is directed at two-group parallel RCTs, extensions to the statement address alternative trial designs, including cluster trials [62] and noninferiority and equivalence randomized trials [63]. A checklist of items that should be included in conference or journal abstracts is due for publication in 2007 [60]. It is highly recommended that the requirements of the CONSORT statement be considered early in the trial design process.

## 24.2.7 ETHICALLY CHALLENGING SCENARIOS IN CLINICAL RESEARCH

### 24.2.7.1 Children

Children, by virtue of their developmental and cognitive abilities, are a vulnerable population in relation to research participation. The Willowbrook Hepatitis Study [2] and many other similar questionable pediatric research studies have shown us that unscrupulous researchers have resorted to the use of children in research trials because they were seen as easy to recruit and manipulate. With the advent of the Nuremberg Code, which required informed consent, research in children declined because it was seen as almost impossible to get fully informed consent from a child of limited cognitive ability. For this reason and the fact that pharmaceutical manu-

facturers saw pediatric markets as too small to warrant expensive pediatric clinical trials, the majority of medications in clinical use today have not been properly tested in children but are being used “off label.” This in itself is a major ethical dilemma as several important differences in disease pathophysiology, pharmacokinetics, pharmacodynamics, and adverse drug reactions occur between children and adults. For example, the effective dose of a single application of an asthma nebulizer will be higher in an adult with effective hand/breathing coordination than a relatively uncoordinated small child. The ability of diazepam to cause sedation in adults but agitation in some children is an example of the wildly varying physiological responses to a drug. The absence of adequate studies in the pediatric population hinders the effective provision of the medical care of children. As such, there has been a recent push by U.S. and European regulators to require drug manufacturers to assess the safety and effectiveness of medications in pediatric patients when pediatric use is anticipated [64, 65]. The U.S. Best Pharmaceuticals for Children Act—2002 creates financial incentives for pharmaceutical companies to engage in pediatric research by allowing a 6-month extension to their exclusive patent protection and funding for research of drugs that no longer have patent protection.

While distributive justice mandates that research should be conducted on children to enhance their health care, there are some instances when it is absolutely inappropriate to conduct research on children [66]. It is ethically appropriate to exclude children from research when:

- (a) The research topic is irrelevant to children (e.g., ischemic heart disease, alzheimer’s disease).
- (b) Existing data in adults are sufficient to judge risks in children.
- (c) Local laws or regulations bar inclusion of children in this type of research.
- (d) A nontherapeutic study which places a child at greater than small increase in minimal risk. Minimal risk is defined as a risk that is “greater than those already encountered in daily life or during the performance of routine physical or psychological examinations or tests.” The FDA, DHHS, and National Institutes of Health (NIH) have produced guidelines on categories of risk in pediatric research and the associated approval requirements [66]. While the degree of risk associated with “routine life” is open to varying interpretations by individual IRBs, it would generally be considered unethical to expose healthy children to any material risk of a serious adverse outcome, such as a phase I study of a new class of drug.

Pediatric research raises two potential dilemmas above and beyond the ethical dilemmas routinely seen in adult research [65–67]:

- (a) *Informed Consent* Informed consent, a process where research participants are given sufficient information about a study to allow them to determine if it the risks and benefits warrant their own involvement, is not possible for a child with limited cognitive powers below the legal age of “consent.” Pediatric research therefore requires a two-part consent process—parental permission and the child’s assent. Central to the requirement of parental permission is the assumption that a loving, protective relationship exists between the

parent/guardian and the child. This assumption has two weaknesses. First, the theologian Paul Ramsey [68] states that a parent does not have the moral authority to permit a child to be put at risk of harm in an experiment from which the child could not benefit medically as a child is not a piece of property but an autonomous individual. Second, in dysfunctional relationships the parents may not always have the child's best welfare at hand. Therefore, if the researcher has any suspicion of a dysfunctional relationship between child and parent, they should defer any decisions concerning that child's participation to an independent IRB. After a parent has given permission for their child to be involved in research, the child's assent must be sought. The child should be given a simple explanation about why the research is being conducted and what procedures and discomfort may occur if they are to be involved. Researchers also need to define risks with the child's perspective in mind, not that of an adult. For example, separation from parents and unfamiliar surroundings may be considered a risk from the perspective of a child but not an adult. Assent should be sought apart from the parents' direct influence and the child must be informed that it is their right to refuse involvement. While childhood assent is always preferable, there are several instances where it is not mandated. For example, assent is not required if the child's capacity to understand the research is limited (intellectual age of less than 7 years, American Academy of Pediatrics) or the potential direct benefit to the health of the child is high and only available through direct participation in the research (e.g., new chemotherapy for a childhood cancer). Apart from these limitations, failure to obtain a child's assent overrides a parent's permission and prohibits that child's involvement in research.

- (b) *Payment for Research Participation* Payment to pediatric research participants becomes particularly problematic because of the child's vulnerability and dependence on their parents as the primary decision makers. Poor families are particularly vulnerable to monetary rewards, and therefore offering large financial incentives may create unnecessary coercion by the parents for their children to participate in research. Only small token gestures of appreciation or reimbursement of direct costs of involvement should be made to ensure payment is not the reason parents are enrolling their children in the research. Furthermore, incentives given to children should not be excessive and, according to American Academy of Paediatrics guidelines [69], should only be revealed after enrollment so that the child's participation is voluntary. This however is contrary to usual informed consent guidelines where incentives should be discussed before enrollment. A reasonable compromise may be to mention in the consent process that a gift will be given to participants without outlining its exact nature.

#### **24.2.7.2 Mentally Impaired**

Over the last 50 years very effective pharmacological treatments for mental disorders such as depression, psychosis, bipolar disorder, and obsessive-compulsive disorder have seen the transition of mental health care from institutions to the general community, resulting in huge benefits to patients and society in general. Without research, none of these life-changing benefits would have materialized.

Guideline 15 of the International Ethical Guidelines for Biomedical Research Involving Human Subjects [12] states that research on mentally impaired individuals is permissible provided that the purpose of the research is to obtain knowledge relevant to the particular health needs of the mentally impaired and that the research cannot be equally well carried out on persons with full mental capacity.

According to Michels [70] the conduct of clinical research in mentally ill patients raises three key ethical questions. Are mentally ill subjects especially vulnerable to exploitation? Are they competent to give informed consent? Are psychiatric research methods particularly dangerous? Following the suicide of a patient with schizophrenia after being asked to cease their antipsychotic medication in the “wash out” period of a clinical trial, regulators have been struggling with the ethical dilemma of whether mentally ill patients should be allowed to participate in research. The U.S. National Bioethics Advisory Commission (NBAC) and DHHS have both published guidelines regarding the ethical conduct of clinical research in mentally ill patients [71, 72]. A summary and discussion of these recommendations are presented below:

- (a) *Impaired Capacity* According to the NBAC, mental capacity to consent to research requires that the subject understand the difference between treatment and research, the nature of the research being conducted, its risks and benefits, available alternatives, and the fact that he or she is making a decision and that this decision can be changed. The subject must not be swayed by a pathological affective state, a false belief, or a dependent relationship that might interfere with the decision or his or her autonomy and must be capable of making a stable, reasoned choice and communicating it. It should be noted that merely having a mental illness does not mean that an individual’s mental capacity to give informed consent is impaired. Different mental illnesses have varying effects on a person’s decision-making capacity. Furthermore, illnesses such as schizophrenia can produce fluctuating levels of capacity as an individual passes through stages of good and bad mental health. It is therefore advisable that researchers carefully consider the timing of recruitment of participants into research studies to avoid periods of heightened vulnerability due to acute mental illness. Furthermore, while not yet mandated, it may be preferable to get an independent expert in mental health to assess a potential research subject’s capacity to give informed consent, especially if this research places a participant at more than minimal risk. Finally, as informed consent is a continual process, a research participant’s capacity to consent should be continually monitored throughout the entire life of the study, preferably by an independent monitor.
- (b) *IRB Provisions* Under U.S. regulations, IRBs that regularly review research involving vulnerable persons should have one or more individuals on that IRB who are expert within the field. In the area of mental health research it has been suggested that an expert in the area of mental health research and an individual from a relevant mental health support group would provide the best assessment of research protocols and therefore protection of research participants.
- (c) *Surrogate Permission* Where permitted by law, individuals with impaired capacity may have a family member or other legally authorized representa-

tive serve as a surrogate for research decisions. Surrogates should be informed of the risks, benefits, and alternatives to the research when they are providing permission. The surrogate should be educated that it is their duty to first act in a manner that reflected the views of the mentally incapacitated individual while they were decisionally capable (substituted judgment). If the values of the individual are unknown, a “best interest” standard should be used. The autonomy of the patient should be respected and therefore their assent to participation in research should be obtained whenever possible. Their right to withdraw from research should be respected unless the research treatment may be in the best interests of the mentally incapacitated patient and not available outside of a research setting.

#### **24.2.7.3 Women and Pregnancy**

Prior to the 1990s women were systematically excluded from participating in research studies primarily because of the fear that unrecognized pregnancy might place the early embryo at risk, increasing liability risk for researchers. Such a policy of exclusion is not just since it leads to an unequal knowledge base regarding the correct use of medications in the male and female population, potentially reducing the quality of clinical care provided to women. Differences in body composition (fat to muscle ratio), hormone fluctuations during the menstrual cycle, and changes in physiology specific to pregnancy make it highly likely that significant differences in pharmacokinetics and pharmacodynamics exist between the two sexes, therefore mandating more balance research protocols [73].

Guideline 16 of CIOMS International Ethical Guidelines [12] states that the potential for becoming pregnant during a study should not in itself be used as a reason for precluding or limiting participation. A paternalistic approach where an investigator, sponsor, or IRB limits a woman’s capacity to be involved in research because of a potential risk to the fetus infringes a woman’s autonomy. McCullough [74] argues that a previsible fetus does not have the moral or legal status of an autonomous individual and as such a woman should have the absolute right to make an autonomous decision concerning her own involvement in potentially harmful research without regard for the well-being of a nonviable fetus. However, in order to sensibly minimize risk to a potential unborn child, ethical guidelines mandate two precautions when conducting research in women of reproductive age [75]. First, research participants should be screened for pregnancy with sensitive and reliable pregnancy tests before enrolment if their participation in the research poses more than a minimal risk to the fetus or if being pregnant may materially increase their own risk during the conduct of the study. Second, researchers should guarantee access to effective contraceptive methods before enrollment in research. Research protocols should not mandate certain types of contraceptive use (e.g., IUCD, contraceptive pill) and respect the women’s autonomy to choose a method, including abstinence, according to her own needs and values.

Clinical research on pregnant women carrying a potentially viable fetus (post 23 weeks gestation) is a larger ethical dilemma as here the fetus is an individual by virtue of its ability to survive *ex utero*. A general prohibition of termination of pregnancy beyond the period of potential viability provides legal support for this moral concept that a fetus’s own health must be considered when conducting research

on women in the later stages of pregnancy. McCullough [74] outlines four criteria for the ethical conduct of phases I–II studies in pregnant women:

- (a) The medication should be reliably predicted to alter the course of pregnant women's condition based on prior animal and human studies.
- (b) Previous animal and/or human studies have documented no deaths or serious or irreversible injury to pregnant women that was caused by the medication.
- (c) Previous animal and/or human studies have documented no deaths or serious or irreversible injury to the fetus that was caused by the medication.
- (d) Previous animal and/or human studies have reported no or only a very low risk of less serious injury to the fetus that was caused by the medication.

Pregnant women should be provided with adequate information regarding the known benefits and risks of research to their own health and that of the fetus to ensure adequate informed consent. Appropriate follow-up of health outcomes of children exposed to an investigational agent during pregnancy should also be arranged to confirm that the investigational agent is not harmful to the fetus.

Consent of a pregnant woman alone is usually sufficient for most research which may have an impact on the fetus. In the United States 45 CFR 46 states that “when research holds out the prospect of direct benefit solely to the fetus then the consent of the pregnant woman and the father should be obtained.” However, international guidelines such as CIOMS [12] and the American College of Obstetricians [73] do not support this need for paternal consent as paternal rights may weaken or infringe maternal autonomy—the right of a woman to take action in decisions that affect her own body and health. At present, the need for maternal, not paternal, informed consent is standard ethical practice in medical research.

#### **24.2.7.4 Critically Ill Patient**

Clinical research involving critically ill patients is necessary to reduce the extreme morbidity and mortality encountered in the intensive care unit (ICU). However, this type of research is ethically challenging for two principal reasons [76]. First, critically ill patients are captive and thus vulnerable as they are dependent on the ICU team for all aspects of care or even life itself. This vulnerability raises concerns about the patient or their surrogate's ability to give informed, autonomous consent to participate in clinical research, even if they can judge the pros and cons of participation. Second, most critically ill patients lack decisional capacity due to their illness (head injury, delirium, and drug-induced coma) or the drugs (sedatives, analgesics) that they are receiving. As a result, their family members are usually asked to provide permission for research participation. While a recent study concerning research in the ICU suggests that surrogates do predict the choices of patients with a reasonably high degree of accuracy [77], there is the potential for a surrogate to make a decision that ultimately contravenes the participant's real wishes.

At the present moment there is no legislation in place governing research in the setting of the critically ill patient. The American Thoracic Society [78] and the American Heart Association [79] have published some very useful guidelines concerning involvement of critically ill patients in clinical research. These guidelines

mirror issues discussed in previous paragraphs related to research in vulnerable persons such as the mentally ill. However, we will outline some potential solutions specific to the ICU setting:

- (a) *Separation of Clinical and Experimental Team* Due to the extreme vulnerability of the critically ill patient and their dependence on the ICU team, it is probably best that researchers separate from the clinical team ask patients or their surrogates for permission to be involved in any study. This ensures that patients/surrogates do not confuse research with therapeutic intent and can feel free to refuse involvement without any perceived pressure that such refusal may harm the standard of routine care being provided to the patient.
- (b) *Consent* As most patients are not in a position to give their own consent, it is permissible for family members to provide surrogate consent provided that the research is of minimal risk or may have some direct benefit to the patient. It is probably unethical to allow a surrogate to make a decision regarding a third person (the patient) that places that individual at more than minimal risk. Alternatives to the use of surrogate consent include retrospective consent, prospective consent, and waiver of consent by the IRB. An example of retrospective consent would be when a small sample of blood is taken as part of routine clinical care and then stored for potential later use in research once the patient has recovered and given consent. In prospective consent a noncritically ill patient is consented for research in the event that he or she may become critically ill later. For example, preoperatively a patient undergoing major surgery may be consented to research on a new therapy to prevent lung infections related to prolonged artificial ventilation in the ICU. Finally, in limited studies on true emergencies where the intervention is minimal, an IRB may waive the need for patient or surrogate consent. For example, a randomized trial between a manual CPR technique and a new but FDA-approved mechanical CPR machine may be undertaken without consent as both are reasonable care and there is no time for consent in a cardiac arrest [29].

#### 24.2.7.5 Research in Undeveloped World

The conduct of clinical research in undeveloped countries raises three principal ethical concerns [80, 81]. First, many individuals from the undeveloped world have only very basic education, making it difficult for them to understand abstract concepts such as placebos, making informed decisions on the benefits and disadvantages of research involvement difficult. Furthermore, health care expenditure in the undeveloped world is paltry compared to western society, with even basic medical care often lacking. If an individual has the chance of receiving some medical treatment in the form of a trial medication, compared to no chance of medical care outside of a research protocol, does this really allow for an autonomous unpressured decision? For these reasons it is potentially more difficult to obtain truly informed consent in the undeveloped world.

The second major ethical issue surrounding research in the developing world is exploitation of communities that are unlikely to benefit themselves from the medical

advances developed by the research. Guideline 10 of the CIOMS ethical guidelines [12] states that “research must be responsive to the needs and the priorities of the population or community in which it is carried out.” Furthermore, the guideline goes on to state that “any intervention or product developed, or knowledge generated, must be made reasonably available for the benefit of that population or community.” It is only just that a community that may potentially be harmed by research should also share in its final benefits (new proven therapy). Unfortunately this has not always been the case. For example, the AIDS Clinical Trials Group protocol 076 was a study in which pregnant women from the undeveloped world were randomized to receive either placebo/routine care or oral antiviral medication throughout pregnancy, intravenous antiviral during labor, and postpartum oral antiviral for the baby in order to determine if such intensive treatment could reduce the vertical transmission of HIV to the child. While this trial did show a very significant reduction in vertical transmission, it was heavily criticized as unethical because the proposed treatment is unlikely to ever be reasonably available to mothers in the third world because of significant cost. The trial protocol cost \$800 per woman and child, 600 times the annual per-capita allocation for health care in Malawi [82]. As such, while proven to be an effective therapy for women in the western world, the results of the trial are unlikely to ever be practically applicable to the community in which the information was gained, making the study exploitative and unethical. Clinical trials can only be ethically performed in the developing world if the pathology in question is clinically relevant to the developing community and the trial intervention, if proven to be effective, is likely to be reasonably available to the community after completion of the research.

The final ethical concern for research in the developed world is an appropriate choice for the “alternative” control treatment in a trial. Some commentators suggest that it is ethical to use a placebo in a clinical trial in the undeveloped world, as no treatment is the default “standard of care” present in these poor countries [83]. These individuals suggest that since half the participants will be exposed to a potentially useful study medication, the “greater good” is still being done, making the study ethical. However, the majority view is to the contrary. The CIOMS guideline [12] states that research participants in the control arm of a trial should receive an established effective intervention (guideline 11). The use of a placebo is only ethically justifiable if there is no established effective intervention or delaying the use of this established intervention would not add any serious risk or cause any irreversible harm. As the CIOMS Guideline 11 states [12], “An economic reason for unavailability of an established effective intervention cannot justify a placebo-controlled study in a country of limited resources when it would be unethical to conduct a study with the same design in a population with general access to the effective treatment outside the study.” The reader is referred to the CIOMS Guideline for a wider discussion of this topic.

#### **24.2.8 FOUR GOLDEN RULES OF ETHICAL CONDUCT IN CLINICAL RESEARCH**

After consideration of the various philosophical theories related to medical ethics and review of the relevant published guidelines it is possible to summarize ethical

research practice into four guiding principles. These principals, or golden rules, are summarized by the acronym AIMS to help facilitate recall, where A refers to respecting patient autonomy, I stands for maximizing the potential impact of the research on society in general, M refers to the mitigation of potential harm to research participants, and S stands for maintenance of scientific integrity in all aspects of clinical research. The following sections outline the key features of each of these golden rules.

#### **24.2.8.1 A: Respect for Patient Autonomy**

Researchers should respect an individual's right to make decisions regarding their future by providing them with information which honestly outlines the risks and benefits of participating in the research in terms that are easily understandable to the average lay person of limited education (informed consent). Researchers should avoid offering excessive financial or other incentives that may impede unbiased decision making on the part of the potential research participant. When a subject lacks the ability to make an informed decision themselves (child, mental incapacity), the researcher must gain informed consent from a legally authorized representative. Research participants must feel free to exit a study at any stage without fear of compromising their standard medical care. Research participants should expect the same degree of respect of their privacy and dignity as would be afforded patients undergoing standard medical care. Maintenance of individual participant's privacy during the conduct of the trial and in the publication of trial results is paramount.

#### **24.2.8.2 I: Maximization of Research Impact on Medical Treatment**

The impact of a piece of research on contemporary medical understanding/treatment can be maximized by considering four issues. First, research protocols should be scientifically well designed so that they have the capacity to answer the question of interest. Poorly designed trials with clinically irrelevant endpoints, inadequate sample sizes, or inherent biases that make firm conclusions impossible are unethical as they consume scarce resources while placing participants at risk of adverse events for no real gain. Proper peer review and IRB assessment should prevent such studies from even commencing. Second, it is important that trials are not designed with very limited inclusion criteria (e.g., white, male, normal weight, 30–40 years age) as the results of these types of trials may not be applicable to the population in general. Justice requires that, if possible, a broad cross section of the community should be approached to be involved in research so that the potential benefits are equitably distributed throughout society. Third, it is a moral imperative that the results of research must be published within the scientific literature, irrespective of the research outcome. Failure to publish negative outcomes could create a situation where an identical study is replicated by an independent research group unaware of the original study outcome, thereby exposing the second group of research participants to unnecessary risk while wasting valuable research resources. Finally, researchers should only conduct experiments that have scientific and social worth and not use human beings in frivolous research.

**24.2.8.3 M: Minimization of Risk to Research Participants**

According to the theory of utilitarianism, it is ethically acceptable to expose an individual to justifiable risk provided the greater good is served. However, there is a moral obligation on the part of the researcher to mitigate risk by designing protocols that minimize risk or provide backup that reduces the consequences of an adverse event if it were to occur. For example, before conducting a phase I study investigating a new drug in healthy volunteers it is imperative that extensive testing in several different animal models has shown this investigational agent to be relatively safe. Furthermore, clinical trials should be supervised by appropriately trained and qualified medical personnel that are able to identify and treat any adverse reaction to a trial medication. The research should be conducted in a facility that has the appropriate equipment available to treat any medical complication of the research. Data-monitoring committees, independent of the research sponsor, should monitor trial data during the conduct of the trial to ensure the welfare of trial participants. These committees significantly enhance the safety of clinical research as they enable early termination of unsafe trials. Finally, it is a legal and moral imperative that all research participants are covered by insurance that will provide free medical care and compensation if they are inadvertently injured as a result of their participation in the research.

**24.2.8.4 S: Scientific Integrity**

Researchers have an ethical obligation to objectively analyze and report data. Improper data analysis or biased reporting of results in the scientific literature is unethical as it could lead to the adoption of medical treatments as standard proven therapy when in fact these treatments may be at best useless or worse even harmful. Careful analysis and recording of data, sharing of data and resources, and respect of research colleagues are all important components of ethical research conduct.

**24.2.9 CONCLUSION**

Our understanding of what constitutes ethical conduct in clinical research has come a long way since the advent of the Nuremberg Code in 1949. Today, the clinical researcher has several excellent guidelines [5, 11, 12] to help with the design and conduct of clinical studies that maximize participant safety and autonomy while still allowing appropriate scientific experimentation. This chapter has outlined the ethical principles used in the development of these clinical research guidelines. It is hoped that with an in-depth knowledge of these principles, researchers will be in a better position to design and conduct scientifically and ethically appropriate clinical trials. We hope that this chapter will facilitate a better understanding of ethical principles and the importance of ethics to clinical research practice.

**APPENDIX A NUREMBERG CODE\***

1. The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, over-reaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonable to be expected; and the effects upon his health or person which may possibly come from his participation in the experiment.

The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs or engages in the experiment. It is a personal duty and responsibility which may not be delegated to another with impunity.

2. The experiment should be such as to yield fruitful results for the good of society, unprocurable by other methods or means of study, and not random and unnecessary in nature.
3. The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study that the anticipated results will justify the performance of the experiment.
4. The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury.
5. No experiment should be conducted where there is an a priori reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.
6. The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment.
7. Proper preparations should be made and adequate facilities provided to protect the experimental subject against even remote possibilities of injury, disability, or death.
8. The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care should be required through all stages of the experiment of those who conduct or engage in the experiment.
9. During the course of the experiment the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.

\*Reprinted from *Trials of War Criminals before the Nuremberg Military Tribunals under Control Council Law No. 10*, Vol. 2, pp. 181–182. Washington, DC: U.S. Government Printing Office, 1949.

10. During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probable cause to believe, in the exercise of the good faith, superior skill and careful judgment required of him that a continuation of the experiment is likely to result in injury, disability, or death to the experimental subject.

## **APPENDIX B WORLD MEDICAL ASSOCIATION DECLARATION OF HELSINKI: ETHICAL PRINCIPLES FOR MEDICAL RESEARCH INVOLVING HUMAN SUBJECTS\***

Adopted by the 18th WMA General Assembly, Helsinki, Finland, June 1964, and amended by the

29th WMA General Assembly, Tokyo, Japan, October 1975

35th WMA General Assembly, Venice, Italy, October 1983

41st WMA General Assembly, Hong Kong, September 1989

48th WMA General Assembly, Somerset West, Republic of South Africa, October 1996 and the 52nd WMA General Assembly, Edinburgh, Scotland, October 2000

Note of Clarification on Paragraph 29 added by the WMA General Assembly, Washington 2002.

Note of Clarification on Paragraph 30 added by the WMA General Assembly, Tokyo 2004.

### **A. Introduction**

1. The World Medical Association has developed the Declaration of Helsinki as a statement of ethical principles to provide guidance to physicians and other participants in medical research involving human subjects. Medical research involving human subjects includes research on identifiable human material or identifiable data.

*\*Clarification of paragraph 29:* The WMA hereby reaffirms its position that extreme care must be taken in making use of a placebo-controlled trial and that in general this methodology should only be used in the absence of existing proven therapy. However, a placebo-controlled trial may be ethically acceptable, even if proven therapy is available, under the following circumstances:

- where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic, or therapeutic method or
- where a prophylactic, diagnostic, or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm.

All other provisions of the Declaration of Helsinki must be adhered to, especially the need for appropriate ethical and scientific review.

*Clarification of paragraph 30:* The WMA hereby reaffirms its position that it is necessary during the study-planning process to identify posttrial access by study participants to prophylactic, diagnostic, and therapeutic procedures identified as beneficial in the study or access to other appropriate care. Posttrial access arrangements or other care must be described in the study protocol so the ethical review committee may consider such arrangements during its review.

2. It is the duty of the physician to promote and safeguard the health of the people. The physician's knowledge and conscience are dedicated to the fulfillment of this duty.
3. The Declaration of Geneva of the World Medical Association binds the physician with the words, "The health of my patient will be my first consideration," and the International Code of Medical Ethics declares that, "A physician shall act only in the patient's interest when providing medical care which might have the effect of weakening the physical and mental condition of the patient."
4. Medical progress is based on research which ultimately must rest in part on experimentation involving human subjects.
5. In medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society.
6. The primary purpose of medical research involving human subjects is to improve prophylactic, diagnostic and therapeutic procedures and the understanding of the aetiology and pathogenesis of disease. Even the best proven prophylactic, diagnostic, and therapeutic methods must continuously be challenged through research for their effectiveness, efficiency, accessibility and quality.
7. In current medical practice and in medical research, most prophylactic, diagnostic and therapeutic procedures involve risks and burdens.
8. Medical research is subject to ethical standards that promote respect for all human beings and protect their health and rights. Some research populations are vulnerable and need special protection. The particular needs of the economically and medically disadvantaged must be recognized. Special attention is also required for those who cannot give or refuse consent for themselves, for those who may be subject to giving consent under duress, for those who will not benefit personally from the research and for those for whom the research is combined with care.
9. Research Investigators should be aware of the ethical, legal and regulatory requirements for research on human subjects in their own countries as well as applicable international requirements. No national ethical, legal or regulatory requirement should be allowed to reduce or eliminate any of the protections for human subjects set forth in this Declaration.

## **B. Basic Principles for All Medical Research**

10. It is the duty of the physician in medical research to protect the life, health, privacy, and dignity of the human subject.
11. Medical research involving human subjects must conform to generally accepted scientific principles, be based on a thorough knowledge of the scientific literature, other relevant sources of information, and on adequate laboratory and, where appropriate, animal experimentation.
12. Appropriate caution must be exercised in the conduct of research which may affect the environment, and the welfare of animals used for research must be respected.

13. The design and performance of each experimental procedure involving human subjects should be clearly formulated in an experimental protocol. This protocol should be submitted for consideration, comment, guidance, and where appropriate, approval to a specially appointed ethical review committee, which must be independent of the investigator, the sponsor or any other kind of undue influence. This independent committee should be in conformity with the laws and regulations of the country in which the research experiment is performed. The committee has the right to monitor ongoing trials. The researcher has the obligation to provide monitoring information to the committee, especially any serious adverse events. The researcher should also submit to the committee, for review, information regarding funding, sponsors, institutional affiliations, other potential conflicts of interest and incentives for subjects.
14. The research protocol should always contain a statement of the ethical considerations involved and should indicate that there is compliance with the principles enunciated in this Declaration.
15. Medical research involving human subjects should be conducted only by scientifically qualified persons and under the supervision of a clinically competent medical person. The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent.
16. Every medical research project involving human subjects should be preceded by careful assessment of predictable risk and burdens in comparison with foreseeable benefits to the subject or to others. This does not preclude the participation of healthy volunteers in medical research. The design of all studies should be publicly available.
17. Physicians should abstain from engaging in research projects involving human subjects unless they are confident that the risks involved have been adequately assessed and can be satisfactorily managed. Physicians should cease any investigation if the risks are found to outweigh the potential benefits or if there is conclusive proof of positive and beneficial results.
18. Medical research involving human subjects should only be conducted if the importance of the objective outweighs the inherent risks and burdens to the subject. This is especially important when the human subjects are healthy volunteers.
19. Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.
20. The subjects must be volunteers and informed participants in the research project.
21. The right of research subjects to safeguard their integrity must always be respected. Every precaution should be taken to respect the privacy of the subject, the confidentiality of the patient's information and to minimize the impact of the study on the subject's physical and mental integrity and on the personality of the subject.
22. In any research on human beings, each potential subject must be adequately informed of the aims, methods, sources of funding, any possible conflicts of interest, institutional affiliations of the researcher, the anticipated benefits and potential risks of the study and the discomfort it may entail. The subject should

be informed of the right to abstain from participation in the study or to withdraw consent to participate at any time without reprisal. After ensuring that the subject has understood the information, the physician should then obtain the subject's freely-given informed consent, preferably in writing. If the consent cannot be obtained in writing, the non-written consent must be formally documented and witnessed.

23. When obtaining informed consent for the research project the physician should be particularly cautious if the subject is in a dependent relationship with the physician or may consent under duress. In that case the informed consent should be obtained by a well-informed physician who is not engaged in the investigation and who is completely independent of this relationship.
24. For a research subject who is legally incompetent, physically or mentally incapable of giving consent or is a legally incompetent minor, the investigator must obtain informed consent from the legally authorized representative in accordance with applicable law. These groups should not be included in research unless the research is necessary to promote the health of the population represented and this research cannot instead be performed on legally competent persons.
25. When a subject deemed legally incompetent, such as a minor child, is able to give assent to decisions about participation in research, the investigator must obtain that assent in addition to the consent of the legally authorized representative.
26. Research on individuals from whom it is not possible to obtain consent, including proxy or advance consent, should be done only if the physical/mental condition that prevents obtaining informed consent is a necessary characteristic of the research population. The specific reasons for involving research subjects with a condition that renders them unable to give informed consent should be stated in the experimental protocol for consideration and approval of the review committee. The protocol should state that consent to remain in the research should be obtained as soon as possible from the individuals or a legally authorized surrogate.
27. Both authors and publishers have ethical obligations. In publication of the results of research, the investigators are obliged to preserve the accuracy of the results. Negative as well as positive results should be published or otherwise publicly available. Sources of funding, institutional affiliations and any possible conflicts of interest should be declared in the publication. Reports of experimentation not in accordance with the principles laid down in this Declaration should not be accepted for publication.

### **C. Additional Principles for Medical Research Combined with Medical Care**

28. The physician may combine medical research with medical care, only to the extent that the research is justified by its potential prophylactic, diagnostic or therapeutic value. When medical research is combined with medical care, additional standards apply to protect the patients who are research subjects.
29. The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic

methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists.

30. At the conclusion of the study, every patient entered into the study should be assured of access to the best proven prophylactic, diagnostic and therapeutic methods identified by the study.
31. The physician should fully inform the patient which aspects of the care are related to the research. The refusal of a patient to participate in a study must never interfere with the patient-physician relationship.
32. In the treatment of a patient, where proven prophylactic, diagnostic and therapeutic methods do not exist or have been ineffective, the physician, with informed consent from the patient, must be free to use unproven or new prophylactic, diagnostic and therapeutic measures, if in the physician's judgement it offers hope of saving life, re-establishing health or alleviating suffering. Where possible, these measures should be made the object of research, designed to evaluate their safety and efficacy. In all cases, new information should be recorded and, where appropriate, published. The other relevant guidelines of this Declaration should be followed.

25.1 INTRODUCTION

The U.S. Food and Drug Administration (USFDA) is a scientific, regulatory, and public health agency that oversees what is estimated to be 25% of the consumer economy. The agency has jurisdiction over most food products, human and animal drugs, therapeutic biologic agents, medical devices, radiation-emitting products, cosmetics, and animal feed [1]. The FDA has a staff of approximately 10,000 employees including chemists, pharmacologists, toxicologists, physicians, microbiologists, veterinarians, pharmacists, lawyers, statisticians, project managers, and others. In this chapter, the role of the FDA and different scientific disciplines in the marketing approval of drug products in the United States are presented.

25.2 REGULATORY HISTORY

The FDA’s mandate has evolved based on a number of legislative acts that have been introduced over the last 100 years. These are discussed below and outlined in Table 1. Regulatory functions were incorporated into the agency’s mission in 1906 with passage of the Federal Food and Drugs Act. The 1906 law forbade interstate and foreign commerce in adulterated and misbranded foods and drugs. Drugs had to abide by standards of purity and quality set forth in the *U.S. Pharmacopeia* and the *National Formulary*, works prepared by committees of physicians and pharmacists, or meet individual standards chosen by their manufacturers and stated on their labels. The law prohibited the adulteration of foods by the removal of valuable constituents, the substitution of ingredients so as to reduce quality, the addition of deleterious ingredients, or the use of spoiled animal and vegetable products.

Another important milestone in the agency’s history took place in 1938 with passage of the Federal Food, Drug, and Cosmetic (FDC) Act, which, for the first time, required new drugs to be shown safe before marketing. The FDC Act also extended the FDA’s jurisdiction to cosmetics and therapeutic devices, authorized factory inspections, and added the remedy of court injunctions to the previous penalties of seizures and prosecutions.

In the late 1950s and early 1960s, a drug used in Europe for its sedative effects (thalidomide) was found to have caused birth defects in thousands of infants. The drug had been kept off the market in the United States. This event, as well as other factors, aroused public support for stronger drug regulation. In 1962, the

TABLE 1 FDA Regulatory Landmarks

| Year | Legislation                     | Features                                                               |
|------|---------------------------------|------------------------------------------------------------------------|
| 1906 | Food and Drugs Act              | Defined FDA regulatory functions                                       |
| 1938 | Food, Drug and Cosmetics Act    | Requirement for safety data                                            |
| 1962 | Kefauver–Harris Drug Amendments | Required demonstration of safety and effectiveness prior to marketing  |
| 1992 | Subpart H                       | Accelerated approval of drugs for serious or life-threatening diseases |
| 1992 | Prescription Drug User Fee Act  | Fees for product applications                                          |
| 1997 | Food and Drug Modernization Act | Several reforms                                                        |

Kefauver–Harris Drug Amendments passed. In addition to more rigorous requirements for the demonstration of drug safety, this legislation required manufacturers to demonstrate to the FDA the effectiveness of their products prior to marketing.

In the 1980s and early 1990s, there was a growing recognition for the need to encourage the timely development and approval of drugs for serious or life-threatening illnesses such as HIV/AIDS (the human immunodeficiency virus/acquired immunodeficiency syndrome) and cancer. In 1992, subpart H was added to the new drug approval (NDA) regulations, allowing for accelerated approval (AA) of drugs for serious or life-threatening diseases where a drug demonstrates an advantage over available therapy or demonstrates its effects in a setting where no available therapy exists. Approval is based on a surrogate endpoint “reasonably likely to predict clinical benefit.” The sponsor must study the drug further to demonstrate clinical benefit in subsequent or ongoing clinical trials [2, 3].

Also in 1992, the Prescription Drug User Fee Act (PDUFA) was enacted, requiring drug and biologic drug manufacturers to pay fees for product applications and supplements. The act also required the FDA to use these funds to increase the number and breadth of reviewer expertise for product applications. In 1997, the Food and Drug Modernization Act reauthorized PDUFA and mandated several reforms in agency practices [4]. Measures were introduced to accelerate review of devices, to regulate advertising of unapproved uses of approved products, and to regulate health claims for foods.

### 25.3 CLINICAL INVESTIGATIONS

In the United States, investigational drugs must be administered under an investigational new drug (IND) application submitted to the FDA. The regulations describe two parties involved in IND submission, the *sponsor*, who is responsible for reporting to the FDA, and the *investigator*, who performs the trial [5]. The sponsor may be a pharmaceutical company, an academic institution, or an individual. Sponsors are to select only investigators “qualified by training and experience as appropriate experts to investigate the drug.”

When an IND is submitted to the FDA, a team of scientific reviewers evaluate the safety data from animals or other sources, evaluate the proposed study, and determine whether patients would be exposed to an unreasonable and significant risk. These issues are discussed individually in the sections below. All studies of nonapproved drugs must be done under an IND. For approved drugs, however, some studies require an IND and others are exempt from the IND requirement.

To determine that an IND is not needed, the following conditions should be met: The study (1) is not intended to support approval of a new indication or a significant change in the product labeling, (2) is not intended to support a significant change in advertising, (3) does not involve a route of administration or dosage level or use in a patient population or other factor that significantly increases the risks associated with the use of the drug product, (4) is conducted in compliance with institutional review board (IRB) and informed consent regulations, and (5) will not be used to promote unapproved indications [5].

The IND process spans the entire period of drug investigation (Fig. 1). It includes the initial IND application and later amendments to provide safety reports or

**FIGURE 1** Drug development timeline. The solid arrows indicate standard time points for meeting with drug developers. The dashed arrows indicate additional time points when the FDA sometimes meets with sponsors.

additional protocols. The initial IND application usually consists of a phase I clinical protocol and data to support the safety of the proposal. The latter would include in vitro, animal, and/or human evidence describing drug toxicity and allowing prediction of a safe starting dose. Manufacturing data describing the composition, manufacture, and control of the drug substance and drug product is also included. After the FDA receives the initial IND, sponsors are required to wait 30 days prior to initiating the proposed study unless they request and receive a waiver of the 30-day review period from the FDA. A multidisciplinary team of FDA reviewers, including physicians, pharmacologist/toxicologists, chemists, statisticians, and clinical pharmacologists determine whether the study is safe to proceed. The FDA may put an IND “on hold” if the agency believes subjects would be exposed to unreasonable risk of injury or if there is insufficient information to assess the risks.

The FDA frequently meets with sponsors and investigators in pre-IND meetings to review proposed IND plans and to clarify IND requirements. Animal studies should use the same or a similar schedule of drug administration proposed for the phase I clinical study. The starting dose for investigational drugs used in human studies is usually based on a preclinical animal model, which may differ based on the type of product and the therapeutic area of development. FDA advice on the specific requirements for a given product should be sought from representatives of the responsible FDA review division.

A critical FDA role in drug development is to meet with sponsors to provide advice on the design and conduct of phase III (and sometimes phase II) clinical trials that will support marketing applications. The multidisciplinary FDA team attending these meetings includes physicians, statisticians, pharmacologists/toxicologists, clinical pharmacologists, and often external expert consultants and patient advocates. FDA chemists also meet with sponsors, often separately, to discuss manufacturing and quality control issues. Sponsors can submit protocols subsequent to these meetings and request a Special Protocol Assessment, which provides for a binding agreement on protocol design [6]. After the clinical trials have been conducted and trial results are available, sponsors again meet with the FDA in pre-NDA meetings to discuss whether a new drug application (NDA) may be warranted and, if so, to discuss details of an NDA submission.

After clinical trials have been completed and an NDA has been submitted, the FDA verifies data quality and judges whether trial results demonstrate that the drug is safe and effective for the proposed use. After approval, the FDA continues to evaluate drug safety and regulate drug marketing.

#### 25.4 NDA REVIEW PROCESS

The package insert describes clinical trial results from data that have been reviewed and validated by FDA review teams. Regulations require that NDAs contain all relevant information about manufacturing, preclinical pharmacology and toxicology, human pharmacokinetics and bioavailability, clinical data, and statistical analyses. NDA applicants must submit financial disclosure information about the investigators. The FDA review of the NDA involves a team of chemists, pharmacologists/toxicologists, clinical pharmacologists, physicians, statisticians, microbiologists, site inspectors, and a project manager. The FDA reviewers evaluate the primary data, verify analyses, and where appropriate perform additional analyses. The FDA field inspectors verify that information on case report forms is supported by source data such as hospital charts and that biological drug concentrations are documented. Inspectors also inspect manufacturing facilities for suitability.

Based on the PDUFA, the FDA performs NDA reviews with either a 6-month or a 10-month goal. Applications representing a significant improvement compared to products that are currently available are assigned priority status and a 6-month review period, whereas standard applications have a 10-month review goal.

The FDA routinely seeks external advice on the design, analysis, and interpretation of clinical trials. These consultants are screened to exclude any potential conflicts of interest. Individual consultants advise the FDA during the design of clinical trials and during the NDA review. After an initial NDA review, the FDA presents selected NDAs to the appropriate advisory committee. This group is composed of medical and/or surgical specialists, statisticians, patient advocates, consumer representatives, and a nonvoting industry representative. At the public meetings of an advisory committee, the NDA applicant summarizes the study results, and the FDA presents its review of the findings. Members of the public may comment on the issues being discussed during the public speaker portion of the meeting. The committee finally votes on the specific questions submitted by the FDA. Although the discussion and the votes by the committee are taken into consideration, the FDA is not obligated to adhere to the advice provided.

#### 25.5 PEDIATRIC INITIATIVES

There has been general recognition of the lack of adequate labeling of drug products for children. In order to encourage evaluation of new therapies in pediatric populations and to optimize submission of pediatric data to support labeling of commercially available drugs, the FDA has undertaken two initiatives, which are outlined in Table 2 and summarized as follows.

A voluntary program, commonly referred to as “pediatric exclusivity,” was outlined in the Food and Drug Modernization Act of 1997. Under this program,

**TABLE 2    FDA Pediatric Initiatives**

| PREA                                           | BPCA                            |
|------------------------------------------------|---------------------------------|
| Applies to drugs and biologics                 | Applies only to drugs           |
| Studies mandatory                              | Studies voluntary               |
| Required only for drug/indication under review | Studies on entire active moiety |
| Orphan indications exempted                    | Includes orphan drugs           |

a commercial sponsor may receive a 6-month extension of existing marketing exclusivity by submitting data from pediatric clinical trials in support of an NDA. The general design of studies to be conducted and data to be submitted are outlined in a pediatric written request letter issued by the FDA to the sponsor. This program applies to drug products, including those with orphan designation. However, biological therapies such as monoclonal antibodies and vaccines are excluded. The Best Pharmaceuticals for Children Act (BPCA) subsequently provided some refinements to the program, including a framework for making summaries of medical and pharmacology reviews available to the public [7].

A mandatory program applying to indications where the disease in pediatric patients is similar to the adult disease, previously known as the “pediatric rule,” was subsequently formally legislated in the Pediatric Research Equity Act (PREA) [8]. This mandatory requirement for sponsors to submit data from pediatric studies when an adult indication is granted applies to a specific drug and indication under review. In order to avoid the potential delay in drug development and in providing access to therapies for life-threatening diseases that can arise when the adult data support approval and pediatric studies are still ongoing, a deferral for submission of the pediatric data may be granted. Both drug and biologic products are subject to the PREA. However, products with orphan designation are excluded from this requirement.

**25.6    ROLE OF STATISTICS IN REGULATORY SETTING**

In 1962 the Kefauver–Harris amendment to the Food, Drug and Cosmetic Act (FD&C Act) led to the provision that the manufacturing companies need to provide substantial evidence of effectiveness and that the evidence show adequate and well-controlled investigations, including clinical investigations, by qualified scientific experts, that proves the drug will have the effect claimed by its labeling” [Section 505(d) FD&C Act of 1962 as amended]. Statistical methodology provides tools for objectively planning, conducting, and evaluating clinical trials. When evaluating the efficacy and safety of a drug from a regulatory perspective, two objectives have to be met: First, the claimed effect is true and, second, the effect is clinically meaningful with acceptable toxicity. The role of a statistical expert at the FDA is, using the data submitted by the applicant, to evaluate whether the claimed efficacy is in fact true. The statistical team works in conjunction with the medical team to evaluate whether the claimed effect is clinically meaningful and has an acceptable toxicity profile.

Before an application [an NDA or biologics license application (BLA)] for marketing approval is submitted to the FDA, product development would typically have

gone through several phases: preclinical phase and clinical phases I–III. Although statisticians are consulted at the design stage of each of these phases, the greatest impact of statistical advice is in planning and designing comparative, randomized, well-controlled studies (phase II or III registration studies). A randomized study mitigates potential selection and reporting biases and balances any known and unknown prognostic factors that may influence the outcome of the study. As detailed in Section 25.3, new product manufacturers can consult FDA staff by submitting the planned study protocol as an IND application. These protocols are reviewed by the FDA staff and comments are sent to the applicant. In reviewing these protocols including special protocol assessments (SPAs), the statisticians critique both the design and planned analysis of the study.

The protocol should clearly identify the study objective, the primary hypothesis (the benefit that is to be demonstrated), study population, and the primary outcome (or endpoint) that is being measured based on which efficacy claim is planned. The primary endpoint could be a binary outcome (e.g., proportion of patients cured of an infection), a continuous variable (e.g., lowering of cholesterol), or a time-to-event endpoint (e.g., overall survival, time to progression of disease). An endpoint may also be defined as a composite endpoint (e.g., myocardial infarction or death). In certain disease settings more than one endpoint may be of primary interest (e.g., the rate of acute rejection and survival for an organ transplant drug). The design and analysis of a trial depends on the endpoint that is being measured. In conducting and evaluating clinical studies, it is important to control false-positive claims or the so-called type I error rates ( $\alpha$ ). The study also should have enough power or low type II error rates ( $\beta$ ), so that a true effect, if it exists, can be detected with the number of patients enrolled in the study. Subjective endpoints, such as symptom measurements, are difficult to evaluate in open-label studies, and potential biases can be minimized in double-blinded studies [9].

In confirmatory, phase III comparative studies [10, 11], there are basically three types of hypotheses that are tested: (1) the new product is superior [new product compared to placebo; new product compared to an active control (standard treatment); the new product has a dose–response relationship]; (2) the new product is noninferior (the new product is not worse than the existing treatment—it may be better or it may have a similar effect); or (3) two products are bioequivalent [absence of any difference between the two products (e.g., generic drugs)]. Marketing applications with claims of superiority or noninferiority of new drugs are reviewed at the Center for Drug Evaluation and Research. For consideration of a noninferiority claim, the assumption that the patient population and the conditions of the current study with the new treatment are similar to the historical placebo-controlled trials with the existing treatment should be met, the effect of size of the existing treatment must be well established, and that a certain prespecified percentage of the historical control effect size is maintained. Because of these assumptions, in general, noninferiority claims are difficult to establish and require large studies. In hypothesis 3, bioequivalence studies of generic products are generally reviewed by the Office of Generic Drugs at the FDA.

The sample size required to conduct a clinical trial that will ensure that the study is informative to test the primary hypothesis depends on the primary endpoint of interest, the smallest difference in treatment efficacy, which is important enough to detect, the probability of type I error (significance level), the probability of type II

error (1, power of the test), the number of interim analyses that are planned, the number of endpoints, and the comparisons that are being evaluated. If interim analyses or multiple comparisons are planned, then the type I error rate allocated for testing the final analysis has to be adjusted so that the overall familywise type I error rate is maintained at the specified level [10]. Sometimes, meta-analysis, a technique combining results from different studies, is used to provide benchmarks for new agents and new indications and in the design stage of clinical trials.

The statistical analysis plan should be prespecified. The statistical analysis plan should include definitions of the primary and secondary endpoints, and the hypotheses and the analysis plan for each of the endpoints. Comparative analyses based on secondary endpoints are considered exploratory and hypothesis generating if the familywise type I error rate is not maintained at the prespecified level. A post hoc analysis and claim based on a subgroup of patients, when the efficacy could not be demonstrated in the overall study population, is considered exploratory and hypothesis generating, and are generally not considered suitable as a basis for drug approval.

During an ongoing clinical trial, any changes in the definition of endpoint, changes in the type of hypothesis being tested, change in study population, additional interim analyses, increasing sample size, and other study modifications are problematic if the modifications or adaptations are not based on established statistical methods. Such modifications could compromise on the integrity of the study and introduce bias in the interpretation of the results, particularly in an open-label study. Too many modifications and adaptations of the study design and conduct are considered as exploratory. In general drug product approval is based on statistically persuasive results that are clinically meaningful with adequate efficacy and safety.

## **25.7 ROLE OF CHEMISTRY, MANUFACTURING, AND CONTROLS (CMC) INFORMATION IN REGULATORY SETTING**

As per regulations [12], the sponsor must submit CMC information that will describe the general method of preparation of the drug substance, physical, chemical, and biological characteristics, drug product formulation, manufacturing process, and controls to provide assurance of the identity, strength, quality, purity, and potency of the investigational drug. The CMC information that is expected in an initial IND (phase I) is more to assure patient safety and less on product and process controls. However, for phase II and phase III studies, as more manufacturing experience is attained with the manufacturing process and the final formulation is chosen, more exhaustive details regarding process and product controls should be provided. The amount of CMC information required is also dependent on the type of molecule to be tested (e.g., synthetic, semisynthetic, naturally derived, biotechnological) and whether there is any previous clinical experience with the study drug.

The amount of CMC information that will be required in an IND will also be dependent on the marketing status of the drug product. For a drug that is already marketed in the United States, the investigator should provide the current approved labeling and/or package insert of the drug. If a drug is not marketed in the United States, but studied under a cross-referenced IND, the sponsor should provide a letter of authorization (LOA) from the sponsor of the cross-referenced IND to allow the

agency to access to the referenced IND. The LOA should clearly specify the name, strength, and dosage form of the drug. If a drug is not marketed in the United States or it is not referenced to an IND, the sponsor should provide CMC information on the study drug appropriate to the phase of the study. If the drug is intended to be administered for intravenous administration after dilution, compatibility data with different diluents and in-use stability data for the duration of administration should be submitted. Please refer to the following guidance documents regarding the CMC information that needs to be submitted to support the proposed clinical study in the IND [13, 14].

If a drug is not marketed in the United States, but approved and marketed in a foreign market, or it is a legally marketed dietary supplement, the sponsor should provide full CMC information [13, 14]. For a limited phase I study, this requirement may be fulfilled by providing the following information: components and composition of the drug product, name of manufacturer/supplier of the drug product, and the labeling and/or package insert.

The sponsor should also provide a certificate of analysis for the lot that is intended to be used in the proposed clinical trial. Additional product-specific information may be required for the drugs approved and marketed outside the United States or for a legally marketed dietary supplement in the United States. When a sponsor is faced with a situation that is unique and not covered by the above guidance(s) [13, 14], the FDA recommends that the sponsor obtain clarification from the review division with regard to the CMC information necessary to support the proposed clinical study. For a botanical drug, the CMC information that needs to be submitted may be different from that of conventional small-molecule drugs [15].

For all drugs, the sponsor should provide a statement in the CMC section (as well as under dosage and administration section of the clinical protocol), as to the labeled dosage form and the strength of the drug product and how the drug will be administered. If the sponsor intends to change from the labeled dosage form, strength, or route of administration, the sponsor should provide relevant information such as release and stability data to support the change as well as to assure that the change will not adversely affect the identity, strength, quality, purity, and potency of the investigational drug. For all investigational drugs, the following labeling and environmental assessment information should be provided; the label for the immediate packaging of the drug product should be provided that includes the following cautionary statement: "Caution: New Drug—Limited by Federal (or United States) law to investigational use" [16].

A statement requesting a categorical exclusion from environmental assessment under provisions provided for in 21 CFR § 25.31(e); Part 25, Environmental Impact Considerations; Subpart C, Categorical Exclusions; Section 25.31, Human Drugs and Biologics, Paragraph (e)—Action on an IND [17].

If a device is used in conjunction with the study drug (e.g., a nebulizer for an inhalation drug or a pump for continuous infusion for home use), information on the manufacturer and model of the device to be employed and a general description of relevant conditions of use (e.g., carrier gas, flow rate, temperature) should be provided. A statement as to whether the device is FDA approved or not approved should also be included. When appropriate, submit adequate information regarding safety instructions for use of equipment and disposal of unused portion of the drug.

## 25.8 ROLE OF CLINICAL PHARMACOLOGY IN REGULATORY SETTING

The purpose of clinical pharmacology and biopharmaceutics data is to support the determination that the drug to be marketed is safe and effective for use in the indicated patient population. The clinical pharmacology data in conjunction with the safety and effectiveness data from the registration clinical trial(s) can be used to understand the relationships between drug dose or concentration and effects, namely patient outcome and toxicity (exposure–response relationships, ER). These relationships allow for better choices regarding optimizing the dose for the patient population, adjusting doses in special clinical situations, and providing information in the product labeling. Some of these studies provide direct support for the assessment of ER, such as pharmacokinetic information derived from clinical studies (see Fig. 1). On the other hand, some clinical pharmacology and biopharmaceutic data provide indirectly to understanding the behavior of the drug in the patient. For instance, in vitro cytochrome P-450 (CYP 450) screening often indicates whether the drug is metabolized by or modulates any of these enzymes. These in vitro data may suggest whether or not in vivo drug–drug interactions might occur between the drug being developed and other medications that may be commonly administered to a particular patient population that may lead to toxicity or reduced effectiveness.

The summation of these studies should provide appropriate information on drug behavior and its safe and effective use in the product labeling. With that goal in mind, the clinical pharmacology and biopharmaceutics studies can be used collectively to address some basic questions about the drug and how to use it appropriately. With respect to labeling the drug, the main questions are: Is this dose the optimal dose for this patient population? Are any dose or dose regimen adjustments needed for patients with specific clinical characteristics? The answer to these questions are quite complex. Many different chemical, pharmacological, and clinical aspects of the drug contribute to the answers. In the Appendix, many questions about the clinical pharmacology of the drug are posed, and these specific answers, once determined, contribute to the overall issues regarding the optimal dose, dose adjustments, and the safe labeling of the drug.

To address many of these specific issues, the FDA has publicly posted or is planning to post Guidances for Industry that describe the current thinking of the FDA on a specific topic [18]. Each of these is intended to be a general set of guidelines to deal with a specific issue; they may not address every situation, but they should be the starting point for dealing with the issue of interest. Essentially, these are located on the FDA website under the Biopharmaceutics, Chemistry, Clinical, and Clinical Pharmacology headings [18]. The Biopharmaceutics and Chemistry Guidances address issues that affect the drug formulation and may have an impact on how the drug product behaves after administration to the patient (i.e., how much drug may be absorbed). For instance, changing the ingredients of a tablet may alter how quickly the tablet dissolves after administration to the patient, which may have an impact on the absorption of the drug and therefore its effect(s). The Clinical Pharmacology Guidances describe what happens to the drug, and hence its impact on the patient once it is administered to the patient. For instance, renal impairment may cause the exposure of drug to increase because drug elimination is reduced. This in turn may increase the rate of drug toxicity and may necessitate a dose adjustment in these patients.

### 25.8.1 Biopharmaceutics Guidances

The Bioanalytical Method Validation Guidance [19] is designed to verify that the analytic method used to measure drug concentration is accurate and reliable for the purpose it is intended. The Food Effect Guidance [20] describes the general issues to be considered when assessing the effect of food on a per oral formulation. It addresses the biopharmaceutics issue of how food taken with a medication can alter the dissolution and absorption of a given product. The outcome of this study is often used to determine how the drug should be administered in future trials and, eventually, the intended patient population. During drug development, it is common for a drug developer to alter the drug formulation. These changes may impact the pharmacokinetics and pharmacodynamics of the drug in the patient, and these formulation changes raise questions about how to “bridge” (compare) data from different studies developed with different formulations. The Dissolution Guidance [21] and the Bioavailability and Bioequivalence Guidance [22] are closely related in purpose. Both methodologies are intended to assess the effect of changes in the product formulation on the pharmacokinetics and, by extension, the pharmacodynamics of a drug. The dissolution guidance describes how an *in vitro* method can be developed using well-defined apparatus and criteria. The purpose is to develop a discriminatory *in vitro* method to assess alterations in the formulation of a per oral drug product (similar approaches can be used to develop an *in vitro* drug release methodology for a liposome drug product). For instance, changing an ingredient may have an impact on the rate that the tablet dissolves in the gastrointestinal milieu. One could expect that this could alter the extent to which a drug is absorbed and the timing of this event. This could result in undesired effects in the patient (reduced effectiveness or increased toxicity). However, significant changes in dissolution do not necessarily indicate clinically significant changes in the behavior of the drug, so monitoring changes in dissolution is the first step in assessing the impact of a formulation change. Such an *in vitro* observation is likely to be further assessed by observing the effect of the new formulation *in vivo*. The Bioavailability/Bioequivalence Guidance [22] describes in general terms the elements of a study for comparing the pharmacokinetics and pharmacodynamics of a preexisting drug formulation with a newly developed one. Studies of dissolution and pharmacokinetics conducted early in drug development can lead to the development of *in vitro*–*in vivo* correlations [23] in which a clinically meaningful dissolution method can be used to predict *in vivo* performance of new formulations. These IVIVC relationships are often used in the development of modified-release drug products.

With regard to clinical pharmacology studies, the characterization of the drug often begins with *in vitro* studies. Protein binding, although not the subject of a specific guidance, is usually assessed with *in vitro* incubations for each new drug. (There are examples of *ex vivo* protein binding determinations as well.) Current scientific thinking is that only free or unbound drug can mediate drug action. Therefore, highly protein-bound drugs ( $\geq 90\%$ ) have their pharmacological effects mediated by only a small fraction of drug. Furthermore, small changes in protein binding for these drugs might be expected to mediate a substantial effect. Therefore, the extent of protein binding to human serum proteins (e.g., albumin,  $\alpha$ -acidic glycoprotein) is commonly performed.

The Drug Metabolism Guidance describes both *in vitro* and *in vivo* studies [24, 25]. The *in vitro* studies describe cytochrome P-450 (CYP 450) screening. The CYP 450 superfamily of enzymes accounts for the majority of drug metabolizing capability in humans. *In vitro* screening often identifies the main isozyme(s) responsible for the metabolism of a particular drug and the extent of its contribution. New drugs can also be screened for their ability to either inhibit CYP 450 isozyme(s) activity or induce their activities and expression. The end result may be reduced drug clearance or increased drug clearance, respectively, which may affect effectiveness and/or safety. These *in vitro* findings can then be used as the basis for deciding on the need to conduct *in vivo* drug–drug interaction studies. It is noteworthy that these *in vitro* studies do not account for the activity of all metabolizing enzymes, and the metabolism and potential drug–drug interactions on non-CYP 450 metabolized drugs are often difficult to assess. One non-CYP 450 enzyme system that has been studied further is the P-glycoprotein (PGP) transporter system. A newly published draft Guidance on Drug Metabolism describes both *in vitro* and *in vivo* studies to assess the impact of new drugs on PGP [26].

Related to the *in vitro* metabolism studies in purpose are the *in vivo* “mass balance” studies. These studies are not the subject of a specific guidance but are referred to in some agency publications. The purposes of these types of studies are generally twofold. The first is to determine whether a novel metabolite is generated in humans that has not been previously characterized (at least in part) in preclinical studies. The second purpose is to assess the route of excretion/elimination from the patient. This latter purpose is of importance because it can indicate that patients with organ dysfunction may have difficulty eliminating the drug, which in turn can lead to excessive drug exposure and toxicity. The results of these studies are used to determine whether pharmacokinetic studies in patients with either renal and/or hepatic impairment should be conducted. One common misinterpretation regarding mass balance studies is that the administration of radiolabeled drug is required. This, in fact, is untrue. Any appropriate methodology may be used to assess mass balance. However, use of radiolabeled drug is often employed because of the considerable sensitivity imparted by the methodology.

### 25.8.2 Clinical Pharmacology Guidances

The basic elements of the pharmacokinetic characterization (clearance, CL, volume of distribution,  $V_d$ , and elimination half-life,  $t_{1/2}$ ) are characterized in the Format and Content of Human Pharmacokinetics and Bioavailability Section of an Application Guidance [27]. Essentially, the kinetics should be determined to better understand the behavior of the drug. Typically, single- and multiple-dose pharmacokinetics are assessed, usually in early studies in volunteers or patients. Dose proportionality is often assessed with the data generated from these studies. The exposure–response guidance describes the different measures that can be used to evaluate the relationships between drug amount and its effectiveness and toxicity(ies) [28]. These relationships are of great importance because they are the basis for understanding the behavior of the drug and for making rational decisions about choosing the optimum dose or altering the dose when necessary. The Population Pharmacokinetic Guidance [29] describes alternative approaches to assessing the pharmacokinetics of a drug. In some drug development circumstances, the execution of a dedicated phar-

macokinetic study with dense sampling may not be feasible. In these cases, an alternative approach can be employed to collect pharmacokinetic data in a more limited fashion. These data are often combined with previously collected data, and the effects of different factors (covariates) such as disease, patient demographics, and patient characteristics can be assessed, often by using sparse sampling.

The guidances on the effect of renal [30] or hepatic impairment [31] on the pharmacokinetics of a drug also describe important studies. Most drugs are renally excreted or metabolized (predominantly by the liver) prior to elimination or sometimes both. As drug exposure is a function of both the administered dose, and the rate of elimination, renal or hepatic impairment can lead to significant reductions in drug elimination, which in turn produce excessive drug exposures (e.g., higher than anticipated plasma concentrations). Sometimes these elevated concentrations lead to toxicities. Ideally, by understanding the pharmacokinetics (PK) and the pharmacodynamics (PD) of the drug in both the general patient population and in those patients with organ dysfunction, rational dose modifications can be made.

The agency has also published a guidance on the evaluation of QT prolongation [32], which describes how to assess the potential of a drug to adversely affect cardiac conduction.

The agency has also been developing new guidances that deal with issues of drug PK in pregnant women [33] or lactating women [34], as well as in pediatric patients [35].

Recently, the FDA also implemented the EOP1/2a Guidance [36]. The purpose of this guidance is to encourage drug developers to employ all of the available pre-clinical biomarker, toxicity, and pharmacokinetic and chemistry information along with existing clinical data on effectiveness, biomarkers, and pharmacokinetics in a comprehensive model and to subsequently simulate the outcomes of different drug development trials with different regimens, combinations, and dosages to help choose the most effective trial design for the pivotal trial. In a similar vein, the agency has also issued the Guidance for Industry on Pharmacogenomic Data Submission [37] in a effort to stimulate the development of testing platforms and analysis and utilization of pharmacogenomic data in clinical trials in order to develop better, targeted therapies.

### 25.8.3 Timing of Studies

With respect to when these studies should be conducted, there is no regulatory requirement. It is up to the drug development sponsor to decide on when and how to allocate resources to these studies. However, there is some sense to the order and timing of these studies. For instance, there may not be too much value in conducting a mass balance study in parallel with the phase III safety and effectiveness trial, if the active metabolites have been identified and organ dysfunction studies have been conducted (or planned). Figure 2 depicts one possible scheme of clinical pharmacology and biopharmaceutics study conduct. According to this scheme, development begins with preclinical studies. The extent of protein binding is determined, and the compound is screened *in vitro* to evaluate it as a substrate for, or inhibitor and/or inducer of, CYP 450 enzymes. The compound is also screened as a substrate or inhibitor of P-glycoprotein. Additionally, biomarkers may be selected as potential indicators of activity based on animal and *in vitro* models. Other preclinical studies

**FIGURE 2** One possible clinical pharmacology drug development scenario is depicted. The FDA does not regulate the timing of studies in drug development.

generate information regarding the toxicity of the compound, including the potential to alter cardiac function (e.g., hERG assay). The analytical method chosen to measure in vivo drug concentrations is often adapted from preclinical to clinical use and validated.

With the first-in-man studies, and ideally throughout the completion of the phase III trial(s), the pharmacokinetics are assessed. Single-dose and multiple-dose pharmacokinetics are usually determined in the dose escalation phase I study(ies), and dose proportionality and time-dependent changes in the pharmacokinetics can be assessed with this data. In some cases, population PK/PD modeling is started with the development of the base model using this data. Collection of samples for pharmacokinetic analyses from phase II may be correlated with markers of effectiveness and toxicity. Drug development according to this scheme would lend itself to an EOP2a analysis, and subsequent simulation of possible phase III trial designs, which may be very helpful in choosing the most efficient regimens, doses, combinations, and/or patient populations. In the late phase I early phase II period, it may be advisable to assess the effect of food on the pharmacokinetics of orally administered drugs in order to decide how to administer the drug in the pivotal trial and the intended patient population. It may also be helpful to consider the effect of two drugs that may be co-administered together. For instance, in oncology, drugs developed for glioblastoma multiforme are often administered with antiepileptic medications, such as phenytoin. The latter drug induces CYP 450 3A4 expression and often reduces the plasma concentrations of the new drug to levels that are too low to be effective. In these cases, the new drug is often developed with concomitant use in all later studies and is labeled for use specifically in combination with each other.

Often in this time frame, thorough QTc studies are performed to assess the potential for the drug to prolong the QT interval, and possibly generate torsades de pointes. Mass balance studies are often conducted some time between the first-in-man studies and phase II. Drug-drug interaction studies and organ dysfunction studies are often conducted in parallel to the phase III, when the decision has been made to pursue the drug marketing. Bioequivalence studies are conducted at various

points during development, from phase I to postdrug approval, depending on the development of the drug formulation and oral preparations with new strengths.

## 25.9 DRUG REGULATION IN GLOBAL ENVIRONMENT

Drug development has become a global effort with clinical trials in several disease areas often involving a multitude of centers across the globe. Even when some individual clinical trials are conducted in one country or region, a package submitted for approval purposes often includes trials conducted in a number of regions around the world. Even when individual trials are conducted in one region, commercial sponsors usually have a global strategy aimed at marketing approval in a number of countries and regions. While international activities take place in virtually every component of the FDA, the Office of International Programs (OIP) is the focal point for the agency's international activities. It provides leadership for FDA's international activities by guiding and supporting agency programs and by developing strategic relationships with other U.S. and foreign governmental agencies and international organizations. While the FDA takes a proactive role in these activities, it is also worthwhile to discuss not only the role of the FDA but to also describe the roles of other regulatory agencies around the world. The following is a brief introduction to drug regulation in Canada, Europe, Australia, and Japan.

The Therapeutic Products Directorate (TPD) is the Canadian federal authority that regulates pharmaceutical drugs and medical devices for human use and is housed within Health Canada (Ministry of Health) [38]. Prior to being given market authorization, a manufacturer must present substantive scientific evidence of a product's safety, efficacy, and quality as required by the Food and Drugs Act. The Biologics and Genetic Therapies Directorate (BGTD) has regulatory oversight for biologics, radiopharmaceuticals, genetic therapies, and the transplantation of tissues, cells, and organs.

With headquarters in London, the European Medicines Agency (EMA) is a decentralized body of the European Union (EU) that coordinates a network of 42 national agencies and has undergone significant changes concurrent with the enlargement of the European Union [39, 40]. Its main responsibility is the protection and promotion of public and animal health through the evaluation and supervision of medicines for human and veterinary use. The EMA began its activities in 1995, when the European system for authorizing medicinal products was introduced, providing for a centralized and a mutual recognition procedure. The EMA has a role in both, but is primarily involved in, the centralized procedure. Where the centralized procedure is used, companies submit one single marketing authorization application to the EMA. A single evaluation is carried out through the Committee for Medicinal Products for Human Use (CHMP) or Committee for Medicinal Products for Veterinary Use (CVMP). If the relevant committee concludes that safety and efficacy is proven, it adopts a positive opinion. This is sent to the Commission to be transformed into a single marketing authorization for the whole European Union. Since 2005, applications for marketing authorization within the European Union for diabetes, AIDS, cancer, neurodegenerative disorders, and for products with orphan designation have required submission exclusively through the centralized procedure [40].

In Australia, the Therapeutics Goods Administration (TGA) has authority in the regulation of prescription and nonprescription medicines, medical devices, and gene technology products. The TGA guidelines are aligned with those of the European Union and the International Conference on Harmonisation (ICH) of drug regulatory activities. Further information on drug regulation in Australia can be found on the official webpage [41].

In Japan, regulatory activities have been consolidated into the Pharmaceuticals and Medical Devices Agency (PMDA) since 2004. The PMDA is authorized by the Ministry of Health, Labor and Welfare (MHLW) and includes a staff of approximately 250 personnel including reviewers. The PMDA is comprised of four offices: Office of Relief Funds, Office of Review, Office of Safety, and Office of Research and Development Promotion. Further information on drug regulation in Japan can be found on the official PMDA webpage [42].

In China, regulation of foods, drugs, cosmetics, and traditional Chinese medicinal preparations is the purview of the State Food and Drug Administration (SFDA). Drugs are regulated by the Center for Drug Evaluation (CDE). Further information on drug regulation in China can be found on the official SFDA webpage [43].

## **APPENDIX CLINICAL PHARMACOLOGY DRUG DEVELOPMENT QUESTIONS**

### **Exposure–Response Questions**

1. What are the concentration/dose–response relationships? (ER, population PK)
  - What are the effectiveness endpoints? In vivo
    - Biomarkers?
    - Clinical outcomes?
  - What are the safety endpoints? In vivo
2. What are the factors that affect the concentration–response relationships? (ER)
  - Do pharmacogenomics affect the ER? In vitro, In vivo (VGDS)
  - What is the extent of protein binding? Does it impact ER? In vitro
  - Are there active metabolites that contribute to ER? In vitro (drug metabolism/drug interaction)
  - What are the characteristics of metabolism and elimination that affect the ER?
  - Is the drug eliminated by metabolism, renal excretion, or both (some other route)? In vitro, in vivo (drug metabolism/drug interaction)
  - Is the drug a CYP 450 isozyme(s) substrate, inhibitor, induce? In vitro
  - Are in vivo drug–drug interaction studies needed to assess impact? In vivo
  - Are labeling instructions necessary?
  - Is the drug a P-glycoprotein substrate or inhibitor? In vitro (drug metabolism/drug interaction)
  - Are in vivo drug–drug interaction studies needed to assess impact? In vivo
  - Are labeling instructions necessary?
  - Are there metabolic polymorphisms that affect metabolism/elimination?
    - In vitro, In vivo (drug metabolism/drug interaction)

- Are in vivo drug–drug interaction studies needed to assess impact?
- Are labeling instructions necessary?
- Are in vivo studies in patients with hepatic impairment needed to assess the need for dose adjustments? In vivo (hepatic impairment)
- Are in vivo studies in patients with renal impairment needed to assess the need for dose adjustments? In vivo (renal impairment)
- Does age have any effect? In vivo (21 CFR 314)
- Does race have any effect? In vivo (21 CFR 314)
- Does gender have any effect? In vivo (21 CFR 314)
- Are the ER the same in pediatric populations? In vivo (Pediatric PK)
- Are specific dosing instructions/regimens required?
- 3. What biopharmaceutics issues affect ER of the drug?
  - Can the active moieties of the drug be accurately measured? In vitro, In vivo (Bioanalytical method validation)
  - What is the extent of absorption? In vitro, in vivo (21 CFR 320, BA/BE, BCS Classification)
  - Are there different formulations of the drug that affect the ER? In vitro, In vivo (BA/BE, dissolution, IVIVC, SUPAC, IR, MR)
  - Are there different oral formulations that absorbed differently?
  - Is there a modified intravenous formulation that affect ER? In vitro, in vivo (Liposome drug products) e.g., liposomal drug, antibody-conjugated drug, etc?
  - How does food affect absorption of an oral formulation? In vivo (Food effect)

## 26.1 INTRODUCTION

Clinical development faces two major challenges: public trust and productivity. Costs in drug development have increased substantially over the past decades [1]. Notwithstanding this development, the number of new drugs that are implemented in clinical practice has not increased but rather decreased in recent years [2]. At the same time, recent opinion polls [3] show that the public trust in pharmaceutical companies has fallen sharply and is now almost at a level comparable to that of the oil and tobacco industries. While some may argue that these challenges of public trust and productivity are difficult to align, we consider both to be essential and indeed mutually dependent. If public trust in clinical trials decreases, recruitment of patients for clinical trials will be more difficult, which in turn will result in even poorer productivity.

The ambition of improving public trust, especially in view of the tragic incident at Northwick Park Hospital in March 2006, has much to do with heightening ethical standards. The dual objective of this chapter is therefore to clarify the nature of the ethical challenges that lie ahead and to specify the design features that can increase productivity in individual clinical trials under ethically acceptable standards. Our question could be formulated as follows: Given that clinical trials should meet stringent requirements, how can productivity be maximized? In order to formulate an answer to this question, we will first have to specify the ethical requirements. Once these have been formulated, we will provide a method of analyzing trial efficiency and will give examples of how productivity can be increased. In doing so, we will consider specifically how to optimize the information per patient, approach sample size determination from a business perspective, and choose between adaptive design options.

This reflection is inspired by decision analysis (DA), which is a method that aims at optimizing different kinds of decisions, often by analyzing trade-offs. The essential assumption of DA is that different objectives can be valued on a common scale. For example, if one treatment offers better health benefits while the other provides better safety, it is possible to compare the two and choose the treatment that maximizes the net utility for the patient. Furthermore, even if the respective health benefits and safety features of these treatments are uncertain, DA offers the possibility of comparing the expected utility of the two treatment options. In this study, the first DA will be patient-centered, meaning that the net utility of the *patient* will be focused. After and secondarily to that, the interests of science and the sponsor of the trial will be considered, and a commercial optimization of clinical trials will be outlined. This priority is, in our minds, the only one that is ethically acceptable.

### 26.1.1 Introducing Public Trust

The study will therefore begin by a broad review of the ethical issues facing clinical development and more specifically randomized clinical trials (RCTs). In doing so, we formulate three minimal ethical requirements that should be met before patients can be enrolled in RCTs: genuine consent, patient benefit optimisation (PBO), and nonexploitation. These requirements are addressed principally to physicians who ultimately are responsible for their patients' health and for the enrollment of their

patients in any RCT. Our requirements do not cover properly scientific or regulatory concerns, and it is taken for granted that any clinical trial must also be examined and approved by an ethical committee or an investigational review board (IRB). In addition, we take for granted that regulatory approval is needed to administer new pharmaceuticals outside clinical trials. A more detailed list of ethical requirements covering such scientific and regulatory issues has been formulated by Emanuel et al. [4].

The core issue being treated here is therefore the physician/patient relationship and how it is affected by the collaboration of the former in clinical development. We argue that this collaboration does call into question the physician's fiduciary commitment to the well-being of his patient, as he or she must concurrently serve the interests of science. Such collaboration, which constitutes a threat to patient trust, can only be ethically justified through the consent process in which the patient acquiesces to participate in an RCT. The patient's informed consent in this matter should therefore not only be a formal but genuine and be based on relevant and appropriate information allowing the patient to formulate a well-reasoned judgment about such participation.

While this genuine consent is a necessary condition, it is not a sufficient prerequisite for trial participation. There are instances when the patient might accept to take part in a trial but when such participation would nonetheless be unethical. Such situations might arise if the patient is not sufficiently informed or free to consent or decline trial participation or when the trial design itself is morally skewed. That is why the physician, who is ultimately responsible for the patient's medical well-being, must be certain that he or she can, in good conscience, propose an RCT to his or her patient. Traditionally, this ethical peace of mind has been sought in the state of equipoise, understood as a state of "genuine uncertainty" on the part of the physician as to the merits of the respective arms of the trials. We argue, in a Bayesian perspective, that such genuine uncertainty in reality never exists. The physician has always a hunch or can second guess, on the basis of medical competence and experience, which arm in the RCT will receive the best treatment. An appeal to equipoise alone will therefore not do. We believe that the only way to ethically justify physician collaboration and patient participation in a RCT is the requirement of patient benefit optimization, that is, the judgment that the patient will benefit more from inclusion in the trial than from exclusion [5].

Besides genuine consent and patient benefit optimization, there is a third ethical requirement that we believe is essential: the principle of nonexploitation. It stipulates that no coercion should be used in the recruitment of patients. In other words, a patient or volunteer must be provided with sufficient freedom to willingly accept or decline an invitation to enroll in a RCT. The research subject might not, for instance, feel free to decline an offer to participate in a trial if this would result in, for example, inferior treatment. Such a situation can arise when research is carried out in developing countries or if patients are required to participate in a clinical study in order to qualify for medical coverage.

### 26.1.2 Introducing Productivity

Within the framework of these ethical requirements, the sponsor must design the most efficient trial. What does efficiency mean, however? Just as different

therapeutic treatments have medical pros and cons, trial designs have also relative benefits and drawbacks. Thus, DA is useful, not only in evaluating the ethical issues involved but even more so in the analysis of efficiency. In Section 26.3.2 we propose a detailed 10-step DA approach to clinical development. In this introduction, we limit ourselves to outlining the four most important steps, which are (1) modeling background information, (2) specifying trial objectives and utilities, (3) identifying design options, and (4) optimizing the decision of the three previous steps.

Experimentation is driven by the need to know more about the medical effects and safety features of a certain drug. It is therefore important to evaluate the information that is already available and to quantify the level of uncertainty. Existing information about the drug's characteristics can usually be compiled from a number of sources. Previous clinical trial data are often limited, especially in early clinical development. To fill in the information gap, investigators can refer to preclinical data, literature on the disease and related drugs, and expert input. In a DA approach, a quantitative model must first be constructed based on already existing information and a set of assumptions. These assumptions are necessarily subjective and should therefore be challenged during the analysis process. Then the objective of the trial must be formulated from a wide enough context in order to avoid suboptimization. The overall objective is then converted into quantitative preferences, which can be called utilities. The utility is thus a function of the outcome of the trial and reflects both the value of information as well as the cost of experimentation. In Section 26.3, we will take the commercial net present value (NPV) as an approximation of the utility of the trial sponsor. Third, DA can help to identify the designs and to tailor them in such a way that they are compatible with the objectives of the experiment. Still today, many trials are given standard designs, without taking into account its specific objectives. We therefore argue that standard procedure, at the outset of any trial, should be to generate, through project team brainstorming, a number of designs by considering common options such as cross-over, adaptive, and enrichment designs. Finally, the fourth step consists in predicting the trial results for the different designs. These predictions are made from the model and are typically carried out by computer simulations. When this is done, the predicted trial outcomes can be combined with the utility function. An expected utility can then be calculated and the optimal trial be designed in view of maximizing this value. By questioning the underlying assumptions and making tentative modifications of them, the robustness of this result can be verified.

The DA approach will thus be the dominating framework when discussing different aspects of study design. We will therefore discuss how much information should be obtained from each patient in view of optimizing the design (Section 26.3.3). Multiple measurements and multiple treatments (cross-over study) for each individual will yield more information but might also cost more and cause methodological problems. It is therefore important to analyze the optimal amount of information to purchase, that is, the optimal sample size when information value is compared with the cost of the experiment (Section 26.3.4). Finally, we will consider some sequential and adaptive designs where the trial design decisions depend on accumulating information (Section 26.3.5).

A number of recent trends in clinical study methodology and technology are supporting the DA approach to trial optimization. Model-based drug development,

and especially pharmacokinetic/pharmacodynamic (PK/PD) modeling, are being used more and more by the industry and are being promoted by regulators. The Food and Drug Administration (FDA) has stated that a drug may, in some instances, be approved on the basis of only one single confirmatory trial when supported by modeling results. The increase in computer speed has opened the way for nonlinear mixed-effect models as well as for Bayesian methods, where a probability model is updated with accumulating data. New design options are identified, and there has been an increasing interest in adaptive designs during the last decade. Web-based data capture has greatly facilitated the practical implementation of sequential and adaptive designs. The interest in decision-analytic approaches is on the upswing, and methodological work is being done in related areas, ranging from the psychology of decision making to the integration of commercial values in sample size determination.

## 26.2 CHALLENGE OF PUBLIC TRUST

From the point of view of medical ethics, clinical trials are problematic because they challenge the generally held view that the principal responsibility of physicians is to further the well-being of the individual patient. This responsibility is the cornerstone of the physician–patient relationship. As Ruth Purtilo argues [6], the professional's priority to further the welfare of the patient:

is interpreted to have the stringency of a special moral obligation on the part of the professional to seek a patient's well-being, guided by that person's health-related concerns and needs. Any other worthy goal, such as furthering knowledge about disease and its cure, or earning a just wage, or maintaining the efficiency or financial solvency of the institution, is not an appropriate beacon to guide the professional in this relationship.

This hallow responsibility is enshrined in most codes of ethics regulating medical conduct and has enjoyed almost universal recognition. In the Oath of Hippocrates (Greece, 4th century B.C.E.), the physician swears to apply his art “for the benefit of the sick according to my ability and judgment” adding that he will keep the sick “from harm and injustice.” In the Indian tradition, the Oath of Initiation (Caraka Samhita) from the first century C.E. puts it another way: “Day and night, however you may be engaged, you shall endeavour for the relief of patients with all your heart and soul.” Similar enjoinders can be found in the Advice to a Physician (Persian tradition 10th century C.E.) and in the 17 Rules of Enjuin (Japanese tradition 16th century C.E.). In modern times, the International Code of Medical Ethics adopted by the World Medical Association in 1949 phrases this obligation as such: “A physician shall act only in the patient's interest when providing medical care which might have the effect of weakening the physical and mental condition of the patient” [7].

Insofar as the objective of clinical trials is to advance science through the randomization of patient treatment, the collaboration of physicians and the involvement of their patients in such trials would seem at first glance to be ethically problematic. The question that looms at the outset of this study is whether clinical

trials may be conducted under ethically acceptable standards. To answer that question we must begin by examining the nature of clinical practice and especially the character of the physician–patient relationship. This reflection will help us to determine whether the collaboration of physicians and the participation of patients in such trials can ever be justified, and if so, under what conditions.

### 26.2.1 Requirement of Genuine Consent

The startling breakthroughs of biomedical science during the last decades, and the promise of more revolutionary treatments and drugs, obscure the simple fact that medicine is primarily a relationship between two individuals. As Thomasma [8] has pointed out, “medicine is not a theory about the body or how the body works, so much as a theory about practice, about the ways in which physicians and patients, other health professionals, and institutions interact to bring about healing” (p. 246). This interaction begins when a person in a vulnerable state due to physical or psychological illness or distress requests assistance and is admitted to medical care. In doing so, the patient assumes that the physician, as the person in charge of his or her care, will act in his or her best interests and will prescribe the most effective medication or treatment available. What characterizes this relationship is therefore trust and responsibility. The patient trusts that the physician will act in his or her best interest while the physician accepts to shoulder the responsibility of taking care of the patient to the best of his or her abilities.

In the Hippocratic tradition, which still shapes our understanding of the ethos of medicine, the physician–patient relationship is understood in terms of a certain kind of friendship [9, p. 20]. The friendship of the physician (*philantropía*) sees to the well-being of the patient and is expressed through the love for his art (*philotekhnía*), which is healing. While there were many practitioners of the art of healing in ancient Greece, such as magicians and exorcists, the Hippocratic physician loved his art as a *techné*, that is, as an empirically established technical body of knowledge useful to his craft. The Hippocratic Corpus [10, p. 314] states unequivocally the commitment of the physician to empirical science:

Do not rely on conclusions that result from mere reasoning, but (rely) on evidence. Arguments in the form of plain rhetoric are false and easily defeated. Therefore, you should stick to the facts and scrutinize them, if you are going to acquire faultless capability, which we call Medicine.

Thus, the Hippocratic physician loved his art through his concern for the well-being of his patient and his patient through the practice of his scientifically established craft [9, p. 45]. In other words, the physician loves his patient as a friend because he can come to his aid by applying his craft and knowing that this craft is well founded and likely to produce good results. In this view, science is an essential medium but still plays an ancillary role to the practical object of medical practice, which is the healing of the patient.

In the context of the discussions of the morality of randomized clinical trials, this view of the physician–patient relationship has undergone a radical change. Medical science is no longer seen as primarily an instrument that permits the physician to

exercise his art of healing but as a competing object of his professional responsibility. In other words, it is no longer only a medium but equally an end of the physician's work and thus regulated by an independent set of values. In a very influential article, Lellouch and Schwartz [11] characterize the conflict of interest facing the physician as one between an individual ethics and a collective ethics.

Clayton [12] spells out what these competing sets of values involve. Individual ethics refers, on the one hand, to the duty of the physician "to apply existing knowledge for the best possible treatment of each individual patient." Collective ethics, on the other hand, refers to two duties of the physician: (1) "to acquire new knowledge so that, by that advance, future patients might benefit" and (2) "having acquired that knowledge, to accurately communicate it to other physicians." Gifford [13] notes the existence of the physician's "therapeutic responsibility," which he believes, *prima facie*, to be incompatible with his collaboration in randomized clinical trials. However, mindful of the benefits that clinical trials bring them, patients might allow the physician to collaborate and would willingly submit themselves to randomized treatments. In this contractual scheme inspired by the philosophy of John Rawls and Robert Nozick, randomized clinical trials could be considered ethical to the extent to which the patients acquiesce to participate and permit the physician to override his or her therapeutic responsibility in order to further a more collective good.

Gifford's contractual approach defers the physician's fiduciary responsibility and places the decision of RCT participation on the shoulders of patients themselves. This approach corresponds well with the insistence upon the informed consent process and the principle of autonomy, which permeates today's ethical climate. This principle of autonomy or permission is widely considered today as the lowest common ethical denominator and the foundation of modern ethics. The reasoning behind one of the major proponent of this view, H. T. Engelhardt [14], is the following. There is a plurality of moral goods, which human beings can pursue and enjoy such as freedom, work, health, pleasure, religious faith, and many others. How these values are ranked in the pursuit of a good life depends very much upon one's political, religious, and philosophical convictions. Furthermore, these different values cannot be arbitrated by appealing to an objective standard, to which everybody can agree. In light of this plurality of moral opinions, it is up to the individual to determine what is good for him or her. A man suffering from prostate cancer might, for instance, want to choose between radical prostatectomy and more conservative methods depending on what outcome he values. If he is younger and still wants to father a child, he might value the preservation of fertility very highly. However, if he has no such thoughts, he might opt for the treatment that offers the best possible outcome in terms of life preservation. It all depends on what values he espouses and what plans he has for the future. Free and informed consent is, in this light, the gold standard of medical ethics.

The principle of autonomy or permission, with its stipulation of free and informed consent, is, in the view of most ethicists, a necessary condition for patient participation in any RCTs, with the possible exception of trials carried out in emergency situations where patients or their next of kin cannot give immediate consent. There is also general agreement that participants should be informed specifically about the relevant details of the randomization process. It is not the quantity of information

given to the research subject that determines whether the consent is free and informed but his or her ability to understand relevant facts in order to make an informed decision. That is why some ethicists talk about “genuine” rather than informed consent [15]. This wording emphasizes the fact that true consent requires health care providers to do their best to communicate accurately and in a way that is understood by patients, volunteers, or relatives. It presupposes that these can understand procedures and risks and react to the limits of their understanding. Moreover, it requires care in detecting and eliminating lack of consent.

While there is general consensus about the necessity of informing patients on randomization procedures as part of the consent process, and prior to trial participation opinions differ on the necessity of informing research subjects about interim data. Those who argue against such disclosure [16] fear that interim data can be unreliable and misunderstood by research participants and the media, which in turn could compromise the completion of RCTs. In a contractual understanding of RCT participation, it is possible to conceive that patients would waive the right to such data, and would accept an “incomplete disclosure” [17] as part of the consent process. Lilford et al. [18] disagree and argue that the praxis of withholding interim data has no public endorsement, is contrary to the spirit of regulations, and is the reflection of a “culture of secrecy and scientific imperialism” that is self-fulfilling. Making interim data available, they argue, would not necessarily reduce recruitment to clinical trials but would most likely increase it because it would enhance public trust in the study. As a result, it would also widen the base of the participants, thus improving the trial’s generalizability. The authors provide the example of the second international study of infarct survival (ISIS 2) in which disclosure of improved survival rates of heart attack patients taking clot busting drugs increased recruitment as sceptical physicians became more interested in the interim results. This example shows that more stringent ethical standards do not necessarily decrease productivity. In some instances they could even increase it.

### **26.2.2 Requirement of Patient Benefit Optimization (PBO)**

The Hippocratic model of the physician–patient relationship, where the physician bears the main burden of responsibility and decision making, is considered by many as too paternalistic. Today, patients want to be full-fledged partners in the clinical process, together with the physician. This is all the more important as the physician’s loyalty to the patient competes with his or her scientific ambitions. The patient must therefore also fend for himself. Informed consent procedures are one step on the way to establishing more equality between patient and physician. Furthermore, a more democratic approach might give added credence to clinical trials and does not necessarily result in less efficiency. On the contrary, more public trust through greater transparency could result in better recruitment and more generalizability. But there are instances where the requirements of informed consent might not be sufficient to make a clinical trial ethically acceptable.

In addition, the principle of autonomy with its requirement of informed or genuine consent builds upon a model of the patient as a rational agent. This model does not describe accurately how patients make clinical decisions concerning their own welfare. Individuals often behave and make decisions irrationally. To compare treatments is often a complex task, involving a multitude of effect, safety, and con-

venience dimensions. When asked to choose between two treatments, we may therefore—irrationally—prefer treatment A to treatment B, B to C, but C to A, thus violating the transitivity axiom in decision theory. Furthermore, many people have difficulties in understanding small risks. Lastly, the patient is not always able to give informed or genuine consent as, for example, in an emergency or situation of distress. Such a situation may arise when the patient is informed that he suffers from a chronic or fatal disease. He may feel that the physician's time is limited and he may interpret a question about trial participation as an advice or wish from his physician. If the physician clearly communicates that he does not know which treatment is best, and has no advice about study participation, the patient may give his formal consent by signing a piece of paper without really understanding the content and relevance of the information received and thus without acting in a truly free and informed manner.

Because patients are not always capable or even willing to act rationally, and bearing in mind that genuine consent is sometimes difficult if not impossible to retrieve, the attending physician ultimately bears the responsibility of furthering the well-being of his patient and assuring that the trial itself is ethically sound. How can this be assured?

Over the past 30 years, the notion of equipoise has been used to ethically justify physician collaboration in RCTs. It was first used in this context by Charles Fried [19] in 1974 when speaking about the “balance of opinion” among physicians and investigators, when no treatment option in a multiarm RCT is perceived to be inferior to the other or others. From this balance of opinion the term has taken a more psychological turn to connote the “state of genuine uncertainty on the part of the clinical investigator regarding the comparative therapeutic merits of each arm in a trial” [20]. According to this standard, RCTs would be morally justified to the extent to which the clinical investigator can honestly claim a “state of genuine uncertainty” between the treatment options incorporated in the study design.

Most ethicists and clinicians agree that true equipoise rarely exists. Clinical trials are financed and conducted because there are reasons to believe that a new drug or treatment option will improve care, which is also why clinicians choose to implement them in their practice. Notwithstanding this *a priori*, there might be, however, scholarly discussions in the scientific community about the relative efficacy of a novel therapy. So while absolute or “theoretical equipoise” might not exist, there might still be a nagging uncertainty among investigators and health care providers about the benefits of the different treatment arms. This practical uncertainty or “clinical equipoise” would be the requirement that scientifically justifies such trials. Another term that is used in this context is the ethical theory of “null hypothesis” pertaining to genuine medical uncertainty. The hypothesis entails that clinical trials are justifiable when no consensus exists about which is the better treatment [12, p. 472].

The null hypothesis theory is an easy and questionable justification of RCTs. Consensus among clinicians and researchers about the benefits of a certain treatment versus an alternative is rare, even regarding established treatments. Given that consensus rarely exists, most if not all RCTs could be considered, according to the equipoise theory, as morally justifiable. Moreover, as Lilford [21] has pointed out, even the justification of “uncertainty” regarding treatment outcomes is indeed a

questionable criterion. “Unknown” or “uncertain” is not equivalent to saying that all possible effects are equally likely. Clinicians and investigators always possess some evidence about the merits of the novel treatment or drug before the trial begins. Such information, which can be the basis for drug modeling, is obtained through animal or in vitro experiments, the same treatment in other diseases or, in some cases, even randomized trials. Saying therefore that the effects of the novel treatment are uncertain is certainly ambiguous. The patient might interpret such a statement as meaning that the recruiter has no idea at all about the benefits of the new treatment, which is not the case. Certainty and uncertainty are not absolute terms, and the physician is therefore most likely to have some idea about relative advantages and disadvantages. As Lilford states, “the blanket term of unknown sidesteps any indication of the magnitude of possible effects, reducing the chance that potential participants will be able to appreciate what is really at stake” [21]. In addition, the whole theory of equipoise and ethical null hypothesis is paradoxical because the more an investigator knows about a compound or a treatment the more he would draw away from equipoise. Oddly, it would encourage ignorance.

The notion of equipoise, as used in the debate over RCTs, is therefore problematic because it places too much emphasis on the physician’s state of mind. Pleading uncertainty, as Lilford points out, says very little about what is known and what should be told to a patient concerning the merits or drawbacks of a certain treatment option. What is really ethically at stake in RCTs is not whether the physician considers himself or herself in a state of equipoise but whether the patient will benefit more from inclusion in than from exclusion from the trial. This is precisely what the requirement of PBO entails. If the patient stands to benefit personally by inclusion in the trial, the RCT would meet the requirement. If he or she does not, the requirement would not be met.

Studies in which patients in the control arm receive the standard treatment while patients in the experimental arm are given a novel drug expected to be superior would fulfill the requirement of patient benefit optimization. With all patients receiving standard treatment as background medication, it is often acceptable to compare the addition of a new drug with the addition of placebo [5]. But what about placebo-controlled trials where patients in the control arm would be given no pharmaceutical treatment at all? Most ethicists agree that there are conditions when placebo-controlled trials are acceptable and others when they are clearly not. If the ailment under investigation is not serious, and when there is minimal risk and minimal burden for research participants, the use of placebo is generally considered as ethical. A trial studying allergic rhinitis is a good example since this ailment typically does not impair health or causes severe discomfort. Since the possibility of harm is minimal, the benefit derived for the patient in the control arm could be the satisfaction of helping others. Such a trial, despite the use of placebo, could therefore meet the requirement of patient benefit optimization. There are, however, other situations where the use of placebo is unethical. If effective, life-saving, or life-prolonging treatment is available, and if research subjects who receive placebo are more likely to suffer serious harm, a placebo-controlled trial is unethical. The disagreements among ethicists, investigators, and clinicians center on whether placebo controls can ever be used in trials where a treatment known to be effective is available and when there is some potential harm to participants being randomized [22].

The Declaration of Helsinki [23], the most authoritative text on matters of research ethics, is not totally clear on this matter. Paragraph 32 states: “The benefits, risks, burdens and effectiveness of a new intervention must be tested against those of the best current proven intervention, except in the following circumstances: the use of placebo, or no treatment, is acceptable in studies where no current proven intervention exists; or where for compelling and scientifically sound methodological reasons the use of placebo is necessary to determine the efficacy or safety of an intervention and the patients who receive placebo or no treatment will not be subject to any risk of serious or irreversible harm. Extreme care must be taken to avoid abuse of this option.” Commentators argue that this wording in the latest revision of the declaration signals a move to a more permissive attitude toward placebo use. This interpretation is motivated by the fact that the 1996 version included the provision that “in any medical study, every patient—including those of a control group, if any—must be assured the best proven diagnostic and therapeutic method” (Paragraph II.3). This sentence, once again, has been eliminated. Despite this omission, the overall tenet of these both versions seems to rule out the use of placebo wherever proven treatment exists. Paragraph 32 in the latest version adopted in 2008 in Seoul, lists two situations where placebo is acceptable: where there are “compelling and scientifically sound methodological reasons,” *or* where the condition under study will not lead “to any additional risk of serious and irreversible harm” [23]. What has led commentators to interpret more leniency regarding placebos is the option of the connector “or” instead of “and” between the two provisions. It would seem therefore that the Declaration of Helsinki, in its present version, could be interpreted as saying that the use of placebos for “compelling and scientifically sound methodological reasons” is permissible even when there is an increased risk of serious harm.

The spirit of the text does not go in that direction and the wording of Paragraph 6 ultimately invalidates such an interpretation. This paragraph states that “in medical research on human subjects, considerations related to the well-being of the human subject should take preference over all other interests.” However, much of the confusion surrounding Paragraph 32 has to do with the terms “best current proven” or “proven” intervention. Does the text mean “proven” in existence, in a local context, according to the judgment and knowledge of the attending physician, or according to the best interests of the patient? The Nuffield Council on Bioethics [25] suggests that “best proven” should mean “the minimum standard of care that should be offered [in the control arm] is the best intervention available as part of the national public health system.”

The Declaration of Helsinki encourages ethically optimized designs that exclude the use of placebos. Consider, for example, a situation where it is scientifically interesting to compare two different drugs, X and Z, which both are available on the market. By giving each patient the drug that is expected to be best for him or her, and assuming that this choice will be different for different patients, it is possible to learn more about the relative merits of the two drugs. Say that X is perceived to be better in patients with mild disease, expressed as a baseline value of a certain covariate below a cut-off  $c$ , while Y is thought to be better for patients with covariate values above  $c$ . If the responses are collected, the results from both groups can be modeled as functions of the covariate and extrapolated so that a comparison of the expected responses of the two treatments can be done. As more and more observations are collected, the estimated cut-off will change and treatment practice will

improve over time. This type of trial would be in conformity with the Declaration of Helsinki ethically optimal but, unfortunately, it is not very efficient or viable compared to standard RCTs.

More often than not, it is desirable for methodological and regulatory reasons that the experimental treatment Y is tested against placebo without using X. Can any such trial withstand the PBO requirement? Imagine a trial where participation is beneficial on average but unfavorable for the patients randomized to one of the treatment arms. Say that mortality is estimated to be 10% for placebo, 9% for the “best proven” therapeutic method C, and 8% for a new nonapproved drug candidate X. In order to get regulatory approval for X, the trial would need to prove its superiority versus placebo, which is much easier and cheaper than to show superiority, or even noninferiority, versus C [26]. Therefore, a blinded trial is proposed where  $\frac{3}{4}$  of the patients are randomized to X and  $\frac{1}{4}$  to placebo. The expected death risk for a patient taking part in this trial is  $\frac{3}{4}(8\%) + \frac{1}{4}(10\%) = 8.5\%$ , which is lower than the 9% risk experienced by the patients that do not take part in the trial and receive C. This trial would meet the requirement of PBO because, statistically, the patient would benefit more from trial inclusion than from exclusion. It is still, however, very debatable whether the trial would be ethically acceptable because it inevitably exposes certain patients to less than “best proven” treatment. This example shows that while the PBO is a necessary ethical requirement, it is not alone a sufficient requirement for ethically validating a trial.

The example above also indicates that the PBO should not be interpreted as an average utility for all participating patients in the trial but should also be relevant and applicable to every individual participant. Retsas [27] has formulated a thought experiment, which illustrates this point through what we will call the VIP principle:

Imagine that you are an acclaimed expert on a particular disease and you are invited to offer your services to your head of state. Will the head of state be enticed to participate in a randomised trial leaving his or her treatment to chance, or will treatment be provided on the best available knowledge of the day? It can be observed safely that there are hardly any prime ministers, secretaries of health, doctors, professors, or similar persons who enlist in the ranks of randomised cohorts that serve the progress of medicine!

Retsas' thought experiment is very general and suggests that all RCTs are unethical. While some ethicists have argued that such is the case [28], most believe that it is not. Retsas is also wrong in stating that “doctors, professors or similar persons” do not participate in RCTs. They often do, and the history of medicine is full of examples of clinical researchers risking their lives with self experiments in the zealous pursuit of scientific knowledge. But the point is well taken that physicians seldom recruit VIPs, be they heads of state or their own children, to RCTs. When human life is truly at stake, leaving treatment option to chance, even when there are reasons to believe that the experimental group stands to benefit, is indeed counterintuitive. The fact that a high percentage of drugs tested in phase III clinical trials never reach the market would lead us to exercise extreme caution. The poignant question that Retsas addresses is this: If VIPs are seldom, if ever, randomized by physicians, why should anybody else be? While the VIP principle might be intuitively sound, reason can still ethically motivate RCTs if every individual patient

can be assured that he or she will receive the best possible treatment or its equivalent.

### 26.2.3 Requirement of Nonexploitation

It has been argued that genuine consent should be a necessary condition for enrollment in a clinical trial. Given that RCTs distort the fiduciary relationship between patient and physician through the latter's participation in what is essentially research and not primarily therapy, the patient's genuine consent is essential in order to reestablish the contractual balance between the two parties. Such a requirement, it has also been argued, is not a sufficient condition for patient enrollment in RCTs. Besides genuine consent, the physician must also ensure that the design of the trial, especially its expected utility, can be aligned with the patient's best overall interests. From an expected utility perspective, the patient should stand to benefit more from inclusion in the trial than from exclusion. There are, furthermore, other cases involving research subjects where the ethical issues involved in the physician–patient relationship are not covered by the two aforementioned requirements, hence the necessity of formulating the requirement of nonexploitation.

A good example of where this requirement is at stake is first-time-in-man (FTIM) trials planned in healthy volunteers. Usually, trial participants are offered economic compensation for the time and discomfort associated with the experiment. Is it unethical to pay these participants for taking medical risks, and would such payment constitute a form of coercion? Assume that there are no discomforts in such a trial, that trial participation is short, that there are no health gains for the volunteers but a slight risk of experiencing an unexpected serious adverse effect. With the possible exception of altruism, there would then be no other reason to participate in the trial other than economic compensation. Assume, furthermore, that a firefighter in the United States is paid to take a small risk in a clinical trial in much the same way that he is compensated for work-related risks. Although it is hard to assess trial risks objectively, it is certainly possible to give some ball-park estimates. Severe adverse events are extremely rare but, as the incident in Northwick Park Hospital in March 2006 shows, they do occur and could potentially lead to death. As a very approximate risk calculation, assume an expected 0.01–0.1 deaths per year globally in FTIM trials, 100 new approved drugs per year, 10 times more drugs tested in humans, and 10 individuals per trial. Then the average death risk for participants in FTIM trials would be about 1 in 100,000 or 1 in 1,000,000. A more careful analysis, using historical data and expert input, may give much better estimates. The risks will also depend on the different kinds of drugs. Hence, there are nonnegligible risks, but these are small and comparable to those taken by some groups as part of their professions. As a comparison, the fatality rate per year in the United States is almost 1 in 1000 for logging workers and fishers and 1 in 4000 for truck and taxi drivers [29]. Healthy volunteers in FTIM studies are paid for their time and for the discomforts they might suffer as a result of the study. From a DA perspective, however, risks and economic gains can be factored in the decision about whether or not to take part in the trial.

The requirement of nonexploitation stipulates that research subjects must be sufficiently free to be able to consent genuinely or, by the same token, to decline trial participation. Generous financial benefits would cast a doubt over certain

persons' capacity to decline an offer of participation, especially those who are economically vulnerable. In this respect, the additional protocol to the Bioethics Convention on biomedical research, adopted by the Council of Europe in January 2005, states very clearly that "no undue influence, including that of a financial nature, will be exerted on persons to participate in research. In this respect, particular attention must be given to vulnerable or dependent persons" [30, Article 12]. The explanatory report of the protocol does not strictly define the term "undue influence" but suggests that it is related to coercion and "may be exerted in particular on a person in a weak or feeble condition, so that very little pressure will overbear the person's will, and make the individual feel that he or she must agree" Furthermore the text specifies that "compensation should not be provided at a level that might encourage participants to take risks that they would not otherwise find acceptable" (Paragraph 64). From an expected utility perspective those who stand to gain the most from trial participation as volunteers, especially the economically weak, would paradoxically be those who are the most discriminated by the requirement of nonexploitation. This short-term discrimination is necessary, however, to protect their long-term interests.

Biomedical research in developing countries is yet another context where the requirement of nonexploitation is especially relevant. Given the accrued risk of exploitation of vulnerable individuals and the potentially huge economic and cultural impact of RCTs in the communities where they take place, the requirement of individual informed consent is not enough to protect the interests of research subjects in this particular context. The European Group on Ethics [31, p. 14] has thus pointed out that "it may be appropriate to seek agreement on the implementation of a research project from persons representative of or invested with a certain authority within the community, or the family." In developing countries, where the capacity of individuals able to consent has been weakened by earlier exploitation or where the principle of autonomy is not widely acknowledged, the consent process must therefore be strengthened by the implication of the larger community. The UK Nuffield Council on Bioethics has also written on the subject and flagged the requirement of nonexploitation as one of three others that should guide biomedical research in developing countries: (1) the duty to alleviate suffering, (2) respect for persons, and (3) sensitivity to cultural differences [25, p. 52].

In most cases, patients in developing countries would receive better medical care while taking part in clinical trials and would therefore generally stand to benefit more from inclusion than exclusion. Seen from an overall benefit perspective, the requirement of nonexploitation could at firsthand discriminate them by placing more obstacles in the way of trial sponsors wishing to conduct such RCTs in developing countries. Such short-term losses would, however, be compensated by creating a better long-term perspectives for individuals as well as developing communities.

The situations detailed above deal with cases where persons able to give consent, and who might wish to participate in a trial, need nonetheless additional protection against possible exploitation at the hands of trial sponsors and collaborating physicians. But what about cases where research might be a condition for treatment? In the United States, the CMS (Centers for Medicare and Medicaid Services) have recently stipulated, for example, that coverage for new users of approved anticancer drugs depends on the willingness of patients to enroll in a clinical trial sponsored by the National Cancer Institute. The CMS policy affects research on tests or treatments

whose efficacy has not been established for the patients being studied. Orentlicher [32, p. 22] argues that such a condition should also extend to research aimed at determining which treatment is most effective when a patient can be offered one of multiple established treatments. Orentlicher's position is motivated by his concern that important studies are being delayed—and medical progress impeded—by difficulties in securing the participation of individuals. In one example he cites, more than half of the patients invited to participate in the study declined with the total recruitment taking twice as long as expected (16 months instead of 8 months).

The Declaration of Helsinki stipulates that participation in any trial is voluntary, that refusal to participate will involve no loss of benefits, and that such participation may be discontinued at any time. Orentlicher's hypothetical protocol would also require voluntary participation and would not deprive the patient of any benefits to which he or she would otherwise be entitled. What he argues for is the individual physician's right to deny care to any patient unwilling to participate in the study. Such a patient would be referred to another physician. The physician–patient relationship is a contractual one and does not oblige the specialized physician to admit any patient who requests medical attention if such medical attention can be received elsewhere and does not represent a danger to the patient in question. Orentlicher argues that trial participation in view of the common good is a valid and ethically justifiable condition for patient care in case the patient can receive equivalent care elsewhere.

Orentlicher's unorthodox position is certainly worth thinking about because it emphasizes that there are societal considerations in any RCT that a strict interpretation of the physician–patient relationship does not cover. Moreover, in the hypothetical protocol that he proposes, the medical interests of the patients are secured given that the methods being compared are well established and that the patients would be treated by another physician if they declined the offer of participation. However, as we stressed in the beginning, the nature of the physician–patient relationship should be inspired both by the sentiments of friendship and care of the doctor toward his patient and the love for his healing art. It is this *philanthropía* that transcends the terms of different protocols or the provisions of trial designs and that ultimately ethically motivates the physician's *philotekhnía* and hence the possibility of carrying out clinical trials.

### 26.3 CHALLENGE OF CLINICAL TRIAL EFFICIENCY

Most experts in the field consider that efficiency in clinical development is far too poor. One reason that explains this is the rather simple design imperfections that can still be found in some trial publications. In addition to weeding out these imperfections, trials can be further enhanced by implementing new design methodology and combining them with novel supporting technologies, such as Web-based data capture. The FDA's Critical Path has identified a large number of possibilities that could increase the productivity in different stages of drug development [33, 34]. We will focus here principally on some of the possibilities that relate specifically to the improvement of clinical trial design. After an overview of the current situation (Section 26.3.1), we will present a DA approach (Section 26.3.2) to a number of design questions. This paradigm is then applied to the different key aspects of a trial

design. Primarily, we will discuss how each patient can contribute more information (Section 26.3.3), analyze the optimal size of a trial (Section 26.3.4), and outline the possibilities that exist to be more adaptive to incoming information (Section 26.3.5).

### 26.3.1 Background

The great advances in medicine have contributed significantly to the prolongation of life expectancy during the last century. As part of this, the role of clinical trials during the second half of the century can hardly be overestimated. New pharmaceutical treatments have almost eliminated many diseases and reduced the risks for and consequences of many others.

Trends in productivity are, however, discouraging for drug development. Despite rapidly increasing development costs, the number of approved new drugs has been declining recently. One important reason for the productivity fall is the increased regulatory demands. A further reason is that drug developers try to solve increasingly difficult medical problems. In areas where there are already at least partly effective treatments, a new drug can often not be compared directly to placebo for ethical reasons. To show an effect versus placebo must thus be done indirectly, by testing the new drug and an active comparator in clinical trials, which requires considerably larger sample sizes [26]. Moreover, diseases for which no effective drugs exist are usually much more complicated and difficult to treat.

As many as half of the drugs entering confirmatory studies (phase III) fail [2]. Some drugs, such as the best-selling Vioxx, have also been withdrawn from the market due to safety findings postapproval. Such failures undermine the public trust in medicines and put increased pressure on regulatory agencies. Regulators may react by increasing the demands for safety documentation before drug approval, which will lead to accelerating development costs. A trend can be seen toward a more frequent need for large outcome trials in order to generate enough data to convince regulators of a positive benefit–risk relation. A net result is that, despite huge investments, too few new pharmaceuticals reach the patients in need.

There are a number of hopeful signs, however. First of all, the FDA has clearly recognized the productivity problems and has launched its Critical Path Initiative [33] as a response. This initiative aims at finding innovative ways to improve drug development, in partnership with academia and industry. The Critical Path Opportunity List [34] from 2006 formulates a large number of suggestions, including the use of different biomarkers, innovative/adaptive study designs, and modeling and simulation. It also flags the need to develop methods for indirect comparisons with placebo, in cases where placebo-controlled trials are unethical [26]. Below, we will focus on issues dealing with clinical study design and will not highlight changes in drug discovery technologies and IT per se. It should be noted, however, that the development of information technologies, such as Web-based data capture, is important for the possibility of conducting sequential and adaptive trials in practice.

### 26.3.2 Decision Analysis Approach to Study Design

As we have noted, the great need for increased efficiency in clinical development is accompanied by new opportunities to improve clinical trial design. A crucial issue

is how to best utilize these possibilities. We will address this challenge by proposing the following systematic, integrated, and quantitative approach:

1. Gather relevant information.
2. Integrate the information into a quantitative model.
3. Define the objectives of the trial.
4. Translate the objectives into a utility function, depending on the trial outcome.
5. Generate a variety of design alternatives.
6. Apply the ethical sift.
7. Simulate the trial outcomes for the interesting designs.
8. Calculate expected utility.
9. Choose the design with maximal expected utility.
10. Check the robustness of the solution to changes in the model assumptions.

The items on this list do not necessarily come in a strict chronological order but are often strongly interrelated. Given that the overall goal is to find a good enough design within the ethical framework, the modeling and DA process will depend on what is needed to accurately answer the design question. Consequently, the proposed approach does not necessarily have to be complicated or time consuming. In many cases, relatively limited work is enough to improve the study design.

This chapter will not describe all the items on the list in depth, as many of them are accurately covered in the existing literature. Much of the literature on modeling is topic specific. A classic text on model building, based in statistics, is Box and co-workers [35]. Pharmacokinetic/pharmacodynamic modeling is described in [36, 37]. Hoppensteadt and Peskin [38] present mathematical modeling for medicine, emphasizing physical processes in physiologic systems but ignoring pharmaceutical interventions. Burman et al. [39] focus on clinical development and provide a shorter, but very similar, version of the list above. Parmigiani [40] treats modeling in medical decision making, taking the perspective of the patient and his treating doctor. This book applies DA and Bayesian methods and describes computer simulations in a relatively nontechnical way. Hunink et al. [41] is an easy read on DA, taking a similar perspective as Parmigiani. It includes a chapter on information gathering (Chapter 8) and notes that subjective components are often needed in the analysis (p. 215). DA can also be viewed from a management perspective [42] and applied to drug development [43]. A common component of decision analysis and decision theory is Bayesian models. Both Spiegelhalter et al. [44] and Berry [45] provide excellent accounts of Bayesian methods in connection to clinical trials and include sections on ethics. More general texts on DA are Raiffa [46] and the broad overview in Howard and Matheson [47].

Simulations, expected utility calculation, and optimization are quite technical matters but specialized programmers and mathematicians do the job. Literature on random simulations includes [48–50]. Mathematical and numerical analysis can sometimes substitute, and often complement, simulations. Many textbooks cover such areas, including optimization. Although items 7–9 on the list above can be carried out by a sufficiently skilled programmer, the robustness checks should be a

concern to the whole scientific team, in interaction with the programmer. The team, and preferably also experts who have not taken part in the modeling, should change the key assumptions and look at how these changes affect the conclusions. If the solution is very sensitive to the value of a parameter, there is a strong indication that more knowledge should be sought regarding its true value. Renewed information gathering or focused experimentation may be indicated.

Naturally, the utilities may be quite different depending on what perspective you take. From a patient perspective, and in order to comply with the spirit and the letter of the Declaration of Helsinki, placebo should preferably not be used. FDA and European regulations stipulate, however, that a positive effect has to be demonstrated versus placebo, by direct or indirect comparison. Finally, a trial sponsor has to consider the return on investments. Although there are complementing company perspectives, we will take the net present value (NPV) as a proxy for the company utility. Profit maximization from the company's side must, however, be made under the constraints outlined above. Among the possible ethically compatible designs, the company will try to maximize the expected NPV for the project or, more generally, for the company. The value of the project will reflect also the regulatory hurdles and the possibilities of convincing payers about the cost-effectiveness of the drug.

Let us now study the key elements of clinical trial design. The following three subsections will address different aspects of this question.

### 26.3.3 Optimizing Information per Patient

The general aim of all experiments is to reduce uncertainty. The obvious way to decrease the uncertainty of trial results is to increase its sample size. In Section 26.3.4, we will apply DA to the problem of finding the optimal sample size. However, the most cost-effective way of retrieving trial information is often to reduce the variance for each patient. There are a number of ways to do this such as devising more than one treatment and several measurements per patient, choosing a more informative response variable, and choosing a patient population with a larger response.

**Covariates and Multiple Measurements** For many chronic diseases, there is a response variable [e.g., cholesterol level, forced expiratory volume (FEV<sub>1</sub>), subjective symptoms, or quality of life (QoL)] that fluctuates over time. Technically, we will assume that the variable follows a linear normal model, implying a linear dependence on covariates as well as normally distributed residual terms. The variability in the response variable during treatment has several different causes. It is standard procedure to include the baseline value of the response variable as a covariate in the linear model, together with other potentially predictive covariates. This will reduce the variability due to explainable differences between patients and may lead to considerably higher efficiency of the trial. These covariate adjustments are part of good statistical practice and concern more the analysis than the study design. Some of the other ways of reducing variability require larger modifications of the study design.

A straightforward example of how DA can be used concerns the decision of how many measurements should be taken per patient. One cause of variability that is not handled by covariate adjustments is the day-to-day fluctuations within each

patient. This variability can be reduced simply by taking measurements on different days and using the average of the observations as the response variable. Many studies collect the necessary information without using it in the analysis. Say, for example, that the objective (item 3 on the list in Section 26.3.2) is to estimate the primary variable in the most cost-effective way as possible. We then proceed by setting up the utility function (item 4). In this case, the cost per information is a function of the number of measurements  $M$  per patient. Whether more than one measurement should be taken is essentially a question of how much of the total (unexplained) variability is attributed to day-to-day variability and how much it costs to reduce it. In a straightforward model (item 2), the variance of the average for a patient is proportional to  $1 + V/M$ , where  $V/(1 + V)$  is the fraction of the observation variance that is attributed to day-to-day variability. Assume (item 2 again) that the cost per patient is proportional to  $1 + CM$ . As information is the inverse of the variance, the cost per unit of information is proportional to  $(1 + CM)(1 + V/M)$ . The number of measurements,  $M$ , can easily be chosen (item 9) to minimize this cost/information ratio, given that the value of the parameters can be estimated (modeled) from existing information (item 1).

Say, for example, that the cost per patient is \$11,000 if only one measurement is taken and that the additional cost per extra measurement is \$1000. Assume as well that 50% of the total response variance of 200 units is due to day-to-day variability. The cost and variance per patient are then  $10,000(1 + 0.1M)$  and  $100(1 + 1/M)$ , respectively. The cost/information ratio,  $1,000,000(1 + 0.1M)/(1 + 1/M)$ , is minimized if  $M = 3$  measurements are made. The cost per patient increases by 18% if  $M = 3$  compared to  $M = 1$ , but the variance per patient decreases by as much as one third. Consequently, the sample size can be decreased by one third, from 200 to 133 per arm if a standard error of 1.0 is to be achieved. The cost per unit of information is reduced by 22%; in a two-arm study the total cost decreases from \$4.4 million to \$3.52 million. A robustness check (item 10) indicates that  $M = 2$  or  $M = 4$  give most of the benefit that is achieved with  $M = 3$ , and that  $M = 2$  is a viable solution for a range of values for the parameters, for example, if the cost per measurement is twice as large as originally assumed.

This example does not indicate that the number of measurements should generally be increased. In other situations the analysis would indicate that costs should be cut by decreasing the number of visits. The point is that the efficiency of a design is often a trade-off between estimation precision and costs. By clearly defining the trial objective, integrating information about variability and economical costs, and quantifying a utility function, the decision problem is clarified. This kind of reasoning is considerably more far-reaching than just deciding on a hunch the number of measurements. In the example above, there could be complications given that the true underlying effect is changing over time, and that there is a nontrivial correlation structure between observations taken on different days. Typically, the effect is increasing toward a steady-state value and the correlation between two observations decrease with the time between the observations. The solution to both these problems is essentially the same: Model the time-effect process and the variability structure and then apply DA to the problem of finding the optimal sample scheme and test variable.

A common way to waste information is to dichotomize data, that is, to replace a continuous response with a zero-one variable in order, for example, to classify

patients as “responders” and “nonresponders” and ignore the rest of the information regarding the response. Occasionally, there are good reasons to classify patients as responders or nonresponders, based on whether a continuous response variable is above or below a specified cut-off value, and base the primary analysis of the constructed zero–one responder variable. However, in most situations, a direct analysis of the original continuous variable gives much more information [51, Section 8.2.4]. If the treatment effect is small, for example, the efficiency gained by using original data is about 57% when the patient population is divided in two approximately equally sized groups based on a normally distributed variable. The efficiency is more than doubled and almost threefold when the dichotomous population split is 80%–20% and 90%–10%, respectively. It is usually possible to model the distribution of the response (item 2), and then the effects of dichotomization are easily investigated by simulating (item 7) the power for the alternative response variables.

**Cross-Over Designs** The between-patient variability is completely eliminated if the patient can serve as his or her own control. This is the idea behind cross-over trials, where two or more treatments are given to each patient during different periods. Such designs are well studied [52, 53] and have been utilized systematically in some areas for many years, especially in phase I trials of pharmacokinetics and also for patient trials in some specific medical indications. However, there are possibilities of expanding the scope of these designs considerably in the future. When a cross-over design can be applied, the efficiency of the trial can normally be reduced drastically. The number of patients in the trial can often be reduced by considerably more than 50%.

There are some clear limitations to the use of cross-over designs, however. Cross-over trials are only possible for chronic diseases and obviously not suitable to investigate, for example, mortality. Their potential is largest in proof of principle and dose finding and for discriminating against similar competitors. They are best suited when the treatment response is relatively fast (asthma, lipids, some lab values, etc.). Carry-over effects have been seen as an important problem. However, there are in many cases possibilities to handle such potential effects by wash-out periods, statistical corrections, or pharmacological modeling.

When a cross-over design is considered as an alternative to a parallel group design, the usual tools of modeling, simulation, and DA can be of help. Using available information (item 1) in terms of earlier trials with the same and similar drugs, between-patient and within-patient variances can often be estimated or at least guessed. The time–effect curve and potential carry-over effects can be modeled in a similar way (item 2). Based on some models, it is possible to predict (item 7), often via simulations, the likely effects in the planned trial. There will often be trade-offs (items 4 and 9), for example, between the treatment duration and factors such as inclusion time, potential bias, and variability. A cross-over design will probably have a shorter inclusion period, as the sample size is lower, but a longer total treatment time. It is sometimes reasonable to shorten the treatment time per period, although this may lead to the steady-state effect not being fully reached.

Cross-over trials make it possible to assess whether there is a between-patient variability in the relative treatment effect. It may even be that treatment A is better in some patients while other patients are better off on treatment B. Parallel trials cannot assess such individual differences in effect between patients with similar

prognostic variables. One extreme version of the cross-over design is worth mentioning in this context. A trial may be conducted in one single patient, exposed to treatments A and B in a series of treatment periods. This design appears to be quite natural. It resembles what a patient suffering from migraine attacks would do to find out which “treatments” are causing the attacks. She occasionally eats chocolate, drinks wine, goes out in heavy sunshine, and notices when the migraine problems occur. Gradually, she will understand her personal risk factors and avoid them. The design, called *N-of-1*, can be much more rigorous, involving blinding and randomization to two or more treatment groups, comparing two or more pharmaceuticals [52, Section 7.4].

*N-of-1* trials may be attractive from an ethical perspective when the aim of the experiment is to find the best treatment for the individual patient, and DA is used to find the optimal criterion for when the testing should stop and the patient receive the better treatment henceforth. However, the signal-to-noise ratio is often too poor to allow firm conclusions on the best treatment for an individual. A combination of data from *N-of-1* trials in several patients can be performed in order to estimate treatment differences more precisely and also estimate how a large percentage of patients would benefit from each treatment.

### 26.3.4 Optimal Amount of Information to Collect in Trial

Having discussed how to optimize the information gathering for each patient, we will now turn to the problem of choosing the optimal amount of information to purchase, that is, to determine the sample size. Clinical trials are commonly dimensioned by specifying a least clinically relevant effect, taking this as the alternative hypothesis, and then calculating the sample size that gives, say, 90% power of detecting any effect. This approach can be severely misleading, we think, as it ignores all relevant information except the least clinically relevant effect. We will sketch how the knowledge and uncertainty regarding effect and safety, regulatory demands, price, market size, and study costs could all help to find the best sample size. However, let us first analyze the notion of “the least clinically relevant effect.” If you have to choose between two drugs with known different effects but identical safety profile, price, dosing, tablet size, and the like, which would you choose? If your 1-year risk of dying is 1% with drug A and 1.1% with drug B, you would clearly choose A. Will the choice be different if the risk is instead 1.001% with drug B? Our conclusion is that all differences are “clinically relevant.” The question about which drug to prefer arises only if both drugs have relative advantages in different aspects. For the patient, there can be a trade-off between effect and safety, for the payor between effect (and safety) and cost.

For the drug developer that tries to maximize the expected net present value (ENPV), study sizing is a trade-off between generating enough information regarding effect and safety on one hand and the cost of the trial on the other. A related and even more fundamental problem is whether any investment at all should be made in developing the drug or if the project should be terminated immediately. It is very complex to optimize a complete clinical development program, as the optimal design of a later phase depends on the data from the earlier phase, and the optimal design of the earlier phase depends on how the results from this phase will be used for designing the later phase. The principle solution to the problem is backward

induction [54], where one starts by analyzing the last phase, given different possible outcomes of earlier phases. After finding how phase III should be designed as a function of the information from phase IIB, phase IIB can be optimized. This process can in principle be carried back to even earlier phases, although computational difficulties and specification of the complex problem may be obstacles.

Consider the problem of dimensioning a phase III trial, assuming that supportive evidence exist and that one successful phase III trial will be enough to get the drug approved. Generally, the utility, as a function of the sample size  $N$  of the trial, is the gain by running the trial minus the cost for doing so. The cost can often be put rather directly in monetary terms. However, the personnel resources may be limited and hard to expand rapidly. Consequently, one may have to consider that if the phase III trial is run, other projects may be delayed or stopped and the net consequences of this should be factored into the cost analysis. As the sample size affects the possible time to market introduction, the time delay may be viewed as a cost. Time effects are, however, related to the trial outcome and are easier to analyze as part of the gain function.

The gain can be complex to analyze, although some market value calculations are routinely done in current practice. The simplest model is to say that the drug is approved if and only if a statistically significant effect versus placebo is shown in phase III, and if it is approved the commercial value is a certain known amount. This model can easily be improved by modeling how the market value will decrease with a delay in study ending time as a result of an increased sample size. There are, however, other factors, such as the market value's dependence on the trial results, that are harder to model. It is often too simplistic, although common, to assume a fixed market value if the drug is approved without considering how good the trial data are. One way of modeling the sales of a drug is to start by analyzing the decision analyses that the patient is doing together with his or her physicians. What is required to choose the new drug in terms of estimated effect, standard error for the effect estimate, safety, price, and the like? Pharmaceutical companies often perform limited market research about such questions by asking physicians to compare different hypothetical drugs. Individual treatment decisions could then be aggregated to form an effect-sales model. It is likely that historical data on, for example, how fast a market is penetrated have to be added in order to find a suitable model.

The commercial and cost models together give a utility function. The design alternatives are all possible sample sizes, including the possibility of stopping the project and not run the trial. Regulators may have requirements for a minimal sample size in order to get enough safety information. With a model for the effect of the drug and for how large the uncertainty is, the trial results can be predicted, by numerical methods or simulations. It is often important to consider the uncertainty in the effect estimate and run Bayesian clinical trial simulations. Combining predicted trial results with the utility function, the expected utility can be calculated for each sample size, and the optimal sample size can be found. The expected utility is relatively flat around the optimum, indicating that the exact sample size is not crucial. The ENPV can be very sensitive to such changes in assumptions concerning costs and gains. However, given that it is optimal to run the trial, the sample size is typically relatively robust against such changes, meaning that the same sample size often gives an ENPV close to the optimal ENPV.

The time to market is essential. If there is an indication that the sample size should be increased, one might therefore consider including a larger number of centers. In analyzing this option, both direct costs and the risk for reduced quality, leading, for example, to a larger unexplained variability, should be considered. The optimal size of an experiment is discussed by Lindley [55] and a review on applications to clinical trials is provided by Pezeshk [56].

**Commercial Limitations** Medical research will likely look for smaller and smaller improvements in many therapeutic areas. Smaller effect differences than what most historic studies have set out to detect may still be of great importance. The vast majority of mortality trials have been dimensioned to detect risk reductions of 20% or more. However, a treatment with 10% additional reduction in, for example, cardiovascular mortality, would of course be of great value. The problem is that smaller effects call for larger trials. The sample size is, at least approximately, proportional to the square of the relative treatment effect. Thus, looking for a risk reduction of 10% instead of 20% will mean that four times more patients are needed in the trial. While the cost for a trial is approximately quadratic in the effect size, the benefit, in the number of spared lives, say, is linear. Thus, small enough relative effect sizes will not be found by clinical trials, although they may translate into a large number of deaths.

Assuming rational payors, the commercial gain of introducing a new pharmaceutical will always be lower than the societal gain, as the price will always be lower, at least for some payors, than the willingness to pay. There are, consequently, research projects that would give a good expected return-on-investment for society, although they would never be run by commercial interest. Noncommercial research therefore has a clear value.

### 26.3.5 Adapting to New Information

For both economic and ethical reasons, it is clearly desirable to adapt the design of a clinical trial in response to accumulating data. Interim data may show, for example, that there is a clear difference between the treatments. The trial can then be stopped, permitting the patients in the control arms of the study to stop receiving the inferior treatment. Alternatively, interim data may indicate that a proposed treatment has no clear benefit over the placebo. The trial can in such a case also be stopped for reasons of futility.

**Group-Sequential Designs** The most well-known example of adaptive designs is the classic group-sequential design [57, 58], which permits a number of interim analyses to be conducted. It allows for the trial to be stopped if interim results are convincing enough according to preset criteria. As a statistically significant result can be obtained both at interim analyses and at the preplanned full sample size, the critical limits for when to claim significance must be adjusted. The result is that a group-sequential trial has to have a somewhat larger maximal sample size than a fixed-size trial if the same power should be obtained. This is the price to pay for the possibility that the trial sometimes can be stopped much earlier than in a trial without interim analyses. With a reasonable group-sequential design, the expected sample size is decreased. Consequently, the cost related to the number of patients

is on average decreased. Among the drawbacks of a sequential design are the cost for the interim analysis per se. Given these costs, it is straightforward to simulate trials and calculate the expected total cost to find which design is best. One can investigate whether it is optimal to include interim analyses, when they should come and what the critical limits for significance should be. There are some additional drawbacks, such as problems with overrunning, that is, that additional trial data may be obtained after an interim analysis that suggested a trial termination. Such data may potentially change the conclusion in the trial. Still, it is possible to simulate this problem and factor it into the DA.

**Flexible Designs** From a DA perspective, the optimal design of a trial may change during a trial if external information is received that changes the utility function or the effect/safety model. Examples of such information is the approval of a competitor drug or the finding of unexpected safety problems in substances with similar chemical properties as the one being developed. It is therefore desirable to be able to change the design during the conduct of a trial. An article by Bauer and Köhne [59] in 1994 gave the impetus to research in flexible designs that allow several types of design modifications in response to interim data or external information. According to Müller and Schäfer [60], “design changes may include increase or reduction of the sample size and of the number and time points of interim analyses, and even changes of the type of statistical test, of the outcome variable, or of the null-hypothesis.” Their stand is that such changes do not have to be preplanned. However, if such flexible designs are getting acceptance and penetrate clinical trial practice, it will constitute a fundamental change compared to the hitherto dominating methodology. Preplanning has always been one of the cornerstones of controlled clinical trials and a basis for the classical statistical analysis of data. Other authors, including Bauer and Köhne [59] in their original work, have been more moderate than Müller and Schäfer [60] regarding when and how flexible designs could be used. The EU reflection study [61] on adaptive designs is quite restrictive to flexible design changes, especially in confirmatory studies.

Sample size reestimation (SSRE) has attracted the greatest interest among the flexible designs. The sample size may, for example, be increased in order to achieve more statistical power if the interim estimate of the treatment effect is lower than anticipated. The fundamentally new technical idea behind flexible designs is to tentatively consider different stages of a trial as different trials altogether. One  $p$  value is calculated for each stage in isolation. These  $p$  values are then combined into a  $p$  value for the complete trial, by weighting together the stagewise  $p$  values. The type I error can be guaranteed, for essentially all kinds of design modifications, as long as the weight for each stage is determined independently of the data from that stage.

The weighted inference is controversial. Jennison and Turnbull [58] have suggested that an adequately developed group sequential design is preferable to an adaptive SSRE that only depends on interim data. The flexible design has, however, the advantage of being able to be modified according to information external to the trial. Another problem with the methodology proposed by Bauer and Köhne [59] is that equally informative observations may receive unequal weight in the analysis, depending on which stage of the trial they are collected. This feature has been criticized for violating the sufficiency principle, leading not only to inefficiency [58] but also in extreme cases to erroneous conclusions [62].

Our tentative conclusions are that careful preplanning of trials is crucial, that there can occasionally still be a genuine need for flexibility, that the weighted test is questionable but that a modification of this test could be of value. The works on flexible designs mentioned above have been based on classical, frequentist statistics. Bayesian statistics can more naturally incorporate sample size modifications and other design changes. Such modifications can be useful in earlier phases but may not be accepted in the confirmatory phase.

## 26.4 DISCUSSION AND CONCLUSIONS

Since World War II, the number of clinical trials has increased rapidly. The importance of these trials can hardly be underestimated. The medical needs continue to be manifold. Despite the clinical needs and the steady increase in the number of clinical trials carried out, there are factors that could threaten their future. In this chapter, we have highlighted the problems concerning ethics and efficiency. Although RCTs represent the gold standard in clinical development, there are alternatives. Observational studies and historic controls can give valuable information, even if their interpretation is not as straightforward as blinded clinical trials. Preclinical experiments and modeling can also substitute some trials.

Clinical trials should be performed in an ethical manner. Failure to do so is not only unethical, per definition, but it also jeopardizes public trust in clinical development. A patient is unlikely to give informed consent unless he or she is convinced that the physician will put the patient's interests first. The concept of informed consent is a fundamental requirement that we have highlighted. In the rare situations where informed consent cannot be given by the patients themselves (studies on unconscious patients or children), the informed consent should instead be given by a guardian *on behalf of and in the interest of* the patient as soon as possible. Likewise, the physician should see principally to the best of his or her patient first and only secondarily to the interests of science. Thus, when the physician also acts as an investigator, he or she is still personally responsible for ensuring that the patient's best interests are safeguarded during trial participation. In addition to genuine consent and patient benefit optimization, an ethical requirement of nonexploitation is needed. Additional requirements may be indicated to cover issues about, for example, payment and trials that are beneficial on average but include nonoptimal treatment arms. While patient enrollment is the responsibility of the physician, the ethical standard of clinical trial is the common responsibility of the investigator, the ethical committee, the sponsor, and the personnel responsible for the planning and the execution of the trial. Personal responsibilities should be stressed to avoid the risk that all actors put the responsibility on someone else, leading to unethical and risky trials.

Ethical requirements constrain trial design, in particular the treatments that can be tested. Depending on the situation and background information, these constraints will sometimes complicate or even obstruct clinical development. Within these limits there are, however, considerable possibilities of optimizing designs that can also be efficient. Several features of a trial design should be considered in the process of trial optimization, such as sample size, patient population, and treatment duration. There are also great possibilities to apply alternatives to the standard

parallel-group nonadaptive design and there is a continuing methodological development. How to choose between all the available options is perhaps the major challenge. Consequently, we anticipate that the most significant changes in trial design will take place in decision process rather than design methodology per se. Model-based drug development is already receiving considerable attention. Still, modeling and DA are clearly underestimated.

## 27.1 BACKGROUND

### 27.1.1 Why Is Proof-of-Principle/Proof-of-Concept (PoP/PoC) Crucial in Drug Development?

Drug development is complex, costly, and time consuming. After decades of fruitful endeavors leading to novel therapies that radically changed the way we treat human disease (e.g.,  $\beta$ -blockers, proton pump inhibitors, SSRIs, HMG-CoA reductase inhibitors, and many others), the pharmaceutical industry began to face increasing and significant challenges. Everyone who is involved in drug development is well aware of issues such as the “innovation gap,” “productivity decline,” and “late-stage attrition.” Indeed, these issues have been on the agenda for some years now and have triggered waves of new paradigms in drug development. Essentially, the pharmaceutical industry has been investing more and more resources in developing new drugs, but this has not been translated into more successful medicines, that is, medicines that are approved by the regulators and well-received by the market. In other words, the output from the R&D machinery has not kept pace with spending. This productivity decline is illustrated in Figure 1 showing escalating drug development costs with no parallel increase in the number of regulatory approvals. The average cost of bringing a new compound to the market is in the neighborhood of \$1.3 billion [1] and the overall clinical success rate is 11% [2]. A nearly 50% attrition rate in phase III is still plaguing pharmaceutical companies [2]; and there is no clear evidence that it is on the decline. Late-stage failures are severe blows that hurt large pharmaceutical companies and might ruin smaller ones, and it is in this context that the importance of early PoP/PoC becomes apparent. Drug developers need to ascertain that only compounds with a high chance of success are selected and progressed through the development process. Although most pharmaceutical companies are trying to adopt “kill early” approaches, this is often hampered by the lack of reliable “killer experiments” and the fear of erroneously discarding valuable assets. For smaller companies such as many in the biotechnology sector, which often lack the resources to take compounds through full clinical development, a positive PoP/PoC significantly improves the chance of finding a partner or successfully licensing out the compound. Regardless of company size, a robust early PoP/PoC has become a key component in contemporary drug development.

### 27.1.2 Definitions

A human PoP/PoC trial is simplistically a trial that provides indications that the compound might work in the intended therapeutic area. Some companies distinguish between a PoP trial in which the pharmacological principle has been

**FIGURE 1** Escalating R&D spending with no increase in output (FDA drug approvals): 2004–2007 approvals include new biologics. (Source: FDA and Pharmaceutical Research and Manufacturers of America, *Pharmaceutical Industry Profile 2008*, PhRMA, Washington, D.C. March 2008).

demonstrated in humans (healthy subjects or patients), usually with the use of a biomarker and a clinical PoC trial where early signs of efficacy are detected, based on solid clinical endpoints or validated surrogates. However, PoP and PoC are often used interchangeably. A broad definition has been proposed by fifth EUFEPS Conference: “A human trial that provides scientifically sound evidence supporting the postulated effects of a new therapeutic drug product, where effects may be relevant pharmacological action or a change in disease biomarkers, established surrogate endpoints, or clinical outcomes, and be beneficial and/or toxic in nature” [3].

### 27.1.3 When Should PoP/PoC Be Established?

As indicated above, spiralling development costs and high attrition rates are forcing drug developers to search carefully for signs of efficacy and potential safety concerns as early in the development process as possible. It is common practice today to conduct a PoP/PoC trial as soon as phase I trials have provided evidence that the compound appears to be reasonably safe in healthy subjects and possesses pharmacokinetic characteristics that are in line with projected clinical use. As shown in Figure 2, a PoP/PoC trial is conducted as a part of phase II.

The PoP/PoC is located at a most crucial “go–no go” decision point in most pharmaceutical R&D organizations. Once PoP/PoC has been established, drug developers (and investors) feel more confident to invest in the subsequent, more costly clinical trials.

**FIGURE 2** Location of PoP/PoC in the drug development process. ER, Exposure–response; NDA, new drug application; MAA, marketing authorization application.

Although PoP/PoC is often linked to a single trial that provides a dichotomous “yes or no” answer, it is more prudent to think of PoP/PoC as a package of key data that have emerged during the early exploratory phase of development. Thus, a positron emission tomography (PET) study in healthy volunteers may provide evidence that a certain compound crosses the brain–blood barrier and binds to a specific receptor in the brain. A human model (Table 3) may show that the compound is effective in a disease-like setting. Pharmacokinetic/pharmacodynamic (PK/PD) modeling of preclinical and human data is used to characterize the exposure–response (ER) relationship and ensure that safe doses are potentially efficacious. Finally, the integrated data package from all of the above provides a reasonable level of confidence to pursue development, that is, a PoP/PoC-based “go decision.”

## 27.2 CONSTANTLY IMPROVING TOOLBOX FOR POP/POC

Despite the serious issues facing the pharmaceutical industry, the scientific advances in biosciences (chemical and imaging biomarkers, pharmacogenetics and pharmacogenomics, proteomics, toxicogenomics, metabonomics) are providing drug developers with useful tools to explore the potential clinical utility of new targets and novel therapeutic agents. These areas of research have become independent disciplines and there is a wealth of literature on each of them. Since biomarkers constitute a key component in PoP/PoC paradigms, they are discussed in some detail next.

## 27.3 BIOMARKERS IN POP/POC TRIALS

The National Institutes of Health (NIH) Biomarkers Definitions Working Group has defined a biomarker as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention” [4]. Although biomarkers have been used in drug development for decades, the new potential of using biomarkers for regulatory purposes (label claims) [5] has intensified the efforts to develop biomarkers that are accepted for ordinary and accelerated approvals. Regulatory initiatives, most notably the Food and Drug Administration’s (FDA’s) Critical Path Initiative have opened new avenues for collaboration between academia,

**TABLE 1** Examples of Biomarkers Accepted by FDA as Surrogate Endpoints

| Condition              | Surrogate                                    |
|------------------------|----------------------------------------------|
| Ischemic heart disease | Plasma cholesterol                           |
| Stroke                 | Blood pressure                               |
| Osteoporosis           | Bone density                                 |
| Diabetes mellitus      | HbA1c                                        |
| Prostate cancer        | Serum testosterone                           |
| HIV/AIDS               | HIV-RNA load and CD4 <sup>+</sup> cell count |

pharmaceutical companies, and regulators aimed at facilitating innovative approaches in the development of novel medicines [6]. A key area in the Critical Path Initiative is biomarkers with a special consortium focusing on the qualification of biomarkers for regulatory decision making. Qualification of biomarkers refers to the process of linking a biomarker with biological processes and clinical endpoints [7, 8]. The highest level of qualification of a biomarker is surrogacy, that is, when the biomarker can substitute for a clinical endpoint [7, 9]. Table 1 shows examples of biomarkers that have been accepted by the FDA as surrogate endpoints.

It should be underscored that while surrogate endpoints and other “valid” biomarkers can and should be used in PoP/PoC trials when available, early clinical development is an exploratory phase, and less well-qualified biomarkers can provide valuable information for internal company decision making. For example, “distal biomarkers”—relative to the clinical endpoint—can be very useful in confirming the pharmacological activity of a given compound in humans [10]. This is especially valuable in two situations: the selection of follow-up or backup compound when the “pathfinder” has demonstrated clinical utility; and the validation of a novel mechanism of action with an uncertain role in the pathogenesis of the disease. Lack of clinical efficacy despite adequate pharmacological effect would disqualify the mechanism of action and stop the development of similar compounds. Also, biomarkers can be very useful in establishing the ER relationship preclinically and translating that relationship into the clinical phases of development (the concept of translational science), facilitating dose selection in PoC studies and beyond [11]. Good examples of the use of biomarkers in early clinical development have been described by Kuhlmann [12]. These included the use of *ex vivo* inhibition of cholesteryl ester transfer protein (CETP) in healthy subjects to establish the pharmacological activity of a CETP inhibitor, the use of leukotriene D<sub>4</sub>-induced bronchoconstriction to establish PoP and dose–response in healthy subjects for a leukotriene receptor antagonist for asthma, and the use of pupillography as a marker for effects of 5-hydroxytryptamine 1A (5-HT<sub>1A</sub>) compounds.

## 27.4 PHARMACOGENOMICS, PROTEOMICS, AND METABONOMICS

The concept of identifying genomic [single nucleotide polymorphisms (SNP), haplotypes, ribonucleic acid (RNA) expression signatures], proteomic [protein profiles in plasma, cerebrospinal fluid (CSF), synovial fluid, etc.], and metabonomic (metabolite patterns in body fluids) markers that identify patients who are likely to respond to treatment and/or to develop serious adverse drug reactions is very exciting albeit

**TABLE 2   Examples of Valid Genetic/Genomic Markers Predicting Clinical Response or Specific ADRs**

| Marker                                       | Drug          | Clinical Relevance                                                                                               |
|----------------------------------------------|---------------|------------------------------------------------------------------------------------------------------------------|
| Her2/neu overexpression                      | Trastuzumab   | Only patients with tumors overexpressing Her2 are eligible for treatment.                                        |
| Philadelphia chromosome (Ph1)                | Busulfan      | Poor response in patients with AML who lack Ph1 chromosome.                                                      |
| PML/PAR alpha gene expression                | Tretinoin     | Clinical response to tretinoin in patients with APL have not been observed in the absence of the genetic marker. |
| Thiopurine methyltransferase (TPMT) variants | Azathioprine  | Increased risk of myelotoxicity in patients with low or absent enzyme activity.                                  |
| HLA-B*1502 allele                            | Carbamazepine | Risk for serious dermatologic reactions in patients positive for the allele.                                     |
| G6PD deficiency                              | Rasburicase   | Drug is contraindicated in patients with G6PD deficiency due to the risk of severe hemolysis.                    |

AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia.

extremely challenging. There are few examples of valid genomic markers that predict clinical outcomes [responder vs. nonresponders; adverse drug reaction (ADR) prone genotypes] and that have been accepted by the FDA as part of the label (Table 2). A comprehensive list of valid genomic biomarkers in the context of FDA-approved drugs is available [13].

However, in the context of early clinical development of novel compounds acting on nonvalidated targets, the identification of such markers remains a major hurdle to overcome. Roses and colleagues described some examples of the use of early pipeline genetics to predict efficacy and side effects of new compounds [14]. These included the identification of gene variant candidates related to efficacy in a phase II obesity drug trial, and the early discovery of the genetic basis (CYP 2C9 polymorphisms) of some of the side effects of the kinase inhibitor lapatinib (Tykerb). The authors rightly underscored that such early findings can only be used to generate hypotheses and that the validation of these markers should await larger clinical trials [14]. The limitations of pharmacogenomic predictor discovery in early clinical trials are discussed in Pusztai [15].

Needless to say, this field is still in its infancy, and the ultimate impact of the “omics revolution” on expediting drug development and reducing attrition rates remains to be seen.

In many pharmaceutical companies, default banking of samples from clinical trials for future genetic/genomic analyses is becoming common practice, although this is sometimes challenged ethically and legally. Since genetically determined variability in drug metabolism, most notably involving CYP 450 enzyme system, impacts significantly on the pharmacokinetics and consequently pharmacodynamics of many drugs, it is prudent to obtain relevant genotypes in healthy volunteers and patients in early clinical trials of compounds known to be mainly metabolized by CYP 450 isoenzymes, primarily CYP 2D6, CYP2C9, and CYP2C19. This would be useful if unexpected PK/PD profiles are observed and potentially reduce the risk of selecting inappropriate doses in PoP/PoC trials resulting in erroneous go–no go decisions.

## 27.5 IMAGING

Advances in medical imaging present a great opportunity in drug development. A number of different imaging technologies are available. These include computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), positron emission tomography (PET), and single photon emission computed tomography (SPECT). If adequately qualified, imaging biomarkers can be very helpful in the early phases of clinical development. Early evidence of biological/pharmacological activity of a new compound as well as useful pharmacokinetic profiles for future dose selection can be obtained. For example, using fluorodeoxyglucose PET (FDG-PET), it could be shown that glucose metabolism was reduced in gastrointestinal stromal tumors in patients treated with imatinib mesylate (Gleevec), indicating an early response that preceded tumor size reduction (on CT) by weeks [16]. The development of a new antidepressant was terminated based on the finding that the compound lacked specific receptor binding, as shown by cerebral PK imaging [17]. Other good examples of the use of imaging in early clinical trials in different therapeutics are described by Pien et al. [18]. The potential advantages of imaging techniques in the different phases of drug development have recently been reviewed by Strack [19].

## 27.6 PHARMACOLOGICAL AND NONPHARMACOLOGICAL MODELS FOR POP/POC TRIALS

### 27.6.1 Pharmacological Models in Healthy Volunteers

In these models, a pharmacological agent, for example, scopolamine is given to healthy subjects to induce symptoms typical of the targeted disease, in this case dementia (cognitive impairment with deterioration of episodic memory and attention) [20, 21]. Compounds with cognition-enhancing characteristics would reduce these symptoms [22], providing early evidence of potential clinical efficacy. Pharmacological models are often used in psychopharmacological research, and, if adequately adapted, some of them can potentially be useful in early clinical development of psychotropic drugs (see [23] for a review). Asthma is another therapeutic area where pharmacological provocation tests in healthy volunteers; using, for example, methacholine [24, 25] or leukotriene D<sub>4</sub> [26] are utilized to demonstrate a pharmacological activity and capture early signs of potential clinical efficacy. It should be pointed out that unless the model used involves a mechanism that is relevant for the pathophysiology of the disease, a positive effect of a new compound in the model merely demonstrates a pharmacological antagonistic activity and does not provide early evidence of efficacy in the targeted disease. For leukotriene receptor antagonists, a class of drugs that target a mechanism known to be involved in the pathophysiology of asthma, a reduction of bronchoconstriction could be demonstrated in the leukotriene challenge as well as in other provocation models using, for example, allergens, methacholine, and ultrasound-nebulized distilled water [27, 28].

If models are to be reliable, a number of criteria should be fulfilled. These include face validity, test–retest consistency, responsiveness to reference drugs [29], and a reasonably high response rate in healthy subjects [23]. Since the clinical

**TABLE 3 Pharmacological and Nonpharmacological Models Used in PoP/PoC Trials**

| Model                                                                                  | Therapeutic Area                         |
|----------------------------------------------------------------------------------------|------------------------------------------|
| Carbon dioxide inhalation                                                              | General anxiety disorder, panic disorder |
| Conditioned aversive anxiety                                                           | Anxiety                                  |
| Scopolamine test                                                                       | Dementia/cognitive disorders             |
| Pain models (mechanical, chemical, thermal or electrical stimulation)                  | Pain                                     |
| Bronchial challenges (allergens, histamine, methacholine, leukotriene, cold air, UNDW) | Asthma                                   |
| Pentagastrin-induced gastric acid secretion                                            | Peptic ulcer, GERD                       |
| Human endotoxemia model                                                                | Sepsis                                   |
| Phenylephrine challenge                                                                | Benign prostatic hyperplasia             |

UNDW, Ultrasound-nebulized distilled water, GERD, gastroesophageal reflux disease.

manifestations of many diseases are multifaceted and not possible to reproduce in a model involving the administration of a single pharmacological agent, it has been suggested that the model can be useful if it provokes the cardinal symptoms of the disease [23]. Table 3 shows examples of pharmacological models that can be used in PoP/PoC trials.

### 27.6.2 Nonpharmacological Models

These use the same general principles as pharmacological models. However, they require rigorous standardization for reliability [23]. Examples of nonpharmacological models used in PoP/PoC paradigms include models of anxiety and panic such as simulated public speaking [30] and conditioned aversive anxiety [30], and nonpharmacological provocation tests of asthma and human experimental pain models (Table 3). The latter have evolved to provide a useful translational tool linking animal findings with data obtained in healthy subjects and patients. Moreover, by adopting a multimodal (mechanical, chemical, thermal, electrical stimuli), multitissue (skin, muscles, viscera) approach, it is now possible to explore different pain pathways and mechanisms and assess responses induced by novel putative analgesics in PoP/PoC trials. This approach is described in a recent review by Arendt-Nielsen and colleagues [31].

### 27.6.3 Provocation Models in Patients

PoP/PoC can also be explored using provocation models in patients. Both pharmacological and nonpharmacological models are potentially useful to progress a new compound through early clinical development. Asthma and allergic diseases are therapeutic areas where provocation models in patients are most frequently used, and the practical setup of the trials does not deviate from that in healthy volunteers. However, since the trials are conducted in the target patient population [27, 28, 32, 33], a positive outcome is more indicative of a successful PoC compared with a positive result from a provocation experiment in healthy subjects. Provocation tests for PoP/PoC in patients have also been used in other therapeutic areas, such as epilepsy. Among the models tested, the technically challenging intermittent photic stimulation in patients with photosensitive epilepsy has been found reliable in

predicting the antiseizure activity of a number of efficacious drugs that were eventually approved [34]. PoP was recently obtained for two novel antiepileptic drugs, brivaracetam, an SV2A ligand, and carisbamate, a new carbamate using this model [35, 36]. Both drugs suppressed generalized photoparoxysmal electroencephalogram (EEG) responses in treated patients. PoP studies in epilepsy using this and other models are discussed in Schmidt [37].

## 27.7 DIFFERENT TYPES OF POP/POC STUDIES

Considering the broad definition of PoP/PoC (see above), PoP/PoC trials are quite variable in terms of objectives, overall design, trial population, endpoints, as well as regulatory requirements.

### 27.7.1 Exploratory Investigational New Drug PoC Trials

These are early clinical studies conducted under the auspices of FDA's Exploratory Investigational New Drug Guidance [38], which covers microdose studies of pharmacokinetics or imaging as well as phase 0 clinical trials to study pharmacologically relevant doses. A microdose is defined as 1/100th of the dose calculated to yield a pharmacologic effect with a maximum dose of 100  $\mu$ g (or 30 nmol for proteins). Imaging studies using microdoses can be very useful in establishing PoP, for example, by demonstrating significant binding of the investigational compound to the target receptor. Since these studies imply single exposures to minute amounts of the test compound, they can be conducted without the standard safety pharmacology and genotoxicity studies.

Phase 0 trials that are designed to study the pharmacologic effects of the test compounds provide a new avenue to early PoC. The FDA accepts the use of doses at which a PK/PD response or target modulation is observed in such trials. However, prerequisites are the lack of an adverse clinical response and that the dose is less than one fourth of the 2-week rodent no adverse effect level (NOAEL), or that the total exposure to drug expressed as the area under the concentration curve (AUC) does not exceed one half of the AUC at NOAEL in the most sensitive species. Due to the lower doses and consequently lower toxicity risks implied, the preclinical pharmacology and toxicology package is less extensive than that required for traditional phase I investigational new drugs (INDs), although safety pharmacology and genotoxicity studies are required. Moreover, if a "go decision" is made, based on the outcome of the study, that is, target modulation is proven, a traditional IND will have to be submitted in order to progress the compound further in clinical development.

One key therapeutic area in which phase 0 exploratory studies are performed is oncology, where there is a great need for new safe and efficacious agents and where early evidence of target modulation (molecular PoC) would potentially expedite the clinical evaluation and facilitate the development of the most promising agents. In phase 0 cancer trials, low doses are administered to a limited number of patients (10–15 patients) [39].

The most critical factor for the success of a phase 0 PoC study in oncology—and other therapeutic areas—is the availability of a sensitive, robust, and qualified/validated pharmacodynamic assay. Kinders and colleagues proposed the following

set of performance criteria for PD assay validation: accuracy, dynamic range, precision, reproducibility and sensitivity [39]. The same group reported the results of an elegant phase 0 trial [40] in which 14 patients with advanced malignancies were treated with low doses of ABT-888, a poly(ADP-ribose) polymerase inhibitor. Using a PD assay that measured the amount of the enzyme polymer in tumor tissue and blood cells as a surrogate for enzyme inhibition, the authors were able to establish the PK/PD relationship and select a dose that had a potential for efficacy with minimized risk of toxicity.

Although the exploratory IND initiative allows for a more flexible mode of developing drugs in oncology and other therapeutic areas, it remains to be seen whether phase 0 PoC studies will result in a more speedy development of safe and efficacious novel drugs.

Apart from the technical challenges that phase 0 PoC trials pose (e.g., PD assay validation), the use of patients in a trial where there is no therapeutic intent (due to subtherapeutic dosing) introduces new ethical standards in clinical research where “benefit to others” is accepted as the sole benefit. This is discussed in a thoughtful editorial [41], where phase 0 trials are described as “ethically challenged and ethically challenging.”

### 27.7.2 Clinical Trials Using Biomarkers or Models in Healthy Subjects

These trials exploit validated or reasonably qualified “fit-for-purpose” biomarkers or models to elicit a clinically relevant pharmacological response in healthy subjects. For example, an early PoP was obtained for degarelix, a GnRH receptor antagonist currently in clinical development for prostate cancer by Ferring Pharmaceuticals, by demonstrating a rapid, profound and sustained reduction in serum levels of testosterone and LH in healthy volunteers (Figs. 3 and 4). The findings were later confirmed in large trials in the target patient population (unpublished data). The availability of a well-validated biomarker/surrogate (testosterone deprivation in prostate cancer) was crucial for the successful PoP/PoC achieved.

**FIGURE 3** Serum testosterone levels in healthy volunteers after the administration of degarelix intravenously, intramuscularly, and subcutaneously. The horizontal dotted line indicates the level of castration (serum testosterone of 0.5 ng/mL) required for efficacy in prostate cancer trials. Median values and quartiles are shown.

**FIGURE 4** Changes (median and quartiles) in serum levels of testosterone and luteinising hormone (LH) after intravenous administration of degarelix (30 µg/kg) to healthy subjects. The response confirms the mechanism of action of the compound (GnRH antagonism leading to LH decline with resultant chemical castration).

### 27.7.3 Clinical Trials Using Biomarkers in Patients

In these trials, biomarkers related to the pathophysiology of the disease are analyzed and drug-induced modulation of these markers is evaluated. For truly innovative, first-in-class therapeutic agents, a biomarker-based PoP/PoC poses significant challenges. The pathophysiology of the disease is often not completely understood. Consequently, the link between the different biomarkers and the disease biology might not be evident. Therefore, a positive change in a biomarker in a patient trial may constitute a positive PoP but does not guarantee a positive clinical outcome. This is unavoidable in all cases where the biomarkers have not yet been clinically validated. However, as discussed above, the use of biomarkers in PoP/PoC trials is a way of increasing the confidence in a particular therapeutic agent or class of agents to make better internal go–no go decisions. The alternative is to rely primarily on huge clinical trials that might fail late and at a much higher cost.

One therapeutic area in which the use of biomarkers during early drug development is of particular interest is Alzheimer's disease (AD). Despite extensive R&D efforts by many large and small pharmaceutical companies, disease-modifying therapies have been elusive. The identification of presymptomatic neurodegenerative changes that are mirrored by changes in specific markers is crucial and remains to be in focus for AD research. A wide array of biochemical markers such as  $\beta$ -amyloid and tau proteins in CSF [42] and imaging-based biomarkers [43, 44] are available, and evidence seems to suggest that a multiple biomarker approach will be necessary [45]. The logistics of large clinical trials in AD and the fact that available symptomatic treatment of AD (cholinesterase inhibitors, memantine) influences the primary clinical endpoint (cognition), thus blurring the potential effects of a truly disease-modifying agent, make biomarker-based PoP/PoC the most attractive approach to develop such important therapies in a huge area of unmet medical need. Other proposed strategies to enhance drug development in this area include enriched population

PoC studies (patients with mild cognitive impairment who are at higher risk of developing AD), implementing alternative, more sensitive clinical outcome measurements and adaptive dose-finding trials (seamless phase IIb–III) [46].

#### **27.7.4 Trials Using Clinical Endpoints for PoC**

In the absence of qualified biomarkers or acceptable surrogates, PoC can only be established by a successful clinical trial conducted in the target patient population using solid clinical endpoints for efficacy. As discussed earlier, biomarkers that are not fully validated can still be useful in demonstrating a pharmacological effect and selecting doses for the “ultimate” PoC trial. PoC trials using clinical outcomes are usually large and can be of long duration, depending on the natural course of the disease, the drug’s mode of action, and the sensitivity of the clinical measurements to therapeutic intervention.

### **27.8 KNOWLEDGE OF EXPOSURE–RESPONSE RELATIONSHIP OF DRUG IS ESSENTIAL FOR SUCCESSFUL POP/POC**

Adequate characterization of the ER relationship of the drug is vital for robust PoP/PoC conclusions and consequently solid go–no go decisions. This is easily understood if one realizes that a primary objective of PoP/PoC trials is to demonstrate some signs of efficacy, be it direct or via a biomarker or other surrogates at a dose that does not elicit unacceptable adverse effects. Failure to explore the ER relationship properly early on carries a risk of selecting inappropriate dose(s) in the PoP/PoC trial and, consequently, making the wrong go–no go decision. Some drug developers still advocate the use of a high, tolerated dose close to the maximal tolerated dose (MTD) in a PoP/PoC trial; “if this doesn’t work, why bother?” While this approach might work when developing compounds with wide therapeutic windows, it ignores the fundamental principles of clinical pharmacology and carries a significant risk of adverse drug reactions arising later in larger trials or even registering too high a dose of the drug. Finally, with increasing safety awareness, regulatory requirements often include the demonstration of the minimum dose that is maximally effective [11].

It should be underscored that a thoughtful integrated learning approach to PoP/PoC is a prerequisite for well-founded decisions. Notwithstanding the cost constraints that many pharmaceuticals companies experience, PoP/PoC strategies should not be “quick and dirty” or “lean and mean” development approaches. A rational scientifically solid and well-engineered PoP/PoC strategy indeed saves time and money by ensuring the progress of good drug candidates and the termination of compounds with poor chances of making it to the marketplace.

### **27.9 PROOF-OF-PRINCIPLE/PROOF-OF-CONCEPT OUTCOMES CAN BE “FALSE DAWNS”**

Despite the importance of PoP/PoC trials in drug development, as underscored in the literature and reiterated in this chapter, positive trial outcomes are by no means

a guarantee of clinical success. As discussed above, PoP/PoC trials usually rely on biomarkers/surrogates/models that might not adequately predict the clinical outcome and therefore fail the ultimate test of efficacy and safety, that is, the confirmatory phase III pivotal trials. Fleming and DeMets reviewed experiences with biomarkers/surrogates that failed to predict clinical outcomes in different therapeutic areas and discussed reasons for failure [47]. These are: (a) The biomarker/surrogate is not in the causal pathway of the disease. (b) The disease involves several pathways and the drug affects only the one mediated by the biomarker. (c) The biomarker is not in the pathway affected by the drug. (d) The drug affects mechanisms that are independent of the disease process [47]. One of the most classic examples of biomarkers/surrogates failing badly in predicting serious clinical outcomes is the use of reduction of ventricular extra systoles as a surrogate for decreased cardiovascular mortality after myocardial infarction. Flecainide, encainide, and moricizine were found to increase mortality [48, 49] despite the fact that they effectively suppressed ventricular arrhythmias. All three drugs were later withdrawn from the market. This and many other sobering examples reflect the fact that conclusive answers on the efficacy and safety of drugs can only be answered by large clinical trials using solid clinical endpoints. Moreover, long-term safety evaluation often requires extensive clinical use after drug approval. However, this does not decrease the value of biomarker-based PoP/PoC as a means of demonstrating relevant pharmacological activity of new compounds and capturing early signs of potential clinical utility. After all, PoP/PoC is primarily an indication that a certain compound is reasonably good enough to develop further.

### 27.9.1 Summary of Selected Human Models Quoted in This Chapter that Can be Used in PoP/PoC Trials

- *Human Endotoxemia Model* This is an experimental model of sepsis using intravenously administered, purified lipopolysaccharide (LPS) from *Escherichia coli* to healthy volunteers. The endotoxin induces changes that mimic early inflammatory and cardiovascular responses in septic shock [50–54]. The model has been widely used to study the mechanisms underlying the pathophysiology of sepsis and can potentially be useful to establish early PoP/PoC for drugs targeting these mechanisms. One limitation of the model is that it may not capture the increased vascular permeability, an important feature of severe sepsis/septic shock [55, 56].
- *Carbon Dioxide Inhalation Model* Inhalation of 7.5% carbon dioxide induces anxiety manifestations in healthy subjects with a sense of fear and tension together with increases in blood pressure and heart rate [57]. This model has been shown to be sensitive to the effects of lorazepam and to some extent paroxetine [58], and might therefore be useful to establish early PoP for new compounds intended for the treatment of generalized anxiety disorder (GAD) and panic disorder.
- *Scopolamine-Induced Cognitive Impairment Model* Cognitive impairment is induced in healthy subjects using subcutaneously or intravenously administered scopolamine; and the effect of cognition enhancers can be monitored, for example, using computerized neuropsychological test battery (CNTB) and quantitative electroencephalography (qEEG) [20–22].

- *Conditioned Aversive Anxiety Model* In this model, skin conductance responses to auditory stimuli are measured. Ten neutral tones are initially presented (habituation phase), and tone 11 is immediately followed by an aversive white noise (unconditioned stimulus). The response to a second presentation of the tones (extinction phase) is recorded. Amplitude as well as spontaneous fluctuations (variability) of the skin conductance response is registered. A positive control such as diazepam is used, and compounds with putative anxiolytic effects are compared with the control [30, 59].
- *Pentagastrin-Induced Gastric Acid Secretion* In this model, maximal/submaximal gastric acid secretion is induced in healthy subjects by intravenous infusion of pentagastrin. The effect of antiulcer/GERD drugs such as proton pump inhibitors on gastric acid output and intragastric pH is measured [60, 61].
- *Phenylephrine Challenge* This model is used to investigate the effect of alpha blockers on urethral tone and blood pressure in order to estimate the selectivity for the effect on urethral smooth muscles relative to the hypotensive response [62]. Phenylephrine, which raises urethral and blood pressure, is administered by dose escalation infusions at the estimated  $T_{\max}$  for the compound, urethral pressure is monitored using a sensor-equipped self-retaining urethral catheter, and blood pressure is recorded simultaneously. New, more selective compounds can be tested in this model establishing PoP/PoC [62].
