prescription of moclobemide and two SSRIs (citalopram and fluoxetine) increased, while that of tricyclics (mainly doxepin and amitriptyline) remained steady. The mean annual fatal toxicity index was highest for tricyclics, such as doxepin, trimipramine, and amitripyline, and lowest for SSRIs.

Educational policies and commercial marketing of antidepressant drugs have led to an increase in the detection and treatment of depression. Conceivably this may be associated with the fall in suicide rates noted in Finland. However, overdosage of tricyclic antidepressants continues to contribute to deaths from suicide. Whether completely replacing tricyclics with less toxic compounds would lower overall suicide rate remains controversial.

The results of a British survey of all deaths due to acute poisoning due to antidepressants are shown in Table 2 (150).

A major problem in evaluating the incidence and severity of complications due to overdosage in adults has been the reporting of individual cases or selected samples, often with the inclusion of patients who have taken several drugs or who have concurrent physical disease. More reliable epidemiological surveys from different countries (45,151,152) have suggested that the mean ingested overdose of a tricyclic antidepressant in adults is around 1000 mg, and that only about 3% of patients take enough to cause fatal complications. There is considerable individual variability in response to overdosage, and there are conflicting reports concerning the degree of correlation between plasma concentrations and complications. One large study showed that plasma concentrations in excess of 1000 ng/ml were associated with coma, convulsions, cardiac dysrhythmias, and a need for supportive measures (21). In other studies there was no clear-cut correlation between plasma concentration and the incidence of toxic complications (153). Cardiac complications have been reviewed above and are serious, but should not deflect attention from other serious effects. A review of all deaths due to these drugs in Britain during 1976 showed that dysrhythmias were less common than supposed (11 of 113 patients who died in hospitals), but that respiratory depression was more frequent (54 of 113

Table 2 Deaths per million prescriptions for antidepressants in the UK

Drug	No. of prescriptions	Total deaths	Deaths per million prescriptions (95% CI)
Tricyclic antidepressants and related drugs	74 598 000	2598	35 (34, 36)
Desipramine	45 000	9	201 (92, 382)
Amoxapine	107 000	10	94 (45, 172)
Dosulepin	26 210 000	1398	53 (51, 56)
Amitriptyline	23 844 000	906	38 (36, 41)
Imipramine	3 354 000	110	33 (27, 40)
Doxepin	1 587 000	40	25 (18, 34)
Trimipramine	2 370 000	39	17 (12, 23)
Clomipramine	4 315 000	54	13 (9.4, 16)
Nortriptyline	1 269 000	7	5.5 (2.2, 11)
Maprotiline	201 000	1	5.0 (0.1, 28)
Trazodone	2 753 000	11	4.0 (2.0, 7.1)
Mianserin	922 000	3	3.3 (0.7, 9.5)
Mirtazapine	324 000	1	3.1 (0.1, 17)
Lofepramine	7 189 000	9	1.3 (0.6, 2.4)
Butriptyline	1000	0	0 (0, 3372)
Iprindole	3000	0	0 (0, 1218)
Viloxazine	10 000	0	0 (0, 357)
Protriptyline	94 000	0	0 (0, 39)
Serotonin re-uptake inhibitors	47 329 000	77	1.6 (1.3, 2.0)
Venlafaxine	2 570 000	34	13 (9.2, 19)
Fluvoxamine	660 000	2	3.0 (0.3, 11)
Citalopram	2 603 000	5	1.9 (0.6, 4.5)
Sertraline	5 964 000	7	1.2 (0.5, 2.4)
Fluoxetine	19 926 000	18	0.9 (0.5, 1.4)
Paroxetine	15 031 000	11	0.7 (0.4, 1.3)
Nefazodone	576 000	0	0 (0, 6.4)
Monoamine oxidase inhibitors	1 203 000	24	20 (13, 30)
Tranylcypromine	367 000	16	44 (25, 71)
Phenelzine	404 000	6	15 (5.5, 32)
Moclobemide	365 000	2	5.5 (0.6, 20)
Iproniazid	200	0	0 (0, 18 444)
Isocarboxazid	68 000	0	0 (0, 55)
Other antidepressants	2 523 000	1	0.4 (0, 2.2)
Flupentixol	28 000	0	0 (0, 2.4)
Tryptophan	28 000	0	0 (0, 133)
Reboxetine	175 000	0	0 (0, 21)
Lithium	5 106 000	37	7.2 (5.1, 10)

Numbers may not add up to the total because of rounding.

patients) (48). Some such deaths might have been avoided by more frequent artificial ventilation and better attention to the principles of supportive care.

Management of overdose

The literature on poisoning with tricyclic antidepressants has been reviewed and recommendations for the management of overdose proposed (SEDA-16, 8) (154). In overdose, physostigmine can reverse life-threatening dysrhythmias, but its effect is short-lasting and it has adverse effects of its own; it should be avoided (154).

Drug–Drug Interactions

General

The large number of drugs with which tricyclic antidepressants interact are summarized in Table 3; those of major concern are discussed in more detail below.

Table 3 Interactions of tricyclic antidepressants with other substances

Interacting substance(s)	Type of interaction(s)	Comments
Alcohol	Additive sedative effects	May be more pronounced with more sedative tricyclic compounds
Anticholinergic drugs	Additive effects on pupils, nervous system, bowel, and bladder	Particularly likely to occur when a tricyclic drug, a phenothiazine, and a antiparkinsonian drug are prescribed concurrently
Anticoagulants	Increased serum concentrations of oral anticoagulant	Tricyclic drugs can interfere with the metabolism of oral anticoagulants
Antiepileptic drugs	Antagonism	Convulsive threshold lowered
	Decreased plasma concentrations of some tricyclic drugs	Hepatic microsomal enzyme induction
Antihypertensive agents	Reversal of hypotensive effects of clonidine, reserpine, α-methyldopa, and guanethidine	Hypertension should be controlled with diuretics, β-blockers, or vasodilators before treatment of depression
Barbiturates	Reduced plasma concentrations of tricyclic drugs	Hepatic microsomal enzyme induction
Calcium channel blockers	Increased plasma concentrations of imipramine and possibly other drugs	
Cigarette smoking	Decreased plasma concentrations of tricyclic drugs	Probably increased metabolism
Cimetidine	Increased systemic availability of tricyclic drugs	Probably due to impaired hepatic extraction
Disulfiram	Increased plasma concentrations of tricyclic drugs	Probably inhibition of metabolism
Diuretics	Increased risk of postural hypotension	Pharmacodynamic interaction
Halofantrine	Increased risk of ventricular dysrhythmias	Prolonged QT interval
Levodopa	Impaired gastrointestinal absorption	May apply to other drugs metabolized in the gut
Monoamine oxidase inhibitors	Increased incidence of weight gain	See text; see also monograph on Monoamine oxidase inhibitors
	Increased anticholinergic effects	
	Hyperthermia, hyper-reflexia, convulsions, death (very rare)	
Membrane-stabilizing drugs (quinidine type)	Synergism	
Methylphenidate	Increased plasma concentrations of tricyclic drugs	Probably inhibition of metabolism
Morphine	Potentiation of analgesic effect of morphine	May be partly due to increased systemic availability of morphine
Nitrates	Reduced effect of sublingual nitrates	Owing to dry mouth
Phenothiazines	Increased plasma concentrations of tricyclic drugs	Due to inhibition of metabolism
	Possible potentiation and/or increased speed of onset of antidepressant effect	
	Enhanced cardiotoxic effects with thioridazine	Presynaptic α_2-adrenoceptor blockade (animal studies)
		Ventricular dysrhythmias can occur
Rifampicin	Decreased plasma concentrations of some tricyclic drugs	Hepatic microsomal enzyme induction
Ritonavir	Possibly increased plasma concentrations of tricyclic drugs	Inhibition of metabolism
SSRIs	Increased plasma concentrations of tricyclic drugs	Inhibition of metabolism
Corticosteroids	Altered systemic availability of tricyclic drugs	Inhibition of metabolism
	Akathisia	Receptor interaction
	Exacerbation of psychosis	
Sympathomimetic agents	Potentiation of hypertensive effects with phenylephrine, noradrenaline, methylphenidate	
	Potentiation of effects of pheochromocytoma	
Thyroid hormones	Can manifest as spurious hyperthyroidism, cardiac dysrhythmias, or, in some cases, enhanced therapeutic actions of tricyclics	Increased receptor sensitivity to catecholamines

Alcohol

Alcohol in combination with tricyclic antidepressants impairs performance, and it is customary to caution patients about the risk of impairment in their ability to drive or handle machinery. Not only can additive impairment occur (mediated at the receptor level), but alcohol can also alter the metabolism of the antidepressant (SEDA-8, 24).

Amines

Tricyclic antidepressants act on both presynaptic and postsynaptic neurons, as well as on alpha- and beta-adrenoceptors. Because their principal action is to block the re-uptake of noradrenaline at the presynaptic neuron, they potentiate the hypertensive effects of both directly acting and indirectly acting amines (155,156). The hypertensive effects of phenylephrine are increased by a factor of 2–3, and of noradrenaline by a factor of 4–8. Even the administration of local anesthetics containing noradrenaline as a vasoconstrictor has proven fatal. The types of compound that can produce this interaction and the symptoms that result have been previously reviewed in detail (SEDA-1, 11).

Anesthetics

In 190 patients taking tricyclic antidepressants that could not be discontinued before surgery, who underwent general and 61 local or regional anesthesia, there were no changes in the cardiovascular effect of halothane, induction time with pentobarbital, propanidid, or ketamine, or the duration of depolarization or recovery time (157). The general conclusion was that it is safer to continue treatment with tricyclic antidepressants than to risk potential disruption from withdrawal before surgery.

Anticoagulants

Tricyclic antidepressants can interfere with the metabolism of oral anticoagulants, increase their serum concentrations, and prolong their half-lives by as much as 300% (SEDA-21, 10) (158). Prothrombin activity should be carefully monitored in patients taking oral anticoagulants.

Antidysrhythmic drugs

Because of their similar lipophilic and surfactant properties, tricyclic antidepressants interact with antidysrhythmic drugs of the quinidine type, interfering with the voltage-dependent stimulus and producing dose-related synergy (159). Cardiac glycosides and beta-blockers are free of this interaction, although animal studies have suggested increased lethality of digoxin in rats pretreated with tricyclic antidepressants (160), while propranolol may potentiate direct depression of myocardial contractility due to tricyclic antidepressants. For all of these reasons, the preferred treatment for tricyclic-induced dysrhythmias is lidocaine, but even this is reported to be only variably effective and possibly to potentiate the hypotensive effects of tricyclic drugs (46).

Antipsychotic drugs

Tricyclic antidepressants lower the seizure threshold and should therefore be used with caution with other agents that can also lower seizure threshold, such as antipsychotic drugs (161).

- A 34-year-old man with schizophrenia responded well to olanzapine 20 mg/day. However, he then had obsessional hand washing and was given clomipramine, which was increased to a dosage of 250 mg/day. He then reported myoclonic jerks with some dizziness, and 10 days later had a generalized tonic-clonic seizure. The combined clomipramine + desmethylclomipramine concentration was 2212 nmol/l, higher than the upper end of the usual target range (1300 nmol/l). An electroencephalogram showed paroxysmal slowing and spike-and-wave activity. Both olanzapine and clomipramine were withdrawn. Later the clomipramine was restarted as monotherapy and a dose of 300 mg/day was reached, which led to an even higher clomipramine + desmethylclomipramine concentration (3234 nmol/l), but there was no clinical or electroencephalographic evidence of seizure activity. However, when olanzapine was added in a dosage of 15 mg/day, myoclonic jerking and abnormal electroencephalographic activity recurred within 7 days.

The seizures occurred in the presence of high concentrations of clomipramine in this case, suggesting a pharmacodynamic drug interaction, since neither agent given alone provoked seizure activity, whereas the combination did. It is, however, possible that clomipramine might have caused a rise in olanzapine blood concentrations, which were not measured.

Benzodiazepines

Four patients developed adverse effects attributable to combinations of benzodiazepines with tricyclic antidepressants, including exacerbations of delusional thought disorders (162).

Corticosteroids

Patients taking prednisone have experienced psychosis, perhaps due to an interaction at dopamine receptor sites (163,164).

Fluconazole

Fluconazole can increase plasma concentrations of amitriptyline, presumably by inhibiting cytochrome P450 isozymes (CYP3A4 and CYP2C19), preventing its demethylation. Two patients taking amitriptyline and fluconazole developed syncope and in one concomitant electrocardiographic monitoring showed a prolonged QT interval and torsade de pointes (165,166). In neither case were serum amitriptyline concentrations measured, but the symptoms were consistent with tricyclic antidepressant toxicity. These case reports suggest that this combination should be used with caution and probably with monitoring of amitriptyline concentrations.

Levodopa

The anticholinergic effects of imipramine and other tricyclic antidepressants can delay gastrointestinal motility enough to interfere with the absorption of various other drugs. Such was the case in an experimental study of the absorption of levodopa in four healthy subjects (167). It is likely that this effect may interfere with absorption of other drugs, especially those, such as chlorpromazine, that are extensively metabolized in the gut.

Methylphenidate

The interaction with methylphenidate may be of particular significance, because of claims that tricyclic antidepressants and methylphenidate have a synergistic effect on mood, owing to interference by methylphenidate with the metabolism of imipramine, resulting in increased blood imipramine concentrations (168). The occurrence of this hypertensive interaction calls for caution in the use of such combinations, for which there is no established evidence.

Monoamine oxidase inhibitors

The interactions of tricyclic antidepressants with MAO inhibitors are so dangerous that they constitute a formidable barrier to their combined clinical use. The temptation to treat refractory patients with this combination is great, but considerable care should be taken (169,170), and it should be remembered that there is no firm proof of the superiority of such combinations. Several reviewers (171–173) have concluded that the dangers of these interactions have been overstated and the potential therapeutic advantages underestimated. On the other hand, reports of serious and fatal complications continue to appear (174,175). Specialists have advised that the combination of an MAO inhibitor with trimipramine or amitriptyline is usually safe, but that imipramine and clomipramine must be avoided.

Phenothiazines

Two Scandinavian patients taking combinations of neuroleptic drugs and tricyclic antidepressants developed epileptic seizures (176). The risk of seizures is greater in patients with brain damage or epilepsy and with high dosages, sudden increases in dosage, or shortly after the introduction of a second compound.

The possible mechanism for these interactions with phenothiazines is raised plasma concentrations of the tricyclic compounds due to competition for the hepatic cytochrome P450 that metabolizes both types of compound (SEDA-9, 30) (177). Antidepressant plasma concentrations may increase by up to 70% (178).

Postganglionic blockers

Tricyclic antidepressants reverse the hypotensive effects of postganglionic blocking agents, guanethidine, reserpine, clonidine, and alpha-methyldopa, and the addition of a tricyclic can result in loss of blood pressure control (159,179). Sudden withdrawal of a tricyclic compound from a patient stabilized with these compounds can also result in serious hypotension. An additional reason for avoiding drugs such as reserpine, methyldopa, and propranolol in depressed cardiovascular patients is that these drugs can also cause or aggravate depression.

Psychotropic drugs

The evidence for interactions with other commonly prescribed psychotropic drugs has been reviewed extensively (SEDA-8, 25).

Salicylates

Tricyclic antidepressants are highly bound to plasma proteins. Theoretically, other drugs that are highly protein bound could displace tricyclic antidepressants from protein binding sites; this would be expected to lead to increased plasma concentrations of unbound antidepressant and a greater likelihood of adverse effects. In practice, however, important interactions of this kind are unusual, probably because these drugs have high apparent volumes of distribution, and the amount of drug that can be displaced from plasma proteins is very small compared with tissue concentrations. Salicylates are highly protein bound, and the effect of adding acetylsalicylic acid 1 g/day for 2 days on the plasma availability of imipramine (150 mg/day) has been studied in 20 depressed patients (180). Acetylsalicylic acid reduced the protein binding of imipramine and while the total plasma concentration of imipramine was not altered, the unbound concentration rose almost four-fold. The number of characteristic adverse effects of imipramine also increased significantly. However, this study was not blind and the results must be in doubt, since it is unlikely that brain concentrations of the drug changed significantly.

Sex hormones

Oral contraceptives have a complex effect on the metabolism of tricyclic drugs, resulting in reduced systemic availability (181). Conjugated estrogens also cause akathisia in some patients taking tricyclic drugs, perhaps due to an interaction at dopamine receptor sites (182).

Sodium valproate

Sodium valproate can increase serum tricyclic drug concentrations (SEDA-21, 22).

- In a 46-year-old woman, in whom valproate 1 g/day was added to clomipramine 150 mg/day, there was a substantial increase in serum clomipramine concentrations (from 185 ng/ml to 447 ng/ml); she had feelings of numbness and sleep disturbance, which disappeared when the dose of clomipramine was reduced (183).

The increase in tricyclic concentrations following valproate is probably partly due to inhibition of CYP2C isozymes, preventing demethylation of tertiary tricyclic antidepressants to the corresponding secondary amines (desmethylimipramine in the case of clomipramine). However, valproate can also increase the plasma concentrations of secondary amine tricyclics, such as nortriptyline (183). The current data suggest that the combined use of tricyclic antidepressants and valproate should be undertaken with caution.

© 2006 Elsevier B.V. All rights reserved.

SSRIs

Fluoxetine can increase blood concentrations of desipramine and nortriptyline (184–187).

St John's wort

St John's wort can cause drug interactions by inducing hepatic microsomal drug-metabolizing enzymes or the drug transporter P-glycoprotein, which causes a net efflux of substrates, such as amitriptyline, from intestinal epithelial cells into the gut lumen (SEDA-24, 12). In 12 patients (9 women, 3 men) the addition of St John's wort 900 mg/day to amitriptyline 150 mg/day led to a 20% reduction in plasma amitriptyline concentrations, while nortriptyline concentrations were almost halved (188).

Thioridazine

The interaction of thioridazine with a tricyclic antidepressant is particularly dangerous, since both cause cardiac toxicity. One report concerned two young patients who developed ventricular dysrhythmias, from which they recovered (189).

Thyroid hormone

Spurious hyperthyroidism occurred in a child taking thyroid hormone and imipramine for enuresis (190). The ability of thyroid hormone to increase receptor sensitivity to catecholamines has long been known, and has been used to enhance the clinical response in some refractory patients, especially women.

Yohimbine

Yohimbine can cause hypertension in patients taking tricyclic antidepressants. A drug history should include the use of herbal remedies before conventional treatments are prescribed.

Trientine

General Information

Trientine is a copper chelator that is used as an alternative to penicillamine in Wilson's disease, although experience with it is limited (1–4).

Organs and Systems

Nervous system

Trientine can, like penicillamine, initially worsen the neurological manifestations of Wilson's disease, presumably by mobilizing and redistributing copper (5,6). It should be started in small doses followed by gradual increases.

Metal metabolism

Excessive excretion of metals (zinc, iron) can occur in patients taking trientine, and can cause deficiency symptoms (7).

Hematologic

There have been several cases of sideroblastic anemia, characterized by an excess of ringed sideroblasts in the bone marrow, as a suspected adverse effect of trientine (8,9).

Gastrointestinal

In two patients the use of trientine was associated with serious colitis (with concomitant duodenitis in one), raising the suspicion of a possible causal relation (6).

Immunologic

- A 44-year-old woman developed antinuclear and anti-double-stranded-DNA antibodies (without clinical signs) while taking penicillamine; the antibodies disappeared after withdrawal, but recurred when she was subsequently given trientine (10).

Trifluoromethane

General Information

Research in animals, including primates, has shown that the inhaled fluorine gas, trifluoromethane (FC-23) can be used as an indicator of cerebral blood flow measured by magnetic resonance imaging (MRI) (1,2). The development of a fluorinated indicator to measure cerebral blood flow with MRI would allow the interleaving of images of cerebral anatomy and metabolism with images of regional cerebral blood flow, all obtainable in one setting by magnetic resonance methods. However, trifluoromethane is not inert and humans do not tolerate concentrations suitable for current MRI technology. Five healthy volunteers inhaled trifluoromethane at concentrations of 10–60% in a double fluid study (3). Concentrations over 30% produced impairment of neuropsychological function.

Organs and Systems

Psychological, psychiatric

In a phase 1, dose-ranging study, trifluoromethane 10–60% impaired neuropsychological function in five healthy men. Symptoms that occurred more often at higher doses included tiredness, difficulty in concentrating, tingling, dry mouth, and loss of appetite (3).

Trifluridine

General Information

Trifluridine, which is active against *Herpes simplex* and *Varicella zoster*, has only been used in topical antiherpetic solutions. It is twice as potent as idoxuridine in 1% solution and 10 times more soluble. Trifluridine has been reported to heal dendritic keratitis faster than idoxuridine, to be as effective as vidarabine when used five times a day, to have no cross-toxicity with idoxuridine or vidarabine, to heal stromal corneal defects more effectively than idoxuridine, and to produce topical allergy, punctal narrowing, and punctal keratitis only rarely. Furthermore, it gives excellent results in herpetic ulcers previously treated with topical glucocorticoids and in idoxuridine-unresponsive ulcers.

Organs and Systems

Immunologic

Trifluridine can cause allergic reactions (1).

Reference

Trihexyphenidyl

See also Anticholinergic drugs

General Information

Trihexyphenidyl (benzhexol) is an anticholinergic drug. It is given in oral doses rising from 2 to 20 mg/day, and even higher doses are used in dystonic patients. A wide range of anticholinergic adverse reactions can occur, but trihexyphenidyl is apparently particularly likely to cause excitement.

Organs and Systems

Cardiovascular

Paradoxical bradycardia has been reported; the reaction was specific to trihexyphenidyl and was not observed when the patient took other anticholinergic drugs (SEDA-12, 125).

Nervous system

Orofacial dyskinesia has been described with trihexyphenidyl in a patient who did not experience this reaction with levodopa (SEDA-18, 160).

Sensory systems

Trihexyphenidyl can precipitate glaucoma in predisposed patients, and blindness has resulted (1).

Psychological, psychiatric

Although it has been thought that high doses of trihexyphenidyl might impair learning in children, a careful study of this question suggested that there is in practice little interference (2).

As little as 8 mg/day combined with levodopa has caused an acute toxic confusional state in some patients.

- A 75-year-old man with a 10-year history of parkinsonism developed fever and acute delirium after taking levodopa plus trihexyphenidyl (3). He had visual hallucinations, was disoriented in time and place, and could respond only to simple questions. He was unable to stand or walk and had paratonic rigidity in all limbs and marked bradykinesia. There were occasional myoclonic jerks in the arms and legs. Deep reflexes were reduced bilaterally, and the plantar reflexes were absent.

Impairment of memory was attributed to trihexyphenidyl in healthy volunteers (SEDA-13, 115).

Long-Term Effects

Drug withdrawal

Acute withdrawal of trihexyphenidyl after a patient has become adapted to it can trigger an encephalopathy, requiring readministration (SEDA-22, 157).

Drug Administration

Drug overdose

Trihexyphenidyl has been misused by drug addicts to produce elation or relieve depression. One patient who took 300 mg with suicidal intent survived the resulting toxic psychosis (4).

Trimethoprim and co-trimoxazole

General Information

Trimethoprim is a 2,4-diamino-5-(3′,4′,5′-trimethoxybenzyl) pyrimidine that inhibits dihydrofolate reductase, the enzyme in folate synthesis after the step that is blocked by sulfonamides (1). Trimethoprim therefore inhibits the conversion of dihydrofolate to tetrahydrofolate. It has been combined with sulfonamides, including sulfamethoxazole, sulfametrol, sulfadiazine, sulfamoxole, and sulfadimidine (2,3).

A widely available fixed combination is co-trimoxazole (Bactrim, Eusaprim, Septrin), which contains trimethoprim and sulfamethoxazole in a ratio of 1:5. Both trimethoprim and sulfamethoxazole have favorable and comparable pharmacokinetics and the combination is bactericidal (4). Synergy between trimethoprim and sulfonamides has conventionally been ascribed to sequential inhibition of dihydropteroate synthetase by sulfonamides (in competition with *para*-aminobenzoic acid) and of dihydrofolate reductase by trimethoprim (in competition with dihydrofolate). However, sulfonamides in high concentrations also inhibit dihydrofolate reductase. Thus, an initial partial sequential blockade by trimethoprim (inhibition of dihydrofolate reductase) and sulfonamides (inhibition of dihydropteroate synthetase) leads to defective protein synthesis and cytoplasmic damage, which in turn results in marked increases in the uptake of both agents and "double strength" inhibition of dihydrofolate reductase (5).

Trimethoprim is fairly active against a variety of Gram-positive cocci and Gram-negative rods. Established indications for co-trimoxazole are infections of the sinuses, ears, lungs, and urinary tract, and infections due to *Salmonella*, *Nocardia*, *Brucella*, *Stenotrophomonas maltophilia*, *Pneumocystis jiroveci*, and *Toxoplasma* (1,6). Co-trimoxazole is also used in the treatment of Wegener's granulomatosis, for prevention of spontaneous bacterial peritonitis, and in patients with advanced HIV infection for the prophylaxis of opportunistic infections (1,6).

There have been few comparisons of the efficacy of trimethoprim and co-trimoxazole. In uncomplicated urinary tract, bronchopulmonary, and ear infections, no advantage of co-trimoxazole over trimethoprim has been documented (7,8). However, in complicated urinary tract infections most studies have shown better results with co-trimoxazole than with trimethoprim alone (9). Despite the widespread use of co-trimoxazole for about 35 years, bacterial resistance has not emerged as a major problem (10,11).

The adverse effects of co-trimoxazole are mostly ascribed to the sulfamethoxazole component. However,

© 2006 Elsevier B.V. All rights reserved.

adverse effects can also be caused by trimethoprim or by the combination. It is important to realize that the culprit agent can only be definitely determined by re-exposure of the single drugs in the individual patient. Thus, in clinical practice it may be impossible to determine the causative compound.

Tetroxoprim is another 2,4-diaminopyrimidine derivative with comparable actions to those of trimethoprim. It is exclusively used in combinations with sulfonamides.

General adverse effects

Severe adverse drug reactions with trimethoprim and co-trimoxazole are rare (12–14). This also applies to children (15). The adverse effects of co-trimoxazole correspond to those expected from a sulfonamide (16). In HIV-infected patients, adverse effects of co-trimoxazole are more frequent and more severe (17–19). Hematological disturbances due to co-trimoxazole include mild anemia, leukopenia, and thrombocytopenia, which may be due to folic acid antagonism. Serious metabolic disturbances that are associated with trimethoprim include hyperkalemia and metabolic acidosis. Trimethoprim can cause hypersensitivity reactions. However, with co-trimoxazole, the sulfonamide is generally believed to be more allergenic (12). Generalized skin reactions predominate. Other effects, such as anaphylactic shock, are extremely rare (20–22). Carcinogenicity due to trimethoprim or co-trimoxazole has not been reported.

Organs and Systems

Respiratory

Cases of allergic pneumonitis and pulmonary infiltrates with eosinophilia have been described with co-trimoxazole (23). Such reactions have not been reported with trimethoprim alone. Pulmonary infiltrates due to co-trimoxazole hypersensitivity in patients with AIDS are particularly worrisome, since they mimic progression of underlying opportunistic pulmonary infections.

- Pneumonitis developed after the administration of co-trimoxazole in a patient with intractable ulcerative colitis complicated by *P. jiroveci* pneumonia. This patient had also previously had sulfasalazine-induced pneumonitis (24).
- A 33-year-old man taking co-trimoxazole developed bilateral pulmonary infiltrates and a fever of 39°C after 2 weeks (25). Co-trimoxazole was withdrawn. The fever resolved 6 days later. A lung biopsy showed non-specific interstitial pneumonia. A lymphocyte stimulation test for co-trimoxazole was positive.

Nervous system

Co-trimoxazole can cause tremor (26), which has been described in patients with AIDS taking co-trimoxazole (27,28).

- A 66-year-old man with pulmonary fibrosis and cor pulmonale was given intravenous co-trimoxazole for 3 weeks followed by oral treatment for an infection with Nocardia farcinica. On day 3 of oral treatment, he developed a tremor in both arms and legs, exacerbated by trying to stay calm. The symptoms resolved 3 days after drug withdrawal.

Aseptic meningitis and meningoencephalitis occur with trimethoprim and co-trimoxazole (29–39). The pathogenetic mechanism is still uncertain.

- A 15-year-old boy developed aseptic meningitis while taking trimethoprim 200 mg in the morning and 100 mg in the evening (40).

Immune complex deposition, immediate hypersensitivity, direct drug toxicity, and induction of anti-tissue antibodies have all been suggested. Interleukin-6 may be an important mediator of trimethoprim-induced aseptic meningitis in some patients. A case with three episodes after re-exposure to co-trimoxazole has been reported (41). Polymorphonuclear or mononuclear cells may preponderate (42). Interleukin-6 may be an important mediator of trimethoprim-induced aseptic meningitis in some patients (43,44).

Ataxia has been described in two patients with AIDS after intravenous use of co-trimoxazole (45).

Extrapyramidal symptoms developed with co-trimoxazole in a girl with dihydropteridine reductase deficiency and rapidly disappeared after withdrawal. This variant of phenylketonuria should be considered in all infants found to have raised phenylalanine concentrations during the neonatal period (46).

Sensory systems

Uveitis in combination with meningitis (47) and uveitis in combination with arthritis and Stevens–Johnson syndrome (48) have been reported with trimethoprim. Uveitis with retinal hemorrhages has also been described (49).

In unmedicated young and elderly volunteers and unmedicated HIV-infected patients, trimethoprim applied to the tongue was primarily described as bitter and medicinal (50).

Psychological, psychiatric

- Delirium occurred after treatment with co-trimoxazole in a patient with AIDS; the episode completely resolved within 72 hours of drug withdrawal (51).

Endocrine

In a child, co-trimoxazole was the probable cause of growth failure (52).

Co-trimoxazole has been suggested to have some antithyroid activity. However, whether this effect is due to trimethoprim alone is still unclear (53,54). Co-trimoxazole 27–31 mg/kg bd orally substantially altered serum total T4 and TSH concentrations and neutrophil counts in dogs within as short a time as a few weeks (55).

Metabolism

Co-trimoxazole can cause reversible hypoglycemia, which may be prolonged, particularly in patients with risk factors for hypoglycemia. Common risk factors include compromised renal function, prolonged fasting, malnutrition, and the use of excessive doses. It has been postulated

© 2006 Elsevier B.V. All rights reserved.

that the sulfonamide mimics the action of sulfonylureas, stimulating pancreatic islet cells to secrete insulin. In elderly people, co-trimoxazole-induced hypoglycemia can cause altered mental state (56,57).

Metabolic acidosis has been observed in patients with AIDS after intravenous co-trimoxazole (58). The acidosis developed 3–5 days after the start of treatment and had a favorable course. It is likely that the sulfonamide was responsible, because of renal loss of bicarbonate.

Nutrition

A median increase in serum homocysteine of 50% (range 27–333%) was found in seven healthy male volunteers after a 2-week course of trimethoprim 300 mg bd (59). Concomitantly, serum folate concentrations fell significantly. By day 50, baseline values of homocysteine and folate were regained. Since tetrahydrofolate serves as a methyl group carrier in the remethylation of homocysteine to methionine, the inhibitory effect of trimethoprim on dihydrofolate reductase may be most important, but other mechanisms could not be excluded.

Electrolyte balance

Hyperkalemia is a relatively common complication of trimethoprim therapy and occurs at both high and standard dosages. It is thought to be caused by a potassium-sparing effect, to which elderly people appear to be particularly vulnerable (60–63). However, pre-existing renal impairment and concomitant potassium sparing diuretics may also contribute (60). In almost all cases the electrolyte changes resolve on withdrawal. Trimethoprim reduces renal potassium excretion by competitively inhibiting epithelial sodium channels in the distal nephron like triamterene. Higher dosages and pre-existing renal dysfunction are associated with an increased risk of hyperkalemia, as are probably other disturbances in potassium homeostasis, such as hypoaldosteronism and treatment with drugs that impair renal potassium excretion. Conversely, alkalinization of the urine and induction of high urinary flow rates block the antikaliuretic effect of trimethoprim in the distal nephron (64).

Co-trimoxazole can reduce potassium excretion and cause life-threatening hyperkalemia (65,66), even in therapeutic doses. In one study with standard dosages of co-trimoxazole, up to 62% of patients developed a peak serum potassium concentration of over 5.0 mmol/l and 21% a peak concentration of over 5.5.mmol/l (12,60,66). About 20–53% of patients with AIDS taking high-dosage co-trimoxazole for *P. jiroveci* pneumonia also develop hyperkalemia, and around 10% reach dangerously high concentrations (over 6.0 mmol/l). Withdrawal of trimethoprim is often required. Alkalinization of the urine and the induction of high urinary flow rates with intravenous fluids and loop diuretics block the antikaliuretic effect of trimethoprim on distal nephron cells (67,68).

Life-threatening hyperkalemia secondary to the use of standard doses of co-trimoxazole has been reported in two renal transplant recipients who developed end-stage renal disease secondary to familial Mediterranean fever, who may be at increased risk of hyperkalemia because of concurrent renal insufficiency, concomitant use of ciclosporin, and associated tubulointerstitial disease (69). In one patient, underlying adrenal insufficiency might have contributed to the hyperkalemia.

- Hyperkalemia due to high doses of co-trimoxazole (14 mg/kg/day trimethoprim and 70 mg/kg/day sulfamethoxazole) occurred in an HIV-positive patient with *P. jiroveci* pneumonia (70).
- Life-threatening hyperkalemia secondary to the use of standard oral doses of co-trimoxazole (trimethoprim 320 mg/day and sulfamethoxazole 1600 mg/day) occurred in a 77-year-old man with moderate chronic renal insufficiency from diabetic nephropathy (71). In addition to hyperkalemia, he developed severe metabolic acidosis; both resolved on appropriate medical intervention and withdrawal of co-trimoxazole.
- A 41-year-old black man with AIDS and sickle cell anemia was treated on two separate occasions with co-trimoxazole and prednisone 40 mg/day for *P. jiroveci* pneumonia (72). On both occasions he developed a hyperkalemic metabolic acidosis together with renal tubular acidosis after several days of therapy.

Concurrent acidosis in patients with trimethoprim-induced hyperkalemia is uncommon, which could be explained if the action of trimethoprim, like that of amiloride, is limited to the cortical collecting tubule but does not affect the medullary collecting tubule, which has a large capacity to secrete hydrogen ions and may therefore prevent the development of acidosis. Predisposing factors for the rare adverse effect of renal tubular acidosis in this case may have been aldosterone deficiency or resistance, medullary dysfunction of sickle cell anemia, and renal insufficiency. All these factors could contribute to impaired renal handling of secretion of hydrogen ions (72).

According to studies on animals, tetroxoprim, which is structurally similar to trimethoprim, has stronger antikaliuretic effects than trimethoprim. Tetroxoprim-induced hyperkalemia has not been described yet. However, tetroxoprim is only rarely used and dosages are low (73).

Trimethoprim uncommonly causes hyponatremia.

- A 78-year-old woman developed severe symptomatic hyponatremia after treatment with anhydrous theophylline and 6 months later developed hyponatremia after treatment with co-trimoxazole for a presumptive urinary tract infection (74).

Hematologic

Most hematological adverse effects associated with trimethoprim have been reported with co-trimoxazole. These include macrocytic and megaloblastic anemia, aplastic anemia, neutropenia, hypersegmentation of leukocytes, thrombocytopenia, and pancytopenia (12,61–63,75–79). Sulfonamides alone have not been associated with folate deficiency, but in combination with trimethoprim they can deplete folate stores in patients with pre-existing deficiency of folate or vitamin B_{12} (80). Treatment with co-trimoxazole can impair the function of mobilized autologous peripheral blood stem cells (81).

Mild hemopoietic suppression due to co-trimoxazole in an immunocompromised host is common, even with low-dose regimens. This effect is notable in combination with

© 2006 Elsevier B.V. All rights reserved.

other marrow-suppressive agents (for example azathioprine, ganciclovir, cyclophosphamide, and allopurinol), malnutrition, or infection (CMV and hepatitis C virus) (82).

Pancytopenia in the setting of severe drug hypersensitivity syndrome due to co-trimoxazole has been reported (83).

- A 53-year-old woman with congenital dyskeratosis took six co-trimoxazole double-strength tablets a day (trimethoprim 960 mg/day and sulfamethoxazole 4800 mg/day) for *P. jiroveci*, plus folic acid, and after 9 days developed a fever (39°C) accompanied by a morbilliform rash and painful cervical lymphadenopathy. She had a white blood cell count of 1.7×10^9/l, with 0.5×10^9/l neutrophils; hemoglobin 7.3 g/dl; platelets 17×10^9/l; and hemolysis. A myelogram showed extensive hemophagocytosis. Polyvalent intravenous immunoglobulin (1 g/kg/day) was given for 2 days. She became apyrexial within 48 hours, accompanied by marked clinical improvement, and recovered within 1 month.

Erythrocytes

Megaloblastic anemia and aplastic anemia occur in very few patients (78,84,85). They develop particularly in patients who have pre-existing low folic acid concentrations and who are not taking folic acid supplements (79,85–87). Patients with megaloblastic anemia should not be treated with co-trimoxazole. Other predisposing factors include other drugs with antimetabolite properties or anticonvulsants (88). In patients with pre-existing folic acid deficiency or with HIV infection, the administration of folinic acid has been advised, in order to reduce the hematological adverse effects. However, preliminary data suggest that adjunctive folinic acid may be associated with an increased risk of therapeutic failure and death (89).

Leukocytes

Agranulocytosis is very rare. If leukocytes are routinely monitored during treatment (more often than clinically indicated), mild leukopenia is encountered in 0.4–10% of patients taking either co-trimoxazole (13,84,90–92) or trimethoprim alone (93).

Platelets

Mild thrombocytopenia is quite common with co-trimoxazole, affecting 0.1% to several% of patients treated (8,9,85,90,92–94). In a retrospective review in Denmark, co-trimoxazole was one of the commonest reported causes of drug-induced thrombocytopenia (11% of reports), with the exception of cytotoxic drugs (95). In a similar review in Sweden from 1985 to 1994 of all drug-induced blood dyscrasias, thrombocytopenia occurred most frequently, the major causes being furosemide (17%) and co-trimoxazole (9%) (96). Older patients were most at risk. However, clinically significant thrombocytopenia is only rarely seen. Although folic acid deficiency may contribute to thrombocytopenia, immunological reactions to either the sulfonamide (75,97) or trimethoprim (98) have been proposed (99,100).

Severe, life-threatening thrombocytopenia associated with co-trimoxazole has been reported (101).

- A 54-year-old white woman took a 10-day course of co-trimoxazole (trimethoprim 160 mg, sulfamethoxazole 800 mg) for chronic sinusitis. One day after finishing the course she developed scattered petechiae on both hands and blood blisters in her mouth. She had a low platelet count of 20×10^9/l. Other laboratory tests were normal, except for a raised blood glucose concentration. She was treated successfully with a transfusion of two units of platelets and oral prednisone. Four days after withdrawal of co-trimoxazole her platelet count increased to 110×10^9/l.

Reports of drug-induced thrombocytopenia have been systematically reviewed (102). Among the 98 different drugs described in 561 articles the following antibiotics were found with level I (definite) evidence: co-trimoxazole, rifampicin, vancomycin, sulfisoxazole, cefalothin, piperacillin, methicillin, novobiocin. Drugs with level II (probable) evidence were oxytetracycline and ampicillin.

In another retrospective analysis of drug-induced thrombocytopenia reported to the Danish Committee on Adverse Drug Reactions, 192 cases caused by the most frequently reported drugs were included and analysed (103). There were pronounced drug-specific differences in the clinical appearance. Early thrombocytopenia was characteristic of cases caused by sulfonamides and co-trimoxazole. These drugs also often caused hemorrhage. Accompanying leukopenia was observed in some cases associated with co-trimoxazole. There were no patient-specific factors responsible for the heterogeneity of the clinical appearance, and factors related to the physician seemed to be of little significance.

Gastrointestinal

Nausea and possibly vomiting occur in a few to 20% of adult patients taking normal dosages of co-trimoxazole (13,94). With trimethoprim alone in a dose of up to 400 mg/day, gastrointestinal tolerance was better and skin reactions were less frequent than with the combination (3). A review of the data from five different centers has shown that gastrointestinal complaints are less frequent with trimethoprim than with the combination (9).

Drug-induced esophagitis is rare, accounting for about 1% of all cases of esophagitis. An incidence of 3.9 in 100 000 has been reported. After the first description, there have been more than 250 observations, with more than 50 different drugs. Among those, the principal antibiotics included tetracyclines (doxycycline, metacycline, minocycline, oxytetracycline, and tetracycline), penicillins (amoxicillin, cloxacillin, penicillin V, and pivmecillinam), clindamycin, co-trimoxazole, erythromycin, lincomycin, spiramycin, and tinidazole. Doxycycline alone was involved in one-third of all cases. Risk factors included prolonged esophageal passage, due to motility disorders, stenosis, cardiomegaly, the formulation, supine position during drug ingestion, and failure to use liquid to wash down the tablet. Direct toxic effects of the drug (pH, accumulation in epithelial cells, non-uniform dispersion) also seem to contribute to the development of drug-induced esophagitis (104).

Antibiotic-associated colitis is only very rarely seen with co-trimoxazole (105,106).

© 2006 Elsevier B.V. All rights reserved.

Liver

Intrahepatic cholestasis associated with phospholipidosis has been reported with trimethoprim (107). In one case trimethoprim caused cholestatic hepatitis after re-exposure (108).

The same types of liver disease occur with co-trimoxazole as with sulfonamides alone (109–111). Mild rises in serum transaminases and cholestatic hepatotoxicity are well reported, usually starting after a latent period of several weeks, and associated with a rash. There have been very few case reports of fulminant hepatic failure associated with co-trimoxazole.

- A 32-year-old woman developed a pruritic maculopapular rash and fever (112). She had taken a 12-day course of co-trimoxazole that had finished 5 days before and was taking no other drugs. She had normal hematological indices but a raised alkaline phosphatase and aspartate transaminase. Serological testing for Epstein-Barr virus, hepatitis A, B, and C, cytomegalovirus, echo virus, rubella, and measles showed no evidence of recent infection. Her rash improved but her general condition worsened and steroids were started. An abdominal CT scan showed a large liver with a moderate amount of ascites. The aspartate transaminase rose to 1330 IU/l and the prothrombin time increased. She developed progressive liver failure and died while awaiting liver transplant. At autopsy the liver showed signs of massive hepatic necrosis with no other abnormalities.
- Hepato-renal insufficiency combined with pancytopenia followed the administration of co-trimoxazole for 10 days for suspected pyelonephritis in a 48-year-old man (113). Hemodialysis was temporarily required, and renal and liver function and blood counts returned to normal afterwards.

Pancreas

Acute pancreatitis, with relapse on re-exposure, has been observed in a patient taking co-trimoxazole (114).

Urinary tract

Trimethoprim interferes with the tubular secretion of creatinine, causing an increased serum creatinine concentration and a reduced creatinine clearance, without affecting true glomerular filtration rate (115–118). Thus, a small increase in serum creatinine concentration at the beginning of treatment is not necessarily indicative of impaired renal function (119,120). Nevertheless, co-trimoxazole may have a direct nephrotoxic effect, mainly in patients with pre-existing renal impairment taking large dosages (115,116,121). This can be prevented by reducing the dose (117,118). If creatinine clearance is reduced to 15–25 ml/minute, the standard dose of co-trimoxazole should be reduced by half after an initial 3 days of treatment with the usual dose.

Treatment with co-trimoxazole (or other antibiotics) can increase the risk of the hemolytic-uremic syndrome in children with gastrointestinal infections caused by *Escherichia coli* O157:H7 compared with children with no antibiotic treatment (122).

Extremely rare instances of crystalluria followed by renal insufficiency due to obstruction have been described in patients taking trimethoprim (123).

Skin

The skin reactions observed with co-trimoxazole can be due to trimethoprim or to the sulfonamide. Data collected from five different centers have shown that skin rashes are less frequent with trimethoprim than with co-trimoxazole (9).

- Generalized erythematous skin eruptions have now been reported in a 20-year-old Japanese woman and a 70-year-old Japanese man taking co-trimoxazole (124). Patch tests showed that trimethoprim alone was responsible for the erythematous popular-type skin eruption in the young woman. The old man's skin responded to both trimethoprim and sulfamethoxazole.

The skin rashes due to trimethoprim and co-trimoxazole are mostly maculopapular and are related to the duration of treatment (125). They occur with a frequency of 1.3–5.9% (94,126–128).

In a randomized, open trial of long-term intermittent co-trimoxazole on recurrences of toxoplasmic retinochoroiditis, four of 54 patients who took a single tablet of co-trimoxazole (trimethoprim 160 mg, sulfamethoxazole 800 mg) withdrew when they developed mild cutaneous erythema that resolved when drug treatment was stopped (129).

Fixed drug eruptions

Fixed drug eruptions have been analysed in 450 patients (130). The ratio of men to women was 10:11. The mean age of the men was 30 years, and that of the women 31 years. In 13% the fixed drug eruption had occurred for the first time, 2.7% had had more than 40 episodes. There was atopy in 11%, and 23% had a positive family history of drug reactions. Co-trimoxazole was the most common cause of fixed drug eruptions. Other antibiotics included tetracycline, metronidazole, amoxicillin, ampicillin, erythromycin, and clindamycin.

Co-trimoxazole was the offender in 75% of 64 cases of fixed drug eruption. The eruption was mainly located on male genitalia, but unusual findings included familial occurrence, symmetrical and asymmetrical non-pigmented lesions, linear lesions, a solitary plaque on the cheek, and wandering lesions (131).

There may be an association between fixed drug eruption and HLA class I antigens. In 42 of 67 patients with fixed drug eruptions caused by co-trimoxazole there were significantly higher frequencies of the A30 antigen and A30 B13 Cw6 haplotype than in 2378 control subjects (132). HLA-B55 (split of B22) was present exclusively in co-trimoxazole fixed drug eruption, and in a higher frequency than in control subjects.

Topical provocation of fixed drug eruption and positive reactions with co-trimoxazole are extremely rare and have never been seen on unaffected skin.

- In a 42-year-old Caucasian woman with histopathologically confirmed fixed drug eruption induced by co-trimoxazole, positive topical provocation by trimethoprim was obtained on both involved and uninvolved skin (133).

© 2006 Elsevier B.V. All rights reserved.

Cross-sensitivity to co-trimoxazole and nimesulide has been reported (134).

- A 10-year-old-boy developed an extensive fixed drug eruption when he took co-trimoxazole (trimethoprim 200 mg, sulfamethoxazole 40 mg bd) 8 weeks after having had a fixed drug eruption due to nimesulide. An oral provocation test with co-trimoxazole 1 month later showed reactivation within 12 hours in the form of severe itching and erythema at the sites of the lesions with one-quarter of the dose.

Erythema multiforme

Erythema multiforme and its related syndromes (Stevens–Johnson syndrome and toxic epidermal necrolysis) are well recognized with co-trimoxazole and can be caused by trimethoprim as a single drug (135). A European review identified sulfonamides (and particularly co-trimoxazole) as a major causative factor in Stevens–Johnson syndrome and toxic epidermal necrolysis, the crude relative risk being far in excess of any other implicated drug (136). In a histopathological study of 111 cases from Germany, co-trimoxazole accounted for 22 cases (20%) (137). There were no histological features that could have discriminated between the different causes of this severe reaction.

- A 34-year-old Asian woman developed toxic epidermal necrolysis associated with co-trimoxazole (160/800 mg bd) (138). She recovered completely without serious sequelae.
- Toxic epidermal necrolysis, associated with co-trimoxazole for sinusitis in a 16-year-old woman, was successfully treated with intravenous immunoglobulins (0.4 g/kg for 5 days) (139).
- Toxic epidermal necrolysis, associated with treatment with co-trimoxazole (480/2400 mg/day) for sepsis in a 66-year-old Caucasian man, was successfully treated with intravenous immunoglobulin (0.75 g/kg for 5 days) (140).
- An 86-year-old man developed severe and extensive toxic epidermal necrolysis within 24 hours of taking co-trimoxazole for a urinary infection (141). He had had an allergic reaction to co-trimoxazole a few years before. He recovered completely without serious sequelae.
- A 50-year-old man took oral co-trimoxazole (trimethoprim 160 mg, sulfamethoxazole 800 mg) and developed toxic epidermal necrolysis 13 days later (142).

In 20 Indian patients (of whom 70% were women) with Steven–Johnson syndrome and ocular involvement, co-trimoxazole was the commonest identifiable risk factor (143). Conjunctival involvement and its sequelae were the major ocular manifestations.

Susceptibility factors

Skin reactions occur with high frequency during co-trimoxazole therapy in patients with AIDS (18,19). Other symptoms in such patients have been described in association with skin eruptions, including fever, neutropenia, thrombocytopenia, and rises in transaminase activities (18,79). The high dosages used to treat *P. jiroveci* in these patients may partly be responsible for the high frequency of adverse effects, since low-dose co-trimoxazole for the prevention of *P. jiroveci* pneumonia reduced the adverse effects from 28 to 9% (144).

Nails

- Co-trimoxazole was suggested to have caused loss of fingernails and toenails in a 3-year-old boy (145). He was initially treated with gentamicin 2 mg/kg intravenously every 8 hours for *E. coli* urinary tract infection, and co-trimoxazole was given once daily in a prophylactic dose. After 2 weeks his fingernails and toenails began to slough. Co-trimoxazole was withdrawn, and within 2 weeks his nails had returned to normal.

Immunologic

The sulfonamide component of co-trimoxazole is generally believed to be more allergenic than trimethoprim. However, trimethoprim alone can cause hypersensitivity reactions more commonly than has previously been thought. Most of these reactions present as generalized skin reactions. The hydroxylamine and other metabolites of sulfamethoxazole can bind covalently to proteins because of their chemical reactivity, resulting in the induction of specific adverse immune responses. Therefore, changes in the activity of detoxification pathways are associated with a greater risk of allergic reactions to sulfonamides. Allergies to sulfonamides, particularly sulfamethoxazole, are more frequent in patients with AIDS, but the reason for this increased risk is not fully understood. No tools are available to predict which patients have a greater risk for developing allergies to sulfonamides. In a small study in HIV-positive patients with hypersensitivity syndrome reaction, the lymphocyte toxicity assay has a strong potential for use as a diagnostic tool to assess co-trimoxazole hypersensitivity (146). Diagnosis is essential to avoid possible progression to severe reactions and readministration of the offending drug.

In patients who absolutely require further treatment, successful desensitization can be achieved (147). Two patients with chronic granulomatous disease who had previously been intolerant of co-trimoxazole completed a 5-day desensitization protocol with a good clinical outcome (148).

Anaphylactic shock is rare, but has been reported with co-trimoxazole (20). However, it is possible that this reaction was due to the sulfonamide compound (21). The case histories of 13 patients (12 women, one man, aged 22–68 years) with anaphylactic reactions to trimethoprim alone that were reported to a national drug safety unit have been analysed (20). Nine were classified as probable anaphylaxis. The casual relation between exposure to trimethoprim and anaphylaxis was classified as definite in three reports, possible in four, and probable in six. In one patient, IgE antibodies against trimethoprim were demonstrated.

- Culture-negative arthritis, bilateral uveitis, mucocutaneous Stevens–Johnson syndrome, and eosinophilia developed in a 31-year-old woman after 3 days of therapy with oral trimethoprim 160 mg bd for a lower urinary

© 2006 Elsevier B.V. All rights reserved.

tract infection (48). At the start of antibiotic therapy, glucocorticoids and local anesthetics were injected into the lateral aspect of the right knee. Recovery was rapid after trimethoprim was withdrawn. Two months later she developed headache, nausea, malaise, and bilateral uveitis after taking trimethoprim again.

With sera from patients with known hypersensitivity to trimethoprim, IgE-specific recognition of three different but related metabolites has been demonstrated, including the entire molecule itself, the 3,4-dimethoxybenzyl group, and the 2,4-diamino-5-(3′,4′-dimethoxybenzyl) pyrimidine group (149). The incidence of adverse reactions in patients with AIDS is higher than in others (12). Most of these effects are not true allergic reactions, but are related to high doses of co-trimoxazole, and include rashes, nausea, and vomiting. They can be reduced in both frequency and severity by corticosteroids, which are often given in moderate to severe *P. jiroveci* pneumonia. The risk of hypersusceptibility reactions (Stevens–Johnson syndrome, neutropenia, hepatotoxicity, aseptic meningitis, thrombocytopenia) is also higher than in other patients. Since many rashes with co-trimoxazole are not necessarily due to allergic mechanisms, a previous rash should not prevent later re-administration. It may be prudent, however, to use a rapid test dose when co-trimoxazole is the treatment of choice (150).

The incidence of adverse reactions to co-trimoxazole in HIV-infected patients is high. Several reports have shown that an incremental increase in drug dosage may allow a significant proportion of patients to tolerate prophylactic dosages of co-trimoxazole. Eight of 14 selected HIV-infected patients (13 men, 1 woman; patients who experienced severe reactions such as anaphylaxis or Stevens–Johnson syndrome were excluded) were successfully desensitized and after a regimen of gradual incremented exposure over 11 days as an outpatient procedure could continue to take co-trimoxazole (151). *N*-acetylcysteine (3 g of a 20% liquid solution bd) did not prevent hypersensitivity reactions to co-trimoxazole in HIV-infected patients (152). Although cross-reactivity can occur, dapsone can be used for patients with mild hypersensitivity reactions to co-trimoxazole for prophylaxis of *P. jiroveci* pneumonia (153).

A syndrome that resembles bacterial sepsis is well recognized in patients with AIDS (154). This reaction can occur within hours of a large dose of co-trimoxazole, but most often occurs on rechallenge.

- A sepsis-like hypersensitivity reaction occurred in 38-year-old HIV-positive Hispanic man after a 14-day course of co-trimoxazole (155).

The mechanism of this unusual reaction is unclear.

Desensitization

Desensitization can be efficient in a large proportion of patients (88%) using a 5-day protocol, in which co-trimoxazole is administered orally in a granular formulation in increasing doses, beginning with trimethoprim 0.4 mg and sulfamethoxazole 2 mg and doubling the dose every 12 hours until the therapeutic dose is achieved (156). Another dosage regimen (12 doses of increasing amounts of co-trimoxazole at half-hour intervals) resulted in an overall success rate of 91% at 1 month in 44 patients (157). Such tolerance induction protocols can be adopted, even during pregnancy without risk to the mother or to the fetus (158).

Another uncontrolled trial of a 6-day desensitization procedure in 33 cases has been reported (159). The protocol started with a dose of 0.2 mg rising to 800 mg over 6 days and 32 of the subjects successfully completed the course. In addition, 12 of 14 cases were successfully re-challenged with co-trimoxazole. However, this study lacked a clear description of follow-up or the reasons for the selection of subjects for desensitization or re-challenge, and cannot be used as a basis for recommending this desensitization technique.

Oral desensitization to co-trimoxazole was successfully achieved in patients with AIDS suffering from fever, rash, and wheezing due to the drug (160–163). In a randomized study of desensitization with rechallenge in HIV-positive patients with previous adverse effects of co-trimoxazole 73 patients were given a 14-day course of trimethoprim 200 mg/day (164). Fourteen had adverse reactions to trimethoprim. The remaining 59 subjects were randomized to a 2-day desensitization technique (34 subjects) or rechallenge (25 subjects). There were seven hypersensitivity reactions in both groups. Clearly there is no advantage of this 2-day desensitization technique over rechallenge with co-trimoxazole in HIV-positive individuals.

In a randomized, double-blind study in HIV patients, gradual introduction of co-trimoxazole was associated with significantly fewer adverse drug reactions compared with standard initiation of therapy (165).

Overall it appears that desensitization to co-trimoxazole is safe in the absence of previous serious adverse events, although it is not yet certain whether desensitization is better than re-challenge or indeed what the ideal desensitization method should be.

Infection risk

There have been rare reports of an association between sulfonamide antibiotics and increased severity of rickettsial infections. Sulfonamides do not increase the pathogenicity of *Ehrlichia* species, but a case of human monocytic ehrlichiosis complicated by ARDS has previously been reported in a patient who had taken oral co-trimoxazole. It has been speculated that oral co-trimoxazole, given for acne, may have contributed to the unusual severity of *Ehrlichia chaffeensis* infection that progressed to respiratory failure in a previously healthy 16-year-old boy (166).

Long-Term Effects

Drug tolerance

Bacteria have developed several mechanisms that make them resistant to trimethoprim. Resistance can occur rapidly, and has been reported in Europe, the USA, Asia, and South America, which may account for the fact that trimethoprim is usually used in combination (1,167,168). However, the clinical significance of resistance to trimethoprim has been debated (1,7,16,169).

© 2006 Elsevier B.V. All rights reserved.

From a total of 31319 *Shigella* strains isolated in Israel between 1990 and 1996, the rates of resistance of *Shigella sonnei*, *Shigella flexneri*, and *Shigella boydii* to co-trimoxazole were 94%, 51%, and 62% respectively; the proportion of strains that exhibited multiple drug resistance was higher for *S. sonnei* than for the other serotypes studied (170).

Among 12 045 isolates of *Streptococcus pneumoniae* collected between 1995 and 1998, resistance to co-trimoxazole increased slightly, from 25% to 29% (171).

Mutagenicity

Genotoxic effects of trimethoprim on cultured human lymphocytes have been described (172). Chromosome studies performed in cultures of peripheral blood lymphocytes did not show significant differences before and after treatment. Cytogenetic studies on bone marrow cells from 12 patients with urinary tract infections treated with co-trimoxazole did not show structural chromosomal aberrations; however, there was an increased number of micronuclei in these patients compared with controls (173).

Second-Generation Effects

Fertility

Whether reported cases of impaired male fertility were due to co-trimoxazole is not clear, since most of the men were being treated for underlying urogenital infections, which may have contributed to reduced fertility (174,175).

Teratogenicity

An early review of newer case reports and placebo-controlled trials involving several hundred patients did not show an increase in fetal abnormalities (176). However, the relative risks of cardiovascular defects and oral clefts in infants whose mothers were exposed to dihydrofolate reductase inhibitors, such as trimethoprim, during the second or third month after the last menstrual period, compared with infants whose mothers had no such exposure, are 3.4 (95% CI = 1.8, 6.4) and 2.6 (1.1, 6.1) respectively (177). Multivitamin supplements containing folic acid reduced the adverse effects of dihydrofolate reductase inhibitors. There have been two reports of severe spinal malformations in the fetuses of HIV-positive women treated with combination antiretroviral therapy and co-trimoxazole (178).

Susceptibility Factors

Renal disease

In renal insufficiency, co-trimoxazole should be used with caution, particularly when there is hyperkalemia (66,115).

Other features of the patient

Co-trimoxazole should not be given to patients with malnutrition, pregnancy, severe liver damage, megaloblastic anemia, agranulocytosis, or bone marrow failure (12,14,87).

© 2006 Elsevier B.V. All rights reserved.

HIV infection

The use of co-trimoxazole in HIV-positive patients has been associated with a high rate of hypersensitivity reactions (40–80%), attributed to the bioactivation of the sulfonamide component, sulfamethoxazole, to its toxic hydroxylamine and nitroso metabolites. In a study of HIV-positive patients with ($n = 56$) and without ($n = 89$) hypersensitivity to co-trimoxazole, functionally significant polymorphisms in the genes coding for enzymes involved in co-trimoxazole metabolism were unlikely to have been major predisposing factors in determining individual susceptibility to co-trimoxazole hypersensitivity (179).

In a randomized, double-blind study in 372 HIV-positive patients with CD4+ counts below 250×10^6/l, gradual initiation of co-trimoxazole treatment was associated with significantly fewer adverse drug reactions compared with standard initiation (180).

The relation between the onset of adverse reactions to co-trimoxazole in HIV-infected patients and the subsequent development of toxoplasmosis, other AIDS-defining events, and survival has been studied in 592 French patients (181). A low CD4 cell count when co-trimoxazole was introduced was the only factor associated with the onset of adverse reactions. The occurrence of toxoplasmosis and first AIDS-defining events was significantly and independently linked to a low CD4 cell count when co-trimoxazole was introduced and to previous co-trimoxazole withdrawal for adverse events, but not to previous co-trimoxazole withdrawal for reasons other than adverse events, compared with patients who did not stop taking co-trimoxazole. The survival rate was significantly shorter among patients who stopped taking co-trimoxazole for adverse events and for other reasons, compared with patients who continued to take it.

Drug–Drug Interactions

Anticonvulsants

Most interactions of trimethoprim and co-trimoxazole with other drugs are due to folic acid antagonism. This may be more pronounced with co-trimoxazole than with either drug alone. Such interactions have previously been suspected with anticonvulsants, such as barbiturates, phenytoin, and primidone, which themselves produce folic acid deficiency and megaloblastic anemia (88). In order to circumvent the risk of folate deficiency, folic acid or folinic acid can be given. There is some concern that folate replacement may antagonize the desired antimicrobial effect, particularly in some protozoal parasites, but this concern has been debated (89).

Azathioprine

In renal transplant patients, combining azathioprine with co-trimoxazole was followed by neutropenia and thrombocytopenia (92).

Coumarin anticoagulants

Co-trimoxazole can significantly augment the hypoprothrombinemic effect of warfarin (182,183), acenocoumarol (184,185), and phenprocoumon (185).

Cytotoxic drugs

Most interactions of trimethoprim and co-trimoxazole with other drugs are due to folic acid antagonism. This may be more pronounced with co-trimoxazole than with either drug alone. Such interactions have been suspected with cytotoxic drugs (186,187). In order to circumvent the risk of folate deficiency, folic acid or folinic acid can be given. There is some concern that folate replacement may antagonize the desired antimicrobial effect, particularly in some protozoal parasites, but this concern has been debated (89).

In children with acute lymphoblastic leukemia co-trimoxazole inhibited 6-mercaptopurine metabolism (186).

In another study, co-trimoxazole produced a 66% increase in systemic exposure to methotrexate (187).

Prolonged treatment with co-trimoxazole can reduce cyclophosphamide requirements in patients with Wegener's granulomatosis (188).

Glucocorticoids

Prolonged treatment with co-trimoxazole can reduce glucocorticoid requirements in patients with Wegener's granulomatosis (188).

HIV protease inhibitors

In an animal model, indinavir nephrotoxicity was potentiated by co-trimoxazole, but nelfinavir alone or in combination with co-trimoxazole was not nephrotoxic (189).

Immunosuppressants

Most interactions of trimethoprim and co-trimoxazole with other drugs are due to folic acid antagonism. This may be more pronounced with co-trimoxazole than with either drug alone. Such interactions have previously been suspected with immunosuppressant drugs (186,187). In order to circumvent the risk of folate deficiency, folic acid or folinic acid can be given. There is some concern that folate replacement may antagonize the desired antimicrobial effect, particularly in some protozoal parasites, but this concern has been debated (89).

Pronounced nephrotoxicity resulted from the interaction of co-trimoxazole with ciclosporin in patients with a renal transplant (190,191).

Lithium

Trimethoprim has the same effect on the kidney as amiloride, whose combined use with lithium can cause a raised serum lithium concentration.

- The addition of trimethoprim caused severe lithium toxicity in a 40-year-old woman with a schizoaffective disorder; following rehydration, she made a good recovery (192).

Methotrexate

Methotrexate, a folic acid antagonist, is used in the treatment of several disorders. Its major action is inhibition of dihydrofolate reductase, a critical enzyme in intracellular folate metabolism. Co-trimoxazole competes with methotrexate in inhibiting dihydrofolate reductase and further impairs DNA synthesis.

- A fatal case of toxic epidermal necrolysis that involved 90% of the total body surface has been described in a 15-year-old boy with T cell acute lymphoblastic leukemia treated concomitantly with co-trimoxazole and methotrexate (193).

The authors suggested that methotrexate toxicity was precipitated by co-trimoxazole.

- Fatal bone marrow suppression has been reported in an 82-year-old woman who took methotrexate 7.5 mg/week for one year for rheumatoid arthritis without hematological problems. She was given trimethoprim 100 mg/day at first and later 200 mg/day. One week later, she developed severe pancytopenia. The bone marrow failed to recover despite treatment with folinic acid and G-CSF, and she died of bronchopneumonia.

In a literature review, the authors found two other cases of bone marrow suppression after treatment with methotrexate and trimethoprim with full recovery of both. This interaction is also listed in the British National Formulary 1997 (194,195).

Oral contraceptives

Some antibiotics interfere with the effects of oral contraceptives, putatively by inhibiting bacterial deconjugation in the bowel and thus reducing their reabsorption after biliary excretion. However, in women taking oral contraceptives, short courses of co-trimoxazole are unlikely to cause any adverse effects on contraceptive control (196).

Phenytoin

Massive hepatic necrosis after exposure to phenytoin and co-trimoxazole is rare.

- Acute liver failure has been reported in a 60-year-old woman after concomitant ingestion of phenytoin and co-trimoxazole over 9 days (197). Autopsy showed acute fulminant hepatic failure.

Drug interactions can potentiate the hepatotoxicity of single agents; withdrawal of co-trimoxazole may be needed in the presence of early liver injury.

Procainamide

Trimethoprim inhibits the active tubular secretion of procainamide (198).

Rifamycins

In 10 HIV-positive patients who had been taking one double-strength tablet of co-trimoxazole daily for more than 1 month, the concentrations of trimethoprim and sulfamethoxazole in serum were significantly reduced after the administration of rifampicin (199).

Trimeprazine

The antihistaminic phenothiazine trimeprazine has significant antibacterial activity in vitro and in vivo, and a combination with trimethoprim is highly synergistic, as shown in vivo in Swiss white mice using *Salmonella typhimurium* as the challenge bacterium (200).

© 2006 Elsevier B.V. All rights reserved.

Zidovudine

In one pharmacokinetic study in eight HIV-infected subjects, the renal clearance of zidovudine was significantly reduced by trimethoprim (201). The authors concluded that zidovudine dosages may need to be reduced if trimethoprim is given to patients with impairment of liver function or glucuronidation. Zidovudine, on the other hand, did not alter the pharmacokinetics of trimethoprim.

Interference with Diagnostic Tests

Serum folate concentration

Serum folate concentrations should not be measured by the radioisotope method in patients taking trimethoprim (202).

Trimetrexate

General Information

Trimetrexate is a lipid-soluble analogue of methotrexate that has been used in the management of *Pneumocystis jiroveci* in patients with AIDS when other therapy has proved ineffective. It has also been used as an antineoplastic drug in the management of various solid tumors. It is given with leucovorin (folinic acid) to minimize hematological toxicity. Trimetrexate can cause neutropenia and/or thrombocytopenia (SEDA-12, 704) (1,2). Fever and raised liver transaminases, while uncommon, have been noticed. The efficacy of trimetrexate is not as high as that of co-trimoxazole and the recurrence rate is markedly higher (3).

Trimipramine

See also Tricyclic antidepressants

General Information

Trimipramine is a sedating tricyclic antidepressant that has been used as a hypnotic (1); it shares this activity with other drugs of its class, notably amitriptyline, dosulepin, doxepin, and trazodone, and with the tetracyclics mianserin and mirtazapine. Trimipramine may be preferred for this purpose, since it has less effect on sleep architecture, including REM sleep (2), and has only a modest propensity to produce rebound insomnia in a subset of patients (3). Sedative antidepressants may be particularly appropriate for individuals at risk of benzodiazepine abuse and patients with chronic pain (4). The usual pattern of tricyclic adverse effects, especially antimuscarinic and hypotensive effects and weight gain, can be expected. Some authors, enthusiastic about GABA enhancers, contend that antidepressants are not useful hypnotic alternatives (5).

Antidepressant drugs of various classes (tricyclics, monoamine oxidase inhibitors, SSRIs) have broad efficacy in generalized anxiety and in panic disorder, for which they are the treatments of choice (6,7). While not likely to cause benzodiazepine-like dependence or abuse, they do have a significant therapeutic latency, and the older drugs are very toxic in overdose.

Triperaquine

General Information

Triperaquine is a 4-aminoquinoline derivative, the adverse reaction pattern of which is unknown. The WHO Scientific Group's report concerning this drug dates from 1984 and there seems to be little or no later information about it in humans.

Triptans

General Information

The triptans are agonists at 5-hydroxytryptamine (5-$HT_{1b/1d}$) receptors, used in the treatment of migraine. They include almotriptan, avitriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan (all rINNs). The way in which the triptans produce their therapeutic effect is not clear. Sumatriptan penetrates the blood–brain barrier poorly and presumably acts peripherally on extracranial blood vessels.

Sumatriptan

Sumatriptan was the first drug of its type to be introduced and has been reviewed (SEDA-18, 171). Most of the information about drugs in this group relates to sumatriptan.

Sumatriptan is effective in the treatment of all features of the headache phase of an acute attack of migraine (SEDA-18, 171) (1). It is available as tablets and suppositories, as prefilled syringes for self-administered subcutaneous injection, and as intranasal spray. Its systemic availability is high (96%) after subcutaneous injection, but rather low (14%) after oral administration because of first-pass metabolism. Its half-life is short (2 hours) and 80% is removed by metabolism. The principal metabolite is an inactive indoleacetic acid analogue. Propranolol, flunarizine, and pizotifen, drugs that are all commonly used in migraine prophylaxis, do not affect the pharmacokinetics of sumatriptan (2,3).

A high proportion of patients respond to a single standard dose of therapy, with minor or mild adverse effects. Because of the short half-life, recurrence of headache within 24 hours is common (50%) but can be effectively treated by a second dose. Any adverse effect is also likely to be brief. The most common adverse effects are a feeling of pressure/stiffness in the neck and throat or of pressure/tightness or pain in the chest. Tingling sensations in the head and arms, dizziness, and tiredness are also commonly reported. Dyspnea can occur in patients with obstructive lung disease. Local reactions at the injection site are usually mild. The reported frequencies of these adverse effects vary widely between clinical trials and postmarketing surveys; this may be attributable to selection of patients in trials and differences in the questionnaires used to evaluate unwanted effects (4,5). Allergic reactions are rare.

Rizatriptan

The available data on rizatriptan have been reviewed. Only safety aspects are mentioned here. With oral administration, adverse effects were mild and transient in placebo-controlled trials. Digestive intolerance, dizziness, somnolence, weakness and fatigue, and pain or pressure sensations were the most commonly mentioned (6).

Zolmitriptan

The available data on zolmitriptan have been reviewed. Only safety aspects are mentioned here. Orally administered zolmitriptan appears to have been generally well tolerated in placebo-controlled studies (7). The most commonly reported adverse events are weakness, heaviness or tightness (other than in the chest), dry mouth, nausea, dizziness, somnolence, paresthesia, a sensation of warmth, and chest pain. They were mild to moderate and resolved without the need for intervention or drug withdrawal. Electrocardiographic changes were as frequent with placebo as with zolmitriptan and were not associated with chest tightness or pressure; changes suggesting an ischemic event were not recorded. Nevertheless, zolmitriptan is not recommended in patients with ischemic heart disease.

A spinal cord infarct temporarily related to zolmitriptan use has been reported after the use of zolmitriptan in a 50-year-old woman with a history of migraine (8).

Comparisons between triptans

Four randomized, double-blind clinical trials in which rizatriptan was compared with sumatriptan have been reviewed (9). The two drugs have similar safety profiles, but the frequency of adverse effects depends largely on the dose, which varied from trial to trial. Adverse events reported in over 5% of patients were somnolence,

© 2006 Elsevier B.V. All rights reserved.

dizziness, weakness/fatigue, nausea and vomiting, abdominal pain, and chest pain.

Seven triptans have been compared and rated as generally very well tolerated (10). Naratriptan, almotriptan, and frovatriptan were considered to have the best safety profiles, although the differences are minor. Coronary vasoconstriction is a potential risk of the entire class, but the risk is minimal in the absence of coronary artery disease or uncontrolled hypertension; significant vascular disease is therefore a hazard of using any of the triptans. Patient preference, however, appears to be more closely related to efficacy than to tolerance.

Organs and Systems

Cardiovascular

Particularly when injected, sumatriptan can cause a transient increase in both systolic and diastolic blood pressures; oral doses, which are usually higher, have this effect to a lesser extent. It is unwise to use sumatriptan in patients with uncontrolled severe hypertension.

Some of the minor discomfort often experienced (tingling, flushing, sensations of heat or cold) may also reflect cardiovascular effects.

Coronary vasoconstriction is a potential risk of all triptans, but the risk is minimal in the absence of coronary artery disease or uncontrolled hypertension. Chest tightness and pain are reported in up to 15% of patients taking sumatriptan and are presumed to be due to vasoconstriction of the coronary arteries. Myocardial infarction has been reported and as a consequence sumatriptan should not be used in patients with cardiovascular disease (11). Intravenous sumatriptan causes some coronary vasoconstriction during diagnostic angiography. Myocardial infarction occurred in a patient who had received sumatriptan 6 mg subcutaneously, but the causal association was not clear.

Cardiac dysrhythmias can occur occasionally.

- A 41-year-old otherwise perfectly healthy woman developed the typical symptoms of a migraine attack after an aerobics class followed by a sauna and took sumatriptan 100 mg (12). She collapsed half an hour later and a resuscitation team diagnosed ventricular fibrillation, which was converted to ventricular tachycardia and later to sinus rhythm. Neither the electrocardiogram nor enzyme changes suggested myocardial infarction. She remained comatose and died 6 weeks later. At autopsy there was no evidence of atherosclerotic coronary disease or any other underlying cardiac disorder.
- A 34-year-old man with migraine had palpitation after taking sumatriptan by nasal spray for a severe headache (13). A similar episode had occurred after he had previously taken sumatriptan. He had atrial fibrillation with a rapid ventricular rate. Sinus rhythm returned spontaneously within a few hours. No structural cardiac abnormality was detected.

Myocardial ischemia secondary to coronary spasm was the putative trigger of atrial fibrillation in the latter case.

Vasoconstriction leading to organ ischemia has been repeatedly reported with triptans. The risk is very low in the absence of pre-existing arterial disease. Nevertheless, cases of myocardial infarction, mesenteric ischemia, and ischemic colitis have been described, as has splenic infarction (14).

- A 48-year-old woman with a low risk of atherosclerotic disease who was not taking oral contraception was admitted with sudden heavy pain in the left hypochondrium. Routine tests were normal, but there was a triangular hypodensity in the spleen on computerized tomography consistent with a splenic infarct. There was a history of postoperative venous thrombosis 15 years before, but tests for thrombophilia were all normal. No source of embolism was identified in the heart or proximal arteries. She had repeatedly taken zolmitriptan over the previous few months for migraine, and the symptoms started 3 hours after the most recent dose.

The temporal relation and the absence of an alternative cause to explain the infarct led the authors to conclude that zolmitriptan had been causative.

Nervous system

One of the main drawbacks of acute migraine therapies, including 5-HT_{1a} receptor agonists, is that headache recurs within 24 hours in about one-third of patients who initially experienced relief after first dosing. Similar recurrence rates and mean time to recurrence are observed for the new triptans as for sumatriptan (15). An increase in migraine frequency is usually the first sign of a developing drug-induced headache. It occurs with sumatriptan and is also reported with the new triptans (16). Headache has also been reported with chronic sumatriptan use and abuse (SEDA-20, 193).

The role of sumatriptan and ergotamine in drug-induced headache has been surveyed in over 2000 patients at a regional headache clinic (17). About 600 had taken ergot derivatives previously and a similar number had used sumatriptan, while nearly 250 had experience of both. Drug overuse was defined as the use of at least one dose of either drug on 18 or more days every month for at least 3 months. By these criteria the rates of ergotamine and sumatriptan overuse were estimated at 14 and 3.5% respectively. Drug-induced headache was much more common among ergotamine overusers than sumatriptan overusers (68 versus 32%).

Fatal cerebellar infarction has been described in a 39-year-old man who took sumatriptan 100 mg for an acute attack of migraine. The cerebellar infarct was diagnosed at autopsy, and intracranial vasospasm was thought to be the likely mechanism (18). It should be noted that stroke has also been documented in patients with migraine, independently of drug treatment.

Akathisia occurred in five fairly young patients after subcutaneous or oral sumatriptan (19). The symptoms were short-lived. Increased serotonergic activity, leading to inhibition of nigrostriatal dopaminergic neurons and extrapyramidal symptoms, was the postulated mechanism. A similar mechanism has been thought to provoke the same symptoms with serotonin re-uptake inhibitors.

Sensory systems

Nasal spray sumatriptan can cause taste disturbance, described as a bad, bitter, unpleasant, or unusual taste (20).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Ischemic colitis has been associated with the use of sumatriptan. Retrospective review and analysis of postmarketing reports showed seven confirmed cases (colonoscopy and/or biopsy) and another has been reported (21). Seven of the patients were women. Sumatriptan was mainly given subcutaneously, the dosages were not excessive, and the median time between the last administration to the onset of symptoms was less than 24 hours in only four patients. All the patients recovered on withdrawal of sumatriptan. Although many of these patients were using other drugs, particularly beta-blocking and NSAIDs, confusing the analysis, the authors suggested that vasoconstrictor effects in the mesenteric circulation associated with the use of sumatriptan played a causative role in inducing the ischemia.

- Two women were investigated for cramping abdominal pain and bloody diarrhea (22). In only one did the episodes completely disappear after withdrawal of sumatriptan. The other underwent an exploratory laparotomy and right hemicolectomy for transmural bowel necrosis.

Nausea, vomiting, and taste disturbances are more common with sumatriptan than placebo (SEDA-19, 207).

Second-Generation Effects

Teratogenicity

There are data from the Swedish Medical Birth Registry relating to 912 infants, whose mothers, at their first antenatal visit, had reported using migraine therapies, in most cases (658) sumatriptan (23). There was no increase in the rate of congenital malformations; slightly more infants than expected were preterm and had a birth weight lower than 2500 g, but none of the differences was statistically significant. These data suggest that sumatriptan is not teratogenic.

Susceptibility Factors

Age

Because of limited experience, sumatriptan is best avoided in children and elderly people.

Other features of the patient

Significant vascular disease is a contraindication to the use of any of the triptans (SEDA-20, 192).

It has been suggested that triptans should not be used in patients with basilar or familial hemiplegic migraine, although some successes have been reported without adverse effects (24).

Drug Administration

Drug formulations

Sumatriptan is available as film-coated tablets, as prefilled syringes for self-administered subcutaneous injection, as intranasal spray, and in a formulation for rectal use. Sumatriptan suppositories appear to be well tolerated: reported adverse events were similar to those during oral or subcutaneous treatment of patients with migraine. Local events involving the anus or rectum were rarely observed (25,26).

Drug–Drug Interactions

Beta-blockers

In four double-blind, placebo-controlled, randomized, crossover studies in 51 healthy subjects a single dose of rizatriptan 10 mg was administered after administration of propranolol 60 and 120 mg bd, nadolol 80 mg bd, metoprolol 100 mg bd, or placebo for 7 days (27). Propranolol 60 or 120 mg bd increased the AUC of rizatriptan by about 67% and the C_{max} by about 75%. Nadolol and metoprolol had no effects.

Similarly, in healthy volunteers co-administration of propranolol resulted in a 56% increase in the AUC of zolmitriptan and a 11% decrease in the AUC of its active metabolite (28).

Clarithromycin

In an open, randomized, 2-way crossover study in 24 healthy volunteers clarithromycin 500 mg orally every 12 hours for 4 days had no effects on the pharmacokinetics of a single oral dose of sumatriptan 50 mg (29).

Ergot alkaloids

The use of sumatriptan is discouraged and even considered contraindicated together with or within 24 hours after ergotamine or ergotamine-type medications, such as methysergide. The contraindication is based on the possibility of severe prolonged vasospasm with the combined use of agents with agonist properties at the same receptors.

- A 20-year-old woman developed generalized tonic–clonic seizures after she took sumatriptan 6 mg followed by three tablets of ergonovine for postpartum headache (30). Cerebral angiography 1 day later showed multiple narrowed segments in the vertebrobasillar and middle cerebral arteries.
- A myocardial infarction occurred in a 43-year-old woman with no known coronary artery disease who was taking methysergide and injected herself with sumatriptan 6 mg because of persisting headache (31).

5-HT re-uptake inhibitors

On theoretical grounds, sumatriptan should not be used with 5-HT re-uptake inhibitors, since this combination could theoretically cause serotonin toxicity. Although case series have suggested that sumatriptan can be safely combined with SSRIs, there are occasional reports of toxicity (SEDA-22, 14).

Treatment of 12 healthy volunteers with paroxetine (20 mg/day for 14 days) did not alter the pharmacokinetics or pharmacodynamic effects of an acute dose of rizatriptan (10 mg orally) (32). These data are reassuring, but it is possible that sporadic cases of 5-HT neurotoxicity could still occur when a triptan is combined with an SSRI.

© 2006 Elsevier B.V. All rights reserved.

Lithium

On theoretical grounds, sumatriptan should not be used with lithium. However, a review of the subject found little substantiation for a severe interaction between sumatriptan and lithium (33).

Monoamine oxidase inhibitors

Some of the triptans are metabolized by monoamine oxidase and they should not be used with monoamine oxidase inhibitors. This includes almotriptan (34), rizatriptan (35), sumatriptan (36), and zolmitriptan (28). The effect of moclobemide on the pharmacokinetics of almotriptan was less than with other triptans (34).

Tritiozine

General Information

Tritiozine is a non-anticholinergic, antisecretory agent. It has been associated with drowsiness and occasional slight increases in transaminases (1).

Organs and Systems

Nervous system

Predominantly sensory neuropathies with Wallerian degeneration of the myelinated fibers occurred in three patients taking tritiozine (2).

Liver

Acute hepatitis has been attributed to tritiozine (3,4).

References

Troleandomycin

See also Macrolide antibiotics

General Information

Troleandomycin is a macrolide antibiotic with actions and uses similar to those of erythromycin.

Organs and Systems

Endocrine

Serum TSH concentrations are moderately but significantly reduced by troleandomycin compared with josamycin or placebo given over 10 days. At the same time serum estradiol concentration was significantly increased (1).

Liver

Most reports associating cholestatic jaundice with the concomitant use of oral contraceptives and macrolides have implicated troleandomycin (2–5). The exact mechanism of this interaction has not been established. Troleandomycin possibly inhibits the metabolism of estrogens and progestogens (6). In most patients jaundice persisted for more than a month after the antibiotic was withdrawn.

Drug–Drug Interactions

Alprazolam

Troleandomycin may inhibit the metabolism of alprazolam by inhibiting CYP3A4 (7).

Carbamazepine

Troleandomycin can cause carbamazepine toxicity by inhibiting CYP3A4 (8).

Ecabapide

Troleandomycin may inhibit the metabolism of ecabapide, a gastric prokinetic drug, by inhibiting CYP3A4 (9).

Ergot alkaloids

Clinically severe interactions between troleandomycin and ergotamine (10–13), resulting in ischemia of the extremities, probably result from inhibition of the metabolism of the ergopeptides (14,15), with raised serum concentrations of dihydroergotamine (16,17).

Quinine

Troleandomycin is an in vitro competitive inhibitor of quinine 3-hydroxylation, which is mediated by CYP3A4, and may therefore interact when co-administered with quinine (18).

Tropicamide

General Information

Tropicamide is an anticholinergic drug that tends to have a greater mydriatic than cycloplegic effect. It is a short-acting atropine-like derivative and has been regarded as an effective and safe mydriatic, used for pupillary dilatation by professionals, who are not always medical doctors.

Organs and Systems

Cardiovascular

A transient ischemic attack occurred in a 64-year-old patient with cardiovascular risk factors who used topical tropicamide (1).

Nervous system

Near fatal anticholinergic intoxication has been reported after routine fundoscopy with tropicamide (2).

- A 62-year-old man underwent fundoscopy after pupillary dilatation with tropicamide eye-drops. Half an hour after fundoscopic examination he had two generalized seizures with respiratory arrest and required intubation and mechanical ventilation. He was treated with physostigmine and made a full recovery.

Immunologic

A solution containing tropicamide 1% and benzalkonium chloride 0.01% (Mydriaticum) was introduced in 1979 to obtain mydriasis and cycloplegia for diagnostic purposes. Contact dermatitis from ophthalmic formulations is common, preservatives being the most frequent causes (3). Allergic contact dermatitis has been reported, implicating tropicamide as a sensitizer (4).

Troxerutin

General Information

Troxerutin, a flavonoid derivative, is claimed to reduce capillary fragility. It is generally well tolerated (SEDA-19, 207), but ineffective (1).

Organs and Systems

Skin

Troxerutin is a yellow substance (SEDA-13, 170), and a few cases of yellow discoloration of the skin, but not of the sclerae, have been observed. The discoloration, which can be mistaken for jaundice, vanishes when the drug is withdrawn.

Tryptophan

General Information

The possibility that mental illness may be alleviated by biogenic amine precursors is an appealing one (SEDA-4, 18). Tryptophan is a naturally-occurring essential amino acid, which has been advocated as an innocuous health food for the treatment of depression, insomnia, stress, behavioral disorders, and premenstrual syndrome. The availability of amino acids in health food stores and a contemporary interest in natural remedies led to reported widespread use of tryptophan to treat depression. It was estimated in 1976 that up to that time several hundred patients with affective disorders had been studied, with results reported in at least 21 papers (1). However, the results of clinical trials with L-tryptophan in the treatment of depressive disorders are inconsistent (2).

It has been suggested that there may be some benefit of using tryptophan in selected patients, particularly those with psychomotor retardation (3). Unfortunately, most of these reports have appeared as letters to the editors of journals (4–6) or as preliminary communications (7). In addition to the possible absence of any consistent effect, there are many plausible reasons to explain the variability in response. Tryptophan has been given in both the racemic and monomeric (levorotatory) forms, both alone and together with a number of substances intended to increase the synthesis or availability of serotonin, including monoamine oxidase (MAO) inhibitors (8), potassium or carbohydrate supplements (9), and co-enzymes such as pyridoxine or ascorbic acid (10). It has also been suggested that tryptophan plasma concentrations have a therapeutic window (4), and that repeated administration induces hepatic tryptophan pyrrolase, resulting in lowered plasma concentrations and loss of therapeutic effect after 2 weeks of treatment (8). Attempts have been made to ameliorate this problem by coadministration of nicotinamide (4).

In addition to the difficulty of interpreting possible benefits due to tryptophan, there is a paucity of information on its adverse effects. This may be partly accounted for by the assumed safety of a natural substance, but it is also contributed to by the preliminary nature of many communications. In at least two studies (5,7) in which tryptophan was compared with a tricyclic antidepressant, inquiry about adverse effects was deliberately avoided, in order to protect the double-blind integrity of the study. Two studies have reported the lack of any consistent or definite changes in hematological values, serum electrolytes, plasma proteins, or liver function tests after 4 weeks of treatment with L-tryptophan up to 8 g/day (7,10). Nausea early in treatment (11), light-headedness, which does not appear to be related to postural hypotension (12), and deterioration in mental status (13,14) have been reported. Hypomania on combining tryptophan with a MAO inhibitor has been reported (14) and toxic effects, including muscle tremor, hypomanic mood, hyper-reflexia, and bilateral Babinski signs, were seen in a patient taking phenelzine and tryptophan.

Eosinophilia–myalgia syndrome

No severe or irreversible adverse effects of tryptophan were reported until 1989, when an eosinophilia–myalgia syndrome was described, and L-tryptophan-containing products were withdrawn from the market (SEDA-15, 518). This syndrome was characterized by an eosinophil count of at least 1×10^9/l and intense generalized myalgia. Other relatively frequent signs and symptoms were fatigue, arthralgia, skin rash, cough and dyspnea, edema of the limbs, fever, scleroderma-like skin abnormalities, increased hair loss, xerostomia, neuropathy, and pneumonia or pneumonitis with or without pulmonary vasculitis. About one-third of the cases required hospitalization, and a substantial number of patients died. The syndrome is suspected to have been due to an unidentified impurity in products from one manufacturer (SEDA-18, 22).

The syndrome appears to be only part of a spectrum of adverse effects associated with tryptophan (15). There has been much discussion, but finally it appears that the links are causal, as consistent findings were found in multiple independently conducted studies and the incidence of eosinophilia–myalgia syndrome in the USA fell abruptly once tryptophan-containing products were recalled (16).

Although L-tryptophan was withdrawn in many countries, in 1994 it became available again in the UK for combination treatment of patients with long-standing refractory depression, on the strict condition that it should only be prescribed by hospital specialists for patients with long-standing resistant depression (SEDA-18, 22). It is also still in use in Canada but not in the USA.

Organs and Systems

Respiratory

A case of interstitial pneumonitis and pulmonary vasculitis was ascribed to L-tryptophan, and unintended rechallenge supported a causal relation (17).

Tubocurarine

See also Neuromuscular blocking drugs

General Information

D-Tubocurarine is the standard non-depolarizing neuromuscular blocking agent against which all others of the group are compared. The molecule has one quaternary and one tertiary nitrogen, the latter being protonated at body pH, making it a bisquaternary entity. Its main action at the neuromuscular junction is to block the access of acetylcholine to the receptor recognition sites competitively; it may also block some ion channels, but only to a small extent and at very high concentrations.

Blockade of neuromuscular transmission by D-tubocurarine is easily reversed (if twitch height has recovered to at least 10%) by anticholinesterases. Sensitivity to D-tubocurarine and other non-depolarizing relaxants is highly variable, even in apparently healthy patients, so that the small doses given for precurarization can lead to appreciable paralysis (1–3). More commonly, residual blockade can be detected postoperatively (4,5), long after the expected recovery of neuromuscular transmission.

About 40–50% of a normal dose of D-tubocurarine is bound to plasma proteins, mostly gammaglobulins (about 25%). This binding is highly variable, giving a variable amount of non-bound drug available for neuromuscular blockade. Metabolism does not occur. Tubocurarine is eliminated principally via glomerular filtration (about 40–60% in 24 hours), but has an alternative pathway for excretion in the bile (normally only about 12% in 24 hours). The initial dose for healthy patients is 0.2–0.5 mg/kg, dependent on the anesthetic agents used and whether suxamethonium is given beforehand or not. Maintenance doses are about one-third of the initial dose and are required at approximately 30–40-minute intervals. Accumulation can occur and is more likely if large doses are given too frequently or if excretion is impaired. Smaller doses should be given if the patient has received D-tubocurarine within the previous 24 hours.

General adverse effects

A fall in blood pressure occurs almost always with D-tubocurarine. It is often mild, but may be marked, particularly if a large dose is given rapidly or if the patient is hypovolemic, or has a diminished cardiac reserve or capacity for vasoconstriction (as is not infrequently the case in old age, in diabetes, and in other diseases with sympathetic neuropathy), and is potentiated by other anesthetic agents such as halothane. Myasthenic patients or patients with other neuromuscular pathology are markedly sensitive to non-depolarizing relaxants.

Histamine-mediated reactions are common, leading to local wheal-and-flare effects near the injection site, frequent hypotension (mostly about a 20% fall), and occasionally bronchospasm.

Malignant hyperthermia has also been reported after D-tubocurarine.

Tumor-inducing effects have not been reported.

Drug resistance

Patients with burns require more D-tubocurarine (and higher plasma concentrations) for the same degree of blockade compared with non-burned patients (6). The mechanism is not known, but it appears not to be altered pharmacokinetics (7). The resistance to non-depolarizing neuromuscular blocking agents (SEDA-8, 136) appears to be influenced by the size of the body surface area burned and by the time which has elapsed since the injury (see Atracurium). In extensive burns dose requirements are increased approximately by a factor of 2–3.

Patients with upper motor neuron lesions such as hemiplegia (8–11) and possibly multiple sclerosis (SEDA-13, 105) (12) can be resistant to various non-depolarizing blockers. Lower motor neuron injury has so far only been reported to produce this phenomenon in rats (13) and dogs. Affected muscles in these conditions are paralysed to a lesser degree than unaffected muscles, and this has to be taken into account when siting the electrodes for monitoring a block and in assessing recovery therefrom. The mechanism is probably a quantitative and/or qualitative change in acetylcholine receptors. Resistance is seen too in patients taking certain drugs such as phenytoin, carbamazepine, and, disputedly, azathioprine.

In liver disease, increased amounts of D-tubocurarine may be required. In the past it has been suggested that this could be due to reduced synthesis of acetylcholinesterase, or to increased concentrations of gammaglobulins binding the relaxant (14), although this is disputed (15). Similar kinetic mechanisms to those suggested for pancuronium may be involved, but there are no studies on D-tubocurarine. In primary liver cancer in children, resistance to D-tubocurarine (and alcuronium) has been reported (SEDA-13, 104) (16).

© 2006 Elsevier B.V. All rights reserved.

Hyperkalemia tends to reduce the neuromuscular blocking effects of tubocurarine.

Organs and Systems

Cardiovascular

D-Tubocurarine commonly causes a fall in blood pressure, associated with a slight tachycardia and a reduction in total peripheral resistance; cardiac output is not affected. The frequency of hypotension is reported as being 20–90%. This wide range probably reflects the methods of measurement, the anesthetic agents used, and the general condition of the patients in the various studies, as well as the criteria for diagnosing hypotension. The magnitude of the fall in blood pressure is generally about 20%, and it occurs within 5 minutes of injection. Histamine release is considered to be the principal cause (17), but blockade of autonomic ganglia may also contribute. It has been suggested that prostacycline, released by histamine acting on H_1 receptors, is the final mediator; intravenous administration of aspirin or an H_1 receptor antagonist beforehand affords some protection (SEDA-15, 126) (18). Ganglion blockade may also contribute, particularly if high doses are used (19). Reduction in venous return secondary to muscle relaxation and alterations in intrathoracic and intra-abdominal pressures may also play a role. The fall in blood pressure can be greatly exaggerated in hypovolemic patients, in the elderly, and in others with reduced sympathetic tone. Tubocurarine should be used very cautiously in such patients or another relaxant should be chosen. Concurrent administration of agents known to cause circulatory depression aggravates the problem. The higher the halothane concentration, for example, the greater the fall in blood pressure after D-tubocurarine (20). Since the degree of hypotension seems to be linked to dose (17) and the rate of injection (21), it seems reasonable to use the smallest dose that produces adequate relaxation (under 0.5 mg/kg) and to inject it slowly (over at least 180 seconds) (SEDA-7, 141).

Respiratory

Tubocurarine can cause apnea. The muscles involved in protecting and maintaining the airway are more sensitive to D-tubocurarine than the muscles of ventilation (22,23) so that aspiration and airway obstruction are possible in the partially curarized patient at a time when spontaneous ventilation is adequate. Airway obstruction in the presence of vigorous respiratory efforts can eventually (and is rarely reported to) lead to negative pressure pulmonary edema (24,25). Hypoventilation can occur after doses as low as 1.5 mg in exceptionally sensitive patients. Postoperative hypoventilation, or apnea, is a danger in patients given certain antibiotics and antidysrhythmic drugs before or after apparently successful spontaneous reversal or antagonism of a non-depolarizing block.

Potentiation of undetected residual curarization can also occur postoperatively from respiratory acidosis.

Histamine release, common with D-tubocurarine, can cause bronchospasm. Tubocurarine is relatively contraindicated in asthmatic patients and in those with an allergic tendency.

Nervous system

Minute amounts of D-tubocurarine have been detected in cerebrospinal fluid (26). Although convulsions have been produced in animals by injection into the cerebrospinal fluid, and it has been suggested that exceptionally large doses can cause depression of medullary centers, there is insufficient information to draw any conclusions.

Pancuronium is reported to lower the MAC for halothane, but whether this is a central or peripheral action is not known.

Gastrointestinal

The motility of the gut may be reduced by tubocurarine, as a result of ganglion blockade.

Body temperature

Tubocurarine has been implicated as a trigger of malignant hyperthermia, particularly in combination with halothane (27), although doubts have been expressed (28). Increased muscular tone is not a feature with D-tubocurarine.

Second-Generation Effects

Pregnancy

Placental transfer of D-tubocurarine occurs (as with all relaxants) and low concentrations of the drug have been detected in umbilical blood. Under normal circumstances no untoward effects have been reported in neonates.

Paralysis occurred in a 28-week fetus, whose mother received D-tubocurarine for status epilepticus, and joint deformities possibly resulting from 4 weeks' maternal curarization during the first trimester have been reported (29).

Experiments in chick embryos have shown that D-tubocurarine can cause retardation of bone growth (30) and that malformations can be produced by in utero curarization (31). Long-term curarization during pregnancy is undesirable.

Susceptibility Factors

Genetic factors

Individual responses to these compounds differ (32–34). Racial differences and environmental factors can influence the response to relaxants and hence the extent of problems due to excessive activity. Patients in the USA reportedly require less D-tubocurarine than in the UK, and the West Indians need more. Difference in cholinesterase activities, perhaps brought about by more organophosphorus insecticides being used in one country than in another, or differences in protein-binding as a result of dietary factors, are possible explanations (35). Vecuronium has been reported to be approximately 30% more potent in Montreal than in Paris (36).

© 2006 Elsevier B.V. All rights reserved.

Age

In the elderly extreme falls in blood pressure can occur with D-tubocurarine (37).

Renal disease

In renal insufficiency the action of D-tubocurarine is increased (38) and prolonged (39).

The half-life in the complete absence of renal function is increased by 70% or more. The reduced ability of plasma proteins to bind the drug (40), if this indeed occurs, will result in a greater proportion of unbound D-tubocurarine and therefore increased potency.

Increased biliary excretion of D-tubocurarine occurs in renal insufficiency and compensates to a varying degree for reduced renal excretion (41). The slower rate of biliary (as opposed to renal) excretion will result in sharply increasing prolongation of neuromuscular blockade if large single doses are used or if multiple doses are given (42). A single small dose will result in little or no prolongation of effect, since redistribution will be mainly responsible for termination of the drug's effect. It has been suggested for several other non-depolarizing relaxants that the initial dose produces less effect in renal insufficiency (SEDA-13, 103).

The problem of accumulation may be marked in intensive care situations, where D-tubocurarine is used to maintain long-term paralysis (42). These patients may also have impaired renal and hepatic function, with protein and electrolyte imbalance. The timing of repeat injections of D-tubocurarine (and, indeed, all relaxant drugs) in such cases should be guided by monitoring of neuromuscular function (by response to single twitch, train-of-four, or tetanic stimulation, which is more sensitive but painful), or clinically by observing the return of muscle tone.

Other features of the patient

In hypovolemic patients, in patients with impaired sympathetic autonomic activity, and in patients operated on in the anti-Trendelenburg position, extreme falls in blood pressure can occur with D-tubocurarine. Hypotension is aggravated by the use of halothane in particular, and by other drugs that produce circulatory depression. In such cases, and in patients with hypertension, coronary artery disease, and arteriosclerosis, D-tubocurarine is better avoided.

Asthmatic and atopic individuals are at special risk from D-tubocurarine's histamine-releasing potential, and severe bronchospasm can result (43).

Greatly increased sensitivity occurs in myasthenia (44) and may even be seen in "premyasthenic" patients with no overt symptoms (45). Increased sensitivity has also been reported in amyotrophic lateral sclerosis (46), von Recklinghausen's disease (47), and ocular muscular dystrophy (48). Patients with Duchenne muscular dystrophy have prolonged block in the regional curare test (49), but other investigators have disputed whether an altered response to non-depolarizing relaxants occurs in this condition.

Patients with thyrotoxic myopathy, as with all forms of myopathy, are exceedingly sensitive to all non-depolarizing agents.

Drug–Drug Interactions

Antidysrhythmic drugs

Class I antidysrhythmic drugs, such as procainamide, lidocaine, propranolol, diphenylhydantoin (50), quinidine (51), and lidocaine (52) have all been claimed to enhance neuromuscular blockade by D-tubocurarine and other non-depolarizing agents. Bretylium (53) and disopyramide (54) are also reported to have their neuromuscular blocking activities potentiated by low concentrations of D-tubocurarine in animal experiments; neostigmine failed to reverse disopyramide-induced blockade (SEDA-13, 102) (55). The greatest hazard from these agents is that they can cause "recurarization" when given postoperatively. With bretylium this can occur several hours after its administration, as a result of its slow kinetics (53). Effects in man have still to be documented for bretylium, but "recurarization" 15 minutes after adequate reversal of vecuronium blockade with neostigmine has been described in a patient given disopyramide intravenously (SEDA-14, 116) (56).

Aprotinin

Reparalysis has been reported when aprotinin was used after operations during which suxamethonium had been given alone or in combination with normal doses of D-tubocurarine (57).

Azathioprine

Azathioprine reduces sensitivity to D-tubocurarine in experimental animals, possibly as a result of phosphodiesterase inhibition, increasing transmitter release (SEDA-4, 87) (58), (SEDA-13, 104).

Calcium channel blockers

Calcium channel blockers, such as verapamil and nifedipine, can potentiate neuromuscular blocking agents (59,60) and it has been suggested that in long-term use they can accumulate in muscle and make block-reversal difficult (61).

Corticosteroids

There have been several contradictory reports of possible interactions of tubocurarine with corticosteroids. In general, it seems that the long-term use of steroids can reduce sensitivity to non-depolarizing neuromuscular blocking agents, while acute administration can cause potentiation (62). Long-term steroid treatment may be associated with the development of a myasthenic syndrome in some patients, who will therefore be very sensitive to neuromuscular blocking agents.

Diuretics

Furosemide (40–80 mg) has been reported to enhance and prolong D-tubocurarine-induced block in anephric patients (63). In animals low doses potentiated D-tubocurarine (and suxamethonium) probably via presynaptic effects, while high doses (1–40 mg/kg in cats) reversed the neuromuscular actions of these relaxants (64). The effects of high doses were similar to those of theophylline,

© 2006 Elsevier B.V. All rights reserved.

and phosphodiesterase inhibition leading to increased acetylcholine release was postulated as a possible mechanism for the antagonism.

Potassium and magnesium loss as a result of the use of diuretics can affect non-depolarizing relaxants.

Doxapram

Doxapram, used as a respiratory stimulant, increased partial D-tubocurarine and pancuronium neuromuscular blockade when used in high concentrations in rats (SEDA-14, 113) (65). There have been no reports in man so far.

Ganglion-blocking agents

Trimetaphan and hexamethonium can potentiate D-tubocurarine-induced block, but clinical reports clearly showing this are lacking. Tubocurarine will increase their hypotensive effect. Neostigmine could theoretically facilitate the postulated end-plate ion channel block of trimetaphan (SEDA-13, 102) (66), which would complicate reversal of neuromuscular block.

Local anesthetics

Local anesthetics have diverse effects on the neuromuscular junction. In very large doses they produce paralysis on their own. When the recommended doses are used for local anesthesia, systemic absorption is small and interaction with relaxants is not to be expected. However, large doses injected intravascularly (accidentally, or therapeutically for dysrhythmias) can potentiate relaxants of both types (67,68).

Magnesium sulfate

Magnesium inhibits the release of acetylcholine and reduces the sensitivity of the postjunctional membrane. Thus, magnesium sulfate can cause neuromuscular transmission failure and enhance the effect of D-tubocurarine and other non-depolarizing neuromuscular blocking drugs (69). Not only have potentiation and prolongation of D-tubocurarine block been reported, but also respiratory depression when magnesium sulfate was given an hour after reversal of the relaxant. Presumably the muscle weakness resulted from potentiation of residual curarization. Whether the effects are additive or synergistic is disputed. Muscle relaxants must be used with caution and in reduced dosage in patients receiving magnesium sulfate. Reversal of the block may be difficult.

Tumor necrosis factor alfa

General Information

Tumor necrosis factor alfa is naturally produced by activated macrophages and monocytes and has pleiotropic effects on normal and malignant cells. Unfortunately, the systemic administration of tumor necrosis factor alfa as a single agent gave disappointing results with severe adverse effects and no significant clinical antitumor effect (SED-13, 1110) (1,2). However, tumor necrosis factor alfa combined with interferon gamma, interleukin-2, or cytotoxic drugs produced positive clinical results, and these combinations reduced the maximum tolerated dose of tumor necrosis factor alfa two to four-fold.

Severe hypotension, thought to be nitrous oxide-mediated, is the main dose-limiting toxicity at all doses. Other frequent and sometimes dose-limiting adverse effects included fever, chills and rigors, myalgias, diarrhea, nausea or vomiting, and local reactions at the injection site. During combination therapy with tumor necrosis factor alfa, hyperbilirubinemia, neurotoxicity, severe febrile reactions, and hypotension were the most frequent complications (SED-13, 1110) (1–4). Transient liver dysfunction, oliguria, and raised creatinine concentrations are common.

Organs and Systems

Cardiovascular

Hypotension, perhaps nitrous oxide-mediated, is a dose-limiting adverse effect of tumor necrosis factor alfa (5).

Severe hypophosphatemia with myocardial dysfunction was noted in patients receiving tumor necrosis factor alfa by continuous hepatic arterial infusion (SEDA-17, 433).

Congestive cardiomyopathy has been attributed to tumor necrosis factor alfa in isolated patients (SED-13, 1110) (6).

Respiratory

A reversible reduction in pulmonary diffusing capacity (7) and pulmonary hemorrhage have been attributed to tumor necrosis factor alfa in isolated patients (SED-13, 1110) (8).

Nervous system

Tumor necrosis factor alfa is considered to be a major neurotoxic agent, and most patients who received large doses developed central nervous system symptoms, most commonly headache, lethargy, fatigue, confusion, disorientation, and reduced performance. Seizures, transient amnesia, aphasia, hallucinations, and diplopia sometimes occur (9).

Psychological, psychiatric

Evaluation of cognitive function in patients receiving tumor necrosis factor alfa alone or combined with interleukin-2 showed reversible attentional deficits, memory disorders, deficits in motor coordination and frontal lobe executive functions (9). There was reversible hypoperfusion in the frontal lobes.

Endocrine

Exacerbation of hypothyroidism was noted in one patient with chronic thyroiditis who received tumor necrosis factor alfa (10).

Metabolism

Metabolic effects of tumor necrosis factor alfa include a reduction in cholesterol and high-density lipoproteins, increases in triglycerides and very low-density lipoproteins, and hyperglycemia.

Hematologic

The hematological effects of tumor necrosis factor alfa mostly consist of dose-related thrombocytopenia and granulocytopenia, and decreased monocyte or lymphocyte counts (SED-13, 1111) (11,12). Septic episodes are sometimes associated with leukopenia. Coagulopathy with laboratory evidence of disseminated intravascular coagulopathy was found in 30% of patients and was sometimes associated with thromboembolic events (13). Other coagulation disorders include transient alterations in prothrombin time, and a rise in the plasma concentrations of von Willebrand factor was found in healthy volunteers (14).

Gastrointestinal

Hemorrhagic gastritis has been attributed to tumor necrosis factor alfa (15).

Immunologic

Anaphylactic-like reactions, dyspnea, or acute bronchospasm have been attributed to tumor necrosis factor alfa in patients also treated with interleukin-2 (16).

Drug Administration

Drug administration route

Local (intralesional, intra-arterial, or intraperitoneal) administration of tumor necrosis factor alfa may well prove to be a more promising and less toxic route of administration. Although mild adverse effects, namely fever, hypotension, and fatigue, were similar to those reported after intravenous administration, coagulation disorders, pulmonary, central nervous system, liver, and renal forms of toxicity were usually not observed (17).

The most interesting and encouraging experience has been obtained using hyperthermic isolated limb perfusion (HILP) of tumor necrosis factor alfa combined with cytostatic drugs (for example melphalan) in melanoma and sarcoma (18). Although systemic toxicity was moderate in this setting, there was still a risk of severe hemodynamic changes, with clinical features of septic shock and a direct nephrotoxic effect of tumor necrosis factor alfa (19,20). A mild neuropathy, marked by transient paresthesia, is also frequent (21). Other rare adverse effects included lung infiltrates, fever, neutropenia, thrombocytopenia, coagulation disorders, transient rise in transaminases and bilirubin, and an increased risk of more severe rhabdomyolysis (SED-13, 1111) (22).

Tylosin

General Information

Tylosin is a polyketide lactone substituted with three deoxyhexose sugars. It is used as an antimicrobial growth promoter in animals. Acquired resistance has been observed in potentially human pathogenic strains isolated from animals (1). Of further concern is the fact that tylosin confers cross-resistance on erythromycin (2).

Typhoid vaccine (including typhoid-paratyphoid vaccine)

See also Vaccines

General Information

The different typhoid vaccines commercially available for civilian use are:

- an oral live attenuated vaccine based on the Ty21a strain of *Salmonella typhi*;
- a parenteral heat-phenol-inactivated vaccine, containing either killed *Salmonella typhi* or killed *Salmonella typhi* and *Salmonella paratyphi* A, B organisms; this

© 2006 Elsevier B.V. All rights reserved.

preparation is no longer recommended by the WHO, although it is still produced in some countries;
- Vi capsular polysaccharide vaccine and vaccines based on auxotrophic mutants of Vi-positive and Vi-negative *Salmonella typhi* (SED-11, 687) (SEDA-12, 278) (SEDA-13, 284) (SEDA-14, 281).

Oral live vaccine

During volunteer studies and field trials using Ty21a vaccine, adverse reactions were rare and consisted of abdominal discomfort, nausea, vomiting, and rash or urticaria. Adverse reactions occurred with equal frequencies among groups receiving vaccine or placebo. There has been a report of a typhoid-fever-like syndrome after the use of Ty21a live oral vaccine (SEDA-15, 350).

Inactivated vaccine

Vaccines administered parenterally are not well tolerated. Severe local pain and/or swelling occurred in 6–40% of vaccinees; systemic reactions have been reported in 9–30% (headache), and in 14–29% (fever); 13–24% of vaccinees missed work or school due to adverse effects. More severe reactions (hypotension, shock) have been reported sporadically (1).

General adverse effects

There have been individual reports of fatal angioimmunoblastic lymphadenopathy, hemolytic uremic syndrome (after typhoid/paratyphoid/diphtheria vaccination), fatal hyperpyrexia (SED-11, 687), transverse myelitis (SEDA-10, 288), erythema nodosum (SEDA-11, 289) (SEDA-14, 281), and Reiter's syndrome (SEDA-15, 350).

The efficacy and safety of typhoid fever vaccine have been estimated in a meta-analysis of about 1.8 million vaccinees in efficacy trials and about 11 000 vaccinees in safety studies (2). The 3-year cumulative efficacy was 73% (65–80%) for two doses of whole cell vaccines, 51% (35–63%) for three doses of Ty21 live attenuated vaccine, and 55% (30–71%) for one dose of Vi vaccine. After immunization, fever occurred in 16% (12–21%) of whole cell vaccine recipients, 2% (0.7–5.3%) of Ty21a vaccine recipients, and 1.1% (0.1–12.3%) of Vi vaccine recipients (Table 1) (3).

A meta-analysis of studies of the efficacy and toxicity of typhoid fever vaccines (SEDA-23, 343) has been criticized as an interesting mathematical exercise but of little practical relevance (4). The meta-analysis had lumped together different parenteral whole-cell vaccines (alcohol-inactivated, formalin-inactivated, acetone-inactivated, and dried whole-cell vaccines), but the only

parenteral killed whole-cell vaccine that is available is the heat-inactivated phenol-preserved vaccine. The analysis should therefore have been limited to heat-phenolized vaccine. It was also mentioned that the quoted data on the occurrence of adverse reactions failed to include the largest clinical trial of Ty21a vaccine. Last but not least, the authors of the meta-analysis failed to relate the severity of reactions connected with the use of parenteral whole-cell vaccine. These adverse reactions, including high fever, malaise, and nausea, make the killed whole-cell vaccine among the most reactogenic vaccine ever licensed. In contrast, oral Ty21a and parenteral Vi vaccines are well tolerated.

Combined meningococcal and typhoid fever vaccine

A combined meningococcal and typhoid vaccine (Mérieux) was evaluated in 158 volunteers in a single-blind study (5). Comparing the effects with those in vaccinees receiving monocomponent vaccines or the combination vaccine, there was no significant difference in the reported frequency or duration of local and systemic reactions. However, vaccinees who received the monocomponent typhoid fever vaccine alone were less likely to complain of swelling or pain at the injection site.

Organs and Systems

Musculoskeletal

Two cases of arthritis temporally connected with the administration of oral typhoid vaccine have been reported (6).

- Arthritis of the knees, ankles, and hands occurred 8 weeks after immunization in a 27-year-old woman.
- Bilateral sacroiliitis was observed in a 66-year-old woman 1 day after she had completed the four-capsule series.

A rheumatologist evaluated both patients and felt that the diagnosis was reactive arthritis, in his opinion most probably vaccine-related. The two cases are the first reports of reactive arthritis following oral typhoid immunization. However, the time-courses (1 day, 8 weeks) make a causal relation doubtful.

Ultrasound contrast agents

General Information

The ideal contrast agent for enhancing ultrasound images and Doppler signals would be non-toxic, injectable intravenously, capable of crossing the pulmonary capillary bed, stable for the duration of the ultrasound examination, and useful for both Doppler and grey scale enhancement.

The first generation of echo contrast agents comprised compounds made of air bubbles stabilized with human serum albumin or D-galactose, which pass through the lung capillaries and reach the left heart chambers. The second generation comprises agents made of stabilized microbubbles of gases of high molecular weight and low solubility in water, mainly fluorocarbons, which provide better resistance to pressure. The high molecular weight fluorocarbon gases have lower diffusivity and blood solubility and thus give better persistence of microbubbles in the circulation. These agents can actually be considered as blood pool agents. Other factors, such as the size and stability of the particles, play a major role in optimal examination. Microbubbles larger than 7 μm will not cross the pulmonary vasculature after intravenous administration and hence the mean size of the microbubbles should be 2–5 μm.

Non-thermal bioeffects can develop with ultrasound equipment with high acoustic input in the presence of ultrasound contrast agents with a high mechanical index. Mechanical index is defined as the maximal rarefactional acoustic pressure divided by the acoustic frequency. Ventricular extra beats have been reported in people subjected to strong ultrasound fields but not with diagnostic ultrasonography, which is generally considered safe and without adverse effects. However, new ultrasound machines can provide high acoustic pressures, and the maximum mechanical index currently allowed is 1.9 (1).

Albumin microspheres

Albunex is a suspension of air-filled human albumin microspheres. In an assessment of the safety of Albunex (Molecular Biosystem Inc USA, Nycomed, Oslo Norway) in imaging the left ventricle in 52 patients, there were no major or minor adverse events and no changes in vital signs (2).

Optison is a second-generation contrast agent based on sonicated human albumin (albumin microspheres containing the gas perfluoropropane). In 191 patients with chronic pulmonary disease and/or cardiomyopathy (aged 21–83 years) given intravenous Optison 0.2, 0.5, 3.0, and 5.0 ml, adverse effects were observed in 6.5% (3). The most frequent adverse events were transient alterations in taste (2.5% of patients), headache (2.0%), and a warm sensation/flushing (2.0%). The adverse events were similar to those reported with first-generation ultrasound contrast agents.

In 50 patients (mean age 59 years) in an intensive care unit who underwent echocardiography examination with intravenous Optison (dose 0.5–1.5 ml), there were no contrast-related adverse effects (4). Good quality echocardiography was obtained in all cases.

Albunex has been compared with Optison in 203 patients undergoing echocardiography (5). There were no clinically significant changes in physical examination, vital signs, or electrocardiography in either group. Adverse effects were few in each group and were most commonly related to flushing, warmth, or taste disturbance. Similar results have been reported from a comparison of Echogen (2% dodecafluoropentane emulsion) with Albunex (SEDA-22, 505) (5).

AIP10119 is a contrast agent that consists of heat-stabilized, air-filled, albumin microcapsules with a median diameter of 4 μm. It contains 1.5×10^8 microcapsules/ml after reconstitution with water for injection. It can be prepared in a formulation with a relatively high acoustic pressure (mechanical index 1.5). In a phase I study in healthy men (mean age 28 years) who received continuous infusions of 1 ml/minute of AIP10119 (mechanical index 1.5) for 10 minutes ($n = 6$) or 20 minutes ($n = 4$) there was a significant dose-dependent increase in the number of ventricular extra beats during end-systolic imaging but not during end-diastolic imaging (1). Nine volunteers received AIP10119 as a single infusion of 1 ml/minute for 25 minutes (mechanical index 1.1) followed by three rapid bolus injections of 1 ml at least 5 minutes apart, the infusion and the series of bolus injections being separated by at least 2 hours; there was no increase in the number of ventricular extra beats. The authors concluded that precautionary measures would include using formulations with a low mechanical index or end-diastolic imaging.

Galactose

The galactose-based ultrasound contrast agents include Echovist and Levovist. Levovist consists of microbubbles less than 8 μm in size. After injection it crosses the lung and enters the systemic circulation. The lack of any adverse effects has been reported in several studies and clinical trials (SEDA-20, 418).

There has been a meta-analysis of the use of Echovist in 986 patients in the assessment of fallopian tube patency. It was well tolerated, although there were adverse events in 47%. By far the most common adverse effect was abdominal pain during the examination (38%). This correlated with tubal patency and was most severe in patients with blockage of both fallopian tubes, presumably because of increased intraluminal pressure. The only other common adverse events were vasovagal reactions (2.8%) and nausea (1.5%), which may not have been directly related to contrast administration (SEDA-22, 505).

Levovist has been assessed in 5073 patients. In addition, spontaneous reporting of adverse events in 100 000 patients given injections of Levovist has been analysed (6). The incidence of adverse events (12%) was similar in the Levovist group and in the controls, who were given isotonic saline. The adverse events included sensations of pain, cold, and warmth during injection, abnormal taste sensations, headache, nausea, and vomiting. There were no serious adverse events. The overall adverse event rate in spontaneous reports was 0.02%. One patient developed bronchospasm, another had a generalized skin rash, and two other patients had urticaria. The other reported adverse events were not serious and may not have been caused by the contrast agent.

© 2006 Elsevier B.V. All rights reserved.

Intravesical Levovist has been used for voiding urosonography in 118 patients (aged 3 weeks to 16 years) (7). The diagnostic accuracy of the examination was high and no adverse effects were reported.

A phase-3 assessment of the accuracy of Levovist (SHU508A, Schering, Berlin) in investigating the portal system has been reported (8). It was injected into peripheral veins in 588 patients in concentrations of 200–400 mg/ml. During the 24 hours after the last injection, pain at the site of injection, vasodilatation, and paresthesia were the only adverse effects definitely related to the injection. There were 18 adverse events in 12 patients and the only severe reaction (fever) was not considered to have been related to Levovist.

There has been further confirmation of the safety of Levovist in a phase 3b clinical trial in 38 patients with hepatocellular carcinoma (9). There were only two minor reactions of nausea and vomiting.

Perfluorocarbons

NC100100

NC100100 (Nycomed, Oslo, Norway) is composed of stabilized perfluorocarbon microbubbles. In a randomized comparison of ^{99m}technetium sestamibi single-photon emission-computed tomography (SPECT) and NC100100 in the assessment of myocardial perfusion in 203 patients with myocardial infarction, NC100100 was well tolerated, with no serious adverse events or deaths (10). Similarly there were no clinically important changes in vital signs, laboratory parameters, or electrocardiography. NC100100 correctly identified the vast majority of normally perfused segments assessed by SPECT.

Octafluoropropane

Octafluoropropane gas encapsulated as microspheres in lipid shells (Definity) is given intravenously as an echocardiographic contrast agent. In a review of its diagnostic efficacy and safety, the authors concluded that it improves the diagnostic accuracy of echocardiographic examinations and has a good safety profile (11). Minor adverse effects were reported, such as headache, back pain, flushing, and nausea. There were no serious adverse effects. However, Definity should not be used in patients with intracardiac shunts or in pregnant or lactating women. It should also be used with caution in patients with severe liver or renal disease.

Perflenapent

Perflenapent emulsion (EchoGen) is an ultrasound contrast agent for echocardiography. It is a liquid-in-liquid emulsion of dodecafluoropentane in water, which becomes a dispersion of microbubbles after hypobaric activation. The microbubbles cross the lung capillary bed and persist in solution much longer than microbubbles of air or other gases of similar size, providing prolonged contrast enhancement. A review of 21 clinical studies involving 743 patients who received perflenapent emulsion and 151 patients who received placebo showed no clinically important abnormalities in laboratory tests, pulse oximetry, vital signs, or electrocardiography. There were adverse events in 6.7% of patients after perflenapent emulsion and 2.6% of patients after placebo. The most frequent adverse effects considered relevant to perflenapent emulsion were vasodilatation (2.8%) and taste disturbances (1.2%). Adverse events were generally mild to moderate, started within 10–20 minutes of contrast administration, and resolved spontaneously within 10–20 minutes. These reassuring findings are in keeping with safety reports about other ultrasound contrast agents (SEDA-22, 505).

A double-blind, placebo-controlled evaluation of perflenapent emulsion as a contrast agent for the liver, kidneys, and vasculature has been reported in 151 patients of whom 12 had adverse effects compared with nine who received placebo (12). Injection site pain, vasodilatation, rash, and rhinitis occurred more often with perflenapent than placebo.

The safety of perflenapent has been evaluated in multicenter phase II studies in 146 patients with congestive heart failure (NYHA class III or IV, mean age 68 years), of whom 99 received perflenapent and 47 received isotonic saline, and in 134 patients with severe chronic obstructive pulmonary disease (FEV_1 no more than 60% of predicted, mean age 65 years), of whom 91 received perflenapent and 43 received isotonic saline (13). Blood pressure, heart rate, respiratory rate, oxygen saturation, the electrocardiogram, FEV_1, complete serum biochemistry, hematology, and mental state were assessed. Adverse events were mild and required no treatment. There was no significant difference in the incidence of adverse reactions between those given perflenapent (15%) and those given placebo (11%). The most frequent adverse events with perflenapent were vasodilatation ($n = 8$), taste disturbance ($n = 6$), nausea ($n = 5$), and headache ($n = 3$).

Perflubron

Perflubron (perfluoro-octylbromide) is composed predominantly of carbon and fluorine, and the absence of protons results in a signal void wherever it is found. When it is given enterically the bowel is labeled as a signal void on the abdominal image.

The enteric use of perflubron has been studied and the authors concluded that it is relatively safe and effective. The main adverse effects were vomiting, which developed in 8% of patients, and a feeling of fullness reported in 5% of cases. Other adverse events involved complaints about the taste of the agent. There were no life-threatening or fatal events (SEDA-21, 484).

An intravenous infusion of an emulsion of perflubron as a hepatic and splenic enhancement agent during CT examination caused lower back pain and transient fever (SEDA-15, 505). This problem appeared to be due to the lipid emulsion and seems to have been overcome with more recent formulations.

Perflutren

Perflutren is an ultrasound agent that consists of perfluoropropane gas encapsulated in lipid microbubbles. It has been used in patients with suspected cardiac disease and suboptimal baseline echocardiography in doses of 5 μl/kg ($n = 85$) or 10 μl/kg ($n = 84$); 42 patients received isotonic saline (14). The magnitude of clinically useful opacification was not dose-dependent, but its duration

© 2006 Elsevier B.V. All rights reserved.

was 81 seconds with 5 μl/kg and 99 seconds with 10 μl/kg. There were no clinically significant changes in physical examination, vital signs, electrocardiography, biochemistry, or hematology. Headache was the most frequent averse event, in nine patients who received perflutren and in three controls.

Simethicone-coated cellulose

Artefacts that arise from gas in the stomach and adjacent bowel often limit the diagnostic accuracy of abdominal ultrasound. Research to overcome this problem has focused on cellulose-based suspensions. An agent has been developed based on simethicone-coated cellulose—SonoRx (Bracco Diagnostics, Princeton, NJ), which displaces and disperses gas bubbles. In a phase 2 clinical study, 93 patients underwent upper abdominal sonography before and after a randomized dose of the contrast agent (200, 400, 600, 800, or 1000 ml) (15). Anatomical visualization was improved as follows: the stomach in 82% of patients, the duodenum in 63%, the pancreatic head and body in 61%, and the pancreatic tail in 67%. There were 14 adverse events in 11 patients and only five were considered to be related to the contrast agent. The main adverse effects were mild diarrhea and nausea.

Sulfur hexafluoride

Sono Vue (BR1) is an ultrasound contrast medium that consists of microbubbles containing sulfur hexafluoride gas stabilized by phospholipids. The diameter of each microbubble is 2.5 μm and there are about 0.5×10^9 microbubbles/ml. It is isotonic with human plasma, has the same viscosity as blood, and has minimal antigenic potential, since it contains no protein material.

The pharmacokinetics of Sono Vue have been studied in 12 healthy volunteers (aged 20–36 years, seven men), who received two intravenous doses of 0.03 and 0.3 ml/kg in random order (16). Sono Vue was rapidly cleared from the blood, with a half-life of 5–7 minutes. About 40–50% of the dose was eliminated in the expired air during the first minute after injection and 80–90% was eliminated by 11 minutes. Within 90 minutes, sulfur hexafluoride could no longer be detected in the expired air in most cases. There were no adverse effects.

The diagnostic efficacy and the safety of Sono Vue has been assessed in 218 patients with suspected coronary artery disease who underwent echocardiography (17). Each received intravenous Sono Vue 0.5, 1.0, 2.0, and 4.0 ml in random order at intervals of at least 5 minutes between injections. There were no clinically significant changes in physical examination, vital signs, or electrocardiography. There were no serious adverse effects, even in patients who had heart failure and a history of myocardial infarction. The non-serious adverse reactions were mild and transient and required no treatment. The most common adverse effects were headache (4%) and nausea (1.4%).

Assessment of vascularity can be useful in differentiating benign and malignant breast lesions using color Doppler examination. However, some neoplasms have low blood flow and Doppler may be suboptimal. In these cases, ultrasound contrast may be beneficial. In a phase II/III, multicenter, randomized study 220 patients with breast lesions in different anatomical areas received intravenous Sono Vue 0.3, 0.6, 1.2, and 2.4 ml (18). Sono Vue improved the quality of Doppler blood flow information in both parenchymal and focal lesions. There were mild adverse events in two patients only; one complained of nausea and the other of discomfort. It is not clear whether these events were related to the contrast agent or not.

The safety of Sono Vue as an intravenous bolus injection of 0.3, 0.6, 1.2, or 2.4 ml in transcranial Doppler examination of the cerebral arteries has been investigated in 40 patients (mean age 64 years) (19). The interval between each dose was at least 10 minutes or until total disappearance of the contrast effect from the previous dose. Eight patients reported 12 adverse events. There were no serious adverse events and no patient withdrew because of an adverse event. The most common adverse events were pain at the injection site, headache, and a feeling of warmth; all were mild.

The safety of Sono Vue has been evaluated in 36 healthy volunteers who were given a single dose of isotonic saline or Sono Vue, 0.003, 0.01, 0.03, 0.06, 0.09, or 0.12 ml/kg and in 30 volunteers who were given cumulative doses of 0.15–0.6 ml/kg (20). The volunteers were aged 20–35 years. Another 12 subjects, patients with chronic obstructive airways disease, were given a single dose of Sono Vue 4 ml and placebo (isotonic saline 4 ml) in two sessions, separated by 48–72 hours. All adverse events were minor or mild and rapidly resolved. The adverse effects in the healthy volunteers were heat at the injection site, facial flushing, headache, and a tingling sensation in the hand (one patient each). There were no differences in the frequencies of adverse events in the different dosages groups or between Sono Vue and placebo. In the patient with chronic obstructive airways disease, vomiting and lethargy occurred in one patient each. There were no significant changes in respiratory function tests (FEV_1, FVC, forced mid-expiratory flow, and oxygen saturation).

The excellent safety and efficacy of Sono Vue at doses of 0.7, 1, 2, and 4 ml has been demonstrated in 138 patients (mean age 57 years) (21). There were mild adverse events, such as headache, nausea, paresthesia, and taste disturbance, but no severe adverse reactions.

Unoprostone

See also Prostaglandins

General Information

Unoprostone is a synthetic prostaglandin analogue of $PGF_{2\alpha}$ used in the treatment of glaucoma. Its mechanism of action is believed to be by enhancing uveoscleral outflow, like latanoprost.

Organs and Systems

Sensory systems

The use of unoprostone in the treatment of open-angle glaucoma and ocular hypertension has been reviewed (1). Most of the literature is in Japanese. The adverse effects of unoprostone are similar to those of latanoprost: conjunctival hyperemia, iris pigmentation, hypertrichosis and hyperpigmentation of eyelashes, and rarely systemic effects (1).

Vaccines

See also Individual agents

General Information

In the early days of vaccine development the majority of untoward effects after immunization were associated with faulty production, and the control of biological products as they exist today has been developed largely as a result of major accidents. For example, the Cutter incident in the USA in 1955, in which a batch of "inactivated" poliomyelitis vaccine containing live poliovirus was inadvertently released, had devastating consequences. The World Health Organization (WHO) subsequently took over the responsibility for international biological standardization. Currently, more than 50 WHO requirements for the manufacture and control of biological substances have been adopted and updated. As a result of the incorporation of WHO requirements, and their strict observance by manufacturers and control authorities, accidents due to faulty production of vaccines have become rare (SEDA-13, 271).

However, during the last two decades rapid increases in immunization coverage have been reported worldwide; globally, 5–10 billion injections are now given each year, mainly for treatment of illness but also for prophylactic purposes such as immunization. Unavoidably, the growth of WHO's Expanded Program on Immunization has sometimes resulted in extension of immunization work into areas of the developing world where logistic support and training programs have not been adequate. In such circumstances, avoidable faults have been made, involving variously improper or inadequate sterilization, incorrect doses and routes of vaccine administration, or substitution of drugs for diluents or vaccines (SEDA-15, 340). The use of unsterilized or improperly sterilized needles and syringes is particularly common in these regions and contributes largely to the spread of hepatitis B and C as well as to the spread of human immunodeficiency virus (HIV) and other blood-borne pathogens. The WHO recognizes this as a major public health problem and has initiated a program of activities to ensure safe injections (1).

In some highly developed countries that have had great success in reducing dangerous infectious diseases through immunization, there are controversial discussions regarding the benefits to harm balance of immunization. Because the incidence of vaccine-preventable diseases is reduced by increasing coverage with an efficacious vaccine, adverse events, both those caused by vaccines themselves (that is true adverse reactions) and those associated with immunization only by coincidence or as a result of faulty routines, become increasingly frequent. Not surprisingly, vaccine safety concerns have become increasingly prominent in successful immunization programs. Chronic illnesses recently claimed to be linked with immunizations include asthma, autism, diabetes, and multiple sclerosis. Given the current increasingly "anti-vaccine" environment that has developed in some countries, it is hard to imagine that the full potential of new vaccines will be harnessed. To avoid damage to current and future immunization programs considered as among the most successful and cost-effective public health interventions, we need to examine critically the factors that have influenced this change in public attitudes.

We have been relatively slow in appreciating the importance that the public now places on vaccine safety. In fact, much of our resource allocations still unfortunately reflect safety last rather than safety first. This reflects in part an unfortunate legacy, in which we have characterized this arena for years in narrow, negative terms of adverse events, instead of the more broad and positive terms of safety. Furthermore, it shows that we have not been as interested in preventing vaccine-induced illnesses as we are in vaccine-preventable diseases (2). Increasing interest in this problem can therefore be observed in many developed and developing countries, and international institutions and organizations, for example the World Health Organization (WHO), the United Nations Children's Fund (UNICEF), and vaccine manufacturers. The careful review of the current knowledge on adverse effects after immunization is a useful contribution to vaccine safety and helps to maintain confidence in immunization programs.

On the other hand, we must not forget that the ultimate goal of an immunization program is control of disease or even its regional elimination or worldwide eradication. A successful immunization program can lead to the eradication of disease and opens up the possibility of ultimately abandoning immunization (and with it the occurrence of adverse effects) completely. Smallpox eradication made it possible to stop smallpox immunization and poliomyelitis eradication, which is expected to be achieved within a few years, will mean the end of polio vaccine.

Surveillance of adverse events following immunization

Currently, in many highly developed countries in which the incidences of dangerous infectious diseases have been markedly reduced through immunization, there are controversial discussions about the balance of benefits and harms in immunization. Vaccine adverse events, both those caused by vaccines (that is true adverse reactions) and those associated with immunization only by coincidence, become more visible than the natural disease. Not surprisingly, vaccine safety concerns have become increasingly prominent in such successful immunization programs. Vaccines have been spuriously linked by various researchers to asthma, autism, diabetes, inflammatory bowel disease, multiple sclerosis, permanent brain damage, and sudden infant death syndrome (SIDS). Modern communication is providing even more penetrating ways of communicating messages on the subject through the World Wide Web. The result is a formidable challenge to immunization service providers. Neil Halsey, head of the Institute for Vaccine Safety at Johns Hopkins University, has summarized the features common to recent publications on vaccine adverse effects:

- a causal link is usually claimed with a disease or condition of unknown or unclear cause;
- the association is claimed by one investigator or a group of investigators;

© 2006 Elsevier B.V. All rights reserved.

- the association is not confirmed by peers or by subsequent research;
- the claims are made with no apparent concern for potential harm from public loss of confidence and refusal to immunize;
- findings of subsequent studies that fail to confirm the original claim never get the publicity given to the original finding, and so the public never gets a balanced view(2,3).

A critical examination (4) of a report (5) of several children whose chronic bowel and behavioral abnormalities were linked to measles, mumps, and rubella (MMR) immunization can be used as an example to underline Halsey's comments. Without effective and credible systems for the detection of vaccine-associated adverse events through pharmacovigilance, for distinguishing causal reactions from coincidental reactions by pharmacoepidemiological or other studies, and for risk communication, vaccine safety concerns may confuse the media and the public.

A concerted effort is needed to improve communications at all levels regarding the real risks associated with vaccines and immunization and helping to reassure the public of the overwhelming safety record of vaccines. The medical community is still preeminent as advice givers to the public on matters of immunization and should play the key role in improved communication (3,6).

The US Vaccine Adverse Events Reporting System (VAERS) has been described (SEDA-14, 919) and the pros and cons of the system have been discussed (7). About 1000 reports per month are submitted by manufacturers (39%), state health coordinators (34%), health care professionals (25%), and parents (2%). Manufacturers' reports are primarily based on information received from health care providers or the parents of vaccinees. As a passive reporting system, VAERS is subject to numerous well-known deficiencies, such as underreporting, incomplete and missing data, and recall bias. Resources are not adequate to allow follow-up for complete or accurate data in all cases. However, VAERS is useful to detect early warning signals and to generate hypotheses. For example, the information from a parent that her daughter had lost her hair after the second and third doses of hepatitis B vaccine initiated a study that found 59 similar cases, including three cases of positive rechallenge. As a result of this study, alopecia was added to the list of adverse reactions in the hepatitis B vaccine package insert. Individual case reports can also trigger a complete review of the VAERS database. For example, three reports of idiopathic thrombocytopenic purpura after measles-containing vaccine were received in a short period of time. The study of idiopathic thrombocytopenic purpura reported in the database found 54 other reports during the period 1990–95, including one case of positive rechallenge, which increased the likelihood that the association was causal.

Reports on adverse events after the administration of the two hepatitis B vaccines licensed in the US (Engerix-B and Recombivax HB) have been compared in two different surveillance systems: VAERS and Vaccine Safety Datalink (VSD) (8). VSD is a computerized record linkage system designed to allow more rigorous evaluation of causality of adverse events after immunization. Since 1989, VSD has actively maintained medical files on over 500 000 children, aged from birth to 6 years enrolled at four West-coast health maintenance organizations. Immunization records, medical diagnoses, and diseases from clinic, hospitalization, and emergency room visits are coded. Whereas VAERS found that the reporting rate for events after brand 1 vaccine was at least three times higher than the reporting rate after brand 2 vaccine, VSD found no difference between rates of hospitalization or emergency room visits in recipients of the two brands. The authors concluded that the results of the VAERS database are subject to the inherent limitations of a passive surveillance system. This study underlined the importance of using other analytical studies, such as VSD, to evaluate preliminary results obtained by VAERS.

Adverse events reported to the VAERS during the period 1991–2001 have been summarized and evaluated (9). The main results were as follows:

- During 1991–2001, annual reports of deaths constituted 1.4–2.3% of all reports, and reports of life-threatening illness constituted 1.4–2.8% of all reports.
- A clinical research team followed up all deaths reported to VAERS; most of these deaths were ultimately classified as SIDS; analysis of the age distribution and seasonality of infant deaths reported to VAERS showed that they matched the age distribution and seasonality of SIDS: both peaked at 2–4 months and during the winter; the reduction in the number of deaths reported to VAERS since 1992–93 parallels the overall reduction in the incidence of SIDS in the US population since the implementation of the "Back to sleep" campaign; the Food and Drug Administration (FDA) and the Institute of Medicine (IOM) reviewed 206 deaths reported to VAERS during 1990–91: only one death was believed to have resulted from a vaccine.
- Intussusception after rotavirus vaccine was described as an example to underline the value of passive surveillance systems as an indicator for carefully designed follow-up studies.
- An increase in the number of reports of Guillain–Barré syndrome after the receipt of influenza vaccine was noted in VAERS data by week 29 of the 1993–94 influenza season; the numbers of reports of Guillain–Barré syndrome increased from 23 during 1991-92 to 40 during 1992–93 and to 80 during 1993–94; a study of the VAERS signal showed that slightly more than one additional case of Guillain–Barré syndrome occurred per 1 million people immunized against influenza, a risk that is less than the risk from severe influenza, which can be prevented by the vaccine.
- A detailed review of VAERS reports received during the first 3 years after the licensure of the *Varicella* vaccine documented that the majority of reported adverse events were minor and serious adverse events were rare.

Terms and definitions used in surveillance programs of adverse events and adverse effects after immunization

Definitions are fundamental to the establishment of any functioning surveillance system. There must be different definitions for monitoring and evaluation. An

© 2006 Elsevier B.V. All rights reserved.

international voluntary collaboration has been established to develop globally accepted standardized case definitions of adverse events following immunization (AEFI). The so-called Brighton Collaboration (initiated in 1999 during a vaccine meeting in Brighton, UK) took into consideration that there is a general lack of widely accepted and implemented case definitions, because only a limited set of case definitions elaborated by WHO has been available internationally. Working groups on fever, local reactions, intussusception, persistent crying, convulsion, and hypotonic-hyporesponsive episodes were already established. The website of the Brighton Collaboration contains information about the process and progress of the collaboration, the work statement for the working groups, a template format for draft definitions, and much more (10).

On behalf of the Brighton Collaboration, an electronic discussion on the wisdom of using the term "adverse event following immunization" (AEFI) has been undertaken during the year 2001. Concern has sometimes been expressed that the word "following" could imply causality. At least 10 alternative terms have been proposed and discussed. Finally, the term "adverse event possibly related to immunization" (AEPRI) received the majority of votes. However, there were many participants in the discussion who believed that the term AEFI should be kept because it is used in many countries as well as in guidelines issued by the WHO and UNICEF and because a change will create new confusion. It therefore seems that the term AEFI will not be replaced (11).

The Brighton Collaboration took into consideration the fact that there is a general lack of widely accepted and implemented case definitions in order to allow comparability between studies. Based on a network of more than 300 participants from 34 countries and collaborating with many national and international organizations, institutions, and manufacturers (for example WHO, FDA, CDC, GlaxoSmithKline), case definitions and guidelines have been developed for intussusception, fever, prolonged crying, seizure, hypotonic-hyporesponsive episodes, and local reactions, such as nodules, swelling, cellulitis, and abscesses. A Brighton Internet site has been created (10).

Monitoring

Data collection is the first step in surveillance. Terms and definitions developed for monitoring purposes should be useful both for practitioners and health workers. Monitoring definitions therefore have to cover a broad range. For monitoring purposes, the term "adverse event" has been introduced, defined as an untoward event temporally associated with immunization, which might or might not be caused by the vaccine or the immunization process. The term "adverse effect" does not seem useful for monitoring purposes, since it relates to an untoward effect after immunization that is linked to the vaccine (antigen or vaccine component) or to the immunization procedure. The term and its definition imply a distinct degree of causality. However, the term "suspected adverse effect" is acceptable.

Evaluation

Statistical analysis and expert evaluation of the collected data should be carried out centrally. Expert evaluation of reports should be based on precise evaluation definitions, taking into account current scientific knowledge. One classification of events is that concerning causality, for example certain, probable, possible, unlikely, unclassified (when no attempt to classify has been made), and unclassifiable events (for example due to lack of data) (12). Alternatively one can classify reports into those for which there is no evidence of a causal relation, those for which evidence is insufficient to indicate a causal relation, those for which the evidence does not indicate a causal relation, those for which the evidence is consistent with a causal relation, and finally those for which the evidence indicates a causal relation (13,14). An evaluated adverse event classified as either "certain" or "probable" or "consistent with a causal relation" or "indicating a causal relation" fulfils the criteria for the recognition of an adverse effect after immunization.

Following WHO's proposal to distinguish four types of adverse events after immunization, the evaluation should furthermore try to distinguish:

- vaccine-induced adverse events (for example BCG lymphadenitis, BCG osteitis, vaccine-associated poliomyelitis, allergic reactions);
- vaccine-precipitated events (for example a simple febrile seizure following DPT immunization in a predisposed child);
- programmatic errors (for example an abscess due to improper sterilization);
- coincidental events (15).

Most commonly, passive surveillance systems are used for the surveillance of adverse events after immunization. Spontaneous reports from health care providers on temporally related adverse events suspected of being caused by the vaccine or the immunization procedure are collected and evaluated. However, the significant degree of under-reporting, together with the non-specific nature of most adverse events reports, highlights the limitations of passive surveillance systems of adverse events after immunization. A critical evaluation of the limitations of the US Vaccine Adverse Event Reporting System (VAERS) (SED-13, 919) and its predecessor, the Monitoring System for Adverse Events Following Immunization (MSAEFI) (SEDA-13, 273) (SEDA-16, 320) has been made by Rosenthal and Chen (16,17). The authors concluded that reports to VAERS and MSAEFI are essentially non-controlled clinical case reports or case series, useful for generating hypotheses but not for testing them. Other controlled studies are therefore often necessary to evaluate hypotheses raised by passive surveillance system reports: whether a given adverse event can be caused by a specific vaccine and if so how commonly it occurs. However, if reporting is reasonably consistent, it may be possible to detect changes in trends of known common adverse events. In addition, passive surveillance remains a potentially cost-effective way of monitoring rare events that cannot be detected in small prelicensing trials.

Cohort studies of rare adverse events would be useful, but are generally not feasible, particularly for economic reasons. One promising alternative approach is the use of large linked databases. The databases appropriate for such studies are derived from defined populations, such

© 2006 Elsevier B.V. All rights reserved.

as members of health maintenance organizations, universal health care systems, and Medicaid programs. Information on both exposure (immunization records) and outcome (for example diagnoses recording potential adverse events) is usually computerized for members of such populations. These databases can be linked for epidemiological studies assessing potential associations between immunization and outcomes. Large linked databases have already been used by various groups to examine the association between DTP vaccine and SIDS, DTP vaccine and neurological events, and MMR vaccine and seizures. The Centers for Disease Control and Prevention (CDC) in Atlanta use large linked databases (now called Vaccine Safety Datalink) in addition to VAERS Vaccine Safety Datalink, covering a defined cohort of approximately 500 000 children up to the age of 5 years (17–19).

An epidemiological and statistical method based on linkage of routinely available computerized hospital admission records with vaccination records has been described by Farrington (20). This active surveillance method has been used to assess the attributable risk of convulsions after DTP and MMR immunization and to investigate the relation between MMR vaccine and idiopathic thrombocytopenic purpura in children under 2 years of age in five districts in England.

Causality assessment of adverse events following immunization (AEFI)

Adverse events following immunization can be causally related to the inherent properties of the vaccine, linked to errors in administration, quality, storage, and transport of the vaccine (programmatic errors), but also occurring coincidentally after immunization. It is therefore necessary to investigate and evaluate AEFI, particularly those that are serious or unknown.

The most reliable way of determining the causality of an AEFI is by randomized comparisons of events in an immunized group with events in a non-immunized group. However, such trials can never be large enough to detect very rare events; postmarket surveillance is required to identify rare events. A Global Advisory Committee on Vaccine Safety, constituted by the WHO in 1999, has developed criteria for AEFI causality assessment. Criteria to be considered are consistency (the findings should be replicable), strengths of association (in an epidemiological sense), specificity, temporal relation, and biological plausibility (according to what is known about the natural history and biology of the disease). Not all these criteria need to be present to establish causality (21).

In Canada, an advisory committee on causality assessment (ACCA) has been established to evaluate serious individual adverse event reports collected through active surveillance of pediatric hospitals or a passive voluntary reporting system. The ACCA is composed of specialists in epidemiology, immunology, infectious diseases, microbiology, neurology, pathology, and pediatrics. A causality assessment form has been developed (including criteria similar to the WHO criteria described above). For final classification of the evaluated adverse events the causality assessment criteria of the WHO (see Table 1) are used. The great majority of reports collected through the surveillance system describe minor or well-known reactions (over 95%); only the most serious and unusual adverse events after immunization requiring detailed review are submitted to ACCA. At each twice-yearly meeting of the ACCA 60–110 reports of severe and unusual reports are evaluated (22).

Table 1 WHO causality assessment criteria for adverse reactions to vaccines

Probability	Criteria
Very likely/ certain	Clinical event with a plausible time relationship to vaccine administration, and which cannot be explained by concurrent disease or other drugs or chemicals
Probable	Clinical event with a reasonable time relationship to vaccine administration, and is unlikely to be attributed to concurrent disease or other drugs or chemicals
Possible	Clinical event with a reasonable time relationship to vaccine administration, but which could also be explained by concurrent disease or other drugs or chemicals
Unlikely	Clinical event whose time relationship to vaccine administration makes a causal connection improbable, but which could plausibly be explained by underlying disease or other drugs or chemicals
Unrelated	Clinical event with an incompatible time relationship to vaccine administration, and which could be explained by underlying disease or other drugs or chemicals
Unclassifiable	Clinical event with insufficient information to permit assessment and identification of the cause

Surveillance systems in different countries and between-country collaboration

Some countries have long experience in monitoring adverse events after immunization, starting with smallpox vaccination.

Worldwide, under 10% of countries have implemented postlicensure surveillance systems. The withdrawal of rotavirus vaccine (Rotashield, Wyeth Laboratories) based on postmarketing surveillance data that showed an excess risk of intussusception after the use of the vaccine convincingly showed that such systems are essential components of vaccine program implementation. However, the event also showed the power of active surveillance systems. Active systems in Minnesota and the Northern California Kaiser Permanente Health Maintenance Organization have provided preliminary data that suggest an increased risk of intussusception after the administration of Rotashield. Further analysis of the data collected both from the passive US national AEFI reporting system (VAERS) and from various active postmarketing surveillance systems led to a decision to withdraw the vaccine from the market (23).

USA

Since March 21, 1988, health care providers and vaccine manufacturers have been required by law to report certain events following specific immunizations (SED-12, 792) to the US Department of Health and Human Services. Table 2 shows the updated table for reportable

© 2006 Elsevier B.V. All rights reserved.

Table 2 Reportable events after vaccination

Vaccine/toxoid	Event	Interval from vaccination
Tetanus in any combination; DTaP, DTP, DTP-HiB, DT, Td, TT	A. Anaphylaxis or anaphylactic shock	7 days
	B. Brachial neuritis	28 days
	C. Any sequel (including death) of the above events	Not applicable
	D. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Pertussis in any combination; DTaP, DTP, DTP-HiB, P	A. Anaphylaxis or anaphylactic shock	7 days
	B. Encephalopathy (or encephalitis)	7 days
	C. Any sequel (including death) of the above events	Not applicable
	D. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Measles, mumps, and rubella, in any combination; MMR, MR, M, R	A. Anaphylaxis or anaphylactic shock	7 days
	B. Encephalopathy (or encephalitis)	15 days
	C. Any sequel (including death) of the above events	Not applicable
	D. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Rubella in any combination; MMR, MR, R	A. Chronic arthritis	42 days
	B. Any sequel (including death) of the above event	No limit
	C. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Measles in any combination; MMR, MR, M	A. Thrombocytopenic purpura	7–30 days
	B. Vaccine-strain measles viral infection in an immunodeficient recipient	6 months
	C. Any sequel (including death) of the above events	No limit
	D. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Oral polio (OPV)	A. Paralytic polio	30 days/6 months
	B. Vaccine-strain polio viral infection	30 days/6 months
	C. Any sequel (including death) of the above events	Not applicable
	D. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Inactivated polio (IPV)	A. Anaphylaxis or anaphylactic shock	7 days
	B. Any sequel (including death) of the above events	Not applicable
	C. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Hepatitis B	A. Anaphylaxis or anaphylactic shock	7 days
	B. Any sequel (including death) of the above events	Not applicable
	C. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Hemophilus influenzae type b (conjugate)	A. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Varicella	A. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Rotavirus	A. Intussusception	30 days
	B. Any sequel (including death) of the above events	Not applicable
	C. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert
Pneumococcal conjugate	A. Events described in the manufacturers' package insert as contraindications to additional doses of the vaccine	See package insert

events after vaccination, effective from August 26, 2002. The VAERS accepts all reports of suspected adverse events after the administration of any vaccine, including but not limited to those certain events required by law to be reported.

Canada

The reporting of vaccine-associated adverse events temporally associated with immunization by health-care providers is voluntary in Canada, except in the province of Ontario, which has specific mandatory requirements. However, there is no evidence of a higher reporting rate with the latter approach. This is partly explained by the fact that immunization in Ontario is usually provided by physicians, who have lower reporting rates than public-health nurses. In addition to its spontaneous voluntary reporting system, Canada also has an active surveillance system, IMPACT, for serious adverse events, vaccination

© 2006 Elsevier B.V. All rights reserved.

failures, and selected infectious diseases. It involves a network of 11 pediatric centers across Canada. The results of the Canadian surveillance system have been reviewed (SEDA-16, 367) (SEDA-17, 363) (SEDA-21, 324) (SEDA-22, 333).

The Netherlands
A special committee of the Health Council of the Netherlands has been created (12), with the task of analysing, classifying, and interpreting the adverse effects which are reported to the National Institute of Health and Environmental Protection in Bilthoven (SEDA-12, 271) (SEDA-13, 278) (SEDA-14, 269) (SEDA-15, 341) (SEDA-16, 365) (SEDA-17, 363) (SEDA-18, 325).

New Zealand
Reported adverse events after immunization in New Zealand from 1990 to 1995 have been presented (24). Reactions at the injection site following adult tetanus + diphtheria vaccine were the most commonly reported (68 reports per 100 000 immunizations). The authors concluded that the picture confirmed the overall safety of vaccines and the value of an adverse events monitoring system.

Spain
In Spain, reports on adverse events after immunization are collected through the Spanish Pharmacovigilance System by means of a yellow card. In children, the most commonly involved pharmaceutical groups were antibiotics, respiratory drugs, and vaccines. A review of reports received over 10 years (1982–91) has been provided (25). In the framework of the Global Training Network, a WHO initiative to improve the quality of vaccines and their use, a model for a simple national system for dealing with vaccine safety and emergencies as they arise has been elaborated. The authors have described the model and have outlined a training program designed to help develop such a system (26).

Other countries
There are other national surveillance programs on adverse events after immunization, for example in Denmark, Germany, Sweden, the UK, Hungary; developing countries such as India (SEDA-17, 363) and Brazil (SEDA-16, 367) have also already started to collect data on severe adverse events.

International surveillance programs
The Program on International Drug Monitoring of the WHO has participation from over 50 member states. In all member countries, national Drug Reaction Monitoring Centers collect reports from health professionals and pass them on for entry into the international database housed at the WHO Collaborating Center for International Drug Monitoring in Uppsala, Sweden. Currently, there are some 2.5 million reports on file, and each year about 200 000 new reports are added. The database generates signals of potentially severe drug toxicity and provides confirmation of signals generated in specific countries. The Center also acts as the guardian of the standardized terminology of adverse drug reactions in computerized systems. Although vaccines are considered to be safe, the work of the Center underlines the importance of collecting information on the safety of vaccines to provide sound reference data in the event of a problem. Since vaccines are administered to healthy people, mostly children, the impact of a perceived problem can be enormous. Because of these considerations, many countries have already established specific programs for the monitoring of adverse events after immunization (27).

Clinical immunization safety assessment centers
The National Immunization Program of the Centers for Disease Control and Prevention (CDC), Atlanta, GA, USA, is trying to set up a network of Clinical Immunization Safety Assessment Centers (CISA). Based on standardized clinical evaluation protocols the centers will assist health care providers in evaluating patients who may have had an adverse reaction after immunization. Furthermore, the centers will evaluate newly hypothesized syndromes or events identified through the routine VAERS (28).

Guaranteeing vaccine quality
During the last 20–30 years, great progress has been achieved in both vaccine production technologies and testing technologies. In addition to sophisticated tests, vaccine regulation entails a number of procedures that ensure safety, including the characterization of starting material, cell banking, seed lot systems, principles of good manufacturing practices, independent release of vaccines on a lot-by-lot basis by national regulatory authorities, and enhanced premarketing and postmarketing surveillance for possible rare adverse events after immunization (29).

Perspectives on prelicensure trials
The withdrawal of tetravalent rhesus-based rotavirus vaccine from the market illustrates an important problem regarding prelicensure testing and its ability to identify rare vaccine-related adverse events. A sample size of 10 000 volunteers may provide excellent estimates of reactogenicity (local and systemic reactions) and efficacy but be inadequate as a denominator for ruling out rare adverse events. Table 3 shows how trial size determines the ability to detect frequent and rare events. Plans for future large prelicensure trials, for example for newly developed rotavirus vaccines, therefore include 10 000–60 000 volunteers. These large trials can be seen as a

Table 3 Sample size necessary to have 80% power to detect an increase in the risk of a rare event

Background rate (1:1 randomization)	Detectable relative risk	Total study population required
1:100	5	1443
1:100	2	5916
1:1000	5	14 428
1:1000	2	59 160
1:10 000	5	144 280
1:10 000	2	591 600

bridge between prelicensure and improved postlicensure surveillance (30,31).

Improving monitoring of vaccine safety through postlicensure studies

Gaps in current vaccine safety monitoring methods have been analysed and the needs for improvements outlined (32,33). The well-known limitations associated with prelicensure trials have led to the expectation that postlicensure studies would address safety issues better. To meet this expectation, steps that should be taken include bar-code labeling of vaccines to improve the accuracy and completeness of information about administered vaccines, establishing immunization registers to provide numerator data, developing generally agreed case definitions for adverse events following immunization (AEFI), to allow comparability between studies, to facilitate long-term follow-up, and to do linked database studies. Only by investing in vaccine safety infrastructure will the high expectations of postlicensure studies be met.

Passive surveillance and reported fatalities

The fatalities reported to the federally administered (US) VAERS have been examined (34). A total of 1266 deaths were reported to VAERS between July 1990 and June 1997. Table 4 shows the numbers of deaths by age (total sample 1199 individuals) and Table 5 shows the causes of death (total sample 1244 individuals).

Nearly half of the deaths were attributed to SIDS. Since 1992/93, the trend of decreasing numbers of reported deaths follows that observed for SIDS overall in the US general population following implementation of the "Back to Sleep" program. Therefore, the VAERS data support the findings of controlled studies that show that the association between infant immunization and SIDS is coincidental and not causal.

Adverse events after immunization—the need for improved research, surveillance, and communication

The success of vaccines is not only impressive and convincing but also makes immunization its own worst enemy. When a naturally occurring disease becomes less common, concerns about vaccine safety increase, particularly since no vaccine can be regarded as being completely safe, although some are very much safer than others. Progress in the development, manufacture, and control of modern vaccines has contributed to the safety of current vaccines. However, it is absolutely necessary to know what the true complications of immunization are, what the gaps in our current knowledge are, and when there is no evidence linking immunization and a suspected adverse effect.

Table 4 Deaths related in time to immunization reported to VAERS 1990–97, by age

Age (years)	Number (%)
Overall	1199 (100)
<1	808 (67)
1–4	117 (9.8)
5–9	18 (1.5)
10–17	17 (1.4)
18–45	43 (3.6)
46–64	55 (4.6)
≥65	141 (12)

Table 5 Causes of death related in time to immunization reported to VAERS 1990–97

Cause of death	Number (%)
Overall	1244 (100)
SIDS	592 (48)
Congenital	38 (3.1)
Infectious	164 (13)
Neoplastic	15 (1.2)
Other	261 (21)
Unknown	174 (14)

Current knowledge about vaccine risks is incomplete, as was noted in extensive reviews in the early 1990s by the IOM in the USA (13,14). Two-thirds of the 76 vaccine-associated adverse events evaluated by the IOM had either no evidence or inadequate evidence to assess the causal role of the vaccine. Specifically, the reviews identified the following limitations:

- inadequate understanding of the biological mechanisms that underlie adverse events;
- insufficient or inconsistent information from case reports and case series;
- inadequate size or length of follow-up of many population-based epidemiological studies;
- limitations of existing surveillance systems to provide persuasive evidence of causation;
- few experimental studies published relative to the total number of epidemiological studies published.

A concerted effort is therefore needed to improve both research on and surveillance of the risks associated with immunization, as well as better communication aiming to reassure health-care providers, parents, and the public (including the media) about the steps taken to ensure vaccine safety and the overwhelming safety record of vaccines. The medical community still has preeminence as the purveyor of advice to the public on matters of immunization and should play a key role in improving communication. Nothing will strengthen our ability to communicate risk more than ensuring that there is adequate capacity and funding for vaccine safety infrastructure and research (2).

The response to a newly published adverse event associated with immunization must be rapid. First, if the reported association is correct, urgent re-evaluation of the immunization program is necessary. However, if the reported association is false, a credible countermessage must be sent, to minimize the negative impact on the immunization program (35).

The pros and cons of the (US) VAERS (SEDA-14, 919) have been critically reviewed (SEDA-23, 336) (36).

Among the many new developments in the communication of adverse events, the increasing role of the Internet should be mentioned. Many national bodies (for example the FDA, Rockville, Maryland, USA, www.fda.gov, or the CDC, Atlanta, Georgia, USA, www.vaers.org) and intergovernmental health authorities

© 2006 Elsevier B.V. All rights reserved.

responsible for licensure of vaccines (for example the European Agency for the Evaluation of Medicinal Products (EMEA), www.eudra.org/emea.html), and/or vaccine safety (for example the World Health Organization, www.who.int/vaccines-diseases/safety/), as well as vaccine manufacturers (through postmarketing surveillance of their products, for example SmithKline Biologicals, www.worldwidevaccines.com), universities, and private organizations have also launched Websites providing information on vaccine safety and immunization risks.

National compensation programs for vaccine-related injuries

The need for some form of compensation when an individual is seriously injured by vaccination, particularly when the immunization has been compulsory or recommended by the health authority, has been accepted in many countries. Table 6 shows details of compensation programs in Canada (the province of Quebec), Denmark, France, Germany, Italy, Japan, New Zealand, Norway, Sweden, Switzerland, Taiwan, the UK, and the USA (37).

In the USA, the National Childhood Vaccine Injury Act of 1986 established the National Vaccine Injury Compensation Program as a federal no-fault compensation system for individuals who may have been injured by specific vaccines. This compensation program relies on a Vaccine Injury Table that lists the vaccines that are covered by the program, as well as injuries, disabilities, illnesses, and conditions (including death) for which compensation may be awarded. To better reflect current scientific knowledge about vaccine injuries, the Vaccine Injury Table was revised in 1995 and has been subsequently further modified. The latest modification, which became effective on December 1, 2004, is shown in Table 7. This revision took into account a review of the literature on specific adverse consequences of pertussis and rubella vaccines performed and published by the IOM (SED-12, 817) (SED-12, 825). In addition to the seven vaccines (diphtheria, pertussis, tetanus, measles, mumps, rubella, and poliomyelitis) included in the first Vaccine Injury Table, the 1997 revision includes hepatitis B, *Hemophilus influenzae* type b, and *Varicella* vaccines, as well as any future licensed vaccine recommended by the Advisory Committee on Immunization Practices (ACIP) for routine administration to children (38).

There are other compensation programs, for example in Japan, where the program covers damage caused by compulsory immunizations; provisions include medical allowance, care giver's allowance, disability pension, and a funeral grant; a national expert committee reviews applications.

Although not focusing primarily on vaccine-induced injury, attention should be paid to a contribution to the field of liability for drug-induced disease (39).

On December 1, 2004, the Secretary published a notice in the Federal Register announcing the addition of hepatitis A vaccines to the Vaccine Injury Table under Category XIV with an effective date of December 1, 2004.

The balance of benefits and harms in immunization

The risks of adverse effects after immunization against diphtheria, pertussis, tetanus, poliomyelitis, measles, and tuberculosis have been discussed in the framework of the WHO Expanded Program on Immunization and compared with the complication rate following natural disease (40). Table 8 presents a comparison of the estimated risks of adverse reactions after DTP immunization with the complication rates of natural whooping cough, while Table 9 shows a similar comparison for measles immunization and natural measles. The authors concluded that no vaccine is without adverse effects, but that the risks of serious complications from vaccines used in WHO's Expanded Program on Immunization are much lower than the risks from the natural disease.

Bioterrorism and prevention through immunization

Anthrax

Human anthrax is endemic in agricultural regions of the world where animal anthrax is common; sporadic cases occur in industrialized countries. Cutaneous, intestinal, and pulmonary anthrax can be distinguished clinically. Untreated cutaneous anthrax has a case fatality rate of 5–10%; death occurs only rarely in properly treated patients. Intestinal and pulmonary anthrax have much higher case fatality rates, even in properly treated patients. Transmission from person to person is very rare. Recently, anthrax has been considered a leading potential agent in bioterrorism. As was first demonstrated in 1979 at Sverdlovsk, USSR (an environmental accident in a biological weapon manufacturing facility), inhalational anthrax accounts for most of the cases and for all deaths following the use of anthrax as an aerosolized biological weapon (41).

In 2001, the first bioterrorist anthrax attack occurred in the USA. From 3 October 2001 to 21 November 2001, the CDC had received reports of 23 human cases of anthrax, 18 confirmed and five suspected. There were five deaths from pulmonary anthrax (42).

Three human vaccines against anthrax are currently available commercially (produced in the UK, the USA, and Russia). Two are inactivated cell-free products, whereas the Russian product contains a live attenuated vaccine. Current vaccine supplies are limited; however, even if enough vaccine were available, mass immunization would not be recommended. Immunization could be considered for essential service personnel and, following a terroristic attack, would be combined with an antibiotic to protect against residual retained spores. In 1970, an anthrax vaccine, derived from a sterile filtrate of an avirulent non-encapsulated strain of *Bacillus anthracis* and adsorbed on to aluminium hydroxide, was licensed by the FDA to protect people who might be exposed to anthrax. The ACIP has recommended immunization with this vaccine for people working with *B. anthracis* in the laboratory, those working with imported animal hides or furs in conditions that are inadequate to prevent exposure to anthrax spores, and military personnel deployed to areas with high risk for exposure. The vaccine was used to protect military personnel during the 1991 Gulf War.

Table 7 National Childhood Vaccine Injury Act: Vaccine Injury Table

Vaccine	Illness, disability, injury, or condition covered	Time interval
I. Vaccines containing tetanus toxoid (for example DTaP, DTP-Hib, DT, Td, or TT)	A. Anaphylaxis	0–4 hours
	B. Brachial neuritis	2–28 days
	C. Any acute complication or sequel (including death) of the above events	Not applicable
II. Pertussis antigen-containing vaccines (for example DTaP, DTP, P, DTP-Hib)	A. Anaphylaxis or anaphylactic shock	0–4 hours
	B. Encephalopathy (or encephalitis)	0–72 hours
	C. Any acute complication or sequel (including death) of the above events	Not applicable
III. Vaccines containing measles, mumps, and rubella viruses in any combination (for example MMR, MR, M, R)	A. Anaphylaxis or anaphylactic shock	0–4 hours
	B. Encephalopathy (or encephalitis)	5–15 days
	C. Any acute complication or sequel (including death) of the above events	Not applicable
IV. Vaccines containing rubella virus (for example MMR, MR, R)	A. Chronic arthritis	7–42 days
	B. Any acute complication or sequel (including death) of the above event	Not applicable
V. Vaccines containing measles virus (for example MMR, MR, M)	A. Thrombocytopenic purpura	7–30 days
	B. Vaccine-strain measles viral infection in an immunodeficient recipient	0–6 months
	C. Any acute complication or sequel (including death) of the above events	Not applicable
VI. Vaccines containing live oral polio virus (OPV)	A. Paralytic polio	
	in a non-immunodeficient recipient	
	in an immunodeficient recipient	0–30 days
	in a vaccine associated community case	0–6 months
	B. Vaccine-strain polio viral infection	Not applicable
	in a non-immunodeficient recipient	
	in an immunodeficient recipient	0–30 days
	in a vaccine associated community case	0–6 months
	C. Any acute complication or sequela (including death) of the above events	Not applicable Not applicable
VII. Vaccines containing polio inactivated virus (for example IPV)	A. Anaphylaxis or anaphylactic shock	0–4 hours
	B. Any acute complication or sequela (including death) of the above event	Not applicable
VIII. Hepatitis B antigen-containing vaccines	A. Anaphylaxis or anaphylactic shock	0–4 hours
	B. Any acute complication or sequel (including death) of the above event	Not applicable
IX. *Hemophilus influenzae* type b polysaccharide conjugate vaccines	No condition specified for compensation	Not applicable
X. Varicella vaccine	No condition specified for compensation	Not applicable
XI. Rotavirus vaccine	No condition specified for compensation	Not applicable
XII. Vaccines containing live, oral, rhesus-based rotavirus	A. Intussusception	0–30 days
	B. Any acute complication or sequel (including death) of the above event	Not applicable
XIII. Pneumococcal conjugate vaccines	No condition specified for compensation	Not applicable
XIV. Any new vaccine recommended by the Centers for Disease Control and Prevention for routine administration to children, after publication of a notice of coverage by the Secretary of the HHS	No condition specified for compensation	Not applicable

Although it has a safety record based on clinical trials carried out in the 1950s and 1960s and on the experience of over 30 years of use by thousands of military personnel, woolworkers, and veterinarians (43,44), the debate over its safety has come to the forefront in recent years, including the hypothesis of an alleged link between anthrax vaccine and disease reported by military personnel after the 1991 Gulf War. As a result of this concern, Congress ordered an in-depth investigation into the safety of the anthrax vaccine. The IOM was asked to initiate a comprehensive study and to report on the safety and efficacy of the vaccine in an effort to answer the questions raised by Congress, the Department of Defense, and the public. Because of immediate concerns over anthrax vaccine safety issues, the IOM provided on 30 March 2000 a letter report to the Department of

Table 8 A comparison of the estimated risks of adverse reactions after DTP immunization with the complication rates of natural whooping cough

Adverse reaction	Whooping cough complication rates per 100 000 cases	DTP vaccine adverse reaction rates per 100 000 immunizations
Permanent brain damage	600–2000 (0.6–2.0%)	0.2–0.6
Death	100–400 (0.1–4.0%)	0.2
Encephalopathy/ encephalitis*	90–4000 (0.09–4.0%)	0.1–3.0
Convulsions	600–8000 (0.6–8.0%)	0.3–90
Shock		0.5–30

*Including seizures, focal neurological signs, coma, and Reye's syndrome

Defense, summarizing the Institute's literature review on the safety of anthrax vaccine, prepared by its Committee on Health Effects Associated with Exposures during the Gulf War (45). The committee evaluated primary peer-reviewed literature and did not draw conclusions from secondary literature. It considered that there have been only a few published peer-reviewed studies of the safety of the anthrax vaccine in humans, and only one published series of studies discussed the long-term follow-up of individuals who received multiple vaccines including the anthrax vaccine. The committee concluded that (a) published studies have reported no significant adverse effects of the vaccine, but the literature is limited to a few short-term studies and (b) in peer-reviewed publications there is inadequate/insufficient evidence to determine whether there is or is not an association between anthrax immunization and long-term adverse health outcomes. The committee considered the findings and conclusions as an early step in the complex process of understanding the vaccine's safety, which began with its licensure in 1970 and includes the 1985 FDA advisory panel's finding that categorized the anthrax vaccine as safe and effective. The committee included in its evaluation the results of the VAERS, and considered the VAERS data as being useful as a sentinel for adverse events but of limited value for assessing the rate of causality of adverse events. The VAERS data are as follows:

(a) From 1 January 1990 to 31 August 2000, 1544 adverse events after anthrax immunization (nearly 2 million doses administered) were reported to VAERS.
(b) The most frequently reported adverse events were local reactions (864 reports).
(c) Other reports included headache (239 reports), arthralgia (232 reports), weakness (215 reports), pruritus (212 reports), and a few other systemic reactions.
(d) There were 76 (5%) serious adverse events (death or life-threatening disease, hospitalization, permanent disability); based on autopsy results, one of two reported deaths was due to aplastic anemia and the other was due to coronary arteritis (46).

- A 34-year-old man reported mild tenderness at the injection site after the first dose of anthrax vaccine; after the second dose he felt sweaty and weak and was pale; 20 hours after the third dose he had a life-threatening anaphylactic reaction (dyspnea, sweating, pallor, and urticarial wheals on the face, arms, and torso). After intensive care measures all his symptoms and signs resolved (47).

In 1997 manufacturers in South Korea started to develop a new anthrax vaccine. However, it will take a few years more to put the vaccine to practical use (42).

Botulism

Worldwide, sporadic cases and limited outbreaks of botulism can occur when food and food products are prepared or preserved by improper methods that do not destroy the spores of *Clostridium botulinum* and permit the formation of botulinum toxin. In industrially developed countries, the case fatality rate of food-borne botulism is 5–10%. Person-to-person transmission of botulism is not known. Botulinum toxin is the most poisonous substance known and poses a major bioweapon threat. In addition to the clinical forms of natural botulism (food-borne, wound, and intestinal), there is a fourth, man-made form of inhalational botulism that results from aerosolized botulinum toxin.

A pentavalent botulinum toxoid (botulinum toxin in different antigenic types) has been used for more than 30 years in some countries to prevent the disease in laboratory workers and to protect troops against attack. Pre-exposure immunization for the general population is neither feasible nor desirable; the vaccine is ineffective for postexposure prophylaxis. Treatment of botulism consists of passive immunization and supportive care. Most licensed antitoxins contain antibodies against the most common toxin types A, B, and E. About 9% of recipients of equine antitoxin developed urticaria, serum sickness, or other hypersensitivity reactions. In 2% of recipients anaphylaxis occurred within 10 minutes of antitoxin

Table 9 A comparison of the estimated risks of adverse reactions after measles immunization with the complication rates of natural measles

Adverse reaction	Measles complication rates per 100 000 cases	Adverse reaction rates per 100 000 vaccines	Background illness rate per 100 000
Encephalopathy/encephalitis	50–400 (0.05–0.4%)	0.1	0.1–0.3
Subacute sclerosing panencephalitis	500–2000 (0.5–2.0%)	0.05–0.1	—
Pneumonia	3800–7300 (3.8–7.3%)	—	—
Convulsions	500–1000 (0.5–1.0%)	0.02–190	30
Death	10–10 000 (0.01–10%)	0.02–0.3	—

administration. Before administering antitoxin the patient should be screened for hypersensitivity (48).

Plague

The large plague pandemics (the Justinian plague in the 6th century and pandemics in the 14th–15th centuries and 19th century) killed millions of people worldwide and were feared as the Black Death, a term that was actually not introduced until Victorian times. There is evidence that all three plagues were caused by the same variant of the plague bacterium, *Yersinia pestis*, var Orientalis (49). Progress in hygiene, public health, and antibiotic therapy make future pandemics improbable.

Wild rodent plague still exists in many parts of the world, including areas of Africa, Latin America, Asia, South-Eastern Europe, and the Western half of the USA. Domestic pets, for example house cats and dogs, can bring infected wild rodent fleas into homes, and the bite of infected fleas can result in human disease. Bubonic, pulmonary, and septicemic plague are life-threatening diseases with very high case fatality rates in untreated patients and in patients in whom treatment is delayed. Pneumonic plague is highly communicable, particularly in overcrowded facilities.

The potential use of *Y. pestis*, the causative agent of plague, as a biological weapon is of great concern. A killed whole bacillus plague vaccine (limited data on reactogenicity; see SED-14, 1086) is no longer available in the USA. This killed vaccine was efficacious in preventing or ameliorating bubonic plague but was ineffective against primary pneumonic plague. A live plague vaccine is manufactured in Russia, but no data on its efficacy and safety are available. Recommendations for antibiotic therapy of plague are available (50).

Smallpox

The last natural case of smallpox occurred in 1977 in Somalia. Because of the success of worldwide coordinated efforts, particularly the use of smallpox vaccine, natural smallpox has been eradicated. In 1989, the WHO declared the global eradication of this dangerous and often deadly disease (the case fatality rate in non-immunized patients was 20–40%). During natural smallpox outbreaks the secondary attack rate in non-immunized contacts was about 50%.

The smallpox virus belongs to the limited number of organisms that could be used as a biological weapon, causing one of the most serious diseases. There is no causal treatment of smallpox available. Immunization is the most effective measure for pre-exposure prevention and postexposure infection control. However, there were severe complications associated with the use of the old vaccines: encephalitis (mainly in primary vaccines; sometimes fatal or causing permanent neurological sequelae), progressive vaccinia (in both primary and secondary vaccinees), eczema vaccinatum (in vaccinees with either active or healed eczema), and generalized vaccinia resulting from viremia.

With the global eradication of smallpox, smallpox immunization was stopped in all countries of the world, and complications of smallpox vaccination became largely of historical interest. However, recently, the threat of bioterrorism has made it necessary again to consider immunization strategies and the potential hazards of immunization. The old vaccine used for prevention of smallpox contained vaccinia virus strains grown on scarified calves. Some countries and manufacturers have retained limited stocks of vaccine, and the WHO has 500 000 doses. However, there is no reserve large enough to meet more than very limited potential emergency needs (51). Strategies for smallpox immunization in emergencies have been elaborated, focusing on priority immunization of individuals at greatest risk and immunization to contain outbreaks (52). However, the old smallpox vaccine hardly meets modern safety requirements. Therefore, the development and licensure of a modern tissue cell culture vaccine and the establishment of new vaccine production facilities is necessary. Various manufacturers have initiated such developments. A British biotechnology company announced its intention to begin clinical trials on immunogenicity and reactogenicity of a newly developed tissue culture smallpox vaccine in early 2002 (53).

Tularemia

Tularemia is a zoonotic bacterial disease that occurs in North America, China, Japan, parts of Europe, and parts of the former USSR. Various wild animals are the reservoir of the causative agent, *Francisella tularensis*, which is transmitted through the bite of arthropods, including ticks and mosquitoes, by eating insufficiently cooked meat, by drinking contaminated water, or by inhalation of dust from a contaminated environment. Clinically, an ulceroglandular type can be distinguished from an oropharyngeal type; inhalation of infectious material can be followed by pneumonia or septicemia, with a 30–60% case fatality rate in untreated patients. Person-to-person transmission of tularemia is not known.

Francisella tularensis is considered to be a dangerous potential biological weapon. Live tularemia vaccines have been developed and used in the USSR (to protect millions of persons in endemic areas) and the USA (as an investigational vaccine to protect laboratory workers). After the administration of the US vaccine, symptoms of ulceroglandular disease were considered milder; however, the vaccine did not protect all recipients against aerosol challenge with *F. tularensis*. The live vaccine is currently under review by the US Food and Drug Administration (FDA), and its future availability is undetermined. Taking into account the short incubation period of tularemia and incomplete protection through immunization with the current live vaccine, post-exposure immunization is not recommended. Treatment with antibiotics is recommended (54).

General adverse effects after immunization

The reports of the Institute of Medicine, National Academy of Sciences, Washington (on adverse events after pertussis and rubella immunization (SED-12, 817) (SED-12, 825) and on adverse events after immunization against tetanus, diphtheria, measles, mumps, poliomyelitis, *H. influenzae* type b, and hepatitis B (SEDA-18, 325) have provided useful reviews (13,14). The 1996 "Update on vaccine side effects, adverse reactions, contraindications,

© 2006 Elsevier B.V. All rights reserved.

and precautions" elaborated and published by the US Advisory Committee on Immunization Practices includes summarized conclusions of evidence for possible associations between specific adverse effects and childhood vaccines (Table 10 and Table 11). The conclusions are based on the reports of the IOM mentioned above (55). The respective chapters of "Vaccines" (56) also provide useful information on adverse effects and immunization risks.

General risks of multiple immunizations

Some parents, particularly in industrialized countries, believe that infants get more vaccines than are good for them, and they fear that too many immunizations could overwhelm the infant's immune system. However, the actual number of antigens that children receive in the USA (the schedule includes 11 vaccines) or in some Western European countries (on average 9 vaccines) has declined when compared with immunization programs used during the 1960s or 1980s. Whereas smallpox vaccine contained about 200 proteins, the current routinely recommended vaccines for children in countries in which whole-cell pertussis vaccine was replaced by acellular pertussis vaccine (for example Austria, Germany, Japan, the Scandinavian countries, the USA) contain a total of 50–125 proteins and polysaccharides. The replacement of whole-cell pertussis vaccine by acellular pertussis vaccine reduced the content of immunogenic proteins and polysaccharides from about 3000 to a range of 2-5. (Table 12) (57).

If vaccines overwhelmed the immune system, smaller immune responses would be expected. However, the authors of many carefully designed studies have concluded that there is no evidence that adding vaccines to combination products increases the burden on the immune system. Young infants have a large capacity to respond to multiple vaccines, as well as to many other environmental challenges. Increased reactogenicity after the receipt of combination vaccines has not been a major issue. Combining antigens usually does not increase the risk of adverse effects, and can actually lead to an overall reduction in the numbers of adverse events (58) despite public concern (59).

The Safety Review Committee of the IOM has reviewed the evidence regarding multiple immunizations and immune dysfunction (60). The review did not support the hypothesis that an infant's immune system is inherently incapable of handling the number of antigens to which children in the USA are exposed during routine immunizations. The committee rejected a causal relation between multiple immunizations and increased risks of infections or type 1 diabetes mellitus. The evidence was inadequate to accept or reject a causal relation between multiple immunizations and allergic disease, particularly asthma.

Organs and Systems

Respiratory

There is a hypothesis that the seeds of immune system problems, perhaps including asthma, may be sown in the early weeks of life and activated later by immunization. However, studies have given inconsistent results. A randomized controlled trial showed no effect of pertussis vaccine on the risk of asthma (61), which was suggested by a cohort study (62). A British cohort study also showed no association between immunization and wheeze, but there was a lower risk of eczema (63). Data from the Christchurch Health and Development Study showed a link between immunization and asthma (64). However, the findings were based on only 23 children who had not received DTP or polio vaccine. There was no effect from measles vaccine. This is somewhat in contrast to data from Africa suggesting that measles may protect against asthma (SEDA-21, 323).

Nervous system

Guillain–Barré syndrome

Many drugs and vaccines are associated with Guillain–Barré syndrome. However, a cause-and-effect relation has generally not been established. The issue has been reviewed (SEDA-21, 323).

Haemophilus influenzae

Guillain–Barré syndrome has occasionally been reported after immunization with a conjugate vaccine against *H. influenzae* type b. In one case there were immunoglobulin antibodies against the *H. influenzae* type b polysaccharide (PRP) component of the vaccine, with a high titer of anti-PRP IgM antibody (65).

Hepatitis

Guillain–Barré syndrome has been reported after the administration of plasma-derived hepatitis B vaccines. In the 3 years between 1 June 1982 and 31 May 1985, an estimated 850 000 people received a new plasma-derived hepatitis B vaccine (Heptavax-B, Merck Sharp and Dohme) and there were 41 reports of the following neurological adverse events: Bell's palsy ($n = 10$), Guillain–Barré syndrome ($n = 9$), convulsions ($n = 5$), lumbar radiculopathy ($n = 5$), optic neuritis ($n = 5$), transverse myelitis ($n = 4$), and brachial plexus neuropathy ($n = 3$) (66). Half occurred after the first of three doses. There were no deaths.

Guillain–Barré syndrome has also occasionally been reported after the administration of recombinant hepatitis B vaccines (67,68).

Influenza

Following the swine-flu immunization campaign in 1976/77 in the USA there was a significant increase in the incidence of Guillain–Barré syndrome in immunized versus non-immunized people, from 2.6 per million to 13.3 per million (69). Peak time of onset was 2–3 weeks after receiving the vaccine, and cases among vaccinees were less likely to have a history of antecedent infection than were cases in unvaccinated persons. Since 1977 the risk of influenza vaccine–induced syndrome appears to be the same as the risk in the non-immunized population.

Measles–mumps–rubella

Guillain–Barré syndrome has been reported to be associated with measles, mumps, and rubella immunization (70).

Polio

Following a mass immunization campaign against poliomyelitis in Finland (1984/85), an analysis based on hospital records covering a population of 1.17 million and 6 years showed a significantly increased incidence of Guillain–Barré syndrome coinciding with the campaign (71).

In a retrospective analysis of the incidence of Guillain–Barré syndrome in Finland in 1981–86 by examination of medical records identified from the nationwide Hospital Discharge Register, based on a population of 5 million people, 247 patients fulfilled the accepted criteria of Guillain–Barré syndrome corresponding to a mean annual incidence of 0.82 per 100 000 (72). Monthly rates showed an increased incidence of Guillain–Barré syndrome in March 1985, a few weeks after the start of the nationwide oral poliovirus vaccine campaign and partly overlapping it. However, the increase had begun just before the onset of the campaign and may have been due to wild-type 3 poliovirus in the population immediately before the campaign and could have been due to that rather than the administration of the oral poliovirus vaccine.

Rabies

Guillain–Barré syndrome was a well-known complication in the era of brain tissue rabies vaccines, and there have

© 2006 Elsevier B.V. All rights reserved.

been a few cases associated with the use of human diploid cell rabies vaccines (73,74).

Tetanus and diphtheria
Tetanus and diphtheria toxoid vaccines are reportedly associated with polyradiculitis, polyneuritis, and mononeuritis (75–77).

Immunization and multiple sclerosis (encephalitis disseminata)
The possible relation between immunization and an attack of encephalitis disseminata has been investigated in an analysis of 16 confirmed cases and 24 suspected cases in connection with the distribution of approximately 100 million doses of vaccines manufactured by Behringwerke (1980–89) (78). The data did not support an increased risk of initial manifestation of encephalitis disseminata or of renewed attacks in patients with preexisting disease.

Studies of the role of influenza or influenza immunization in multiple sclerosis have been reviewed by Jeffery (79). He considers that in patients with multiple sclerosis and advanced disability influenza can constitute a life-threatening illness. Even in patients who have minimal disability, severe influenza can be followed by secondary bacterial infection. The risk of relapse after influenza may be as high as 33%, whereas the risk of relapse after influenza immunization appears to be negligible. The only exception to the general rule that influenza immunization is beneficial for patients with multiple sclerosis is in patients with rapidly evolving neurological deficits due to active disease, in whom immunization should be withheld pending treatment with high-dose glucocorticoids to suppress inflammation or stabilization through immunomodulatory treatment. In the absence of active disease, Jeffery strongly recommends influenza immunization for patients with multiple sclerosis. Regarding hepatitis B immunization and multiple sclerosis, Jeffery recommends hepatitis B immunization only for patients with multiple sclerosis at high risk of hepatitis B infection. If a high-risk patient has active multiple sclerosis, immunization should be withheld until the disease activity has been adequately treated. With regard to other immunizations, Jeffery has made similar recommendations: immunization should be postponed if a patient with multiple sclerosis shows disease activity.

Musculoskeletal

A child with fibrodysplasia ossificans progressiva developed permanent heterotopic ossification at the injection site after intramuscular DTP immunization (80). The authors considered that intramuscular injections in children with fibrodysplasia ossificans progressiva were potentially risky, but that subcutaneous injections could be carried out.

Immunologic

The questions of whether early childhood immunization affects the development of atopy and whether it causes allergic reactions have been reviewed (81). The authors concluded that immunization programs do not explain the increasing incidence of allergic diseases, but that individual children may uncommonly develop an allergic reaction to a vaccine.

Non-sterile injection equipment can transmit HIV and other infectious agents, including hepatitis viruses. There is also a possibility of needle transmission from an HIV-infected person to a vaccinator. Data from the USA show that the risk of transmission of HIV through needle stick is very low, perhaps 20 times lower than in the case of hepatitis B, and in the order of one per 100 accidents. Furthermore, the types of injections given during immunization sessions do not as a rule cause bleeding. The risk of transmission is thus extremely low. No instances of immunization-related spread of HIV to other infants have been reported, and if proper sterilization of needles and syringes is performed and vaccines are administered correctly the risk of HIV transmission is zero (82). However, the use of unsterilized or improperly sterilized needles and syringes is common, particularly in many developing countries, and contributes largely to the spread of hepatitis B and C, as well to the spread of human immunodeficiency virus and other blood-borne pathogens. These risks are recognized by the WHO as major public health problems and led the Organization to initiate a broad program of activities to ensure safe injection techniques (1). The guidelines published by WHO and UNICEF in 1986/87 (83,84), which can be set out briefly as follows, are still valid. Essentially they state that:

(a) a single sterile needle and a single sterile syringe should be used with each injection;
(b) reusable needles and syringes are recommended for use in developing countries; they should be steam-sterilized between uses; boiling is an acceptable alternative procedure when steam sterilization is not available;
(c) disposable needles and syringes should only be used if an assurance can be obtained that they will be destroyed after a single use;
(d) disease transmission by use of jet injectors is theoretically possible and has been demonstrated in human beings in a single situation (SEDA-11, 296); until further studies clarify the risks of disease transmission with different types of injectors, their use should be restricted to special circumstances in which large numbers of persons need to be immunized within a short period of time.

Jet-gun-associated infections
The first outbreak of a disease in which a jet injector was implicated as the vehicle of transmission has been reported. Thirty-one attendees at a weight-reduction clinic in Southern California experienced hepatitis B after daily parenteral injections of human chorionic gonadotrophin given by jet injectors; transmission appeared to have resulted from the multiple repeated jet injections (85). WHO and UNICEF have stated in their "Guidelines for selecting injection equipment for the Expanded Program on Immunization" that the use of jet injectors should be restricted to circumstances in which reusable or disposable equipment is not feasible because of the large number of persons to be immunized within a short period of time (83).

© 2006 Elsevier B.V. All rights reserved.

A new type of needleless jet-injector (Mini-Imojet) administers liquid vaccines from a single-use, prefilled cartridge ("imule"), thereby avoiding the risk of cross-contamination. Administration of various vaccines by jet-injector has been compared with standard syringe technique. All the jet-administered vaccines were of equivalent or superior immunogenicity. The most common reactions were mild (minor bleeding, superficial papules, erythema, induration). The technical and safety advantages of the Mini-Imojet reinforce the potential use of this technique for mass immunization (86).

Mixed bacterial vaccines

Starting in the 1920s, very many different mixed bacterial vaccine products (including inactivated bacteria such as *Staphylococcus aureus*, *Streptococcus* species, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Klebsiella pneumoniae*, *H. influenzae*) were marketed worldwide. Currently, there are still several products available in European countries, and one product in the USA. Most vaccines have been used for treatment of recurrent and chronic infections of the respiratory tract. The efficacy of these products is doubtful. Delayed hypersensitivity to bacterial products is common. Delayed reactions, sometimes associated with vague malaise or myalgia, can occur after the administration of maintenance doses for months. If delayed skin reactions are accompanied by any systemic symptoms, administration of the mixed vaccine should be drastically reduced or stopped (87).

Immunization and autoimmune disease

Autoimmunity is characterized by the development of one or several immune responses, directed against antigenic components of the host. The detection of antibodies against host antigens (autoantibodies) or autoreactive T cells does not indicate current or future disease, and autoimmunity does not always result in autoimmune disease. An autoimmune disease results from autoimmunity when autoantibodies or autoreactive T cells reach the corresponding antigen in a target organ and become pathogenic, or when autoantibodies form pathogenic immune complexes with antigens released from host cells. An autoimmune disease can be clinically silent for months or years before the destruction of the tissues involved leads to clinical symptoms, for example the appearance of type 1 diabetes following the autoimmune destruction of pancreatic islets.

As many as 5% of individuals in Europe and North America have some form of autoimmune disease. There is clear evidence that genetic predisposition is necessary for the development of some autoimmune diseases. In genetically predisposed individuals an infection can induce or trigger an autoimmune disease. Of the many potential environmental factors, infections are the most likely cause. The causal linkage between some infections and autoimmune diseases has raised the question as to whether autoimmune diseases might also be triggered by vaccines (88).

Autoimmune diseases include autoimmune thrombocytopenia, Graves' disease, hemolytic anemia, Hashimoto's thyroiditis, insulin-dependent diabetes mellitus (diabetes type 1), multiple sclerosis, myasthenia gravis, rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, and Reiter's syndrome (88–90).

The number of publications that include claims and counterclaims about the risk of autoimmune diseases after immunization is increasing. However, only in rare instances has evidence established a causal relation or favored acceptance of a causal relation:

(a) Rabies vaccine produced in rabbit nervous tissue caused acute disseminated encephalomyelitis in some immunized individuals (91).
(b) During the US swine flu immunization campaign (1976–77) immunized individuals had a much higher risk of Guillain–Barré syndrome than non-immunized individuals (relative risk 7.60); currently, the risk of Guillain–Barré syndrome after immunization (one additional case per million people immunized) is estimated to be substantially lower than the risk of severe influenza and its complications (92).
(c) Idiopathic thrombocytopenia can occur after MMR immunization (about one case in 30 000 immunized children); however, the risks of thrombocytopenia after natural measles or rubella are respectively five and 10 times higher (88,93).

For other potential association between vaccines and autoimmune diseases, the evidence favors rejection of a causal relation:

(a) hepatitis B vaccine and multiple sclerosis (SEDA-24, 374) (SEDA-25, 386);
(b) vaccines and diabetes mellitus (94,95);
(c) Lyme disease vaccine and a treatment-resistant form of autoimmune arthritis; however, owing to public misperception and the promotion of false concerns about its safety, the demand for Lyme disease vaccine did not reach a sustainable level and the manufacturer withdrew it (SEDA-24, 366) (SEDA-26, 357).

How to assess a potential link between a vaccine and an autoimmune condition

Careful epidemiological studies should be the basis of conclusions about an association between a specific vaccine and a particular autoimmune disease. Wraith and colleagues took into account WHO recommendations for the assessment of adverse events after immunization and established the following four basic principles that apply to autoimmune diseases:

1. consistency of findings in various studies;
2. strength (in an epidemiological sense);
3. specificity;
4. temporal relation (95).

Death

Sudden infant death syndrome and multiple immunizations

Current recommendations call for infants and very young children to receive multiple doses of vaccines during their first year of life, and since SIDS is the most frequent cause of death in highly developed countries during that early period of life, it is important to take into account concerns

© 2006 Elsevier B.V. All rights reserved.

that multiple immunization might play a role in SIDS. SIDS is the diagnosis most commonly used to explain unexpected sudden death of uncertain cause occurring mainly in infancy at 2–7 months of life, sometimes later. By definition, the cause or causes of SIDS are unknown, but risk factors (for example maternal characteristics, prenatal factors, and postnatal conditions, including the infant's sleeping position) have been identified. The results of the most comprehensive analysis "Vaccinations and sudden unexpected death in infancy" have been provided by the Immunization Safety Review Committee of the IOM (96). The committee reviewed an extensive collection of material, primarily from published peer-reviewed scientific and medical literature. The causality conclusions of the committee were as follows:

(a) The evidence favors rejection of a causal relation between exposure to multiple vaccines and SIDS.
(b) The evidence favors acceptance of a causal relation between diphtheria toxoid and whole cell pertussis vaccine and death due to anaphylaxis in infants; however, anaphylaxis of infants following vaccination is very rare, and a fatal outcome is extremely rare.
(c) The committee has not recommended a policy review of the recommended (US) childhood immunization schedule on the basis of concerns about SIDS.

The committee also noted that there are studies that show that vaccinated infants are at a reduced risk of SIDS (96,97).

Susceptibility Factors

It is well known that immune deficiency can play a distinct role in the development of adverse effects after immunization, particularly in connection with the administration of live virus vaccines. The first such experience was with smallpox vaccine; people with immune defects had a markedly increased risk of complications, for example generalized vaccinia. Disseminated BCG infection is usually associated with severe abnormalities of cellular immunity. The risk of vaccine-associated poliomyelitis is increased in immunodeficient children. There have been several reports of adverse events or death after measles immunization in immunodeficient children. Based on these experiences, there is a general consensus that live vaccines should not be given to people with immune deficiency diseases or to those whose immune response is suppressed because of leukemia, lymphoma, generalized malignancy, or therapy with glucocorticoids, alkylating agents, antimetabolites, or radiation (SEDA-12, 268).

Various studies in both symptomatic and asymptomatic HIV-infected individuals have failed to show any special sensitivity to adverse effects after other immunizations, for example in children receiving live oral or inactivated polio vaccine, DPT or DT vaccine, or measles vaccine (98–101).

Recommendations by the US ACIP, WHO's Global Programme on Immunization, and the European Advisory Group on Expanded Program on Immunization have all been published in detail (SEDA-12, 270) (SEDA-13, 273). Based on the recommendations elaborated by WHO and ACIP, similar recommendations have been prepared in other countries. WHO recommends that non-immunized individuals with symptomatic HIV infection should not receive BCG, but should receive the other vaccines; whereas ACIP recommends that children with symptomatic HIV infection should not receive live virus or live bacterial vaccines. Taking into account the hazard of measles in children with AIDS and HIV-infection, ACIP additionally recommends measles vaccine for all (both symptomatic and asymptomatic) HIV-infected children.

Drug Administration

Drug additives

Thiomersal

Thiomersal (see the monograph on Mercury and mercurial salts) has been used as an additive to biologics and vaccinessince the 1930s because it is very effective in killing bacteria used in several vaccines and in preventing bacterial contamination, particularly in opened multidose containers. Some but not all vaccines contain thiomersal. Billions of children and adults have been immunized worldwide and there is no scientific data that thiomersal-containing products have caused problems of toxicity in humans. The main causes of concern with thiomersal are allergic reactions and the potential risk of neurotoxicity. The WHO has recommended a Permissible Total Weekly Intake (PTWI) of 200 μg for non-pregnant adults. Owing to the vulnerability of the developing brain, the PTWI for pregnant women and infants should be lower, but there is currently no international recommendation for maximum intake in infants. Considering the thiomersal content of some vaccines, intake of mercury in infants can exceed that which could be considered safe. The US Public Health Service, the American Academy of Pediatrics, and US vaccine manufacturers are in agreement that thiomersal should be eliminated from vaccine manufacture as soon as possible. Similar conclusions were reached in 1999 in a meeting attended by the European vaccine manufacturers, European regulatory agencies, and the FDA. Already, many new vaccines are thiomersal-free and the manufacturers are committed to the target of reducing as much as possible the thiomersal content in all vaccines. However, given that the known risks of not immunizing children far outweigh the unknown and much smaller risk of thiomersal, clinicians and parents are encouraged to continue immunizing all infants with the currently available vaccines despite their thiomersal content (102).

Questions and answers on thiomersal have been provided by the WHO, which has underlined the fact that the risk of adverse effects of thiomersal is theoretical, uncertain, and at most extremely small (103). However, the WHO aims to replace thiomersal with other preservatives in the long term. Combination vaccines can reduce the amount of mercury to an absolute minimum.

In 2001 the Immunization Safety Review Committee of the Institute of Medicine issued a report on thiomersal-containing vaccines and neurodevelopmental disorders (104). "The committee concluded that although the hypothesis that exposure to thiomersal-containing

© 2006 Elsevier B.V. All rights reserved.

vaccines could be associated with neurodevelopmental disorders is not established and rests on indirect and incomplete information, primarily from analogies with methylmercury and levels of maximum mercury exposure from vaccines given in children, the hypothesis is biologically plausible. . . . [However,] the evidence is inadequate to accept or reject a causal relationship between thiomersal exposure from childhood vaccines and the neurodevelopmental disorders of autism, attention deficit/hyperactivity disorder, and speech or language delay." Hypersensitivity to thiomersal is a contraindication to immunization (105).

Vaccine adjuvants

A vaccine adjuvant is defined as an agent that increases specific immune responses to an antigen (106). The only vaccine adjuvants currently licensed by the FDA are aluminum salts. All other adjuvants are considered experimental and must undergo special preclinical testing. Real and theoretical risks of vaccine adjuvants comprise various local acute or chronic inflammation with formation of abscesses and nodules; induction of hypersensitivity to the host's own tissues, producing autoimmune arthritis, amyloidosis, anterior uveitis; cross-reactions with human antigens, such as glomerular basement membranes or neurolemma, causing glomerulonephritis or meningoencephalomyelitis; sensitization to tuberculin or to other skin test antigens; carcinogenesis; pyogenesis; teratogenesis; abortion; and adverse pharmacological effects, such as hypoglycemia.

Drug contamination

Since the problem of bovine spongiform encephalitis (BSE) emerged in Europe around 1987, the WHO and ministries of health have been alert to the danger that BSE-contaminated materials might be used in biological products, including vaccines. Guidelines were created that ensured that when bovine materials were needed in a biological product, the materials were obtained from countries that were free from BSE. Bovine products are used in the production of certain vaccines, in creating seed lots, or in amplifying the seed lot into working lots. The material is generally calf serum, which, even if it came from an infected animal, is extremely unlikely to transmit the prions that cause the disease. An exceptional situation arose on 20 October 2000, when the UK withdrew one manufacturer's OPV because of the possibility that the vaccine had been manufactured using serum from calves that were from a BSE-infected country. Even though the risk was extremely remote, the health authorities decided to have the vaccine withdrawn. This particular product was not the main OPV used in the UK. To clarify the situation in the UK and to reassure countries throughout the world that there were no implications for OPV used in the eradication of poliomyelitis, the WHO issued the following position statement (107): "On 20 October 2000, Evans/Medeva Oral Polio Vaccine (OPV), which to the knowledge of the World Health Organization has only been used in the United Kingdom and Republic of Ireland, was recalled in the UK. This vaccine has never been used in the immunization campaigns that are ongoing as part of the Global Polio Eradication Initiative. The recall was prompted by evidence that the Evans/Medeva vaccine was manufactured in contravention of European Union guidelines, and was not based on any adverse events related to the vaccine. The specific concern is that fetal bovine calf serum (FCS) from the UK was used in the manufacture of the Evans/Medeva vaccine, at a time when there was a risk of bovine spongiform encephalopathy (BSE) in that country. WHO endorses the recall step as a precaution, even though FCS is removed in the manufacturing process of the vaccine and there is no evidence that FCS could transmit BSE. Due to this breach of EU guidelines and acting on a precautionary basis, the Health Departments in the UK have withdrawn remaining shelf stocks of the Evans/Medeva brand of polio vaccine, which had already ceased production. The World Health Organization imposes strict production and quality controls to ensure the safety and efficacy of OPV. WHO recommends that manufacturers use the safest source of materials from countries which have not reported indigenous BSE cases and have a compulsory BSE notification system, compulsory clinical and laboratory verification of suspected cases and a surveillance program. The Global Polio Eradication Initiative only distributes vaccine supplied by vaccine manufacturers who follow National Control Authorities' criteria provided by WHO."

Two advisory committees of the US FDA, the Transmissible Spongiform Encephalopathies Advisory Committee and the Vaccines and Related Biologicals Product Advisory Committee, said at a joint meeting on 3 August 2000 that vaccines made from bovine-derived materials from countries with a known or uncertain risk of BSE carry only an infinitesimal risk of new variant Creutzfeldt–Jakob disease, and that no change in US immunization practice is indicated (Evans G, personal communication, 3 August 2000).

Vacuum devices

General Information

Vacuum tumescence constriction therapy is the use of an external device that creates a vacuum to cause penile erection, which is then maintained by a constriction band. It produces rigidity sufficient for intercourse in 91% of men, with satisfaction in 80%.

Adverse effects of this procedure have been reported (1): ecchymosis (37%), discomfort (28%), hematoma (10%), numbness (6.9%), penile skin irritation, and edema. Subcutaneous penile hematoma occurred in two patients using anticoagulants and penile gangrene occurred in one patient; all had worn the constriction band overnight (2). The current recommendation is to apply the constriction band for not more than 30 minutes.

- A 55-year-old African–American, tetraplegic after a motor vehicle accident in 1969, had been using an erection aid device for 4–5 years (3). He used the device, but forgot the constricting ring, which remained on overnight. The next morning his penis was markedly swollen and 2 days later he developed septicemia. He had a gangrenous penis and necrotizing fasciitis with a foul smelling discharge.

Vaginal tampons

General Information

A tampon is a pad made of cotton, cotton wool, sponge, or other materials, used in surgery for the control of hemorrhage or absorption of secretions. Vaginal tampons are widely used to absorb menstrual flow, and have been used to absorb disagreeable secretions in women with inflammatory diseases of the vagina or cervix and to administer drugs locally after operations (1). They have also been used to collect vaginal material for diagnostic purposes (2). Tampons containing miconazole have been used to treat vaginal candidiasis (3).

Toxic shock syndrome

Toxic shock syndrome is generally associated with the use by women of internal vaginal tampons, but does not occur solely in those circumstances. Two large clinical epidemiological studies (4,5) have contributed to an understanding of the conditions that lead to toxic shock syndrome. Of all patients with toxic shock syndrome, 95% were women; in 98% of cases it began during the menstrual period, and in 98% *Staphylococcus aureus* phage group 1 was isolated from the vaginal swab. In no case was the organism isolated from the blood. It is clear that shock was caused not by bacteremia but by an epidermal toxin. Only some 8% of healthy controls harbored *S. aureus* vaginally. The mortality rate of toxic shock syndrome is estimated to be 10–15% (6,7). Since contamination with staphylococci, vaginal and extravaginal, usually occurs without any clinical consequences, special attention has focused on the association with vaginal tampons. A particular brand (Rely) has been withdrawn from the market, but other brands have also been linked with the syndrome.

A number of surviving patients had several recurrences during subsequent menstrual periods (up to five), these events each being progressively less severe in their clinical course (8,9). Insertion of a contraceptive diaphragm can trigger the toxic shock syndrome, even at times other than during menstruation.

Pathogenesis

The pathogenesis of toxic shock syndrome is not well understood. The tampons are not contaminated, and they cannot be regarded as the direct cause of toxic shock syndrome; they are rather a trigger for the events that lead to the syndrome. A plausible explanation is that the toxin produced by *S. aureus* accumulates in the tampon and is absorbed either directly from the vagina or after reflux of menstrual blood through the fallopian tubes into the peritoneal cavity. In support of this, some cases have occurred in women who have left the tampon in situ for a long time (up to 3 days). It is unclear why the incidence of toxic shock syndrome has increased since 1978. Highly absorbent tampons may partly explain this, but that is not the only explanation. The toxic shock syndrome is likely to be the result of the coincidence of staphylococcus in the vagina and conditions favoring their growth or colonization, such as a tampon saturated with menstrual blood.

Incidence and susceptibility factors

The risk of toxic shock syndrome in association with vaginal tampons is small: 10–15 per 100 000 menstruating women per year. Poor hygiene (leaving tampons in situ for several days) is not the only cause; toxic shock syndrome has been described in women changing their tampons regularly. Women who have previously had febrile episodes during menstruation should use tampons with utmost restraint or abandon them in favour of external tampons.

Toxic shock syndrome has also been described in association with use of a vaginal contraceptive sponge; vaginal cultures grew *S. aureus* (10).

Women using contraception, either oral contraceptive pills or topical spermicides, appear to be at lower risk of developing toxic shock syndrome. A study of patients with toxic shock syndrome found only six spermicide users and eight oral contraception users, against 60 not using a contraceptive method (11). It has been suggested that an antibacterial effect of spermicidal ingredients prevents the intravaginal growth of *S. aureus*. The postulated protective action of oral contraceptives has been explained by reduced menstrual flow and duration, and an alteration in cervical mucus.

Valaciclovir

General Information

Valaciclovir is the L-valyl ester of aciclovir. After oral administration, it is rapidly and extensively converted to aciclovir by first-pass metabolism, resulting in plasma aciclovir concentrations previously only attainable with intravenous administration. Like aciclovir, valaciclovir is generally well tolerated. Compared with oral aciclovir, the systemic availability of aciclovir from oral valaciclovir is markedly improved.

Valaciclovir is highly active against *Herpes simplex* and *Herpes zoster*. It is also effective in suppressing recurrent episodes of genital herpes (1). Prophylactic administration of high doses of valaciclovir to prevent CMV disease was effective in patients with AIDS and in liver transplant recipients (2,3).

Observational studies

In a double-blind comparison of two regimens of valaciclovir 500 mg bd for recurrent genital herpes, a 5-day course ($n = 398$) and a 3-day course ($n = 402$), there were no significant differences in therapeutic outcome or adverse events between the two regimens (4). The most common adverse events were headache (10%), nausea (4%), diarrhea (3%), and fatigue (1.5%).

Comparative studies

The effects of aciclovir and valaciclovir for anogenital herpes have been studied in HIV-infected individuals in two controlled trials (5). In the first study, 1062 patients with CD4+ counts over 100×10^6/l received valaciclovir or aciclovir for 1 year and were assessed monthly. In the second study, 467 patients were treated episodically for at least 5 days with valaciclovir or aciclovir and were assessed daily. Valaciclovir was as effective as aciclovir for suppression and episodic treatment of herpesvirus infections. Hazard ratios for the time to recurrence with valaciclovir 500 mg bd and 1000 mg od compared with aciclovir were 0.73 (95% CI = 0.50, 1.06) and 1.31 (0.94, 1.82). Valaciclovir 1000 mg bd and aciclovir had similar effects on the duration of infective episodes (HR = 0.92; CI = 0.75, 1.14). The most common adverse events, which occurred at similar rates with all regimens, were diarrhea, headache, infections, rashes, nausea, rhinitis, pharyngitis, abdominal pain, fever, depression, and cough.

Placebo-controlled studies

In large, placebo-controlled comparisons of the efficacy of valaciclovir and aciclovir in treating or suppressing recurrent genital *Herpes simplex* infections in immunocompetent people, dosages up to 2 g/day were well tolerated, with safety profiles comparable to aciclovir (1,6). In a comparison of high-dose valaciclovir (8 g/day) with two doses of aciclovir (0.8 and 3.2 g/day) for prophylaxis of cytomegalovirus disease in patients with advanced human immunodeficiency virus infection, intention-to-treat analysis showed a trend toward earlier mortality in those who received valaciclovir. In those who actually received valaciclovir, survival was significantly shorter. In view of the unexplained trend toward earlier mortality, as well as higher frequencies of renal toxicity (see the section on Urinary tract) and premature treatment discontinuation, the authors concluded that the dose of valaciclovir was too high and that better tolerated doses, which maintain a protective effect on cytomegalovirus disease, need to be identified (2).

Organs and Systems

Nervous system

Valaciclovir is a prodrug of aciclovir and can therefore cause similar effects, as two cases of nervous system effects have demonstrated (7).

- A 65-year-old man was given valaciclovir 1 g bd for 36 hours and had reduced concentration and was incoherent. All investigations were normal or negative. He improved rapidly on withdrawal of valaciclovir.
- A 44-year-old man was given valaciclovir 1 g tds for 5 days and developed a fever, disorientation, confusion, ataxia, dysarthria, and photophobia. All investigations were normal or negative. He was given antimicrobial drugs, including aciclovir, but his symptoms did not improve until the aciclovir was withdrawn.

Elderly patients and people with chronic renal insufficiency are most susceptible to the neurotoxic effects of aciclovir: confusion, hallucinations, dizziness, irritability, ataxia, tremor, myoclonus, and seizures. The symptoms usually occur within 3 days of the start of therapy and resolve within 5 days after withdrawal. Plasma aciclovir concentrations do not correlate with symptoms. Lumbar puncture and CT scans of the head are essentially unremarkable. The most common electroencephalographic abnormality is diffuse generalized slowing of brain wave activity.

Psychological, psychiatric

At high doses (8 g/day) hallucinations and confusion were a significant concern (2,3), but similar symptoms have also occurred at lower doses and in patients with renal insufficiency.

- Ocular and auditory hallucinations have been reported in a 60-year-old female patient on CAPD (8).
- A 58-year-old man with chronic renal insufficiency, who was hemodialysed twice a week, was treated with valaciclovir (1 g tds) for *Herpes zoster* (9). Two days

© 2006 Elsevier B.V. All rights reserved.

later he became disoriented, dizzy, dysarthric, and experienced hallucinations. The serum aciclovir concentration was 21 μg/ml. Treatment was discontinued and he was treated with hemodialysis for 6 hours, resulting in marked clinical improvement. The next day his symptoms of dysarthria recurred, but immediately and completely resolved after a second hemodialysis.

Hematologic

In one study, high-dose valaciclovir was associated with an increased risk of a thrombotic microangiopathy-like syndrome, reported as thrombocytopenic purpura or hemolytic-uremic syndrome (2). This syndrome occurred in 14 of 523 patients who received valaciclovir and in only four of 704 patients who received aciclovir after a median of 54 (range 8–84) weeks of treatment. The precise relation to valaciclovir remains unclear, since eight of 14 patients who were treated with valaciclovir had stopped treatment at least 1 week before the onset of the syndrome. In addition, all patients with thrombotic microangiopathy-like syndromes had taken multiple concomitant medications, and most had other intercurrent illnesses, which could have explained the hematological and renal abnormalities. The authors concluded that additional data are required to understand the role of valaciclovir and other medications for thrombotic microangiopathy-like syndromes, which are recognized with increasing frequency in patients with advanced HIV disease.

Gastrointestinal

Nausea, vomiting, and abdominal pain were commonly reported in human volunteers, but only diarrhea was significantly associated with exposure (10).

Urinary tract

Aciclovir is excreted renally. High plasma concentrations of aciclovir can lead to precipitation in renal tubules, causing impaired renal function, which is generally reversible. Since oral valaciclovir can result in plasma aciclovir concentrations comparable to those attained with intravenous dosing, reversible impairment of renal function can also occur after prolonged use of high-dose valaciclovir. Indeed, in a study of high-dose valaciclovir for prevention of cytomegalovirus disease in HIV-infected people, there was an association between treatment with valaciclovir and moderate nephrotoxicity (serum creatinine more than 1.5 times the upper limit of normal; estimated creatinine clearance under 50 ml/minute) (2).

Second-Generation Effects

Fetotoxicity

In a phase I trial, valaciclovir administered in the third trimester of pregnancy was well tolerated (11).

Susceptibility Factors

Renal disease

Adverse effects of valaciclovir, the L-valyl ester of aciclovir, can be associated with increased drug concentrations when the dose is not adjusted for reduced renal function. For example, aseptic meningitis has been associated with valaciclovir in a patient with renal insufficiency (12).

- An 88-year-old man with renal insufficiency took valaciclovir 1000 mg tds. After the first dose, he became disoriented and incontinent. Valaciclovir was withdrawn, but the symptoms continued and progressed to drowsiness and nuchal rigidity. After an extensive work-up, aseptic meningitis was diagnosed.

Given the patient's age and renal dysfunction, it is likely that excessive valaciclovir accumulation was responsible for this presentation.

Drug–Drug Interactions

Cimetidine

In an open, single-dose study of the effects of probenecid and cimetidine on the pharmacokinetics of valaciclovir and its metabolite aciclovir in 12 healthy men, valaciclovir 1 g, valaciclovir plus probenecid 1 g, valaciclovir plus cimetidine 800 mg, and valaciclovir with a combination of probenecid and cimetidine were studied (13). At three subsequent administrations, drug regimens were alternated among groups so that each group received each regimen. Probenecid and cimetidine respectively increased the mean C_{max} of valaciclovir by 23 and 53% and its AUC by 22 and 73%. Probenecid and cimetidine also respectively increased the mean aciclovir C_{max} by 22 and 8% and its AUC by 48 and 27%. The combination had a greater effect than either drug alone. Neither cimetidine nor probenecid affected the absorption of valaciclovir.

Probenecid

In an open, single-dose study of the effects of probenecid and cimetidine on the pharmacokinetics of valaciclovir and its metabolite aciclovir in 12 healthy men, valaciclovir 1 g, valaciclovir plus probenecid 1 g, valaciclovir plus cimetidine 800 mg, and valaciclovir with a combination of probenecid and cimetidine were studied (13). At three subsequent administrations, drug regimens were alternated among groups so that each group received each regimen. Probenecid and cimetidine respectively increased the mean C_{max} of valaciclovir by 23 and 53% and its AUC by 22 and 73%. Probenecid and cimetidine also respectively increased the mean aciclovir C_{max} by 22 and 8% and its AUC by 48 and 27%. The combination had a greater effect than either drug alone. Neither cimetidine nor probenecid affected the absorption of valaciclovir.

Valerianaceae

See also Herbal medicines

General Information

The family of Valerianaceae contains four genera:

1. *Centranthus* (centranthus)
2. *Plectritis* (seablush)
3. *Valeriana* (valerian)
4. *Valerianella* (cornsalad).

Valeriana species

Valeriana (all-heal, amantilla, heliotrope, valerian), 400–900 mg 30–60 minutes before bedtime, is a traditional herbal sleep remedy (1), but although it has subjective effects on sleep objective sleep measures have been inconsistently affected (2). The roots of members of the *Valeriana* (valerian) species contain valepotriates, which have alkylating properties. Valtrate/isovaltrate and dihydrovaltrate are mutagenic in bacterial test systems in the presence of a metabolic activator, and their degradation products baldrinal (from valtrate) and homobaldrinal (from isovaltrate) are mutagenic even without metabolic activation. These latter compounds also have direct genotoxic effects. As far as is known, decomposition of dihydrovaltrate does not yield baldrinals.

The amounts of valepotriates and baldrinals in valerian extracts depend on the botanical species: root extracts of *Valeriana officinalis* contain up to 0.9% of valepotriates, compared with 2–4% and 5–7% of valepotriates in root extracts of *Valeriana wallichii* and *Valeriana mexicana* respectively.

Another relevant variable is the dosage form: when a herbal tea is prepared by hot extraction from valerian root, up to 60% of the valepotriates remain in the root material and only 0.1% can be recovered from the tea. A freshly prepared tincture contains 11% of the valepotriates originally found in the root material. Storage at room temperature rapidly reduces this to 3.7% after 1 week and 0% after 3 weeks. In view of this rapid degradation, it is not surprising that commercially available tincture samples yield baldrinals.

Valerian-containing tablets and capsules provide up to 1 mg of baldrinals per piece.

Valepotriates are poorly absorbed from the gastrointestinal tract, but 2% is degraded in vivo to baldrinals after oral administration of valtrate/isovaltrate to mice. In other words, a tablet with 50 mg of valepotriates may add 1 mg of baldrinals to the amount of baldrinals, which are already present before ingestion. In contrast to the valepotriates, the degradation product homobaldrinal is absorbed fairly well after oral administration to mice. As much as 71% of the administered dose can be recovered from the urine in the form of baldrinal glucuronide. Since no unchanged homobaldrinal can be demonstrated in body fluids or liver samples after oral administration, the compound appears to undergo substantial first-pass metabolism. As this glucuronidation leads to loss of its mutagenic properties, the primary target organs that are at risk from valepotriates and baldrinals are the

gastrointestinal tract and the liver (3). However, the toxicological significance of all these data is still unclear, since the carcinogenic potential of valerian formulations has not been evaluated.

Adverse effects

Liver

- A 13-year-old child with fulminant seronegative liver failure required liver transplantation (4). A liver biopsy showed non-specific necrosis of more than 90% of hepatocytes. Possible exogenous toxic factors were ruled out and it was thought that the most likely cause of the liver damage was self-medication with Euphytose, a herbal mixture of *V. officinalis*, *Ballota nigra*, *Crataegus oxyacantha*, *Passiflora incarnata*, and *Cola nitida*.

The authors suggested that of these medicinal plants valerian was the most likely to have caused the liver damage. However, it could just as easily have been due to one of the other constituents or some other cause entirely.

Drug withdrawal

Delirium has been attributed to valerian withdrawal (5).

- A 58-year-old man who had regularly taken excessive doses of valerian root extract for many years was given naloxone postoperatively and developed extreme tremulousness and worsening ventilation. His condition deteriorated and he became delirious. He was treated with midazolam, lorazepam, and finally reducing doses of clonazepam and made an uneventful recovery.

The authors suggested that the anxiolytic action of valerian is similar to that of benzodiazepines and that the patient had been suffering from a valerian withdrawal syndrome.

Drug overdose

In one case of overdose with about 20 times the recommended therapeutic dose, there were only mild symptoms, all of which resolved within 24 hours (6).

In 23 patients who took an overdose of "Sleep-Qik" (valerian dry extract 75 mg, mean dose 2.5 g, hyoscine hydrobromide 0.25 mg, and cyproheptadine hydrochloride 2 mg) the main problems were central nervous system depression and anticholinergic poisoning (7). There was no evidence of liver damage, subclinical, acute, or delayed. It is unlikely that valerian contributed to the adverse effects in these cases.

Valproic acid

See also Antiepileptic drugs

General Information

Valproic acid is available as sodium, magnesium, and calcium salts, as the free acid, and as a coordination compound, valproate semisodium (divalproex sodium), which comprises the sodium salt of valproic acid and free valproic acid in a 1:1 molar ratio. All share the same active principle (valproic acid) and have virtually identical tolerability, although the formulation influences the incidence of gastrointestinal adverse effects. Valpromide (rINN) is a prodrug of valproate, to which it is converted with a half-life of less than 1 hour. Valnoctamide (rINN) is an isomer of valpromide.

The therapeutic uses of valproate in psychiatric conditions have been reviewed (1,2). The major adverse effects in one study of 150 patients were tremor (9.3%), gastrointestinal effects (8.9%), drowsiness (8.6%), hair loss (7.9%), weight gain (6.9%), weakness (6.9%), dizziness (4.1%), thrombocytopenia (2.9%), and headache (2.7%).

General adverse effects

Weight gain, gastrointestinal symptoms, hair loss, and tremor are relatively common adverse effects. Sedation, fatigue, dizziness, headache, ataxia, insomnia, and behavioral problems are less frequent than with other anticonvulsants. Hyperammonemia is relatively common, but it is often asymptomatic. Fatal liver failure has an incidence of up to 1:600 in young infants, but is extremely rare in adults. Uncommon effects include parkinsonism, encephalopathy, pseudoatrophy of the brain, pancreatitis, and disorders of hemostasis (especially thrombocytopenia).

Hypersusceptibility reactions

Hypersusceptibility reactions can affect any organ and system, but are very rare. Lupus-like syndrome has been reported.

Second-generation effects

Valproate can cause fetal malformations, particularly neural tube defects (2–3% risk).

Organs and Systems

Cardiovascular

Very rarely, valproate-induced carnitine deficiency adversely affects cardiac function (see Metabolism in this monograph).

Hypotension has been attributed to valproate (3).

- In an 11-year-old girl who was treated with intravenous valproate (30 mg/kg over 1 hour) for status epilepticus, the blood pressure fell from 130/80 mmHg to 70/55 mmHg after about 40 minutes of infusion. Her seizures stopped, but her blood pressure fluctuated for several hours between 90/60 mmHg and 60/30 mmHg, requiring intravenous fluids and pressor therapy. Endotracheal intubation was also performed and she eventually recovered.

In this case a relatively high dosage of valproate, concurrent *Varicella* infection, and previous use of benzodiazepines may have contributed.

In 775 patients who received intravenous phenytoin, valproate, or placebo, intravenous site reactions occurred in 18% of patients who received valproate (4). Most of the events (70%) occurred in the first intravenous site and all occurred in peripheral administration sites. When patients who received the drug by central line were excluded, the estimated incidence was 21%. There were fewer adverse events when phenytoin was given alone than when it was given together with valproate.

Respiratory

Respiratory failure and truncal weakness occurred in one patient given dosages up to 3200 mg/day, the association being proven by withdrawal and rechallenge (SEDA-18, 68).

Fatal pulmonary hemorrhage occurred during high-dose valproate monotherapy in a 30-year-old woman (5). It was accompanied by a low platelet count (15×10^9/l).

Nervous system

Tremor is seen in 15% of patients taking valproate (6), although its incidence can increase to over 60% at serum drug concentrations in a high range (80–150 μg/ml) (7); it is clinically reminiscent of essential tremor and responds to dosage reduction. Asterixis has been associated with intoxication by most anticonvulsants, but with valproate it can occur at therapeutic drug concentrations (SEDA-12, 133) (8).

Sedation, fatigue, dizziness, headache, ataxia, and insomnia are less frequent with valproate than with other anticonvulsants. However, encephalopathy, sometimes associated with hyperammonemia and/or liver failure, has been described on several occasions, with symptoms ranging from acute confusion to stupor and even deep coma (SEDA-18, 69) (9). The stupor tends to be associated with bilaterally synchronous high-voltage, slow-wave EEG activity. Psychiatric symptoms and increased seizure frequency can also occur. Although in some cases valproate-induced stupor can be associated with increased epileptiform activity, it appeared to be triggered by a cortical non-epileptic mechanism in six patients who developed negative myoclonus and stupor after taking valproate for a few days (SEDA-19, 74).

Rarely valproate causes a parkinsonian-like reaction (SEDA-18, 69) (SEDA-19, 74). Involuntary movements and twitching of the face and limbs have been also reported. Intermittent choreiform movements were observed in two girls and one man, all with pre-existing severe brain damage, after they had taken valproate for 27 years (SEDA-20, 68).

When a 25-year-old woman with a hypothalamic hamartoma was given valproate (up to 2500 mg/day) in addition to phenytoin and phenobarbital, she became increasingly somnolent and spike and wave activity in her electroencephalogram deteriorated to the point when she appeared to be in absence status (10). Her blood ammonia concentration was about three times the upper limit of the reference range. During wakefulness, electroencephalographic paroxysms increased with increasing plasma valproic acid concentrations and resolved (together with mental status changes and hyperammonemia) when valproate was withdrawn. The data are suggestive of a paradoxical effect of valproic acid on spike and wave activity, possibly related to the underlying pathology or hyperammonemia.

A most unusual adverse effect, uncontrollable laughter, was reported in two men aged 17 and 20 years (11). The laughter persisted for 4–6 hours after an intravenous injection of 800 mg valproate over 1 hour.

Valproate rarely causes severe mental deterioration and CT/MRI findings suggestive of cortical atrophy, reversible after withdrawal (SEDA-20, 67). Two possible additional cases have been reported in women with juvenile myoclonic epilepsy aged 22 and 46 years (12). In one case mental function and brain atrophy regressed over a few months after stopping valproate, while in the other cognitive function improved but CT/MRI abnormalities persisted. The authors suggested that valproate-induced pseudoatrophy of the brain may not be always fully reversible, especially when the interval between onset of the condition and diagnosis is prolonged (2 years in this case). However, the possibility exists that the persistent cortical atrophy had other causes in their patient.

Retrospective studies have suggested that anticonvulsants may be associated with peripheral nerve dysfunction. This has been studied prospectively in 81 patients (aged 13–67 years) without polyneuropathy who took sodium valproate ($n = 44$) or carbamazepine ($n = 37$) as monotherapy in standard daily doses (13). After 2 years one patient had clinical signs of polyneuropathy and six patients had symptoms of polyneuropathy, but electrophysiology did not show significant changes or trends. Only one patient had abnormal electrophysiological findings, which were only subclinical, and eight patients had abnormal values at two subsequent visits. There were no consistent patterns, and the data were unaffected when the drugs were examined separately or when patients were grouped according to whether or not they had symptoms of polyneuropathy. The authors concluded that previously untreated young to middle-aged patients who take valproic acid or carbamazepine for 2 years are not at risk of polyneuropathy.

Valproate can cause altered visual evoked potentials and brainstem evoked potentials (14). In 100 epileptic

© 2006 Elsevier B.V. All rights reserved.

patients aged 8–18 years taking valproate in a modified-release formulation, interpeak latencies of I-III and III-V of brainstem evoked potentials were significantly delayed and N75/P100 and P100/N145 amplitudes in the visual evoked potentials were reduced.

Valproate toxicity has been reported to have caused a neurodegenerative condition that mimicked multisystem atrophy in a 67-year-old woman (15).

Valproate can occasionally cause aggravation of absence seizures in children (16). Eight patients with typical and myoclonic absence epilepsy and electroencephalography that showed generalized 3-Hz spike-and-wave had an increase in the frequency of absence seizures within days of valproate introduction. Dosage increments resulted in further aggravation. Serum concentrations of valproate were in the target range in all cases. All the children improved on valproate withdrawal; in five valproate was reintroduced, resulting in further seizure aggravation.

In one report of 36 adults chronically treated with valproate at a veterans' clinic, intellectual deterioration, sleep disorders, sexual dysfunction, personality changes, hearing difficulties, gait instability, tremor, parkinsonism, bradykinesia, abulia, and upper motor neuron signs were found in a large proportion, but selection bias was likely (17). The severity of symptoms and signs varied from minimal to a degree that could lead to diagnosis of Parkinson's disease or dementia. Improvement followed valproate withdrawal, and in two patients retested by CT scan cerebral atrophy regressed after drug withdrawal.

Psychological, psychiatric

Psychotic reactions had been reported to the WHO monitoring system on 16 occasions by 1993, and other occasional cases have been published (SED-13, 149) (18).

Behavioral problems are less frequent with valproate than with other anticonvulsants and include sedation, hyperactivity, irritability, and aggression (19).

There has been a randomized, double-blind, single crossover study of the effects of sodium valproate on cognitive performance and behavior in eight children with learning and behavioral problems associated with electroencephalographic epileptiform discharges but without clinical seizures (20). The children became more distractable, had increased delay in response time, and had lower memory scores while taking valproate. Their parents reported higher internalizing scores on the Child Behavior Checklists.

Although valproate has little effect on cognitive function compared with other anticonvulsants, it can occasionally cause reversible dementia, sometimes associated with MRI evidence of pseudoatrophy of the brain (SEDA-20, 67) (SEDA-21, 76). The presentation can be striking, with progressive motor and intellectual deterioration and apathy appearing shortly after the introduction of valproate, or sometimes after as long as 2 years. Many affected patients have relatively high serum drug concentrations (100–120 mg/l), other signs of toxicity, such as tremor and ataxia, and normal electroencephalographic background activity. The presentation differs from valproate-induced stupor, in which consciousness is impaired, and there may be clinical or electroencephalographic signs of increased seizure activity. In all cases, clinical and imaging signs improved rapidly after drug withdrawal. The incidence of this syndrome is probably very low, although there is concern about possible underdiagnosis.

Endocrine

The use of valproate in young women has been associated with an increased incidence of menstrual abnormalities (21), polycystic ovaries, and hyperandrogenism (SEDA-18, 69) (SEDA-20, 68). Of 22 valproate-treated women who underwent endocrine evaluation, 13 were obese and 11 had marked weight gain (mean 21 kg) after starting valproate (22). There were polycystic ovaries, hyperandrogenism, or both in 64%, but the clinical relevance of these findings remains uncertain.

The syndrome of polycystic ovaries and hyperandrogenism associated with weight gain and hyperinsulinemia was reversible in 16 women with valproate-related polycystic ovaries and/or hyperandrogenism who were switched to lamotrigine (23). While taking valproate, they had centripetal obesity with associated hyperinsulinism and unfavorable serum lipid profiles. After switching to lamotrigine, in the 12 patients available for follow-up at 1 year, body-mass index and fasting serum insulin and testosterone concentrations fell, whereas HDL cholesterol/total cholesterol ratios increased from 0.17 to 0.26. The total number of polycystic ovaries fell from 20 to 11 after 1 year of lamotrigine.

Pubertal growth arrest has been described in a 12-year-old girl who had taken valproate for 18 months (SED-13, 152) (24).

Among 45 valproate-treated girls aged 8–18 years, hyperandrogenism (serum testosterone concentrations more than two standard deviations above the mean for healthy controls) was seen in 38% of prepubertal girls, 36% of pubertal girls, and 57% of postpubertal girls (25). Obesity was more common in postpubertal valproate-treated girls than in controls. The authors concluded that valproate may cause hyperandrogenism in girls with epilepsy during the sensitive period of pubertal maturation.

There were increased serum androgen concentrations in 60% of those who took valproate (22).

The endocrine consequences of valproate or carbamazepine monotherapy have been evaluated in a cross-sectional study in two groups of women with epilepsy, who were treated for at least 2 years with valproate ($n = 52$) or carbamazepine monotherapy ($n = 53$) (26). Menstrual disturbances were reported by 29 of the women, 12 of those taking valproate and 17 of those taking carbamazepine. Polycystic ovaries were found in 28 patients, of whom 13 were taking valproate and 15 carbamazepine. Postprandial concentrations of insulin, C-peptide, and proinsulin were significantly higher with valproate than carbamazepine, but there were no differences in the fasting state. In conclusion, this study did not show an increase in the frequency of polycystic ovaries in valproate-treated women, although valproate does appear to increase glucose-stimulated pancreatic insulin secretion.

Metabolism

Valproate can cause hyperglycinemia and hyperglycinuria, sometimes with raised spinal fluid glycine

© 2006 Elsevier B.V. All rights reserved.

concentrations (SED-12, 133). These changes are usually asymptomatic.

Chronic valproate treatment did not change serum concentrations of lipids, vitamin B12, or folic acid in 26 children with epilepsy (27).

Weight gain

Weight increase, sometimes associated with increased appetite, occurs in 8–60% of patients taking valproate (6) and may be unrelated to dose.

A randomized, double-blind study was conducted for 32 weeks to analyse weight change in patients taking lamotrigine ($n = 65$; mean age 35 years; target dosage 200 mg/day) and valproate ($n = 68$; mean age 30 years; target dosage 20 mg/kg/day) (28). Weight remained stable in the patients taking lamotrigine. However, there was significant weight gain in the patients taking valproate by the 10th week of treatment, and weight continued to increase throughout the study. After 32 weeks, mean weight gain was significantly higher in those taking valproate (5.8 kg) compared with lamotrigine (0.6 kg). Similar proportions of patients taking lamotrigine (29%) or valproate (26%) were seizure-free. The frequencies of adverse events were similar in the two groups.

The mechanisms involved have been assessed in 40 women with epilepsy evaluated before and after 1 year of therapy (29). At the end of follow-up, 15 patients were obese and had higher serum leptin and insulin concentrations than patients who did not gain weight. The rise in serum leptin is consistent with that observed in other types of obesity.

In a prospective cohort study of the role of insulin and leptin (a signal factor that regulates body weight and energy expenditure) in valproate-related obesity, 81 patients with epilepsy taking valproate and 51 healthy controls were analysed (30). Mean serum insulin concentrations were significantly higher in the valproate-treated patients than in the controls, despite similar body mass indexes. Furthermore, serum insulin concentrations were significantly higher both in lean men and lean women compared with lean controls of same sex and similar body mass indexes. This implies that the hyperinsulinemia seen in obese people taking valproate is not merely a consequence of insulin resistance induced by weight gain. Serum leptin concentrations did not differ between the valproate-treated patients and the controls. Thus, both obese and lean patients taking valproate have hyperinsulinemia, suggesting insulin resistance. This may be one of the factors that leads to weight gain during valproate treatment. Similar findings, that is increased insulin concentrations without changes in leptin concentrations, have also been published in three other reports from one center (26,31,32).

Hyperammonemia

Hyperammonemic encephalopathy has been attributed to valproate (33).

- A 61-year-old man with epilepsy had altered consciousness after his dose of valproate was increased because of poor seizure control. Electroencephalography showed triphasic waves and high-amplitude delta-wave activity with frontal predominance. Although serum aspartate transaminase and alanine transaminase were normal, the serum ammonium concentration was high at 960 ng/ml (reference range 30–470). Serum amino acid analysis showed multiple minor abnormalities. Valproate was withdrawn. He improved within 4 days and the electroencephalogram, serum ammonium concentration, and amino acid profile were normal by day 8.

In two other cases the addition of topiramate was thought to have precipitated valproate-induced hyperammonemic encephalopathy (34). Recovery occurred after withdrawal of valproate or topiramate. The authors suggested that topiramate may have contributed to the hyperammonemia by inhibiting carbonic anhydrase and cerebral glutamine synthetase.

Asymptomatic hyperammonemia, with ammonia concentrations as high as 140 mmol/l, has been found in up to over 50% of patients (35) and may be due to increased renal production or inhibition of nitrogen elimination, although carnitine deficiency, nutritional influences, metabolic abnormalities secondary to increased glycine or propionic acid concentrations, and multiple drug therapy may play a role (SED-13, 149) (35). In individual patients, the condition can be associated with severe symptoms (SEDA-20, 69). Deaths have occurred after the use of valproate in patients with ornithine transcarbamylase deficiency (SED-12, 133) (36), (SED-13, 149) (37). Additional evidence points to a need for caution in patients with any enzyme disorder: an 18-year-old woman with progressive dementia and spastic paraparesis became comatose with hyperammonemia when taking valproate; moderate hyperammonemia persisted for months after drug withdrawal, coma recurred without exposure to valproate, and congenital argininemia was diagnosed (38). Carnitine supplementation has been proposed in symptomatic hyperammonemia caused by valproate (see below).

Valproate-induced hyperammonemic encephalopathy has been reviewed (39). Proton magnetic resonance spectroscopy was performed in a patient with valproate-induced hyperammonemic encephalopathy; there was a significant fall in the choline and myoinositol resonances and an increase in glutamine in the hyperintense basal ganglia lesions (40). A similar pattern has been observed in other hyperammonemic encephalopathies, such as hepatic encephalopathy. In another study in seven patients with valproate-related hyperammonemia serum or cerebrospinal fluid glutamine concentrations were initially raised in most patients, sometimes in the absence of hyperammonemia (41).

Carnitine deficiency

Valproate is often associated with low carnitine concentrations and occasionally with true carnitine deficiency, especially in young children with neurological disabilities taking several anticonvulsants. The condition is usually asymptomatic, but it can occasionally cause significant toxicity (42).

- Life-threatening cardiac dysfunction in a 7-year-old boy required urgent carnitine supplementation (SEDA-17, 74).
- In one patient with acute valproate-associated encephalopathy associated with biochemical evidence of severe carnitine deficiency and a defect in valproate

© 2006 Elsevier B.V. All rights reserved.

metabolism, L-carnitine substitution corrected the biochemical abnormalities, but the patient died (SED-13, 150) (43).
- In another case, there was late-onset lipid storage myopathy, with secondary carnitine deficiency (SED-13, 150) (44).

While measurement of carnitine concentrations is advisable in patients with symptoms and signs suggestive of carnitine deficiency (SED-12, 133) (45), indiscriminate carnitine supplementation is unwarranted. A panel of pediatric neurologists recently recommended intravenous carnitine for valproate hepatotoxicity and for valproate overdose (SEDA-20, 69), whereas oral supplementation was suggested for patients with symptomatic valproate-associated hyperammonemia, multiple risk factors for valproate hepatotoxicity, and infants and young children receiving valproate (46). It was mentioned that carnitine might be deleterious in some disorders of long-chain fatty acid oxidation. Others have considered carnitine to be valuable in valproate-induced hyperammonemia, but have suggested reserving it for patients with subnormal blood carnitine concentrations or known risk factors for carnitine deficiency (47). In a double-blind trial in 47 children taking carbamazepine or valproate, carnitine (100 mg/kg/day for 4 weeks) was not more effective than placebo in improving subjective well-being (SEDA-19, 74).

Nutrition

Concentrations of plasma homocysteine, plasma pyridoxal 5′-phosphate (active vitamin B6), serum folate, erythrocyte folate, and serum vitamin B12 have been measured both fasting and after methionine in 60 epileptic patients (aged 14–18 years) and 63 sex- and age-matched controls before therapy and after 1 year of therapy with valproate or carbamazepine (48). After 1 year the patients who took valproate and carbamazepine had significantly increased plasma homocysteine concentrations compared with both baseline and control values and there was a significant fall in serum folate and plasma pyridoxal 5′-phosphate. Serum vitamin B12 and erythrocyte folate were unchanged.

The genetic determinants of this effect on homocysteine have been determined in 136 epileptic children taking carbamazepine or valproate as monotherapy (49). Nutritional determinants (folate and vitamins B6 and B12) and genetic determinants (MTHFR 677CT) of plasma homocysteine were studied in a random sample of 59 of those children. Total homocysteine concentrations were significantly increased and folate and vitamin B6 concentrations were significantly reduced. Carbamazepine lowered folate concentrations in association with hyperhomocysteinemia, which seemed to be related to the homozygous MTHFR 677CT mutation. Valproate, although also associated with hyperhomocysteinemia, only reduced vitamin B6 concentrations, independent of the MTHFR genotype.

In 15 patients who had a serious adverse reaction to valproate (including behavioral changes and emesis in six, raised aspartate transaminase in three, raised aspartate transaminase and pancreatitis in one, thombocytopenia in two, and unexpected death in two), erythrocyte glutathione peroxidase activity and plasma selenium and zinc concentrations were significantly reduced, whereas erythrocyte glutathione reductase activity was significantly raised relative to matched healthy controls or patients with good tolerance of valproate (50). These findings may indicate a role for selenium-dependent antioxidant activity in individual susceptibility to the adverse effects of valproate.

Mineral balance

- Hyponatremia (serum sodium of 128 mmol/l) was discovered accidentally in a 50-year-old man during follow-up for Henoch-Schönlein nephritis (51). He was taking sodium valproate 2000 mg/day. Repeated water loads at different dosages of valproate confirmed that the ability to excrete water was dose-dependently reduced.

Fluid balance

Edema has been attributed to valproate.

- A 42-year-old man with bipolar disorder developed peripheral edema 14 days after starting treatment with valproate in a dosage of 1400 mg/day (52). Within 3 weeks he gained 11 kg in body weight, his legs were very swollen, and periorbital edema was present after a night's sleep. Blood chemistry and hematology tests were normal. The diagnosis was avid salt retention by the renal tubules, secondary to treatment with valproate, and recovery occurred when diuretics were given and valproate was substituted with lithium.
- An 18-year-old woman also developed leg edema while taking valproate 800 mg/day for epilepsy (53). Although she had taken valproate for 10 years without edema, the lack of alternative explanations and the disappearance of the condition after withdrawal suggested a drug-related effect. She also had dysmenorrhea, hirsutism, and obesity, which were thought to have been caused by valproate.

There have been eight other published cases of valproate-induced edema, plus two additional cases in whom edema developed when risperidone was added to valproate.

- Severe peripheral edema occurred in a 42-year-old man taking valproate 1.5 g/day and resolved on withdrawal (52).

The authors proposed that increased GABA activity had inhibited natriuresis by altering the action of nitric oxide in the kidneys or by inhibiting the central production of C-type natriuretic peptide.

Hematologic

Hematological abnormalities, mostly of little or no clinical significance, occur in about 30% of patients taking valproate (SEDA-18, 69).

Thrombocytopenia can be caused by autoimmune mechanisms (SED-13, 150) (54), tends to be related to high serum drug concentrations, and often responds to dosage reduction (SEDA-19, 74). Of 131 patients randomized to high plasma concentrations of valproic acid (80–150 μg/ml), 36 (27%) had at least one platelet count below 75×10^9/l, compared with only one patient in a group randomized to drug concentrations of 25–50 μg/ml (55).

As well as reducing platelet count or function valproate can impair procoagulatory thrombocytic functions as reflected by reduced platelet activation and an increased thrombin time (56). Valproate-induced platelet

© 2006 Elsevier B.V. All rights reserved.

dysfunction may be related, at least in part and in some patients, to inhibition of the arachidonic acid cascade (57).

- There was a small reduction in platelet count (from 150 to 110 × 10^9/l) in association with gastrointestinal symptoms in a 45-year-old man when he took valproate 750 mg tds, but not when he took the same dose of divalproex, an enteric-coated formulation (58).
- A small reduction in platelet count (from 170 to 110 × 10^9/l) in a 37-year-old woman was associated with disproportionate perioperative bleeding (59). An antiplatelet antibody was also detected and the authors therefore proposed that valproate must also have caused reduced platelet aggregation.
- Small reductions in red cell, white cell, and platelet counts occurred in a 65-year-old man taking valproate; the changes were dose-related but did not merit the description of pancytopenia that the authors used in the title of their paper (60).

Bleeding complications occasionally occur. In an unusual case, thrombocytopenic purpura, anemia, and reticulocytosis occurred in a 3-month-old breast-fed infant whose mother was taking valproic acid 1200 mg/day. The serum valproic acid concentration in the infant was 6.6 μg/ml, and recovery occurred when breast-feeding was stopped (61).

Depressed fibrinogen concentrations have been reported (SED-12, 134) (62,63), but they are unlikely to be important, except perhaps in patients due to undergo surgery. However, two neonates from mothers who had taken valproate during pregnancy developed bleeding associated with fibrinogen depletion soon after birth, and one of them died from afibrinogenemia (SEDA-19, 75).

In one study there were marked reductions in von Willebrand factor and ristocetin co-factor in most valproate-treated children (SEDA-17, 74), leading to deranged hemostasis, although not always to a clinically important extent. In the event of bleeding or need for surgical procedures, a high-purity factor VIII concentrate (Haemate P) provided sufficient hemostasis in valproate-induced von Willebrand's disease, despite the fact that Haemate P is ineffective in the platelet type of the disease (64). Despite frequent changes in hemostasis and blood coagulation in patients taking valproate, bleeding complications during or after neurosurgery are uncommon (SEDA-21, 76).

Very rare effects include bone-marrow suppression associated with platelet autoantibodies and coagulopathy, transient leukopenia, lethal bone-marrow failure due to self-poisoning, reversible intravascular hemolysis, and pure red cell aplasia (SED-12, 134) (65–68).

A 5-year-old girl with acquired protein C deficiency had a stroke while taking valproate (69). The authors then measured protein C concentrations in 20 children taking valproate monotherapy and 20 children taking other anticonvulsants. There were significantly lower protein C concentrations in those taking valproate. Protein S and antithrombin III were not affected. Despite this, there is no known association between valproate therapy and a risk of thromboembolic disease, and the clinical relevance of this effect on protein C is not clear.

Gastrointestinal

Gastrointestinal symptoms, such as nausea, anorexia, vomiting, gastritis, and diarrhea, occur in 36% of patients (6), although over 20% may be affected at high dosages (7). Stomatitis, parotid gland enlargement, and gingival hyperplasia are exceedingly rare (SED-13, 151) (70–72).

In a retrospective survey, gastrointestinal adverse effects were less common in 150 patients taking valproate semisodium than in an equal number taking valproic acid (15 versus 29%), despite the fact that serum valproic acid concentrations were comparable in the two groups (73). Patients taking valproate semisodium were less likely to discontinue medication because of gastrointestinal adverse effects (4 versus 13%). The difference was ascribed to the enteric-coated formulation of valproate semisodium.

The suggestion that divalproex (valproate semisodium) causes fewer gastrointestinal adverse reactions than valproate (SEDA-23, 94) (58) has been challenged (74). In other cited studies divalproex was associated with a higher risk of gastrointestinal effects.

Liver

Liver abnormalities due to valproate range from transient dose-related asymptomatic rises in liver enzymes (in as many as 40% of patients) to rare and often fatal hepatic failure. Rises in liver enzymes up to three times normal may abate, even without a reduction in dosage, but the drug should be withdrawn if the rise in enzyme concentrations is greater.

At least 132 patients have died of liver failure (and/or pancreatitis) (75). The risk is highest (1:600) in children under 2 years of age with complex neurological disorders taking valproate as part of a multidrug regimen (46,76). In older patients the incidence is no more than 1:37 000 for monotherapy and 1:12 000 for multidrug therapy. Deaths beyond 20 years of age are exceedingly rare. Risk factors include mental retardation, congenital abnormalities, neurological disorders, familial hepatic disease, the addition of valproate within 3 months of liver dysfunction, and concomitant salicylate use. Fatal hepatotoxicity usually occurs within the first 3 months, although the proportion of patients who developed their first symptoms after 6 months has increased lately, possibly because of greater awareness of the problem and a reduced death rate, owing to rapid drug withdrawal (75). The presenting symptoms include nausea, vomiting, loss of appetite, reduced alertness, apathy, coma, fever, jaundice, hemorrhage, edema, and increased seizure frequency, including status epilepticus. The importance of fever and increased seizure frequency as diagnostic features may have been underestimated in the past.

A Reye-like syndrome, as yet only in children, has also been described. The mechanisms involved remain elusive, and possible roles of carnitine deficiency (46) and hepatotoxic metabolites (SED-13, 151) (77) have been discussed.

Knowledge of symptoms is more important than laboratory tests in early detection and prevention, although monitoring liver function during the first 6 months of therapy is recommended. There is some

© 2006 Elsevier B.V. All rights reserved.

evidence that hepatotoxicity is related to carnitine deficiency, and retrospective data suggest that the outcome can be improved by early intravenous administration of carnitine (46).

- Valproate-induced fatal liver failure developed in a 29-year-old woman with Friedreich's disease (78). The first symptoms (apathy during febrile upper airways infection) occurred after 2 months of therapy at a dosage of 20 mg/kg. The drug was withdrawn 10 days later, when she had hepatic encephalopathy and a severe bleeding diathesis; supportive treatment was provided but she died after 4 weeks.

This was the third published case of fatal valproate liver toxicity in an adult with Friedreich's disease, suggesting that this condition is a predisposing factor. Although the risk of valproate hepatotoxicity in adults is much lower than in children, adults still represented over 15% of the cases known to the authors. Overall, a total of 26 other adults (age range 17–62 years) with fatal valproate-induced liver failure have been reported: of these, 3 were taking monotherapy and 12 had no underlying disease or a clearly non-metabolic and non-hepatic disease. The duration of treatment before the first symptoms varied between 6 days and 6 years.

Fatal hepatitis has been reported in a child taking valproate (79).

- An 8-year-old boy with complex partial seizures had taken valproate for more than 3 years. His sister developed uncomplicated hepatitis A, and 1 month later he became jaundiced, developed fulminant hepatic failure, quickly became encephalopathic, and died, despite withdrawal of valproate, aggressive supportive therapy, and treatment with carnitine. He had positive hepatitis A IgM; other causes for acute hepatitis were ruled out. Liver pathology showed distended hepatocytes with cholestasis and microvesicular changes.

The authors thought that valproate-induced hepatotoxicity may have exacerbated this child's infective hepatitis.

Hepatotoxicity due to valproate has been attributed to reactive hepatotoxic metabolites of valproate, which are normally detoxified by glutathione conjugation followed by mercapturic acid metabolism to their respective *N*-acetylcysteine conjugates (80).

The Alpers–Huttenlocher syndrome, progressive neuronal degeneration of childhood, which is associated with seizures and abnormal liver function tests, can lead a clinician to use valproate, which can then precipitate acute liver damage, as has been reported in five cases (81). In all cases liver transplantation for valproate-induced liver damage was then associated with worsening neurological function. In another case Alpers–Huttenlocher syndrome was misdiagnosed as valproate toxicity (82).

The association between valproate and raised transaminase activities has been studied in a retrospective review of the medical records of patients positive for hepatitis C virus (83). Of 214 patients 28 were taking valproate and 186 were not. The controls and those who had been hepatitis-positive for longer were significantly more likely to have worse hepatotoxicity. Valproate, either alone or in the presence of other potential hepatotoxins, was not associated with raised transaminases.

Pancreas

There have been over 50 published reports of acute pancreatitis associated with valproate (SEDA-18, 70) (84), including several confirmed by rechallenge. Deaths have occurred from hemorrhagic pancreatic necrosis; complications can include pleural and pericardial effusions, coagulopathy, pseudocyst, ascites, wound infection, and pneumonia (SED-13, 151) (85). Hepatotoxicity can coexist. There is suggestive evidence that end-stage renal insufficiency (SEDA-22, 92) and mental retardation (84) can be predisposing factors.

In a study of intravenous valproate in status epilepticus, three of 19 patients (ages and dosages not specified) developed a rise in serum lipase activity above 4000 IU/ml within 1–3 weeks (86); one of these developed overt exudative pancreatitis. Based on these data, it may be prudent to monitor serum lipase when using intravenous valproate.

However, in a review of valproate-induced pancreatitis (87) the author discouraged routine checking of amylase activity in the absence of other clinical signs and symptoms.

Urinary tract

Enuresis in children can occasionally be a problem (88). There have been single cases of Fanconi syndrome (SED-13, 151) (89), and hematuria with acute renal insufficiency (SEDA-20, 69).

A child with developmental delay and epilepsy developed glycosuria about 16 months after starting to take valproic acid (90). Laboratory evaluation showed global defects in proximal tubule function, consistent with the De Toni–Debré–Fanconi syndrome. The authors reviewed the literature on this rare complication, which is reversible on valproate withdrawal.

Skin

Skin rashes are uncommon (2–4%), and photosensitivity and cutaneous vasculitis, if they occur at all, are exceedingly rare (SED-13, 152) (91,92).

Cutaneous pseudolymphoma has been attributed to valproate (93).

- A 41-year-old man presented with an erythematous papule, histologically mimicking a non-epidermotropic T cell lymphoma. Polymerase chain reaction in the skin biopsy showed monoclonal rearrangement of the T cell receptor gamma gene. Withdrawal of valproate was followed by regression of the lesion, but 5 months after substitution by carbamazepine, two further papules appeared, with similar histological features. Carbamazepine was withdrawn and the lesions disappeared without relapse over 4 years.

Hair

Hair loss and changes in hair texture or color are seen in 1–11% of patients (SED-12, 135) (6,94,95). Alopecia has been reported in 4% of patients with concentrations below 50 μg/ml and in 28% of patients with serum drug concentrations above 80 μg/ml (7).

© 2006 Elsevier B.V. All rights reserved.

Musculoskeletal

Accumulation of microvesicular lipid droplets between myofibrils adjacent to mitochondria was found in muscle biopsies from seven children taking valproate (SEDA-22, 92). Ultrastructural abnormalities in the mitochondria suggested that these could have resulted from impaired mitochondrial fatty acid oxidation.

Sexual function

- A 32-year-old man developed infertility and a low sperm count (under 50×10^6/l), with no motile sperm, less than 10% viability, and 100% with abnormal structure while taking valproate monotherapy for 5 years (96). Within 4 months of switching to felbamate, he and his wife conceived twin girls, and the sperm abnormalities were largely reversed.

These findings suggest that occasionally valproate can cause male infertility.

Reproductive system

Polycystic ovary syndrome (polycystic ovaries, hyperandrogenism, obesity, hirsutism, anovulatory cycles, and menstrual disorders) is more common in women with epilepsy. Valproate has been associated with alterations in reproductive hormonal function beginning in the first month of treatment. Serum androgen concentrations increase in patients taking valproate but the profile of hormonal changes is different in women and men (97). Animal studies have corroborated the adverse ovarian and endocrine effects of valproate (98). Four review articles have dealt with this reported adverse event, highlighting controversial views (99–102).

The estimated prevalence of polycystic ovary syndrome in patients with epilepsy is 13–25%, compared with 4–6% in the general population (99). Polycystic ovary syndrome has been described in women with epilepsy taking valproate, especially those who start treatment before 20 years of age (22,103), and the frequency is high: in a cross-sectional study of 22 women taking valproate monotherapy, 59% were obese and 64% had polycystic ovaries, hyperandrogenism, or both (22).

In a prospective study of polycystic ovary syndrome in 52 controls and 72 women with epilepsy (37 taking valproate monotherapy and 35 carbamazepine monotherapy), the frequency of polycystic ovaries, hyperandrogenism, or both was significantly higher in those taking valproate than in the controls (70 versus 19%) (104). They occurred in 20% of the patients taking carbamazepine. The obese women taking valproate who had polycystic ovaries or hyperandrogenism or both had hyperinsulinemia and associated unfavorable changes in serum lipid concentrations consistent with insulin resistance. In both obese and lean women, polycystic ovaries and related hyperandrogenism were similarly found. Most of the abnormalities were reversed when valproate was withdrawn (23).

Three women taking valproate developed hyperandrogenism and polycystic ovaries, associated in two cases with weight gain and menstrual disorders (105). Valproate was replaced by lamotrigine, and the serum testosterone concentrations fell in all three women, the polycystic changes disappeared from the ovaries in two, and the two women who had gained weight and developed amenorrhea lost weight and started menstruating. In the light of this report others have clarified the distinction between polycystic ovary syndrome and polycystic ovary morphology, and have pointed out that it was not clear which of these valproate had actually caused (106,107). The report also contrasts with a report that polycystic ovary syndrome was identified in two of 19 patients taking no medications, four of 38 patients taking valproate or carbamazepine monotherapy, and one of 36 patients taking more than one antiepileptic drug, suggesting that polycystic ovary syndrome in women with focal epilepsy is not related to valproate or carbamazepine (108).

Although the association between polycystic ovary syndrome and valproate treatment appears to be established, current published studies are limited, owing to small sample sizes and diverse definitions of polycystic ovary syndrome. Thus, the true clinical relevance and frequency of the association needs further investigation in large, multicenter, prospective studies.

Women taking valproate should be asked about menstrual disorders. The presence of a menstrual disorder, hirsutism, or weight gain should trigger thorough evaluation and, if necessary, valproate withdrawal.

Immunologic

Hypersensitivity reactions to valproate are rare. Lupus-like syndrome has been reported occasionally with valproate (SEDA-19, 75) (SEDA-20, 69) and valpromide (109).

In vitro tests have shown that valproate can increase the viral burden in HIV-infected individuals by potentiating replication of the virus (110). In a retrospective review of 11 HIV-positive patients with behavioral disturbances taking valproate HIV-1 viral load did not increase in six of the nine patients who had measurements between the first week and 3.5 months after the start of valproate treatment; no follow-up was available for the other three (111). These data suggest that, contrary to in vitro data, HIV-1 viral load is not adversely affected by valproate in the presence of effective antiretroviral therapy.

Body temperature

Hypothermia related to valproate has been reported in a child (112). There have been five previously described cases in adults or elderly patients (113).

- A 2-year-old boy was admitted after a prolonged febrile seizure that stopped only after he was given several doses of benzodiazepines plus phenobarbital. A CT scan showed a right arachnoid cyst. He was given valproate 13 mg/kg/day and 2 days later developed hypothermia (33.8–34.5°C). He was lethargic and irritable. Valproate was withdrawn. His lethargy improved within 48 hours and the temperature slowly returned to normal over the course of 1 week.

Second-Generation Effects

Teratogenicity

The association of valproate with spina bifida, cardiac malformations, hypospadias, porencephaly, and other

© 2006 Elsevier B.V. All rights reserved.

specified anomalies of the brain, anomalies of the face, coarctation of the aorta, and limb reduction defects has been found.

There has been a case-control study of the relation between prenatal exposure to valproate and the presence of limb deficiencies in newborn infants, using data from the Spanish Collaborative Study of Congenital Malformations (ECEMC) (114). Of 22 294 consecutive malformed infants (excluding genetic syndromes) and 21 937 control infants with specified data on anticonvulsants during gestation, 57 malformed infants and 10 control infants had been exposed to valproate during the first trimester of pregnancy. Of the malformed infants who had been exposed to valproate 21 had congenital limb defects of different types (including overlapping digits, talipes, clubfoot, clinodactyly, arachnodactyly, hip dislocation, and preaxial and postaxial polydactyly); three had limb deficiencies. After controlling for potential confounding factors there was an odds ratio of limb deficiencies of 6.2 (CI = 1.3, 30). The estimated risk for women taking valproate of having a baby with limb deficiencies was around 0.42%.

Fetotoxicity

Two neonates born of mothers who had taken valproate during pregnancy developed bleeding associated with fibrinogen depletion soon after birth, and one of them died from afibrinogenemia (SEDA-19, 75).

Of 17 infants born of mothers taking valproate, 12 had possible withdrawal effects (irritability, jitteriness, abnormal tone, seizures, feeding problems), which correlated with the dosage of valproate during the last trimester, and four of the affected children also had hypoglycemia (SEDA-18, 70).

Three cases of lung hypoplasia after prenatal exposure to valproate have been reported in two female siblings and an unrelated girl (115). The two siblings had no other malformations, whereas the third neonate had a number of major birth defects. All three died a few hours after birth. The possibility that lung hypoplasia was caused by valproate remains speculative.

Fetal valproate syndrome comprises a number of typical dysmorphic features and major organ system anomalies (116). In a case file review of 2220 children with craniosynostosis, detailed maternal health information was obtained in 1676 cases (117). Of these, 17 mothers had taken valproate monotherapy during pregnancy. All 17 children had trigonocephaly (caused by premature fusion of the metopic suture). Their IQs were 45–100 (mean 75). IQs were significantly higher in patients who underwent surgery before 6 months of age. This is the first study to have reported trigonocephaly associated with fetal valproate syndrome.

Five patients with fetal valproate syndrome and autism have been described (118).

Lactation

In an unusual case, thrombocytopenic purpura, anemia, and reticulocytosis occurred in a 3-month-old breast-fed infant whose mother was taking valproic acid 1200 mg/day. The serum valproic acid concentration in the infant was 6.6 μg/ml; recovery occurred when breast-feeding was stopped (61).

Susceptibility Factors

Genetic factors

Deaths have occurred after the use of valproate in patients with ornithine transcarbamylase deficiency (SED-12, 133) (36) (SED-13, 149) (37). Additional evidence points to a need for caution in patients with any enzyme disorder.

- An 18-year-old woman with progressive dementia and spastic paraparesis became comatose with hyperammonemia when taking valproate; moderate hyperammonemia persisted for months after drug withdrawal, coma recurred without exposure to valproate, and congenital argininemia was diagnosed (38).

Carnitine supplementation has been proposed for the treatment of symptomatic hyperammonemia caused by valproate.

Since glutathione peroxidase deficiency could predispose to severe reactions such as pancreatic or hepatic failure in children, screening for such deficiency might prove useful (SEDA-17, 72).

Age

At least 132 patients have died of liver failure (and/or pancreatitis) (75). The risk is highest (1 : 600) in children under 2 years of age with complex neurological disorders taking valproate as part of a multidrug regimen (46,76). In older patients the incidence is no more than 1:37 000 for monotherapy and 1:12 000 for multidrug therapy. Deaths beyond 20 years of age are exceedingly rare.

Valproate should not be prescribed for children with metabolic defects possibly associated with Reye-like symptoms, including acyl CoA-dehydrogenase deficiency (SEDA-22, 92) (75). In patients under 2 years old and in children with psychomotor retardation metabolic screening should be performed before therapy, and the drug should be avoided whenever a metabolic defect is known or suspected.

Hepatic disease

Valproate should be avoided in patients with a personal or family history of liver disorders or pancreatic dysfunction (75,119).

Other features of the patient

At least 132 patients have died of liver failure (and/or pancreatitis) (75). Risk factors include mental retardation, congenital abnormalities, neurological disorders, a family history of hepatic disease, the addition of valproate within 3 months of liver dysfunction, and concomitant salicylate use.

- A 24-year-old man with demyelinating disease had fulminant progression of the disease after he experienced valproate-induced hyperammonemic encephalopathy (120).

© 2006 Elsevier B.V. All rights reserved.

Although the role of hyperammonemia is uncertain, this case raises concern for possible risks in using valproic acid in patients with fulminant demyelinating disease.

The importance of hypoalbuminemia as a risk factor in valproate toxicity has been emphasized (121).

- A 53-year-old woman had a heart transplantation and developed worsening cardiac function, possible rejection, and increased lethargy. Her dose of valproate had been adjusted based on the total serum valproate concentration, but hypoalbuminemia prompted the measurement of the unbound serum valproate concentration, which was high. When the dose of valproate was adjusted based on the unbound rather than the total serum concentration she eventually improved.

Non-linear protein binding of valproate can result in disproportionate increases in unbound drug; adverse effects can then result when dosage adjustments are based solely on measurement of total valproate serum concentrations in patients with hypoalbuminemia.

Drug Administration

Drug formulations

Extended-release (ER) divalproex (valproate semisodium) is not bioequivalent to delayed-release (DR) divalproex. In a randomized, crossover study in 36 healthy volunteers the bioequivalence of divalproex ER once a day and divalproex DR at 14% and 20% lower daily doses given twice a day were compared (122). The two formulations gave equivalent exposure (AUC) with lower peak and higher trough concentrations, that is less fluctuation during the dosage interval, with divalproex DR.

Drug administration route

The successful use of intravenous valproate in psychiatric practice has been described (123). The safety of rapid infusion of valproate has been studied in 20 patients with acute repetitive seizures, who received 20 mg/kg loading doses at rates of 33–555 mg/minute (124). Consciousness and respiratory function were not affected. There was no significant local irritation. Two patients with significant contributing factors developed hypotension and required vasopressors.

Drug overdose

- After a valproate overdose a 27-year-old man developed seizures, hypernatremia, respiratory failure, metabolic acidosis, liver failure, and bone marrow depression (125). His plasma valproic acid concentration was 1414 μg/ml. Treatment with hemodialysis was effective in enhancing valproic acid clearance, while hemoperfusion was relatively less effective, because of saturation of the column. Overall, the half-life of the drug was reduced from over 20 hours before treatment to less than 3 hours during hemodialysis/hemoperfusion; drug removal was probably favored by saturation of drug binding to plasma proteins, which resulted in a low unbound fraction (32% at the start of treatment). He was comatose for 5 days but recovered fully thereafter.

A beneficial effect of high-flux hemodialysis without hemoperfusion has been described in valproate overdose (126).

- A 25-year-old white woman took an unknown amount of valproic acid, became comatose, and developed hypotension and lactic acidosis. Her valproic acid concentrations rose to over 8400 μmol/l. High-flux hemodialysis was performed for 4 hours; the calculated half-life during the procedure was 2.7 hours, compared with a posthemodialysis value of 23 hours, suggesting that high-flux hemodialysis had increased the clearance rate of valproic acid. Her hemodynamic status and mental function improved in conjunction with the acute reduction in valproic acid concentrations.

Three patients who took overdoses of valpromide presented with no symptoms or only moderate ones and serum valproate concentrations below or within the usual target range; in two cases more than 3 hours after ingestion (127). However, there was marked deterioration more than 10 hours after ingestion, when serum valproate concentrations were in the toxic range.

Drug–Drug Interactions

General

An encephalopathy leading to stupor is occasionally observed after valproate is added to other anticonvulsants.

Valproate has no enzyme-inducing properties and does not interact with oral contraceptives.

Carbamazepine

In patients taking carbamazepine, valproate slightly increases the serum concentration of the active metabolite carbamazepine-10,11-epoxide, by inhibiting epoxide hydrolase and perhaps also by inhibiting the glucuronidation of carbamazepine-10,11-trans-diol (128).

Valpromide is a more potent inhibitor than valproate of carbamazepine epoxide hydrolase in vitro (129) and in six healthy volunteers it caused a marked rise in carbamazepine-10,11-epoxide, prolonging the half-life of carbamazepine-10,11-epoxide from 6.4 to 21 hours and reducing its clearance three-fold, suggesting that valpromide inhibits epoxide hydrolase in the liver in vivo as well as in vitro, despite the fact that it is rapidly converted in vivo to valproate (130).

In 12 adults with epilepsy taking carbamazepine, valpromide produced a larger increase in plasma concentrations of carbamazepine-10,11-epoxide than valproate (131).

In healthy subjects valnoctamide 200 mg tds for 8 days prolonged the half-life of carbamazepine-10,11-epoxide from 7 to 20 hours and reduced its oral clearance fourfold, suggesting that valnoctamide, like its isomer valpromide, is a potent inhibitor of carbamazepine epoxide hydrolase (130).

Clozapine

Chronic valproate (600–1500 mg/day) has been associated with a slight increase in plasma clozapine concentrations and a slight fall in norclozapine concentrations (132). These changes are unlikely to be clinically significant.

© 2006 Elsevier B.V. All rights reserved.

Lamotrigine

Valproate inhibits the metabolism of lamotrigine (133).

Levodopa

Valproate caused a fall in growth hormone concentrations at varying times after the administration of levodopa (134).

Panipenem–betamipron

- The intravenous administration of panipenem + betamipron in a 22-year-old man and in two young girls resulted in a marked and rapid fall in the serum concentrations of valproic acid to 0–40% of the pretreatment concentration (135). In two patients, the effect was associated with epileptic seizures. Serum valproic acid began to rise again within 2 hours of stopping the antibiotic.

Although the mechanism of this interaction is unknown, animal studies suggest that suppression of the enterohepatic circulation of valproic acid may have been involved (136).

Phenobarbital

Valproate inhibits the metabolism of phenobarbital (137).

Phenytoin

Serum phenytoin concentrations can be increased or reduced by valproate (138): since valproic acid displaces phenytoin from plasma proteins, therapeutic and toxic effects of phenytoin occur at total phenytoin concentrations lower than usual.

Risperidone

Steady-state plasma concentrations of risperidone and 9-hydroxyrisperidone have been measured in 23 patients taking risperidone alone and in 10 co-medicated with sodium valproate (139). Valproate had no effect on the kinetics of risperidone.

Salicylates

Simultaneous use of salicylates and valproate should be avoided (140).

Sertraline

- In a 34-year-old man with bipolar depression treated with valproate, the addition of sertraline (100 mg/day) was associated with signs of valproate intoxication and an increase in serum valproic acid concentration from 378 to 1127 μmol/l (141). The serum valproic acid concentration returned to baseline after sertraline withdrawal.

Inhibition of valproic acid metabolism was a probable cause for this interaction.

Tricyclic antidepressants

In 10 patients taking amitriptyline 125 mg/day, for 20 days valpromide increased amitriptyline and nortriptyline plasma concentrations from 71 to 106 ng/ml for amitriptyline, and from 61 to 101 ng/ml for nortriptyline (142).

Zidovudine

At a concentration of 100 μg/ml, valproic acid inhibits the glucuronidation of zidovudine in human liver microsomes by 50% (143). This observation explains the previously reported effect of valproate to increase plasma zidovudine concentrations in HIV-infected patients.

Diagnosis of Adverse Drug Reactions

The tentative target range for plasma concentrations is 350–700 μmol/l (50–100 μg/ml).

Valsartan

See also Angiotensin II receptor antagonists

General Information

Valsartan is a highly selective antagonist at angiotensin II type 1 (AT_1) receptors (1). It has a half-life of about 8 hours, and is metabolized to a negligible extent. Most of its clearance is via the feces.

In 1378 patients with mild to moderate hypertension valsartan 80 mg/day has been compared with losartan 50 mg/day and placebo for 8 weeks (2). This study confirmed the excellent tolerance profile, not different from placebo, of both angiotensin II receptor antagonists.

Vancomycin

General Information

Vancomycin is a narrow-spectrum glycopeptide antibiotic with potent antistaphylococcal activity. It was developed in the early 1950s. Early formulations contained substantial impurities, which were presumably responsible for some adverse reactions (1). When rapid infusion rates are avoided, vancomycin is rarely associated with serious toxicity. Reviews have suggested that the potential for vancomycin to cause significant ototoxicity or nephrotoxicity has been exaggerated (2,3). Improved manufacturing has resulted in a purer product and fewer toxic effects, but vancomycin is still associated with potentially serious adverse reactions (4).

Vancomycin inhibits bacterial cell wall synthesis and is bactericidal during cell division at therapeutic concentrations. Bacterial resistance to vancomycin has not been an issue during the first decades of its use. More recently, vancomycin-resistant enterococci have been recovered with increasing frequency from hospitalized patients. In some institutions, multidrug-resistant and vancomycin-resistant enterococci have become important nosocomial pathogens, difficult to treat. Vancomycin-resistant enterococcal bacteremia is associated with a poor prognosis. Judicious use of vancomycin and broad-spectrum antibiotics is recommended, and strict infection control measures must be implemented to prevent nosocomial transmission of these organisms (5).

Vancomycin is particularly useful in infections caused by meticillin-resistant or penicillinase-producing staphylococci and diphtheroids, as well as in the prophylaxis of bacterial endocarditis and in the treatment of antibiotic-associated colitis. Sufficient fecal concentrations can be achieved with oral therapy. It is poorly absorbed from the gastrointestinal tract and painful when injected intramuscularly. It diffuses moderately well into bone tissue (6).

Lactoferrin, a protein contained in tears, increases the activity of vancomycin against biofilms of strains of *Staphylococcus epidermidis* and may be therapeutically helpful in the treatment of infections such as endophthalmitis associated with intraocular lenses (7).

Observational studies

In a prospective, observational study of 742 consecutive patients (390 men; mean age 51 years, range 17–86), the incidence, outcomes, and predictive factors of vancomycin-associated toxic effects in general oncology practice were assessed (8). In all, 47% had hematological malignancies, and of the patients with solid tumors, primary urogenital (12%) and breast (10%) tumors were most common. In 72% vancomycin was given in a dosage of 2 g/day, 16% received a prophylactic dose of 1 g/day, and 12% had another regimen not specified. Phlebitis occurred in 3%, predominantly those with recently inserted central venous catheters. All responded promptly to local therapy, and withdrawal of the catheter or vancomycin was never required. Skin rashes occurred in 11%. However, all but four patients concomitantly received a beta-lactam antibiotic. None of the rashes

© 2006 Elsevier B.V. All rights reserved.

required withdrawal, although the beta-lactam antibiotic was often withdrawn. There was clinical evidence of ototoxicity in 6% of the patients who received other ototoxic drugs and only 3% of patients who were not receiving other ototoxic drugs. There was nephrotoxicity in 17%. Logistic regression was used to derive a model of risk of nephrotoxicity. Factors associated with an increased risk of nephrotoxicity included administration of other mild to moderate nephrotoxic agents or APACHE II scores over 40. Raised serum vancomycin concentrations did not reliably predict subsequent nephrotoxicity. The derived model was prospectively tested in a validation set of 359 patients. Sensitivity of the Nephrotoxicity Risk Index for any nephrotoxicity was 71% and for serious nephrotoxicity 100%. Specificity for any nephrotoxicity was 90% and for serious nephrotoxicity 81%. A main limitation of the study was the lack of patients who received only vancomycin. The concomitant administration of other agents may therefore have confounded the results.

The adverse effects of once-daily or twice-daily vancomycin were not significantly different in 121 hospitalized patients (9). Nephrotoxicity developed in 11 and 7.7% of the patients respectively; hearing loss in 3.2 and 16%; phlebitis in 14 and 23%; and red man syndrome in 14 and 9.6%.

Comparative studies

In a prospective, randomized trial in 34 drug abusers a short course of a combination of a glycopeptide (vancomycin or teicoplanin) with gentamicin was significantly less effective in right-sided endocarditis caused by *Staphylococcus aureus* than a combination of cloxacillin and gentamicin (10).

Use in non-infective conditions

Many parents of children with regressive-onset autism have noted antecedent antibiotic exposure followed by chronic diarrhea. In a subgroup of children, disruption of indigenous gut flora might promote colonization by one or more neurotoxin-producing bacteria, contributing at least in part to their autistic symptoms. In 11 children with regressive-onset autism who had broad-spectrum antimicrobial exposure followed by chronic persistent diarrhea, oral vancomycin resulted in short-term improvement; however, these gains had largely waned at follow-up (11).

Red man syndrome

A unique and peculiar adverse reaction related to the rapid infusion of large doses is the so-called red neck or red man syndrome. It is the most common adverse reaction to vancomycin, characterized by fever, chills, paresthesia, and erythema at the base of the neck and the upper back, and can be followed by a hypotensive episode (12). It is not a true allergic reaction. It seems to be due to vancomycin-induced release of histamine and possibly other vasoactive substances without the involvement of preformed antibodies (13,14). In rat peritoneal mast cells vancomycin provoked histamine release dose-dependently; fosfomycin inhibited this effect (15).

Antihistamines (H_1 receptor antagonists) prevent anaphylactoid reactions to vancomycin (16). The recommended method of administration is by intravenous infusion of a solution of 0.25–0.5% over 60 minutes, and patients have to be monitored closely. A possible red man syndrome has also been associated with systemic absorption of oral vancomycin in a patient with normal renal function (17).

In a prospective, randomized, double-blind, placebo-controlled study in 30 patients who required vancomycin chemoprophylaxis before elective arthroplasty, oral pretreatment with either a histamine H_1 receptor antagonist (diphenhydramine 1 mg/kg) or a histamine H_2 receptor antagonist (cimetidine 4 mg/kg) significantly reduced the histamine-related adverse effects of rapid vancomycin infusion (18).

It has been stressed that near-fatal red man syndrome can also occur after slow administration of vancomycin (19).

- An 83-year-old white man became distressed and had nausea and facial flushing after 10 minutes of a slow infusion of vancomycin (1 g scheduled over 2 hours). Despite interruption, he developed suffocating respiratory distress requiring intubation and mechanical ventilation. Uncharacteristic of anaphylactoid reactions, he became severely hypertensive. Subsequently, his condition rapidly normalized. During the acute event, there was an increase in serum troponin concentration.
- A 45-year-old man developed hypotension, bradycardia, a change in consciousness, and an erythematous macular rash 10 minutes after the slow infusion of 0.1% vancomycin (20). After appropriate management, he recovered well and was discharged on the following day.

In 50 patients, in whom vancomycin 15 mg/kg was continuously infused at a constant rate over 30 minutes, the occurrence of pruritus suggested that systemic vascular resistance was falling, exposing the patient to a risk of hypotension (21). Therapy with a beta-blocker appeared to confer protection against this hemodynamic effect.

Pretreatment with H_1 and H_2 receptor antagonists (diphenhydramine 1 mg/kg and cimetidine 4 mg/kg) intravenously serially over 3 minutes starting 10 minutes before the infusion of vancomycin permitted rapid vancomycin administration (1 g over 10 minutes) in 17 of 19 patients compared with eight of 19 patients treated with placebo in a prospective, randomized, double-blind, placebo-controlled study of patients undergoing elective arthroplasty (22). Hypotension occurred in 2 versus 12 of the patients, and 12 versus 19 of the patients had a rash. Serum histamine concentrations were raised after vancomycin administration in both groups.

Possible synergism between vancomycin and narcotics in the induction of red man syndrome due to histamine release has been suggested in a 19-year-old women treated with fentanyl and vancomycin during orthopedic surgery (23). Evidence from an animal study has suggested that the risk can also be enhanced by the co-administration of muscle relaxants, resulting in enhanced release of histamine (24).

Pharmacoeconomics

The pharmacoeconomic impact of adverse effects of antimicrobial drugs is enormous. Antibacterial drug reactions

© 2006 Elsevier B.V. All rights reserved.

account for about 25% of adverse drug reactions. The adverse effects profile of an antimicrobial agent can contribute significantly to its overall direct costs (monitoring costs, prolonged hospitalization due to complications or treatment failures) and indirect costs (quality of life, loss of productivity, time spent by families and patients receiving medical care). In one study an adverse event in a hospitalized patient was associated on average with an excess of 1.9 days in the length of stay, extra costs of $US2262 (1990–93 values), and an almost two-fold increase in the risk of death. In the outpatient setting, adverse drug reactions result in 2–6% of hospitalizations, and most of them were thought to be avoidable if appropriate interventions had been taken. In a review, economic aspects of antibacterial therapy with vancomycin have been summarized and critically evaluated (25).

In a randomized, prospective, cost-effectiveness study both teicoplanin and vancomycin were assessed as second-line therapy in 66 neutropenic patients after the failure of empirical treatment with a combination of piperacillin + tazobactam and amikacin (26). The primary success of second-line therapy was equivalent, and the direct total costs were similar. Acquisition costs per dose were in favor of vancomycin, but costs derived from administering vancomycin and serum concentration monitoring led to similar costs for both regimens. With the exception of the red man syndrome, which occurred in 10% of vancomycin-treated patients but none of the teicoplanin-treated patients, toxicity (renal, liver, and ear toxicity, diarrhea, phlebitis) was also similar.

In a retrospective cost analysis, the records of 527 patients with acute leukemia were studied (27). They had been treated in a multicenter, randomized trial for febrile neutropenia with ceftazidime and amikacin plus either teicoplanin (6 mg/kg in a single dose; $n = 275$) or vancomycin (30 mg/kg/day in 2 doses; $n = 252$). Clinical responses were equivalent. Again the higher acquisition costs for teicoplanin were counterbalanced by the lower incidence of adverse events and easier administration, resulting in overall similar costs for both regimens. A total of 8% of patients treated with vancomycin reported adverse events compared with 3.2% of patients treated with teicoplanin. Rashes occurred in 6.0 versus 1.4% respectively. Nephrotoxicity, ototoxicity, fever, and hypotension occurred in very few patients.

Organs and Systems

Cardiovascular

Vancomycin can cause phlebitis if infused peripherally (28,29).

Nervous system

It is still controversial whether vancomycin can cause ototoxicity when given alone. However, vancomycin can augment the ototoxicity of aminoglycosides (30). Tinnitus and dizziness have been noted, resolving on withdrawal (31). Hearing loss can be transient or permanent. If vancomycin is combined with aminoglycosides, toxicity may be additive (32).

Sensory systems

Eyes

In 118 consecutive patients undergoing cataract surgery, the use of supplementary prophylactic vancomycin in the irrigating solution during extracapsular lens extraction was significantly associated with an increased incidence of angiographic and clinical cystoid macular edema (33).

Ears

The risk of ototoxicity has been assessed in a prospective study in 16 patients on continuous ambulatory peritoneal dialysis treated with two infusions of vancomycin (30 mg/kg) in 2 liters of peritoneal dialysate administered at 6-day intervals for episodes of peritonitis (34). Patients who were too ill to respond appropriately, those with pre-existing sensorineural hearing loss, those with a narrow auditory canal, those with a discharging ear or perforated tympanic membrane, and those receiving concurrent ototoxic drugs were excluded. The authors found no evidence of ototoxicity (pure-tone audiometry, electronystagmography, and clinical assessment), even with repeated courses of vancomycin. Average serum concentrations were in the target range. No adverse effects were recorded, except for a transient generalized pruritus in one patient after the start of infusion.

In a prospective multicenter study in 152 children with peritoneal dialysis-associated peritonitis one patient with vancomycin intoxication had a 20–30 dB increase in hearing threshold (35).

Hearing loss due to vancomycin toxicity has been treated by hemoperfusion and hemodialysis (36).

- A 14-month-old girl with chronic renal insufficiency due to renal dysplasia was empirically treated with ceftazidime and vancomycin for fever. Her calculated creatinine clearance was 10 ml/minute/1.73 m^2. She erroneously received vancomycin 1.5 g in 3 doses 6 hours apart. Her serum creatinine concentration increased and her vancomycin concentrations remained markedly high (338 mg/l 5 hours after the third dose). The half-life of vancomycin was 145 hours. Hearing loss developed. Continued charcoal hemoperfusion and hemodialysis were used to treat the disorder. Thrombocytopenia was noted as significant consequence of hemoperfusion. The patient did not fully recover her previous renal function and became dialysis dependent. The audiogram normalized by 6 months.

Metabolism

Lactic acidosis occurred in a 56-year-old woman who was given intravenous vancomycin 1 g bd for 10 days (37).

Hematologic

Hemophagocytosis after vancomycin and teicoplanin occurred in a 45-year-old woman (38).

Treatment with vancomycin can rarely cause reversible pancytopenia (39).

- Neutropenia occurred in a 48-year-old man 16 days after the start of vancomycin therapy (40). Vancomycin was withdrawn and he was given a granulocyte-colony

© 2006 Elsevier B.V. All rights reserved.

stimulating factor. He was then rechallenged with a single dose of vancomycin 1 g. His white blood cell count fell to 600 $\times$ 10^9/l but returned to normal with continued granulocyte-colony stimulating factor therapy.

- A 43-year-old white woman was given vancomycin for a suspected methicillin-resistant *S. aureus* infection (41). On day 10 she developed a fever, chills, and a disseminated lacy macular rash. Vancomycin was withdrawn but reinstituted 48 hours later. Another 24 hours later, she again developed a fever, chills, and a confluent erythematous rash. Sepsis developed, and ceftazidime was added. There was thrombocytopenia (118 $\times$ 10^9/l), and a fall in the white blood count (from 7.6 to 3.5 $\times$ 10^9/l) and hemoglobin (from 13.8 to 12.2 g/dl). One day later the leukocyte count was 2.6 $\times$ 10^9/l and the hemoglobin fell to 10 g/dl. Both drugs were withdrawn. The rash disappeared, the temperature returned to normal, and the blood cell counts completely recovered 4 days later.
- An 87-year-old white woman was treated with vancomycin for an abscess due to methicillin-resistant *S. epidermidis* (42). On day 30, her white blood cell count fell to 0.5 $\times$ 10^9/l after a total dose of 55 g of vancomycin. Vancomycin was withdrawn, and the white blood cell count returned to normal within 5 days. After 6 weeks vancomycin was reintroduced, and the white blood cell count fell to 0.325 $\times$ 10^9/l after a total dose of 14 g of vancomycin on day 9, but resolved rapidly after vancomycin was withdrawn.

Leukocytes

Vancomycin-induced neutropenia occurs in about 2% of treated patients, and complete recovery takes place in 2–5 days after withdrawal (43,44). It occurs after prolonged treatment with high doses in patients with normal renal function (for example more than 20 days of more than 15–20 mg/kg) or in the prolonged presence of high serum concentrations in patients with severe renal insufficiency (45). After withdrawal of vancomycin, neutropenia disappeared promptly. The bone marrow seemed to be unaffected. Other cases of agranulocytosis related to vancomycin therapy have been reported (46–48).

Neutropenia normally recovers after drug withdrawal, and the neutrophil count can recover when vancomycin is replaced by teicoplanin (49).

- A 35-year-old man was given vancomycin (1.5 g bd) for a wound infection with a coagulase-negative staphylococcus, a peptostreptococcus, and a coryneform Gram-positive bacillus. On day 37 hi white blood cell count was 2.8 $\times$ 10^9/l (baseline 5.2) with a low neutrophil count (0.5 $\times$ 10^9/l). Vancomycin was withdrawn and 2 days later he was given teicoplanin 400 mg/day, by which time the cell count had increased to 3.5 $\times$ 10^9/l, neutrophils 0.9 $\times$ 10^9/l. On day 45, the total white cell count was 4.9 $\times$ 10^9/l, neutrophils 2.3 $\times$ 10^9/l. Teicoplanin was continued for 1 month, and the white cell count remained normal.

A direct toxic effect of vancomycin and/or an immune-mediated mechanism (antineutrophil antibodies, sensitized lymphocytes) have been discussed.

- A typical case of vancomycin-induced neutropenia has been reported in a 39-year-old woman with sickle cell SS disease treated with vancomycin for methicillin-resistant coagulase-negative staphylococcal bacteremia (50). However, in addition to neutropenia, the clinical course was defined by a febrile period characteristic of drug fever, with delayed onset and resolution 48 hours after vancomycin was withdrawn. In this case, fluconazole and cefazoline were also administered, but their contribution to neutropenia was judged unlikely (negative rechallenge with fluconazole, withdrawal of cefazoline after less than 5 days of therapy).

Platelets

Thrombocytopenia is a rare adverse effect of vancomycin and may be associated with the presence of vancomycin-dependent antiplatelet IgG antibodies. Reports of drug-induced thrombocytopenia have been systematically reviewed (51). Among the 98 different drugs described in 561 articles the following antibiotics were found with level I (definite) evidence: co-trimoxazole, rifampicin, vancomycin, sulfisoxazole, cefalothin, piperacillin, methicillin, novobiocin. Drugs with level II (probable) evidence were oxytetracycline and ampicillin.

- Vancomycin-associated thrombocytopenia has been reported in a 72-year-old woman who was treated with gentamicin and vancomycin for infectious endocarditis due to *Clostridium pseudodiphtheriticum* (52). On the 4th day of treatment, the platelet count fell and reached a nadir of 14 $\times$ 10^{12}/l on day 7. Two days after withdrawal of vancomycin (day 8) the platelet count began to rise and reached 150 $\times$ 10^{12}/l within 5 days. Vancomycin-dependent antiplatelet IgG antibodies were not detected 10 days after vancomycin.
- Thrombocytopenia also developed in a 72-year-old man who was treated with vancomycin for staphylococcal sepsis after treatment with gemcitabine for metastatic pancreatic cancer (53). On day 12 thrombocytopenia developed, reached a nadir on day 18 (13 $\times$ 10^{12}/l), and did not respond to platelet transfusions. Bone-marrow megakaryocytes were adequate. Platelet-associated IgG and IgM were increased. Vancomycin was withdrawn on day 28, with prompt recovery of the platelet count to 136 $\times$ 10^{12}/l in 10 days.

Vancomycin was associated with subsequent thrombocytopenia in a retrospective study that included 193 patients in a surgical trauma intensive care unit (54).

Patients undergoing allogeneic hemopoietic stem cell transplantation always require platelet transfusions, but the increase in platelet count is often less than expected. The factors responsible for poor responses to platelet transfusions in this clinical setting are largely unknown. In a prospective study in 87 consecutive transplanted children univariate analysis showed that concomitant therapy with vancomycin is significantly associated with a lower post-transfusion corrected increment in platelet count (55).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Antibiotic-associated diarrhea can develop with any antibacterial agent. Vancomycin has been implicated as a rare cause of diarrhea associated with *Clostridium difficile* (56), despite the fact that vancomycin is often used to treat it.

- Diarrhea developed in a 60-year-old man on chronic hemodialysis after 20 doses of parenteral vancomycin (250 mg at each dialysis) (57). Although culture for *C. difficile* was not performed, latex agglutination was positive for *C. difficile* toxin.

A few other cases of antibiotic-associated diarrhea with vancomycin have been described in association with *C. difficile*. This paradoxical association, although very uncommon, should be considered in patients who develop diarrhea during vancomycin therapy.

Urinary tract

Of 69 neonates (including 8 with peak vancomycin concentrations over 40 μg/ml) with culture-proven *S. aureus* or coagulase-negative staphylococcal septicemia who received vancomycin for more than 3 days, 6 had a doubling of serum creatinine concentration during vancomycin treatment, and all were in the group with peak serum vancomycin concentrations under 40 μg/ml (58).

Nephrotoxicity of vancomycin is often mild and reversible after withdrawal. It occurs in 6–17% of courses (59). Higher frequencies of nephrotoxicity were reported when vancomycin was used in combination with an aminoglycoside, which is consistent with toxicological data obtained in rats (60). Nevertheless, evidence of synergistic toxicity between vancomycin and aminoglycosides is controversial (2,31,59). Endotoxins seem to potentiate the nephrotoxic effect of vancomycin, at least in rats (61).

Acute interstitial nephritis has been reported in a patient receiving vancomycin (62).

- A 64-year-old white man was treated with intravenous cloxacillin 2 g 4-hourly for a *S. aureus* sternal wound infection and osteomyelitis. On day 14, cloxacillin was discontinued because of a fall in renal function. Urinalysis was positive for occasional red blood cells and hyaline casts, but there were no eosinophils. He was given intravenous vancomycin 1.5 g 36-hourly. Renal function gradually improved and the dosing regimen was adjusted to 1.5 g/day. Predose vancomycin serum concentrations were 11.0 and 6.3 mg/l on days 23 and 30 respectively. On day 32, oral ciprofloxacin 500 mg bd was added for suspected sepsis (catheter tip cultures grew *Klebsiella pneumoniae*, although blood cultures were negative). Other medications were enteric-coated aspirin, warfarin, acebutolol, and digoxin. The next day, a progressing maculopapular rash developed and the patient continued to have a fever. Acute interstitial nephritis was confirmed by kidney biopsy. Hemodialysis was required, and he was treated with prednisone and made a gradual recovery. Four months later, he was treated with vancomycin for a relapse of the sternal infection. His eosinophil count rose and peaked at 18%, and there were eosinophils in the urine.

The authors found four other published cases of vancomycin-induced acute interstitial nephritis.

There was a fall in residual renal function during episodes of peritonitis in a prospective multicenter study in 152 children with peritoneal dialysis-associated peritonitis (35). The study evaluated the efficacy, safety, and clinical acceptance of combination treatment, including a glycopeptide (teicoplanin or vancomycin) and ceftazidime, each given either intermittently or continuously. Irreversible anuria developed in 19% of the patients with residual diuresis. In patients who retained residual renal function, there was a strong trend toward a decreased residual glomerular filtration rate (−11%). There was no difference with respect to the type of glycopeptide or the mode of use. Aminoglycosides were used concomitantly in only 12 patients and did not seem to affect the evolution of residual renal function. Underdosing/non-adherence or overdosing occurred in 8.2% of continuously treated versus 4.9% of intermittently treated patients. Intermittent and continuous intraperitoneal treatment with glycopeptides and ceftazidime were equally efficacious and safe when measured by objective clinical criteria.

In children with febrile neutropenia and Gram-positive bacteremia associated with antineoplastic drug therapy, teicoplanin was significantly less nephrotoxic than vancomycin (63).

The effect of co-administration of fosfomycin on glycopeptide antibiotic-induced nephrotoxicity for 3 days has been investigated in rats (64). Fosfomycin reduced glycopeptide antibiotic-induced nephrotoxicity, as shown by reduced urinary excretion of *N*-acetyl-beta-D-glucosaminidase and fewer histological signs of nephrotoxicity in those treated with a combination of glycopeptide and fosfomycin compared with a glycopeptide alone. In addition, the higher the dose of fosfomycin, the more it reduced urinary *N*-acetyl-beta-D-glucosaminidase activity, suggesting that the role of fosfomycin in alleviating nephrotoxicity is dose-dependent. There was significantly less accumulation of teicoplanin and vancomycin in the renal cortex of rats treated with glycopeptide antibiotics plus fosfomycin compared with the glycopeptide antibiotics alone.

Skin

Epidermolysis bullosa acquisita occurred in a 73-year-old man after a course of vancomycin for 15 days (65).

A fixed drug eruption after the fifth dose of vancomycin 1 g occurred in a 45-year-old white woman (66).

Vancomycin reportedly caused a severe delayed skin reaction with allergic cross-reactivity between vancomycin and teicoplanin requiring steroid therapy (67).

- A 68-year-old woman who was being treated with vancomycin for *S. epidermidis* bacteremia developed pruritus and a generalized maculopapular skin rash after 2 weeks. After a short course of prednisolone, she was given teicoplanin and developed general malaise, fever, conjunctival injection, an extensive rash, and later blisters on the legs, again requiring treatment with steroids.

Erythema multiforme

Erythema multiforme has been attributed to vancomycin (67).

© 2006 Elsevier B.V. All rights reserved.

- A 70-year-old woman given vancomycin postoperatively developed fever on day 5 and vancomycin was withdrawn. She then developed a generalized urticarial rash with oral and vaginal erosive lesions on day 6, requiring treatment with steroids and antihistamines. The diagnosis was confirmed by skin biopsy.

Vancomycin can cause the severe forms of erythema multiforme, both Stevens–Johnson syndrome (involvement of 10–30% of the skin surface) (68) and toxic epidermal necrolysis (more than 30% of the skin surface involved); both conditions include mucosal involvement.

- A 53-year-old white woman with liver cirrhosis took vancomycin (1 g bd) for sepsis due to methicillin-resistant *S. aureus* and a catheter-associated infection due to *Enterococcus faecalis*, developed oral and vaginal mucositis and conjunctivitis followed by a maculopapular rash (69). The diagnosis was confirmed by skin biopsy. Vancomycin was replaced by teicoplanin and corticosteroids; the symptoms disappeared within 7 days.
- A 36-year-old white woman with relapsing acute myeloid leukemia took ceftazidime (2 g tds) and aciclovir for febrile neutropenia and *Herpes labialis*. She developed an itchy rash and treatment was changed to imipenem (500 mg qds for 5 days), vancomycin (1 g bd for 3 days), and gentamicin (2 mg/kg for 3 days); chemotherapy included idarubicin, cytarabine, etoposide, ondansetron, and dexamethasone for 3 days. Within a few days the rash developed into blisters and erosions, affecting more than 80% of the skin. The diagnosis was confirmed histologically, and she subsequently died from shock (70).

Linear IgA bullous disease

Linear IgA bullous disease is an autoimmune subepidermal disorder, characterized by a linear deposition of IgA along the blister base, with a predominantly neutrophilic dermal infiltrate. Most often idiopathic, a subset of linear IgA bullous disease is induced by drugs, and intravenous vancomycin is the best-documented drug that triggers it (71). The diagnosis can be confirmed by direct immunofluorescence (72,73). In some cases the blisters resolve only after withdrawal of therapy and in others glucocorticoid therapy is required.

In a review of 17 cases the features were: mean age 65 years; 11 men/6 women; eruption latency 1–15 days; normal trough concentrations (when reported); cutaneous manifestations included bullous, urticarial, erythematous, and targetoid erythema multiforme-like lesions favoring the trunk, extremities, palms, and soles, and sparing the head and neck; six patients had mucosal involvement (74). The gold standard for diagnosis is direct immunofluorescence of the perilesional skin. Circulating antibasement membrane zone antibodies were identified only in a minority of patients. Therapies included drug withdrawal, prednisone, and dapsone. No spontaneous recurrences were reported.

Linear immunoglobulin A bullous disease has been reported in a 69-year-old white woman treated with vancomycin and ciprofloxacin, in a 53-year-old white man with septic shock, and in other cases in which both vancomycin and *Varicella zoster* infection were present as triggers (75–78).

- An 87-year-old white woman treated with vancomycin and phenytoin and a 65-year-old white man with renal insufficiency developed linear immunoglobulin A bullous disease (79,80).
- A 72-year-old woman developed a bullous eruption on her palms, soles, and conjunctivae a day after receiving vancomycin (intravenously and via a cecostomy tube) for staphylococcal sepsis (81). Immunofluorescence of the skin biopsy showed linear IgA deposition along the basement membrane. The lesions cleared over the next 2 weeks after withdrawal of vancomycin.
- A blistering eruption developed in the skin and buccal mucosa of a 79-year-old man after 8 days of vancomycin therapy for an infected leg ulcer (82). Biopsy showed linear IgA deposition along the basement membrane. The lesions cleared spontaneously within two days of withdrawal.
- After 7 days of antibiotic therapy with intravenous vancomycin, gentamicin, and ticarcillin + clavulanate for *Pseudomonas aeruginosa* and *S. aureus* sepsis, confluent erythematous-based vesicobullae developed in a 65-year-old woman with subarachnoid hemorrhage secondary to a ruptured aneurysm (72). Other medications included ranitidine, glyceryl trinitrate, nimodipine, ferrous sulfate, and phenytoin.
- On the tenth day of antibiotic therapy with vancomycin, imipenem, and gentamicin for an infected enterocutaneous fistula, widespread bullae developed in a 60-year-old woman (72).
- In a 71-year-old woman with pneumonia, vesicles and bullae developed on the eighth day of antibiotic therapy that consisted of one dose of intravenous vancomycin followed by a course of nafcillin (73).
- A 52-year-old woman was given vancomycin 1 g intravenously bd and within 12 hours developed a generalized pruritic maculopapular rash (83). Over the next few days, the lesions progressively worsened and transformed into hemorrhagic and non-hemorrhagic vesicles and bullae. Mucosal surfaces, palms, and soles were spared. The skin lesions completely healed without scarring within 2 weeks of vancomycin withdrawal. There was no recurrence 5 months later.

Sexual function

- Prostatitis due to vancomycin-resistant enterococci has been reported in a 42-year-old liver transplant recipient (84). The organism, *Enterococcus faecium*, was resistant to vancomycin, ampicillin, ciprofloxacin, and doxycycline. Treatment with a combination of rifampicin and nitrofurantoin for 6 weeks resulted in a long-lasting cure.
- Priapism has been reported in a 37-year-old man with a 30-year history of severe diabetes mellitus after two doses of vancomycin 1 g intravenously for treatment of methicillin-resistant *S. aureus* bursitis (85).

The authors noted that an interaction between vancomycin and other medications (cefazolin, aztreonam, ciclosporin, prednisone, mycophenolate mofetil, and co-trimoxazole) could not be ruled out.

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Allergic reactions with vancomycin, such as rashes, chills, fever, and eosinophilia, can occur in up to 5% of patients. Severe anaphylactic reactions are rare. Alpha-tryptase is only detected in the blood during systemic anaphylactic reactions, having been released by degranulation from activated mast cells. Plasma tryptase activities were unchanged, independent of increased histamine concentrations, antihistamine pretreatment, and clinical symptoms of anaphylactoid reaction in 40 patients receiving vancomycin (1 g over 10 minutes) before elective arthroplasty (86). The authors conclude that plasma tryptase activities can be used to distinguish chemical from immunological reactions.

Vancomycin anaphylaxis is a major management problem in patients with methicillin-resistant *S. aureus* sepsis. However, desensitization in patients with previous anaphylaxis is possible (87).

- An anaphylactic reaction occurred in a 77-year-old woman 5 minutes after the start of a vancomycin infusion, when she had received only 40 mg (88). She became unconscious and had a severe cardiovascular collapse, from which she was resuscitated with intravenous ephedrine and adrenaline.
- A 47-year-old white woman with end-stage renal disease had had anaphylactoid shock after vancomycin 1 g intravenously infused over 1.5 hours and gentamicin 90 mg 3 years before, despite premedication with diphenhydramine (89). She was treated with doubling doses of vancomycin every 30 minutes for methicillin-resistant *S. epidermidis*. She had no reaction.

The authors of the second report could not exclude that the previous anaphylactoid reaction had not been due to gentamicin, as no specific testing was done. Although successful vancomycin desensitization has been described, this would be the first time in a patient with a history of anaphylactoid reaction.

In some patients the clinical presentation of red man syndrome is identical to that of acute IgE-mediated anaphylaxis. Vancomycin desensitization should therefore be considered for severe red man syndrome reactions that do not respond to premedication and a slower rate of infusion, and in anaphylactic reactions to vancomycin when substitution of another antibiotic is not feasible. Rapid desensitization is preferred, as it is effective in the majority of patients and enables administration of vancomycin within 24 hours. In patients who fail rapid desensitization, a slow desensitization protocol may be tried (90).

Vasculitic rashes have been described rarely. Two case reports have suggested that there may be cross-reactivity between vancomycin and teicoplanin with respect to biopsy-proven leukocytoclastic vasculitis (91). In both cases, vancomycin-induced vasculitis improved after drug withdrawal. Teicoplanin was started and the rash reappeared several days later. In one case the rash faded after teicoplanin had been withdrawn. In the other, teicoplanin was continued, but the rash improved after prednisolone was given.

Long-Term Effects

Drug resistance

The increasing rate of antimicrobial drug resistance has been a matter of great concern and is the most serious unwanted effect of these drugs. However, in spite of the fact that the problem is now very well recognized (SEDA-25, 279), it continues to grow.

History

Most antimicrobial drugs are natural products, that is they are produced by micro-organisms such as bacteria or fungi, often found in the soil. In fact, they can be looked upon as nature's regulatory principle for microbial society. Resistance to antimicrobial drugs is therefore a natural phenomenon. Before the introduction of penicillin in the 1940s, resistance to antimicrobial drugs was not a clinical problem. At that time, the large majority of commensal and infectious bacteria associated with infections in man were susceptible.

Over the last six decades, however, increased use of antimicrobial drugs, not only in human medicine, but in other areas, such as veterinary medicine, agriculture, and fish farming, has had an enormous impact on the microbial society. Nearly everywhere, the numbers of susceptible strains have reduced and resistant strains or variants have increased in numbers. It has been repeatedly reported that the susceptibility profile of bacteria in any human compartment, such as the skin, intestine, and respiratory tract, is very different from what it was in the pre-antibiotic era, and even 15 years ago. The same trend is reported from hospitals and homes. Multidrug resistance, that is resistance to several antimicrobial drugs, is commonly found in bacteria that cause infections as well as in commensal organisms.

A few decades ago, it was a common opinion that various compartments in nature have their own flora. As an example, it was claimed that you could use antimicrobial drugs relatively freely in fish farming without increasing the burden of resistance in humans. Now we have learned the lesson. Micro-organisms circulate everywhere, and there is a continuous exchange of strains between all compartments in nature (humans, animals, birds, fish, etc.). Even if a bacterial species is host-specific, the genetic material that codes for resistance is not. In fact, antibiotics have shown that bacteria have great genetic adaptability, in terms of their ability to exchange genetic traits among genera and species which are evolutionarily millions of years apart. Antibiotic resistance genes on plasmids and transposons flow to and from nearly all types of bacteria. Sometimes they leave the plasmid and jump into bacterial chromosomes; sometimes they jump back again.

However, this knowledge is not being heeded everywhere. Small doses of antimicrobial drugs as "growth promoters" are still commonly used, even in countries in which the health authorities should be aware of the problems. It is easy to blame developing countries for using antimicrobial drugs as growth promoters, or for selling antimicrobial drugs over the counter without prescription, but it took the European Community many years before it started to look into the problem of using antimicrobial

© 2006 Elsevier B.V. All rights reserved.

drugs as growth promoters. The history of cross-resistance between avoparcin and vancomycin may have provided important background for this alteration in attitude.

Avoparcin and vancomycin are glycopeptide antibiotics, large molecules that are produced by a variety of environmental micro-organisms, which may therefore contain genes that code for antimicrobial drug resistance. Both of these drugs are mostly active against Gram-positive bacteria, such as enterococci and staphylococci. In Europe, avoparcin was allowed to be used as an animal food additive in many countries, while the use of vancomycin was limited to humans. Nobody bothered about the possibility of cross-resistance between avoparcin and vancomycin until 10 years ago. After the emergence of vancomycin-resistant enterococci and after more than 2 years of hard lobbying by several groups, avoparcin was withdrawn from the market in the European Community. However, in the meantime, vancomycin-resistant enterococci had become widespread in many European countries.

Instead of focusing on the development of resistance to a specific antimicrobial drug in a specific species, we should focus on the microbial community as a single entity or a "metagenome". Any use of any microbial agent might cause resistance to develop in one or more microbial species. When such genes have first become established, they may float around and be picked up by other species. This approach to the development and spread of resistance can, and should, be applied to the microbial flora in all mammals, as well as in the environment. The consequence of this approach is that we should, every time we prescribe an antimicrobial drug, try to find a drug that hits nothing but the pathogen in the infected organ(s). Of course, this can be difficult and sometimes even close to impossible. But that should not stop us from trying. For example, in nearly all cases, a third-generation cephalosporin for acute pharyngitis caused by Group A streptococci, or of a fluoroquinolone for acute cystitis, are not the best alternatives.

Ecology

In our struggle for prudent use of antimicrobial drugs, the so-called eco-shadow concept represents a challenging way of following alterations in mammalian and environmental ecosystems produced by exposure of these systems to antibiotics (92). In brief, an eco-shadow (ecological shadow) can be defined as any alteration in any ecosystem following exposure of the system to an antimicrobial drug (or any compound that influences the system). The alterations can be of variable length and may involve a variable number of species and functions, including the development and spread of resistance. When possible, the sum of all the alterations caused by an antibiotic can be included in an "eco-shadow index." A large eco-shadow or high eco-shadow index indicates a high tendency to the development of microbial resistance.

At present, it seems that Europe has taken the lead in the fight against antimicrobial drug resistance. At the Fourth European Conference on Antibiotic Resistance, organized by the European Commission and held in Rome in November 2003, it was strongly emphasized that only a multidisciplinary approach, involving all stakeholders—physicians, researchers, industry, politicians, and patients—can overcome the problem of increasing resistance. It is to be hoped that this problem will be established as a major objective for the forthcoming European Centre for Disease Prevention and Control.

Reports of organisms that are resistant to vancomycin

The first case of methicillin-resistant *S. aureus* with intermediate resistance to vancomycin was documented in May 1996. Additional cases have been described in the USA:

- a 59-year-old man with diabetes mellitus and chronic renal insufficiency suffering from peritonitis;
- a 66-year-old man with diabetes who developed a septicemia after 18 weeks of vancomycin treatment for recurrent methicillin-resistant *S. aureus* bacteremia;
- a 79-year-old man with diabetes and chronic renal insufficiency, who developed intermediate vancomycin-resistance after a 6-week therapy with vancomycin for MRSA bloodstream infection.

In the last case the strain was identical to eight MRSA isolates obtained from hospitals in the New York City metropolitan area, and all eight isolates, but not control isolates, could be transformed in vitro to develop intermediate resistance to vancomycin. Both the presence of glycopeptides and environmental factors, as demonstrated by increased resistance of *S. aureus* to antibiotics in the presence of prosthetic material in animals, can exert selective pressure to develop new resistance mechanisms (93–95).

There are reports of vancomycin-dependent enterococci that grow only in the presence of vancomycin and are best treated by withdrawal of the compound (96).

Vancomycin/glycopeptide intermediately resistant and methicillin-resistant *S. aureus* have been described in Japan, Europe, the Far East, and the USA. Some vancomycin-susceptible strains of *S. aureus* contain subpopulations with intermediate resistance to vancomycin (heterogeneous strains), and these may escape laboratory detection (93,94,97–99).

Numerous risk factors have been identified for infection with vancomycin-resistant enterococci. In one study the severity of mucositis in cancer patients was significantly associated with vancomycin-resistant enterococci (100). Previous vancomycin therapy was also believed to be a risk factor. However, a meta-analysis concluded that the reported strong association between vancomycin treatment and hospital-acquired vancomycin-resistant enterococci results from selection bias, confounding by duration of hospitalization, and publication bias (101).

Glycopeptide resistance in a cluster of three clinical isolates of vancomycin-resistant *Enterococcus faecium* was due to vanD, which was located on the chromosome and was not transferable to other enterococci. These isolates were indistinguishable but differed from the strain in which vanD-mediated resistance has been reported previously (102). A type of acquired glycopeptide resistance, named vanE, has been characterized in *E. faecalis* BM 4405. It results in low-level resistance of vancomycin but susceptibility to teicoplanin (103). Defects in penicillin-binding protein 4 result in a distorted peptidoglycan composition of the cell of vancomycin-resistant and teicoplanin-resistant laboratory mutants of *S. aureus* and are suggested to be part of the mechanism of glycopeptide resistance in these microbes (104).

© 2006 Elsevier B.V. All rights reserved.

Vancomycin-dependent enterococci growing only in the presence of vancomycin are best treated by withdrawing vancomycin (96). However, vancomycin-independent revertants can rapidly emerge in vitro, endangering the cure of patients treated by interruption of vancomycin only (105).

In a study of antibiotic resistance in enterococci from raw meat, there was a high prevalence of glycopeptide-resistant strains (106). Resistance to vancomycin was significantly associated with resistance to teicoplanin, erythromycin, tetracycline, and chloramphenicol.

The prevalence of vancomycin-resistant enterococci (VRE) has been investigated in 49 laboratories from 27 European countries, which collected 4208 clinical isolates; 18 vanA and 5 vanB isolates of VRE were identified (107). The prevalence of vanA VRE was highest in the UK (2.7%), while the prevalence of vanB VRE was highest in Slovenia (2%). Most vanA and vanB vancomycin-resistant enterococci were identified as *E. fecium*. A total of 71 isolates containing the vanC gene were identified. The prevalence of vanC VRE was highest in Latvia and Turkey, where rates were 14 and 12% respectively. Two-thirds of these isolates were identified as *Enterococcus gallinarum* and one-third as *Enterococcus casseliflavus*.

In 155 methicillin-resistant strains of *S. aureus* isolated from patients in Thailand, one-point population analysis identified three methicillin-resistant strains, which contained subpopulations of cells with reduced susceptibility to vancomycin (108).

Susceptibility Factors

Renal disease

Vancomycin is eliminated almost exclusively by renal excretion. In oliguria 1 g can produce therapeutic plasma concentrations for 10–14 days. Hemodialysis fails to remove vancomycin from the body to any significant extent. If renal function is compromised, even oral therapy with vancomycin can lead to high and potentially toxic serum and CSF drug concentrations (109).

Drug Administration

Drug contamination

Vancomycin underwent spontaneous chemical modification when kept at room temperature at neutral pH in aqueous solutions containing traces of formaldehyde or acetaldehyde (110). In vitro studies on two different strains of bacteria showed that the resulting compounds had reduced antibacterial activity.

Drug administration route

In a multicenter, prospective, randomized comparison of continuous infusion of vancomycin (targeted serum plateau concentrations of 20–25 μg/ml) and intermittent infusions of vancomycin (targeted serum trough concentrations of 10–15 μg/ml) in 119 critically ill patients, microbiological and clinical outcomes and safety were similar (111). Continuous infusion of vancomycin produced the target concentration faster, and fewer samples were required for monitoring. Serum creatinine concentrations and creatinine clearance increased non-significantly from baseline to the end of treatment in the two groups. There was nephrotoxicity in 21 patients (10 of whom received the continuous infusion). Vancomycin given concomitantly with other antibiotics was associated with a significant increase in the serum creatinine concentration, but not when it was given alone. Dialysis was required for three of those who were given intermittent infusions and six of those who were given continuous infusions. Red man syndrome was reported in one patient who was given an intermittent infusion, and phlebitis and fever in two patients who were given continuous infusions.

Drug overdose

- Accidental 10-fold vancomycin overdose in a 6-month-old girl resulted in flushing and a transient rise in serum creatinine concentration, but she recovered completely without specific therapeutic intervention (112).
- Two preterm twins, born in the 35th week of gestation, accidentally received an overdose of vancomycin as an intravenous bolus injection (113). Both were treated from the day of birth with piperacillin (100 mg/kg/day) and cefotaxime (100 mg/kg/day) for congenital pneumonia. On the 6th day of antibiotic therapy, vancomycin (38 and 35 mg/kg respectively) was given over 1 minute. A few minutes later the twins developed flushed faces and trunks and peripheral cyanosis. Other findings were a prolonged capillary refill time, apnea and hypoxemia, bradycardia (40–60/minute), a fall in systolic blood pressure of 10 mmHg, and metabolic acidosis (pH 7.29 and 7.24 and base excess −10.5 and −10.9 respectively). Metabolic acidosis and the red man syndrome disappeared after 30 minutes. Serum vancomycin concentrations were 32 and 34.5 μg/ml respectively 9 hours after administration. Fundoscopy and repeated otoacoustic emissions were normal. There was minimal reduction in creatinine clearance. Tubular proteinuria, paralleled by increased activity of *N*-acetyl-beta-D-glucosaminidase in the urine, resolved completely within 1 week.
- Hemodialysis with high-efficiency dialysis membranes resulted in a removal of plasma vancomycin of about 60% (calculated half-life 2 hours) in two children with initial plasma vancomycin concentrations of 238 μg/ml and 182 μg/ml (114).
- In a 6-day-old neonate with a solitary hypodysplastic kidney, suspected sepsis, and acute renal insufficiency, venovenous hemodiafiltration with a high-flux membrane was successfully used to treat a 10-fold overdose of vancomycin (115).

Multiple-dose activated charcoal does not increase the elimination of vancomycin and is therefore not recommended for detoxification of acute poisoning (116).

Drug–Drug Interactions

Aminoglycoside antibiotics

Vancomycin is more nephrotoxic than teicoplanin when it is combined with aminoglycosides (117).

© 2006 Elsevier B.V. All rights reserved.

Beta lactam antibiotics

Vancomycin and ceftazidime are incompatible in vitro because of precipitation due to the alkaline pH of vancomycin relative to ceftazidime. This phenomenon was encountered in two cases of post-traumatic endophthalmitis (118). Immediately on local administration of the antibiotics, which were injected using different needles and syringes for each drug, dense yellow-white precipitates were observed along the needle tract in the vitreous cavity. During follow-up the vitreous opacities gradually disappeared over a period of 2 months, with complete resolution.

Co-administration of imipenem + cilastatin may reduce the nephrotoxicity of vancomycin, as suggested by a study in rats (119).

Dexamethasone

Intravitreal application of dexamethasone may reduce the elimination of intravitreal vancomycin and may enhance this therapy, as suggested by an in vivo study in rabbits (120).

Dobutamine

In critically ill patients, co-administration with dobutamine can enhance vancomycin clearance by increasing cardiac output and renal blood flow and by interacting with the renal anion transport system, increasing glomerular filtration rate and renal tubular secretion (121).

Dopamine

In critically ill patients, co-administration with dopamine can enhance vancomycin clearance by increasing cardiac output and renal blood flow and by interacting with the renal anion transport system, increasing glomerular filtration rate and renal tubular secretion (121).

Fosfomycin

Co-administration of fosfomycin may reduce the nephrotoxicity of vancomycin, as suggested by a study in rats (119).

Furosemide

Preterm infants often receive theophylline for apnea of prematurity and furosemide to improve dynamic lung compliance and to reduce total pulmonary resistance. In 10 preterm infants receiving furosemide plus theophylline, vancomycin was introduced according to the generally recommended dosing schedules but failed to achieve anticipated therapeutic concentrations (122). In nine infants the addition of furosemide to vancomycin plus theophylline resulted in a fall in serum vancomycin concentrations to subtherapeutic within 24 hours, and only in one did vancomycin concentrations remain within the target range. The addition of furosemide reduced the serum creatinine concentration by 24% (range 12–43). These data suggest that furosemide enhances the excretion of vancomycin, and an acute and transient increase in glomerular filtration rate and creatinine clearance may be the explanation.

Gelatin

Vancomycin is incompatible with gelatin-containing fluids, resulting in precipitation (123).

Levofloxacin

Changes in pharmacokinetics were studied in male Wistar rats when intravenous vancomycin 100 mg/kg and levofloxacin 20 mg/kg were administered together (124). There was an increase in the AUC and half-life of vancomycin. There was also an increase in the AUC and a delay in the t_{max} of levofloxacin, but no effect on C_{max}; these data suggested delayed absorption of levofloxacin. Concomitant administration had no effect on the correlation between serum and hepatic tissue concentrations of levofloxacin, but it markedly reduced the correlation between the serum and renal tissue concentrations of vancomycin. Vancomycin increased serum creatinine concentrations 8 hours after administration. However, there was no difference in animals who received monotherapy compared with animals who received combined therapy. The authors suggested the cautious use of a combination of levofloxacin and vancomycin and advised monitoring blood concentrations of vancomycin in such cases.

Neuromuscular blocking drugs

Some authors stress the fact that vancomycin can interact with anesthetic drugs, particularly muscle relaxants. In the reported cases anaphylactoid reactions were seen, with intense erythema and marked permeability changes (125).

Monitoring Therapy

There is evidence that predose concentrations of teicoplanin are related to clinical outcome; the evidence is less conclusive for vancomycin. Predose concentrations can be linked to some toxic effects (nephrotoxicity for vancomycin and thrombocytopenia to teicoplanin) (SEDA23.26.77) (126,127). Monitoring of serum concentrations has therefore been advocated to reduce potential nephrotoxicity and ototoxicity due to interpatient variability in vancomycin pharmacokinetics. However, routine monitoring is probably unnecessary in most patients (3,128). Clinical settings in which monitoring is wise include combination therapies with an aminoglycoside and treatment of patients with poor or unstable renal function (2). Vancomycin-induced nephrotoxicity is clearly related to drug plasma concentrations: trough vancomycin concentrations over 15 μg/ml were associated with significantly more nephrotoxicity (129).

In a prospective study to determine if standardized vancomycin doses could produce adequate serum concentrations in 25 full-term neonates with sepsis 13 had adequate peak vancomycin serum concentrations (20–40 mg/ml) and one had a peak concentration with a risk of ototoxicity (over 40 μg/ml) (130). Only 12 had adequate trough concentrations (5–10 mg/ml) and 7 had a risk of nephrotoxicity (over 10 μg/ml). There was no significant difference between peak or trough concentrations and good or bad clinical outcomes.

Intravenous vancomycin 30–40 mg/kg/day, divided every 6 hours, was given to167 infants and children without cancer and 42 cancer patients aged 3 months to 17.5

© 2006 Elsevier B.V. All rights reserved.

years with normal serum creatinine concentrations and without evidence of renal dysfunction (131). In 93% of the children without cancer, peak serum vancomycin concentrations were in an adequate target range (8–55 μg/ml). However, 10% of the children with cancers had peak serum vancomycin concentrations below 10 μg/ml, and 21% had trough concentrations less than 5 μg/ml; an increased dosage was required to achieve adequate peak concentrations. There were no treatment failures. The authors suggested the following guidelines:

- the serum creatinine concentration should be measured within 24 hours of beginning therapy, to verify normal renal function, and weekly thereafter to detect an eventual reduction in creatinine clearance;
- an increase of serum creatinine of more than 44 μmol/l (0.5 mg/dl) over baseline should be followed by monitoring serum vancomycin concentrations;
- peak and trough vancomycin serum concentrations measurements are not necessary in children without cancer receiving 40 mg/kg/day or less who have normal renal function and do not receive other potentially nephrotoxic drugs; this approach should be individualized, based on factors such as degree of illness, poor clinical response, or persistent positive cultures;
- monitoring should be considered for patients with cancer, neonates, those receiving concurrent nephrotoxic drugs, patients with renal insufficiency, and for dosages over 40 mg/kg/day.

Fluorescence polarization immunoassay determination of serum vancomycin concentrations can result in falsely high vancomycin concentrations in excess of 30–80% in patients with renal dysfunction. This is due to the formation of a non-toxic, non-microbiologically active pseudometabolite, the vancomycin crystalline degradation product (132). A report on a 48-year-old man underlies the significance of resulting underdosing and eventually suboptimal clinical response (133).

Managing Adverse Effects

Vancomycin clearance is minimally altered by hemodialysis using standard cuprophane membranes. However, it is significantly increased using a high-flux polysulfone membrane.

- A 17-year-old anuric woman with end-stage renal insufficiency received a massive overdose of vancomycin (40 mg/kg/day for 8 days) and was treated three times with high-flux hemodiafiltration with a polysulfone membrane (134). The vancomycin concentration fell from 101 to 17 mg/l at the end of the procedure. There were no adverse effects of either vancomycin or hemodiafiltration.
- In a 46-year-old African-American woman with sickle-cell disease there was clinically significant removal of vancomycin during a plasma exchange transfusion (135).

Varicella vaccine

See also Vaccines

General Information

A live attenuated *Varicella* vaccine was developed in 1973 by Takahashi using the Oka strain, which was isolated from a boy with chickenpox and named after the boy. Several producers use this live vaccine strain, for example Biken Institute, Merck, Sharp & Dohme, and SmithKline Beecham. Whereas the first Oka strain vaccines needed to be stored at −20°C, subsequent reformulation of the vaccine provided a shelf-life of up to 2 years at +2°C, with

© 2006 Elsevier B.V. All rights reserved.

immunogenicity and safety comparable to other Oka strain *Varicella* vaccines (1). The safety and efficacy of *Varicella* vaccine have been critically reviewed (2).

Non-infective uses

In an experimental model of multiple sclerosis, repeated high doses of antigen (myelin basic protein) deleted both the clinical and pathological manifestations of the disease. The effects of *Varicella* vaccine on 50 patients with chronic progressive multiple sclerosis have therefore been studied (3). The patients were immunized with *Varicella* vaccine and followed for 1 year. All were seropositive for *Varicella* before immunization and all had rises in *Varicella* antibodies after being given the vaccine. There was improvement in 14 patients, 4 became worse, and 29 were unchanged. Four patients developed mild chickenpox after immunization. No other untoward adverse effects occurred.

General adverse effects

There have been many clinical trials to assess the immunogenicity and safety of *Varicella* vaccine, in both healthy and immunocompromised individuals (SEDA-12, 285) (SEDA-13, 290) (SEDA-14, 285) (SEDA-15, 289) (SEDA-17, 379). The vaccine was safe and immunogenic. The reports of different investigators were similar. Mild local reactions at the injection site were the most commonly reported adverse effects, occurring in about 10% after the first and second dose. Vaccine-associated rashes about 1 month after the first dose were reported in about 6% of vaccinees, sore throat in 8%, and fever over 37.8°C in 2%. Rash and fever after the second dose of vaccine were reported by less than 1% of vaccinees. Maculopapular or papulovesicular rashes occurred much more often in vaccinees with suspended chemotherapy (42%) (4,5).

Oka strain *Varicella* vaccine (Merck) has been evaluated in immunocompromised children with leukemia in remission (6,7). Most children had chemotherapy stopped 1 week before and 1 week after immunization; glucocorticoids were also stopped for 3 weeks (from 1 week before to 2 weeks after immunization). *Varicella* vaccine was safe, immunogenic, and effective in leukemic children at risk of serious disease or death from chickenpox. The major adverse effect was a mild rash in 50% of the children within 1 month of immunization, about 40% of whom were treated with aciclovir. A mild form of *Varicella* developed in 14% of immunized children exposed to *Varicella* (household contacts). The vaccine protected completely against severe *Varicella*. Leukemic vaccinees were less likely to develop zoster than were comparable children with leukemia who had wild type *Varicella*.

Between 1987 and 1993, *Varicella* vaccine developed by the Biken Institute was given to 1.39 million individuals in Japan and 1.93 million individuals in South Korea. Adverse effects occurred in 6.9% of vaccinees. Despite more than 100 well-documented contacts with *Varicella* patients, only 2% of those immunized developed breakthrough *Varicella*, with very mild clinical features (8).

In 1995, live virus *Varicella* vaccine (Oka strain) was licensed in the USA. Of the 6574 reported adverse events 4% (67.5 per 100 000 doses) after immunization were serious, while the majority were minor reactions, such as rash, redness, or injection site pain (9). About 10% of immunized children developed mild chickenpox. A total 193 vaccinees reported neurological symptoms, including Bell's palsy, convulsions, and demyelinating syndromes; febrile seizures accounted for half of the cases of convulsions. There were 14 deaths, but a role for the vaccine was not proven.

Organs and Systems

Hematologic

Acute thrombocytopenic purpura developed 3 weeks after *Varicella* immunization (10).

Skin

Extensive *Varicella* vaccine-associated rashes occurred in four leukemic children; there was a relation between rash and glucocorticoid treatment (11).

Immunologic

In one case a hypersensitivity vasculitis developed 2 weeks after *Varicella* immunization (12).

Infection risk

Spread of infection to the siblings of immunized leukemic children has been observed. Between 18 and 36 days after the receipt of *Varicella* vaccine 2–10% of exposed children developed mild *Varicella* and/or seroconversion to *Varicella* virus.

Transmission of the *Varicella* vaccine virus from a toddler (with a history of allergic diathesis) to his pregnant mother has been reported and discussed (SEDA-22, 354).

Complicated wild *Varicella* in immunized individuals has been reported (13); among the two cases the first reported case of *Varicella* meningitis occurring in a child with documented immunization and seroconversion (14).

Cases of zoster both in healthy and in immunosuppressed persons have been reported (15–17).

A 19-month-old girl was immunized against *Varicella* at 15 months of age and later developed zoster infection (18). Viral cultures from various lesions isolated *Varicella zoster* virus. The Oka vaccine strain was revealed by polymerase chain reaction.

There have been three case reports of suspected reactivation of *Varicella zoster* through hepatitis A vaccine, influenza vaccine, and simultaneous administration of rabies and Japanese encephalitis vaccine (19).

- A 53-year-old woman without signs of immunodeficiency developed zoster in the left T10 dermatome 14 days after influenza immunization. The rash resolved without sequelae. Five months later she received another injection of influenza vaccine and 12 days later developed zoster in the left T1 dermatome. Recovery was prolonged.
- An 80-year-old woman with carcinoma developed long-lasting left thoracic zoster 6 days after influenza

© 2006 Elsevier B.V. All rights reserved.

immunization. Influenza vaccination before and after the event had no adverse effect.
- A 27-year-old man developed zoster in the second and third branches of the trigeminal nerve 1 day after immunization against rabies and Japanese encephalitis.

Zoster in childhood is unusual and probably even less common after *Varicella* immunization.

- A 6-year-old boy developed a zoster infection (with a vesicular rash in a left second thoracic dermatome pattern on his back extending to the back of his left arm) 15 days after the receipt of *Varicella* vaccine (Oka strain) (20). Molecular biological analysis of the virus isolated from the vesicles showed a pattern consistent with wild-type *Varicella zoster* virus.

The authors felt that this case mandated a careful review of all cases of zoster after *Varicella* immunization. Zoster induced by *Varicella* immunization could have implications for the use of immunization to prevent zoster in the elderly, a population with almost uniform *Varicella zoster* latent virus and at higher risk of zoster.

Susceptibility Factors

Age

In 29 children aged 1–12 years with chronic liver disease who received one dose of *Varicella* vaccine, seroconversion rates at 8 weeks after immunization were 100% (21). The geometric mean titers tended to relate to the severity of liver disease. Local and systemic reactions did not differ from reactions reported in healthy children.

- A 5-year-old boy developed zoster-like vesicular lesions 4 years after *Varicella* immunization. Virological examination showed *Herpes simplex* virus type 1, and so the vesicular lesions could not be attributed to the *Varicella zoster* virus vaccine strain, demonstrating the difficulty in confirming causality between time-related events (22).

Other features of the patient

To determine the safety and immunogenicity of *Varicella* immunization in HIV-infected children, 41 children (aged 1–8 years) who were asymptomatic or mildly affected (according to CDC stages) received two doses of live attenuated *Varicella* vaccine 12 weeks apart (23). Two months after the second dose, 60% of the recipients had anti-*Varicella* antibody in their serum. A minority of recipients developed mild local or systemic reactions. The immunization had no effect on the clinical stage of HIV infection or the HIV RNA plasma load.

Live virus vaccines, such as *Varicella*, are contraindicated in pregnancy.

Drug–Drug Interactions

Other vaccines

Reaction rates were not increased if the administration of *Varicella* vaccine was combined with other vaccines, for example MMR vaccine (SEDA-15, 358).

Vasopressin and analogues

See also Individual agents

General Information

Vasopressin, a hypothalamic octapeptide that is secreted by the neurohypophysis, has both antidiuretic and vasoconstrictor properties. Its short half-life (about 10 minutes) necessitates continuous intravenous infusion or frequent nasal application.

Because its vasoconstrictor effects limit the use of the native hormone, analogues with greater or lesser affinity for vasopressin V_2 receptors and more selective antidiuretic effects have been developed:

- argipressin (8-arginine vasopressin)
- desmopressin (*N*-deamino-8-D-arginine vasopressin, DDAVP); desmopressin is covered in a separate monograph
- felypressin (2-phenylalanine, 8-lysine vasopressin)
- lypressin (8-lysine vasopressin; pig vasopressin)
- ornipressin (8-onithine vasopressin)
- terlipressin (triglycyl-lysine vasopressin).

Vasopressin receptor antagonists, such as relcovaptan (an antagonist at V_{1a} receptors), lixivaptan and tolvaptan (V_2), and conivaptan (mixed V_{1a}/V_2), are also under development (1).

Desmopressin has little vasoconstrictor effect but has potent antidiuretic action, through renal vasopressin V_2 receptors, and at high doses hemostatic properties, by increasing concentrations of factor VIII and von Willebrand factor in the blood.

Ornipressin is a selective agonist at vasopressin V_1 receptors and has weaker antidiuretic activity than the native hormone.

Terlipressin, a long-acting vasopressin analogue, is metabolized to the active drug lysine vasopressin. The use of terlipressin to treat acute variceal bleeding has been reviewed (2,3).

Although vasopressin and its analogues have been used in the acute management of bleeding esophageal varices, they do not reduce mortality (2,3) and the rate of adverse effects is higher than with octreotide (3).

Uterine and abdominal cramps, nausea, and an urge to defecate have been reported in vasopressin-treated patients.

Organs and Systems

Cardiovascular

Dose-related adverse effects of vasopressin include skin pallor, hypertension, cardiac dysrhythmias, and myocardial ischemia or infarction; treatment has to be stopped in 20–30% of patients because of these effects (3).

Intestinal and peripheral vasoconstriction can follow prolonged infusion, resulting in gangrene of intestinal segments or of skin, fingers, or limbs. This has been fatal in several cases, and vasopressin should be withdrawn if skin necrosis occurs (SEDA-13, 1310) (4).

Of 10 patients with hepatorenal syndrome one had to be withdrawn 2 hours after receiving 12 units of ornipressin (6 IU/hour) because of a ventricular tachydysrhythmia, and an infusion of dopamine 2–3 micrograms/kg/minute was started (5).

Terlipressin has similar, but less pronounced, systemic hemodynamic effects to vasopressin, including increases in mean arterial pressure and reduced heart rate (6). Of 105 patients who had continuous terlipressin infusions for variceal bleeding in a multicenter study, lower limb ischemia developed in two and cardiac ischemia in one (7).

Of 86 cirrhotic patients treated with terlipressin 10 developed a tachycardia, four developed atrial fibrillation, and one developed ventricular tachycardia. Four patients in the same study developed hypertension (8). In another study, tachycardia occurred in 23% of patients randomized to pitressin for acute variceal bleeding and 8% developed transient hypertension (9).

Myocardial ischemia has been associated with terlipressin (10).

- A 61-year-old man with coronary artery stenosis became hypotensive during elective surgery, refractory to ephedrine (cumulative dose of 36 mg over 45 minutes). Immediately after terlipressin 1 mg, he developed hypertension and bradycardia, with evidence of myocardial ischemia.

One of 21 patients with hepatorenal syndrome developed finger ischemia on the fourth day of intermittent intravenous terlipressin and recovered after terlipressin was stopped (11).

Respiratory

An elderly patient (over 70 years old) with cirrhosis and hepatorenal syndrome developed severe bronchospasm and died after intravenous terlipressin administration; the mechanism was not determined (12).

Electrolyte balance

Profound hyponatremia due to reduced free water clearance is a predictable dose-related effect of vasopressin (13). This is a particular risk in patients who are unconscious or who have disturbed thirst sensation (SEDA-22, 487).

Of 105 patients who had continuous infusions of terlipressin for variceal bleeding in a multicenter study, four developed hyponatremia, severe in one case (7).

High-dose terlipressin (1 mg intravenously every 4 hours for 5 days) was associated with severe hyponatremia and

© 2006 Elsevier B.V. All rights reserved.

loss of consciousness in one of 45 cirrhotic patients in a randomized trial (8). Of course, cirrhosis itself is associated with hyponatremia.

Hematologic

Mild lymphangitis was reported in one of 105 patients in a multicenter study of the effects of terlipressin (7).

Gastrointestinal

Tongue ischemia and ischemic colitis have been described after 4–9 days of treatment with ornipressin 6 IU/hour combined with plasma volume expansion (14).

Skin

Skin necrosis is often reported after vasopressin therapy. In a retrospective study, two of five patients treated with a continuous infusion of terlipressin developed skin necrosis at the infusion site and a third developed scrotal necrosis (12).

- A 46-year-old woman with septic shock had a peripheral venous infusion of vasopressin 0.04 U/minute in addition to dobutamine, via the subclavian vein; extravasation of vasopressin to local soft tissue resulted in ischemic skin necrosis (15).

Purpuric skin necrosis, due to local vasoconstriction, has been reported in 19 patients within a few days of starting vasopressin infusion (16).

Bullous necrosis developed within 48 hours of starting an infusion of terlipressin in a 44-year-old man (17). There have been only four previous reports of skin necrosis.

Musculoskeletal

Rhabdomyolysis has been attributed to terlipressin (18).

- A 36-year-old man with nephrotic syndrome was given an infusion of terlipressin (an intravenous bolus of 2 mg followed by 2 mg over 24 hours) to treat diffuse gastric bleeding, and 12 hours later developed acute pain and livedo reticularis in both legs. High plasma concentrations of myoglobin and creatine kinase confirmed the diagnosis of toxic rhabdomyolysis, thought to be due to the vasoconstrictor action of terlipressin. He made a gradual recovery over the next few weeks after terlipressin was withdrawn.

Pre-existing blood vessel disease due to amyloidosis may have contributed to the outcome in this patient.

Vecuronium bromide

See also Neuromuscular blocking drugs

General Information

Vecuronium is a monoquaternary analogue of pancuronium, with a similar speed of onset, a duration of action of 15–30 minutes, rapid spontaneous recovery, and virtually no cumulative effects (1). Being monoquaternary, it is more lipophilic than pancuronium. About 30% is bound to plasma proteins. It is deacetylated in the liver, the principal metabolite being 3-desacetylvecuronium, which is believed to have about 50% of the neuromuscular blocking potency of the parent drug in man; small amounts of 17-desacetylvecuronium and 3,17-didesacetylvecuronium are also formed. In balanced anesthesia vecuronium is slightly more potent than pancuronium, but during halothane anesthesia it has been reported to be 1.4 times as potent as the latter. Suitable doses during balanced anesthesia are similar to those for pancuronium; potentiation by volatile agents (2) allows these doses to be reduced, after equilibration has occurred between the volatile agent and the tissues, by 25 or 45% when halothane or enflurane are used (3,4). In another study, after 1 hour of constant 90% neuromuscular blockade under nitrous oxide (60%), isoflurane (1.2% end-tidal), or enflurane (1.2% end-tidal) anesthesia the vecuronium infusion requirements were reduced by as much as 70% (compared with the nitrous oxide/fentanyl group) (SEDA-13, 105) (5).

In animals, histamine release, cholinesterase inhibition, and autonomic effects are minimal and occur only at concentrations of vecuronium considerably greater than those required for neuromuscular block (6–9). Interactions with antimicrobial drugs, analgesics, and anesthetic agents were similar to those known for other non-depolarizing relaxants, apart from a possible potentiating effect by metronidazole (6). These animal findings have been confirmed in man by the relative paucity of reported adverse effects. In man, the intradermal injection of vecuronium produces a considerably smaller local histamine reaction than d-tubocurarine, metocurine, pancuronium, or atracurium do (10,11) and plasma histamine is not raised in the clinical dose range (12,13). Nevertheless, minor skin reactions have been reported (14,15), as well as hypotension (16) and severe anaphylactoid reactions with circulatory collapse (17,18) and bronchospasm (19,20). Cross-sensitivity with pancuronium may occur (SEDA-10, 111).

Organs and Systems

Cardiovascular

The expected cardiovascular stability of vecuronium has been confirmed in man (2,21–23). Even doses as large as 0.28 mg/kg in patients undergoing coronary artery bypass grafting produced negligible effects (24). Bradycardia is the only cardiovascular adverse effect reported, and this is seen in association with opioids such as fentanyl (25) and sufentanil (SEDA-11, 125) (26) or other drugs that are themselves capable of producing bradycardia. The lack of vagolytic and sympathomimetic activity of vecuronium means that it does not counteract the bradycardia or the hypotensive effects of other drugs or surgical manipulations. It is an ideal relaxant for patients with pheochromocytoma (27).

Musculoskeletal

Masseter muscle rigidity is a rare but potentially dangerous adverse effect of suxamethonium and can prevent successful airway management. Furthermore, it can be the first sign of malignant hyperthermia and rhabdomyolysis. Non-depolarizing neuromuscular blocking agents are thought to be safe with regard to masseter muscle rigidity. However, masseter muscle rigidity not associated with the use of suxamethonium can also complicate airway management (28).

- A 42-year-old woman had anesthesia induced with propofol 200 mg, vecuronium 8 mg, and mask ventilation with oxygen, nitrous oxide, and 2% isoflurane. Laryngoscopy proved impossible because of spasm of the masseter muscles, and the airway was secured by blind nasal intubation. There was no evidence of rigidity of other muscle groups. Body temperature and end-tidal carbon dioxide concentration remained in the reference ranges. Masseter muscle rigidity persisted throughout the operation and resolved during recovery from anesthesia after neostigmine 2.5 mg had been given.

The authors suggested that in this case the phenomenon had been caused by vecuronium. Masseter muscle rigidity persisted during anesthesia and resolved during recovery from anesthesia after neostigmine had been given and isoflurane inhalation had been stopped. If vecuronium caused muscle rigidity in this case it was probably not mediated by effects on acetylcholine receptors, but rather by an interaction of vecuronium with ion channels (sodium, potassium, and/or calcium), but it is hard to imagine how this effect could have been antagonized by a cholinesterase inhibitor. It therefore seems likely that the masseter muscle rigidity was rather caused by isoflurane, which would explain why the symptoms improved after withdrawal of isoflurane. There have been previous reports of masseter muscle rigidity associated with non-depolarizing neuromuscular blocking agents (SEDA-21, 144) (29,30). The mechanism is unclear. One wonders how muscle specimens from these patients might react to exposure to an inhalational anesthetic during in vitro contracture testing. Regarding the link between masseter muscle rigidity and malignant hyperthermia, muscle biopsy would not be inappropriate in patients who have masseter muscle rigidity severe enough to prevent mouth opening and conventional orotracheal intubation.

Second-Generation Effects

Fetotoxicity

There is placental transfer of vecuronium, but no effects have been detected in the newborn (the feto-maternal concentration ratio is about 10% less than for pancuronium (31). Postpartum, vecuronium has been reported to have an appreciably longer duration of action (SEDA-13, 105) (32,33) when given in a dose of 0.1 mg/kg.

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Age

Spontaneous recovery of neuromuscular function after a bolus dose of vecuronium (0.1 mg/kg) was significantly prolonged in elderly patients compared with younger adults (SEDA-17, 153). The elimination half-life was significantly prolonged (125 versus 78 minutes) and the plasma clearance reduced (2.5 versus 5.6 ml/kg/minute) in the elderly versus the younger patients.

Renal disease

About 25–30% of an injected dose of vecuronium is excreted in the urine in normal patients, mostly as unchanged drug. Renal dysfunction has been reported as having no significant effect on the duration of action of vecuronium (SEDA-11, 125) (34–36). Nevertheless, slight resistance to the neuromuscular blocking effect of an initial dose (ED_{50} increased by 20%) and a small reduction (of 23%) in infusion requirements to maintain a 90% block after 1 hour of relaxation have been described in end-stage renal insufficiency (SEDA-13, 103) (37). These findings are in line with those for other non-depolarizing agents, with the exception of atracurium; the changes, however, are minor compared with the older relaxants, as is to be expected from the kinetics of vecuronium. There is a slight tendency for the action of vecuronium to be prolonged in renal insufficiency, and monitoring of neuromuscular transmission is advisable if several doses are to be given.

Hepatic disease

In liver disease (cirrhosis and cholestasis), the plasma clearance of vecuronium is reduced, its half-life is increased, and its duration of action is prolonged (SEDA-10, 112) (38,39). Rapid uptake in the liver appears to be an important factor in its plasma clearance and in determining its relatively short duration of action; it is estimated that about 40% of the injected drug is excreted via the bile (40). Prolongation of the action of large single doses and accumulation after repeated doses are therefore to be expected in liver disease.

Drug–Drug Interactions

Azathioprine

In humans with renal insufficiency, azathioprine 3 mg/kg produced a negligible and transient reduction in neuromuscular blockade maintained by infusion of vecuronium (37).

Carbamazepine

Resistance to vecuronium has been described in patients taking carbamazepine (41).

Ciclosporin

Ciclosporin can cause considerable prolongation of the neuromuscular paralysis induced by vecuronium (42), causing difficulties with reversal (SEDA-14, 116) (43). Potentiation of vecuronium in cats has also been described (SEDA-12, 188) (44).

Disopyramide

Disopyramide has also been associated with impairment of neostigmine antagonism of vecuronium-induced neuromuscular blockade (45).

- A 63-year-old man was given vecuronium 70 μg/kg followed by increments of 20 μg/kg, and three intravenous doses of disopyramide 10 mg for supraventricular extra beats, followed by an infusion of 25 mg/hour. Paralysis was reversed using atropine 0.75 mg and neostigmine 2.5 mg. The twitch height returned to normal and the train-of-four was above 85%, but the responses to tetanic stimulation at 100 and 50 Hz remained severely depressed (10 and 45% respectively). The plasma concentration of disopyramide was 5.1 μg/ml.

Phenytoin

Acute administration of phenytoin (10 mg/kg intravenously) has been reported to enhance slightly, but statistically significantly, steady blockade maintained by an infusion of vecuronium (SEDA-15, 124) (46). This is in contrast to reports of resistance to non-depolarizing neuromuscular blocking agents, including vecuronium, associated with long-term phenytoin (SEDA-13, 104) (47).

Testosterone

Testosterone enanthate, given over 10 years to produce virilization, has been claimed to have been responsible for a case of marked resistance to vecuronium (SEDA-14, 116) (48).

Venlafaxine

See also Antidepressants, second-generation

General Information

Venlafaxine inhibits the re-uptake of both serotonin and noradrenaline. Trials have shown efficacy comparable to that of tricyclic antidepressants, and it may be particularly effective in refractory depression (1)(2).

Reported adverse effects were nausea, somnolence, dry mouth, insomnia, dizziness, constipation, weakness, nervousness, and sweating. Other adverse effects include nervousness, weight loss, and a dose-dependent increase in blood pressure.

Because of its serotonin-potentiating effect, venlafaxine can cause a serotonin syndrome when combined with monoamine oxidase (MAO) inhibitors (SEDA-20, 9) (SEDA-21, 13).

Adverse sexual effects are reported in a frequency similar to that of SSRIs (SEDA-20, 9).

Withdrawal reactions have been reported in several cases after abrupt discontinuation (SEDA-21, 13) (3)(4).

Preliminary data suggest that venlafaxine is safer in acute overdose than tricyclic antidepressants but more dangerous than SSRIs. Seizures have been reported in several cases of overdose (5–7).

Organs and Systems

Cardiovascular

A meta-analysis of the effect of venlafaxine on blood pressure in patients studied in randomized placebo-controlled trials of venlafaxine, imipramine, and placebo showed that at the end of the acute phase (6 weeks) the incidence of a sustained rise in supine diastolic blood pressure (over 90 mmHg) was significantly higher in both active treatment groups: venlafaxine 4.8% (135/2817), imipramine 4.7% (15/319), and placebo 2.1% (13/605) (8). The effect of venlafaxine in causing a rise in diastolic blood pressure appeared to be dose related, with an incidence of 1.7% in patients taking under 100 mg/day and 9.1% in those taking over 300 mg/day.

These data confirm that venlafaxine, particularly in higher dosages, can significantly increase blood pressure. At high doses, venlafaxine inhibits the re-uptake of noradrenaline as well as that of serotonin, which probably accounts for the pressor effect.

In physically healthy subjects venlafaxine has a generally benign cardiovascular profile, although hypotension and dose-related hypertension have been reported (SEDA-23, 20).

Venlafaxine is often used in high doses in patients with treatment-resistant depression. If there is continuing failure to respond, electroconvulsive therapy might be used, often in combination with venlafaxine. A 73-year-old woman taking venlafaxine (112.5 mg/day) had sustained hypertension for several hours after her first treatment (9). However, electroconvulsive therapy can cause transient hypertension, and the patient had essential hypertension controlled by bendroflumethiazide. It is therefore possible that the reaction might have occurred had she not been taking venlafaxine. Nevertheless, the fact that venlafaxine can cause hypertension when used as sole treatment suggests that blood pressure should be monitored carefully in patients receiving electroconvulsive therapy and venlafaxine together, particularly if there is a history or current evidence of hypertension.

Venlafaxine has not been studied systematically in patients with cardiovascular disease, although there are reports that older patients can have clinically significant disturbances of cardiac rhythm (10).

- A 69-year-old woman with stable angina and mild single-vessel coronary artery disease developed acute myocardial ischemia within a week of starting venlafaxine (75 mg/day).

Taken together with the information that the authors cited in their review, the current data suggest that venlafaxine should be used with caution in patients with established cardiovascular disease.

Nervous system

Antidepressant drugs, such as tricyclic antidepressants and SSRIs, suppress rapid eye movement (REM) sleep, the period of sleep during which dreaming occurs. Despite this, antidepressant treatment is sometimes associated with recurrent nightmares. Venlafaxine also suppresses REM sleep and was associated with nightmares in a 35-year-old woman with body image disturbance; the nightmares remitted when the venlafaxine was withdrawn (11). The authors speculated that indirect activation of 5-HT_2 receptors might have played a causal role, because 5-HT_2 receptor antagonists, such as nefazodone, can be helpful in the treatment of nightmares, for example in patients with post-traumatic stress disorder.

Sensory systems

Tricyclic antidepressants predispose to acute angle closure glaucoma, probably through an anticholinergic action. However, acute angle closure has also been reported with SSRIs, suggesting that all serotonin-potentiating drugs can cause glaucoma (SEDA-21, 13) (SEDA-23, 17).

- Acute angle closure glaucoma has been reported in a 45-year-old woman taking venlafaxine (75 mg/day) and chlorpromazine (150 mg/day) (12). She had previously taken low-dose dosulepin (75 mg/day), chlorpromazine, and SSRIs without ophthalmic problems.

Chlorpromazine has mild anticholinergic properties and may have contributed to the angle closure in this case. She also had hypermetropia which is an another risk factor for glaucoma. However, this case supports the view that potent blockade of serotonin re-uptake can cause glaucoma in predisposed subjects.

Psychological, psychiatric

The use of antidepressants in patients with documented bipolar illness is often associated with a risk of manic illness (13).

© 2006 Elsevier B.V. All rights reserved.

- A 63-year-old man with a long history of bipolar illness and alcohol dependence took nefazodone 400 mg/day for 8 months, with no relief of a depressive episode. He was also taking valproate 1500 mg/day as a mood stabilizer, aspirin 81 mg/day, ranitidine 300 mg/day, and docusate calcium 240 mg/day. Nefazodone was tapered over 4 days and venlafaxine begun in a dosage of 37.5 mg/day and gradually increased to 150 mg/day over 3 weeks. Venlafaxine led to improvement in depressive symptoms, but 6 days after the dose reached 150 mg/day he became agitated, verbally and physically threatening, grandiose, and sexually disinhibited. He also had paranoid thinking and appeared to be hallucinating. The venlafaxine was withdrawn but the manic symptoms persisted and eventually required increases in the dosages of valproate and antipsychotic drugs.

This report illustrates the difficulty of treating depression in bipolar disorder with antidepressants. The presence of a mood stabilizer did not prevent the manic episode that emerged during venlafaxine treatment, and it is in any case difficult to know whether the mania was in fact due to the venlafaxine or instead represented a spontaneous mood swing.

Electrolyte balance

It is well established that SSRIs can cause hyponatremia. Similar cases have now been reported with venlafaxine.

- A 90-year-old woman had a depressive disorder in addition to other medical problems, including congestive cardiac failure, seizures, dementia, and osteoporosis (14). She was also taking phenobarbital 120 mg/day, enalapril 40 mg/day, furosemide 80 mg/day, calcium carbonate 1300 mg/day, and nortriptyline 50 mg at night. She was given additional paroxetine 20 mg/day, but there was no clinical response and she was changed to venlafaxine, increasing to 75 mg/day. Two months later her sodium concentration had fallen to 130 mmol/l and the furosemide was withdrawn. However, 4 months later the sodium concentration had fallen to 124 mmol/l. The venlafaxine was then withdrawn and the sodium normalized within a week and remained within the reference range for the following year.

This was a complex case, because of the multiple medical problems and treatments. However, it has been reported that since the launch of venlafaxine in Australia in 1996, the Adverse Drug Reactions Advisory Committee there has received 15 reports of hyponatremia, suggesting that the association is real (15).

Liver

Raised liver enzymes have been rarely found in patients taking venlafaxine, and it appears that hepatitis may also be rare adverse effect (16).

- A 44-year-old woman developed weakness with abnormal liver function tests (aspartate transaminase 661 IU/l) about 6 months after starting to take venlafaxine 150 mg/day. Biopsy showed confluent necrosis in zone 3, with unaffected portal tracts. No other cause for the hepatitis could be found. The clinical and biochemical features resolved within 12 weeks of withdrawal of venlafaxine.

Hair

SSRIs can cause occasional, idiosyncratic hair loss in some patients (SEDA-19, 10), and this has also been attributed to venlafaxine (17).

- A 50-year-old woman took venlafaxine 75 mg/day for depression, and the dosage was increased to 150 mg/day after 2 weeks. After 4 weeks she noted increased hair loss when brushing or washing her hair. After 3 months she stopped taking venlafaxine and 1 month later her hair loss stopped completely. However, 10 months later she had another depressive episode and was again successfully treated with venlafaxine. Once again she noted excessive hair loss. She was subsequently treated with sertraline 50 mg/day, which helped her depression without causing hair loss.

The fact that sertraline did not cause hair loss in this patient suggests that the mechanism was not related to blockade of serotonin re-uptake.

Sexual function

Antidepressant drugs can rarely cause priapism. The agent most often implicated has been trazodone, perhaps because of its α_1-adrenoceptor antagonist properties. In general venlafaxine has an inhibitory effect on sexual function, but perhaps, like SSRIs, it can rarely cause priapism (18).

- A 16-year-old youth taking venlafaxine (150 mg/day) had several episodes of prolonged erections, which persisted for several hours after intercourse. The episodes remitted after the venlafaxine was withdrawn.

Pain on ejaculation is also a rare adverse effect of tricyclic antidepressants and SSRIs and has been reported with venlafaxine (19).

- Painful ejaculation occurred in a 59-year-old man taking venlafaxine 150 mg/day. It remitted when the venlafaxine was withdrawn and did not recur when citalopram 40 mg/day was used instead.

Long-Term Effects

Drug withdrawal

Both SSRIs and venlafaxine can cause troublesome withdrawal symptoms (SEDA-22, 12) (SEDA-22, 17). Because venlafaxine blocks the re-uptake of both serotonin and noradrenaline the mechanism of venlafaxine-induced abstinence symptoms is not clear.

- A 72-year-old woman taking venlafaxine 150 mg/day for depression was abruptly switched to the noradrenaline re-uptake inhibitor maprotiline 75 mg/day; 1 day later she developed agitation, sweating, nausea, vomiting, tinnitus, and insomnia (20). These symptoms continued for another week, but disappeared on the second day of sertraline treatment 50 mg/day.

© 2006 Elsevier B.V. All rights reserved.

The symptoms experienced by this patient were typical of venlafaxine and SSRI withdrawal (although they could also be experienced after sudden withdrawal of tricyclic antidepressants). The fact that they were relieved by a serotonin but not a noradrenaline re-uptake inhibitor suggests that venlafaxine-induced withdrawal symptoms are mediated by serotonergic mechanisms.

Drug Administration

Drug overdose

Venlafaxine is generally regarded as being reasonably safe in overdose relative to conventional tricyclic antidepressants.

However, it has been associated with occasional reports of cardiac conduction disturbances at both therapeutic doses and in overdose (SEDA-24, 19).

Deaths have been described after venlafaxine overdose, but in combination with other agents and alcohol. However, there have been two fatal cases of overdosage in which venlafaxine was the only agent detected postmortem (21). It therefore appears that venlafaxine can occasionally prove fatal in overdosage, probably through cardiac conduction abnormalities and seizures (21,22). It is possible that poor metabolizers may be especially liable to develop toxic effects.

- A 44-year-old woman took an overdose of venlafaxine 3 g. An electrocardiogram showed sinus rhythm and incomplete right bundle branch block (23). She was monitored in an intensive care unit and 10 hours later a further electrocardiogram showed atrial fibrillation with a wide QRS complex. Both of these abnormalities resolved with sodium bicarbonate (100 ml of a 1 M solution). No further conduction disturbances were noted over the following days.

The authors suggested that the effect of venlafaxine on cardiac conduction is mediated by its ability to block the fast inward sodium current in cardiac myocytes. This might promote membrane stabilizing effects in a similar way to tricyclic antidepressants. They recommended that the management of venlafaxine overdose should include cardiac monitoring.

Drug–Drug Interactions

Caffeine

Venlafaxine 150 mg/day did not alter the disposition of caffeine, a probe of CYP1A2 activity (24). This suggests that at therapeutic doses venlafaxine, in contrast to fluvoxamine (SEDA-22, 13), does not inhibit CYP1A2.

Dexamfetamine

Psychostimulants, such as dexamfetamine, are being increasingly prescribed for patients who meet the criteria for adult attention deficit disorder. Many such patients also have co-morbid major depression.

- A 32-year-old man taking dexamfetamine 15 mg/day developed the serotonin syndrome, with shivering, sweating, myoclonus, and pyrexia, following the addition of venlafaxine 150 mg/day (25). Venlafaxine and dexamfetamine were withdrawn, and he was given the serotonin receptor antagonist, cyproheptadine (32 mg over 3 hours). His symptoms remitted a few hours later and he subsequently restarted dexamfetamine without incident. A later trial of citalopram, while he was still taking dexamfetamine, also led to symptoms of serotonin toxicity.

The combination of stimulants and SSRIs is not uncommon in clinical practice, but reports of serotonin toxicity are unusual, perhaps because drugs such as dexamfetamine and methylphenidate predominantly release dopamine and noradrenaline rather than serotonin. However, psychostimulants do cause some degree of serotonin release, which might have been sufficient to cause serotonin toxicity in this case.

Fluoxetine

Four depressed patients (age range 21–73 years) had anticholinergic adverse effects when venlafaxine 37.5 mg/day was added to fluoxetine 20 mg/day (26). Venlafaxine does not have direct anticholinergic effects, but could cause them indirectly as a result of its ability to increase noradrenergic neurotransmission. This effect would be expected only at much higher doses of venlafaxine than those used here, which led the author to suggest that in the presence of CYP2D6 inhibition by fluoxetine, venlafaxine concentrations could have been substantially higher than expected.

Imipramine

In six healthy men, venlafaxine (150 mg/day for 10 days) produced an increase of 28% in the systemic availability of a single dose of imipramine (100 mg); the availability of the active metabolite of imipramine, desipramine, was also increased (27). These data suggest that venlafaxine inhibits CYP2D6; the effects appear to be modest relative to those of fluoxetine and are similar to those produced by sertraline.

Monoamine oxidase inhibitors

There have been previous reports of serotonin toxicity when venlafaxine was combined with therapeutic doses of conventional MAO inhibitors (SEDA 20, 21). The serotonin syndrome has been reported in four patients who were switched from the MAO inhibitor phenelzine to venlafaxine (28). In two of the subjects, the 14-day washout period recommended when switching from phenelzine to other antidepressant drugs had elapsed.

- A 25-year-old woman had been taking phenelzine 45 mg/day for refractory migraine and tension headache, but suffered intolerable adverse effects (weight gain, edema, and insomnia). Phenelzine was withdrawn and 15 days elapsed before she took a single dose of venlafaxine 37.5 mg. Within 1 hour she developed agitation, twitching, shakiness, sweating, and generalized erythema with hyperthermia (38°C). Her symptoms resolved within 3 hours with no sequelae.

These cases suggest that even after the recommended 2-week washout from MAO inhibitors, venlafaxine can

© 2006 Elsevier B.V. All rights reserved.

provoke serotonin toxicity in some patients. In principle it should be possible to switch from one conventional MAO inhibitor to another without a washout period. However, there have been reports that patients who switched from phenelzine to tranylcypromine had hypertensive reactions, with disastrous consequences (29). Whenever possible, a 2-week washout period when switching MAO inhibitors or when introducing serotonin re-uptake inhibitors seems advisable.

Quinidine

Venlafaxine is metabolized by CYP2D6. In healthy volunteers the oral clearance of venlafaxine (37.5 mg/day for 2 days) was fourfold less in poor metabolizers ($n = 6$) than extensive metabolizers ($n = 8$) (30). Administration of the CYP2D6 inhibitor quinidine, 200 mg/day for 2 days, to the extensive metabolizers reduced the oral clearance of venlafaxine to the level seen in poor metabolizers. Quinidine had no effect on venlafaxine clearance in subjects who were poor metabolizers before treatment. The authors suggested that poor metabolizers may be at particular risk of venlafaxine toxicity, as could subjects who take inhibitors of CYP2D6.

Risperidone

Unlike SSRIs, venlafaxine only weakly inhibits CYP2D6. Venlafaxine (up to 150 mg/day for 10 days) modestly but significantly increased the plasma AUC of a single dose of risperidone (1 mg) in 38 healthy volunteers in an open longitudinal design, but did not affect its active metabolite, 9-hydroxyrisperidone (31). The authors suggested that their study had shown a small potentiating effect of venlafaxine on risperidone availability, probably through weak inhibition by venlafaxine of CYP2D6. Venlafaxine is therefore less likely to increase risperidone concentrations than are fluoxetine and paroxetine.

Trifluoperazine

Drugs that potentiate the function of serotonin, such as venlafaxine, can produce pharmacodynamic interactions with dopamine receptor antagonists, perhaps because serotonin pathways can inhibit dopamine neurotransmission.

- A 44-year-old man with major depression had been taking the antipsychotic drug trifluoperazine (3 mg/day) for anxiety for several years (32). He was given venlafaxine 75 mg/day, and 12 hours after the first dose developed anxiety and malaise. He was sweating and had tremor and rigidity. His blood pressure fluctuated and his creatine phosphokinase activity was raised at 11 320 IU/l. A diagnosis of neuroleptic malignant syndrome was made and he was given dantrolene and bromocriptine. His symptoms settled within 24 hours and trifluoperazine was reintroduced uneventfully.

This case suggests that venlafaxine can rarely increase the risk of neuroleptic malignant syndrome in patients taking a dopamine receptor antagonist. However, this combination of drugs is often used, and it is not clear why only very few patients appear to be susceptible to this reaction, and then only on some occasions.

Verapamil

See also Calcium channel blockers

General Information

Verapamil is a phenylalkylamine calcium channel blocker, with actions mainly on the heart.

Organs and Systems

Cardiovascular

Heart failure

Verapamil can cause cardiac failure, because it has a potent negative inotropic effect and causes increased capillary filtration pressure by vasodilatation (1). There are also reports of drug-induced acute right heart failure in patients with pulmonary hypertension due to valvular heart and chronic pulmonary obstructive airways diseases (2).

- A 16-year-old boy who took long-term verapamil after a Mustard operation for transposition of the great arteries developed severe congestive heart failure, which did not respond to diuretics. Systemic vascular resistance was increased by 75% and pulmonary vascular resistance by 150%; the cardiac index was reduced from 3.0 to 1.8 l/minute/m^2. Ejection fraction and atrial pressure were unchanged and neurohormonal causes were excluded. The heart failure resolved after withdrawal of verapamil.

Cardiogenic shock after the ingestion of verapamil has been reported, in one case with a small dose (3).

- A 78-year-old woman with a history of biventricular heart failure developed cardiogenic shock after she took a single tablet of verapamil 80 mg. She was resuscitated with artificial ventilation, dobutamine, noradrenaline, and calcium gluconate. Toxicological analysis showed an unexpectedly high plasma verapamil concentration, which was attributed to liver failure.

In patients with advanced heart failure a single oral therapeutic dose of verapamil may have a severe toxic effect.

Cardiac dysrhythmias

Relatively harmless and asymptomatic disturbances of heart rhythm are common during treatment with verapamil. For example, Wenckebach phenomenon (Mobitz type I second-degree atrioventricular block), sinus bradycardia and junctional escape, and accelerated junctional rhythm have been seen during the treatment of angina pectoris (4). In the DAVIT II study (5), 23 of 878 patients who took verapamil and seven of 897 who took placebo in a survival study after myocardial infarction developed second- or third-degree AV block. It has been suggested that the extent of PR prolongation may be proportional to the pharmacological effect of verapamil in patients with sinus rhythm (6). Patients with diseased conduction systems can develop atrioventricular block, sinoatrial block, sinus arrest, or sinus bradycardia with verapamil (7).

Severe cardiac conduction disturbances have been reported in patients with chronic renal insufficiency taking verapamil, mainly related to modified-release formulations.

- A serious bradydysrhythmia with complete atrioventricular block occurred after some months of conventional verapamil at normal doses and dose-adjusted digoxin in a 72-year-old woman with chronic renal insufficiency of unknown cause; the atrioventricular block resolved after 2 hours of hemodialysis (8).

Problems can also occur in patients with aberrant conduction pathways; for example, verapamil caused an increased ventricular response in patients with Wolff–Parkinson–White syndrome associated with atrial fibrillation (9–11). The danger lies in provocation of ventricular fibrillation from advanced anterograde conduction in accessory pathways (12).

Nervous system

Myoclonic dystonia has been described in a 70-year-old man who took verapamil for supraventricular tachycardia for 10 months; the abnormal movements disappeared within 3 weeks of substituting diltiazem, but rechallenge was not attempted (13).

Myoclonic seizures have been attributed to verapamil (14).

- An 18-month-old girl with supraventricular tachycardia was given intravenous verapamil 0.2 mg/kg, which was discontinued after half the dose had been given, because she developed irregular, repetitive, jerky movements in both upper and lower limbs which lasted for 2 minutes. As the supraventricular tachycardia had not responded, second and third doses of 0.2 mg/kg

© 2006 Elsevier B.V. All rights reserved.

were given intravenously under diazepam cover, but similar myoclonic seizures occurred again. There were no predisposing factors.

Fasciculation occurred when a patient with background peripheral neuropathy was given verapamil (SEDA-16, 197).

Feelings of "painful coldness and numbness" in the legs, in the absence of a neurological deficit, have been reported with verapamil (15); the symptoms disappeared with drug withdrawal and recurred with rechallenge.

Endocrine

There was a significant rise in serum alkaline phosphatase of skeletal origin in a group of patients taking verapamil for hypertension. It was associated with a slight increase in parathyroid hormone, indicating involvement of bone metabolism, although there was no change in the urinary excretion of calcium, phosphate, or potassium. It has yet to be shown whether verapamil causes osteopenia in man, as it does in animals (SEDA-16, 197).

Verapamil-induced hyperprolactinemia has been reported in a 74-year-old man, who presented with impotence and who was subsequently found to have a benign 6 mm pituitary microadenoma (16). The withdrawal of verapamil was associated with the normalization of serum prolactin concentrations.

The mechanism for this adverse effect is unclear and has not been reported with other calcium channel blockers.

Hair

Increased hair growth has been associated with modified-release verapamil (SEDA-17, 238).

Musculoskeletal

Arthralgia has been associated with verapamil (17).

- A 28-year-old man with migraine and vascular pain of the face was given verapamil 480 mg/day when sumatriptan did not control the pain. Verapamil was withdrawn after 1 month and reintroduced in a dosage of 960 mg/day after a new episode of pain. He then developed arthralgia in the right hand and arm, which disappeared after withdrawal and recurred after rechallenge.

Susceptibility Factors

In therapeutic doses, verapamil has a negative dromotropic effect, reflected in plasma concentration-dependent prolongation of the PR interval and AV nodal block. PR interval prolongation is detectable even after small single doses. The effects of rheumatoid arthritis on the pharmacokinetics and pharmacodynamics of verapamil have been studied in eight patients and eight age- and sex-matched healthy volunteers (18). Verapamil and norverapamil concentrations were substantially increased in the patients with rheumatoid arthritis, accompanied by significantly less dromotropic activity. Regardless of the mechanism involved in the altered pharmacokinetics of verapamil, the rise in drug concentrations was accompanied by a significant reduction in dromotropic activity. Therefore, administration of verapamil to patients with rheumatoid arthritis may require close attention to prevent therapeutic failure.

Drug Administration

Drug overdose

Verapamil poisoning can cause cardiac toxicity with cardiogenic shock, conduction abnormalities (including life-threatening dysrhythmias), hypotension, and death.

- A 15-year-old woman survived a total of 65 minutes cardiac arrest after taking 7200 mg of verapamil and 240 mg of paroxetine, which potentiates verapamil toxicity (19). Despite the length of cardiopulmonary resuscitation, with evidence of subsequent myocardial damage and renal impairment, she was discharged 17 days after admission, having made a full recovery, without evidence of neurological impairment.

The authors considered that the lack of neurological damage may have been related to the possible neuroprotective effect of a large dose of verapamil.

- A 28-year-old man developed rhabdomyolysis and acute renal insufficiency 10 hours after taking four capsules containing verapamil 180 mg plus trandolapril 2 mg. He survived with gastric lavage and activated charcoal 70 g. By 4 hours after admission he was awake and complained of diffuse muscle cramps and myalgia. Creatinine and creatine kinase reached 565 μmol/l (6.7 mg/dl) and 10 700 U/l respectively. After 6 days the laboratory tests were all within the reference ranges.

The authors suggested that rhabdomyolysis should be considered in patients with myalgia and muscle cramps taking verapamil plus trandolapril, and that routine serum creatinine kinase should be checked (20).

Non-cardiogenic pulmonary edema has been reported after the ingestion of a large quantity of verapamil (21).

- Two 19-year-old-girls developed pulmonary edema after taking massive overdoses of verapamil (6000 mg and 7200 mg). In each case a chest X-ray showed diffuse bilateral patchy infiltration. Left ventricular size and function was normal on transthoracic echocardiography. They were both treated successfully with mechanical ventilatory support.

Several mechanisms may be involved in non-cardiogenic pulmonary edema subsequent to verapamil intoxication, including leaky capillary syndrome attributable to inhibition of prostacyclin, a cellular membrane protector. Prolonged hypotension and a shock-like state may also contribute. The authors recommended pressor/inotropic therapy and mechanical ventilation as therapy.

Different therapeutic approaches have been described in suicide attempts with verapamil.

- Enoximone has been used to treat cardiogenic shock in a case of self-poisoning with verapamil 2.4 g in a 40-year-old woman; treatment with calcium and noradrenaline had been unsuccessful (22).

© 2006 Elsevier B.V. All rights reserved.

- A 41-year-old man who had taken 4800–6400 mg of verapamil presented 5 hours later and had a cardiac arrest; cardiopulmonary resuscitation was started and he underwent percutaneous cardiopulmonary by-pass, to maintain adequate tissue perfusion and sufficient cerebral oxygen supply until the drug concentration was reduced and restoration of spontaneous circulation was achieved (23).
- Severe poisoning with modified-release verapamil was associated with respiratory failure in a 27-year-old man, who presented 2 hours after taking 24 g, one of the largest reported overdoses (24). He survived after receiving 4 days of partial liquid ventilation as a part of his medical management.
- A 61-year-old woman developed profound hypotension, bradycardia, oliguria, and multifocal myoclonus after verapamil overdose. Her serum verapamil concentration was 800 ng/ml (1760 nmol/l) (usual target range 50–200 ng/ml, 110–440 nmol/l). She was treated with supportive care, vasopressin, dopamine, and calcium gluconate. After about 60 hours the myoclonus and hemodynamic compromise resolved completely (25).
- Two patients took 2400 mg and 9600 mg of verapamil, resulting in life-threatening hypotension and bradycardia, needing cardiac pacing and resuscitation (26). Gastric lavage was not carried out in the first patient, owing to clouded consciousness. Both patients underwent plasmapheresis within 4 hours of ingestion, with dramatic improvement. However, the first patient died 38 hours after admission with multiorgan failure, probably because of the long period of cardiogenic shock. The second patient survived without infirmity, despite the higher verapamil dose.

The authors of the last report emphasized the role of vigorous gastrointestinal lavage with repeated administration of activated charcoal to reduce gastrointestinal absorption of the drug.

Drug–Drug Interactions

ACE inhibitor

The addition of low doses of verapamil to ACE inhibitor therapy reversed ACE inhibitor-induced increases in creatinine concentrations in eight elderly hypertensive patients (27). During an average of 25 weeks, ACE inhibitors significantly reduced blood pressure, but serum creatinine concentrations rose. During an average of 10 weeks, the addition of verapamil did not reduce the blood pressure further, but the serum creatinine concentrations were normalized. Verapamil appears to have a beneficial effect, through dilatation of constricted afferent and efferent arterioles and reduction of the mesangial cell contraction induced by endothelin-1, factors that have been implicated in the increase in intraglomerular pressure and proteinuria due to ACE inhibitors.

Calcium adipinate and calciferol

Treatment of osteoporosis with calcium adipinate and calciferol counteracts the antidysrhythmic effect of verapamil (28).

Ciclosporin

Calcium channel blockers are given to transplant patients for their protective effect against ciclosporin-induced nephrotoxicity. Verapamil has been particularly preferred, as it causes a significant increase in plasma ciclosporin concentrations and also seems to have a direct immunosuppressive action. However, in a study in 152 kidney transplant recipients, verapamil increased the incidence of postoperative infections (29). The patients, all of whom were taking ciclosporin, were assigned either to verapamil 240 mg/day or to no verapamil; during a postoperative period of 2–14 months, the incidence of infections was 22% (17/77) of those given verapamil compared with 5% (4/75) of the others. However, since the study was not randomized, it is not possible to draw reliable conclusions.

Dofetilide

By increasing its rate of absorption, verapamil produced transient rises in peak plasma concentrations of dofetilide in 12 young healthy male volunteers (30). During combination treatment at steady state there was a significant, albeit modest, increase in the mean C_{max} and AUC of dofetilide. These changes were associated with corresponding short-lived increases in its pharmacodynamic effect, as measured by changes in the QT_c interval. These two drugs should not be administered concurrently.

Grape fruit juice

The interaction with grapefruit juice observed with several calcium channel blockers, including felodipine, nifedipine, and nisoldipine, has not been confirmed with verapamil. A single dose of grapefruit juice had no effect on the pharmacokinetics of verapamil in 10 hypertensive patients taking chronic verapamil (31).

Macrolide antibiotics

Verapamil is both a substrate and an inhibitor of CYP3A4, which is inhibited by clarithromycin and erythromycin. Giving these macrolide antibiotics during verapamil therapy is likely to reduce the first-pass metabolism of verapamil, increase its systemic availability, and impair its elimination. In patients taking this combination, verapamil should be started in a low dosage and its hemodynamic effects should be monitored closely.

Clarithromycin

- A 53-year-old woman had periods of dizziness and episodes of fainting when she stood up 24 hours after having been given clarithromycin for an acute exacerbation of chronic obstructive pulmonary disease and verapamil for atrial fibrillation (32). One day later she developed severe hypotension and bradycardia (32). Since her symptoms matched those of severe verapamil overdosage, the drug was withdrawn and her condition improved within two days.
- A 77-year-old hypertensive woman receiving both verapamil and propranolol for hypertrophic cardiomyopathy and paroxysmal atrial fibrillation developed symptomatic bradycardia within 2–4 days of initiation of both

© 2006 Elsevier B.V. All rights reserved.

erythromycin or clarithromycin on two separate occasions, for pneumonia and sinusitis respectively (33).

Erythromycin

- A 79-year-old white woman developed extreme fatigue and dizziness (34). Her heart rate was 40/minute and her blood pressure 80/40 mmHg. An electrocardiogram showed complete atrioventricular block, an escape rhythm at 50/minute, and QT_c interval prolongation to 583 milliseconds. This event was attributed to concomitant treatment with verapamil 480 mg/day and erythromycin 2000 mg/day, which had been prescribed 1 week before admission.

This is the first report of complete AV block and prolongation of the QT interval after co-administration of erythromycin and verapamil, both of which are principally metabolized by CYP3A4. Both drugs are potent inhibitors of CYP3A4 and P-glycoprotein, which may be the basis of this interaction.

The effects of a combination of erythromycin and verapamil on the pharmacokinetics of a single dose of simvastatin have been studied in a randomized, double-blind, cross-over study in 12 healthy volunteers simultaneously taking the three drugs. Both erythromycin and verapamil interacted with simvastatin, producing significant increases in the serum concentrations of simvastatin and its active metabolite simvastatin acid. The mean C_{max} of active simvastatin acid was increased about five-fold and the AUC_{0-24} four-fold by erythromycin; verapamil increased the C_{max} of simvastatin acid 3.4-fold and the AUC_{0-24} 2.8-fold. There was a substantial interindividual variation in the extent of these interactions. Concomitant use of erythromycin, verapamil, and simvastatin should be avoided (35).

Rifampicin

Rifampicin reduces the systemic availability of verapamil, presumably by enzyme induction in the liver (36).

General Information

The genera in the family of Verbenaceae (Table 1) include mangrove and vervain.

Vitex agnus-castus

Vitex agnus-castus (chaste tree, hemp tree, monk's pepper) is a plant with estrogen-like activities, used for a variety of gynecological problems, particularly on the European continent, particularly premenstrual symptoms (1).

Adverse effects

Vitex agnus-castus can cause ovarian hyperstimulation and increase the risk of miscarriage.

- A woman took *V. agnus-castus* during an unstimulated cycle while undergoing in vitro fertilization (2). She had considerable derangements of gonadotrophin and ovarian hormone concentrations.

Vesnarinone

See also Phosphodiesterase type III, selective inhibitors of

General Information

Vesnarinone is an inhibitor of phosphodiesterase type III, and has a positive inotropic effect. Although vesnarinone was originally developed for the treatment of cardiac failure, its action on tumor cells has prompted its use in the treatment of cancer. In 26 patients who received combinations of vesnarinone and gemcitabine there was no pharmacokinetic interaction between the two drugs (1). Although there were cases of neutropenia and thrombocytopenia, those effects could have occurred with gemcitabine alone and could not necessarily be attributed to vesnarinone. Other adverse effects of the combination included nausea and vomiting, anorexia and fatigue,

© 2006 Elsevier B.V. All rights reserved.

diarrhea, headache, and fever. There were no cases of QT interval prolongation or ventricular dysrhythmias. There were rises in hepatic transaminase activities in up to 25% of cases. Again it was not possible to distinguish between adverse effects of gemcitabine and vesnarinone.

Organs and Systems

Hematologic

Vesnarinone causes reversible neutropenia in up to 2.5% of patients (2,3). In 3833 patients with heart failure of Class III or IV and a left ventricular ejection fraction of 30% or less despite optimal treatment, followed for 286 days, there was dose-dependent agranulocytosis, in 0.2% of those taking vesnarinone 30 mg/day and 1.2% of those taking 60 mg/day (3).

Gastrointestinal

In 3833 patients with heart failure of Class III or IV and a left ventricular ejection fraction of 30% or less despite optimal treatment, followed for 286 days, there was a slight increase in the risk of diarrhea, which occurred in 17% of those taking 60 mg/day compared with 12% of those taking placebo and 14.5% of those taking 30 mg/day (3).

Death

Vesnarinone has been reported to reduce mortality at low doses and to increase it at high doses (SEDA-18, 199) (2,4). In 3833 patients with heart failure of Class III or IV and a left ventricular ejection fraction of 30% or less despite optimal treatment, followed for 286 days, vesnarinone 60 mg/day was associated with significantly more deaths and a shorter duration of survival (3). The increased death rate was due to an increase in sudden deaths, presumably because of cardiac dysrhythmias. There were similar trends in patients who took 30 mg/day, but the changes were not significant. In contrast to the increased mortality with vesnarinone there was a short-term increase in quality of life, which occurred during the first 16 weeks but was not maintained at 6 months. Probably the increased mortality due to vesnarinone outweighs the improvement in quality of life.

Vidarabine

General Information

Intravenous vidarabine is effective in the treatment of kerato-uveitis in animals and man, and has been used intravenously to treat herpetic eye infections in man (1). It has also been used as an ointment for treating superficial keratitis that does not respond to idoxuridine, but it penetrates the eye poorly (2). It is no longer used because of unacceptable toxicity and inferior activity compared with newer drugs for *Herpes simplex* and *Varicella zoster*. Its rapid inactivation and poor solubility are practical disadvantages.

Long-Term Effects

Mutagenicity

Vidarabine is oncogenic and mutagenic in animals (3).

Vigabatrin

See also Antiepileptic drugs

General Information

Vigabatrin is used mainly in the treatment of refractory partial seizures and infantile spasms. Weight gain and mostly transient sedation are its most common adverse effects, but visual field defects are the main cause for concern and severely restrict its use.

In a placebo-controlled add-on comparison of three dosages of vigabatrin (1, 3, and 6 g/day) in 174 patients with partial epilepsy, fatigue, drowsiness, and dizziness were the most common treatment-related adverse events, especially at the highest dosage (1). The incidence of severe events was 2.2% in the placebo group and 8.7, 11, and 16% with 1, 3, and 6 g/day respectively. The

© 2006 Elsevier B.V. All rights reserved.

proportion of patients who withdrew owing to adverse events was 2.2% in the placebo group and 6.5, 11, and 18% with 1, 3, and 6 g/day respectively. Four vigabatrin patients (three of whom were taking 6 g/day) had a reduction in erythrocyte counts to 3.4–3.5 $\times$ 10^9/l. Symptoms suggestive of retinal toxicity were not reported, but the duration of treatment was short (18 weeks) and there was no formal ophthalmological testing. Overall, efficacy and safety data from this trial suggested that 3 g/day gave optimal results. Although higher dosages may provide additional benefit in selected patients, the occurrence of retinal toxicity (see below) warrants caution about the use of high doses.

Vigabatrin has been studied in an open 1-year extension of a randomized, double-blind, placebo-controlled Canadian trial in 97 adults with resistant partial epilepsy (2). There was a mean weight gain of 3.7 kg by the end of the study. Treatment was discontinued in 12% because of adverse effects. Neurological/psychiatric adverse effects were the most common reason for withdrawal, including three behavioral reactions attributed to the drug.

In a single-blind, randomized trial of vigabatrin for 2 weeks in children with newly diagnosed infantile spasms the children were randomly assigned to low-dose vigabatrin (18–36 mg/kg/day) or high-dose vigabatrin (100–148 mg/kg/day) (3). The time to response was evaluated during the first 3 months, and safety was evaluated during the entire study. Eight of 75 children who took low-dose vigabatrin and 24 of 67 who took high-dose vigabatrin responded. The time to response was significantly shorter in those who took high-dose vigabatrin and in those with tuberous sclerosis. The most common treatment-related adverse events were sedation (42/167), insomnia (15/167), and irritability (15/167). There were no dose-related adverse events, and adverse event rates were similar in the low-dose and high-dose groups. Only nine patients withdrew because of adverse events.

Vigabatrin efficacy and tolerability have been evaluated for a mean of 16 months in children in a retrospective study of 73 patients (mean age 87 months) (4). In 16% of the children vigabatrin was given as monotherapy and patients with either partial or generalized seizures were included. Vigabatrin was highly effective in 30 children (over 90% seizure reduction) and partially effective in 4 (50–90% seizure frequency reduction). There were adverse effects in 24%, the commonest being irritability, aggression, opposition/defiance, self-injurious behaviors, and deterioration in behavioral control. There was seizure deterioration in 7% of the children; worsening of myoclonic seizures was most common. Visual field testing by perimetry was possible in only 12 of the children; 2 had visual field constriction.

Organs and Systems

Nervous system

Central nervous system adverse events are mostly mild and transient and consist especially of drowsiness and fatigue. Other effects include irritability, nervousness, dizziness, headache, confusion, and depression. In a double-blind add-on trial at dosages of 2 or 3 g/day, drowsiness, diplopia, ataxia, and visual abnormalities were the only adverse effects that increased with dosage (5).

In a randomized open comparison of carbamazepine and vigabatrin in newly diagnosed epilepsy (6), patients randomized to vigabatrin reported less frequent drowsiness (44 versus 62%) and dizziness (7 versus 20%), and more frequent myoclonic jerks (14 versus 2%) and visual scintillae (16 versus 0%).

Like other GABAergic drugs, vigabatrin can aggravate absence seizures and may precipitate absence status in patients with generalized epilepsies. Occasionally, absence seizures are also precipitated in patients with partial epilepsy, as in a 28-year old man who developed de novo absence status 4 days after the dosage of vigabatrin was increased to 2 g/day (7).

Vigabatrin produces intramyelinic edema (neuronal vacuolization) in rats, mice, and dogs, but probably not in non-human primates (8). These findings have been reassessed on the background of clinical safety data, to determine the potential for a similar effect in man (8). In animals intramyelinic edema correlates with changes in multimodality-evoked potentials and MRI, but many studies in patients treated with vigabatrin in dosages of 1–6 g/day for up to 12 years have failed to provide evidence for similar changes in humans. Histological examinations of autopsy brain tissue from 24 patients exposed to vigabatrin for 0.6 months to 9.6 years also failed to show any evidence of astrocytosis or axonal changes similar to those associated with vigabatrin-induced microvacuolization. These findings do not provide any support to the hypothesis that intramyelinic edema occurs in patients treated with vigabatrin.

Acute encephalopathy has previously been attributed to vigabatrin in adults. There has also been a case in a child (9).

- A 6-month-old girl with infantile Alexander disease with hydrocephalus developed apathy, somnolence, and stupor, with slowing of background encephalographic activity, 3 days after starting vigabatrin, which was withdrawn. During the next 2 days her symptoms abated and after 10 days her electroencephalogram normalized.

Vigabatrin can exacerbate myoclonic and absence seizures and occasionally other seizure types, especially in children with generalized epilepsies. After the administration of vigabatrin, seizures worsened in all of four children with Angelman syndrome (10), and generalized seizures occurred for the first time in a boy with succinic semialdehyde dehydrogenase deficiency (SEDA-21, 77). De novo myoclonic jerks and precipitation of status epilepticus have also been reported (SEDA-20, 70).

There have been several reports of acute encephalopathy (SEDA-18, 71) and occasional cases of akathisia, hyperkinesia, and dyskinesias. Toxicology studies in mice, rats, and dogs showed dose-related intramyelinic edema, with microvacuoles in the white matter of the brain, but there is no evidence that these have clinical relevance (SEDA-21, 77).

Sensory systems

Vigabatrin causes a variety of changes in visual function, including reductions in visual field, visual acuity, color

© 2006 Elsevier B.V. All rights reserved.

vision, and electroretinographic and electro-oculographic amplitudes (11–16).

Visual field defects

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: collateral
Time-course: long-term
Susceptibility factors: male sex

Severe symptomatic visual field constriction, affecting mostly the peripheral fields and without loss of visual acuity, was first reported in 1997 in three patients who had taken vigabatrin for 2–3 years (17), and reports continue to appear (18–24). Electrophysiological investigations suggested damage to the outer retina, and there was no recovery for up to 12 months after withdrawal. Over 50 other cases of visual field defects (including asymptomatic cases) were published thereafter, and 28 were known to the manufacturer before the initial publication (SEDA-21, 78) (SEDA-22, 92).

Features

Visual field loss due to vigabatrin has been studied in 18 patients taking long-term treatment (0.5–9.5 years) and five controls (25). Of the 18 patients taking vigabatrin, there were mild visual field defects in six right eyes and eight left eyes, and severe defects in nine right eyes and eight left eyes. Most of the defects were peripheral constriction with nasal predominance.

Even patients with relatively severe constriction can partly compensate through adjustments in eye movements. Because the disorder develops insidiously, these patients may remain unaware of their condition, even though their visual impairment puts them at risk in special circumstances, such as driving a car.

The safety of continuing vigabatrin therapy in adults who have taken prolonged treatment (over 2 years) has been assessed by serially monitoring changes in visual function over 1 year of continued therapy (26). Fifteen patients who continued to take vigabatrin had visual function testing (visual acuity, color vision, and kinetic and static perimetry) every 3 months for 1 year. Nine had normal visual fields and six had visual field constriction. During follow-up, they showed no worsening of visual acuity, color vision, or visual field constriction, beyond that measured in the initial test. This study showed that mild changes in visual function after long-term vigabatrin generally remain stable with continued treatment. However, patient consistency was variable and repeated testing was necessary in some cases to assess the reliability of the apparent worsening or improvement experienced by some patients.

Frequency

Visual field defects have been commonly reported in patients taking vigabatrin (10–30%) (27,28), although if asymptomatic cases are included, the incidence may be as high as 40% (29) or even 60% (30). In an observational cohort study the prevalence was relatively low, at 0.8% of 7228 patients (31); however, this result was challenged as a probable underestimate, because of the use of a questionnaire to elicit the diagnosis (12–14). These different rates have probably been related to the diverse methods of patient inclusion and visual field testing.

In a prospective study in patients evaluated for epilepsy surgery, absolute concentric contraction of the visual field of 10–30 degrees was found in 20 (17%) of 118 patients who had ever taken vigabatrin, compared with none of 39 patients who had never taken vigabatrin (27). Men were more frequently affected than women (21 versus 6%), and the degree of visual field loss was more severe in patients who had taken vigabatrin for more than 2 years. None of the affected patients complained spontaneously of visual field loss.

Expert review of 25 cases of visual field defects reported to the manufacturer suggested that in 13 of the patients the visual field loss could not be assigned to an alternative known cause and had to be ascribed to vigabatrin (11). In an open extension study in Japan, 29 of 99 patients treated with vigabatrin for 2.7–6.7 years had visual field defects attributed to vigabatrin (11).

Among 57 patients aged 19–73 years treated with vigabatrin as add-on or as monotherapy for 2–14 years, there were mildly abnormal or severely abnormal fields in 14 and 8 patients respectively (32). Two patients with severe field abnormalities were symptomatic.

Of 20 consecutive patients treated with vigabatrin 12 had visual field constriction, severe in four and symptomatic in two (33). Visual field defects were more common in patients who were also taking valproate. Although most reports concerned adults, children may also be affected (34).

In a randomized monotherapy trial in newly diagnosed epilepsy, seven of 32 patients who were still taking vigabatrin after 3–9 years had concentrically constricted visual fields, and the defect was rated as severe in two (35). Of the seven patients with field defects, five had reduced oscillatory potentials and two also had abnormal a and b waves in rod and cone electroretinography. In contrast, none of the 20 patients who were still taking carbamazepine had abnormal visual fields. There is also preliminary evidence that a pre-existing visual field defect increases susceptibility to vigabatrin-induced visual field constriction.

In a double-blind, randomized study in patients with partial epilepsy three of 32 patients taking vigabatrin had abnormal visual perimetry after the end of the study (36).

In a retrospective study in 158 patients with partial epilepsy visual field defects were detected in 21 (13%); 13 patients had concentric visual field constriction without subjective spontaneous manifestations. Of these 13 patients, 9 were taking vigabatrin (37).

The efficacy and adverse effects of steroids and vigabatrin in children with infantile spasms have been reviewed (38). The authors found a high rate of visual field defects and concluded that although vigabatrin is efficacious it does not seem to be more effective than steroids or corticotrophin, and that the benefits of vigabatrin do not justify the associated risks of possible irreversible visual changes.

The prevalence of visual field constriction associated with vigabatrin has been evaluated in 91 children aged 5.6–18 years (39). There were visual field defects in 17,

© 2006 Elsevier B.V. All rights reserved.

but there was wide intrasubject variation between successive test sessions, and children often performed better in later test sessions, making evaluation difficult.

Pathophysiology

Electroretinographic findings in affected patients are consistent with reduced inner retinal cone response (40,41), but interpretation of the results has been disputed (42,43).

Visual fields have been studied in eight patients with vigabatrin-attributed visual field loss; six were no longer taking vigabatrin (44). Seven patients had marked visual field constriction with some sparing of the temporal visual field; the eighth had concentric constriction. Two patients had subnormal Arden electro-oculography indices; one patient had an abnormally delayed photopic b wave; five patients had delayed 30-Hz flicker b waves; and seven patients had delayed oscillatory potentials. Multifocal electroretinography confirmed that the effects occurred at the retinal level.

Visual fields, visual evoked potentials, and electroretinography have been assessed in 24 children treated with vigabatrin; 13 had at least one abnormal study (45). There was visual field constriction in 11 of 17 patients who had perimetry; five of 15 patients who underwent visual evoked potential testing and four of 11 who underwent electroretinography had abnormal examinations. Abnormal visual evoked potentials and electroretinography were mostly found in children who also had visual field constriction. Of five patients who were taking vigabatrin alone, three had abnormalities; however, all the other patients were taking other antiepileptic drugs and additive effects could not be ruled out.

The retinal electrophysiological markers associated with vigabatrin-attributed visual field loss have been distinguished from those associated with current vigabatrin therapy in 8 previous and 18 current vigabatrin users (46). They underwent electro-oculography, electroretinography, and automated static threshold perimetry and 22 healthy subjects underwent electroretinography. Of 26 patients exposed to vigabatrin, 18 had visual field loss; none taking other antiepileptic drugs had this type of visual field abnormality. The presence and severity of the visual field loss were significantly associated with the latency (implicit time) and amplitude of the electroretinographic cone function. The amplitude of the cone flicker response was the strongest predictor of visual field loss. The electro-oculogram, the photopic and scotopic electroretinogram, and the latency of the electroretinographic second oscillatory potential were not significantly related to the presence of visual field loss. Vigabatrin was significantly associated with the photopic amplitude, the scotopic a-wave latency, and the latency of the second oscillatory potential.

The pathological features of visual field constriction have been described in a patient taking vigabatrin (47).

- A 41-year-old man who had taken vigabatrin for 2 years in doses of 3–6 g/day developed bilateral concentric visual field defects, with greater loss in the nasal fields. Vigabatrin was withdrawn. Later he had a cardiopulmonary arrest and died. At postmortem there was peripheral retinal atrophy with loss of ganglion cells, severe in the peripheral retina and less severe in the maculae. There was loss of nerve fibers in the optic nerves, chiasm, and tracts. There was no evidence of intramyelin edema.

These findings suggest that vigabatrin may be directly associated with direct retinal injury (to the ganglion cells). The degree of cell loss suggested that the visual field loss was irreversible.

Mechanism

The mechanism responsible for the development of the visual field defects is unknown. However, they may be related to accumulation of GABA in the retina. In rats treated either with vigabatrin or tiagabine, vigabatrin reduced the activity of GABA transaminase and increased GABA concentrations in the brain, but these effects were more pronounced in the retina, in which vigabatrin concentrations are as much as five-fold higher than in the brain (48). On the other hand, tiagabine concentrations are considerably lower in the retina than in the brain. Tiagabine has not been associated with visual field defects.

Vigabatrin-induced inhibition of ornithine transaminase has been suggested as an alternative mechanism (49).

Diagnosis

Visual field defects are difficult to detect by simple clinical examination, even in patients with severe constriction at perimetric assessment. Visual field testing should be done before treatment and at regular intervals thereafter. Patients should be questioned about visual disturbances and referred to an ophthalmologist if relevant symptoms are recognized.

Potential correlations between visual field defects and the results of ophthalmological tests have been assessed. The use of the electroretinogram as a marker for vigabatrin-induced visual field alterations has been questioned (42), and the suggestion has been made that the electroretinographic changes described in some patients on vigabatrin may be due to a physiological effect of GABA not necessarily related to retinal toxicity (43). Of 20 consecutive patients 14 had a reduced light/dark ratio (Arden ratio) in the standard electro-oculogram and 10 had absent oscillatory potentials in the electroretinogram (33). Overall, 17 patients had abnormal electro-oculography, electroretinography, or both, although only 12 had constricted visual fields at perimetric testing.

The value of electroretinography and electro-oculography in the early diagnosis of vigabatrin-associated visual field defects has been assessed in 30 patients with temporal lobe epilepsy (50,51). The patients were stratified into three groups: (A) concentric contraction of the visual field associated with vigabatrin ($n = 15$), (B) normal visual field with vigabatrin use ($n = 11$), and (C) normal visual field without vigabatrin ($n = 4$). There were abnormal electrophysiological results in 50% of the patients in group A. The electro-oculographic Arden ratio was lowered in 57%. The amount of visual field loss and the total dose of vigabatrin used correlated only weakly with the results of electroretinography and electro-oculography. These results suggest that ocular electrophysiology is not a good method for detecting patients at risk of vigabatrin-related visual field defects. Regular visual field examination remains the

© 2006 Elsevier B.V. All rights reserved.

cornerstone in screening. This has been confirmed by a retrospective, comparative case series in which the degree of electroretinal dysfunction was analysed using electroretinography in 40 patients taking vigabatrin, 24 as monotherapy (52). There was no statistically significant relation between the frequency of electrodiagnostic abnormalities and the duration of use or the total cumulative dosage of vigabatrin.

Dose-relation

Visual function has been studied in 21 epileptic patients taking vigabatrin and compared with visual function in 11 similar epileptic patients who had never taken it, in order to investigate whether the severity of visual field defect is related to the dose of vigabatrin and to consider other factors that may correlate with severity (53). Nine of 20 patients taking vigabatrin complained of blurring of vision compared with two of 11 controls. Four patients taking vigabatrin described flickering lights compared with one control. None had a posterior vitreous detachment. Three of 30 eyes of patients taking vigabatrin had distant visual acuity of 6/12 or worse compared with three of 22 controls, and five of 30 had near visual acuity worse than N6 compared with one of 22 controls. A mean of 1.73 Ishihara plates were misread by patients taking vigabatrin compared with 0.18 in the controls. There was a significant correlation between the severity of visual field defect and the total dose of vigabatrin.

In a cohort study of 99 patients taking vigabatrin, the prevalence of visual field defects increased significantly with increasing total vigabatrin dose. The prevalence ranged from four of 51 patients who had been exposed to 1 g/day or less to six of 8 patients taking a total dose of 3–5 g/day (28).

Time-course

The longer the duration of vigabatrin treatment and the higher the dose the greater the probability of field defects (28,30,51).

In a reference cohort of 42 patients exposed to other antiepileptic drugs without vigabatrin, 7 had visual field defects, but in all of them this could be ascribed to a known cause (11). The prevalence of visual field loss ascribed to the drug did not differ between patients treated for less than 4 years and those treated for more than 4 years (32 versus 28%), suggesting that the disorder is unlikely to increase with continuous treatment beyond 4 years. Visual field loss occurred in 17 of 45 men (38%) versus 12 of 54 women (22%), indicating that men have a two-fold increase in risk. Age, body weight, daily or cumulative vigabatrin dose, and concomitant antiepileptic drugs did not predict the occurrence of visual field loss. The appearance in the central field out to 30° eccentricity was typically that of a localized bilateral binasal loss, particularly with static threshold perimetry, extending in an annulus over the horizontal midline, together with a relative sparing of the temporal field. In severe cases, there was a concentric appearance. All cases except one were asymptomatic. The authors concluded that the visual field defect induced by vigabatrin is unique in pattern and profound in terms of frequency of occurrence and location and severity of the loss.

Susceptibility factors

Concentric visual field loss found in the presurgical evaluation of patients with drug-resistant temporal lobe epilepsy taking vigabatrin has been studied and related to potential susceptibility factors in 157 consecutive patients with drug-resistant temporal lobe epilepsy (27). There was absolute concentric contraction of the visual field of 10–30 degrees presurgically in 20 of 118 patients who had ever used vigabatrin and in none of 39 who had not. Men were significantly more often affected than women (15 of 72 versus 5 of 85). The degree of visual field loss correlated with the duration of vigabatrin medication. There was no correlation of visual field contraction with a history of meningitis as potential cause of the epilepsy, duration of the epilepsy, status epilepticus in the medical history, or histological abnormality of the brain tissue removed. Ophthalmological examination of the patients with concentric contraction showed no abnormalities. None of the patients with concentric contraction complained spontaneously of their visual field loss.

The long-term retinal effects of vigabatrin in children are unknown, and visual field testing is usually impossible. Recent evidence has suggested that a short course of vigabatrin (6 months) in children with infantile spasms may be sufficient (54) and minimizes the potential for visual adverse effects.

Reversibility

Vigabatrin-induced visual field loss is generally considered to be irreversible (28,51), although partial reversibility has been described in some cases.

Long-term changes in the concentric contraction of the visual field have been studied in 27 patients with temporal lobe epilepsy taking vigabatrin (55). Concentric contraction of the visual field did not change in 16 patients who stopped taking vigabatrin before the first examination but there was slight but significant worsening of visual field loss in 11 patients who continued taking vigabatrin. The authors concluded that vigabatrin-associated visual field loss is not reversible and that progression can occur when vigabatrin is continued.

The reversibility of visual function loss from vigabatrin has been studied in 13 patients who had discontinued the drug up to a year before because of lack of efficacy or reductions in visual field (56). Although electroretinographic cone implicit time improved, most of the patients did not have improvement in either clinical measures of visual function (that is visual acuity, color vision, visual fields) or in electroretinographic amplitudes. However, several patients who had minimal visual field loss while taking vigabatrin had substantial recovery of the electroretinographic amplitudes. There was no association between recovery of function and either duration of treatment or cumulative dosage. Multifocal electroretinography showed a diffuse loss of function that was not isolated to the periphery.

In contrast, in another study there was partial reversibility of visual field constriction and retinal function after withdrawal in two patients (57).

Of 30 children with epilepsy (14 boys and 16 girls, aged 4–20 years) taking vigabatrin for infantile spasms and simple and complex partial epilepsy, who had never complained of ophthalmologic disturbances, 4 had visual field

© 2006 Elsevier B.V. All rights reserved.

constriction in the nasal hemifield (58). In one child, visual abnormalities were stable even 10 months after vigabatrin withdrawal, while in another there was improvement 5 months after withdrawal.

- Although in a 10-year-old girl a severe visual field defect was said to have reversed after withdrawal (59), repeat confirmatory testing was not performed before the withdrawal of vigabatrin and the pattern of constriction was suggestive of an artefact related to inadequate compliance with the testing procedure (J Wild, personal communication, 1999).

However, other preliminary reports have suggested that reversibility of the visual field defects may in fact occur following early withdrawal (57,60).

Of 12 vigabatrin-treated patients with visual field defects re-examined 2–10 years after vigabatrin withdrawal, all still had visual field defects (28). In five cases there was apparent worsening. Exceptional cases of reversible visual field defects have been reported in children (61). However, perimetry assessment in children is burdened with multiple methodological problems that usually preclude reliable results.

In a study in 60 adults with partial epilepsy, progression or reversibility of vigabatrin-associated visual field defects were examined (51). The patients had taken vigabatrin for 7 months to 14 years as monotherapy or add-on therapy and were examined with repeated kinetic Goldmann perimetry. A follow-up examination was performed after 4–38 months in 55 patients. There was vigabatrin-associated visual field constriction in 40%, and in 13% the defect was severe. During follow-up after withdrawal of vigabatrin, there was no significant recovery of visual fields in any patient. Conversely, there was no progression in those who continued therapy.

Effects of other antiepileptic drugs and interaction with vigabatrin

Other antiepileptic drugs can also alter visual evoked potentials and brainstem evoked potentials. Visual field defects associated with various antiepileptic drugs (carbamazepine, diazepam, gabapentin, phenytoin, tiagabine, and vigabatrin) have been reviewed (37).

In 100 epileptic patients aged 8–18 years taking carbamazepine or valproate in modified-release formulations either alone or with added vigabatrin interpeak latencies of I-III and III-V of brainstem evoked potentials were significantly delayed and N75/P100 and P100/N145 amplitudes in the visual evoked potentials were reduced (62). However, the addition of vigabatrin did not worsen the effects caused by the other two drugs alone.

Retinal dysfunction

Retinal dysfunction has been retrospectively assessed in 29 children taking vigabatrin 25–114 mg/kg/day for 6.5 years (63). Ophthalmic examination was performed before treatment and every 6 months thereafter. Four children developed eye changes (retinal pigmentation, hypopigmented retinal spots, vascular sheathing, and optic atrophy). Visual evoked potentials were abnormal in 16. Electroretinography and electro-oculography were not performed.

Color vision defects

There was abnormal color perception in 32% of 32 patients taking vigabatrin monotherapy; in four cases there was an abnormality in the blue-yellow axis (64). In the same patients there was a positive correlation between visual contrast sensitivity and the size of the visual field; macular photo-stress and glare tests were equal in both groups and did not differ from normal values; there was no effect on glare sensitivity (65).

Changes in color vision have been investigated in healthy volunteers who took a single oral dose of either vigabatrin or carbamazepine in a single-blind, placebo-controlled, randomized trial (66). All underwent color visual-evoked potential testing and color perimetry at baseline and after taking placebo, vigabatrin (2000 mg), or carbamazepine (400 mg). Carbamazepine caused mild overall impairment of the chromatic and achromatic systems. Vigabatrin caused selective blue impairment, consistent with GABAergic inhibition in the retina. The relation of this change in color perception to visual field defects, if any, is unknown.

Psychological, psychiatric

Although abnormal behavior, psychosis, and depression occur with increased frequency (around 2–4% or even higher) in patients with refractory epilepsy, the risk is increased during treatment with vigabatrin or on its abrupt withdrawal (SEDA-18, 71) (SEDA-19, 76) (SEDA-20, 70) (SEDA-21, 77) (67). The risk depends on the patient's characteristics, the dosage, and the rate of dose escalation. In the manufacturer's safety database, the incidence of psychosis was reported as being 1.1% or 0.64% based on postmarketing Prescription Event Monitoring (68). However, in adults with refractory partial epilepsy, severe behavioral or mood disturbances can be anticipated in 26% of treated cases (SEDA-18, 72), although higher figures have also been presented (SEDA-20, 70). In one study depression occurred with a frequency of about 9% with vigabatrin and 1% with placebo (5).

Psychiatric complications occur in both children and adults. While there is some evidence that a positive psychiatric history may increase the risk (and may represent a relative contraindication), behavioral and mood disturbances can occur in patients who had no similar episodes in the past. A retrospective survey of 50 patients with vigabatrin-associated psychosis ($n = 28$) or depression ($n = 22$) suggested that psychosis tends to occur in patients with more severe epilepsy and may be related to a right-sided EEG focus or suppression of seizures (64% of patients were free of seizures). On the other hand, patients with depression tended to have a past history of depressive illness and to have had little or no change in seizure frequency (69). To minimize risks, vigabatrin should be introduced in low dosages and increased slowly, and it should not be withdrawn abruptly. Psychiatric symptoms usually remit with drug withdrawal, although if treatment needs to be continued, neuroleptic medication may be useful.

That vigabatrin can cause psychosis and depression has been confirmed in an analysis of data from double-blind, controlled, add-on trials (70). Compared with placebo, vigabatrin-exposed patients had a significantly higher

© 2006 Elsevier B.V. All rights reserved.

incidence of events coded as depression (12 versus 3.5%) and psychosis (2.5 versus 0.3%). Although these events occurred during the first 3 months, most of the studies lasted 12–18 weeks and therefore definite conclusions could not be reached about timing.

Metabolism

Weight gain occurs in as many as 40% of patients during the first 6 months of therapy.

Mouth and teeth

Gingival overgrowth occurred in a 29-year-old man who had taken vigabatrin for 5 years for partial epileptic seizures (71).

Liver

Liver toxicity, if it occurs, is exceedingly rare. Fatal acute hepatic failure was described in a 3-year-old boy (SEDA-21, 78).

Pancreas

Pancreatitis occurred in a patient whose polytherapy included vigabatrin (SEDA-20, 58), but cause and effect was uncertain.

Skin

Skin reactions to vigabatrin are very rare. One case of erythema multiforme was complicated by concomitant multiple pathology, and cause and effect was dubious (SEDA-20, 71).

Susceptibility Factors

Renal disease

Acute encephalopathy with stupor and generalized slow wave electroencephalographic activity developed in three men with mild renal insufficiency aged 24–74 years within 1–3 days of starting vigabatrin (1–2 g/day) or increasing the dosage (from 2 to 3 g/day) (72). The symptoms subsided rapidly after drug withdrawal or dose reduction. Special caution is recommended when vigabatrin is used in patients with impaired renal function.

Drug Administration

Drug overdose

Doses of vigabatrin up to 10 g have been taken without serious effects. Toxic manifestations include vertigo, tremor, sedation, coma, myoclonic jerks, and psychosis. Gastric lavage within 1–2 hours is recommended after doses in excess of 12 g in adults and 2 g in children (SEDA-22, 85). The development of discontinuous partial complex status epilepticus in a patient with partial epilepsy who had taken a 20 g overdose 6 days earlier was considered to be a possible effect of withdrawal (SEDA-22, 85).

- After an overdose of vigabatrin 45 g, a 17-year-old girl developed a behavioral disorder (73). A CT scan of the brain was normal but an electroencephalogram showed abnormal delta waves.

Drug–Drug Interactions

Carbamazepine

One report suggesting that carbamazepine reduces serum vigabatrin concentrations (SEDA-21, 80) requires confirmation.

Although vigabatrin is not metabolized by liver enzymes it increased serum carbamazepine concentrations by at least 10% in 66 epileptic patients aged 10–66 years with focal seizure onset with or without secondary generalization (74).

Ethinylestradiol

Vigabatrin does not produce enzyme induction and did not generally alter the kinetics of ethinylestradiol and levonorgestrel, although two women had an approximate 50% reduction in ethinylestradiol concentrations during vigabatrin treatment (SEDA-21, 80).

Phenytoin

Vigabatrin can reduce serum phenytoin concentrations by about one-third, but this interaction is inconsistent.

Interference with Diagnostic Tests

General

Vigabatrin can produce an abnormal urinary amino acid pattern, which can be diagnostically confusing (SEDA-16, 74). It increases plasma and urinary alpha-aminoadipic acid concentrations, possibly complicating the diagnosis of alpha-aminoadipicaciduria (SEDA-20, 71).

Vigabatrin inhibits alanine transferase, and the resulting underestimation of enzyme activity could mask evidence of hepatic disease (SEDA-20, 70).

Viloxazine

See also Antidepressants, second-generation

General Information

Viloxazine, a bicyclic compound, is related structurally (but not pharmacologically) to the beta-adrenoceptor antagonists. In animal tests, its profile shows properties of both the imipramine-like compounds (reversal of reserpine-induced hypothermia) and amphetamine (stimulation of the electroencephalogram). A review of animal and clinical data confirmed the impression that viloxazine has efficacy comparable to that of imipramine but with a different adverse effects profile (1). There is a reduced frequency of anticholinergic and sedative effects and a tendency to lose rather than to gain weight. However, viloxazine has some limiting adverse effects of its own. These include nausea, vomiting, and gastrointestinal distress, which may be reduced by the use of an enteric-coated formulation (2,3). Viloxazine has also been implicated in migraine, even in patients with no previous history (4).

Organs and Systems

Cardiovascular

Although hypotension and tachycardia can occur, an extensive review of its animal and clinical pharmacology

© 2006 Elsevier B.V. All rights reserved.

suggested that viloxazine is relatively free of direct cardiotoxic effects (1). In a controlled comparison of doxepin and viloxazine (150–450 mg/day), one patient taking viloxazine developed chest pain after 26 days; an electrocardiogram confirmed changes compatible with ischemia but there were no progressive electrocardiographic or enzyme changes, and the patient recovered fully after being dropped from the study (5).

Nervous system

Viloxazine has previously been reported to lack epileptogenic properties (SEDA-10, 52). In a review of eight patients (six reported to the UK Committee on Safety of Medicines and two in Japan) it was concluded that there was a possible causal connection with seizures in only two cases, and that such an association was inconsistent with the results of animal studies and with a worldwide review of clinical trials (6). The reviewers concluded that if there is a risk of inducing epilepsy with viloxazine, it is probably only one-tenth that of tricyclic compounds.

Drug Administration

Drug overdose

It has been claimed that viloxazine is relatively free of cardiotoxic effects and therefore safe in patients who take an overdose. Indeed, 12 cases of overdose have been reported, with complete recovery and no electrocardiographic changes (SEDA-1, 9). In an authoritative review it was concluded that although coma, hypotension, and loss of tendon reflexes have been reported, serious complications do not develop in most cases (7).

Drug–Drug Interactions

Carbamazepine

In seven patients with epilepsy taking carbamazepine the addition of viloxazine 300 mg/day resulted in a pronounced increase in plasma carbamazepine concentrations (8.1–12.1 ng/ml), with symptoms of intoxication (dizziness, fatigue, ataxia, and drowsiness), resolving on withdrawal of viloxazine (8). The mechanism was unclear, but serum concentrations of phenytoin in two patients were unchanged.

Vinca alkaloids

See also Cytostatic and immunosuppressant drugs

General Information

From among nearly 30 different alkaloids that have been isolated from the periwinkle *Catharanthus roseus* (Apocynaceae), vincristine and vinblastine have been assessed to have the highest antitumor activity. Both have a large dimeric asymmetric structure composed of a dihydroindole nucleus (vindoline ring) and an indole nucleus, linked by a carbon–carbon bond. In contrast, the derivatives vindesine (deacetyl vinblastine amide sulfate (DVAS)) and vinorelbine are semisynthetic (1–3). Finally, vinflunine, the latest semisynthetic vinca alkaloid, is a fluorinated derivative that is still under clinical investigation and has a different inhibitory action than other vinca alkaloids. Preliminary results suggest that this congener may be less toxic on the peripheral and autonomic nervous systems (4).

Vincristine (rINN)

Vincristine is part of many chemotherapeutic regimens, based on its lack of myelosuppressive toxicity. It is used, for example, in the treatment of acute lymphocytic leukemia (ALL), acute myeloid leukemia (AML), lymphomas, neuroblastoma, brain tumors, and Wilms' tumor. The generally recommended dose in adults is 1.4 mg/m^2/week intravenously (5). Some clinicians have recommended an absolute upper limit of 2 mg, but this limitation is still a matter of debate (6). The usual pediatric dosage is 1.5–2 mg/m^2, but for children weighing 10 kg or less or who have a body surface area less than 1 m^2, the manufacturers recommend that treatment should be begun at 0.05 mg/kg once a week (5).

Vinblastine (rINN)

Vinblastine is used in combination with other cytotoxic agents for the treatment of disseminated Hodgkin's disease stages III and IV, non-Hodgkin's lymphoma, histiocytic lymphoma, and advanced carcinoma of the testis. It has also been used for the treatment of bladder cancer, melanoma, and renal cell cancer. The usual adult dosage is 3–6 mg/m^2 intravenously for the treatment of testicular germ cell tumors and Hodgkin's disease (1,2).

© 2006 Elsevier B.V. All rights reserved.

Vindesine (rINN)

Vindesine (DVAS) was the first semi-synthetic vinca alkaloid derivative introduced into clinical oncology. It differs solely from vinblastine in the nature of the substituted functional group attached to the vindoline ring. Vindesine has been most extensively studied in the treatment of non-small cell lung cancers. A randomized study has shown that vindesine (3 mg/m^2 intravenously) was substantially better than vincristine (1.4 mg/m^2 intravenously) both given weekly for 4 weeks, then every 2 weeks for 1 month, then monthly. However, another study showed that vindesine may be inferior to the structurally related vinorelbine in the treatment of advanced non-small cell lung cancers with overall response rates of 9 and 29%, respectively. Vindesine has also been used in patients with advanced malignant melanomas. Potential indications that have been studied with vindesine include head and neck cancer, ALL, lymphomas, and breast cancer. However, its precise role and clinically relevant advantages to other available vinca alkaloids needs further investigation (7–10).

Vinorelbine (rINN)

Vinorelbine has become a pivotal agent for treating adjuvant non-small cell lung cancer (stages IB-III) and the palliative treatment of non-small cell lung cancer (stages IIIB and IV), often in combination with drugs like cisplatin. In addition, vinorelbine plays an important part in the treatment of advanced and metastatic breast cancer. Its role in the treatment of advanced cervical cancer is still under investigation. The usual intravenous dosage is 20–30 mg/m^2 (vinorelbine base) given once a week. In contrast to the other congeners, vinorelbine can also be taken orally based on its absolute systemic availability of about 44% after administration as a capsule. Oral dosages of 60 and 80 mg/m^2 have been said to be pharmacokinetically and clinically equivalent to intravenous dosages of 25 and 30 mg/m^2 respectively (2,11).

Mechanism of action

All four vinca alkaloids block mitosis with metaphase arrest. Their antitumor activity is based on their high binding affinity to intracellular tubulin, which is the protein subunit of the spindle microtubules. The binding constants of vincristine, vinblastine, and vindesine for tubulin are 8, 6, and 3.3 nmol/l respectively (9,10). The formation of complexes between the vinca alkaloids and tubulin prevents the polymerization of the tubulin subunits to microtubules, which results in depolymerization of microtubules and inhibition of microtubule assembly. Based on the fact that microtubule assemblies also play a pivotal role in the movement of neurotransmitter substances along neuronal axons, vinca alkaloids can cause neurotoxicity, particularly at higher concentrations (9,10).

Pharmacokinetics

After intravenous administration, plasma concentrations of vinca alkaloids fall triphasically, with an initial rapid phase. All four congeners are extensively distributed into peripheral compartments, but passage across the blood–brain barrier is limited (11,12). In addition to tissue binding, vinca alkaloids bind to blood constituents like human platelets and lymphocytes. Binding to plasma proteins has been estimated to be from about 80% to more than 90%, with an unbound fraction of about 0.10–0.20. Binding to whole blood is usually higher than in serum, which reflects substantial binding to platelets (11,12).

All four congeners are extensively metabolized in the liver and excreted in the bile (13). Their metabolic biotransformation is primarily mediated by CYP3A. Deacetylvinorelbine, the primary metabolite of vinorelbine, has remarkable antitumor activity; however, the amounts detected in blood after conventional doses of vinorelbine are very low, which suggests that this metabolite does not contribute significantly to the overall antitumor activity of vinorelbine (14,15). Based on the pivotal role of CYP3A isozymes during the catabolism of vinca alkaloids, care is warranted when using concomitant drugs that inhibit these isozymes (16,17).

The half-lives of vinblastine, vindesine, and vinorelbine are all about 24 hours; vincristine has a much longer half-life of about 3.5 days (5). Because biliary and fecal drug excretion is of major quantitative importance during the elimination of vinca alkaloids, patients with impaired hepatic clearance and increased bilirubin concentrations may need dosage modification in order to avoid critical drug accumulation. CYP3A4 activity measurement (for example by the monoethylglycinexylidide test) might be the most appropriate method to estimate individual capacity to metabolize drugs like vinorelbine; however, such methods have not yet been routinely established in most cancer centers. Empirically, it is prudent to reduce doses by about 50% in patients with liver volume replacement by tumor that exceeds 75% (18).

Vinorelbine is the only vinca congener that can also be used orally. Its oral availability averages 43% and is not affected by food (19). The interpatient variability in blood concentrations is in the same range as after intravenous administration (15).

General adverse effects

The most important adverse effects of vinca alkaloids include nervous system disorders, hematological effects, and gastrointestinal discomfort. Respiratory and cardiovascular adverse effects have to be particularly considered during combination chemotherapy. All the vinca alkaloids are tissue irritants, and extravasation without any adequate supportive management can result in severe local ulceration (1,2,5,8,20).

Vinca alkaloids are primarily metabolized by CYP3A4, inducers, inhibitors of which can significantly change their pharmacokinetics (16,17,21).

Organs and Systems

Cardiovascular

Vinca alkaloid-associated myocardial infarction, angina pectoris, and transient electrocardiographic changes related to coronary ischemia are limited to case reports (22–24). In addition, patients with these adverse effects

© 2006 Elsevier B.V. All rights reserved.

received combination cancer chemotherapy, containing drugs such as bleomycin and cisplatin, which both have been suggested to cause cardiovascular adverse effects.

- A 64-year-old Japanese man developed chest pain with concomitant lateral ST segment depression after treatment with intravenous cisplatin 70 mg/m^2, vincristine 1.2 mg/m^2, and bleomycin 12 U/m^2. There was no history of predisposing factors and the symptoms disappeared quickly with glyceryl trinitrate. During the following cycle, containing cisplatin and verapamil as an antianginal agent, chest pain did not reoccur (23).
- A 46-year-old man developed a Q-wave inferior and a right ventricular myocardial infarct with postinfarction angina after the third cycle of vincristine + doxorubicin for multiple myeloma. The patient had no risk factors for ischemic heart disease, except for a positive smoking history, nor for hyperviscosity (24).

There is some evidence that both vincristine and doxorubicin are more often associated with ischemic heart disease than other cancer chemotherapeutic agents. Whether drug-induced platelet activation, altered clotting, or endovascular damage are responsible for vascular toxicity is still unclear. The risk of ischemic heart disease must therefore be kept in mind when patients receive a combination of doxorubicin and vincristine, especially when potential risk factors have been identified. Whether the structural similarity between vinca alkaloids and ergot alkaloids, which are vasospastic, is relevant is highly speculative.

After administration of vinorelbine, chest pain occurs in up to 5% of patients. However, subsequent analysis showed that most patients had underlying cardiovascular disease or a tumor in the chest, making interpretation difficult (2,20). Three patients developed acute cardiopulmonary toxicity after vinorelbine therapy (25). The symptoms mimicked acute cardiac ischemia, but with no electrocardiographic changes or raised cardiac enzymes. In two patients, tachypnea, râles, wheezing, and severe dyspnea responded to inhaled salbutamol. One patient developed pulmonary edema and bilateral pleural effusions, which contained no malignant cells when drained.

Venous discomfort and venous chemical phlebitis have been reported with vinorelbine 30 mg/m^2, with an incidence of up to 31% (26,27). The risk is increased in obesity (27). Pain along the vein occurred in five of 43 patients receiving vinorelbine 30 mg/m^2/week; none developed extravasation, but their symptoms were very similar (28). A similar rate of toxicity, 4.5%, has been reported in a review of the use of vinorelbine in 321 patients with breast cancer (29).

Respiratory

Acute shortness of breath and bronchospasm have been reported after the administration of vinca alkaloids, for example vinblastine and vindesine (30–34). The respiratory effects, including abrupt onset of progressive dyspnea, non-productive cough, pleuritic chest pain, profound wheezing, and diffuse basal crackles, were more common when mitomycin was used concomitantly. The onset of symptoms can be rapid (for example a few minutes to 1–5 hours after administration) or subacute (for example up to 2 weeks). If patients have pre-existing pulmonary dysfunction, intensified treatment, including glucocorticoids, may be indicated. Most case reports with vinca alkaloid-associated pulmonary toxicity included vinblastine, usually in combination with other known pneumotoxic agents, or thoracic irradiation. Patients receiving combination chemotherapy including vinca alkaloids should be monitored carefully for pulmonary symptoms. The underlying mechanism of vinca alkaloid pulmonary toxicity is unclear, but may involve a hypersensitivity reaction.

Nervous system

The most commonly reported dose-limiting toxic effect of vinca alkaloids is a mixed sensorimotor polyneuropathy (35). Vincristine has been associated with highest incidence, followed by vindesine and vinblastine; vinorelbine causes less neurotoxicity than the other congeners (2,5,8,36). The neurotoxic effects of vinca alkaloids are reversible (5).

The vinca alkaloids may have synergistic effects on the nervous system. Amongst 17 patients with metastatic breast cancer given the four-drug combination, vincristine + vinblastine + doxorubicin + cyclosphosphamide, there was a high incidence of acute neurotoxicity at half the usual therapeutic dose of vincristine and vinblastine (37).

Nerve palsies

Cranial nerve palsies can occur with the vinca alkaloids (38–42).

There have been several reports of isolated vincristine-induced recurrent laryngeal nerve paralysis (38,43–47).

Peripheral neuropathy

The features of vinca alkaloid-induced polyneuropathy include early loss of tendon reflexes at the ankles and distal paresthesia, followed by loss of touch, pain, and vibration sensations. Other symptoms include headache, malaise, weakness, dizziness, severe face and jaw pain, and vocal cord paralysis. The first symptoms usually occur a few days after drug administration (36). Gastrointestinal discomfort, particularly constipation, abdominal pain, and adynamic ileus, can occur through an autonomic neuropathy (5,48).

Higher drug concentrations during monotherapy (possibly related to impaired drug excretion in patients with hepatic dysfunction) or prolonged periods of treatment are important predisposing factors for more severe forms of neurotoxicity. The same is true of concomitant use of potent CYP3A inhibitors, such as erythromycin, itraconazole, or quinupristin/dalfopristin, which can increase plasma vinca alkaloid drug concentrations (5).

Of 22 patients given vindesine 2 mg/m^2 on 2 consecutive days weekly, four developed a peripheral neuropathy with paresthesia, and five developed muscle weakness with loss of deep tendon reflexes (49). Neuropathies were pronounced at sites of pre-existing nerve damage. If a tumor had previously damaged peripheral nerves, or if a chordotomy had been performed, the paresthesia that developed at that site was often painful. Neurotoxicity

© 2006 Elsevier B.V. All rights reserved.

was reversible, and the longest interval to full recovery was 3 months.

In 40 patients, orofacial pain developed as a manifestation of neuropathy about 3 days after vincristine administration, lasting for a mean duration of 2 days. Half of the patients were affected in the first week, and pain was commonest in young patients and in smokers (50).

With vinorelbine, incidence rates of 1.3% for peripheral neuropathies (mainly loss of deep tendon reflexes) and 4.1% for autonomic neuropathies (manifested by constipation) have been reported from a European overview of 321 patients (29).

The pathogenesis of vincristine-induced neuropathy has not been fully elucidated, but very probably altered axoplasmic transport processes are of major importance, since neurons treated with vincristine lose portions of their axonal microtubules (35). There is marked interindividual variability in sensitivity to this toxic effect, partially based on different predisposing factors, for example diabetes mellitus, pretreatment with other potentially neurotoxic agents (such as cisplatin and taxanes), or familial disorders (such as Charcot–Marie–Tooth syndrome) (37,51,52).

Several drugs have been proposed to be neuroprotective, including folinic acid, vitamin B_1, vitamin B_6, glutamic acid, Org 2766, insulin-like growth factor (IGF-1), and nerve growth factor. However, most drugs have been studied in experimental systems and there are only a few case reports suggesting clinical benefit. In contrast, folinic acid, vitamins B_1, B_{16}, and B_{12}, which were promising in experimental systems, failed to provide protection from vincristine-induced neuropathy in clinical studies. In the case of L-glutamic acid, which can be given orally, there was some neuroprotective activity; however, more information is needed to exclude any impairment of vincristine-induced antineoplastic activity, when both agents are used together on the same day (5).

The ACTH analogue Org 2766 was studied in a randomized, double-blind, placebo-controlled trial as a neuroprotective agent in patients receiving vincristine (53). In spite of positive results, the study design was later criticized because of a significantly higher number of younger patients in the Org 2766 group. In addition, there are contradictory results on the potential effect of Org 2766 on the overall antineoplastic activity of vincristine.

In a prospective, double-blind, placebo-controlled study, concurrent oral administration of 500 mg glutamic acid tds with vincristine reduced the incidence of subjective and objective signs of vincristine neurotoxicity (54). There were no differences in constipation, weakness, or loss of knee reflexes. There were no severe gastrointestinal adverse effects.

During recent years, more attention has been paid to nerve growth factor as a neuroprotective agent, since it may induce microtubule assembly, especially during neurite outgrowth. For instance, patients with a sensory neuropathy related to the use of cancer chemotherapy including paclitaxel, vincristine, or cisplatin had a significant reduction in plasma nerve growth factor concentrations (5). Acetyl-L -carnitine has been considered for neuroprotection because it increases nerve growth factor expression. However, as in the case of L-glutamine or Org 2766, more information is needed to evaluate any potential effect on vincristine antitumor efficacy.

Pre-existing neurological disease can predispose to severe vincristine neuropathy (55). For example, Charcot–Marie–Tooth disease is regarded as a contraindication to the use of vincristine (56). There have been four cases of vincristine-induced neuropathy in Charcot–Marie–Tooth disease; one was fatal, and in the other three there was severe quadriplegia, which resolved. A predisposition to vincristine neuropathy has been described in a patient with pre-existing Friedreich's ataxia (56). When vincristine 0.625 mg/m^2/week was given to 264 patients for a maximum of 10 weeks, the incidence of grade 3/4 neuropathy rate was 7%, suggesting that dose intensity rather than total dose may be important for determining the severity of this toxic effect. The rate of grade 1–4 neuropathy was 56% (57).

Finally, the aminothiol amifostine has been proposed to be effective in preventing vincristine-induced neurotoxicity; however, clinical data are still lacking to assess its role as a neuroprotective agent in terms of vinca alkaloids (5).

Myeloencephalopathy

Central nervous system toxicity is unusual with vinca alkaloids, because they do not readily cross the blood–brain barrier. However, fatal myeloencephalopathy can occur a few hours after accidental intrathecal drug administration (58,59), with severe bilateral leg pain, and over the next 36 hours progressive leg weakness, urinary retention, meningism, fever, and somnolence. Other effects include absence of deep tendon and gag reflexes and disappearance of rectal tone. In spite of high-dose folinic acid rescue, patients became comatose, for example by the fourth day after injection, with loss of brain stem function a few days later.

Seizures

Seizures associated with intravenous use of vinca alkaloids are very rare (60–62). Some cases may have been due to SIADH-associated hyponatremia. Other forms include tumor-related effects, nervous system infections, or cerebral hemorrhage, which often make direct causal relations between drug exposure and nervous system adverse effects very difficult.

- An 8-year-old girl with leukemia had tonic-clonic convulsions and life-threatening encephalopathy after intravenous vincristine. After the second dose (1.5 mg/m^2 in combination with prednisone) she developed seizures and bilateral translucencies in the CT scan. When vincristine was withdrawn in subsequent cycles, the symptoms disappeared (61).

Four of 350 patients without a history of seizures developed generalized seizures 5–6 days after the first, second, and eleventh doses of intravenous vincristine. However, seizures did not recur in later cycles. It is difficult to implicate vincristine as a cause of these adverse effects (62). Tonic-clonic seizures were only reported in four patients 7 days after vindesine administration. All patients had pre-existing cerebral deposits

© 2006 Elsevier B.V. All rights reserved.

of melanoma, possibly mimicking nervous system adverse effects (8).

Sensory systems

Eyes

Reversible visual damage has been attributed to vincristine.

- An 18-year-old man with lymphocytic leukemia became completely blind for 6 months after a fifth 10-day cycle of therapy with vincristine 2 mg intravenously followed by cyclophosphamide 600 mg orally for 5 days with prednisolone 100 mg orally for 5 days (63).
- A 15-year-old girl developed bilateral optic atrophy after treatment with weekly vincristine, posterior craniectomy, and whole neuraxis radiation therapy (64). Withdrawal resulted in recovery of visual function.

In 50 patients, ptosis and diplopia related to vincristine occurred in 16 (64). The exact pathomechanism of this adverse effect has not been elucidated.

Studies on monkeys have demonstrated visual loss and optic atrophy with intravitreous injection of vincristine. Clinical reports of postvincristine optic atrophy are rare. Most are irreversible, progressing to permanent blindness. There is commonly coexistent peripheral or cranial neuropathy (65). It is possible that certain patients are predisposed to vincristine-induced optic atrophy. Optic neuropathy after a single small dose of vincristine has been reported in a single case; the dose of vincristine was small (1275 mg), and the latent period before onset of visual loss was brief (6–8 weeks) (66). Previously reported cases have had multiple injections of vincristine and the latent period was longer than 3 months.

Ears

Vinca alkaloids can have ototoxic effects, such as tinnitus and transient hearing loss. In addition, vestibular disorders can cause dizziness, nystagmus, and vertigo (67,68).

- A 29-year-old man with recurrent Hodgkin's disease was treated with the ABVD regimen (doxorubicin, bleomycin, vinblastine, and dacarbazine) (69). He complained of tinnitus after each treatment cycle, with an onset of about 6 hours and a duration of 7–10 days. These symptoms interfered with reading, watching television, and general concentration. Based on audiography before and several hours after several cycles, there was evidence of mild sensorineural hearing loss in the high-decibel range 48 and 72 hours after drug administration. Six months after the completion of cancer chemotherapy, there was still some mild high-frequency sensorineural hearing loss in the left ear.

The authors concluded that vinblastine may have been responsible, because the other agents have not yet been associated with ototoxicity and because vincristine can cause ototoxicity too. The mechanism of this adverse effect is unclear but it may involve vinca alkaloid-associated damage to the eighth cranial nerve. This means that care should be taken when vinca alkaloids are used together with platinum compounds, especially cisplatin.

Endocrine

A rare but well-known adverse effect of vinca alkaloids, including vinorelbine, is the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (70–72). The diagnosis is usually based on clinical and laboratory findings. There are falls in plasma sodium (below 120 mmol/l), chloride (below 90 mmol/l), and osmolality (below 230 mosm/kg). Further features include lethargy, anorexia, nausea, listlessness, and rarely coma, particularly when serum sodium falls below 110 mmol/l. Treatment is based on withdrawal of the causative agent and the administration of 0.9% saline and potassium (for example 40 mmol/l) at an infusion rate of 200 ml/hour. Further treatment strategies include demeclocycline (for example 300 mg bd), which can be continued for the duration of further vinca alkaloid-containing cycles. In one case demeclocycline prevented SIADH during further courses of vinorelbine (72).

Asian patients have been proposed to be at higher risk of SIADH during treatment with vincristine. Between 1983 and 1999, 76 cases of hyponatremia and/or SIADH related to the use of vincristine were reported to the global adverse event database of Eli Lilly and Company. The average age of the patients was 36 years (range 2 weeks to 86 years) and 62% were male. Most of the patients had received vincristine for leukemia or lymphomas. Of the 76 reports, 39 included background information on race: 35 patients were Asian, three were Caucasian, and one was black. The authors concluded that there may be a correlation between race and vinca alkaloid-associated SIADH/hyponatremia; however, the reasons are still unclear (73).

Hematologic

The most frequent adverse effect of vinblastine, vindesine, and vinorelbine is hematological toxicity (1,2,5,7,8). Leukopenia, particularly neutropenia, occurs more often than thrombocytopenia or anemia. The nadir in the leukocyte count after vinblastine occurs 4–10 days after administration, with recovery within another 7–14 days. Blood counts should generally be measured weekly and before the administration of each dose, in order to avoid severe forms of myelosuppression, neutropenic fever, or infections (20).

Oral vinorelbine is also associated with neutropenia. In one small study in patients with breast cancer treated with 50–160 mg/week, the incidence of grade 3–4 neutropenia was 32% (14). The incidence of severe neutropenia is higher with vinorelbine than the other vinca alkaloids. However, mean recovery (about 9 days) appears to be somewhat shorter with vinorelbine than with compounds vinblastine and vindesine (average 14–21 days) (1,2).

Gastrointestinal

Constipation is common when vinca alkaloids cause an autonomic neuropathy. Laxatives such as lactulose or polyethylene glycol-containing solutions can prevent

© 2006 Elsevier B.V. All rights reserved.

adynamic subileus during treatment courses containing vinca alkaloids (48,74).

In contrast to constipation, nausea and vomiting are neither frequent nor dose-limiting adverse effects of vinca alkaloids. The regular use of antiemetics, such as 5-HT_3 receptor antagonists in combination with dexamethasone, is not recommended. However, oral vinorelbine has been associated with more severe forms of nausea and vomiting, with a frequency that is higher than after intravenous administration; in these patients and in particular those with predisposing factors for nausea and vomiting, metoclopramide and 5-HT_3 receptor antagonists are justified (75).

Skin

Vinca alkaloids are potential vesicants (76–78) and accidental drug extravasation can cause severe soft tissue ulceration. The initial symptoms include marked pain, erythema, and local swelling for several hours up to a day; later effects include blisters and severe painful skin ulcers, several days and 3 weeks after extravasation respectively. The lesions usually heal very slowly and sometimes require surgical intervention. Because vinca alkaloid extravasation can have severe effects, the use of antidotes is highly recommended when extravasation is suspected. In addition, venous irritation can be worsened if the vinca alkaloid is infused over at least 20–30 minutes rather than 6–10 minutes.

Among several antidotes for the treatment of vinca alkaloid extravasation, hyaluronidase is the most effective (79). Seven patients with extravasation of vincristine, vinblastine, or vinorelbine received hyaluronidase 250 units diluted in 6 ml of 0.9% saline, through the indwelling needle or, when the needle had been already removed, as six subcutaneous injections around the extravasation site. None developed skin necrosis. Local mild skin warming in order to produce local vasodilatation may have an additional beneficial effect, but should be avoided when simultaneous extravasation of a vinca alkaloid and an anthracycline is suspected, because local warming can worsen the anthracycline-associated local reaction, whereas local cooling, which is generally beneficial in anthracycline-related extravasation alone, can worsen skin necrosis due to vinca alkaloids (76).

Hair

Vinca alkaloids are associated with a low incidence of alopecia. In about 10% of patients, there can be gradual thinning of hair, but very few patients develop total hair loss (1,5,7).

Reproductive system

Based on comparative studies of the relative gonadal toxicity of several antineoplastic agents in experimental models and humans, the vinca alkaloids vinblastine and vincristine have negligible potency for killing stem cells. Permanent recovery of sperm counts and preserved ovarian function, depending on the patient's age at the time of treatment and the total cumulative dose, can be expected after treatment with vinca alkaloids (80–82).

Body temperature

Nine of 31 Japanese children receiving maintenance vincristine chemotherapy for either leukemia or lymphoma developed a fever over 38°C (83). An allergic mechanism was proposed. Concurrent glucocorticoids as part of the regimen appeared to be protective. Younger children were at greater risk. Peak temperatures occurred within 24 hours of vincristine administration. The pyrexia lasted from 6 hours to 4 days and the condition was self-limiting.

Long-Term Effects

Drug tolerance

Resistance to vinca alkaloids can be mediated by glycoprotein B, a transmembrane pump that is part of the multidrug resistance (MDR) phenotype (5).

Mutagenicity

Vinca alkaloids are less mutagenic than other cytotoxic agents like the *N*-Lost derivatives or bleomycin. Positive or negative results in mutagenicity tests depend on the test system used. For instance, vinorelbine significantly increased the frequencies of micronuclei in binucleate lymphocytes (84). In Chinese hamster ovary cells vinorelbine arrested cells at the first metaphase and caused an increase in abnormal anaphases, containing chiefly lagging chromosomes and multipolar spindles (85). These results suggest that vinorelbine does not directly damage DNA, but acts on spindle microtubules, altering chromosome movement and causing aneuploidy. However, it has no mutagenic effects in the Ames test.

Tumorigenicity

In the International Agency for Research and Treatment of Cancer (IARC), the vinca alkaloids were classified in group 3, which means that they cannot yet be classified in group 1 (proven human carcinogens), 2A (probably carcinogenic), or 2B (possibly carcinogenic) (86,87).

Second-Generation Effects

Teratogenicity

There is evidence that vinca alkaloids are teratogenic. Vinblastine caused malformations after first trimester administration (88–90). However, since vinca alkaloids are often combined with other cytotoxic drugs, it is difficult to relate any teratogenic effect to the vinca alkaloid alone (88). In mice and rabbits, vinblastine was embryotoxic and fetotoxic (89). However, it is unclear whether vinca alkaloids can cross the placenta because of their high molecular weights (about 1000 g/mol).

- Two pregnant women with breast cancer received two or three courses of intravenous vinorelbine 20–30 mg/m^2 and fluorouracil 500–750 mg/m^2 at 24, 28,

© 2006 Elsevier B.V. All rights reserved.

and 29 weeks of gestation; there were no adverse effects in the two newborns (90). A third patient also had epirubicin and cyclophosphamide and her infant, who had been exposed to the four-drug regimen, developed transient anemia at 21 days of age which resolved spontaneously. All three infants were developing normally at 2–3 years of age.

According to the FDA classification, the potential therapeutic benefits of vinca alkaloids have to be outweighed with the potential teratogenic risks (FDA classification D). All women of childbearing potential should be advised to avoid becoming pregnant while receiving cytotoxic cancer chemotherapy (80).

Drug Administration

Drug administration route

In seven patients (median age 7 years), limb and jaw muscle pain, starting at days 3–5 of an intravenous infusion of vincristine and requiring opiate analgesia, was the most pronounced adverse effect (68).

Guidance on the safe administration of intrathecal chemotherapy has been issued in the UK (91), following a case in which vincristine was fatally injected into the cerebrospinal fluid (92).

Drug–Drug Interactions

Asparaginase

Asparaginase and vincristine should not be used together on the same day, since simultaneous administration can cause increased vincristine toxicity. It has been suggested that this is due to a deleterious effect of asparaginase on hepatic function, reducing the metabolism of vincristine (5).

Carbamazepine

In a small pharmacokinetic study the clearance of vincristine was 65% greater than in patients who were not taking carbamazepine and the half-life and AUC of vincristine were reduced by 35 and 43% respectively (93).

Erythromycin

Toward the end of a phase I study of vinblastine plus oral ciclosporin to reverse multidrug resistance, three patients also received erythromycin to raise their ciclosporin concentrations; all developed severe toxicity consistent with a much higher dose of vinblastine than was actually given (94).

Itraconazole

The concomitant use of itraconazole with vincristine increased the incidence of neurotoxicity in children and adults with ALL (95,96).

- A 19-year-old woman developed severe abdominal pain and constipation 28 days after starting to take itraconazole as antifungal prophylaxis when receiving vincristine for ALL. She had hypertension, marked abdominal distension and tenderness, and absent bowel sounds. Withdrawal of itraconazole resulted in resolution of symptoms and vincristine was continued (96).
- A 72-year-old patient developed painful oral mucositis and constipation 3 days after being given vinorelbine and itraconazole (97). Further complications included neutropenia and hypoxia and he died.

Concomitant use of itraconazole 2.5 mg/kg/day and vincristine in five children receiving vincristine resulted in hypertension, paralytic ileus, and SIADH (95).

Phenytoin

In a small pharmacokinetic study, the clearance of vincristine was 65% greater than in patients who were not taking phenytoin and the half-life and AUC of vincristine were reduced by 35 and 43% respectively (93).

Vincamine

General Information

Vincamine is an alkaloid extracted from the plant *Vinca minor*. Ethyl apovincaminate is a related synthetic ethyl ester of vincaminic acid. These drugs have spasmolytic effects similar to those of reserpine, but also have metabolic effects, including, in high doses, inhibition of phosphodiesterase. Although increased cerebral blood flow has been reported after the intravenous administration of vincamine, there have been no reliable studies of blood flow after oral medication. Improvement in scores on some psychometric tests have been obtained in some patients with cerebrovascular disease, but no clear-cut practical benefit has been demonstrated.

Organs and Systems

Cardiovascular

Commercial formulations obtained from the alkaloids in *Vinca minor* may not be free from adverse effects. Ventricular dysrhythmias have been observed, but only after intramuscular or intravenous administration, and they seem to reflect a direct effect on myocardial cells. Hypokalemia and a prolonged QT interval seem to be predisposing factors. Vincamine should therefore be avoided in patients with a prolonged QT interval (SEDA-2, 183) (SEDA-5, 206) (SEDA-5, 207) (SEDA-7, 228).

Psychological, psychiatric

Vincamine has minor psychoactive effects (1).

Vinegar

General Information

Vinegar was used topically in a Turkish neonate with suspected sepsis (1). The child was treated with antibiotics and his grandmother decided in addition to rub his upper thorax, back, and arms with vinegar. As a result the child developed chemical burns on the treated areas. Fortunately he made a full recovery after the grandmother stopped the treatment.

Viscaceae

See also Herbal medicines

General Information

The family of Viscaceae contains four genera of mistletoe:

1. *Arceuthobium* (dwarf mistletoe)
2. *Korthalsella* (korthal mistletoe)
3. *Phoradendron* (American mistletoe)
4. *Viscum* (mistletoe).

Phoradendron flavescens

In 14 cases of accidental exposure to *Phoradendron flavescens* (*Phoradendron serotinum*, American mistletoe) there were no symptoms, but there was one death from intentional ingestion of an unknown amount of an elixir brewed from the berries (1). In 92 patients aged 4 months to 42 years (median 2 years), 14 were symptomatic, 11 related to mistletoe exposure. All the symptomatic cases had onset of symptoms within 6 hours. The symptoms included gastrointestinal upsets ($n = 6$), mild drowsiness ($n = 2$), eye irritation ($n = 1$), ataxia ($n = 1$), and seizures ($n = 1$). Treatment included gastrointestinal decontamination in 54 patients, ocular irrigation in one, and an intravenous benzodiazepine in one; decontamination did not affect the outcome. The amount ingested ranged from one berry or leaf to more than 20 berries or five leaves. Eight of ten patients who had taken at least five berries were symptom-free. Of 11 patients who took only leaves (range 1–5 leaves), three had gastrointestinal upsets. There were no cardiovascular effects in any case.

Viscum album

The stems and leaves of *Viscum album* (all heal, bird lime, devil's fuge, golden bough, mistletoe) contain alkaloids, viscotoxins, and lectins. While the toxicity of

© 2006 Elsevier B.V. All rights reserved.

the alkaloids remains to be assessed, the viscotoxins and lectins have been found to be very poisonous in animals when given parenterally. Mistletoe is a widely used alternative treatment for cancer, without convincing evidence of efficacy (2).

Adverse effects

Liver

Mistletoe is sometimes assumed to have hepatotoxic potential, based on a case report of hepatitis due to an herbal combination product claimed to have had mistletoe as one of its ingredients (3). However, the allegation that mistletoe was the probable cause of the illness has been rightly criticized, inter alia because the botanical material was not authenticated. The incriminated product also contained skullcap, which is hepatotoxic.

Immunologic

Parenteral administration of *V. album* can cause serious allergic reactions (4), and anaphylactic reactions have been described (5).

Tumorigenicity

- A 73-year-old man with a 5-year history of centrocytic non-Hodgkin's lymphoma presented with subcutaneous nodules in the abdominal wall at the sites where he had previously received subcutaneous injections of mistletoe (6). The nodules turned out to be infiltrations by the centrocytic lymphoma. The patient died 6 weeks later of bilateral pneumonia. The authors hypothesized that mistletoe has a growth-promoting action on lymphoma cells, mediated by high local concentrations of interleukin-6 liberated from the skin by mistletoe lectins.

Vitamin A: Carotenoids

See also Vitamins *and* Vitamin A: Retinoids

General Information

The carotenoids are a class of hydrocarbons (carotenes) and their oxygenated derivatives (xanthophylls) that consist of eight isoprenoid units joined in such a manner that the arrangement of the units is reversed at the center of the molecule, so that the two central methyl groups are in a 1,6-positional relationship and the remaining nonterminal methyl groups are in a 1,5-positional relationship. Their nomenclature has been standardized by IUPAC [http://www.chem.qmul.ac.uk/iupac/carot/], and their formal names are all based on the term "carotene."

Vitamin A is a family of fat-soluble vitamins, of which retinol is the most active form. Beta-carotene is a provitamin carotenoid that is converted to retinol more efficiently than other provitamin carotenoids. Other provitamin carotenoids include alpha-carotene and (trivial names) b-cryptoxanthin, lycopene, lutein, and zeaxanthin; they are widely available in foods.

Canthaxanthin is an orange carotenoid that occurs naturally in fruits, vegetables, mushrooms, shellfish, algae, and other forms of marine life. It has been approved by the US Food and Drug Administration as a food coloring agent and has been promoted as a skin-tanning agent in oral formulations that supply larger amounts than would be normally consumed as a food additive. Unlike other carotenoids, canthaxanthin is not a precursor of vitamin A, and therefore does not carry the risk of hypervitaminosis A. Retinopathy, due to deposition of canthaxanthin, causes gold-yellow deposits around the macula. Canthaxanthin-associated aplastic anemia has been reported (1).

Vitamin A activity can be expressed either as international units IU (1 IU equaling 0.3 micrograms of all-*trans*-retinol or 0.6 micrograms of all-*trans*-beta-carotene) or, more correctly, in retinol equivalents (RE) where 1 RE equals 1 microgram of all-*trans*-retinol, 6 micrograms of all-*trans*-beta-carotene or 12 micrograms of other provitamin A carotenoids. Table 1 gives the activities of different forms of vitamin A in RE and IU.

The Average Requirement for vitamin A is 500 and 400 micrograms RE/day for adult men and women respectively, the Population Reference Intake 700 and 600 micrograms RE/day, and the Lowest Threshold Intake 300 and 250 micrograms RE/day. While a slightly higher Population Reference Intake is advised in pregnancy and lactation (700 and 950 micrograms RE/day respectively), concern about the possible teratogenic effect of vitamin A has led many European health authorities to advise pregnant women against taking vitamin A

Table 1 Relative activities of different forms of vitamin A

Vitamin A	Activity in RE	Activity in IU
Retinol (1 mg)	1000	3330
Retinyl acetate (1 mg)	870	2900
Retinyl palmitate (1 mg)	550	1830

© 2006 Elsevier B.V. All rights reserved.

supplements (2). However, much higher doses (over 60 000 micrograms RE/day or 200 000 IU/day) are routinely distributed at half-yearly intervals to children in populations deemed to be suffering from vitamin A deficiency, mainly in developing countries. Toxicity is occasionally observed during these massive-dose prophylactic programs (3), and their safety has sometimes been called into question (4,5). One study has suggested that high-dose vitamin A supplements cause modest adverse effects in children recovering from pneumonia (6).

Chronic toxic reactions are generally more frequent than acute toxic reactions, which are uncommon at dosages below 30 000 micrograms RE/day (7). Supplements that contain 8000 micrograms RE (25 000 IU) or more of vitamin A per capsule are available as over-the-counter formulations in many countries (8). The "Nutrient and Energy Intakes for the European Community" (9) advises against single doses over 120 000 micrograms RE, and regular doses over 9000 micrograms RE/day in men and 7500 micrograms RE/day in women.

The recommended daily allowance of vitamin A for children up to 12 years of age is 1500–4500 IU. Toxic reactions occur when retinol-binding proteins in the plasma are saturated with vitamin A. Excess vitamin A is bound to plasma lipoproteins, and in this form it causes toxic effects when it comes into contact with cells (10). Acute vitamin A intoxication can occur after ingestion of 500 000 IU in adults and proportionately less in children. Chronic intoxication is more common, and in children it can occur even with doses as small as 1500 IU/kg/day. The problem is under-recognized in children, and cases often present as diagnostic dilemmas.

The reference range for serum concentrations of vitamin A is 300–1500 IU/l (0.5–2.8 μmol/l) (11).

General adverse effects

Acute intoxication has been observed after ingestion of vitamin A-rich liver from the polar bear, halibut, or shark, or after the use of fish oil supplements used to lower plasma lipids. In adults, toxic doses have been in the range of one or more million units of vitamin A, but in children as low as 10 000 micrograms RE, or even in a few children under 650 micrograms RE/day (12). Symptoms occur at 6–24 hours after ingestion and include acute drowsiness, irritability, vertigo, headache, delirium and convulsions, intolerance of food, and diarrhea (SEDA-8, 344).

Long-term administration of 3000 micrograms RE/day (10 000 IU/day) can cause chronic hypervitaminosis A, and at greatest risk in this regard are those with impaired liver function (12,13). The risk further increases with low body weight, protein malnutrition, renal disease, hyperlipoproteinemia, high alcohol consumption, and ascorbic acid deficiency (7). Because of the multisystem manifestations of hypervitaminosis A, the symptoms are often misjudged and the diagnosis delayed. The main symptoms of chronic intoxication include malaise, intracranial hypertension, chronic headache, vertigo, nystagmus, photophobia, hyperkeratosis, gastrointestinal complaints, changes in the skin and mucous membranes, tenderness and pain in the bone and joints, and fever.

Chronic intoxication with vitamin A has been reported to cause variously hypercalcemia, hyperglycaemia, increased alkaline phosphatase, hypoproteinemia, hypoprothrombinemia, increased sulfobromphthalein retention, raised serum transaminases, low serum ascorbic acid, reduced protein content of the cerebrospinal fluid, raised urinary hydroxyproline, and hypercalciuria (SED-8, 800) (14). It is not always clear, however, whether these deviations are a cause or an effect of hypervitaminosis A.

In some patients, adverse effects, especially disturbed liver function, become evident only when irreversible damage, for example liver cirrhosis or fibrosis with portal hypertension, is already present. It seems that the total cumulative intake of vitamin A, rather than the level of dosage, may be the critical factor for damage to the liver (15); this might hold true also for other adverse effects. A review found dosage ranges in reported cases of adverse events over the last 50 years to range from 650 to 20 000 micrograms RE/kg/day, and duration of administration to range from 41 to 3600 days, with an exponential relation between dose and duration with regard to symptoms of hypervitaminosis A (7). To avoid toxic reactions, the authors recommended, as a rule of thumb, that the daily dose (NB: in IU/kg) multiplied by the duration (in days) should not exceed one million.

Allergic reactions do not occur, but increased serum IgM concentrations were reported in patients with severe liver disease after prolonged administration of vitamin A (15).

Tumor-inducing effects of vitamin A have so far been suggested only with regard to prostatic cancer, especially in those 70 years of age and over (SEDA-13, 346).

Organs and Systems

Nervous system

Acute poisoning with vitamin A produces symptoms such as drowsiness, sluggishness, irritability, an irresistible desire to sleep, severe headache, and papilledema. In some cases papilledema is the only symptom (SEDA-11, 333) (16,17). In young children, raised intracranial pressure with bulging of the fontanelle, papilledema, and diplopia have been observed (SED-8, 799, 801) (SEDA-15, 411) (18).

In 50% of chronic vitamin A intoxications intracranial hypertension occurs, sometimes together with skin and hair changes, musculoskeletal pain, and fatigue (19). Benign intracranial hypertension (pseudotumor cerebri), vertigo, and papilledema have appeared after the intake of 3500–7000 micrograms RE/day of vitamin A for 2 years; in young children even a few months of treatment may precipitate these conditions (20) and symptoms can occur at low doses (even in a few children as low as 650 micrograms RE/kg/day) (12). Nystagmus, diplopia, photophobia, palsy of the ocular muscles, retinal hemorrhage, and protrusio bulbi (SED-8, 801) (21) have all been reported with vitamin A, and are an effect of raised intracranial pressure.

- A 15-year-old girl developed headache, vertigo, nausea, and epistaxis, diplopia, and reduced visual

© 2006 Elsevier B.V. All rights reserved.

acuity (22). She had taken Arovit corresponding to vitamin A 200 000 IU/day for 6 months for acne. Ophthalmoscopy showed bilateral papilledema and minor bilateral abducens paresis. She had hypercalcemia (3.24 mmol/l) and a reduced parathyroid hormone concentration, a mild anemia (10.5 g/dl), and thrombocytopenia (112×10^9/l). Lumbar puncture showed a pressure of 62 cm H_2O with otherwise normal liquor. Her serum vitamin A concentration was 1.5 micrograms/ml (reference range 0.3–0.7 micrograms/ml).

Pseudotumor cerebri due to hypervitaminosis A is a serious complication, which can cause permanent visual impairment. Patients who take retinoids require proper surveillance. Raised serum concentrations of retinoids can persist for weeks after withdrawal.

Hypervitaminosis A can be a frequently overlooked cause of chronic headache (23). The precise cause of this, and of increased intracranial pressure in hypervitaminosis A, is controversial and unclear (24).

Psychological, psychiatric

Daily doses of 1 000 000 μg RE of vitamin A can cause acute symptomatic psychosis, with striking disturbances in the electroencephalogram and pathological changes in the cerebrospinal fluid (25). After withdrawal of vitamin A and administration of low doses of neuroleptic drugs the psychotic symptoms disappeared within a week.

Neuropsychiatric changes were reported to be the earliest dose-limiting symptomatic toxicity in patients with cancer taking high doses of retinol (26).

Metabolism

People with severe hypertriglyceridemia associated with Type V hyperlipoproteinemia may be at increased risk of hypervitaminosis A, even with moderate degrees of vitamin A supplementation (27). Long-term vitamin A administration is associated with an increase in serum cholesterol and serum triglyceride concentrations (28) and consequently might be linked with atherosclerosis (SEDA-8, 345) (29,30).

Mineral balance

Vitamin A toxicity in an adult woman resulted in hypercalcemia with renal insufficiency (31).

- An 86-year-old woman developed anorexia, thirst, and nocturia. During the previous 7 months her weight had fallen by 11 kg. She was taking domperidone and 1–6 vitamin tablets daily, each of which contained retinol palmitate 600 IU and colecalciferol 200 IU. She had hypercalcemia (serum calcium 3.34 mmol/l) and renal insufficiency (serum creatinine 333 μmol/l). Other causes of hypercalcemia were excluded.

In chronic vitamin A ingestion, risk factors for vitamin A toxicity are age, body weight, and renal insufficiency. The hypercalcemia caused by chronic vitamin A ingestion is explained by upregulation of osteoclasts by retinol metabolites.

Fluid balance

Edema and ascites are sometimes seen in chronic intoxication (SEDA-8, 799) (32,33).

Hematologic

High doses of vitamin A reduce the stability of the lipoprotein boundary layer of the erythrocytes, which can lead to hemolysis and anemia (34). Neutropenia, leukocytosis, thrombocytopenia, aplastic anemia, and increased sedimentation rate have also been reported after high doses of vitamin A (35–38).

Vitamin A toxicity appears to occur only when the amount of vitamin A exceeds the binding capability of the retinol binding protein. Hypervitaminosis A can cause severe anemia and thrombocytopenia, resulting from retinol-dependent bone marrow cell growth inhibition (39).

- A 3-month-old boy who was given Arovit (an aqueous solution of vitamin A palmitate, Roche, Italy), corresponding to vitamin A 62 000 IU/day for 80 days, developed signs of retinol intoxication (severe normochromic normocytic anemia, hemoglobin 5.9 g/dl, leukocyte count 6.2×10^9/l with lymphocytes 74%, neutrophils 17%, eosinophils 3%, and monocytes 6%, platelet count 20×10^9/l). The blood film showed anisopoikilocytosis. He had increased concentrations of unbound retinol, with high concentrations of retinyl esters and a raised retinol:retinol binding protein ratio. Vitamin A was withdrawn and 15 days later his hemoglobin rose to 7.5 g/dl and the platelet count to 105×10^9/l. The reticulocyte count increased from 8 to 300×10^9/l. The bone marrow showed normal populations of erythroid and myeloid cells and megakaryocytes. The retinyl esters fell by about 80% after 3 months.

These are the first findings to suggest that infant hypervitaminosis A can cause severe anemia and thrombocytopenia, probably due to the direct effect of vitamin A on the growth of all bone marrow cells. Investigation of the effect of retinol on the growth of the pluripotent hemopoietic cell line K-562 and on bone marrow mesenchymal stem cells showed strong inhibition of cell proliferation at concentrations similar to those found in vivo. Subsequent biochemical analysis of the cell cycle suggested that the effect was mediated by upregulation of the cyclin-dependent kinase-inhibitors $p21^{Cip1}$ and $p27^{Kip1}$.

Mouth and teeth

Dryness and scaling of the lips, gingivitis, and bleeding from the gums are common symptoms of acute vitamin A intoxication (32,35).

Gastrointestinal

Nausea, vomiting, and anorexia are common symptoms of acute vitamin A intoxication (34).

Liver

Enlargement of the liver, spleen, and lymph nodes in adults taking vitamin A were first reported many years ago (34–36).

© 2006 Elsevier B.V. All rights reserved.

The hepatotoxic effects of vitamin A have been reported after consumption of doses of about 100 000 IU/day for periods ranging from weeks to months, as well as after daily supplementation with 25 000 IU for a couple of years, accompanied by an increase in plasma vitamin A concentration to 10 times normal in users of health foods. The smallest daily supplement of vitamin A reported to be associated with liver cirrhosis is 25 000 IU taken for 6 years (15).

Liver biopsies have been performed in some patients with chronic vitamin A intoxication. Perisinusoidal fibrosis and massive accumulation of lipid-storing cells were found. Impairment of blood flow by perisinusoidal fibrosis probably resulted in secondary alterations in hepatocytes, including cellular atrophy and formation of cytoplasmic bullae. Histological examination also showed central vein sclerosis and focal congestion associated with perisinusoidal storage. The vitamin A concentration in the liver was increased (40–42).

For the diagnosis of hypervitaminosis A, plasma concentrations and retinol-binding protein may be misleading. Cases have been reported of hepatic fibrosis, secondary to chronic ingestion of massive doses of vitamin A, where plasma concentrations of vitamin A and retinol-binding protein at the time of diagnosis were within the reference range (43).

Long-term observation of 41 patients with varying forms of liver disease, all caused by prolonged vitamin A consumption, has given further insight into the range of histological lesions and the prognosis of liver disease related to hypervitaminosis A (15). Clinical examination showed hepatomegaly in 18 of the patients, splenomegaly in 13, signs of chronic hepatic disease in 12, ascites in 9, and icterus in 8. Repeat liver biopsies in three patients 3–6 years after diagnosis showed progression from steatosis or fibrosis to fully developed micronodular cirrhosis in all cases, showing that the liver damage can be irreversible. Nine patients died during follow-up, six of terminal liver failure. However, plasma retinol concentrations were above the reference range in only about 40%.

Liver damage due to vitamin A is not always irreversible; one patient, after prolonged intake of excessive amounts of vitamin A for treatment of psoriasis (90 000 micrograms RE/day), had not only reversible chronic intoxication, but reversible portal hypertension and deranged liver function tests without any histological signs of cirrhosis (44). In a similar case, portal hypertension disappeared after 6 months on a low vitamin A diet. The fact that there was no reduction in Ito cells either in size or number suggests that lipid venous obstruction is unlikely to be the only mechanism responsible for portal hypertension in vitamin A-induced liver disease (45).

Even moderate doses of vitamin A, when taken over a prolonged period of time, can cause significant hepatocellular injury, as seen in three family members with symptoms and biochemical evidence of hepatitis, who had taken 7000–15 000 micrograms/day RE (20 000–45 000 IU/day) for 7–10 years (46). A similar case involved a 45-year-old woman who had taken an over-the-counter supplement over 6 years, and developed severe and fatal liver damage (47).

Clinical presentations, changes in liver function tests, and liver morphology have previously been examined in 41 consecutive patients with vitamin A hepatotoxicity (15). The cause of liver disease was suspected at initial interview in only 13 instances, and there was histological evidence of fat-storage hyperplasia with fluorescent vacuoles in the other cases. Cirrhosis was found in 17 cases, mild chronic hepatitis in 10, non-cirrhotic portal hypertension in 5, and "increased storage" alone in 9. During a mean follow-up period of 4.6 years, six patients died of causes related to the liver disease. Precise appraisal of drug consumption was obtained in 29 cases. Among them the total cumulative intake was the highest in patients with cirrhosis (423 MIU) and significantly lower in those with non-cirrhotic liver disease (89 MIU). The smallest continuous daily consumption leading to cirrhosis was 25 000 IU for 6 years, whereas higher doses (greater than or equal to 100 000 IU/day) taken for 2.5 years resulted in similar histological changes.

Liver fibrosis induced by beta-carotene therapy for pigmentary retinopathy has been reported (48).

- A 66-year-old woman with a pigmentary retinopathy that had been treated for 30 years with antocyanosides combined with beta-carotene (total dose 165 g) developed anicteric cholestasis. Liver biopsy showed pronounced portal fibrosis with normal bile ducts and no evidence of portal inflammation. The usual causes of chronic hepatic diseases were excluded. The serum concentration of vitamin A was 0.43 (reference range: 0.5–0.8) mg/ml. After withdrawal of beta-carotene and administration of ursodeoxycholic acid for 6 months the cholestasis resolved.

Another feature of vitamin A hepatotoxicity, namely respiratory symptoms caused by hepatic hydrothorax, associated with excessive vitamin A consumption has been reported (49).

- A 52-year-old woman, who had taken multivitamin supplements daily for 17 years and vitamin A whenever she had a cold, became progressively breathless, with 18 kg weight loss, increasing abdominal girth, increasing fatigue, leg weakness and pain, worsening chronic diarrhea, and intermittent nose bleeds. Her total vitamin A intake over 17 years had been at least 63 MIU (average 10 273 IU/day) and in the previous year she had taken at least 98 MIU (270 000 IU/day). When she noted pruritus, epistaxis, hair loss, and nail degeneration, she reduced her vitamin A intake to 66 000–150 000 IU/day. She was thin with alopecia, dry skin, and dystrophic nails, and was in mild respiratory distress with reduced breath sounds throughout the right lung and mild expiratory wheezes at the apices. There was no hepatomegaly or splenomegaly, but her liver was tender. Her serum vitamin A concentration was within the reference range. She had marked ascites, a pleural effusion, and partial collapse of the right lung. Liver biopsy showed changes consistent with vitamin A hepatotoxicity, namely prominent aggregates of hypertrophied perisinusoidal hepatic stellate cells, focal pericellular fibrosis, and mild perivenular fibrosis.

Urinary tract

In chronic intoxication, polyuria, increased frequency of micturition, urinary incontinence, enuresis, and acute

© 2006 Elsevier B.V. All rights reserved.

renal insufficiency due to tubular necrosis can occur (SED-11, 800).

Patients with renal dysfunction are known to have raised circulating vitamin A concentrations. In chronic dialysis patients, the concentration can rise steadily. The significantly increased osmotic fragility of erythrocytes observed in hemodialysed patients also seems to be related to high vitamin A concentrations. However, the similarity between uremic symptoms and those of vitamin A excess may explain why hypervitaminosis A in uremic patients is rarely reported as being associated with clinical toxicity (SEDA-12, 327).

Skin

In acute intoxication, peeling of the entire skin can occur as a delayed symptom (50). Among the early and most commonly reported symptoms of chronic vitamin A intoxication are erythema, pruritus, hyperkeratosis, and dryness, hemorrhages, and fissures of the lips. A yellow to yellow-orange discoloration of the skin, reduced tolerance to sunlight, changes in pigmentation, hair loss, and brittle nails have been observed (34,36,51–53).

Musculoskeletal

Excessive doses of vitamin A lead to accelerated resorption of trabecular and cortical bone because of increased osteoclastic activity. A raised alkaline phosphatase, increased urinary hydroxyproline concentrations, and hypercalciuria correlate with these findings (54). One study suggested that high dietary intake of retinol might be associated with osteoporosis (55).

Pain in the bones and joints is a common symptom in patients taking vitamin A. Bone tenderness often occurs without other bone symptoms, but possible complications include elevation of the periosteum, hyperostosis, and in children premature closure of the epiphyses of the long bones, causing growth arrest (54,56).

- There were skeletal deformities involving the lower limbs and the spine in a 15-month-old girl who had received a total dose of 3.5 million micrograms RE (10.5 million IU) of vitamin A during the previous few months (57).
- Skeletal signs were seen in a nursing infant who was given 35 drops of a vitamin formulation five times a day during the first month of life, corresponding to vitamin A 8000 micrograms RE/day, plus vitamin D 5000 IU/day, vitamin E 15 mg/day, and vitamin C 250 mg/day. Other symptoms included hydrocephalus, cutaneous effects, and hepatic signs (58).
- A fatal case of hypervitaminosis A involved a premature neonate who died after having ingested 30 000 micrograms RE/day (90 000 IU/day), that is 60 times the recommended intake of vitamin A, for 11 days. On autopsy the skeleton showed marked alterations of endochondral bone formation. There was also evidence of accelerated resorption of bone, hypercalcemia, and metastatic calcification of the skin, soft tissues, and organs (59).

These three cases illustrate a common misunderstanding with regard to vitamins found among medical and nonmedical people alike: vitamins are believed to be innocuous substances, and since a little of them is good for you, much must be even better. Table 2 puts this misconception into perspective (60).

Table 2 Toxic doses of vitamin A

Exposure	Population	Country or region	Retinol equivalents (micrograms)
Toxic concentrations	Adults	Nordic	7500
	Adults	Australia	20 000
	Pregnant woman	Australia	10 000
	Pregnant woman	USA	5000–10 000
Chronic intoxication[a]	Children		758/kg
	Adults		15 000–30 000
Acute intoxication[b]	Children		22 500–30 000
	Adults		300 000–600 000

[a] Defined as repeated and prolonged intake of high doses
[b] Defined as intake of single (or multiple) very high doses

Reproductive system

The effects of all-*trans*-retinoic acid on the male reproductive system include gynecomastia, discomfort, potency disorders, reduced fertility, and ejaculatory failure (61). The incidence is reported to be very high, but exact figures do not seem to be available.

Immunologic

Large doses of vitamin A in children in poor socioeconomic conditions have often for logistic reasons been combined with other health-care interventions, such as immunization. A randomized, case-control study of 336 infants receiving either 33 000 micrograms RE/day (100 000 IU) of vitamin A or placebo simultaneously with measles vaccine showed a lower seroconversion to measles in the vitamin A group (62).

Long-Term Effects

Tumorigenicity

Negative outcomes in several supplementation trials of beta-carotene, especially the results of the Finnish Alpha-Tocopherol Beta-Carotene (ATBC) Cancer Prevention Study (63) (SEDA-20, 363), have again revived discussion about the carcinogenic potential of beta-carotene. The ATBC trial showed that there was a statistically significant increase in the incidence of lung cancer in heavy smokers who took beta-carotene.

Problems concerning the interactions of cigarette smoking, cancer, and carotenoids have been reviewed (64).

Over several decades, evidence has accumulated that a diet rich in fruit and vegetables is associated with a lower risk of cardiovascular disease and various forms of cancer, principally cancer of the lung and stomach, but also esophageal, oral, breast, and prostate cancer (65,66). It is possible that this effect is in part due to their beta-carotene content.

© 2006 Elsevier B.V. All rights reserved.

Beta-carotene and other micronutrients have been claimed to counteract oxidative processes that participate in various stages of carcinogenesis, and increased consumption of fruit and vegetables rich in carotenoids lowered urinary indices of oxidized lipids and DNA in healthy subjects (67). Although beta-carotene and other carotenoids are excellent in vitro quenchers of singulett oxygen and beta-carotene, and may also protect lipids from radical-initiated peroxidation under certain conditions, evidence for antioxidant properties of beta-carotene in vivo is much less compelling (68). Assessment of the antioxidant benefit of beta-carotene is especially complicated by the fact that carcinogenesis is a very complex multistage process, in which oxidative pathways play variable and incompletely understood roles. While a few early supplementation trials suggested a beneficial role of beta-carotene (66), many other studies did not show such an effect. The proposed beneficial properties of carotenoids appear to be consistent with findings that cigarette smokers generally have subnormal serum concentrations of various carotenoids and other micronutrients, such as vitamin C, supposed to be caused by the increased oxidative stress associated with smoking and its attendant activation of the inflammatory and immune systems. On the other hand, the low concentrations in smokers could also result from lower intake of these micronutrients. Lower concentrations of carotenoids and other micronutrients are also observed in passive smokers (69,70).

The constituents of cigarette smoke can degrade beta-carotene (71,72), but the conclusion that smoking causes increased carotenoid metabolism demands the demonstration of raised carotenoid oxidation products. Moreover, the consistent observation of subnormal carotenoid concentrations but unchanged alpha-tocopherol concentrations (70) suggests that factors other than oxidative stress contribute to the relative carotenoid deficiency.

The assumption that remedying the carotenoid deficit would minimize the risks of cancer and heart disease associated with passive smoking has not been supported by several large randomized supplemention trials. In two major trials there was an increased incidence of cancer with beta-carotene supplementation in both smokers and asbestos workers. Of course, both high-risk groups might already have been in the early stages of cancer development at the start of the studies (63,64).

These surprising findings have raised an interesting apparent paradox: how can supplementation with beta-carotene, a presumed antioxidant and possible chemoprotective agent, enhance cancer formation, even though this is thought to involve oxidative processes? In some experimental systems carotenoids have prooxidant properties at high concentrations, but these are not reached in vivo (69,70). Another mechanism is an increase or alteration in carotenoid metabolism in high-risk groups, resulting in the formation of metabolites or oxidation products that could be procarcinogenic (for instance by interfering with retinoid signaling pathways, by promoting DNA damage, or by inducing cytochrome P450 enzymes that might promote carcinogen activation) (66,73). Such induction of cytochrome P450 enzymes might also enhance the catabolism of retinoic acid, which plays an important role in lung epithelial proliferation and differentiation. Down-regulation of the retinoic acid receptor, RARb, by beta-carotene supplementation has been shown in recent studies in ferrets (73). RARb may act as a tumor suppressor gene. Moreover, lung expression of the proto-oncogenes c-jun and c-fos was increased in animals exposed to cigarette smoke and also receiving beta-carotene supplements (73).

In general, the negative outcomes of several supplementation trials and the lack of proof that carotenoids form the primary beneficial component of fruit and vegetables should serve as a warning against unregulated supplementation with these individual micronutrients, especially in view of the potential carcinogenic effect of carotenoids.

The carcinogenic effect of beta-carotene has recently been found to be reduced by vitamin E (74), suggesting that, rather than individual micronutrient supplementation, combinations of various such substances might be more advantageous.

Second-Generation Effects

Pregnancy

The benefits and safety of maternal and infant vitamin A supplementation administered with each of the three diphtheria-tetanus-pertussis (DPT) and poliomyelitis immunizations and with a fourth dose of measles immunization have been assessed in a randomized, double-blind, placebo-controlled study in 9424 mother–infant pairs from Ghana, India, and Peru (75). Vitamin A 200 000 IU was given to 4716 mothers and 25 000 IU to their infants with each of the first three doses of DPT/poliomyelitis immunization at 6, 10, and 14 weeks. Placebo was given to 4708 mothers and their infants. At 9 months, with measles immunization infants in the vitamin A group were given a further dose of 25 000 IU and those in the placebo group received 100 000 IU. At 6 months there was a small reduction in vitamin A deficiency in the vitamin A group compared with controls; this effect was no longer apparent at 9 months. There were no significant differences in mortality throughout the study. Adverse effects were a bulging fontanelle (in under 1% of the infants) and vomiting. Among the infants without a bulging fontanelle before the start of the study, more of the vitamin A recipients than placebo recipients had a bulging fontanelle within 48 hours of the dose at 6, 10, and 14 weeks. After the fourth dose at 9 months, a bulging fontanelle was more common among the controls than among the infants given vitamin A. However, after each dose under 1% of the infants in either group had a bulging fontanelle. Of the 62 infants in the vitamin A group who had a bulging fontanelle reported at 24 hours after a dose, the bulging had resolved within 48 hours in 445 (73%). Among the controls, in whom almost all the instances of bulging were reported with the 100 000 IU dose, 25 of 42 had resolution of bulging within 48 hours. Under 3% of mothers in each group reported a bulging fontanelle after each dose. Vomiting occurred only within 48 hours after administration of the fourth dose in 167

© 2006 Elsevier B.V. All rights reserved.

(4.9%) infants in the vitamin A group versus 236 (6.5%) in the control group. There were no significant differences in convulsions or raised temperature at any dose.

Teratogenicity

Although the retinoids are markedly teratogenic, vitamin A is less so. In animals vitamin A excess can be teratogenic, as can vitamin A deficiency. In humans several cases of teratogenicity associated with vitamin A have been observed (76–78), and high incidences of spontaneous abortions and birth defects have been observed in women who have taken therapeutic doses of isotretinoin (13-*cis*-retinoic acid) during the first trimester of pregnancy. Recommendations about dosages of vitamin A in pregnant women have been issued by several institutions (2), including the Teratology Society (8) and the American College of Obstetricians and Gynecologists (79). The Health Protection Branch of Health and Welfare Canada accepted the recommendation that the use of retinoic acid for acne be regarded as contraindicated in women during pregnancy and in those of childbearing age (80).

A study in Hungary of 1203 births to women who had taken a supplement containing 2000 micrograms RE (6000 IU)/day, compared with 1510 who had taken placebo, did not show any evidence of teratogenic effect (81). The lower limit of supplementation recommended varied between 1600 and 3300 micrograms RE (5000 and 10 000 IU) of vitamin A per day (SEDA-14, 330).

However, vitamin A may be harmful at even lower doses than had previously been appreciated, the prevalence of cranial neural crest tissue defects being 3.5 times higher when dietary and supplemental consumption of preformed vitamin A, taken together, exceeded 5000 micrograms RE (15 000 IU) than when it was 1600 (5000 IU) or less (82). For supplements considered alone, the prevalence of such defects was 4.8 times higher in the group consuming over 3300 micrograms RE (10 000 IU) than in the group consuming under 1600 micrograms RE (5000 IU). The risk seemed to start rising when consumption passed a threshold of about 3300 micrograms (10 000 IU).

The minimum human teratogenic daily dose of vitamin A is estimated to be 25 000–50 000 IU, and one report has suggested that it may be as little as 10 000 IU (82). The National Research Council's Committee on Dietary Allowance advocates a recommended daily allowance (RDA) of 800 retinol equivalents/day for non-pregnant women of childbearing age and pregnant women. The RDA is equivalent to 2700 IU of vitamin A obtained from a supplement as retinol or 4800 micrograms of beta-carotene. The committee of the American College of Obstetricians and Gynecologists recommends supplementation with 5000 IU/day as the maximum intake before and during pregnancy. This is well below the probable minimum human teratogenic dose. Prenatal multivitamin formulations in common use contain 5000 IU or less vitamin A, but vitamin tablets containing 25 000 IU or more of vitamin A are available as over-the-counter formulations. Pregnant women or those planning to become pregnant should be cautioned about the potential teratogenicity of high doses of vitamin A supplements. Warnings on labels were recommended as early as 1987 (8).

A summary of some cases of birth defects associated with high maternal intake of vitamin A is given in Table 3 (12).

To get further information about the teratogenicity of high doses of vitamin A, the European Network of the Teratology Information Services (ENTIS) prospectively evaluated data from 423 pregnancies exposed during the first 9 weeks of gestation to 10 000 IU/day or more (83). The presence of major structural malformations, excluding chromosomal and genetic diseases, was evaluated in 311 infants exposed to a median daily dose of vitamin A of 50 000 (range 10 000–300 000) IU/day. Three infants had a major malformation: pulmonary stenosis, stenotic anus with fistula, and bilateral inguinal hernia. There were no congenital malformations among 120 infants exposed to more than 50 000 IU/day. When the birth prevalence rate of major malformations in the study group was compared with two internal control groups of infants exposed to "high" doses of vitamin A later in pregnancy, and non-teratogenic doses, the respective rate ratios were 0.28 (CI = 0.06, 1.23) and 0.50

Table 3 Some cases of birth defects associated with high material intake of vitamin A

Maternal intake	Duration	Symptoms	Other conditions
Reports of individual cases			
~500 000 IU	Single dose, 2nd month	Preauricular appendices, epibulbar dermatoid (eye malfunctions similar to Goldenhar's syndrome)	Dose caused acute toxicity in the pregnant woman
150 000 IU	Periconceptual 2 to +3 months	Facial dysmorphism, pterygium colli, distended abdomen, absence of external genitalia and of anal and urethral openings, polycystic kidneys, dysmorphism of lumbar spine	Fetus aborted at 20 week because of spinal abnormality and polycystic kidney
25 000 IU	0–13 weeks	Unilateral ureteral duplication with one ureter ending in the vagina, hydronephrosis, hydroureters	
50 000 IU	14th week to term		
Reports of multiple cases			
18 000–100 000 IU	Before and throughout pregnancy	Abnormalities of the head, face, ears, eyes, mouth, lips, jaws, heart, and urinary system; other defects	Cases reported by physicians to the FDA; cases reported to the State Birth Defects Registry

© 2006 Elsevier B.V. All rights reserved.

(CI = 0.14, 1.76). There was no evidence for an increased risk of major malformations, associated with high vitamin A doses during organogenesis.

The incidence of the acute adverse effects of an oral dose of vitamin A 400 000 IU given to a newly delivered mother and a oral dose of 50 000 IU given at the same time to her baby has been assessed in a randomized, double-blind, placebo-controlled study, with follow-up 1 or 2 days after dosing in 839 mothers and babies, of whom 788 were assessed (84). The incidence of reported adverse effects was low. Only two mothers in each group spontaneously reported bulging fontanelles in their babies. One of these babies (in the placebo group) was reported to have been vomiting. The rates of bulging fontanelles were 1.5% and 1.0% in the treatment and control groups respectively (OR 1.48; CI = 0.35, 7.19) Only one baby (in the vitamin A group) of the 11 who had bulging fontanelles was symptomatic (with vomiting, possibly due to raised intracranial pressure). Maternal symptoms did not differ between the groups. Other reported symptoms in the vitamin A group ($n = 398$) compared with the controls ($n = 390$) were vomiting (6 versus 4.8%) and irritability (7.5 versus 5.4%). From these results it can be concluded that these large doses of vitamin A are well tolerated by newly delivered mothers and babies.

Susceptibility Factors

Age

Young children seem to be particularly at risk of vitamin A toxicity. Symptoms of chronic intoxication are seen with intakes of 800–16 000 micrograms/kg RE (2500–50 000 IU/kg) (21). Children with restricted protein intake may have reduced tolerance to vitamin A.

The National Prophylaxis Program for Prevention of Blindness due to Vitamin A Deficiency has been implemented in India since the 1970s and covers all children aged 9 months to 3 years (85). Children aged 9–12 months received a single dose of 100 000 IU and those aged 1–3 years received 200 000 IU every 6 months. According to the Assam State Government, 700 children of 3.2 million who were given vitamin A became ill and more than 15 children died. Whether all these cases were a direct consequence of high-dose vitamin A is being investigated. One of the possible reasons is overdose of vitamin A, because of use of a new 5 ml measuring cup, which was used instead of the traditional 2 ml spoon.

Hepatic disease

At special risk of vitamin A toxicity are those whose liver function is compromised by drugs, viral hepatitis, or protein-energy malnutrition (12). Elderly people may also be at increased risk for similar reasons but also from different causes. In addition to protein deficiency, alcohol intake and co-existing liver and renal disease may be present (86).

In alcoholics vitamin A supplementation, which might be a useful therapeutic measure, is complicated by the hepatotoxicity of large doses of the vitamin and the fact that chronic alcohol consumption results in an enhanced susceptibility to this effect (87).

Drug Administration

Drug formulations

The effects of variations in pharmaceutical formulation on plasma concentrations of vitamin A have only been partly documented. Vitamin A in aqueous dispersion results in higher plasma concentrations than in oily formulations (88).

Drug administration route

Vitamin A added to infusions can be absorbed by the plastic containers often used (89).

Drug overdose

Two children with vitamin A toxicity have been reported (90).

- A 2-year-old girl developed anorexia, lethargy, and bilateral leg pain and refused to walk. She had been unwell for the previous 3 weeks. She was lethargic and irritable and had tenderness over both tibial surfaces and an erythematous rash over her back and both elbows. She had a raised calcium concentration (3.05 mmol/l), a serum phosphate concentration in the reference range, and a raised serum vitamin A concentration (3.9 μmol/l; reference range 1.3–2.9 μmol/l). A skull X-ray showed widening of the coronal suture, and a leg X-ray showed abnormal metaphyseal densities at the knees and ankles. Radionuclide bone scans showed increased uptake in both anterior tibiae, anteriorly in multiple ribs close to the costochondral junctions, in the distal right ulnar shaft, and in the distal left femoral shaft. Her parents had given her a vitamin supplement containing 9000 IU/ml vitamin A 3 ml/day for several months. On withdrawal of the vitamin supplement her symptoms resolved over 2 weeks.
- A 4-year old boy presented with a 4-day history of bilateral leg pain and refusal to walk. He had tenderness over both tibial surfaces, generalized skin exfoliation, and reduced visual acuity in both eyes. Symmetrical bone scan changes (increased uptake throughout each ulna and tibia and foci in the 10th and 11th ribs and 11th thoracic vertebra), together with benign intracranial pressure, suggested vitamin A toxicity. His dermatologist had prescribed oral etretinate, but his parents had withdrawn it after consulting a naturopath. He was then given numerous medications, including vitamin A, D, and E supplements, calcium, and magnesium. After withdrawal of all vitamin supplements his condition steadily improved, except for visual acuity, which was unchanged.

These two cases clearly underline the importance of a detailed drug history, including the use of complementary medicines.

Drug–Drug Interactions

Ethanol

Ethanol and retinol are converted to their corresponding aldehydes by isozymes of alcohol dehydrogenase and

© 2006 Elsevier B.V. All rights reserved.

other dehydrogenases. The pathways of retinol metabolism have been described in hepatic microsomes, partly involving cytochrome P450 isozymes, which can also metabolize various drugs. Multiple interactions of retinol, ethanol, and other drugs can therefore occur (91).

It is not therefore surprising that prolonged use of alcohol, drugs, or both not only results in reduced dietary intake of retinoids and carotenoids, but also accelerates the breakdown of retinol, through cross-induction of degradative enzymes. There is also competition between ethanol and retinoic acid precursors. Depletion of retinol and retinoic acid precursors is associated with hepatic and extrahepatic pathology, including carcinogenesis and fetal defects. Unfortunately, correction of vitamin A deficiency by supplementation is complicated by the intrinsic hepatotoxicity of retinol, which is potentiated by concomitant alcohol consumption. Furthermore, the precursor of vitamin A, beta-carotene, interacts with ethanol, interfering with the conversion of beta-carotin to retinol, while the combination of beta-carotene with ethanol results in hepatotoxicity.

In smokers who also consume alcohol, beta-carotene supplementation promotes pulmonary cancer and possibly cardiovascular complications.

It was already known in 1987 that foods that provide large amounts of retinol increase the risk of cancer of the esophagus (92,93), and in an epidemiological study the increased risk of cancer associated with the use of cigarettes and alcohol was enhanced by the ingestion of foods containing retinol (94).

The effect of alcohol abuse, one of the most common aggravating factors in vitamin A toxicity, has been elucidated. Vitamin A toxicity was potentiated in patients who took 10 000 IU/day for sexual dysfunction, and this effect was attributed to excess alcohol consumption (95). In animals, potentiation of vitamin A toxicity by ethanol resulted in striking hepatic inflammation and necrosis accompanied by a rise in serum glutamate dehydrogenase and aspartate transaminase (96).

Alcohol may also act indirectly by causing liver disease, which in turn can affect the capacity of the liver to export vitamin A, thereby enhancing its local toxicity. In alcoholics the carrying capacity of retinol binding protein was increased, even in those with low serum retinol concentrations (97). In such cases, caution in the amount of vitamin A used for therapy is recommended. Similarly, diets that are severely deficient in protein can affect the capacity of the liver to export vitamin A and enhance its hepatotoxicity.

In contrast to retinoids, carotenoids were considered non-toxic, even when taken chronically in large amounts, until recently, when it was found that ethanol interacts with carotenoids, interfering with their conversion to retinol. In baboons, the consumption of ethanol together with beta-carotene resulted in more striking hepatic injury than consumption of either compound alone (98). This interaction occurred at a total dose of 7.2–10.8 mg of beta-carotene per Joule of diet. This dose is common in people who take supplements and is the same order of magnitude used in the Beta-Carotene and Retinol Efficacy Trial (CARET) (30 mg/day) (99) and in another study (20 mg/day for 12 weeks) (100). The amount of alcohol given to the baboons was equivalent to that taken by an average alcoholic. The well-known toxicity of ethanol was potentiated by large amounts of beta-carotene, and the concomitant administration of both beta-carotene and alcohol resulted in striking liver lesions, characterized by increased activity of plasma liver enzymes, an inflammatory response, and striking autophagic vacuoles and alterations in the endoplasmic reticulum and mitochondria (101).

Besides its hepatotoxic effects, beta-carotene supplementation can also cause cardiovascular complications in smokers and potentiate carcinogenicity. The Alpha-Tocopherol, Beta-Carotene and Cancer Prevention Study (ATBC) (72) and CARET (99) showed that supplementation of beta-carotene in smokers increased the incidence of death from coronary artery disease. Recent results suggest that beta-carotene participates as a pro-oxidant in the oxidative degradation of LDL, and that raised LDL concentrations may cancel the protective effect of alpha-tocopherol (102).

The two trials also showed that beta-carotene supplementation increased the incidence of pulmonary cancer in smokers. Because heavy smokers are commonly heavy drinkers it was supposed that alcohol might have contributed to the increased incidence of lung cancer. Subsequent analysis showed that there was indeed a relation between the incidence of pulmonary cancer and the amount of alcohol consumed.

As detrimental effects result from deficiency as well as an excess of retinoids and carotenoids, and since both have similar adverse effects in terms of fibrosis, carcinogenesis, and possibly embryotoxicity, therapeutic measures must pay attention to the narrow therapeutic window, especially in drinkers, in whom alcohol narrows the therapeutic window even further by promoting the depletion of retinoids and by potentiating their toxicity (91).

Liquid paraffin

Liquid paraffin used as a laxative can reduce the absorption of vitamin A and other fat-soluble vitamins (D, E, and K) (103).

Oral contraceptives

Earlier studies suggested that oral contraceptives could lead to an increase in plasma concentrations of vitamin A (104), the inference being that increased vitamin A concentrations might have a negative effect on conception, and that this might provide an explanation for the reduced fertility sometimes seen during the period immediately following withdrawal of contraceptive steroids. More recent work has not supported this theory.

Vitamin A: Retinoids

See also Vitamins *and* Vitamin A: Carotenoids

General Information

Vitamin A (retinol) is a key regulator of epithelial cell proliferation and differentiation. Aberrations in these processes are a feature of many skin diseases, and dermatologists have therefore long taken an interest in vitamin A as a therapeutic agent. However, marginal efficacy and unacceptable adverse effects (Table 1) have minimized the usefulness of vitamin A itself. Therefore, derivatives of vitamin A (retinoids) have been developed.

Tretinoin

Tretinoin (*all-trans*-retinoic acid), a natural metabolite of vitamin A, was the first vitamin A analogue to be used orally, with some success, but its general therapeutic ratio did not differ markedly from that of vitamin A itself.

Tretinoin cream is used extensively for the treatment of acne and photodamaged skin, and local irritant dermatitis is common. With normal use, absorption is minimal and systemic adverse effects are therefore not expected.

Topical tretinoin has also been used as an ophthalmic ointment 0.01% in the treatment of squamous metaplasia associated with dry eyes. In 161 patients with either keratoconjunctivitis sicca or conjunctival cicatricial diseases (Stevens–Johnson syndrome, inactive pemphigoid, radiation-induced dry eye, drug-induced pseudopemphigoid, and toxic epidermal necrolysis) there were no beneficial effects in the former, but significant reversal of conjunctival keratinization in the temporal bulbar site in the latter (1). Adverse effects were limited to blepharoconjunctivitis and resolved on withdrawal.

Tretinoin has been evaluated in 26 patients with histologically confirmed adenocarcinoma of the prostate and manifestations of progressive metastatic disease (2). They received a single oral dose of tretinoin 45 mg/m^2/day for 7 days followed by no treatment for 7 days before starting to take tretinoin again. Toxicity was mostly mild. There was cheilosis in eleven patients and vomiting in one. In eight patients there were transient rises in serum

Table 1 Clinical effects of chronic hypervitaminosis A, in order of decreasing frequency (3,4)

Scaling of skin, erythema, pruritus, altered hair growth
Dry mucous membranes, cheilitis, angular stomatitis, gingivitis, glossitis
Pain and tenderness of the bones, restricted movement
Occipital headache
Hyperirritability, sleep disturbances
Papillary edema, diplopia
Anorexia, weight loss
Hepatomegaly, sometimes with splenomegaly
Peripheral edema
Fatigue, lassitude, occasionally somnolence
Hemorrhages, epistaxis, increased menstrual bleeding

triglyceride concentrations up to three times normal, returning to normal within 3–6 weeks, despite continuation of tretinoin. One patient had a severe headache with vomiting on day 1 and required a 30% dosage reduction. No patient withdrew because of toxicity.

Fatal adverse effects have been reported in patients given tretinoin for acute promyelocytic leukemia (5). Of 82 patients with acute promyelocytic leukemia, 35 developed leukocytosis and 22 had fatal adverse effects (15 with the retinoic acid syndrome and 7 with intracranial bleeding). Leukocytosis was a risk factor for fatal adverse effects. The authors suggested that the combination of tretinoin with low-dose harringtonine can reduce the incidence of leukocytosis-related intracranial bleeding and glucocorticoids can reduce mortality from the retinoic acid syndrome.

In another study of 413 patients with acute promyelocytic leukemia treated with tretinoin plus daunorubicin, the retinoic acid syndrome occurred in 64 cases, of which 5 were fatal (6).

Tretinoin 70, 110, 150, 190, or 230 mg/m^2/day has been given to 26 patients with advanced potentially hormone-responsive breast cancer taking tamoxifen 20 mg/day (7). At all doses headaches, nausea, skin changes, and bone pain occurred. The headaches were most severe during the first week of treatment, peaking at the end of the first week. They were sometimes associated with nausea and occasionally with vomiting, although there was no other evidence of raised cerebrospinal fluid pressure. Headaches and nausea tended to subside during the weeks when tretinoin was not given and recurred during the weeks of tretinoin reintroduction, although their severity tended to wane with subsequent cycles of treatment. Similarly, skin reactions, such as erythema and desquamation, were dose-related and were most severe during the initial cycles of treatment. Bone pain occurred intermittently. There was life-threatening hypercalcemia in one patient, but it was felt to be due to disease progression. The dose of 230 mg/m^2/day produced unacceptable headache and skin toxicity, but doses of up to 190 mg/m^2/day were tolerable.

A dry scaling skin rash and cheilitis were the most common adverse effects in 14 patients with prostate cancer treated with tretinoin and 20 patients treated with a combination of *cis*-retinoic acid and interferon α-2a (8). There was anorexia and significant weight loss in under 10% of the patients, but one patient discontinued treatment because of persistent fatigue and anorexia. Hematological toxic effects included leukopenia, neutropenia, anemia, and thrombocytopenia. Two patients with mild urinary hesitancy had acute urinary outlet obstruction within 1 week of starting *cis*-retinoic acid plus interferon. There were mild rises in hepatic transaminases and serum triglycerides in over half of the patients. Most triglyceride concentrations were below 2.3 (reference range 0.6–1.9) mmol/l, but one patient had an extreme rise of triglycerides to 3280 mg/dl. Sensory and mood changes were mild and occurred mostly in those given *cis*-retinoic acid plus interferon. Headaches were the most common neurological abnormality with tretinoin. Pulmonary adverse effects were dyspnea and a non-fatal pulmonary embolism in one patient treated with tretinoin. Other adverse effects included constipation, fever, nausea, vomiting, diarrhea, fatigue, and stomatitis.

In 21 patients with squamous cell carcinomas of the head and neck randomized to tretinoin 45, 50, or 150 mg/m^2 either once daily or as divided doses every 8 hours for 1 year, severe adverse effects included headache in five patients, hypertriglyceridemia in six, mucositis in two, and hyperbilirubinemia, raised alkaline phosphatase, colitis, raised lipase, xerostomia, eczema, and arthritis in one patient each (9). The dose had to be reduced in seven of eight patients with severe toxicity at 90 mg/m^2/day. Three of nine patients taking 45 mg/m^2/day required dose reductions. The plasma AUC of tretinoin did not correlate with the severity or frequency of adverse effects. From these results it can be concluded that 15 mg/m^2/day every 8 hours is a tolerable dose for 1 year in patients with squamous cell carcinomas of the head and neck.

The adverse effects of tretinoin 50 mg/m^2/day for 3 months have been studied in 20 patients with emphysema in a randomized, double-blind, placebo-controlled trial (10). The treatment was well tolerated and associated with only mild adverse effects, including skin changes, such as dry skin and cracking lips in 15 (1 placebo), transient headache in 13 (1), hyperlipidemia in 11 (5), pruritus in 6 (2), muscle/bone pain in 6 (0), generalized fatigue in 6 (2), raised transaminases in 5 (1), a sensation of clogged ears in 3 (2), nausea in 2 (0), hair loss in 2 (0), and blurred vision in 1 (1).

Etretinate and isotretinoin

Since the beginning of the 1980s two synthetic retinoids, etretinate (the ethyl ester of trimethoxymethylphenyl retinoic acid; Tigason; Tegison) and isotretinoin (13-*cis*-retinoic acid; Acutane; Roaccutane), have been successfully administered for a variety of skin disorders, all of which involve disordered epidermal or epithelial cell growth and differentiation as prominent pathogenic features, for example psoriasis, ichthyosis, Darier's disease, lichen planus, and pityriasis rubra pilaris. Isotretinoin has been of great value in the treatment of cystic acne and acne conglobata, with no serious long-term adverse effects (11,12). It has also been used for milder forms of acne (13,14).

Acitretin

In 1990, etretinate (Tigason) was replaced by acitretin (Neo-Tigason), an aromatic retinoid, a carboxylic acid metabolite of etretinate (15). It is effective in pustular psoriasis and psoriatic palmoplantar keratoderma and in combination with PUVA or topical therapy (calcipotriol or glucocorticoids) in the treatment of other forms of psoriasis. It has also been used to treat disorders of keratinization (ichthyosis, palmoplantar keratoderma, Darier's disease) and severe cutaneous forms of lichen planus. It prevents new skin carcinomas in patients with xeroderma pigmentosum and those who are immunosuppressed. The main advantage of acitretin is its short half-life of 50 hours, compared with over 80 days for etretinate (16).

© 2006 Elsevier B.V. All rights reserved.

Adapalene

Topical retinoids and similar drugs, including tretinoin, adapalene, and tazaroten, are the most commonly used topical drugs for acne (17). Adapalene is a synthetic polyaromatic retinoid and is formulated in a water-based gel (1.0%, Galderma Labs Inc, San Antonio, TX). In a double-blind, multicenter, parallel-group, randomized study the efficacy and adverse effects of 0.1% adapalene gel and 0.1% tretinoin gel in a microsphere formulation were compared over 12 weeks (18). The two drugs had similar effects on the resolution of acne lesions, but tretinoin was significantly more effective in reducing the number of comedones. There were no statistically significant differences between tretinoin and adapalene in the incidences of erythema, burning/stinging, or itching. Most patients had at least one sign of cutaneous irritation over the course of the study (tretinoin 95%, adapalene 91%). The most common adverse effect was erythema (tretinoin 83%, adapalene 66%), followed by peeling (80% and 66%), dryness (67% and 65%), burning/stinging (45% and 36%), and itching (37% and 35%). There were significant differences in the incidence of cutaneous effects in favor of adapalene for dryness at week 8 (tretinoin 34%, adapalene 18%) and week 10 (29% and 12%), and for peeling at week 3 (56% and 39%), week 6 (46% and 26%), week 8 (45% and 17%), and week 10 (35% and 17%). There were no serious adverse events in either group.

In another comparison of the efficacy and adverse effects of adapalene gel 1% or 0.025% tretinoin gel in 150 Chinese patients, similar effects were observed (19). In both groups skin irritation was mild, but it was more pronounced with tretinoin. Burning was the most common unwanted effect in those who used tretinoin compared with adapalene (34 versus 11%). There was dryness of the skin in 34% of those who used tretinoin and in 22% of those who used adapalene. The respective frequencies of scaling were 26 and 15%, and of erythema 26 and 2.7%. Pruritus was the only adverse effect experienced exclusively by those who used adapalene, and it occurred in under 4%. Overall, 46% of those who used tretinoin had some form of irritation, compared with 32% of those who used adapalene.

General adverse effects

Although the various retinoids have similar toxicity profiles, they differ in the extent to which they affect various body systems. Cutaneous and mucous membrane symptoms (up to 70%) are by far the most prominent adverse effects; patients who use isotretinoin have a 50% incidence of conjunctivitis and irritation of the eyes. Musculoskeletal symptoms occur in up to 15% of users. Hypersensitivity reactions are rare and consist of occasional drug rashes. The occurrence of sarcomas in patients treated with isotretinoin may well be a chance finding (SEDA-21, 164); retinoids may prevent or even cure certain malignancies (20). All the retinoids are strongly teratogenic (21–23).

The incidence and time-course of adverse events during a 4-month course of oral isotretinoin (1 mg/kg) for severe acne have been studied prospectively in 189 patients (24). Most of the adverse events were most often reported during the first 3 months of treatment. However, only a few patients were seen every month as scheduled and only 50 of 189 filled in the questionnaire at 4 months.

Table 2 Features of tretinoin toxicity in 22 patients

Organ system	N (%)	Symptoms	N (%)
Tretinoin-related toxicity	12 (55)	Retinoic acid syndrome	3 (14)
Cardiovascular	5 (23)	Pericardial effusion	1 (5)
		Weight gain	5 (23)
		Arterial hypotension	2 (9)
Respiratory	3 (14)	Adult respiratory distress syndrome	2 (9)
		Pleural effusion	1 (5)
		Pulmonary infiltrates	1 (5)
Nervous system	6 (27)	Headache	6 (27)
		Raised intracranial pressure	1 (5)
Liver and metabolism	12 (55)	Raised transaminases	6 (27)
		Raised bilirubin	1 (5)
		Raised triglycerides	2 (9)
Hematologic	4 (18)	Leukocytosis	4 (18)
Skin and musculoskeletal	4 (18)	Dry skin	1 (5)
		Itching	1 (5)
		Joint/bone/muscle pain	3 (14)
		Osteonecrosis	1 (5)

In a retrospective study, 22 children taking tretinoin (median age 9.3 years, range 1.8–16.3) for a median of 38 (6–138) days were compared with 22 taking conventional therapy (median age 12.3 years, range: 3.2–16.7) (25). Overall, 12 of 22 patients had symptoms associated with tretinoin (Table 2). Three developed the retinoic acid syndrome.

Retinoic acid syndrome

The retinoic acid syndrome is a generalized severe capillary leakage syndrome with leukocyte activation, which results in weight gain, pulmonary infiltrates or pleural effusions with acute respiratory distress, and fever without infection. It occurs in up to 25% of patients. Postmortem reports of patients who have died from this syndrome have shown infiltration of maturing myeloid cells and edema in the lungs (26). The myeloid cells are considered to release various types of cytokines responsible for symptoms such as fever, weight gain, and heart failure. Improvement can be obtained by glucocorticoid treatment, which suppresses the effects of cytokines. Chest CT provides an accurate assessment of the size, number, and distribution of pulmonary opacities associated with the syndrome, as has been demonstrated anecdotally (27).

Of 69 patients with acute promyelocytic leukemia treated with tretinoin for 5 years, 15 developed retinoic acid syndrome (28). The following features were found on chest radiographs: an increased cardiothoracic ratio, an increased pedicle width, pulmonary congestion in 13, pleural effusion in 11, ground-glass opacities, septal lines, and peribronchial cuffing in 9,

© 2006 Elsevier B.V. All rights reserved.

consolidation and nodules in 7, and an air bronchogram in 5. Three patients had pulmonary hemorrhages and bilateral, diffuse, poorly delineated nodules and ground-glass opacities on radiography. Lung infiltrates cleared completely within 8 days after administration of prednisolone.

- A 69-year-old man developed dyspnea, hypoxia, and heart failure 4 days after starting to take tretinoin 70 mg/day. His highest white blood cell count was 72 × 109/l. A plain chest X-ray showed two pulmonary opacities, increased attenuation in the left lower lobe, and bilateral pleural effusions, but a chest CT also showed multiple irregular-shaped opacities localized in the centrilobular and subpleural regions. He improved over 10 days with prednisolone (total dose 5750 mg) and daunorubicin (total dose 360 mg).

The retinoic acid syndrome, its incidence and clinical course, has been investigated in 167 patients taking tretinoin as induction and maintenance therapy for acute promyelocytic leukemia (29). The syndrome did not occur during maintenance therapy. During induction it occurred in 44 patients (26%) at a median of 11 (range 2–47) days. The major manifestations included respiratory distress (84%), fever (81%), pulmonary edema (54%), pulmonary infiltrates (52%), pleural or pericardial effusions (36%), hypotension (18%), bone pain (14%), headache (14%), congestive heart failure (11%), and acute renal insufficiency (11%). The median white blood cell count was 1.45×10^9/l at diagnosis and 31×10^9/l (range 6.8–72×10^9/l) at the time the syndrome developed. Tretinoin was continued in eight of the 44 patients, with subsequent resolution in 7. It was withdrawn in 36 patients and then reintroduced in 19, after which the syndrome recurred in 3, with one death attributable to reintroduction of the drug. Ten of these 36 patients received chemotherapy without further tretinoin, and 8 achieved complete remission. Of seven patients in whom tretinoin was not reintroduced and who were not given chemotherapy, five achieved complete remission and two died. Two deaths were definitely attributable to the syndrome.

In 63 patients with acute promyelocytic leukemia taking tretinoin (60 mg/day) the rates of leukocytosis, intracranial hypertension, and retinoic acid syndrome were 57%, 9.5%, and 3.2% respectively; the death rate was 11% (30). The authors suggested that progressive leukocytosis during tretinoin therapy should be an indication for chemotherapy (for example, with homoharringtonine); if the white cell count excceds 10×10^9/l before treatment, the patient should be given homoharringtonine only; if it is below 5.0×10^9/l homoharringtonine plus tretinoin should be used.

A syndrome similar to that of the retinoic acid syndrome occurred after 10 days of tretinoin therapy in a patient with a relapse of acute myeloblastic leukemia (31).

- A 75-year-old woman whose acute myeloblastic leukemia relapsed was treated with one dose of intravenous idarubicin (10 mg/m^2), cytarabine 20 mg subcutaneously for 10 days, and oral tretinoin 45 mg/m^2/day. Ten days later she developed a persistent fever. A chest X-ray and a CT scan showed bilateral pleural effusions and interstitial infiltrates, but no pulmonary embolus. Tretinoin was withdrawn and she was given intravenous dexamethasone 10 mg every 12 hours. Her fever disappeared within 24 hours and her respiratory distress gradually improved during the next 24–48 hours. A chest X-ray 7 days later showed total resolution.

The incidence, clinical features, and outcome of retinoic acid syndrome have been analysed in 413 cases of newly diagnosed acute promyelocytic leukemia (26). Patients under 65 years old with a white blood cell count below 5 x 10^9/l were initially randomized to tretinoin followed by chemotherapy or to tretinoin with chemotherapy started on day 3. In patients with white cell counts over 5×10^9/l chemotherapy was rapidly added if the white cell count was greater than 6, 10, and 15×10^9/l by days 5, 10, and 15 of tretinoin treatment. The retinoic acid syndrome occurred during induction treatment in 64 of 413 patients (15%). Clinical signs developed after a median of 7 (range 0–35) days. In two cases they were present before the start of treatment; in 11 they occurred on recovery from the phase of aplasia due to the addition of chemotherapy. Respiratory distress (98% of patients), fever (81%), pulmonary infiltrates (81%), weight gain (50%), pleural effusion (47%), renal failure (39%), pericardial effusion (19%), cardiac failure (17%), and hypertension (12%) were the main clinical signs. Mechanical ventilation was required in 13 patients and dialysis in 2. A total of 55 patients (86%) who experienced the retinoic acid syndrome achieved complete remission, compared with 94% of patients who had no retinoic acid syndrome, and nine died of the syndrome. None of the patients with complete remission who received tretinoin for maintenance had recurrence of the syndrome. The syndrome was associated with a lower event-free survival and survival at 2 years.

Retinoic acid syndrome has been reported in a patient who developed diffuse alveolar hemorrhage while being treated with tretinoin for acute promyelocytic leukemia (32).

- An 18-year-old woman developed promyelocytic leukemia and was given tretinoin and dexamethasone. At 15 days she developed significant hemoptysis and respiratory failure, requiring mechanical ventilation. Her temperature was 39.1°C and she had disseminated intravascular coagulation. A lung biopsy showed diffuse interstitial neutrophilic infiltration, interstitial fibrinoid necrosis, and diffuse alveolar hemorrhage; pulmonary capillaritis was diagnosed. She was given intravenous methylprednisolone 1 g/day for 3 days followed by a tapering dose of oral prednisolone. She subsequently completed a full 45-day course of tretinoin.

Organs and Systems

Cardiovascular

An increased risk of thrombotic events, especially coronary thrombosis, has been reported in elderly patients taking retinoids (33). Two patients with acute promyelocytic leukemia developed thrombus in the right ventricle during induction treatment with tretinoin plus idarubicin (34).

© 2006 Elsevier B.V. All rights reserved.

- A 51-year-old man with acute promyelocytic leukemia suddenly developed hypoxemia, pulmonary infiltrates, and arterial hypotension, without fever or thoracic pain on day 11 of tretinoin treatment. He was pancytopenic, his coagulation parameters were normal, and cardiological examination was normal. High-dose dexamethasone (10 mg bd) was started, with prompt resolution of the clinical and radiological signs. Eight days later echocardiography showed a 3 cm non-homogeneous mass in the right ventricle. He was given subcutaneous low molecular weight heparin and the thrombus started to get smaller after 17 days. Oral anticoagulant therapy was started, and there was a further reduction of the size of the thrombus over the following year.
- A 32-year-old woman with acute promyelocytic leukemia developed severe retinoic acid syndrome after 3 days, with respiratory failure, fever, and bilateral lung infiltrates. Withdrawal of tretinoin and treatment with dexamethasone and antibiotics rapidly ameliorated the syndrome, and on day 10 tretinoin was restarted. However, routine echocardiography showed a 3 cm pedunculated mass in the right ventricle. There was consistent and stable reduction of the mass after 1 year of oral anticoagulant therapy.

Respiratory

The manufacturers have on record in the USA several pulmonary adverse effects during isotretinoin therapy, including worsening of asthma (SEDA-21, 162), recurrent pneumothorax, pleural effusion, interstitial fibrosis, pulmonary granuloma, and deterioration in lung function tests. Exercise-induced asthma (35) may be caused by a significant reduction in the forced expiratory flow rate (36) and a drying effect of isotretinoin on the mucous membranes of the respiratory tract (37).

Respiratory distress has been attributed to tretinoin.

- A 56-year-old woman with acute promyelocytic leukemia developed a fever of unknown origin, weight gain of 5 kg, and respiratory distress 9 days after the start of treatment with tretinoin 45 mg/m^2 (38). Her white cell count rose to 21 $\times$ 10^9/l despite treatment with cytosine arabinoside and idarubicin. A chest X-ray showed bilateral alveolar opacities. She recovered fully after 5 days of treatment with dexamethasone 10 mg bd.
- A 24-year-old woman with acute promyelocytic leukemia took tretinoin, and 2 days later developed dyspnea and general aching (39). Her total leukocyte count was 5.04 $\times$ 10^9/l, her PaO_2 was 42.5 mmHg, and a chest X-ray showed bilateral parenchymal infiltration consistent with respiratory distress syndrome. She recovered within 3 days of treatment with low-dose cytarabine and glucocorticoids, without withdrawal of the retinoic acid.

Although the retinoic acid syndrome involves the lungs, pulmonary hemorrhage has only rarely been reported. Two patients with acute promyelocytic leukemia developed severe lung hemorrhage during the first 3 weeks of treatment with tretinoin, shortly after the administration of chemotherapy (40).

- A 36-year-old man with acute promyelocytic leukemia was given tretinoin 45 mg/m^2/day, daunorubicin, and cytarabine. A week later his platelet count fell to 10 $\times$ 10^9/l, and the next day he developed dyspnea, hemoptysis, and fever. A chest X-ray showed diffuse bilateral patchy pulmonary infiltrates. Tretinoin was withdrawn, but despite high doses of glucocorticoids and blood products, hemoptysis and respiratory failure continued for 6 weeks, when he improved.
- A 59-year-old man with acute promyelocytic leukemia was given tretinoin 45 mg/m^2/day and chemotherapy. On day 6, his fibrinogen concentration fell to 940 mg/l and he developed a fever (39°C), dyspnea, and hypotension. A chest X-ray showed a right pleural effusion. Tretinoin was withdrawn and he was given dexamethasone. However, he deteriorated and developed hemoptysis. Despite glucocorticoids and blood products his pulmonary bleeding continued unabated. On day 29 he developed Gram-negative sepsis and died.

Eosinophilic pleural effusion has been attributed to isotretinoin (3).

Pneumonia has also been reported as a possible adverse effect (SEDA-20, 155) (36).

Nervous system

Nervous system disturbances include fatigue, lassitude, vertigo, sweating, hypesthesia, paresthesia, dizziness, fever, amnesia, delirium, flu-like symptoms, somnolence, pseudotumor cerebri, hyperirritability, sleep disturbance, lethargy, depression (41), and psychological changes. There was a direct correlation between intracranial hypertension and the use of isotretinoin in a retrospective study of spontaneous reports (42).

- An 8-year-old girl with acute promyelocytic leukemia was given cytarabine, etoposide, idarubicin, and tretinoin 25 mg/m^2/day (43). Five days later she developed fever, pleural effusions, and ascites, but the symptoms resolved spontaneously. On day 65 (cumulative dose of tretinoin 1.6 g/m^2) she had nausea and vomiting, severe headache, and diplopia. There was paralysis of the left trochlear nerve bilateral papilledema. A cranial MRI scan was normal. The intracranial pressure was not measured. Tretinoin was withdrawn and she was given glucocorticoids, mannitol, acetazolamide, and pethidine. Her symptoms resolved within 2 days.

A case of multiple mononeuropathies has been attributed to tretinoin (44). The neurological symptoms resembled atypical pseudotumor cerebri with focal neurological signs.

- A 23-year-old woman with acute promyelocytic leukemia was given tretinoin (45 mg/m^2/day) together with daunorubicin and cytarabine. She had a slight headache after the administration of tretinoin. On the 17th day an acute subdural hematoma required operation. Her headache persisted and she complained of diplopia, and burning pain and contact dysesthesia of the back of the left hand and the right foot, with accompanying weakness on

© 2006 Elsevier B.V. All rights reserved.

day 21. Electrophysiology showed reduced conduction velocity and amplitude in the right peroneal nerve. She also had a right abducens nerve palsy and visual disturbance. There was no papilledema. MRI scan of the brain was normal. On day 51 tretinoin was discontinued. Her symptoms of peripheral neuropathy and the electrophysiological findings gradually improved as did her headache and dry skin, despite continued chemotherapy. The right abducens nerve palsy partly resolved.

The relation between isotretinoin and seizures is still unclear (SEDA-18, 169).

The possible negative effects of short-term oral acitretin 1 mg/kg/day on peripheral nerve function have been assessed in a small prospective study in 13 patients (45). Patients with conditions related to peripheral neuropathy were excluded. There was a fall in the mean amplitude of the sensory action potential of the superficial peroneal nerve after 1 and 3 months of therapy. There was a significant change in one or more neurophysiological parameters in three of 13 patients after 1 month and in nine of 13 patients after 3 months. None of the patients had detectable neurological abnormalities at any time during therapy. Acitretin was withdrawn, and after 6 months three patients gradually improved. Further studies are needed to determine whether neurophysiological evaluation should be routine during treatment with oral retinoids. Peripheral neuropathy has rarely been observed (SEDA-17, 183).

Sensory systems

Eyes

Ocular findings are among the more frequent adverse effects in patients taking isotretinoin (46,47), the most common being blepharoconjunctivitis, which also occurs in those who use tretinoin ophthalmic ointment (1).

Ocular adverse effects secondary to isotretinoin are generally benign in nature and reversible on reduction or withdrawal of therapy. However, papilledema necessitates withdrawal. Corneal opacities should be monitored closely. Although they do not usually interfere with vision, prudence dictates withdrawal of isotretinoin or reduction of the dosage when corneal opacities develop (48). Several cases of cataract have been (unconvincingly) ascribed to isotretinoin (SEDA-19, 157). Etretinate and isotretinoin have caused photophobia and reduced night vision (SEDA-17, 183), and possibly ectropion (SEDA-16, 152).

Corneal opacities after treatment with oral isotretinoin generally disappear after withdrawal. However, in one case they were persistent (49).

- A 39-year-old woman developed corneal opacities while taking oral isotretinoin 1 mg/kg for 6 months. The opacities persisted for at least 6 years after discontinuation of the drug. She had worn soft hydrophilic contact lenses for 10 years before, but without signs of corneal opacity 1 month before treatment was started.

Xerophthalmia, carrying a high risk of blindness, requires the immediate administration of massive doses of vitamin A. An infant who received intramuscular vitamin A for xerophthalmia secondary to cystic fibrosis developed an acute sixth nerve palsy (50).

- A 5-month-old boy with cystic fibrosis and xerophthalmia was given intramuscular vitamin A 50 000 IU (water-miscible retinyl palmitate). After the first dose prominent bulging of the fontanelle developed, but the infant remained alert and was feeding well. Two days later another dose of 50 000 IU was given in two divided doses over 2 days. These doses were well tolerated, with gradual improvement of the bulging fontanelle over 1 week. Five days later, a complete abduction deficit of the left eye developed, in keeping with an acute sixth nerve palsy. There were no other signs of raised intracranial pressure. The sixth nerve palsy resolved fully over the next 2 months. There were no other neurological sequelae. After discharge the infant continued to take oral vitamin A supplements.

In one study, 236 cases of adverse ocular reactions possibly associated with isotretinoin were evaluated (Table 3) (48).

Ears

Unilateral earache has been reported in two patients (SEDA-9, 134). Excessive cerumen production and otitis externa have also been reported.

Taste and smell

Taste and smell can be altered by isotretinoin (SEDA-16, 153) and loss of taste has been attributed to it (SEDA-21, 163).

Table 3 Adverse ocular effects associated with isotretinoin exposure in 236 patients (51)

Adverse effects	No. of patients
Eyelids	
Blepharoconjunctivitis or meibomianitis (52)	88
Photodermatitis	6
Cornea	
Corneal opacities	12
Dry eyes	47
Contact lens intolerance	19
Optic nerve	
Papilledema or pseudotumor cerebri	18
Optic neuritis	3
Congenital abnormalities	
Microphthalmos	5
Orbital hypertelorism	2
Optic nerve hypoplasia	4
Cortical blindness	1
Others	
Blurred vision	39
Myopia	5
Impaired night vision and dark adaptation (SEDA-10, 25)	3
Ocular inflammation (uveitis, scleritis, retinitis, ophthalmitis, iritis)	7

Psychological, psychiatric

In 1998 depression, psychosis, and suicidal ideation, suicide attempts, and suicide were added to the product label of isotretinoin. Since then the FDA has received increasing number of reports of these problems (53). From the time that isotretinoin was marketed in 1982 up to May 2000 the FDA received 37 reports of patients taking isotretinoin who committed suicide, 110 reports of patients who were hospitalized for depression, suicidal ideation, or suicide attempts, and 284 reports of patients with depression who did not need hospitalization (54). In 62% of the suicide cases a psychiatric history or possible contributing factors were identified, and 69% of patients hospitalized for depression had either a previous psychiatric history of possible contributing factors. Drug withdrawal led to improvement in about one-third of the patients, while in 29% depression persisted after withdrawal. In 24 cases dechallenge and rechallenge were positive. However, since this was a series of spontaneous reports, and since there are no good data on the incidence of depression and suicide among adolescents with acne, a causal relation cannot be concluded.

A change in dreaming pattern has been reported in two patients, occurring within 2–3 weeks after the start of treatment with isotretinoin 40 mg/day for cystic acne (55). One patient also reported increased irritability and bouts of depression. In both patients all the symptoms abated after 4–5 weeks without a change in isotretinoin dosage.

Endocrine

Small reductions in indices of thyroid function have been observed in patients taking etretinate (56). Thyrotoxicosis may have been triggered by isotretinoin in one patient (SEDA-12, 136).

Metabolism

Alterations in lipid metabolism are common and include increases in serum triglyceride and cholesterol concentrations, sometimes persisting after withdrawal of the therapy, and reductions in high-density lipoprotein cholesterol. The incidence of raised serum lipids during therapy with oral isotretinoin 1 mg/kg/day for acne has been reviewed retrospectively in 876 patients, of whom 54 had raised serum cholesterol concentrations (over 5.2 mmol/l) and 45 had triglyceride concentrations above 2.26 mmol/l (57).

Symptoms of hyperlipidemia and the metabolic syndrome have been investigated in a cross-sectional study in young adults who had used isotretinoin for acne for at least 4 weeks (mean dosage 0.56 mg/kg). Those in whom triglyceride concentrations increased by at least 1.0 mmol/l during therapy were termed hyper-responders ($n = 102$), and those in whom triglyceride concentrations changed by 0.1 mmol/l or less were termed non-responders ($n = 100$) (58). Despite similar pretreatment body weights and plasma lipid concentrations, 4 years after completion of isotretinoin therapy the hyper-responders were more likely to have hypertriglyceridemia (OR = 4.8; 95% CI = 1.6, 14), hypercholesterolemia (OR = 9.1; CI = 1.9, 43), truncal obesity (OR = 11.0; CI = 2.0, 59), and hyperinsulinemia (OR = 3.0, CI = 1.6, 5.7) than non-responders. In addition, more hyper-responders had at least one parent with hypertriglyceridemia. Genotypes containing apoE ε2 and apoE ε4 alleles were over-represented among hyper-responders. Although a comparison of hyper-responders with non-responders may lead to overestimation of the risk, these data suggest that those who develop hyperlipidemia while taking isotretinoin are those who are already at risk of hyperlipidemia and the metabolic syndrome.

The consequences of hypertriglyceridemia are not well understood, but there may be an increased risk of cardiovascular disease and pancreatitis (SEDA-13, 123). Patients with an increased tendency to develop hypertriglyceridemia include those with diabetes mellitus, obesity, increased alcohol intake, and a positive family history. With a short course (16 weeks) of isotretinoin it is sufficient to ensure there is no hyperlipidemia before the start of therapy, and to determine the triglyceride response to therapy on one occasion after 4 weeks (59).

Mineral balance

Hypercalcemia has been reported as an adverse effect of systemic retinoid therapy (60).

- A 12-year-old girl with neuroblastoma and normal renal function developed severe hypercalcemia while receiving isotretinoin 160 mg/m^2/day (61). Her hypercalcemia resolved with hydration, diuretic therapy, and temporary withdrawal of isotretinoin. Despite a dosage reduction to 80 mg/m^2/day, severe hypercalcemia recurred during the next treatment cycle. Further treatment with isotretinoin was made tolerable by shortening the duration of the remaining cycles.
- An 11-year-old boy with acute promyelocytic leukemia was given *all-trans*-retinoic acid 47 mg/m^2/day (62). On day 10 he developed headache and nausea. The dose was reduced to 39 mg/m^2/day and he was given glycerol, but his symptoms of pseudotumor cerebri continued. Cranial CT showed neither space-occupying lesions nor brain edema. On day 25, hypercalcemia (3.2 mmol/l) was observed. In spite of conventional therapy the serum calcium concentration continued to rise to 4.0 mmol/l. Tretinoin was withdrawn on day 33. Within 1 week his symptoms resolved. On the second day of a second phase of *all-trans*-retinoic acid therapy, he again developed nausea and headache and the serum calcium concentration gradually increased to 3.3 mmol/l by day 7. Raised concentrations of type 1 cross-linked *N*-telopeptide and deoxypyridinoline suggested increased bone resorption. A bisphosphonate (pamidronate 30 mg) was administered intravenously; the calcium normalized within 2 days and the nausea and headache resolved.

Fluid balance

Generalized edema has been attributed to etretinate (63).

Hematologic

Altered blood clotting due to hypoprothrombinemia, raised erythrocyte sedimentation rate (64), altered red cell count (64), reduced white cell count (64),

© 2006 Elsevier B.V. All rights reserved.

thrombocytopenia (SEDA-12, 136), and eosinophilia (SEDA-13, 122) have all been observed incidentally (SEDA-17, 184).

Of 31 patients with acute promyelocytic leukemia (15 men and 16 women, median age 43 years) 4 received tretinoin 45 mg/m^2/day and intravenous tranexamic acid 1–2 g for 6 days, 9 received tretinoin, daunorubicin, and cytarabine followed by thioguanine, 15 received chemotherapy, tretinoin, and tranexamic acid, 2 received chemotherapy and tranexamic acid, and 1 received chemotherapy only (65). Three of the four patients who received tretinoin plus tranexamic acid had sudden and rapid deterioration in their condition, leading to early death. At postmortem there were widespread microvascular thromboses in unusual sites (for example the brain and kidneys). The rapid progression to multiorgan failure and the widespread nature of the microthrombi suggests the need for caution in the simultaneous use of tretinoin and tranexamic acid.

Thrombosis during induction treatment with tretinoin, aprotinin, and chemotherapy has been described (66).

Transient polycythemia has been reported during treatment with isotretinoin for severe nodular acne (67).

- A 53-year-old man's hematocrit increased from 0.46 to 0.51 after he had taken isotretinoin for 11 months (180 mg/day for 3 months, 80 mg/day for 6 months, then 20 mg/day). No secondary causes of polycythemia were found and the hematocrit fell to 0.48 3 months after withdrawal of isotretinoin.

The reference range for hematocrit in men is 0.41–0.49, and so the clinical relevance of this observation is unclear.

Attacks of paroxysmal nocturnal hemoglobinuria may possibly be provoked by isotretinoin (SEDA-19, 156).

Extramedullary relapse of acute promyelocytic leukemia, which is rare after chemotherapy alone, was more common after tretinoin, but it is not clear whether it truly increases the risk of extramedullary recurrence and what the risk factors are. In a retrospective analysis of the incidence of extramedullary relapse in patients after prior treatment with tretinoin and in patients previously treated with chemotherapy alone (68) three of the 13 patients who received tretinoin had extramedullary involvement compared with none of the 11 patients previously treated with chemotherapy alone (RR = 2.1; CI = 1.34, 3.29). The retinoic acid syndrome during prior induction treatment was significantly associated with extramedullary relapse (three of five patients with the retinoic acid syndrome versus none of eight without the syndrome (RR = 5.0; CI = 1.4, 17)). Thus, tretinoin may predispose patients with acute promyelocytic leukemia to extramedullary involvement at relapse and the retinoic acid syndrome is a risk factor.

Gastrointestinal

The gastrointestinal adverse effects of retinoids include anorexia, nausea, vomiting, weight loss, stomach pain, thirst, splenomegaly, and acute esophagitis (SEDA-21, 162). Proctosigmoiditis has been reported (SEDA-13, 123).

- Ulcerative colitis occurred in a 17-year-old boy shortly after he had completed a 5-month course of isotretinoin (dose not stated) for acne (69). There was no family history of inflammatory bowel disease.

Although three other cases of inflammatory bowel disease during isotretinoin therapy have been reported (70–72), there have also been reports of the safe use of isotretinoin in patents with a history of inflammatory bowel disease (that is without exacerbation of the inflammatory bowel disease) (70,73,74). Since retinoids are being increasingly used to treat moderately severe acne, larger studies are needed to elucidate the relation between retinoid use and inflammatory bowel disease.

Vasculitis and necrosis of the ileum developed in a patient with acute promyelocytic leukemia treated with *all-trans*-retinoic acid (75).

- A 29-year-old woman with acute promyelocytic leukemia was given tretinoin 45 mg/m^2. On day 20 she developed pain in both hands, wrists, feet, and ankles, with erythema and edema. On day 24 her fever increased to over 38°C and the white blood cell count was 10.9×10^9/l. She was given dexamethasone (8 mg intravenously on three consecutive days) and all her symptoms quickly resolved, but on day 37 she developed a low-grade fever and polyarthralgia, which persisted. On day 42 she had a profuse bloody stool and her abdominal pain worsened and spread all over the abdomen. At emergency operation there was segmental necrosis in several parts of the ileum, with inflammation invading the serosa. Histology of the ileum showed a leukocytoclastic vasculitis. After operation tretinoin was withdrawn and she had no fever, edema, arthralgia, or abdominal pain thereafter.

Liver

Hepatomegaly is an adverse effect of retinol and tretinoin. Transient slight rises in liver enzymes, notably aspartate transaminase, alanine transaminase, and alkaline phosphatase, are common, but some cases of hepatotoxicity due to etretinate and acitretin (SEDA-20, 154) have also been reported (76), as has cholestatic jaundice due to etretinate (77). Etretinate may have played a role in a case of liver failure leading to death (76).

The incidence of raised liver enzymes during therapy with oral isotretinoin 1 mg/kg/day for acne has been retrospectively reviewed in 876 patients (57). Liver enzymes (aspartate transaminase, alanine transaminase, and γ-glutamyl transferase) were transiently raised in a minority of patients (number not stated).

Acute liver damage has been attributed to tretinoin (78).

- A 40-year-old man with acute promyelocytic leukemia was given tretinoin 45 mg/m^2/day and intravenous daunorubicin. After 3 weeks his alkaline phosphatase rose to 370 (reference range 82–198) U/l, the gamma-glutamyltranspeptidase to 198 (reference range 7–43) U/l, and the direct bilirubin to 39 (reference range below 10) μmol/l. He had painful hepatomegaly without splenomegaly. Abdominal Doppler ultrasound ruled out biliary tract injury. Percutaneous liver biopsy showed intracellular cholestasis with preservation of hepatic architecture. He was given dexamethasone and

© 2006 Elsevier B.V. All rights reserved.

tretinoin was withdrawn. After 3 days the symptoms and hepatomegaly abated.

Pancreas

Acute pancreatitis is a rare but serious adverse effect of tretinoin. Three cases associated with isotretinoin-induced hyperglyceridemia have previously been described and two cases associated with tretinoin (79,80).

- A 48-year-old man received tretinoin (45 mg/m^2/day) followed 9 days later by combination chemotherapy for 5 days (81). On day 15 he developed acute epigastric and upper left quadrant pain. He had raised serum lipase (1312 IU/l; reference range 27–208), amylase (509 IU/l; 30–110), and triglycerides (7.77 mmol/l; 0.45–1.82). Abdominal CT showed mild trabeculation of the peripancreatic adipose tissue, but no lithiasis or dilatation of the biliary ducts. Acute pancreatitis caused by hypertriglyceridemia was diagnosed and he was given supportive treatment plus fenofibrate (200 mg/day), without withdrawal of tretinoin. His lipase, amylase, and triglycerides normalized over 10 days.

Urinary tract

Impaired renal function has rarely been caused by isotretinoin (82) and etretinate (83). Abnormalities in urinary proteins, inflammation of the urethral meatus, and nephrolithiasis have rarely occurred. Urethritis may occur more often than has been realized (SEDA-21, 162) (84).

Nephrotic syndrome developed after 4 months treatment with isotretinoin 40 mg/day (85). No other causes were found and the symptoms disappeared within some months with appropriate treatment.

During tretinoin therapy, some patients with retinoic acid syndrome or with a hypercoagulable state develop acute renal insufficiency, usually accompanied by dysfunction of other organs. A patient with acute promyelocytic leukemia developed renal insufficiency alone during tretinoin treatment (86).

- A 72-year-old Japanese man with acute promyelocytic leukemia was given tretinoin 48 mg/m^2 plus idarubicin. On day 17 oliguria occurred and tretinoin was withdrawn on day 20 when the serum creatinine concentration rose to 619 μmol/l (7.0 mg/dl). There were no signs or symptoms of retinoic acid syndrome. A needle biopsy of the left kidney on day 38, when the serum creatinine concentration was 212 μmol/l (2.4 mg/dl), showed granulomatous tubulointerstitial nephritis. The glomeruli were mostly intact and there were no fibrin thrombi or leukemic cell infiltration. After one course of consolidation therapy he was discharged with a normal serum creatinine concentration.

Two cases of bone-marrow transplant nephropathy that developed coincident with retinoid therapy have been reported (87).

- A 3-year-old boy with a neuroblastoma was given cisplatin, adriamycin, and cyclophosphamide for five induction cycles and radiation to sites of residual bony metastases 1 month before autologous bone-marrow transplant, which resulted in an absolute neutrophil count of 500 × 10^6/l on day 9 and a self-sustaining platelet count over 50 × 10^{12}/l on day 72. He was randomized to receive retinoids 80 mg/m^2 bd by mouth, beginning on day 100 after bone-marrow transplant. Before beginning *cis*-retinoic acid, his highest serum creatinine concentration was 44 μmol/l on day 8. When *cis*-retinoic acid was begun, his hemoglobin was 9.8 g/dl and his platelet count 97 × 10^{12}/l. At the end of the second 2-week cycle of retinoic acid he developed a severe headache and diastolic hypertension (BP 120/108 mmHg), a blood urea nitrogen concentration of 4 mmol/l, serum creatinine of 133 μmol/l, hemoglobin of 5.8 g/dl, and platelet count of 57 × 10^{12}/l. Urinalysis showed erythrocytes and protein. Renal biopsy showed mesangiolysis, wide capillary loops, focal intimal thickening, and vacuolization of glomerular and tubular cells. His hematuria and proteinuria persisted for 4 weeks, and his blood urea nitrogen and serum creatinine gradually improved, as did the hypertension.
- A 5-year-old boy with a neuroblastoma was treated in the same way. On day 105 after bone-marrow transplantation he developed hypertension (BP 140/92 mmHg), hematuria, proteinuria, and a raised serum creatinine. His hemoglobin and platelet count fell. His urine contained protein 800 mg/l, a few hyaline casts, and 25–30 erythrocytes per high-power field. When nephritis developed, *cis*-retinoid acid was withdrawn. He gradually improved, and his urine cleared of casts, erythrocytes, and protein within 4 weeks.

Skin

Adverse effects of oral retinoids on the skin are common (up to 70%). The symptoms and signs are listed in Table 4. Three cases of scrotal ulceration during *all-trans*-retinoic acid therapy for a microgranular variant of acute promyelocytic leukemia (88,89), together with eight other reported cases (90–92), suggest that this adverse effect is specific for tretinoin. The incidence has been estimated at 12% (88). The pathogenesis is unknown, but it has been suggested to be a manifestation of the retinoic acid syndrome (88). Improvement after the withdrawal of tretinoin and the administration of glucocorticoids supports this assumption. However, activation of neutrophils by superoxide production may also be involved.

Acute febrile neutrophilic dermatosis (Sweet's syndrome) can occur in patients with acute promyelocytic leukemia given a retinoid. Sweet's syndrome is characterized by five cardinal features: fever, neutrophilia, multiple raised painful asymmetric erythematous cutaneous plaques, dermal infiltrates consisting of mature neutrophils, and a rapid response to glucocorticoid therapy. In up to 10–20% of cases it precedes or coincides with a diagnosis of malignancy, most commonly acute myelogenous leukemia. In cases associated with tretinoin the symptoms come on at 7–34 days and the skin lesions are seen on the face, limbs, and back.

- A 58-year-old woman was given tretinoin 45 mg/m^2/day for acute promyelocytic leukemia and after 9 days she developed symptoms of upper respiratory tract infection and fever (38.2°C) (96). The next day

Table 4 The adverse effects of oral retinoids on the skin and hair

Acne fulminans (SEDA-11, 137)
Angular stomatitis
Balanitis (rare)
Blepharoconjunctivitis
Bullous pemphigoid (SEDA-17, 184)
Cheilitis
Cystic and comedonal acne (SEDA-15, 142)
Dissemination of *Herpes simplex*
Dry mucous membranes
Epistaxis
Eruptive xanthomas (one report)
Erythema multiforme (SEDA-14, 124)
Erythema nodosum (SEDA-21, 163)
Erythroderma
Excess granulation tissue (SEDA-9, 134)
Facial cellulitis (*Staphylococcus aureus*)
Facial dermatitis
Facial erythema
Follicular eczema
Generalized edema
Gingivitis, bleeding gums
Glossitis
Hair curly, possibly due to the combination of isotretinoin + azathioprine (SEDA-21, 163)
Hair discoloration (SEDA-19, 157)
Hair growth disturbed
Hair loss
Hair thinning
Hair "unruly" (SEDA-11, 136)
Hirsutism
Hyperhidrosis
Hyperpigmentation
Hypopigmentation
Irritant dermatitis
Melasma (SEDA-21, 163)
Mucosal erosions
Mycosis fungoides-like dermatitis (SEDA-10, 125)
Nail deformities (softening, fragility, Beau's lines, onycholysis, onychomadesis, onchoschizia, paronychia, curly fingernails) (37)
Nail growth reduced
Nasal carriage of *Staphylococcus aureus* (SEDA-12, 131)
Nummular eczema (SEDA-12, 136)
Osteoma cutis exacerbation
Papulopustular palmoplantar eruptions
Pemphigus vulgaris (SEDA-20, 155)
Petechiae
Photoallergy (SEDA-17, 184)
Phototoxicity (SEDA-17, 184)
Pityriasis rosea-like dermatitis
Polyarteritis nodosa (93)
Porokeratosis exacerbation (SEDA-16, 152)
Prurigo nodularis (SEDA-12, 131)
Pruritus
Pseudoporphyria (SEDA-17, 184)
Psoriasis as a Koebner phenomenon (SEDA-13, 123)
Pyogenic granuloma
Rosacea-like eruption
Ruptured striae atrophicae
Sarcoid-like granulomas (SEDA-19, 157)
Scaling of the skin
Scalp folliculitis
Skin fragility and erosions (SEDA-22, 168)
Skin odor abnormal
Skin sticky
Thyroglossal cyst (SEDA-20, 155)
Toxic epidermal necrolysis
Vasculitis (94,95)
Vulvitis
Wound healing delayed
Xeroderma

multiple erythematous and painful cutaneous plaques appeared on her limbs. Her white cell count was 5.71×10^9/l. A skin biopsy showed a normal epidermis with subepidermal edema and dense diffuse perivascular aggregates composed of granulocytes and scattered eosinophils, compatible with Sweet's syndrome. Prednisolone 20 mg/day had no effect, but after 2 days treatment with cytarabine and daunorubicin the rash started to fade and gradually disappeared. Remission was achieved after one course and *all-trans*-retinoic acid was subsequently renewed without complications.

- A 39-year-old man with acute promyelocytic leukemia was given tretinoin 45 mg/m^2 (97). His leukocyte count rose to 34.3×10^9/l on day 11. On day 18 he developed rigors, mild dyspnea, and a fever (39°C). He had exquisite pain in the right posterior tibial muscle and had several 2-mm erythematous papular and pustular lesions on his limbs and trunk. He was given a cephalosporin and developed painful bilateral nodules in the quadriceps, posterior tibial, and right biceps muscles. An MRI scan showed focal areas of increased T2 signals in the quadriceps muscles bilaterally, in most of the left sartorius and soleus muscles, and in all the compartments of the right leg. There was thickening of the adjacent fascia with subcutaneous edema. Tretinoin was withdrawn and he was given dexamethasone 16 mg/day. The cutaneous lesions improved dramatically and tretinoin 45 mg/m^2 was restarted. The symptoms did not recur.
- A 35-year-old woman with acute promyelocytic leukemia was given tretinoin 45 mg/m^2/day. On day 9 she became febrile (39.5°C) and had a sore throat with pharyngeal erythema and tender lymphadenopathy. The fever persisted despite cephalosporins, vancomycin, and antibiotics for anaerobic cover. On day 20 she developed severe bilateral anterior leg pain and both anterior tibial muscles were tender. Creatine kinase activity was 348 (reference range 38–176) U/l. Tretinoin was withdrawn and she was given intravenous dexamethasone 10 mg/day. Her fever resolved, her pain abated, and her leg muscles felt softer and less tender. Tretinoin was reintroduced and her symptoms returned.
- A 46-year-old man with promyelocytic leukemia was given tretinoin 45 mg/m^2 plus daunorubicin 60 mg/m^2/day for 3 days and cytarabine 200 mg/m^2/day by continuous infusion for 7 days (98). He became febrile on day 3 and was given cefotaxime and vancomycin. On day 6 he developed non-pruritic, erythematous, violaceous vesicles on the limbs and upper trunk. His temperature rose to 40°C and he gained 4.5 kg, which was attributed to a mild retinoic acid

© 2006 Elsevier B.V. All rights reserved.

syndrome. Skin biopsy showed infiltration by neutrophilic granulocytes and marked edema in the dermis, without vasculitis or evidence of leukemic cells, fungi, or herpesvirus. Hepatic enzymes were moderately increased. The clinical presentation and histopathological findings were consistent with Sweet's syndrome. Tretinoin was withdrawn and he was given dexamethasone 40 mg/day for 10 days and then tapering doses of prednisone. He improved, and tretinoin was reintroduced without recurrence.

With topical application of tretinoin, special care should be taken when other drugs are given simultaneously. Dramatic photosensitivity has been associated with the combination of fluorouracil, prochlorperazine, and topical tretinoin (99).

- A 52-year-old woman with a colonic cancer was treated with chemotherapy after surgical resection. She had been applying topical tretinoin (Renova; Ortho Pharmac, Raritan N) cream 0.05% nightly to her face for about 5 years. During that time she had applied a sunscreen while outdoors and had tolerated tretinoin without incident. Her daily oral multivitamin supplement contained 5000 IU of retinol equivalents. About 3 days after her last dose of chemotherapy (leucovorin, fluorouracil, prochlorperazine) she exposed her face to the sun for about 1 hour after applying her usual sunscreen. Shortly afterwards the skin on her face became erythematous and worsened over several days. Her eyes became edematous, itchy, and painful. Within a week the skin on her face had completely desquamated. She stopped using tretinoin. The reaction began to improve and she was pain-free within 1 week. Her appearance returned to normal after about 10 days. During a second cycle of chemotherapy she received the same drugs as during the first, except tretinoin, and reported no significant change in sun exposure or sunscreen application. She tolerated subsequent cycles without adverse skin effects. After completing her monthly chemotherapy cycles, she resumed topical tretinoin without adverse effects.

Leukemia cutis is very rare in acute myelocytic leukemia. Cutaneous relapse in acute promyelocytic leukemia has been reported during a period of complete hematological remission after treatment with tretinoin (100).

- A 51-year-old man with acute promyelocytic leukemia was given induction chemotherapy and tretinoin 45 mg/m^2. After 1 month he developed discrete erythematous papules, although marrow biopsy suggested hematological remission. The papules were disseminated on all his limbs, trunk, and scalp, and were scattered, discrete, and 2–3 mm in diameter. Biopsy showed a moderate perivascular infiltration of medium to large atypical cells, mainly in the upper dermis, suggesting infiltrating promyelocytes. The clinical, histological, and histochemical findings were compatible with leukemia cutis. One week later, a bone-marrow biopsy still showed hematological remission.

Musculoskeletal

Musculoskeletal symptoms occur in 15% of patients who take isotretinoin. These are usually mild and consist of pain, tenderness, and muscle stiffness. Creatine kinase activity can rise, especially in individuals engaging in strenuous physical activity (SEDA-10, 124). Clinical and subclinical muscle damage has been reported from etretinate, acitretin, and isotretinoin (SEDA-21, 162, 163).

Skeletal abnormalities associated with retinoid therapy include Achilles tendonitis (SEDA-17, 185), acute arthritis (SEDA-18, 168) (101), bridging of vertebral bodies, diffuse idiopathic skeletal hyperostosis (DISH), disc narrowing, nasal bone osteophytosis, osteoma cutis, hyperostosis, extraspinal calcifications, costochondritis, enthesiopathy, ossification of tendons and ligamentous insertions, ossification of the posterior longitudinal ligament, periosteal thickening, premature epiphyseal closure, reduced bone density/osteoporosis (102), skeletal aches and pains, slender long bones, and Tietze's syndrome.

Stiff man syndrome has been described 10 days after the start of oral isotretinoin treatment (1 mg/kg/day) and resolved completely within 2 weeks of withdrawal (103). There were no motor or sensory nerve conduction abnormalities. There were no conditions known to be associated with stiff man syndrome, either at the time or during 5 years of follow up.

Adult onset Still's disease occurred after 3 months of oral isotretinoin (104). No other causes were found and the symptoms disappeared with appropriate treatment within some months.

Reproductive system

Breast discharge has been reported (105). Menstrual disturbances occur, and may be under-reported (SEDA-13, 121, 123). Vaginal bleeding in a 64-year-old woman was convincingly ascribed to the daily use of tretinoin cream 0.05% to her face, suggesting a systemic effect (SEDA-16, 159).

Adverse effects of isotretinoin affecting the male reproductive system reported to the manufacturer include gynecomastia, local inflammation/discomfort, potency disorders, reduced fertility, and ejaculatory failure (SEDA-18, 168) (106).

Immunologic

Hypersensitivity reactions to retinoids are rare and consist of occasional drug rashes.

- Immunomodulatory effects of isotretinoin in the treatment of facial acne (40 mg/day for 4 weeks) were blamed for a recurrence of pulmonary alveolar proteinosis in a 16-year-old girl, in whom it had been in spontaneous remission for 2 years (107).

Although the time-course of this effect was suggestive, it should be borne in mind that about 25% of patients with this disease have exacerbations without a clear cause.

Body temperature

An increase in the frequency of attacks of familial Mediterranean fever has been reported after the start of systemic therapy with isotretinoin for nodulocystic acne (108).

© 2006 Elsevier B.V. All rights reserved.

- A 32-year-old man with familial Mediterranean fever had one or two attacks per year while taking colchicine twice daily for 10 years. During the first month after starting to take isotretinoin 50 mg/day he had three typical attacks, increasing to one attack a week after dosage increments to 60 mg/day and later 80 mg/day. Isotretinoin was withdrawn and he had no further attacks of familial Mediterranean fever during the following 10 months. Rechallenge was not performed.

Long-Term Effects

Mutagenicity

The reported occurrence of sarcomas in some patients treated with isotretinoin may be a chance finding (SEDA-21, 164); retinoids may prevent or even cure certain malignancies (20).

Second-Generation Effects

Teratogenicity

Retinoids are strongly teratogenic (21). Pregnancy should be ruled out and an effective form of contraception must be used for at least 1 month before starting therapy, during therapy, and for at least 1 month (isotretinoin) or 2 years (acitretin) after therapy is stopped. Retinoid-induced teratogenicity has been reviewed (22,23).

There are few data about the safety of topical retinoids during pregnancy. The risk of teratogenicity of topical tretinoin, if any, appears to be minimal (SEDA-18, 164) (109). However, there is a case report (110).

- A baby was born missing its right ear and external auditory canal. At 20 months an MRI scan of the brain showed focal atrophy and encephalomalacia of the right parieto-occipital lobe. His mother had used topical tretinoin (Retin A 0.025%) on her face and a large surface of the back before conception and during the first 2–3 months of pregnancy. His father had used oral isotretinoin before conception.

This type of ear abnormality is a typical feature of retinoic acid embryopathy. Given the pattern of malformations in this child, the authors thought that maternal use of topical tretinoin had been responsible. Three other cases of fetal malformations after topical tretinoin use have been reported (111–113).

Multiple congenital anomalies occurred after exposure to isotretinoin in the first trimester (114).

- A neonate whose mother had taken isotretinoin 40 mg/day during the first 2 months of pregnancy had absent auricles, tachypnea, and feeding difficulties. There were signs of heart failure, and echocardiography showed a large subpulmonary ventricular septal defect (Taussig–Bing malformation) and a secundum atrial septal defect. Both great arteries originated from the anterior right ventricle, and there was tricuspid insufficiency. A cranial CT scan showed atresia of the external ear canal, tympanic membrane, middle ear, and antrum. Other ear structures were normal. The child died at home.

Previously published information on outcomes after maternal exposure to topical tretinoin has been limited to three case reports (111–113). A fourth case has been reported (110).

- A boy, born at 41 weeks weighing 4090 g, had no right auricle or external auditory canal. Before conception and during the first months of pregnancy his mother had used topical tretinoin (Retin A 0.025%) on her face and a large area of her back. She had also used vitamins during pregnancy. His father had used oral isotretinoin before conception. At 16 months the baby was babbling. Optokinetic response was diminished and there was no oculovestibular response. At 20 months he was non-verbal and had poor receptive language, compatible with cognitive impairment. A cranial CT scan showed calcification of the right posterior hemisphere and MRI showed reduction in the volume of the right cerebral hemisphere, an infarct in the deep basal ganglia, focal atrophy, and encephalomalacia of the right parieto-occipital lobe. MRA showed marked attenuation of the posterior cerebral artery with poor declination of the more distal cortical, temporal, and occipital branches. A PET scan showed severe hypometabolism of the right posterior parietal, occipital, and temporal lobes, right basal ganglia, and thalamus, and mild hypometabolism of the left cerebellum.

Susceptibility Factors

Renal disease

The concentration of vitamin A is raised in chronic renal insufficiency, because reduced filtration of low molecular proteins results in increased concentrations of retinol binding protein. A retrospective evaluation of 18 liver biopsies in 71 patients on hemodialysis taking therapeutic doses of vitamin A showed hyperplasia of stellate cells in 7, but no evidence of fibrosis (115).

In a patient with renal insufficiency, stellate cell hyperplasia was accompanied by fibrosis (116).

- A 51-year-old man, with a 9-year history of renal insufficiency and an alcohol intake of 4 U/week, underwent transplant nephrectomy. At surgery, ascites and liver cirrhosis were noted. A needle biopsy of the liver 1 month later showed nodular regenerative hyperplasia but no cirrhosis. There were subendothelial vacuolated cells, suggestive of modified stellate cells, and there was adjacent focal perisinusoidal fibrosis. His medications included one multivitamin/mineral supplement per day containing vitamin A 4000 IU. His vitamin A concentration was 1045 (reference range 490–720) ng/ml. Viral and antibody studies were negative.

Drug Administration

Drug formulations

A novel intravenous liposomal formulation of tretinoin (Atragen®, Aronex Pharmaceuticals Inc, The Woodlands, TX), which provides a reliable dose for

© 2006 Elsevier B.V. All rights reserved.

patients who are unable to swallow or absorb medications, has been evaluated in 69 patients with acute promyelocytic leukemia (117). Liposomal tretinoin (90 mg/m^2) was given every other day until complete remission or a maximum of 56 days. Treatment after complete remission was liposomal tretinoin with or without chemotherapy. Adverse effects (grade 1–2 according to the NCI common toxicity criteria) were the retinoic acid syndrome in 18 patients (grade 3/4 in 10), leukocytosis ($n = 36$), headache ($n = 46$), dry skin ($n = 23$), hypertriglyceridemia ($n = 23$), fever ($n = 18$), nausea ($n = 13$), stomatitis ($n = 11$), vomiting ($n = 10$), cheilitis ($n = 9$), exfoliative dermatitis ($n = 9$), rash ($n = 8$), myalgia ($n = 8$), liver enzyme abnormalities ($n = 7$), bone pain ($n = 6$), arthralgia ($n = 5$), raised LDH activity ($n = 4$), pseudotumor cerebri ($n = 4$; with severe headache, papilledema, increased CSF pressure, and absence of structural cranial lesions by CT or MRI scanning), hypercholesterolemia ($n = 4$), chills ($n = 4$), pruritus ($n = 3$), and diarrhea ($n = 2$).

Drug overdose

The possible symptoms and signs of overdosage are essentially the same as in hypervitaminosis A (see Table 1). The toxicity of overdosage appears to be low, and symptoms are restricted to headache and mucocutaneous adverse effects (118).

Drug–Drug Interactions

Alcohol

Concomitant intake of alcohol induces the transformation of acitretin to etretinate, which has a much longer half-life (84–168 days) (119).

Carbamazepine

No increase in seizure susceptibility was noted in a number of epileptic patients taking concomitant phenytoin, sodium valproate, or carbamazepine. However, it is recommended that carbamazepine concentrations be measured during therapy (12).

Tetracycline

Concurrent use of tetracycline has been considered contraindicated because of the risk of benign intracranial hypertension. However, although either compound alone can provoke this rare adverse effect, there is no evidence of any additive effect (12).

Vitamin B_{12} (cobalamins)

See also Vitamins

General Information

Vitamin B_{12} is a mixture of cobalamins. Dietary vitamin B_{12} is converted to the active forms, methylcobalamin (mecobalamin) and adenosylcobalamin. The Average Requirement of total cobalamins in adults is 1.0 microgram/day and the Population Reference Intake is 1.4 micrograms/day. The Lowest Threshold Intake is 0.6 micrograms/day. Hydroxocobalamin (rINN; vitamin B_{12a}) and cyanocobalamin (rINN) have been used therapeutically.

All the cobalamins have the same pattern of adverse reactions. The adverse effects of high doses of cobalamins include urticaria, eczematous and exanthematous skin lesions, and anaphylactic reactions (SEDA-4, 265), but it is not clear whether the reactions are caused by the drug itself, a preservative, or possibly by contaminants. High oral or parenteral doses of vitamin B_6 and especially hydroxocobalamin are also on rare occasions suspected to induce acne which is, however, always benign (SEDA-5, 347) (1). Several cases of vitamin B_{12}-induced folliculitis and acneiform eruptions have been described, in one case in connection with a patient receiving total parenteral nutrition (2).

Organs and Systems

Cardiovascular

Syncope was induced by intramuscular injection of hydroxocobalamin in a paraplegic patient (3).

- An 81-year-old man had been a prisoner of war 58 years before and had been fed mainly rice. At that time he had developed complete loss of power and sensation in the right leg, weakness in the left leg, and weakness and impaired sensation in the right arm; he had become almost blind and deaf in both ears. When he was given vitamin B tablets his sight became almost normal within 1 month, but recovery

© 2006 Elsevier B.V. All rights reserved.

of motor power was slower. In 1945 he returned home and was given injections of vitamin B_{12} on and off without adverse effects. In 1997 he had a serum vitamin B_{12} concentration of 91 ng/l (reference range 223–1132), a normal folate concentration, a hemoglobin of 15.7 g/dl, and an MCV of 95 fl. He was given intramuscular vitamin B_{12} 1 mg every 4–6 weeks. In 1998 he fainted about 10 minutes after an injection of vitamin B_{12}. His blood pressure was 60/30 mmHg. Soon after the next injection the patient fainted again and developed red patches and blisters over his arms, chest, and legs. Oral vitamin B_{12} without intrinsic factor resulted in 3.47% excretion in 24 hours. Vitamin B_{12} with intrinsic factor led to a urinary excretion of 1.49%. No reactions to oral vitamin B_{12} were reported.

Hematologic

A mild form of polycythemia with peripheral vascular thrombosis has been described in patients with pernicious anemia treated with high doses of vitamin B_{12} (4).

Immunologic

Allergy to vitamin B_{12} injection is infrequent, but can be serious. Positive results of basophil histamine release assay and skin testing suggest an IgE-mediated mechanism (5). Severe hypersensitivity to cyanocobalamin or hydroxocobalamin has been reported in patients who took the other cobalamin without further allergic reactions (6).

- A 45-year-old woman with pernicious anemia was given intramuscular hydroxocobalamin and developed mild generalized pruritus (7). Subsequent monthly injections of hydroxocobalamin 1 mg were followed by incrementally worsening pruritus and then frank urticaria. The last of nine injections was followed by urticaria, bronchospasm, and oropharyngeal angioedema, which responded to adrenaline. She underwent skin prick and intradermal testing with hydroxocobalamin and cyanocobalamin. Wheal-and-flare reactions occurred after injection of hydroxocobalamin, suggesting an IgE-mediated response. There was no reaction to cyanocobalamin. She subsequently had a reaction to subcutaneous cyanocobalamin 0.1 ml (100 micrograms) and then intramuscular cyanocobalamin 0.5 ml (500 micrograms). Her macrocytic anemia resolved with monthly cyanocobalamin. After 1 year she had an episode of delayed urticaria after a routine injection of cyanocobalamin. Skin prick and intradermal tests were again negative with cyanocobalamin, but there were wheal-and-flare reactions to hydroxocobalamin. She then tolerated monthly intramuscular cyanocobalamin for over 12 months.
- A 42-year-old woman who had received monthly intramuscular cyanocobalamin for 4 years developed Quincke's edema. She was given hydroxocobalamin instead, each injection being preceded by 4 mg of dexamethasone. After 13 years of this treatment she had not had any allergic reactions.
- A 35-year-old woman who had received monthly intramuscular hydroxocobalamin for 6 years developed anaphylactic shock immediately after a dose. Later she was given cyanocobalamin with terfenadine 120 mg/day for 2 days before each injection. After 3 years she had not had any allergic reactions.

Skin prick and intradermal tests, with increasing concentrations of hydroxocobalamin and cyanocobalamin, and histamine release tests on blood basophils with hydroxocobalamin and cyanocobalamin were negative in the second and third patients.

One way of dealing with vitamin B_{12} allergy is to use the alternative compound after skin testing to exclude cross-reactivity. If cross-reactivity occurs, desensitization may be considered. Alternatively, oral B_{12} can be used.

Vitamin D analogues

See also Vitamins

General Information

The group of D vitamins includes the following naturally occurring compounds:

- lumisterol (vitamin D_1)
- ergocalciferol (calciferol or vitamin D_2)
- colecalciferol (vitamin D_3)
- dihydrotachysterol (vitamin D_4)

© 2006 Elsevier B.V. All rights reserved.

- 25-hydroxycolecalciferol (calcifediol)
- 1α,25-dihydroxycolecalciferol (calcitriol)
- 24,25-dihydroxycolecalciferol.

Ergocalciferol is derived from ergosterol in the diet. Colecalciferol is derived from endogenous cholesterol. Both are also synthesized in the skin. Colecalciferol and ergocalciferol are converted in the liver by hydroxylation to calcifediol, which is weakly active. Calcifediol is activated in the kidneys by further hydroxylation to alfacalcidol, which is highly active, and calcitriol, which is weakly active. Calcitriol is deactivated by further hydroxylation in the kidney to 1α,24,25-trihydroxycolecalciferol.

Synthetic derivatives of vitamin D include:

- 1α-hydroxycolecalciferol (alfacalcidol)
- 19-nor-1,25-dihydroxycalciferol (paracalcitol) (1)
- 1α-hydroxycalciferol (doxercalciferol).

Of these alfacalcidol has been the most widely used. It is hydroxylated in the liver to calcitriol, thus bypassing the kidney. Unlike calcitriol, which acts in the small intestine to stimulate absorption, doxercalciferol remains inactive until it reaches the liver, where it undergoes transformation to active vitamin D (2). As a result, doxercalciferol minimizes the risk of hypercalcemia by 67–80%. The manufacturers claim that doxercalciferol is as potent as calcitriol in lowering parathyroid hormone concentrations.

Dietary intake and synthesis of vitamin D in the skin under the influence of ultraviolet light complement one another. In practice, the Population Reference Intake for adults is 5–10 micrograms/day and for infants and children 10–25 micrograms/day. Colecalciferol 1 microgram = vitamin D 40 IU.

The reference ranges for serum concentrations are [http://europa.eu.int/comm/food/fs/sc/scf/]:

- calcifediol 130–150 nmol/l
- calcitriol 50–145 pmol/l
- 24,25-dihydroxycolecalciferol 2–10 nmol/l.

Alfacalcidol and calcitriol have some advantages over calciferol, but their high potency involves a risk of hypercalcemia even after small dosage increments, because of increased intestinal calcium absorption. Because of this, constant vigilance is required to prevent hypercalcemia, especially in patients with chronic renal insufficiency and associated renal osteodystrophy.

Comparative studies

The efficacy of intravenous paricalcitol and calcitriol and the risks of hypercalcemia and hyperphosphatemia have been studied in an international, randomized, double-blind comparison in 38 patients in dialysis units (3). The end points were a reduction of at least 50% in baseline parathyroid hormone concentration and the occurrence of hypercalcemia and hyperphosphatemia. Paricalcitol was started at a dose of 0.04 micrograms/kg and increased in 0.04 micrograms/kg increments every 4 weeks to a maximum allowable dose of 0.24 micrograms/kg or until there was at least a 50% fall in serum parathyroid hormone concentration. Calcitriol was started at a dose of 0.01 micrograms/kg and increased in 0.01 micrograms/kg increments every 4 weeks to a maximum allowable dose of 0.06 micrograms/kg or until there was at least a 50% fall in serum parathyroid hormone concentration. Mean baseline serum parathyroid hormone, calcium, and phosphorus concentrations were similar. Reductions in parathyroid hormone occurred more rapidly with paricalcitol than with calcitriol, but there were no differences in serum calcium concentrations throughout the study between the groups. However, the respective percentages of subjects who had severe hyperphosphatemia (serum phosphorus over 0.84 mmol/l) after 8, 16, and 20 weeks were about 18, 16, and 14% in 19 patients treated with calcitriol and 6.8, 8.6, and 9.8% in 19 patients treated with paricalcitol. The results of this study suggest that paricalcitol reduces parathyroid hormone concentrations more rapidly than calcitriol does, with fewer episodes of hyperphosphatemia.

Placebo-controlled studies

In two placebo-controlled trials, 90% of dialysis patients with moderate to severe secondary hyperparathyroidism who received doxercalciferol for 16–24 weeks had about a 70% reduction in parathyroid hormone concentrations. The most frequently reported adverse effects include edema, headache, and malaise.

General adverse effects

Vitamin D intoxication is characterized by hypercalcemia and hypercalciuria as a result both of excessive gastrointestinal calcium absorption and of enhanced mobilization of calcium from bone (SEDA-8, 804) (4–6). Unintentional intoxication can result from the addition of vitamin D to food, especially to milk and milk products, for prevention of vitamin D deficiency. The established dosage for prophylaxis of vitamin D deficient rickets, 400 IU (10 micrograms), is commonly regarded as safe. The large vitamin D doses used in hypoparathyroidism, renal osteodystrophy, vitamin D-resistant rickets, and osteomalacia can predispose to intoxication. Close clinical and biochemical monitoring of patients taking vitamin D or vitamin D analogues is necessary, since intoxication can occur independent of dose and the period over which the drug has been taken.

The initial symptoms of hypervitaminosis D include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Renal function can be impaired at an early stage, with polyuria, polydipsia, nocturia, reduced urinary concentrating ability, and proteinuria.

The characteristic features of chronic intoxication are deposition of calcium salts in various tissues. A follow-up study of 24 children with vitamin D intoxication (13 900–200 000 IU/day) for up to 13 years showed that 23% of the patients had permanent damage. The severity of renal, neurological, and digestive symptoms was related to the daily dose, but the final consequences depended on the duration of overdosage (7). Vitamin D intoxication has also been seen after so-called "Stoss" prophylaxis in children, that is the use of single very

© 2006 Elsevier B.V. All rights reserved.

high doses of vitamin D, and it has therefore been suggested that this procedure should be avoided (8).

It has been postulated that it is calcifediol that is the main factor involved in vitamin D intoxication (9). The serum concentration of this metabolite can remain high for several months after ingestion of excessive amounts, at least in infants (SEDA-12, 329) (10).

In elderly people, the amount of body fat is usually increased and total body fluid is reduced. These changes affect drug distribution and should be considered when administering lipophilic substances such as vitamin D, which can have a higher relative distribution volume, a longer half-life, increased accumulation, and prolongation of the pharmacological effect. Reduced dosages of vitamin D should therefore be considered in older patients (11).

Allergic reactions to vitamin D are rare and tumor-inducing effects are not reported.

Organs and Systems

Cardiovascular

Some individuals develop hypertension in response to vitamin D, which in some of them may be directly related to hypercalcemia and which may be reversible when renal function is normalized (12). Metastatic calcification is observed in various tissues (13), but arterial calcification is the most usual. In some patients undergoing dialysis, calcification of the blood vessels has been so extensive that cannulation could not be performed (14).

Respiratory

Calcification of the lung from vitamin D is rare, but has been reported in an infant after ingestion of toxic doses (15).

Nervous system

There have been very occasional reports of mental disturbances, including depression (16), cerebellar ataxia, peripheral facial paresis, apathy, lack of interest, and (in cases of acute poisoning) even stupor (SEDA-8, 804) (17–19). Mental changes can occur before the appearance of any somatic symptoms. There may be a correlation between the seriousness of hypervitaminosis D and the extent of electroencephalographic changes (20–22).

Sensory systems

Band keratopathy has been reported in patients taking vitamin D (23), as have calcium deposits in the cornea and the conjunctiva (24).

Tympanic membrane calcification can lead to severe, irreversible conductive deafness (25).

Mineral balance

Hypercalcemia

A single high dose of vitamin D can usually be given without ill effects, even though some workers have described subsequent characteristic changes in the concentrations of phosphorus and calcium in the blood (SEDA-8, 804) (5,26,27). However, long-term administration, especially with intoxication, is characterized by hypercalcemia and hypercalciuria as a result both of excessive gastrointestinal calcium absorption and of enhanced mobilization of calcium from bone (SEDA-9, 637) (4–6). Hypercalcemia is not necessarily accompanied by clinical symptoms and disappears within 48 hours when the drug is withdrawn. In patients with hypoparathyroidism or chronic renal insufficiency, the rate of reversal of hypercalcemia after stopping treatment with the vitamin D analogues is slower than in healthy subjects. In these diseases, frequent control of blood biochemistry is recommended during treatment with vitamin D analogues (28).

In a comparative study the efficacy and adverse effects of calcitriol and ergocalciferol were investigated in 18 children with chronic renal insufficiency and histological evidence of renal osteodystrophy. Whereas therapeutic effects were similar with ergocalciferol and calcitriol, hypercalcemia was more common in the calcitriol-treated patients (11 episodes following calcitriol therapy and three episodes following ergocalciferol therapy) (29).

Calcitriol + calcium carbonate has been compared with calcium carbonate alone over 12 months in a prospective, randomized trial in 15 patients with secondary hyperparathyroidism (30). Calcitriol 2 micrograms was given after each dialysis; the dose of calcium carbonate was adjusted as needed to maintain calcium and phosphate concentrations at 2.4–2.6 and 1.0–1.5 mmol/l respectively. During the first 6 months, one patient taking calcitriol had an asymptomatic episode of hypercalcemia (2.8 mmol/l), which resolved on reduction of the dose of calcitriol to 1 microgram. In the control group two patients had asymptomatic episodes of hypercalcemia (each 2.9 mmol/l) during the first 6 months. There were two episodes of asymptomatic hypercalcemia (3.2 and 2.9 mmol/l) in two patients taking calcitriol during the last 6 months of the study, requiring a reduction in dose to 0.5 micrograms in one patient. There was one episode of hypercalcemia (2.8 mmol/l) in the control group during the last 6 months of the study.

Two cases of hypercalcemia following the administration of vitamin D analogues in end-stage renal insufficiency have been reported (31).

- A 10-year-old boy with terminal renal insufficiency and secondary hyperparathyroidism was treated with calcitriol (0.5 mg/day; 0.02 mg/kg). His serum calcium rose to 3.05 mmol/l with a parathyroid hormone concentration of 51 pg/ml (reference range 15–65 pg/ml; the target range is 2–4 times higher). Calcitriol was withdrawn, hemodialysis was performed, and oral calcium acetate 2 g/day was administered as a phosphate binder. His calcium returned to normal after 4 months.
- A 12-year-old girl with terminal renal insufficiency was given alfacalcidol (0.5 mg/day; 0.02 micrograms/kg) and calcium carbonate (1 g/day) and developed calcification of the papillary muscles, of the ventricular septum, and of the atrioventricular valves, with sinus bradycardia and heart block that required a cardiac pacemaker. Her serum calcium was 2.7 mmol/l, phosphate 3.14 mmol/l, and parathyroid hormone 23 pg/ml. Calcidiol and calcium carbonate

© 2006 Elsevier B.V. All rights reserved.

were withdrawn and hemodialysis was continued. She was given Sevelamer hydrochloride 4 g/day as a phosphate-binder and then several months later calcium acetate 5.2 g/day. After a further 4 months her laboratory values were near the upper limit of the reference ranges.

Because of its potent effects on parathyroid hormone, intestinal calcium absorption, and bone calcium mobilization, calcitriol can cause hypercalcemia, often precluding its use in therapeutic doses (32). Hyperphosphatemia is also a persistent problem in patients on chronic hemodialysis and can be aggravated by therapeutic doses of calcitriol. The use of large doses of calcium carbonate or acetate to control phosphate absorption can increase the risk of hypercalcemia from calcitriol (33).

Severe vitamin D intoxication with spontaneously reversible anemia and bisphosphonate-responsive hypercalcemia has been reported (34).

- A 31-year-old woman developed diffuse musculoskeletal pain. She had been taking calcium and dihydrotachysterol up to 4 mg/day for 6 months for hypoparathyroidism after subtotal thyroid resection. She had severe hypercalcemia (4.1 mmol/l), no detectable intact parathyroid hormone, renal insufficiency (serum creatinine 486 μmol/l), and a normochromic anemia (6.6 g/dl). Rehydration and forced diuresis initially improved renal function and reduced the serum calcium concentration, but the calcium concentration after 4 weeks was still 3.0 mmol/l and it did not normalize until she was given a single intravenous dose of pamidronate 15 mg.

Severe hypercalcemia in a child receiving vitamin D was associated with hyperlipidemia (35).

- An 11-month-old girl developed polyuria, polydipsia, and vomiting. She had been given vitamin D 400 IU/day for just 1 month. A misdiagnosis of rickets was made, and 1 month before admission she was given bolus vitamin D 600 000 IU in two doses 15 days apart. Her serum calcium concentration was 5.5 mmol/l; total cholesterol, high density lipoprotein cholesterol, very low density lipoprotein cholesterol, low density lipoprotein cholesterol, and triglyceride concentrations were respectively: 6.37 mmol/l, 0.77 mmol/l, 1.37 mmol/l, 4.1 mmol/l, and 3.0 mmol/l. After 16 days of therapy with intravenous fluids, furosemide, glucocorticoids, calcitonin, magnesium sulfate, and phosphorus, her serum calcium concentration fell below 3 mmol/l. Her hyperlipidemia resolved gradually.

Ectopic calcification

The prevalence and etiology of ectopic calcification due to alfacalcidol and associated susceptibility factors have been examined in 60 patients with systemic lupus erythematosus (13). The prevalence of ectopic calcification was 40%. Localization of calcification was in peripheral arteries (6.7%), in periarticular areas (33%), and in other soft tissues (17%). The incidence of lupus nephritis and nephrotic syndrome were significantly higher in those with ectopic calcification. Total protein concentrations (70 g/l) in patients with ectopic calcification were significantly lower than in patients without calcification (75 g/l). Significantly more of the patient with ectopic calcification had received alfacalcidol (63 versus 19%). The authors concluded that alfacalcidol therapy and lupus nephritis increase the risk of ectopic calcification in patients with systemic lupus erythematosus.

Hypomagnesemia

Primary infantile hypomagnesemia is an uncommon cause of neonatal hypocalcemic seizures, but it is an important condition to recognize, because magnesium supplementation corrects the magnesium deficit, reverses the hypocalcemia due to hypoparathyroidism, and prevents further seizures (36). There is evidence of genetic heterogeneity, but the number of gene loci is not known and phenotypic classification is still evolving. Several reports have described primary infantile hypomagnesemia in children of unaffected Arab parents (37,38). One of the first reported patients, now an affected adult, used calcitriol as an alternative to the parenteral magnesium injections that had been part of his life for more than 20 years and developed hypomagnesemia (39).

- A 22-year-old man, first reported at 4 months of age and currently free of neurological deficits, had had intermittent and chronic diarrhea due to large oral doses of magnesium for hypomagnesemic tetany. On the hypothesis that modest hypercalcemia might prevent the tetany, he was given calcitriol 5 micrograms/day for 5 days. Despite the resultant increase in serum calcium concentration, he developed tetany and a fall in serum magnesium concentration from 0.63 to 0.39 mmol/l (reference range over 0.65 mmol/l). The calcitriol was withdrawn, and 33% of his usual oral magnesium supplement was given by continuous nasogastric infusion; the serum magnesium concentration rose to 0.60 mmol/l.

Mouth and teeth

High doses of vitamin D can affect dental development. In one case, caused by incorrectly fortified milk, there was dental hypoplasia and focal pulp calcification (40).

Pancreas

In patients with pancreatitis associated with hypercalcemia of unclear origin, vitamin D poisoning can be responsible, especially when episodes are recurrent (41). Metastatic calcification of the pancreatic ducts has also been reported (42,43).

Urinary tract

Daily doses of more than 40 micrograms of vitamin D can cause calcium deposition in the kidneys. Renal damage is largely due to this. Tubular function is impaired first, glomerular function later (44,45). Medullary nephrocalcinosis can develop as a result of therapy with high doses of vitamin D combined with calcium; this is mainly seen in infants and schoolchildren. Ultrasound screening of children treated with high doses of vitamin D and calcium is therefore recommended (46). Early high-dosage prophylaxis or treatment can cause nephrocalcinosis and hypercalciuria in children (47,48).

© 2006 Elsevier B.V. All rights reserved.

There is controversy about whether the long-term use of C1-hydroxylated vitamin D analogues in non-dialysed patients with chronic renal insufficiency is associated with an impairment of glomerular filtration rate (SEDA-9, 639) (49). Treatment with these drugs should be restricted to patients with severe renal osteodystrophy. A proper dose should be administered in order to avoid a deleterious effect on renal function. Serum calcium and creatinine concentrations should be monitored carefully. The treatment should be withdrawn if hypercalcemia develops.

A comparison between treatment of postmenopausal osteoporosis with calcitriol together with etidronate or calcitonin showed no improvement in spinal bone mineral density, but rather a high rate of adverse events indicating nephrotoxicity (50).

There have been increasing numbers of reports of nephrocalcinosis diagnosed by renal ultrasound in patients with X-linked hypophosphatemia treated with vitamin D and phosphate, and a study of a small group of treated and untreated patients pointed to an association between this therapy and nephrocalcinosis (51).

In a French analysis of 22 510 urinary calculi performed by infrared spectroscopy, drug-induced urolithiasis was divided into two categories: first, stones with drugs physically embedded ($n = 238$; 1.0%), notably indinavir monohydrate ($n = 126$; 53%), followed by triamterene ($n = 43$; 18%), sulfonamides ($n = 29$; 12%), and amorphous silica ($n = 24$; 10%); secondly, metabolic nephrolithiasis induced by drugs ($n = 140$; 0.6%), involving mainly calcium/vitamin D supplementation ($n = 56$; 40%) and carbonic anhydrase inhibitors ($n = 33$; 24%) (52). Drug-induced stones are responsible for about 1.6% of all calculi in France. Physical analysis and a thorough drug history are important elements in the diagnosis.

Skin

The efficacy, safety, and tolerability of twice-daily calcitriol ointment 3 micrograms/g ($n = 60$) has been investigated and compared with 0.25–2% dithranol cream (once daily for 30 minutes; $n = 54$) in an 8-week prospective, randomized, open, parallel-group trial in 114 patients with plaque psoriasis (53). Skin irritation was reported by three patients who used calcitriol and by 39% of those who used dithranol. Three patients who used calcitriol and four who used dithranol reported adverse effects on the skin (pruritus, erythema, rash, dry skin, eczema). One patient with 75% skin involvement used 3.38 mg of calcitriol over 56 days (about 140 g of ointment per week without any effect on serum calcium).

Vitamin D_3 has been reported to cause hyper-reactivity of skin with pseudoxanthoma elasticum (39).

- A 68-year-old woman with pseudoxanthoma elasticum was given oral vitamin D_3 0.25 micrograms/day. After 2 weeks she developed new yellow papules on pre-existing plaques on the neck and abdomen, without itching or pain. Biopsy showed a thicker epidermis and more abundant calcium deposition than in a biopsy before treatment. Electron microscopy showed electron-dense deposits between the degenerated elastic fibers, which had been surrounded by normal collagen fibers before treatment. After treatment with vitamin D_3 there were lucent areas that suggested unusual mineralization in association with electron-dense deposits. Serum concentrations of calcium were within the reference range throughout.

Musculoskeletal

In children with chronic renal insufficiency, secondary hyperparathyroidism has been treated with intermittent calcitriol therapy. There is some reason to believe that growth is negatively influenced by this therapy, possibly due to the direct inhibitory effects of calcitriol on chondrocyte activity (54).

Of 19 chronic hemodialysis patients taking a combination of alfacalcidol and calcitriol for 12 months, six had increased bone resorption, six had reduced bone resorption, and seven had no change. Histologically documented aggravation of hyperparathyroidism was associated with a statistically significant increase in plasma concentrations of phosphate and parathyroid hormone. The administration of vitamin D analogues may therefore be either beneficial or noxious depending on whether or not induced hyperphosphatemia is adequately prevented (55).

A child with X-linked hypophosphatemic rickets developed vitamin D intoxication during treatment with alfacalcidol and phosphorus. Besides the usual findings in this condition he had precocious synostosis of the skull, with signs of raised intracranial pressure. In view of earlier reports of coincidence of craniostenosis and X-linked hypophosphatemic rickets the authors pointed to the possibility that intoxication with alfacalcidol was the precipitating factor. In addition, hypersensitivity to alfacalcidol was found 2 months after the end of treatment, with normal concentrations of calcitriol (56).

In severe hypervitaminosis D signs of hypomineralization and demineralization of the long bones and calcification of the soft tissues can be seen radiologically. Some cases of hypervitaminosis D with hypercalcemia and acute renal insufficiency have been reported in patients with osteoporosis or osteomalacia who have taken pharmacological doses of vitamin D for extended periods of time. This suggests that such therapy should be avoided. Vitamin D for prophylaxis or treatment of osteoporosis has no benefits greater than those from calcium alone or calcium with estrogens and fluoride (SEDA-14, 332) (57).

Second-Generation Effects

Teratogenicity

High doses of vitamin D during pregnancy, possibly together with genetic factors, can precipitate a severe form of idiopathic hypercalcemia and a clinical abnormality in the offspring, comprising valvular stenosis of the aorta, peculiar facies, mental retardation, and abnormal tooth formation. However, such abnormalities can also occur in the absence of hypervitaminosis D, and the doses needed to treat hypoparathyroidism in pregnancy, for example 100 000 IU/day, have been well tolerated (58,59).

© 2006 Elsevier B.V. All rights reserved.

- A 28-year-old woman with hereditary insensitivity to calcitriol took oral calcitriol in doses of 17–36 micrograms/day (usual dose for hypocalcemia 0.25–1.0 micrograms/day) during pregnancy (60). Her serum calcitriol concentration was extraordinarily high throughout gestation. At delivery, the calcium concentration was 2.40 mmol/l in maternal serum and 2.52 mmol/l in cord serum. The concentration of total calcitriol in cord serum was high (470 pg/ml; normal mean for placental venous serum 19 pg/ml); mostly derived from transplacental passage of maternal calcitriol and not from fetoplacental biosynthesis. The child had mild hypercalcemia in the first 2 days of life, showing that the calcitriol measured in the cord serum was active in vivo. The child had no somatic features of the syndrome of elfin facies and supravalvular aortic stenosis.

This case demonstrates that high serum vitamin D concentrations need not be teratogenic, although the maternal metabolite can enter the fetal circulation.

Susceptibility Factors

Age

Neonates with subcutaneous fat necrosis can have transient hypersensitivity to vitamin D (61). There is a relation between the syndrome known as infantile idiopathic hypercalcemia and vitamin D intake and/or vitamin D metabolism (26).

Renal disease

There is increased sensitivity to vitamin D in patients who are undergoing renal dialysis and who have an abnormal calcium/phosphorus ratio. Patients on continuous ambulatory peritoneal dialysis (CAPD) who develop secondary hyperparathyroidism may already have low bone turnover or adynamic bone lesions, and if treated indiscriminately with calcitriol their low bone turnover can get worse (62).

Other features of the patient

There is increased sensitivity to vitamin D in sarcoidosis (63).

Drug Administration

Drug formulations

Calcium combined with colecalciferol in one tablet (Orocal) has been compared with calcium administered in a sachet (Ostram) plus colecalciferol as a separate tablet (Devaron) in 119 elderly women (64). Three patients taking the combined formulation withdrew because of adverse effects (all gastrointestinal disturbances), but none of those taking the separate tablets. Of those taking the combined tablet ($n = 59$) 43 and 39 patients had adverse effects at 6 and 12 months respectively, compared with 46 and 41 of the 60 patients taking separate tablets. For the most part, patients complained of arthralgia and gastrointestinal complaints. None of the patients had symptomatic calcium nephrolithiasis.

Drug overdose

Fortification of margarine and dairy products with vitamin D is mandatory in some countries, and permitted in others. Infant formula and liquid milk are commonly fortified with vitamin D, and two studies have shown that fortification can be vastly in excess of what is stated on the label (65,66). In one case this was detected when hypervitaminosis D was found in the population. In one case hypercalcemia occurred after prolonged feeding with a premature formula that was higher than normal in vitamin D (67).

Vitamin D intoxication occurred in a 7-week-old infant after an overdose of calcitriol (68).

- A 7-week-old boy lost weight, became dehydrated and apathetic, and developed muscular hypotonia and mild leukocyturia. His serum calcium was 4.1 mmol/l, his urine calcium 3.1 mmol/l, and his serum phosphate 51 micrograms/ml. He had been given vitamin D 200 000 U/day for 30 days in error, instead of the usual 500 U/day. Parathyroid hormone was unmeasurably low. The serum concentration of calcitriol on day 1 was 61 pg/ml (reference range 20–135), and the serum concentrations of calcifediol were 980, 2660, and 8280 ng/l (reference range 100–620) on days 8, 20, and 34 respectively. He was treated with a calcium-free diet, prednisolone, phenobarbital, fluids, and furosemide for 8 weeks. His nephrocalcinosis persisted and after 8 months a large area of suppurative, aseptic, subcutaneous necrosis in the left upper leg perforated. At 2 years of age he was well.

As routine prophylaxis with vitamin D is not entirely safe, because of errors of prescription or dispensing, and because of its narrow therapeutic range one should remember that the daily requirements of 100–400 U are usually met by the fortification of formula milk with 40 U/100 g alone. When an infant is breastfed the mother should ensure that her diet is adequate in vitamin D.

A case of accidental ingestion of a veterinary vitamin D concentrate (colecalciferol in peanut oil; 2 million IU/g) as a cooking oil sheds some light on the mechanism of pathogenesis in hypercalcemia in vitamin D toxicity. Serum concentrations of calcifediol in nine of the cases were 8–15 times greater than the upper limit of the reference range, while total calcitriol concentrations were increased in only three patients. The percentage of unbound calcitriol was increased in all patients, as was the total calcitriol concentration. Increased unbound calcitriol concentrations might play a role in the pathogenesis of hypercalcemia in vitamin D toxicity (69).

Hypercalcemia has been associated with the ingestion of an over-the-counter vitamin D supplement (70).

- A 42-year-old man who for 2 years had taken a supplement containing vitamin D_2 had a serum calcium concentration of 3.75 mmol/l and a serum calcifediol concentration of 487 ng/ml (reference range 9–47). He had normal concentrations of calcitriol, parathyroid hormone, angiotensin-converting enzyme, and thyroid hormone, and had normal bone marrow, radiography, and CT of the chest, neck, and abdomen. Vitamin D_2

© 2006 Elsevier B.V. All rights reserved.

was withdrawn and he was rehydrated. He was advised to wear sunscreen at all times when outdoors. Three months after discharge the results of all blood tests were in the reference ranges, including serum concentrations of calcium and calcifediol.

Examination of three lots of the over-the-counter formulations the patient had used showed mean vitamin D contents of 1.3, 13, and 22 mg/g of powder. The patient had taken 3 g/day, or 156 000–2 604 000 IU/day of vitamin D_2, which is about 80–1300 times the recommended safe upper limit of 2000 IU/day.

Drug–Drug Interactions

Anabolic steroids

The combined effects of vitamin D, calcium, and anabolic steroids in the treatment of senile osteoporosis have been investigated (71). Neither methandienone nor vitamin D_3 alone but only the two together seemed to increase coronary morbidity and mortality, and possibly in women only. Simultaneous use of these two drugs should be avoided.

Calcium carbonate

Symptomatic reversible hypercalcemia was seen in two elderly patients taking apparently safe amounts of vitamin D and thiazide diuretics. Their unusual susceptibility to this effect resulted from an interaction with calcium carbonate which had been taken simultaneously. In the presence of other predisposing factors, hypercalcemia can develop in patients taking calcium carbonate 5–10 g/day (72,73).

Enzyme inducers

Anticonvulsants (barbiturates and phenytoin) and other drugs that induce liver enzymes (such as rifampicin) can accelerate the hepatic catabolism of vitamin D and can lead to reduced serum concentrations of calcifediol and osteomalacia. Prophylactic vitamin D treatment of patients taking long-term enzyme inducers can be helpful and should be given at least in cases of anticonvulsant-drug-induced osteomalacia (74,75).

Vitamin E

See also Vitamins

General Information

Vitamin E is a family of compounds that include several different isomers of tocopherols and tocotrienols, of which the most important is thought to be alpha-tocopherol, the form of vitamin E that has mostly been used in clinical trials (1). The actions of the different isoforms have not been fully elucidated.

It was suggested many years ago that vitamin E could be useful in patients with peripheral arterial disease, but the evidence is meager and incomplete. Nowadays, vitamin E is expected to have a role in the prevention of atherosclerosis, through inhibition of oxidation of low-density lipoprotein. The hypothesis that oxidative modification of low-density lipoprotein contributes to the progression of atherosclerosis is supported by an impressive amount of in vitro and animal data. Some epidemiological studies have associated high dietary intake or high serum concentrations of alpha-tocopherol with a reduced risk of cardiovascular events. Large intervention studies with clinical endpoints have tested the hypothesis that daily supplementation with a high dose of alpha-tocopherol reduces ischemic vascular events. In over 2000 patients there was a substantial reduction in non-fatal myocardial infarction, but not in cardiovascular deaths (2). Daily administration of 400 and 800 IU of vitamin E was well tolerated, and only 11 patients stopped treatment because of diarrhea, dyspepsia, or a rash. Withdrawals due to adverse effects were equally distributed between the placebo group and the two treatment groups.

Since vitamin E requirements depend on dietary polyunsaturated fatty acids, which vary considerably between individuals, it has not been seen as expedient to establish a single Population Reference Intake value.

General adverse effects

Several reviews of the adverse effects of vitamin E have been published (3,4), especially relating to premature infants (5), in whom high doses have been associated with infectious complications and fatal hepatic failure. In adults, thrombophlebitis, thromboembolism, pulmonary embolism, hypertension, fatigue, gynecomastia, and breast tumors have been described as particularly serious effects of vitamin E, but there is little evidence about their frequency. Diarrhea and abdominal pain can occur. For some of these effects there seems to be a dose relation. A dose of 800 mg/day for 30 days had no reported adverse effects in healthy elderly subjects (6). Table 1 shows reported adverse effects related to dosage in a review of about 50 publications on vitamin E (7).

Organs and Systems

Cardiovascular

Vitamin E 300 mg/day can increase serum cholesterol by an average of 1.9 mmol/l (74 mg/100 ml) (8). It is therefore advisable to use vitamin E with caution in patients with a family history of heart disease. Some studies have shown that vitamin E can prevent atherosclerosis and serious adverse events were not reported in these studies (2,9,10).

Hematologic

Significant depression of bactericidal activity of leukocytes and mitogen-induced lymphocyte transformation occurred after the administration of dl-tocopherol 300 mg/day for 3 weeks (11).

Reduced platelet adhesion to collagen has been described (12), and experimentally confirmed (13) and has been seen with doses of vitamin E from 400 mg/day (14).

Table 1 Adverse effects of high doses of vitamin E

Dosage (mg/day)	Symptoms or changes
	Clinical effects
>300	Gastrointestinal irritation, nausea, vomiting, headache, muscular weakness, dizziness, stomatitis, visual complaints
400	Thrombophlebitis, urticaria, vaginal bleeding
800	Faintness, fatigue, creatinuria
1200	Ecchymoses
1600	Deterioration of angina pectoris
Unknown	Deterioration of diabetes mellitus
Unknown	Transient hypertension
Unknown	Allergic contact dermatitis
Unknown	Gynecomastia, breast cancer
	Laboratory findings
300	Increased concentrations of lipids, cholesterol, carotenoids, and coagulation factors
>300	Reduced incorporation of thymidine into phytohemagglutinin-stimulated lymphocytes, reduced bactericidal activity of leukocytes, and reduced blood glucose concentrations
600	Decreased concentrations of triiodothyronine and thyroxine in serum
600	Increased concentrations of free cholesterol in LDL and VLVD fractions
800	Increased serum creatine kinase, creatinuria
1000	Increased excretion of steroids in the urine
1200	Increased warfarin action
Unknown	Increased dehydroepiandrosterone concentrations in blood
Unknown	Increased gonadotrophin concentrations

Skin

Although there is no proof of any beneficial effects of topical use of vitamin E, it continues to be popular. Allergic contact dermatitis has been reported rarely (15).

Susceptibility Factors

Age

Premature neonates are reported to have a relative deficiency of vitamin E at birth, which has been associated with hemolytic anemia (16). Since there was an increased incidence of necrotizing enterocolitis when oral tocopherol was given to such infants (7,8,17,18), parenteral tocopherol was for a while recommended for use in very ill neonates (19,20).

There were increasing numbers of commonly fatal cases of the so-called "E-Ferol syndrome" during the 1980s (SEDA-12, 329) (21), a condition characterized by progressive unexplained thrombocytopenia, renal dysfunction, cholestasis, and ascites (22). E-Ferol was an intravenous vitamin E formulation, but the syndrome was subsequently shown to be due to polysorbate 80, which was used as an emulsifier in the formulation (23–25).

Preterm infants receiving under 25 mg/kg/day of tocopherol acetate intravenously had highly variable serum tocopherol concentrations. High serum concentrations correlated with the occurrence of necrotizing enterocolitis (26).

An increased incidence of infection, even sepsis after intramuscular injection, as an adverse effect of megadose vitamin E therapy in very low birth weight infants was first reported in Japan in 1986 (SEDA-12, 330). In a review of the literature in 1992 it was concluded that pharmacological serum concentrations of vitamin E might predispose premature infants to infectious complications, possibly caused by an inhibitory effect of vitamin E on the formation of superoxide anion in leukocytes (27).

There was a statistically significant increase in the risk of retinal hemorrhage with parenteral vitamin E in premature infants (28). This has led some researchers to conclude that tocopherol should not be recommended for the prevention of retinopathy in prematurity (29), particularly in infants with birth weights of less than 1 kg.

Other features of the patient

An increased tendency towards gingival bleeding was noted in a recent 7-year prospective study of smokers who had been given alpha-tocopherol supplementation in comparison with non-receivers. Acetylsalicylic acid further increased the risk of bleeding.

Drug–Drug Interactions

Acetylsalicylic acid

Alpha-tocopherol supplementation may increase the risk of clinically significant bleeding, particularly when it is combined with acetylsalicylic acid (30). Although acetylsalicylic acid and its derivatives are widely used, reliable pharmacoepidemiological data about drug usage frequency in the population are sparse. Among reports of serious adverse effects resulting from acetylsalicylic acid and other salicylates (31–37), of special interest are potential adverse effects in those who concurrently take vitamin E formulations (38,39).

The first pharmacoepidemiological survey was published in 1995, covering data from 1984 to 1988 (40), and the population-based data collected in Germany from 1984 to 1999 have been analysed, including data from five epidemiological surveys, concerning total drug usage, physiological, clinical chemistry and hematological data, and information about the serum concentrations of active drugs and/or their metabolites (40). The data were analysed with regard to the usage of salicylates and drugs

© 2006 Elsevier B.V. All rights reserved.

with potential interactions relevant to the highly sensitive balance between hemostasis and bleeding. Special attention was paid to serum concentrations of the various tocopherols, because of their potential activity in anticoagulation processes (39,41,42).

The data are representative of the resident population aged 25–69 years in the first four surveys and the age group 18–79 years in the last (1997–99), covering more than 20 000 study participants.

Patient drug usage data for the 7 days before the clinical examination were recorded using a standardized questionnaire in all the surveys (40). Measurements of salicylic acid and tocopherols were by HPLC with fluorescence detection or GC/MS (43).

In male users of salicylates and vitamin E the frequency of co-medication with lipid lowering drugs was 14%, with cardiovascular drugs 11%, and with analgesics 9%. Of female users of salicylates and vitamin E, 23% also took mineral products, 11% thyroid drugs, 10% estrogens, and 9% beta-blockers.

In all surveys salicylate use was higher in women (14%) than men (12%). Owing to massive advertising, vitamin E consumption has risen since the first survey, and was 5.6% in women and 3.6% in men in the German population aged 18–79 years (survey 1997–99). Co-medication with salicylates was observed in 17% of the vitamin E users (55% women, 45% men) and 90% of the reported concomitant use was in those over 50 years.

Mean salicylate concentrations in those who used acetylsalicylic acid as an analgesic were 8.3 μmol/l in 1985, and 16.5 μmol/l in 1988, 1991, and 1998, while salicylate concentrations in subjects who used acetylsalicylic acid as an antiplatelet drug fell from 9.8 μg/ml in 1985 to 7.8 μg/ml in 1988, 3.0 μg/ml in 1991, and 0.8 μg/ml in 1998. This fall in serum salicylate concentrations reflects changes in the usual dose of acetylsalicylic acid.

In contrast the mean concentrations of α-tocopherol in vitamin E users increased from 28 μmol/l in 1985 to 29 μmol/l in 1988, 35 μmol/l in 1991, and 56 μmol/l in 1998. Controls not taking any medications had much lower serum concentrations of α-tocopherol (7.5, 9.8, 11.8, and 18.3 μg/ml). Concentrations of β-tocopherol, γ- tocopherol, and δ-tocopherol in users of vitamin E were lower by up to 50% in users of vitamin E formulations. From these data the authors concluded that there is a considerable risk in the availability of over-the-counter drugs, especially those that can affect the balance between blood clotting and hemorrhage, such as salicylates and α-tocopherol. Since women over 40 in particular tend to use so-called dietary supplements, in the belief that such products might prevent illness, and because there is unrestricted advertising in the mass media, physicians should obtain a clear medication history from their patients.

The fact that blood concentrations of β-tocopherol, γ-tocopherol, and δ-tocopherol are lowered by α-tocopherol (42) should be taken into account in investigations on the clotting and bleeding balance and in cancer research.

Oral anticoagulants

Vitamin E therapy in vitamin K-deficient subjects and subjects taking anticoagulants reduces active plasma prothrombin concentrations (44).

There have been two cases of coagulation disorders with the herbal drug cucurbicin, each tablet of which contains vitamin E 10 mg (45). Cucurbicin is an approved herbal drug in Sweden, traditionally used for micturition difficulties. The active components are extracts from the fruit of *Serenoa repens* and the seed of *Cucurbita pepo*.

- A 73-year-old man with a common cold, who had been taking cucurbicin three tablets daily for more than 1 year, developed a coagulation disorder, with an international normalized ratio (INR) of 2.1, despite a normal albumin concentration and no anticoagulant treatment. His INR improved to 1.4 on treatment with vitamin K, but did not normalize until cucurbicin was withdrawn 1 week later.
- A 61-year-old man, who had taken warfarin and simvastatin for a long time and had an INR of 2.4, started to take cucurbicin five tablets daily for micturition difficulties. After 6 days his INR had increased to 3.4. After withdrawal of cucurbicin the INR returned to the previous value within 1 week.

No anticoagulant effect has been reported with either of the major components of cucurbicin. However, vitamin E antagonizes the effect of vitamin K and can cause an increased risk of bleeding, especially in patients taking oral anticoagulants. The amount of vitamin E in cucurbicin that these two patients consumed was 30–50 mg/day, corresponding to the recommended dose of 40–50 mg daily for vitamin E deficiency. The two cases suggest that caution should be exercised when cucurbicin is used concurrently with warfarin.

Vitamin K analogues

See also Vitamins

General Information

Vitamin K is the name of a group of compounds, all of which contain the 2-methyl-1,4-naphthoquinone moiety. Common nomenclature is:

- vitamin K_1 (phytomenadione; rINN)
- vitamin K_2 (phytonadione; rINN)
- vitamin K_3 (menadione; rINN).

Vitamin K is routinely administered in many countries to newborn babies in varying doses and by various routes, most commonly either orally or by intramuscular injection, to prevent hemorrhagic disease of the newborn (see Table 1).

Phytomenadione given intravenously is generally tolerated well. However, intravenous administration of small amounts (2–5 mg) can be followed by severe short-lasting cyanosis, dyspnea, tachycardia, and low blood pressure in patients with cardiac failure. Flushing and sweating can occur. Anaphylactoid reactions may be due to the excipient Cremophor EL. The most important adverse effects are jaundice and kernicterus, which can occur in small and premature babies, even after small doses, probably because of immature liver function.

Organs and Systems

Cardiovascular

Results of intravenous administration of 100 sequential doses of vitamin K in 45 patients (34 men, 11 women) have been retrospectively reviewed (1). Vitamin K_1 was administered as Aquamephyton. The dose averaged 9.7 (range 1–20) mg. The mean age was 44 (range 18–66) years. Many of the patients were seriously ill and had significant underlying surgical and medical problems, as evidenced by the fact that 16 died. However, none of the deaths was attributable to vitamin K. In the 11 instances in which the duration of administration was noted, the mean time was 49 (range 12.5–60) minutes. Only one patient had an episode of transient hypotension.

- A 37-year-old man with a history of ethanol abuse presented with hepatic failure and non-cardiogenic pulmonary edema after an overdose of paracetamol, codeine, ibuprofen, and diazepam. He received two doses of Aquamephyton (phytonadione) over 2 days and 10 minutes after the second dose his blood pressure fell to 79/40 mmHg.

In this study the incidence of adverse effects was 1%, contrasting with the impression that one obtains from reading the medical literature on vitamin K, which suggests an overall incidence of less than 1%.

Nervous system

Kernicterus can occur in small and premature babies, even after small doses of vitamin K, probably because of immature liver function. In its 1997 clinical practice guidelines, the Canadian Paediatric Society recommended that, in order to prevent haemorrhagic disease of the newborn, phytomenadione be given as a single intramuscular injection to all newborns within 6 hours of birth, in a dose of 1 mg for infants with a birth weight of more than 1500 g and half this dose for smaller infants. The dose is crucial, since overdosage carries a serious risk of kernicterus, especially in premature infants. There is only a remote possibility that this treatment might increase the risk of childhood cancer.

Cerebral vein thrombosis developed after the administration of 10 mg of phytomenadione in two patients with chronic intestinal inflammation assumed to be part of an autoimmune disease (2).

Hematologic

High doses of vitamin K can occasionally cause hemolytic anemia (3).

Severe hemolysis has been attributed to vitamin K in patients with glucose-6-phosphate dehydrogenase deficiency, particularly if infection is present (4,5).

In severe hepatocellular disease the prothrombin concentration can be further depressed by high doses of vitamin K (6,7).

Skin

Skin reactions have been observed after intramuscular injection of phytomenadione.

Presentation

The English-language literature on adverse skin reactions associated with intramuscular or subcutaneous phytomenadione has been reviewed (8). Vitamin K is generally well tolerated subcutaneously or intramuscularly. However, erythematous eczematous plaques have been well documented. Of 39 skin reactions due to

Table 1 Classification of hemorrhagic disease of the newborn

Syndrome	Time of presentation	Common bleeding sites	Comments
Early disease	0–24 hours	Cephalohematoma, intracranial, intrathoracic, intra-abdominal	Maternal drugs a frequent cause (for example warfarin, anticonvulsants)
Classic disease	1–7 days	Gastrointestinal, skin, nasal, circumcision	Mainly idiopathic, maternal drugs
Late disease	2–12 weeks	Intracranial, skin, gastrointestinal	Mainly idiopathic, can be the presenting feature of an underlying disease (for example cystic fibrosis, α_1-antitrypsin deficiency, biliary atresia; there is often some degree of cholestasis

© 2006 Elsevier B.V. All rights reserved.

phytomenadione, 32 were eczematous and 91% of the patients were women, average age 39 (range 9–64) years; in four cases there were small vesicles within the plaques (9–12).

As a rule, only a rash occurs, generally after high doses of the oil-soluble analogue. However, intramuscular injection of phytomenadione can also cause lumbar scleroderma around the injection site. The scleroderma is reported to develop in four stages; erythematous, erythematous pigmented, established scleroderma, and resolvent scleroderma. Localized pseudoscleroderma (Texier's syndrome) has also been reported (13). This particular adverse reaction has occurred mainly in patients with hepatic insufficiency (SEDA-12, 330), but skin reactions have also been seen in patients with a normal hepatic condition (14,15). Brown pigmentation in the trochanteric region has been reported in a patient with cirrhosis.

Localized eczema at the site of subcutaneous injection has been reported (8).

- A 50-year-old woman taking warfarin had an INR of 8 and was given phytomenadione 10 mg subcutaneously (Sabex, containing propylene glycol 2% and polyethylene glycol 10%) and 12 hours later another 5 mg. One week later she developed two red, pruritic, warm, indurated areas, measuring 2 × 4 and 8 × 10 cm, at the two separate injection sites. A skin biopsy showed minimal spongiosis of the epidermis and an edematous dermis with a dense perivascular lymphocytic infiltrate and numerous eosinophils.

A severe localized and subsequently generalized dermatitis occurred after intramuscular injection of phytomenadione (16).

- A 40-year-old woman with no pre-existing hepatic disease was given intramuscular phytomenadione (Konakion) 1 ml/day (10 mg/ml) on 4 days before open cholecystectomy for gallstones. She then noticed a pruritic erythematous patch on her anterior left thigh, and over the next 4 weeks four patches appeared on her thighs and became larger (maximum diameter 15 cm), vesicular, weeping, hot, indurated, and intensely itchy. Topical calamine lotion, 1% hydrocortisone cream, and Paxyl cream (lidocaine and benzalkonium chloride) and oral cefalexin had no effect. The eruption then spread to the operation wound site, the face, neck, and arms. Oral prednisolone resulted in gradual improvement over the next 4 weeks, but residual erythema persisted for nearly 6 months.

Other presentations include erythematous pruritic plaques associated with epidermal keratosis, focal spongiosis, and perivascular infiltrates of lymphocytes and eosinophils or scleroderma-like hypodermic indurations (17). In such cases, intradermal tests may be positive for phytonadione.

Timing

The lesions usually appear 4–16 days after intramuscular injection, and persist for up to 2 months (18,19), sometimes leaving a scar lasting for years (20). The median number of days between the administration of phytomenadione and the appearance of the eruption was 13 days, but eruptions have appeared as early as 30 minutes and as late as 4 weeks after injection. In 13 of 32 cases it took more than 2 months for the reaction to resolve.

Frequency

Skin reactions to vitamin K are rare, only about 40 cases having been reported.

Relation to dose

In some early reports it was postulated that a minimum dose was necessary to cause eruptions, but there have been later reports of adverse skin reactions after small doses (range 10–440 mg).

Histopathology

Histopathological examination typically shows epidermal changes, including spongiosis with or without intraepidermal vesicles. In the dermis there is a perivascular mononuclear cell infiltrate, which may also be interstitial, often containing eosinophils.

Mechanism

Various formulations of phytomenadione contain different inactive ingredients, including polysorbate 80, propylene glycol, sodium acetate, glacial acetic acid, polyethoxylated castor oil (Cremophor EL), dextrose, and benzyl alcohol. Based on negative results with these ingredients, it appears that phytomenadione itself is the antigen that leads to adverse skin reactions. Of 10 patients with liver disease and prior exposure to phytomenadione (Konakion), 4 had positive results to patch-testing with vitamin K (21). Intracutaneous tests have supported the generally accepted hypothesis that the phenomenon is due to type IV hypersensitivity.

Treatment

No particular therapy is effective. It is not known whether the minute quantities of phytomenadione that are present in some foods, such as parsley, kale, brussels sprouts, spinach, cucumber, soy bean oil, and green and black tea leaves, preclude effective dietary therapy. Since the mechanism of this reaction is thought to be delayed hypersensitivity, another potential therapeutic approach is topical application of tacrolimus (FK-506), a potent inhibitor of interleukin 2 and T cell activation. Tacrolimus up to now has only been shown to suppress allergic contact dermatitis to dinitrophenol.

Immunologic

Allergic reactions have been attributed to phytomenadione, menadione, and vitamin K_4. In mice, menadione caused marked hypodynamia and hypothermia. This effect was potentiated by riboflavin. Allergic reactions to the systemic administration of vitamin K are immunologically mediated, and generally arise in patients with coagulation or liver problems.

Intradermal tests with phytomenadione and menadione caused an allergic skin reaction 7–22 days after injection in 13 of 145 healthy subjects. The results suggested that the index of cutaneous sensitivity lies somewhere between 5.5 and 8.9%. On the other hand, the absence of adverse effects with oral phytomenadione is striking. Continuation of treatment orally can in some cases prevent dermatitis (10). No cross-sensitivity has been seen between phytomenadione and menadione (22). Anaphylactoid reactions, some fatal, to phytomenadione

© 2006 Elsevier B.V. All rights reserved.

have been reported (SEDA-15, 416) mainly from intravenous use (23).

The recommendation that prolongation of the international normalized ratio (INR) to over 6.0 should be corrected with parenteral phytomenadione (24,25) is not accompanied by the caveat that the intravenous route entails the risk of life-threatening, non-IgE-mediated anaphylactic reactions and even death, due to the use of polyethoxylated castor oil (Cremophor EL) as a solvent (26). A severe reaction to intravenous phytomenadione has been reported (27).

- A 74-year-old woman, taking warfarin, presented with an INR of 6.2. She was given a slow intravenous injection of phytomenadione (Konakion, Roche Products Ltd) 0.25 ml (500 μg) over about 60 seconds, and soon after felt profoundly unwell and complained of severe backache. She was given chlorphenamine 10 mg by rapid intravenous injection and adrenaline 1 mg in 10 ml of water over 30 minutes, with a good result.

An unusual case of allergy to vitamin K, with a relapsing and remitting eczematous reaction, has been described after an intramuscular injection of vitamin K_1 (28).

- A 27-year-old woman with cystic fibrosis and pancreatic insufficiency was given intramuscular vitamin K_1 into her thigh. The next day transient erythema occurred over the injection site and 6 weeks later there was localized pain, erythema, and edema. She was given intravenous cefuroxime for presumed cellulitis, but over the next few days the features became more consistent with localized eczema; she was given oral prednisolone 30 mg/day, super-potent topical corticosteroids, corticosteroid injections, and corticosteroids under occlusion with Duoderm, all of which failed to result in improvement. She then also developed an eczematous reaction to the Duoderm dressing. Patch tests were positive to vitamin K_1 and cross-reacted with vitamin K_4. She was also positive to colophonium and ester gum rosin, the dressing adhesive. Recurrent angio-edema persisted for several months and 2 years later she still had symptoms at the injection sites.

In all reported cases, only the whole formulation of vitamin K_1 (in its vehicle) or vitamin K_1 alone elicited positive patch tests. When individual additives were tested the results were negative. No previous exposure to vitamin K_1 was required for the development of type IV hypersensitivity, and primary sensitization occurred within 1–2 weeks or after a longer time period, as in the patient described here.

Long-Term Effects

Tumorigenicity

The relation between neonatal vitamin K administration and childhood cancer has been investigated in three case-control studies.

In a retrospective study 685 children who developed cancer before their 15th birthday were compared with 3442 controls matched for date and hospital of birth (29). There was no association between the administration of vitamin K and the development of all childhood cancers (unadjusted odds ratio 0.89; 95% CI = 0.69, 1.15) or of all cases of acute lymphoblastic leukemia (1.20; 0.75, 1.92), but there was a raised odds ratio for acute lymphoblastic leukemia 1–6 years after birth (1.79; 1.02, 3.15).

However, no such association was seen in a separate cohort-based study not dependent on case-note retrieval, in which the rates of acute lymphoblastic leukemia in children born in hospital units in which all babies received vitamin K were compared with those born in units in which less than a third received prophylaxis. It was concluded that on the basis of currently published evidence neonatal intramuscular vitamin K administration does not increase the risk of early childhood leukemia.

In another study children aged 0–14 years with leukemia ($n = 150$), lymphomas ($n = 46$), central nervous system tumors ($n = 79$), a range of other solid tumours ($n = 142$), and a subset of acute lymphoblastic leukemia ($n = 129$) were compared with 777 children matched for age and sex (30). Odds ratios showed no significant positive association for leukemias (1.30; 0.83, 2.03), acute lymphoblastic leukemia (1.21; 0.74, 1.97), lymphomas (1.06; 0.46, 2.42), central nervous system tumors (0.74; 0.40, 1.34), and other solid tumors (0.59; 0.37, 0.96). There was no association with acute lymphoblastic leukemia in children aged 1–6 years. The authors concluded that they had not confirmed the observation of an increased risk of childhood leukemia and cancer associated with intramuscular vitamin K.

In another study 597 cases and matched controls were compared. The association between cancer generally and intramuscular vitamin K was of borderline significance (odds ratio 1.44); the association was strongest for acute lymphoblastic leukemia (1.73) (31). However, there was also an effect of abnormal delivery. The authors suggested from the lack of consistency between the various studies so far published, including their own, and the low relative risks found in most of them, that the risk, if any, attributable to the use of vitamin K cannot be large, but that the possibility that there is some risk cannot be excluded. They recommended that prophylaxis using the commonly used intramuscular dose of 1 mg should be restricted to babies at particularly high risk of vitamin K deficiency; alternatively, a lower dose might be given to a larger proportion of those at risk.

Ecological studies of the relation between hospital policies on neonatal vitamin K administration and subsequent occurrences of childhood cancer have been analysed using data from selected large maternity units in Scotland, England, and Wales (32). The study covered 94 hospitals, with a total of 2.3 million births during periods when intramuscular vitamin K was routinely used and 1.4 million births when a selective policy was in operation. An increased risk was occasionally associated with vitamin K (highest odds ratio 1.25 for acute lymphoblastic leukemia in one hospital), but the overall results were not significant, and there was no evidence to support the previously suggested doubling of the risk of childhood cancer.

On the basis of all these results it is unlikely that there is a greatly increased risk of childhood cancer attributable to intramuscular vitamin K given to newborns, if indeed there is any risk at all.

Susceptibility Factors

High doses of vitamin K can cause relapses in patients with thrombosis and myocardial infarction treated with dicoumarol (33).

Drug Administration

Drug formulations

In a worldwide post-marketing surveillance program a conventional formulation of phytomenadione (Konakion), which contains Cremophor EL (polyethoxylated castor oil), was compared with a new mixed micellar formulation (Konakion MM) (34). During 1974–95 an estimated 635 million adults and 728 million children were given Konakion or Konakion MM. Of the 404 adverse events reported in 286 subjects (see Table 2) 387 (96%) were associated with Konakion, which had 95% of sales. Konakion MM accounted for 4% ($n = 17$) of the reported adverse effects and 5% of sales. Of the 17 adverse events 13 reported with Konakion MM were minor injection site reactions. Overall, 120 of the adverse events were serious, of which 117 (98%) were associated with Konakion. There were 85 probable anaphylactoid reactions (of which six were fatal) with conventional Konakion, compared with one non-fatal anaphylactoid reaction with Konakion MM. During the last 12 months of postmarketing surveillance, there were 14 serious adverse events reported in an estimated 21 million individuals treated with Konakion, but none in the 13 million who received Konakion MM. These results suggest that formulations of phytomenadione that are solubilized with Cremophor EL have a higher profile of adverse events, including anaphylactoid reactions, than the newer mixed micellar formulation Konakion MM.

Drug administration route

A case-control study in 1990 suggested a causal relation between intramuscular administration of vitamin K to neonates and the subsequent development of leukemia (35). Later studies have not been able to confirm this finding (30,36–38), although the results are not sufficiently conclusive to rule out the possibility that there is some risk (29,31).

Rapid intravenous administration of vitamin K can cause facial flushing, sweating, fever, a rise in blood pressure, a feeling of constriction in the chest, and cyanosis. Cases of cardiovascular collapse after intravenous injection of phytomenadione and phytonadione have been reported (39). Intravenous injection of phytomenadione is recommended to be performed slowly at a rate not exceeding 5 mg/minute.

The safety and efficacy of intravenously administered phytonadione have been retrospectively studied in patients taking long-term oral anticoagulants (40). Of 105 patients, 85 initially received intravenous phytonadione 0.5–1 mg,

and 29 received a second dose. Only two of the 105 patients had suspected adverse reactions to phytonadione. Both were men with prior lung disease (one with an adenocarcinoma and one with chronic obstructive lung disease) and were to receive a 0.5 mg dose of phytonadione. During the phytonadione infusion both patients developed dyspnea and chest tightness, which resolved within 15 minutes of stopping the infusion; neither patient had hypotension.

Drug–Drug Interactions

Warfarin

An interaction of warfarin with a nutritional supplement containing vitamin K has been reported (41).

- A 72-year-old man taking warfarin (42.5 mg/week) to prevent thromboembolism related to atrial fibrillation/flutter wanted to take an over-the-counter nutritional supplement containing vitamin K (Nature's Life Greens, a blend of more than 20 herbs). He was instructed to withhold two doses of warfarin. Two weeks later he had an INR of 1.68; however, he had missed three doses of warfarin within the previous 10 days because of cataract surgery. Two weeks later his INR was 3.34. The warfarin dosage was reduced from 42.5 to 40.5 mg/week and the INR was in the target range 2 weeks later.

This report underlines the need for monitoring the use of nutritional and herbal products in patients taking warfarin.

Ubidecarenone (coenzyme Q10; ubiquinone-10) is chemically closely related to phytonadione. It is also widely available as a non-orthodox over-the-counter product, and several patients have been described in whom a reduced effect of warfarin was observed after the addition of non-orthodox ubidecarenone (42,43).

Vitamins

See also Individual agents

General Information

Vitamins are essential organic substances, usually obtained from food. They are required by humans in amounts ranging from micrograms to milligrams per day. The fat-soluble vitamins are:

- vitamin A (carotenoids)
- vitamin D (calciferols)
- vitamin E (tocopherols and tocotrienols)
- vitamin K

The water-soluble vitamins include:

- vitamin B_1 (thiamine, aneurin)
- vitamin B_2 (riboflavin)
- vitamin B_3 (niacin)
- vitamin B_5 (pantothenic acid)
- vitamin B_6 (pyridoxine)
- vitamin B_7 (folic acid)
- vitamin B_{10} (biotin)
- vitamin B_{12} (cobalamins)
- vitamin C (ascorbic acid)

The vitamins are chemically heterogeneous, but all are essential for normal growth, development, and maintenance of the human organism (1). They cannot be synthesized by the organism itself, with the exception of vitamin D, and have to be supplied externally. The main indications for vitamin supplementation are threatening or manifest deficiency states.

The word "vitamin" itself is a misnomer, created in 1911 by one of the early nutrition researchers, the Polish biochemist Casimir Funk (1884–1967). He knew that the substances he was trying to identify were not necessarily "amines," but felt that because of the great public health importance of these newly identified substances, a name was needed "that would sound well and serve as a 'catch word'" (2). His choice proved successful; the label "vitamin" has proved to have extraordinary appeal.

Vitamins are not infrequently used by medical workers as placebos against poorly defined general malaise, often without consideration of the patient's actual vitamin status (3). Self-medication with vitamin supplements is very common in most countries, and commonly the users are not objectively vitamin deficient (4). In general, physicians in an industrialized society can expect that about half of their adult patients will currently be taking vitamin supplements (5); among athletes 75% have been found to use supplements (6).

As micronutrient deficiencies more or less ceased to be a large public health problem in Western countries, the attention of scientists and manufacturers turned towards the many other functions that vitamins have in human metabolism. For the last several decades, pharmacological doses of most vitamins have been claimed to be of therapeutic value in a wide variety of conditions, which have only a superficial resemblance to the classic vitamin deficiency syndromes. The literature on which many of these claims are based unfortunately often consists of poorly conducted clinical trials or anecdotal reports. Properly designed studies are relatively few in number. No authoritative body has proposed quantitative recommendations or reference values for public health policy.

Reference values for vitamins

In the early 1990s European nutritionists, in the light of an increasing body of evidence, changed the nomenclature with regard to what used to be called the Recommended Dietary Allowance (RDA), Recommended Daily Intake (RDI), or Nutrient Reference Value (NRV) (7). When in 1993 the Scientific Committee for Food of the European Communities published a report entitled "Nutrient and Energy Intakes for the European Community" (8), a new approach was introduced, allowing for more flexibility in regard to quantitative values. Based on what is known about the Average Requirement (AR) for a nutrient in a population, and assuming a normal distribution of requirements, a value two standard deviations above the Average Requirement is called the Population Reference Intake, a dose at which deficiency of the micronutrient is probable in under 2.5% of any population. Similarly, a value two standard deviations below the Average Requirement, called the Lowest Threshold of Intake, denote a dose at which the probability of deficiency in a population is almost 97.5%. These values are given in Table 1. In the USA, the National Academy of Sciences has a different procedure and nomenclature (9). Each vitamin is treated separately and the reports of expert panels are published separately as they become available. US Dietary Reference Intakes commonly establishes four levels of reference values, including a Tolerable Upper Intake, which is the dose of greatest interest in the context of adverse effects. Values of Tolerable Upper Intake have also been recommended by

Table 1 Daily vitamin requirements for adults (men; women in parentheses if different)

Vitamin	Lowest Threshold of Intake	Average Requirement	Population Reference Intake	Tolerable Upper Intake
Vitamin A (carotenoids; micrograms RE)	300 (250)	500 (400)	700 (600)	3000
Vitamin B_1 (thiamine; micrograms/MJ)	50	72	100	–
Vitamin B_2 (riboflavin; micrograms)	0.6	1.3 (1.1)	1.6 (1.3)	–
Vitamin B_3 (niacin; mg/MJ)	1.0	1.3	1.6	8
Vitamin B_6 (pyridoxine; micrograms/g protein)	–	1.3	1.5	25
Vitamin B_7 (folic acid; micrograms)	160	230	300	1000
Vitamin B_{12} (cobalamins; micrograms)	0.6	1.0	1.4	–
Vitamin C (ascorbic acid; mg)	32	46	60	1000
Vitamin D (ergocalciferol; micrograms)	–	–	5–10	50

Drug Administration

Drug overdose

The symptoms that are commonly reported in vitamin overdose are listed in Table 2.

Table 2 Notable symptoms reported with chronic and acute vitamin overdosage (SEDA-13, 345) (6,10)

Vitamin	Adverse effects
Vitamin A	Hypercarotenosis
	Increased intracranial pressure
	Headache
	Sleep disturbances
	Nausea, vomiting, diarrhea
	Chronic liver disease
	Dry skin, fissures, depigmentation, and pruritus
	Alopecia
	Bone tenderness
	Teratogenesis (renal and nervous system)
Vitamin B_3 (niacin)	Hypotension
	Dysrhythmias
	Headache
	Hyperglycemia
	Hyperuricemia, gout
	Peptic ulcer
	Hepatotoxicity
	Skin flushing
	Pruritus
	Alopecia
Vitamin B_6 (pyridoxine)	Peripheral sensory neuropathy
	Ataxia
Vitamin C	Impairment of work at high altitudes
	Gastrointestinal symptoms
	Oxalate stones in predisposed persons
	Possible teratogenesis and carcinogenesis in very high doses
Vitamin D	Hypertension
	Hypercalcemia
	Metastatic calcification
	Bone demineralization
	Renal calcinosis and kidney failure
Vitamin E	Increased action of warfarin
Vitamin K	Hemolytic anemia
	Neonatal jaundice

There is widespread and easy availability of high-dose single and multiple vitamin formulations, often presented as food supplements. This creates a potential for chronic or sporadic intake of high doses of vitamins and the occurrence of unanticipated adverse effects (11,12). The cases often involve children, who may be specially vulnerable to the effects of overdosage. The Canadian Paediatric Society's Nutrition Committee in 1990 issued a warning to physicians, based on an estimate that as many as 10% of healthy Canadian children were being exposed to vitamin polypharmacy and a substantial risk of accidental overdose (13).

According to some authors, the increased accessibility and use of high-dose vitamin formulations has been encouraged by the multi-million-dollar health food industry, increased emphasis placed by physicians on more "natural" approaches to disease treatment, a population of consumers interested in so-called "holistic medicine," and the marketing of these formulations in many countries without regulatory control. In therapeutic use, the physician has to keep in mind the benefit to harm balance of using high-dose vitamin supplements for disorders in which proof of efficacy is lacking (14).

Since vitamin overdose can produce unexpected, often vague, signs and symptoms, physicians should ask patients who present with inexplicable symptoms, including those listed in Table 2 (15), about their use of unusual or unapproved therapies, including vitamins in megadoses (10). It has been suggested that a medical history is not complete without vitamin/mineral supplement information (6).

Food fortification and "designer foods" specially formulated to prevent chronic diseases are enthusiastically advocated by the vitamin industry and its proponents (16). Unrestrained vitamin fortification added to unrestrained supplementation with these substances has now in some countries led to the potential for rather high cumulative amounts of intake in some populations. There is growing concern about the safety of chronically high doses of some of these, where the therapeutic margin between deficiency and toxicity may not be all that wide (15,17–19).

Voriconazole

See also Antifungal azoles

General Information

Voriconazole is a triazole that is structurally related to fluconazole. It has two interesting properties, activity against *Aspergillus* species and sufficient solubility in water to be administered parenterally. It is active against a wide spectrum of clinically important fungi, including *Candida* species, *Trichosporon beigelii*, *Cryptococcus neoformans*, *Aspergillus* species, *Fusarium* species, and other hyaline, dematiaceous, and dimorphic molds (1,2). It has demonstrated efficacy in various animal models of invasive fungal infections (1,2).

Pharmacokinetics

Voriconazole has a half-life of about 6 hours and undergoes complex hepatic metabolism. There is wide intersubject variability in the disposition of voriconazole, which is at least partly related to a CYP2C19 polymorphism. Voriconazole has the potential for drug–drug interactions mediated by CYP3A4, CYP2C9, and CYP2C19.

The kinetics of voriconazole are non-linear, as shown in 42 healthy men (3). Two groups of subjects participated. Group 1 ($n = 28$) took part in two study periods, each consisting of 14 days separated by a minimum 7-day washout period. During one of the periods, 14 subjects received intravenous voriconazole 6 mg/kg bd on day 1 followed by 3 mg/kg bd on days 2–7 and were then switched to 200 mg bd orally on days 8–14. During the other period, they received 6 mg/kg bd intravenously on day 1 followed by 5 mg/kg bd on days 2–7 and were then switched to 400 mg orally bd on days 8–14. The other 14 subjects in group 1 received a matching placebo throughout the study. In group 2 ($n = 14$), 7 subjects received 6 mg/kg intravenously bd on day 1 followed by 4 mg/kg bd on days 2–7 and were then switched to 300 mg bd orally on days 8–14. The other seven received a matching placebo. Voriconazole had non-linear pharmacokinetics, attributed to saturable metabolism. For intravenous dosing, a 1.7-fold increase in dose resulted in 2.4- and 3.1-fold increases in C_{max} and AUC respectively; a two-fold increase in oral dosing resulted in 2.8- and 3.9-fold increases in C_{max} and AUC respectively. The mean C_{max} after oral dosing was 63–90% of the intravenous C_{max}. After the switch from intravenous to oral dosing, most subjects achieved steady state by day 4. Voriconazole was well tolerated; the most commonly reported adverse events were mild to moderate headache, rash, and abnormal vision. Visual function tests conducted on all subjects detected no further abnormalities during voriconazole treatment and one abnormality (abnormal color vision test) during placebo treatment. All visual disturbances were mild to moderate in intensity, and all resolved spontaneously within 2 days of onset. No subject in any treatment group had a serious adverse event.

Observational studies

The efficacy of voriconazole has been demonstrated in non-comparative phase I/II studies in patients with oropharyngeal and esophageal candidiasis and acute and chronic invasive aspergillosis (4). In phase III clinical trials, it was superior to conventional amphotericin for first-line therapy of invasive aspergillosis and yielded comparable success rates but less proven and probable breakthrough infections compared with liposomal amphotericin as empirical antifungal therapy in patients with persistent neutropenia (5).

© 2006 Elsevier B.V. All rights reserved.

Voriconazole had excellent clinical efficacy in a non-comparative phase I/II studies in patients with oropharyngeal and esophageal candidiasis and acute and chronic invasive aspergillosis (6).

In an open, non-comparative, multicenter study in immunocompromised patients with proven or probable invasive aspergillosis, 116 patients were treated with intravenous voriconazole 6 mg/kg bd twice and then 3 mg/kg bd for 6–27 days, followed by 200 mg bd orally for up to 24 weeks; voriconazole was given as primary therapy in 60 (7). There were good responses in 56; 16 had a complete response and 40 a partial response; there was a stable response in 24 patients. There were adverse events in 91% of the patients who received at least one dose of voriconazole, but only 15% were attributed to the drug. The most common adverse events attributed to voriconazole were skin rash (8.7%), reversible visual disturbances (11%), and raised liver function tests (15%). There was evidence of a concentration-dependent incidence of adverse events: six of seven patients with voriconazole plasma concentrations over 10 μg/ml developed adverse events requiring drug withdrawal.

Comparative studies

Amphotericin

Voriconazole has been compared with liposomal amphotericin for empirical antifungal therapy in a randomized, international, multicenter trial in 837 patients (415 assigned to voriconazole, 4 mg/kg bd (6 mg/kg bd on day 1) and 422 to liposomal amphotericin, 3 mg/kg/day) (8). The overall success rates were similar (26% with voriconazole and 31% with liposomal amphotericin); however, there were significantly fewer documented breakthrough fungal infections in patients who received voriconazole (8 versus 21). Those who received voriconazole had fewer severe infusion-related reactions, less mild nephrotoxicity, as defined by increases in serum creatinine to over 1.5 times baseline, and less hypokalemia; however, there was no difference whatsoever in the proportion of patients with more profound renal compromise (increased serum creatinine to over 2.0 times baseline; 7.0 versus 7.6%). The incidence of hepatotoxicity, as measured by raised hepatic transaminases and alkaline phosphatase, was similar in the two groups; increased serum bilirubin to over 1.5 times baseline was more common in patients who took amphotericin. Patients who received voriconazole had more episodes of transient visual changes than those who received liposomal amphotericin (22 versus 1%) and more episodes of visual hallucinations (4.3 versus 0.5%). Parenteral voriconazole was changed to the oral formulation in 22%, with a reduction in the mean duration of hospitalization by 1 day in all patients but by 2 days in patients at high risk (with relapsed leukemia or after allogeneic bone marrow transplant). Toxicity or lack of efficacy caused 9.9% of those who received voriconazole and 6.6% of those who received amphotericin to withdraw.

In a comparative, randomized, unblinded trial for primary therapy of invasive aspergillosis, 144 patients received either intravenous voriconazole (6 mg/kg bd on day 1, then 4 mg/kg bd for at least 7 days) followed by 200 mg bd orally, and 133 received intravenous amphotericin deoxycholate (1–1.5 mg/kg/day); other licensed antifungal treatments were allowed if the initial therapy failed or if the patient had an intolerance to the first drug used (9). Most patients had allogeneic hemopoietic cell transplants, acute leukemia, or other hematological diseases. At week 12, 53% of the patients in the voriconazole group and 32% of those in the amphotericin group (difference = 21%; 95% CI = 10, 33%) had a successful outcome. The survival rate at 12 weeks was 71% in the voriconazole group and 58% in the amphotericin group (hazard ratio = 0.59; 95% CI = 0.40, 0.88). Transient visual disturbances were more common with voriconazole (45 versus 4.3%). The most frequent descriptions of such disturbances were blurred vision, altered visual perception, altered color perception, and photophobia. Of the patients who received voriconazole, 9% had hallucinations or confusion considered possibly related to the drug compared with 3.7% of those who received amphotericin. Infusion-related reactions (fever, chills, or both) were more common in those who received amphotericin (3.1 versus 25%), as were severe, potentially related adverse events (13 versus 24%); the most frequent events were renal impairment (14%) in those who received amphotericin and liver function abnormalities (4.8%) in those who received voriconazole.

Other antifungal azoles

In a multicenter, randomized, double-blind, double-dummy, parallel-group, dose-escalation comparison with fluconazole, the safety, tolerability, and pharmacokinetics of oral voriconazole were investigated in 24 subjects at high risk of fungal infections (with hematological malignancies, solid tumors, or autologous bone marrow transplants) (10). The subjects were randomized to receive voriconazole 200 mg bd ($n = 9$), voriconazole 300 mg bd ($n = 9$), or fluconazole 400 mg od ($n = 6$) for 14 days. There was an approximate five-fold accumulation of voriconazole during the dosing period and evidence of non-linear pharmacokinetics. Voriconazole was generally safe and well tolerated. Mild, reversible visual disturbances were the most commonly reported adverse events but they were not associated with treatment withdrawal. No patient developed a breakthrough fungal infection.

The efficacy, safety, and tolerability of voriconazole and fluconazole have been compared in 391 immunocompromised adults with esophageal candidiasis in a randomized, double-blind, multicenter trial (11). Most of the patients (94%) had AIDS. Following randomization, they took either voriconazole (200 mg bd) or fluconazole (400 mg on day 1 followed by 200 mg od) for a median of 14 or 15 days respectively. Treatment was continued for 7 days after the resolution of all signs and symptoms but was not allowed to exceed 42 days. The two drugs achieved comparable success rates (98% voriconazole, 95% fluconazole), as assessed by esophagoscopy in the primary efficacy analysis in 256 patients. More patients discontinued voriconazole because of laboratory test abnormalities (3.5 versus 1%) or treatment-related adverse events (2.5 versus 0.5%). The most frequent

© 2006 Elsevier B.V. All rights reserved.

adverse event with voriconazole was transient visual disturbances (23 versus 8%); other clinical adverse events were similar in frequency. Increases of over three times the upper limit of the reference range in aspartate transaminase (20 versus 8%), alanine transaminase (11 versus 7%), and alkaline phosphatase (10 versus 8%) were more frequent with voriconazole.

Organs and Systems

Sensory systems

Visual adverse events, in particular enhanced brightness of light and color, are common with voriconazole (11). These visual adverse effects are transient and reversible. So far, comprehensive ophthalmological investigations have not shown any morphological correlates or long-term visual sequelae in any patient.

Liver

Liver function test abnormalities in patients taking voriconazole are not unexpected for an azole and can be explained by its extensive hepatic metabolic clearance (12).

Susceptibility Factors

Age

Although the disposition of voriconazole in children aged 12 years and over is similar to that in adults, children aged 2–11 years need larger dosages to achieve the same exposure that was effective in interventional trials in adults (13).

The safety and efficacy of voriconazole have been studied in 58 children (aged 9 months to 15 years; median 7 years) who were treated in the manufacturer's compassionate release program (14). They received voriconazole for an invasive fungal infection if they were refractory to or intolerant of conventional antifungal drugs. Voriconazole was given intravenously as a loading dose of 6 mg/kg every 12 hours on day 1 followed by 4 mg/kg every 12 hours thereafter. When feasible, the route of administration was changed from intravenous to oral (100 or 200 mg bd for patients weighing under or over 40 kg, respectively). At the end of therapy (mean 93 days, range 1–800), 26 patients had a complete or partial response, 4 had a stable response, 25 failed therapy, and 4 were withdrawn because of intolerance of voriconazole. Two had treatment-related serious adverse events (ulcerated lips with rash and raised hepatic transaminases or bilirubin). A total of 23 patients had voriconazole-related adverse events, three of which required withdrawal of voriconazole. The most commonly reported adverse events included raised hepatic transaminases or bilirubin ($n = 8$), skin rashes ($n = 8$), abnormal vision ($n = 3$), and a photosensitivity reaction ($n = 3$). The authors concluded that these data support the use of voriconazole for invasive fungal infections in children who are intolerant of or refractory to conventional antifungal drugs.

Drug–Drug Interactions

Ciclosporin

The interaction of voriconazole with ciclosporin has been investigated in a randomized, double-blind, placebo-controlled, crossover study in kidney transplant recipients with stable renal function (15). During the first study period (7.5 days), subjects taking ciclosporin 150 mg/day received either concomitant voriconazole (200 mg every 12 hours) or a matching placebo. After a washout period of at least 4 days, they were switched to the other treatment. In the seven subjects who completed both regimens, concomitant administration with voriconazole resulted in a 1.7-fold increase (90% CI = 1.47, 1.96) in mean ciclosporin AUC during a dosage interval. Ciclosporin C_{max} and t_{max} were not significantly affected, but C_{min} was increased by voriconazole by a mean of 2.48 (range 1.88–3.03) times. Seven subjects withdrew during voriconazole administration, six for reasons that were considered to be drug-related; most were attributable to increased ciclosporin concentrations. Although not serious, all causality-related adverse events were more frequent during voriconazole administration than during placebo administration. Thus, when voriconazole is initiated or withdrawn in patients who are already taking ciclosporin, blood ciclosporin concentrations should be carefully monitored and the dose of ciclosporin adjusted as necessary.

Wound dressings, substances used in

General Information

Substances that are used in wound dressings include hydrogels, hydrocolloids, alginates, and polyurethane foams. Medicaments that they contain include wool wax alcohols (amerchol, cetearyl alcohol, propylene glycol), plant resins/ethereal oils (balsam of Peru, colophony, fragrance mix, propolis), and topical antibiotics.

Organs and Systems

Immunologic

Patients with chronic venous insufficiency and venous leg ulcers are at risk of sensitization to topical medications. The frequency of sensitization in these patients is up to 67% (1). In a study using an expanded European standard series and 20 different wound dressings for patch-testing in 36 patients with chronic venous insufficiency, sensitization to modern wound dressings was found in 8.3% (three cases) and was caused by propylene glycol as an ingredient of hydrogels (2). However, it must be emphasized that positive patch test reactions to propylene glycol can indicate irritation rather than contact allergy. There were no cases of sensitization to hydrocolloids, alginates, or polyurethane foams. The rank order of allergens was headed by ointment bases (sensitization to wool wax alcohols in 33% of patients; amerchol 19%; cetearyl alcohol 14%; propylene glycol 8.3%), followed by plant resins/ethereal oils (balsam of Peru 22%; colophony 14%; fragrance mix 8.3%; propolis 5.6%), and topical antibiotics (neomycin sulfate 17%; chloramphenicol 14%) (3).

WR-242511

General Information

WR-242511 is an 8-aminoquinoline that is being tested for activity against *Pneumocystis jiroveci* (1). In animals, it was more likely than primaquine to cause methemoglobinemia (SEDA-12, 703) (2).

WR-243251

General Information

WR-243251 is a floxacrine analogue, a dihydroacridinedione. It is active in vitro against chloroquine-resistant, mefloquine-resistant, and pyrimethamine-resistant strains of malaria (1). By analogy to quinacrine and floxacrine, there is concern about possible dermatological, cardiac, and neuropsychiatric toxicity and vascular adverse effects.

Xamoterol

See also Beta-adrenoceptor antagonists

General Information

Xamoterol is a beta-adrenoceptor antagonist/partial agonist that was developed for use in mild cases of cardiac failure and to treat atrial fibrillation (1). In more severe cases, however, it can actually worsen heart failure and increase mortality (2), because when sympathetic nervous system activity is high its beta-adrenoceptor antagonist properties predominate. It has therefore been withdrawn from the market (SEDA-18, 159).

Xenon

See also General anesthetics

General Information

Xenon is a heavy gas (symbol Xe; atomic no 54) that is normally present in the atmosphere. It has been used as an anesthetic and as a diagnostic tool in functional neuroimaging (1).

Xenon has many characteristics of the ideal anesthetic (2). It has no effects on the cardiovascular system and has low solubility, enabling faster induction of and emergence from anesthesia. Although its high cost limits its use, the development of closed rebreathing systems has led to further interest. A European multicenter trial is under way.

Xenon-enhanced CT scanning in functional neuroimaging is based on the use of stable xenon gas, which is radiodense and lipid-soluble, as an inhaled contrast agent. The patient inhales a mixture of xenon, usually 26–33%, and oxygen for several minutes via a face mask. The inhaled xenon dissolves in the blood and passes into the brain parenchyma. CT scans can be acquired before, during, and after inhalation. Fast spiral CT has improved the capability of this technique.

General adverse reactions

Overall, about 10% of patients have unpleasant but usually transient adverse reactions. Xenon is a narcotic gas, more potent than nitrous oxide, and inhalation of 71% xenon is sufficient for anesthesia in 50% of patients. Lower concentrations of xenon are currently used, but some euphoric or dysphoric effects are still observed and can cause temporary exacerbation of neuropsychiatric symptoms. Mild nausea can also occur, and patients should have an empty stomach before the scan to reduce the risk of vomiting and possible aspiration. Very rarely, apnea can occur and can be reversed by instructing the patient to breathe. Like other narcotic gases, xenon causes mild cerebral vasodilatation.

Organs and Systems

Psychological, psychiatric

The subjective, psychomotor, and physiological properties of subanesthetic concentrations of xenon have been studied in 10 volunteers (3). Xenon sedation was well tolerated and was not associated with any adverse physiological effects. In particular, there was no nausea or vomiting. It was preferred to sedation with nitrous oxide and was subjectively dissimilar (xenon was more pleasant).

Xipamide

See also Diuretics

General Information

Xipamide is a non-thiazide diuretic that acts mainly on the distal tubule (1). Its maximal diuretic effect is as great as that of furosemide, but its duration of action is longer and similar to that of the thiazides. Thus, like metolazone, it occupies an intermediate position between the two main groups of diuretics and can be used in renal insufficiency. However, xipamide does appear to present some risks, and it is not clear that these are outweighed by any advantages.

Organs and Systems

Metabolism

At equivalent therapeutic doses, the metabolic effects of xipamide are greater than those of the thiazides or furosemide (SED-11, 200).

Skin

A photoallergic skin reaction has been described in a patient taking xipamide (SEDA-16, 222).

Yellow fever vaccine

See also Vaccines

General Information

Yellow fever vaccine contains the 17D virus strain grown in chick embryo tissue. The older (Dakar) yellow fever vaccine was prepared from more virulent material and often caused encephalitis, the risk in children being particularly high (SED-8, 712).

General adverse effects

The adverse effects of yellow fever vaccine have been documented by an expert group of the WHO (1).

Apart from minor postimmunization reactions the most common adverse effects are on the nervous system and allergic reactions.

On about the sixth day after immunization, under 5% of vaccinees develop fever, headache, and backache, lasting for 1–2 days.

Organs and Systems

Nervous system

About 20 cases of encephalitis have been recorded over a period of 40 years (SEDA-14, 1097). They all occurred in children: 12 in infants under 4 months old, two at 4 months, one at 6 months, one at 7 months, and one at 3 years of age. The last mentioned case was the only fatal one (17D virus was isolated from the brain), all the others recovered fully.

Encephalitis occurred after yellow fever immunization in a child older than 3 years of age and one over 9 months; a 13-year-old boy developed the disease 1 week after receipt of vaccine (2). The patient recovered after 1 month. There have been reports of encephalitis in a 29-year-old man and meningoencephalitis in two adults, suspected to be caused by the 17D yellow fever vaccine (3,4).

A case report of provocation of multiple sclerosis was published in 1967 (5), but this has not been confirmed.

Immunologic

Rash, erythema multiforme, urticaria, angioedema, and asthma occur infrequently, predominantly in people with a history of allergy, especially to eggs (1).

Severe immediate hypersensitivity reactions (type 1), sometimes accompanied by anaphylactic shock and circulatory collapse, have been described very rarely (1). Allergic reactions of the Arthus phenomenon type, characterized by local swelling and necrosis following less than 24 hours after immunization, have occurred in rare instances. Some of these cases have been fatal.

Two episodes have been reported from the Ivory Coast (1974) and Ghana (1982) (1). In the Ivory Coast, there were 39 cases of severe reactions with eight deaths following a mass campaign, in which 730 000 persons were immunized. The clinical features were uniform: a few hours after immunization the vaccinees developed signs of local inflammation. In severe cases, edema and inflammation were followed by cardiovascular collapse. Bacterial contamination could have been the cause: during the campaign, five-dose vaccine ampoules were pooled to prepare 50 and 100 doses for use in jet injectors. In Ghana, six vaccinees developed fulminant reactions 2–6 hours after immunization, including two deaths. The clinical features resembled those in the Ivory Coast episode. In 2001, during a mass vaccination campaign against yellow fever in Abidjan, the Ivory Coast, more than 2.6 million doses were administered and 87 adverse events were notified, of which 41 were considered to be vaccine-related. There was one case of anaphylaxis and 26 cases of urticaria, five of which were generalized (6).

People who are known to be suffering from allergy must be tested intradermally before immunization.

Multiorgan failure

There have been reports of seven cases of serious adverse events (including six deaths) after yellow fever immunization (7–11). The cases occurred from 1996 to 2001 in Australia ($n = 1$), Brazil ($n = 2$), and the USA ($n = 4$). The two people in Brazil were immunized with vaccine containing the live attenuated 17DD yellow fever strain and the others received vaccine containing the live attenuated 17D-204 strain; both strains are derived from the original 17D vaccine strain. All seven became ill within 2–5 days after immunization and required intensive care. Illness was characterized by fever, lymphocytopenia, thrombocytopenia, raised hepatocellular enzymes, hypotension, and respiratory failure. Most also had headache, vomiting, myalgia, hyperbilirubinemia, and renal insufficiency requiring hemodialysis. In some aspects the disease was similar to natural yellow fever. The causal association between multiorgan failure and the receipt of yellow fever vaccine is supported in most cases by isolation of the vaccine virus and histopathological changes; in cases with lack of specimens the temporal association and the similarity of the clinical presentations makes a causal association likely.

Susceptibility Factors

Age

Infants under 9 months old are not generally immunized, except if they live in rural areas with a history of yellow fever epidemics (immunization at 6 months) or in an active epidemic focus (immunization at 4 months) (1).

Yohimbine

General Information

Yohimbine is a major carboline alkaloid in the bark of *Pausinystalia* species, such as *Pausinystalia yohimbe* (*Corynanthe yohimbe*), *Pausinystalia macrocerus*, *Pausinystalia paniculata*, and *Pausinystalia trilles*i. It is also found in *Pseudocinchona africana* and *Rauwolfia canescens*.

Yohimbine is an alpha$_2$-adrenoceptor antagonist and has been used in the treatment of erectile dysfunction. At high doses its most common effects are increased blood pressure, slight anxiety, and increased frequency of micturition (1). In a systematic review of randomized controlled trials (2), the following adverse events were noted: hypertension, allergic skin reactions, anxiety, dizziness, chills, headache, sweating, agitation, tachycardia, gastrointestinal symptoms, diarrhea, loss of energy, and increased urinary frequency.

Organs and Systems

Cardiovascular

In 25 unmedicated subjects with hypertension yohimbine 22 mg increased mean blood pressure by an average of 5 mm Hg, plasma noradrenaline by 66%, and plasma dihydroxyphenylglycol by 25% at 1 hour after administration (3). The magnitude of the pressor response was unrelated to baseline pressure but correlated positively with baseline noradrenaline concentration and with the yohimbine-induced increment in plasma noradrenaline.

In 25 healthy volunteers and 29 sex- and age-matched untreated hypertensive patients yohimbine 10 mg caused a significant increase in diastolic pressure only in the hypertensive patients (4).

In patients taking tricyclic antidepressants, hypertension can occur at a dose of 4 mg tds. The toxicity of yohimbine can be enhanced by other drugs, such as phenothiazines.

Angina pectoris has been attributed to yohimbine (5).

- A patient with CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) paradoxically experienced worsening of Raynaud's phenomenon when using yohimbine for erectile dysfunction (6).

Respiratory

Bronchospasm has been attributed to yohimbine (7).

Nervous system

In a double-blind, placebo-controlled study in eight patients receiving methadone, yohimbine 4 mg/kg intravenously caused objective and subjective opioid withdrawal symptoms and increased craving for opioids (8). This was attributed to increased sensitivity of postsynaptic responses to noradrenaline.

Sensory systems

In a placebo-controlled, crossover study in seven healthy subjects oral yohimbine 0.4 mg/kg caused a significant but transient reduction in P50 auditory gating (9).

Psychological, psychiatric

Yohimbine commonly causes anxiety; in eight patients with panic disorder this effect was reduced by fluvoxamine (10).

Manic symptoms have been attributed to yohimbine (11).

In a placebo-controlled study in 18 combat veterans with post-traumatic stress disorder and 11 healthy controls, intravenous yohimbine 0.4 mg/kg significantly increased the amplitude, magnitude, and probability of the acoustic startle reflex (used as a model to investigate the neurochemical basis of anxiety and fear states) in the veterans with post-traumatic stress disorder but not in the controls (12).

Hematologic

Agranulocytosis has been attributed to yohimbine (13).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

A lupus-like syndrome in conjunction with generalized erythroderma and progressive renal insufficiency has been attributed to yohimbine (14,15).

Drug Administration

Drug overdose

- In a 62-year-old man who took yohimbine 200 mg the only adverse effects were tachycardia, hypertension, and anxiety of brief duration (16).

This case suggests that yohimbine overdose is relatively benign.

- A 16-year-old girl who took yohimbine in the form of an alleged aphrodisiac known as "yo-yo" had an acute dissociative reaction accompanied by weakness, paresthesia, and incoordination, followed by anxiety, headache, nausea, palpitation, and chest pain; she also had hypertension, tachycardia, tachypnea, sweating, pallor, tremor, and an erythematous rash (17). Serum adrenaline and noradrenaline concentrations were raised. Her symptoms lasted about 36 hours and resolved spontaneously.

Drug–Drug Interactions

Phenytoin

Yohimbine can cause loss of the antiepileptic action of phenytoin (2).

Tricyclic antidepressants

Yohimbine has a sialogenic effect in depressed patients with a dry mouth due to tricyclic antidepressants or neuroleptic drugs (18).

However, there is an increased risk of hypertension when tricyclic antidepressants are combined with yohimbine (19).

Zafirlukast

See also Leukotriene receptor antagonists

General Information

Zafirlukast is a leukotriene receptor antagonist, used in the treatment of asthma.

Organs and Systems

Liver

In the early clinical trials a range of doses of zafirlukast were used. With higher doses (80 mg bd) serum liver enzymes were occasionally raised. In subsequent clinical trials with 20 mg bd, a raised alanine transaminase activity was twice as common as in patients taking placebo (1).

Sporadic cases of severe hepatotoxicity (2–4), requiring orthotopic liver transplantation for subacute liver failure in two cases (5), prompted a revision of the "Adverse Events" section in the Physicians' Desk Reference (6).

Hepatitis has been attributed to zafirlukast in two cases.

- A 54-year-old asthmatic man developed subacute hepatitis and hepatic encephalopathy while taking zafirlukast 20 mg bd for 8 months and co-amoxiclav 2 g/day for a few days (3). He also took antihistamines, inhaled glucocorticoids, and beta-blockers (not specified). A percutaneous liver biopsy showed severe hepatocellular necrosis and eosinophilic infiltrates without prominent cholestasis. Raised transaminases and total serum bilirubin normalized within 3 months after withdrawal of zafirlukast and co-amoxiclav and the use of intermittent, high-dose, parenteral glucocorticoids, followed by oral tapering.
- A 55-year-old asthmatic woman had subacute liver injury with severe hepatic necrosis and eosinophilic infiltrates while taking zafirlukast 20 mg bd and salbutamol sulfate nasal spray for 5 months (4). There was no evidence of viral, metabolic, alcohol-related, or autoimmune hepatitis. Zafirlukast was withdrawn and liver function normalized within 2 months.

The authors concluded that subacute hepatitis in the second patient had been related to zafirlukast, but suggested that co-amoxiclav might also have been a precipitating factor. The long latency between the start of zafirlukast treatment and the onset of hepatotoxicity and the slow response to drug withdrawal and glucocorticoid treatment are reminiscent of previous cases of zafirlukast-related hepatotoxicity.

Drug–Drug Interactions

Aspirin

The plasma concentrations of zafirlukast rise when it is administered concurrently with aspirin (7).

Macrolide antibiotics

Zafirlukast 20 mg bd for 12 days did not interfere with the metabolism of azithromycin or clarithromycin (8). However, the plasma concentrations of zafirlukast are reduced when it is administered concurrently with erythromycin (7).

Terfenadine

The plasma concentrations of zafirlukast are reduced when it is administered concurrently with terfenadine (7).

Theophylline

The plasma concentrations of zafirlukast are reduced when it is administered concurrently with theophylline (7). Conversely, zafirlukast can increase serum theophylline concentrations.

- A 15-year-old girl with asthma, who had taken theophylline 300 mg bd for several years, with serum concentrations of about 61 μmol/l started to take zafirlukast (9). Her serum theophylline concentration increased to 133 μmol/l. Rechallenge confirmed the effect.

The authors proposed that zafirlukast had inhibited CYP1A2, by which theophylline is metabolized.

Warfarin

Zafirlukast reduces the clearance of warfarin, resulting in a clinically significant prolongation of prothrombin time (10). The mechanism for this interaction is thought to be inhibition of cytochrome P450 enzymes, such as CYP2C9.

Zalcitabine

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Zalcitabine is a nucleoside analogue reverse transcriptase inhibitor. Because of the high incidence of nervous system adverse effects and the availability of less toxic alternatives, zalcitabine is no longer used.

Comparative studies

Several large-scale studies of the efficacy of combined antiretroviral treatment with zalcitabine and zidovudine in HIV-infected patients (compared with zidovudine monotherapy or a combination of zidovudine and didanosine) have not shown unexpected adverse effects (1–4). The most common adverse effects in patients taking zalcitabine were peripheral neuropathy and aphthous mouth ulcers.

Organs and Systems

Nervous system

A peripheral neuropathy is often observed in patients treated with didanosine, stavudine, and zalcitabine (5,6). It usually occurs after prolonged treatment (more than 4 months), most often with zalcitabine, and often requires drug withdrawal, but it is sometimes not fully reversible. Mitochondrial alterations have been demonstrated in Schwann cells of peripheral nerves and dorsal root ganglia in rabbits treated with zalcitabine (7).

Hematologic

Thrombocytopenia has been observed in patients using zalcitabine and didanosine (8,9).

Zaleplon

General Information

Zaleplon is a non-benzodiazepine that induces sleep comparable to other hypnotics but with significantly fewer residual effects (1), related at least in part to its short half-life. It is a pyrazolopyrimidine hypnotic that binds selectively to the $GABA_{A1A}$ receptor, previously known as the benzodiazepine type 1 (BDZ_1) receptor. Whereas such agonist selectivity was hoped to confer advantages in terms of the risk of adverse effects, in practice zaleplon is similar to the older non-selective benzodiazepines in terms of both efficacy and safety (2–4). The so-called "Z drugs," including zaleplon, are significantly more expensive than benzodiazepines and are therefore likely to be less cost-effective (5).

Pharmacokinetics

After oral administration zaleplon is well absorbed (71%) and peak concentrations are reached in about 60 minutes. However, it undergoes presystemic elimination and has a systemic availability of about 30%. Its adverse effects include anterograde amnesia, depression, paradoxical reactions (for example restlessness, agitation), dependence, and withdrawal symptoms (related to the dose and duration of treatment). Although the data are limited, it is thought to be relatively safe in overdose, unless it is combined with other CNS depressants.

The pharmacokinetics and absolute oral systemic availability of zaleplon have been assessed in a partially randomized, single-dose, crossover study in 23 healthy subjects, who received intravenous infusions of zaleplon 1 and 2.5 mg during the first and second periods and were

© 2006 Elsevier B.V. All rights reserved.

then randomly assigned to receive an oral dose of 5 mg or an intravenous infusion of 5 mg in a crossover design (6). The oral and intravenous doses of zaleplon were well tolerated. Somnolence, abnormal vision, diplopia, and dizziness were the most commonly reported adverse events.

Pharmacological effects

Initial pharmacodynamic data suggested that sleep latency is improved by zaleplon and there is no significant next-day psychomotor impairment or memory impairment (7), and evaluations at zaleplon peak plasma concentrations show much less impairment than with other hypnotics, suggesting an improved benefit-to-harm balance for zaleplon compared with older agents. However, outcome data are mainly from industry-sponsored trials and are often difficult to compare. Differences between zaleplon and benzodiazepine hypnotics may have been exaggerated (3,4).

Zaleplon can be used to treat symptoms of insomnia with little next-day psychomotor or memory impairment. However, further research is needed.

Comparative studies

A review of published studies of zaleplon has shown that it has a quick onset of action and undergoes rapid elimination, which results in an arguably better safety profile than previously available agents (8). In addition, rebound insomnia and other withdrawal effects have not been demonstrated with zaleplon, and it is well tolerated in both young and older patients. These characteristics may be advantageous for patients who should not receive benzodiazepines.

Placebo-controlled studies

Three doses of zaleplon have been compared with placebo in outpatients with insomnia in a 4-week study (9). During week 1, sleep latency was significantly shorter with zaleplon 5, 10, and 20 mg than with placebo. The significant reduction in sleep latency persisted to week 3 with zaleplon 10 mg and to week 4 with zaleplon 20 mg. Compared with placebo, zaleplon 10 mg and 20 mg also had significant positive effects on sleep duration, number of awakenings, and sleep quality. Pharmacological tolerance did not develop with zaleplon and there were no indications of rebound insomnia or withdrawal symptoms after discontinuation. There was no significant difference in the frequency of adverse events with zaleplon compared with placebo. The authors concluded that zaleplon provides effective treatment of insomnia with a favorable safety profile.

Zaleplon versus triazolam

Zaleplon and triazolam have been compared in two concurrent multicenter, randomized, double-blind, placebo-controlled crossover studies in chronic insomniacs (10). Study 1 compared zaleplon (10 and 40 mg) with triazolam (0.25 mg) and placebo; study 2 compared zaleplon (20 and 60 mg) with triazolam (0.25 mg) and placebo. All doses of zaleplon produced significant reductions in sleep latency, and triazolam 0.25 mg reduced sleep latency comparable with zaleplon 10 mg. Only triazolam and zaleplon 60 mg produced significant increases in total sleep time compared with placebo. Zaleplon 40 and 60 mg and triazolam also reduced the percentage of REM sleep compared with placebo. There was no evidence of residual daytime impairment with zaleplon, but triazolam produced significant impairment in performance on a digit copying test. There were more adverse events with zaleplon 60 mg compared with triazolam 0.25 mg and placebo. The most frequently reported adverse events with all treatments included headache, dizziness, and somnolence.

Zaleplon versus zolpidem

Zaleplon and zolpidem have been compared in two concurrent multicenter, randomized, double-blind, placebo-controlled crossover studies in chronic insomniacs (10). In study 1, zaleplon 10 mg, zolpidem 10 mg, or placebo were given double-blind to 36 healthy subjects under standardized conditions in a six-period, incomplete-block, crossover study (11). The subjects were gently awakened and given the medication at predetermined times, 5, 4, 3, or 2 hours before morning awakening, which occurred 8 hours after bedtime. When they awoke in the morning, subjective and objective assessments of residual effects of hypnotics were administered. There were no serious adverse experiences during the study; all adverse events were mild to moderate. The most commonly reported adverse events associated with zaleplon were weakness and somnolence. Weakness, depersonalization, dizziness, and somnolence were the most frequent nervous system adverse events associated with zolpidem.

Zaleplon has been compared with zolpidem 10 mg and placebo in 615 adult outpatients with insomnia (12). After a 7-night placebo (baseline) period, the patients were randomly assigned to receive one of five treatments in double-blind fashion for 28 nights (zaleplon 5, 10, or 20 mg; zolpidem 10 mg; or placebo), followed by placebo for 3 nights. Sleep latency, sleep maintenance, and sleep quality were determined from sleep questionnaires each morning. Rebound insomnia and withdrawal effects on withdrawal were also assessed. There was no evidence of rebound insomnia or withdrawal symptoms on withdrawal of zaleplon after 4 weeks. The frequency of adverse events in the active treatment groups did not differ significantly from that in the placebo group.

The pharmacokinetics and pharmacodynamics of zaleplon (10 or 20 mg) and zolpidem (10 or 20 mg) have been investigated in a randomized, double-blind, crossover, placebo-controlled study in 10 healthy volunteers with no history of sleep disorder (13). The half-life of zaleplon was significantly shorter than that of zolpidem. Zaleplon produced less sedation than zolpidem at the two doses studied, and the sedation scores in the zaleplon groups returned to baseline sooner than in the zolpidem groups. Zaleplon had no effect on recent or remote recall, whereas zolpidem had a significant effect on both measures.

Organs and Systems

Psychological, psychiatric

- A 25-year-old unmarried Asian woman with high intellectual functioning and psychiatric history developed

© 2006 Elsevier B.V. All rights reserved.

illusions and hallucinations and a feeling of superior psychosocial adjustment, with no current or prior medical or depersonalization within several minutes of taking zaleplon 10 mg (14). The illusions and visual hallucinations resolved after 15 minutes, but she continued to have light-headedness and fatigue, which gradually resolved by the next day.

Drug–Drug Interactions

Alcohol

The addition of alcohol to the Z drugs, zaleplon, zolpidem, and zopiclone, produces additive sedative effects without altering their pharmacokinetics (15).

The effects of alcohol combined with either zaleplon or triazolam have been studied in 18 healthy volunteers (16). Triazolam, with and without ethanol, impaired digit symbol substitution, symbol copying, simple and complex reaction times, and divided attention performance compared with placebo. Zaleplon without ethanol impaired only digit symbol substitution and divided attention tracking, but when it was combined with ethanol all measures were impaired. However, zaleplon without ethanol was consistently better than triazolam alone. Zaleplon produced less performance impairment and a shorter period of ethanol potentiation than triazolam.

Cimetidine

Cimetidine increases plasma concentrations of the Z drugs and increases their sedative effects (15); this occurs to a lesser extent than the similar effect on benzodiazepines that are exclusively metabolized by CYP3A4.

Digoxin

The interaction of zaleplon with digoxin has been investigated in 20 subjects (17). There were one or more adverse effects in 18% of those who took digoxin alone and 35% of those who took digoxin plus zaleplon, but these were all mild and resolved quickly. Zaleplon had no significant effects on selected pharmacokinetic and pharmacodynamic properties of digoxin.

Erythromycin

Erythromycin increases plasma concentrations of the Z drugs and increases their sedative effects (15); this occurs to a lesser extent than the similar effect on benzodiazepines that are exclusively metabolized by CYP3A4.

Ibuprofen

The interaction of zaleplon with ibuprofen has been investigated in 17 subjects (18). Healthy adult volunteers were given zaleplon 10 mg alone, ibuprofen 600 mg alone, or zaleplon 10 mg plus ibuprofen 600 mg in an open, randomized, crossover study. The adverse effects were mild and resolved without intervention. The authors concluded that there was no evidence of a significant interaction between zaleplon and ibuprofen.

Ketoconazole

Ketoconazole increases plasma concentrations of the Z drugs and increases their sedative effects (15); this occurs to a lesser extent than the similar effect on benzodiazepines that are exclusively metabolized by CYP3A4.

Rifampicin

Rifampicin significantly induces the metabolism of zaleplon and reduces its sedative action (15), although the effect is less than the effect of rifampicin on triazolam or midazolam, probably because they are more exclusively metabolized by CYP3A4.

Zidometacin

See also Non-steroidal anti-inflammatory drugs

General Information

Zidometacin differs from indometacin in having an azido group in the *para*-position, where indometacin has a benzyl group. It appears to be less ulcerogenic in animals. However, epigastric pain, burning, and nausea have been experienced by patients taking zidometacin (1).

Reference

1. Friez L. Preliminary clinical experience with zidometacin. Acta Ther 1985;11:109.

Zidovudine

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Zidovudine is a nucleoside analogue reverse transcriptase inhibitor. Its adverse effects include hematological complications, severe headache, insomnia, confusion, nausea, vomiting, abdominal discomfort, myalgia (myopathy), and nail pigmentation (1).

Observational studies

Oral zidovudine in a dosage of 200 mg every 4 hours for 42 days was used as prophylaxis in health-care workers after percutaneous exposure to blood or body fluids from HIV-infected patients. Adverse reactions occurred in 73%, the most frequent being nausea (47%), headache (35%), and fatigue (30%). Of selected hematological laboratory markers only platelet counts increased significantly over 4 weeks. Although adverse reactions were not very severe and none of the laboratory changes was considered clinically significant, treatment was poorly accepted and stopped prematurely by 30% (2). Current guidelines for postexposure prophylaxis recommend a much lower dosage (300 mg bd) with much better tolerance (3).

Comparative studies

The safety and efficacy of lamivudine (300–600 mg/day) in combination with zidovudine (600 mg/day) in the treatment of antiretroviral-naive and zidovudine-experienced HIV-infected persons has been compared with zidovudine monotherapy in two placebo-controlled studies of 129 and 223 patients (4,5). There were no significant differences in the incidence or severity of adverse effects between patients taking zidovudine alone or in combination with lamivudine. In both studies gastrointestinal symptoms, notably nausea, were the most commonly observed adverse reactions, occurring in 5–11% of zidovudine-experienced patients and 23–29% of antiretroviral drug-naive individuals. Although one antiretroviral drug-naive patient taking combined therapy had an asymptomatic rise in pancreatic amylase activity, acute pancreatitis was not observed in either study. Grade 1 peripheral neuropathy was reported in one zidovudine-experienced patient taking low-dosage lamivudine (150 mg bd) and zidovudine.

Several large-scale studies of the efficacy of combined antiretroviral treatment with zalcitabine and zidovudine in HIV-infected patients (compared with zidovudine monotherapy or a combination of zidovudine and didanosine) have not shown unexpected adverse effects (6–9). The most common adverse effects in patients taking zalcitabine were peripheral neuropathy and aphthous mouth ulcers.

Organs and Systems

Nervous system

Various nervous system adverse effects of zidovudine have been reported, which may or may not be directly related to the drug. These include seizures, confusion, and acute encephalopathy occurring after zidovudine dosage reduction (10).

Metabolism

Lipodystrophy is a common adverse effect of antiretroviral drugs, particularly the NRTIs and has been reported with zidovudine (11).

- A 42-year-old woman developed abdominal and dorsocervical fat enlargement after having taken zidovudine for over 10 years. Zidovudine was withdrawn and the lesions improved considerably over the next 26 months.

Hematologic

The main dose-limiting adverse reactions of zidovudine therapy in HIV-infected adults and children are hematological complications (12). When zidovudine was introduced it was given in about twice the dosage used today. Consequently, hematological adverse effects occur at a much lower frequency than previously reported (13,14).

Almost uniformly, zidovudine treatment results in a progressive increase in the erythrocyte mean cell volume, which cannot be prevented by supplementation with vitamin B_{12} and folinic acid (15). Zidovudine can cause anemia (16) and reversible pure red cell aplasia (17). While recombinant erythropoietin is useful in correcting

© 2006 Elsevier B.V. All rights reserved.

zidovudine-induced anemia, some cases of anemia are associated with high serum erythropoietin concentrations and normocytic cells, indicating bone marrow unresponsiveness to erythropoietin (18). Measuring baseline serum erythropoietin concentrations may help to predict the response to this very costly hormone supplementation.

Zidovudine can cause neutropenia (16).

Thrombocytopenia has been observed in patients using zidovudine and didanosine (19,20).

Skin

Fatal toxic epidermolysis has been attributed to zidovudine (21) as has cutaneous hypersensitivity (22).

Zidovudine can occasionally cause unusual pigmentation, probably depending on the individual's pigmentary pattern (23).

Nails

The presenting sign of neutropenia in a neonate treated with prophylactic zidovudine for reduction of perinatal transmission was, unusually, severe paronychia of the large toes as a result of *Candida albicans* and *Escherichia coli* infection (24). The paronychia resolved after treatment with oral fluconazole and topical antiseptics. Paronychia of the large toes has also been observed when filgrastim (recombinant granulocyte colony stimulating factor) was used alongside chemotherapy in poor-risk patients with myelodysplastic syndrome (25), and there is some evidence that paronychia (even in the absence of blood disorders) can occur as an independent adverse reaction to various antiretroviral drugs, including indinavir and lamivudine (26).

Closely similar is the strong evidence from case-control studies that ingrowing toenails are associated with the use of indinavir (27) and possibly other similar compounds, but not lamivudine.

Musculoskeletal

Myopathy has been well described with long-term zidovudine and is reversible after withdrawal (28). Phosphorus magnetic resonance spectroscopy has been used to study the changes in phosphorylated metabolites (ATP, phosphocreatine, and inorganic phosphate) during exercise in 19 healthy volunteers, 6 untreated HIV-positive individuals, and 9 zidovudine-treated patients with biopsy-proven myopathy (29). Zidovudine altered the normal muscle energy metabolism in the patients with myopathy, suggesting that it reduces maximal work output, and thus the maximal rate of mitochondrial ATP synthesis, in human muscle. So far, the syndrome has not been associated with any other NRTI (30) and it has been suggested that other factors might contribute to the development of zidovudine-associated myopathy (31). Mitochondrial abnormalities have also been observed in biopsies from untreated patients infected with HIV-1, suggesting that the virus itself can also cause myopathy.

To assess the contribution of zidovudine to the mitochondrial damage, the effects of zidovudine on non-infected co-cultures of spinal ganglia, spinal cord, and skeletal muscle in fetal rats have been studied (32). There were significant changes not only in the mitochondria but also in the nuclei of all cells tested. These changes depended less on the concentration of zidovudine than on the duration of exposure.

Multiorgan failure

A well-documented case has shown that zidovudine can cause type B lactic acidosis and acute respiratory and hepatic failure (33).

- A 34-year-old obese woman developed nausea, vomiting, and intermittent diarrhea. Her current medications included zidovudine. She had tachypnea and tender hepatomegaly, and a CT scan of the abdomen showed hepatomegaly with fatty infiltration. The serum bicarbonate concentration was low and the lactate concentration three times normal. The tachypnea and dyspnea worsened as the lactate concentration rapidly increased to 15 times normal, and she died in acute respiratory and hepatic failure with multiorgan dysfunction.

Second-Generation Effects

Pregnancy

Zidovudine during pregnancy and delivery, followed by treatment of the infant for 6 weeks, prevents maternofetal transmission of HIV, and is associated with minimal short-term toxicity to both mother and child and no increased incidence of neonatal structural abnormalities (SEDA-19, 279) (34).

Zidovudine is relatively well tolerated in pregnancy, with anemia, neutropenia, or thrombocytopenia occurring in 10% and abnormalities of serum electrolytes and liver function in 5% (34).

Teratogenicity

There has been a randomized cohort study in the USA of children from 122 pregnancies in which zidovudine was given and of children from 112 pregnancies in which only a placebo was used (35). The median age of the children at the last follow-up visit was 4.2 years. There were no significant differences between children exposed to zidovudine and those who received placebo in terms of sequential data on lymphocyte subsets, weight, height, head circumference, and cognitive/developmental function. There were no deaths or malignancies. Two children (both exposed to zidovudine) were still being followed for unexplained abnormal fundoscopy. One child exposed to zidovudine had a mild cardiomyopathy on echocardiography at the age of 48 months but was clinically asymptomatic.

Lactation

Since zidovudine seems to be relatively well tolerated both in pregnancy and in neonates, there is also much reason to consider its use during lactation in order to reduce vertical transmission of HIV. Indeed, many would regard it as highly preferable to abandoning breastfeeding by HIV-infected women. In a critical double-blind West African study the effects of a 6-month course of treatment in prenatal and lactating

© 2006 Elsevier B.V. All rights reserved.

mothers were examined (36). Eligible participants were women aged 18 years or older who had confirmed HIV-1 infection, were 36–38 weeks pregnant, and gave written informed consent. Exclusion criteria were severe anemia, neutropenia, abnormal liver function, and sickle cell disease. They were randomly assigned to zidovudine ($n = 214$; 300 mg bd until labor, 600 mg at the start of labor, and 300 mg bd for 7 days) or to matching placebo ($n = 217$). The Kaplan-Meier probability of HIV infection in the infant at 6 months was 18% in the zidovudine group and 28% in the placebo group, a relative efficacy of 0.38. In current and follow-up observations over 6 months, no major adverse biological or clinical events were reported in excess among women or children in the zidovudine group. The authors concluded that a short course of oral zidovudine given during the peripartum period is well tolerated and provides significant reduction in early vertical transmission of HIV-1 infection despite breastfeeding.

A second related study showed similar results (37), and the two papers together provide impressive evidence that it is proper and defensible to use zidovudine in breastfeeding mothers.

Susceptibility Factors

Age

The only recognized toxic effect in infants is anemia within the first 6 weeks of life, which is not associated with premature delivery, duration of maternal treatment, degree of maternal immunosuppression, or maternal anemia. An 18-month follow-up of 342 children born to mothers who had taken zidovudine or placebo during pregnancy has recently been reported (38). There were no differences in growth parameters or immune function in uninfected children. In addition, no childhood neoplasias were reported in either group.

Drug–Drug Interactions

Atovaquone

Atovaquone can potentiate the activity of zidovudine by inhibiting its glucuronidation (39).

Clarithromycin

Clarithromycin has an unpredictable effect on the absorption of zidovudine; blood concentrations may rise or fall (40,41).

Cytotoxic drugs

In 13 HIV-infected patients with cancer, the mean pharmacokinetics of zidovudine (AUC, half-life, oral clearance, and oral apparent volume of distribution) were no different with or without chemotherapy (42). However, there was a 57% reduction in C_{max} and a 66% increase in t_{max} after chemotherapy. There were no differences in the urinary excretion of zidovudine or zidovudine glucuronide. The authors concluded that these minor changes did not warrant any change in the dosage of zidovudine during concurrent chemotherapy.

Oxazepam

There was a striking incidence of headache in a small series of patients when zidovudine was given with oxazepam (43).

Paracetamol (acetaminophen)

Paracetamol (acetaminophen) increased the clearance (and possibly reduced the effects) of zidovudine (44,45).

Probenecid

In two healthy volunteers, co-administration of probenecid 500 mg every 6 hours altered the pharmacokinetics of a single oral dose of zidovudine 200 mg (46). There was an increase in the average AUC, with a corresponding reduction in oral clearance, attributed to an inhibitory effect of probenecid on the glucuronidation and renal excretion of zidovudine.

Eight subjects took zidovudine for 3 days with and without probenecid 500 mg every 8 hours for 3 days, and then additional quinine sulfate 260 mg every 8 hours (47). Probenecid increased the AUC of zidovudine by 80%. Quinine prevented the probenecid effect but had no effect on zidovudine kinetics when it was taken without probenecid by four other subjects. All of the effects were secondary to changes in zidovudine metabolism, since neither probenecid nor quinine changed the renal elimination of zidovudine.

Rifamycins

Rifampicin, a well-known enzyme inducer, increased the metabolism of zidovudine, and the effect persisted for 2 weeks after rifampicin had been withdrawn (48).

Zileuton

General Information

Zileuton is an inhibitor of 5-lipoxygenase, the first step in the conversion of arachidonic acid to cysteinyl leukotrienes. It is starting to be used in the long-term control of asthma (1). It has also been used to treat acne (2), atopic dermatitis (3), and the Sjögren–Larsson syndrome (4).

Organs and Systems

Hematologic

In 10 patients with asthma, zileuton treatment for 2 weeks significantly increased thromboxane B2 concentrations and spontaneous platelet aggregation (5). These results suggest that zileuton may be associated with an increased risk of thrombosis.

Liver

In 2947 patients at 233 centers in the USA randomly assigned in a 5:1 ratio to zileuton plus usual asthma care or usual asthma care alone, the patients who took zileuton had significantly fewer corticosteroid rescues, required less emergency care, had fewer hospitalizations, and had greater increases in FEV_1 (6). They also had significantly greater improvements in asthma symptoms. There were increases in alanine transaminase activity to three times or more the upper limit of the reference range in 4.6% of patients taking zileuton and 1.1% of those receiving usual care; most of the increases occurred during the first 2–3 months. There were no cases of jaundice or chronic liver disease.

Zinc

General Information

Zinc is a bluish-white metallic element (symbol Zn; atomic no. 30) that is found in minerals such as franklinite, ghanite, goslarite, hemimorphite, smithsonite,

© 2006 Elsevier B.V. All rights reserved.

sphalerite, willemite, and wurtzite. Sphalerite, which contains zinc sulfide, is the most abundant source.

Zinc deficiency and toxicity have been reviewed (1,2). Zinc supplementation reduces the incidence of infection and increases the survival rate after infections in elderly people (3). However, oral zinc sulfate has been overused in many fields of therapy, particularly in dermatology, despite the fact that some of the indications once claimed for it have been discredited and only a few disorders have been clearly shown to result from zinc deficiency. Dosages have often been high, for example the equivalent of 45 mg of metallic zinc three times a day. Zinc oxide is used topically as an astringent and protectant. Zinc chloride is used as an astringent and a desensitizer for dentine. Zinc sulfate is sometimes used as an ophthalmic astringent. Zinc oxide is used as an anti-infective agent. Zinc is also found in some freely available alternative remedies and in non-medicinal products such as shampoos.

Zinc acetate (Galzin, Gate Pharmaceutical Co), developed for the treatment of Wilson's disease (4), has been used in maintenance therapy of adult and pediatric disease, but it also has efficacy in the treatment of pregnant women and presymptomatic patients from the start. It also has value as adjunctive therapy for the initial treatment of symptomatic patients. Its mechanism of action involves induction of intestinal cell metallothionein, which blocks copper absorption from the intestinal tract. Negative copper balance is caused by blockade not only of absorption of food copper but by blockade of reabsorption of the considerable amount of endogenously secreted copper in saliva, gastric juice, and intestinal secretions. It is therefore effective in controlling copper concentrations and toxicity in Wilson's disease.

The main advantage of zinc over other anticopper agents is its extremely low toxicity. The only adverse effect is some degree of initial gastric irritation in about 10% of patients, which usually abates and becomes insignificant over time. As with all long-term therapies, compliance is a problem in some patients and dictates regular monitoring by measurement of 24-hour urine copper and zinc. As with all anticopper therapies, overtreatment can cause copper deficiency over a long period of time. This is to be avoided, particularly in children, because copper is required for growth.

Zinc can be beneficial in zinc deficiency. Severe depletion of zinc in two patients with advanced cancer and malnutrition was accompanied by cutaneous bleeding, a prolonged bleeding time, and abnormal platelet aggregation (5). Both had very low serum and urinary zinc concentrations. Oral zinc without any additional therapy was rapidly followed by control of bleeding and normalization of bleeding time and platelet aggregation. Discontinuation of zinc caused the return of the bleeding and abnormal laboratory findings.

Organs and Systems

Nervous system

Clioquinol (5-chloro-7-iodo-8-hydroxyquinoline) was used 30 years ago as an oral antiparasitic agent and to increase the intestinal absorption of zinc in patients with acrodermatitis enteropathica, a genetic disorder of zinc absorption. However, the use of clioquinol was epidemiologically linked to subacute myelo-optic neuropathy (SMON), characterized by peripheral neuropathy and blindness, which affected 10 000 patients in Japan. Withdrawal of oral clioquinol led to the elimination of SMON, but the mechanism of how clioquinol induces neurotoxicity is unclear. There is now evidence that zinc may have been implicated.

The effect of clioquinol-metal chelates has been tested on neural crest-derived melanoma cells (6). The effect of clioquinol chelates on cells was further studied by electron microscopy and by a mitochondrial potential-sensitive fluorescent dye. Of the ions tested, only clioquinol-zinc chelate was cytotoxic. This cytotoxicity was extremely rapid, suggesting that its primary effect was on the mitochondria, and electron microscopic analysis showed that the chelate caused mitochondrial damage. This was further confirmed by the observation that the chelate reduced the mitochondrial membrane potential. The phenomenon of clioquinol-mediated toxicity appeared to be specific to zinc and was not seen with other metals tested. Since clioquinol causes increased systemic absorption of zinc, it is likely that clioquinol-zinc chelate was present in appreciable concentrations in patients with SMON and may have been the causative toxin.

Hematologic

The use of megadoses of vitamin and mineral supplements has become common, and adverse effects can occur.

- A 17-year-old man developed fatigue after taking large daily doses of zinc supplements for 6–7 months in an attempt to treat his acne (7). He initially took 50 mg/day, but because his acne did not improve he increased the dosage to 100 mg tds. He had anemia and neutropenia. His plasma zinc concentration was 1.95 (reference range 0.50–0.95) μg/ml 1 month after withdrawal and 1.69 μg/ml 1 month later. His plasma copper concentration was 0.12 (reference value 0.90–2.35) μg/ml. When his anemia and neutropenia had resolved 4 months later, the zinc and copper concentrations had returned to normal.

Zinc sulfate can cause copper deficiency by inducing the production of metallothionein in intestinal cells and thus lowering copper absorption; copper deficiency can lead in turn to sideroblastic anemia (8), neutropenia, and osteopenia (9).

- A 17-year-old man with anaemia, leukopenia, and neutropenia had been self-medicating with over-the-counter zinc formulations for acne for almost 2 years at doses of up to 300 mg/day (10). Serum copper and serum ceruloplasmin concentrations were less than 100 (reference range 70–155) ng/ml and 20 (23–49) μg/ml respectively. His serum zinc concentration was 2 (0.6–1.3) μg/ml. Within 1 month of withdrawal, and without copper supplementation, the ceruloplasmin concentration had risen to 90 μg/ml. By 2 months his complete blood count was normal.

It is not clear whether zinc itself also causes anemia directly, or whether the effect is exerted solely through

© 2006 Elsevier B.V. All rights reserved.

this interaction with copper, but with the increasingly popular sale of zinc supplements this adverse effect merits attention as a possible cause of unexplained blood disorders (11).

Gastrointestinal

Zinc compounds that are soluble in water or in gastric fluid are poisonous. If zinc sulfate is given on an empty stomach, gastric acid can convert it to zinc chloride, which is a powerful caustic agent; it is therefore not surprising that gastric irritation, nausea, vomiting, hemorrhagic erosive gastritis, and diarrhea are common adverse reactions.

Bacitracin zinc has been used for giardiasis (12), in which it appears effective. In the doses used, adverse effects have been limited to nausea, abdominal discomfort, and diarrhea in a small number of patients. Similar effects have been noted when zinc gluconate lozenges were administered for the common cold (13).

- A 10-year-old girl accidentally ingested an acid soldering flux solution (pH 3.0; zinc chloride 30–60%) (14). Systemic effects after ingestion were unremarkable, except for lethargy. Thus, chelation therapy was not considered. Severe gastric corrosion was caused by local caustic action. An antral stricture of the stomach developed about 3 weeks later, and she had a modified Heineke–Mikulicz antropyloroplasty. Postoperatively, she made an uneventful recovery. However, although she was tolerating a normal diet, a barium meal showed that her stomach was totally aperistaltic.

In this case careful long-term follow-up was considered necessary, because of the potential risk of malignancy in the damaged stomach.

Liver

The use of zinc acetate in Wilson's disease has been reviewed and recommended rather than copper chelation, because of limited adverse effects. However, liver damage has been attributed to zinc in a patient with Wilson's disease (15).

- A 25-year-old woman with Wilson's disease took oral zinc acetate 50 mg tds and 21 days later developed right hypochondrial pain, nausea, vomiting, fever, arthralgia, and tender hepatomegaly. Her hemoglobin was at 10.5 g/dl, aspartate transaminase 393 U/l, and alanine transaminase 911 U/l. Oral zinc was withdrawn and oral D-penicillamine (250 mg qds) was prescribed. One week later she was asymptomatic, and her liver enzymes returned to normal within 4 months.

Skin

Lichen planus has been attributed to zinc in dental materials.

- A 74-year-old woman, who had extensive odontitis treated with root canal disinfection and dental metal restorations, developed painful erosion and erythema of the upper lip mucosa, white streaks on the buccal mucosa, and white lesions on the gums (16). Histology showed lichen planus. Her 14 dental metal restorations contained 5.3% zinc, and patch-testing was positive with zinc chloride and negative with all the other metal components. The lichen planus resolved 3 months after removal of the metal restorations.

Zinc products are extensively used in shampoos and other non-medical items and severe reactions occasionally occur. In one instance a shampoo based on zinc pyrithione caused a serious relapse in a woman with stable psoriasis (SEDA-22, 251).

Reproductive system

The efficacy and safety of intravaginal zinc sulfate + usnic acid as adjuvant therapy for human papillomavirus genital infection has been studied before or after radiosurgical treatment in 100 patients (17). Papillomavirus lesions disappeared in 93% of the patients in the control group and in 100% of the others. Re-epithelialization after 1 month was complete in only 28% of the control group but in 65% of the treated patients; after 2 months it was complete in 76% of the controls and in 94% of the others. Treatment before radiosurgical treatment resulted in a reduction of the overall area of lesions in 88% of cases. Three months after radiosurgical treatment there was significantly less recurrence in those treated with usnic acid and zinc sulfate. Adverse effects were limited to local pain and irritation and were well tolerated.

Immunologic

Zinc can reportedly impair immune responses (18).

Drug Administration

Drug dosage regimens

When zinc is used therapeutically, the dosage of zinc often considerably exceeds the recommended daily allowance for healthy adults (15 mg of elemental zinc). In view of its adverse effects, it is advisable to limit the dosage to two or three times this amount. To reduce the unwanted gastrointestinal effects it may be helpful to use zinc acetate rather than zinc sulfate (19).

Drug overdose

- A very old woman accidentally ingested a formulation containing zinc and copper sulphate (20). At 90 minutes after ingestion, the peak plasma concentrations were 20 mg/ml for zinc and 2 μg/ml for copper. The major complications were gastric and bronchial inflammation, due to the corrosive properties of these compounds. There were also systemic manifestations, with cardiovascular failure and renal insufficiency, but the patient made a complete recovery.
- A schizophrenic patient died after ingesting 461 coins, the first reported case of a death associated with zinc intoxication (21). The patient presented with clinical manifestations consistent with the local corrosive as well as systemic effects of zinc intoxication and died 40 days after admission with multisystem organ failure. Many British post-1981 pennies, which contain mostly

© 2006 Elsevier B.V. All rights reserved.

zinc, were severely corroded through prolonged contact with gastric juice. Tissue samples of the kidneys, pancreas, and liver obtained at autopsy contained high concentrations of zinc and showed acute tubular necrosis, mild fibrosis, and acute massive necrosis respectively.

Zingiberaceae

See also Herbal medicines

General Information

The genera in the family of Zingiberaceae (Table 1) include cardamom and ginger.

Zingiber officinale

Zingiber officinale (ginger) contains a variety of compounds, including diarylheptanoids and the phenol gingerol. It has been used to treat motion sickness and other forms of nausea and vomiting, and may have some efficacy (1).

Adverse effects

Skin

Of about 1000 patients with occupational skin diseases, five had occupational allergic contact dermatitis from spices (2). They were chefs, or workers in kitchens, coffee rooms, and restaurants. In all cases the dermatitis affected the hands. The causative spices were garlic, cinnamon, ginger, allspice, and clove. The same patients had positive patch test reactions to carrot, lettuce, and tomato.

Among 55 patients with suspected contact dermatitis, skin patch tests that were positive at concentrations of both 10% and 25% were most common with ginger ($n = 7$), nutmeg ($n = 5$), and oregano ($n = 4$); other spices produced no responses or one positive response (3). Positive

reactions at only one concentration were more likely at 25%: nutmeg ($n = 5$), ginger and cayenne ($n = 4$), curry, cumin, and cinnamon ($n = 3$), turmeric, coriander, and sage ($n = 2$), oregano ($n = 1$), and basil and clove ($n = 0$).

Drug interactions

Ginger may potentiate the effects of oral anticoagulants (4).

- A 76-year-old white woman taking long-term phenprocoumon, with an INR in the target range, began using ginger products (5). Several weeks later, her INR rose to 10 and she had epistaxis. The INR returned to the target range after ginger was stopped and vitamin K1 was given.

Zipeprol

General Information

Zipeprol is a centrally acting cough suppressant. Because it has hallucinogenic effects, it has been abused, particularly in Korea.

Long-Term Effects

Drug abuse

Abuse of zipeprol can be a problem (SEDA-17, 211), and has been associated with severe neurological symptoms.

Drug Administration

Drug overdose

A retrospective study of cases of eprazinone, eprozinol, and zipeprol intoxication collected at the Poison Control Center in Paris from 1975 to 1982 noted 199 cases of accidental or intentional acute poisoning. In seven cases, seizures were observed, all after ingestion of eight times the therapeutic dose. They resolved rapidly and without recurrence with symptomatic treatment (1).

In Korea, from 1991 to 1998, a total of 69 zipeprol-related deaths were reported (2). In 96% of cases involving zipeprol alone, the victims were in their teens and twenties. The male/female ratio was 3.5:1. The blood concentration of zipeprol was 0.8–38 μg/ml when zipeprol was taken alone and 0.1–35 μg/ml zipeprol when it was taken with dextromethorphan.

Ziprasidone

See also Neuroleptic drugs

General Information

Ziprasidone is a dibenzotheolylpiperazine compound with a receptor binding profile similar to that of other atypical antipsychotic drugs, and a high affinity for serotonin (5-HT_{2A}) receptors and a lower affinity for dopamine (D_2) receptors; it also has high affinities for 5-HT_{1A}, 5-HT_{1D} and 5-HT_{2C} receptors and inhibits serotonin and noradrenaline reuptake. Two extensive reviews of the clinical pharmacology of ziprasidone have appeared (1,2).

On February 5, 2000, the FDA approved ziprasidone for the treatment of schizophrenia (www.fda.gov). However, the FDA has been concerned with the possibility that ziprasidone and a number of other drugs might increase the risk of the specific potentially fatal cardiac dysrhythmia, torsade de pointes. The FDA did not approve ziprasidone in 1998, because of evidence that it can cause prolongation of the QT interval, and they asked that specific safety data be gathered. The safety data were submitted in 1999. Although QT prolongation is still a theoretical concern, over 4000 patients have been treated in clinical trials without evidence of torsade de pointes. In addition, overall mortality in the trials was similar to that seen with placebo and other neuroleptic drugs. The FDA labelling does not include a so-called "black-box warning" and does not require an electrocardiogram before or during treatment. However, the labelling does warn physicians and patients about QT interval prolongation and the possible risk of sudden death. The labelling suggests that doctors use their best judgment, based on the health status of the individual, as to whether to use ziprasidone as first-line treatment or only after other available drugs have failed. There is no requirement that patients have regular heart check-ups while taking this drug.

Comparison with placebo

Ziprasidone has been used in 28 children and adolescents (aged 7–17 years) with Tourette's syndrome in

© 2006 Elsevier B.V. All rights reserved.

an 8-week pilot study (3). They were randomly assigned to ziprasidone (5–40 mg/day; $n = 16$) or placebo ($n = 12$). Ziprasidone significantly reduced tic frequency. There was one case each of somnolence and akathisia, both with the highest dose of ziprasidone; these were considered to be severe but did not necessitate withdrawal.

Comparison with benzodiazepines

Ziprasidone 20 mg ($n = 30$) has been compared with diazepam 10 mg ($n = 30$) and placebo ($n = 30$) in a randomized, parallel-group, double-blind study in nonpsychotic subjects who were anxious before undergoing minor dental surgery (4). The peak anxiolytic effect of ziprasidone compared with placebo was similar to that of diazepam but had a later onset. However, at 3 hours after the dose, the anxiolytic effect of ziprasidone was significantly greater than that of placebo and somewhat greater than that of diazepam. The sedative effect of ziprasidone was never greater than that of placebo, whereas diazepam was significantly more sedative than placebo 1–1.5 hours after the dose. Ziprasidone was generally well tolerated; only one patient reported treatment-related adverse events (nausea and vomiting) and, unlike diazepam, ziprasidone did not reduce the blood pressure. Dystonia, extrapyramidal syndrome, akathisia, and postural hypotension were not seen with ziprasidone. Ziprasidone may therefore have anxiolytic effects in addition to its neuroleptic properties.

Organs and Systems

Cardiovascular

Three extensive reviews of ziprasidone have devoted particular attention to the possibility of QT interval prolongation (5–7). Ziprasidone up to 160 mg/day prolongs the QT_c interval on average 5.9–9.7 ms (data from 4571 patients); a QT_c interval of over 500 ms was seen in two of 2988 ziprasidone recipients and in one of 440 placebo recipients. In an open study in 31 patients with schizophrenia, ziprasidone given for 21–29 days prolonged the QT_c interval by 20 ms (95% CI = 14, 26).

- A 38-year-old woman with a psychosis who took 4020 mg of ziprasidone had borderline intraventricular conduction delay (QRS duration 111 ms); the QT_c interval was 445 ms (8). She oscillated between being drowsy and calm, and alert and agitated; her blood pressure fell from 129/81 to 99/34 mmHg 4 hours later. She also had diarrhea and urinary retention.

Nervous system

In a randomized, Phase III, double-blind study, ziprasidone 80 mg/day and 160 mg was more effective than placebo in patients with acute exacerbations of schizophrenia or schizoaffective disorders ($n = 302$) (9). After 6 weeks, somnolence (19%) and akathisia (13%) were more frequent with ziprasidone 160 mg than with placebo (5 and 7% each). Benzatropine was required at some time during the study by 20% of the patients taking ziprasidone 80 mg/day, 25% of those taking ziprasidone 160 mg/day, and 13% of those taking placebo. The long-term safety of ziprasidone is unknown.

Tardive dyskinesia has been associated with ziprasidone in a 49-year-old man with bipolar disorder (10).

Psychological, psychiatric

Three cases of hypomania in patients with depression have been reported (11).

Metabolism

Ziprasidone is said to be associated with less weight gain than the other atypical neuroleptic drugs and than most typical ones (1,2).

Musculoskeletal

Rhabdomyolysis with pancreatitis and hyperglycemia has been reported in a middle-aged woman with schizoaffective disorder (12).

Drug–Drug Interactions

Pfizer, the marketing authorization holder of ziprasidone, has promoted several pharmacokinetic studies. Oral contraceptives (ethinylestradiol 30 μg/day plus levonorgestrel 150 μg/day) (13), lithium 900 mg/day (14), ketoconazole 400 mg/day (15), and carbamazepine (100–400 mg/day) (16) had no effects on the pharmacokinetics of ziprasidone (40 mg/day).

Zirconium

General Information

Zirconium is a metallic element (symbol Zr; atomic no. 40) that occurs in minerals such as baddeleyite and eudialyte.

Topical zirconium can cause hypersensitivity granulomas in sensitized persons, which has led to the removal of zirconium salts from antiperspirants (SEDA-22, 242). Complexes of zirconium and aluminum are non-sensitizing and are still commonly used as active ingredients in topical antiperspirants. However, a granulomatous reaction to this material has been reported (1).

Zofenopril

See also Angiotensin converting enzyme inhibitors

General Information

Zofenopril is a prodrug that, once absorbed, undergoes rapid and complete hydrolysis to the sulfhydryl-containing active ACE inhibitor zofenoprilat. The use of zofenopril in hypertension and in acute myocardial infarction has been extensively reviewed (1).

Reference

1. Borghi C, Ambrosioni E. Zofenopril: a review of the evidence of its benefits in hypertension and acute myocardial infarction. Clin Drug Invest 2000;20:371–84.

Zolpidem

General Information

Zolpidem and alpidem are imidazopyridines, chemically distinct from the benzodiazepines and appear to bind selectively to a subset of benzodiazepine receptors (1). This property may account for their apparently milder withdrawal effects and, in the case of alpidem, a relative dominance of anxiolytic over sedative and cognitive effects (2). Zolpidem has hypnotic efficacy comparable to short- and medium-acting benzodiazepines, and has similar or possibly fewer adverse effects at therapeutic doses (3–5), except for gastrointestinal disturbances, which appear to be more common, and visual hallucinations, especially in women (SEDA-17, 46) (SEDA-18, 45) (SEDA-21, 40). On the other hand, zolpidem unexpectedly causes as much memory impairment as triazolam, if not more, at least in young healthy adults (SEDA-19, 33). Also surprising is the same author's later contention that zolpidem causes less memory impairment than do the benzodiazepine hypnotics (SEDA-21, 40), presumably including triazolam. Zolpidem may also be relatively toxic in overdose, owing to respiratory depression (6), but later observations have suggested that it may not be any more toxic than the benzodiazepines (SEDA-21, 40). At normal doses zolpidem is said to be at least as safe as standard benzodiazepines in patients with respiratory compromise (SEDA-21, 40). The effects of zolpidem are reversed by flumazenil (7).

Subjective responses to treatment with zolpidem were assessed in 16 944 outpatients with insomnia. Nausea, dizziness, malaise, nightmares, agitation, and headache were the most common adverse events reported. There was one serious adverse reaction in a 48-year-old woman, who developed paranoid symptoms during the documentation phase. There were no life-threatening adverse events (8).

The safety and tolerability of zolpidem have been investigated in two multicenter studies, in which 8.9% and 7.5% of the patients reported an adverse event (9). The most frequent events were related to the central nervous system (somnolence, headache, confusion, vertigo), but gastrointestinal and cutaneous symptoms were also frequently reported.

In a double-blind, placebo-controlled, crossover study, 10 patients with "probable progressive supranuclear palsy" took single oral doses of zolpidem (5 and 10 mg), co-careldopa (levodopa 250 mg plus carbidopa 25 mg), or placebo in four separate trials in random order (10). Zolpidem, unlike levodopa or placebo, reduced voluntary saccadic eye movements, and the 5 mg dose produced a statistically significant improvement in motor function. The adverse effects of zolpidem included drowsiness and

© 2006 Elsevier B.V. All rights reserved.

increased postural instability and were more marked after a dose of 10 mg.

Zolpidem has been investigated in a multicenter, double-blind, placebo-controlled, parallel-group, randomized study in 138 adults, who were experienced air travelers (11). They were randomized to zolpidem 10 mg or placebo for three (or optionally four) consecutive nights, starting with the first night-time sleep after travel. Sleep was assessed with daily questionnaires. Compared with placebo, zolpidem was associated with significantly improved sleep, longer total sleep time, reduced numbers of awakenings, and improved sleep quality. It was not associated with improvement in sleep latency. No unexpected or serious adverse events were reported and the most common adverse event was headache in both groups.

Zolpidem 10 mg/day and zopiclone 7.5 mg/day, given at night, have been compared in a 14-day, double-blind study in 479 chronic primary insomniacs (12). With zolpidem 68% of the patients were rated at least "moderately improved," versus 62% with zopiclone. However, with zolpidem sleep-onset latency improved in significantly more patients (86 versus 78%). In addition, significantly fewer patients who took zolpidem had drug-related adverse events (31 versus 45%); bitter taste accounted for 5.8% of such complaints with zolpidem compared with 40% with zopiclone. In conclusion, zolpidem was at least as effective as zopiclone but showed significantly less rebound on withdrawal; overall it was better tolerated.

Improvement in social and occupational function has been attributed to zolpidem (13).

- A recovering 60-year-old alcoholic woman developed reduced cognitive function, including considerable memory loss, praxis disorders, and an inability to join in conversation. A CT scan showed non-specific cerebral atrophy. She was given zolpidem 10 mg for insomnia, which she took at first at 2200 hours, but then earlier, at 1900 hours. After starting to take it at the earlier time she talked more easily and could wash the dishes and do the housework, things that she had lost the ability to do. This beneficial effect was detectable 45–60 minutes after the dose of zolpidem, lasted for 3 hours after each administration, and then abated. The subjective improvement in cognitive function was confirmed several times by her general practitioner.

Three patients had improvements in dystonia and parkinsonism after taking zolpidem 10 mg (14). The improvement in dystonia began at 15–45 minutes and optimal benefits were observed after 1–2 hours. The mean duration of action was 4.5 hours initially, falling to 2–3 hours with chronic use. This is similar to that reported in patients with progressive supranuclear palsy, and corresponds to the drug's half-life (2.5 hours). Sleepiness was noted at doses over 10 mg bd.

Organs and Systems

Nervous system

Zolpidem 10 mg, temazepam 15 mg, and placebo have been compared in 630 healthy adults in a multicenter study (15). They were given 15 minutes before lights out, with polysomnographic monitoring for 7.5 hours. Subjective questionnaires and performance tests, including digit symbol substitution and symbol copying, were administered before and after sleep. Neither drug significantly reduced objective sleep latency, but zolpidem reduced awakenings compared with temazepam. Both improved sleep efficiency and most subjective sleep measures, and zolpidem was superior to temazepam in five of six subjective outcome measures. Symbol copying, morning sleepiness, and morning concentration were not altered. Zolpidem 10 mg provided greater subjective hypnotic efficacy than temazepam 15 mg in this model of transient insomnia, with reduced polysomnographic awakenings.

Zolpidem was identified in the blood of 29 subjects arrested for impaired driving (16). In those in whom zolpidem was present with other drugs and/or alcohol, the symptoms reported were generally those of nervous system depression and included slow movements and reactions, slow and slurred speech, poor coordination, lack of balance, flaccid muscle tone, and horizontal and vertical gaze nystagmus. In five subjects in whom zolpidem was the only drug detected, signs of impairment included slow and slurred speech, slow reflexes, disorientation, and lack of balance and coordination. Therapeutic doses of zolpidem can affect driving adversely, and concentrations above the target range further impair both driving ability and consciousness.

Psychological, psychiatric

Like the benzodiazepines, zolpidem can produce a variety of paradoxical effects, including disturbances of mood, perception, and behavior. In 192 surgical patients zolpidem 8 mg but not 16 mg caused such effects, particularly anxiety, 1 hour after administration (17).

The acute effects of zolpidem and triazolam have been compared in 10 non-drug-abusing subjects using a Digit-Enter-and-Recall task with varying delay intervals (9, 10, and 20 seconds) (18). Zolpidem and triazolam impaired performance as a function of dose after all intervals. However, zolpidem produced significantly less impairment than triazolam after the longest delay (20 seconds). Zolpidem and triazolam produced comparable dose-related impairment of the digit symbol substitution, circular lights, and picture recall/recognition tasks. The results suggested that zolpidem may have less potential than triazolam to impair recall, which may be due to differences between these compounds in terms of their benzodiazepine-receptor binding profiles.

Delirium has been attributed to zolpidem (19,20).

- A 26-year-old woman was treated at a psychiatric inpatient unit for psychotic depression. She had neither formal thought disorder nor perceptual disturbances and was cognitively intact. Ten days later she was stabilized on fluoxetine, risperidone, and benzatropine. She then developed flu-like symptoms, and 3 days later took zolpidem 10 mg to help her to sleep. After 30 minutes she was found agitated, confused, and rambling, and wanted to go to the beach. Her speech was disorganized and she had visual hallucinations. Her gait was ataxic. There were no signs of meningeal irritation. Her temperature was 37.3°C, her

© 2006 Elsevier B.V. All rights reserved.

pulse 114/minute, and her blood pressure 116/78 mmHg. When she was evaluated the next morning, her delirium had cleared and she made a full recovery.

- An 86-year-old white woman with headaches and diplopia took zolpidem 5 mg and about 2 hours later became restless, disoriented, and physically agitated. She was given haloperidol and needed restraining for her own safety. Her symptoms resolved by day 5 and she had no recollection of the incident. Rechallenge was not attempted.

Liver

Liver damage has been attributed to zolpidem (21).

- A 53-year-old woman first took zolpidem for insomnia in July 1996. In September 1996 she again took zolpidem 20 mg/day and 2 days later had developed sudden epigastric pain associated with pale stools and dark urine but no fever; she stopped taking zolpidem and the abdominal pain resolved spontaneously within 12 hours. In April 1997, she had another episode of abdominal pain after taking zolpidem. Eleven days later her serum alanine transaminase and gamma-glutamyltranspeptidase activities were 50 IU/l and 89 IU/l respectively. In June 1997 ultrasound showed a normal biliary tract. Viral hepatitis and concurrent infections with Epstein-Barr virus and cytomegalovirus were excluded.

Long-Term Effects

Drug abuse

There has been a literature review of the abuse potential of zolpidem (22). There were 15 published cases of abuse or dependence. In six patients the abuse was secondary to other forms of abuse or dependence. The authors concluded that the abuse potential of zolpidem is much less than with other hypnotics and that it is also safer than conventional hypnotics. Patients with a history of other substance abuse may be considered as being at risk of later abuse of zolpidem.

However, there is a risk of abuse and dependence from chronic use of zolpidem in high doses (23).

- A 67-year-old Caucasian woman, who had previously been treated for depression, anxiety, and insomnia, as well as alcohol, barbiturate, and benzodiazepine dependence, was given zolpidem 10 mg at bedtime for insomnia. She increased the dose without the knowledge of her physicians, using up to 100 mg/day for 1.5 years, alternating it with various benzodiazepines obtained from multiple physicians when zolpidem was unobtainable. She developed severe generalized tremor, psychomotor agitation, facial flushing, and anxiety, despite taking chlordiazepoxide 300 mg in divided doses during the first 24 hours of detoxification. A tapering dose of zolpidem was initiated and the chlordiazepoxide was tapered. Her symptoms completely subsided within 30 minutes of a single dose of zolpidem 15 mg.

Drug dependence

Four cases of former drug or alcohol abusers with personality disorders have been described; all developed dependence while taking high doses of zolpidem (24).

Drug withdrawal

Zaleplon has been compared with zolpidem 10 mg and placebo in 615 adult outpatients with insomnia (25). After a 7-night placebo (baseline) period, the patients were randomly assigned to receive one of five treatments in double-blind fashion for 28 nights (zaleplon 5, 10, or 20 mg; zolpidem 10 mg; or placebo), followed by placebo for 3 nights. Sleep latency, sleep maintenance, and sleep quality were determined from sleep questionnaires each morning. Rebound insomnia and withdrawal effects on withdrawal were also assessed. After withdrawal of zolpidem, the incidence of withdrawal symptoms was significantly greater than after withdrawal of placebo, and there was suggestion of significant rebound insomnia in some patients who had taken zolpidem compared with placebo. The frequency of adverse events in the active treatment groups did not differ significantly from that in the placebo group.

Withdrawal-induced seizures have been described in a woman taking various benzodiazepines and zolpidem (26).

- A 43-year-old woman had had insomnia since she was a child. At the age of 15 benzodiazepine therapy improved her sleeping, but when she gradually stopped taking benzodiazepines the insomnia returned after a few days. At the age of 26 she was abusing several benzodiazepines, including diazepam and flunitrazepam. At the age of 30 she was taking high doses of bromazepam every evening before going to sleep. After 1 month, she abruptly stopped taking bromazepam and during withdrawal had an epileptic seizure. During the next few years, she had periods of relative well-being, but also two further periods of benzodiazepine abuse, both resulting in seizures after withdrawal. Finally, a physician prescribed zolpidem. Two months later she increased the dose to 450–600 mg/day. After another month of abuse, she was forced by an unexpected event to discontinue the zolpidem and 4 hours later had an epileptic seizure, similar to the previous ones. She started taking zolpidem again, the drug abuse continued, and her fits settled. Six months later she underwent a planned program of zolpidem withdrawal.

Susceptibility Factors

Hepatic disease

The adverse effects of zolpidem can be enhanced in hepatic cirrhosis (27).

- A 41-year-old white man developed postoperative complications 11 months after liver transplantation. His mental status began to deteriorate secondary to hepatic encephalopathy. One day before admission he was given zolpidem 5 mg for sleep and 1 hour later he awoke in a stupor and was not oriented to place or

© 2006 Elsevier B.V. All rights reserved.

time. He became increasingly incoherent and verbally abusive.

Although this patient's worsening mental state could have been explained by the natural history of the encephalopathy, it is possible that zolpidem exacerbated his decline.

Drug Administration

Drug dosage regimens

A review of six studies in over 4000 patients has suggested that non-nightly administration of zolpidem is effective and does not appear to be associated with withdrawal symptoms or dose escalation (28). On the other hand, a case report has suggested that stopping and restarting zolpidem can trigger visual hallucinations; the same phenomenon was observed three times in a healthy 23-year-old Chinese woman (29).

Drug overdose

Two deaths due to acute intentional zolpidem overdose have been reported (30).

- A 36-year-old woman with a history of psychiatric illness, including paranoid disorder, depression with panic episodes, and stress disorder, was found dead in bed. Caffeine, risperidone, and zolpidem were found in her urine.
- A 58-year-old woman with a history of hypertension and mental illness (manic depression and schizophrenia) was found dead in bed, with white foam around her mouth. Zolpidem and carbamazepine were found in her urine.

The cause of death in both cases was thought to have been acute zolpidem overdose, but it is not clear how risperidone and carbamazepine could have been excluded as possible contributors.

- A 44-year-old white man, who had had major depression and anxiety disorder for 25 years, became drowsy after swallowing 20 tablets (10 mg) of zolpidem (31). He was not taking any other medications at the time. A few hours later he became unresponsive and comatose and developed respiratory depression with hypoxia and mild hypercapnia. He subsequently made a full recovery after appropriate medical support.

Drug–Drug Interactions

Antifungal imidazoles

Potential interactions of zolpidem with three commonly prescribed azole derivatives (ketoconazole, itraconazole, and fluconazole) have been evaluated in a controlled clinical study. Co-administration of zolpidem with ketoconazole impaired zolpidem clearance and enhanced its benzodiazepine-like agonist pharmacodynamic effects. Itraconazole and fluconazole had a small effect on zolpidem kinetics and dynamics. The findings were consistent with in vitro studies of differentially impaired zolpidem metabolism by azole derivatives (32).

Similarly, itraconazole 200 mg did not alter the pharmacokinetics and pharmacodynamics of zolpidem 10 mg in 10 healthy volunteers (33). Therefore, unlike triazolam, zolpidem may be used in normal or nearly normal doses together with itraconazole.

Drugs that compete for hepatic oxidative pathways

Omeprazole, like cimetidine, can impair benzodiazepine metabolism and lead to adverse effects (SEDA-18, 43). Other drugs, including antibiotics (erythromycin, chloramphenicol, isoniazid), antifungal drugs (ketoconazole, itraconazole, and analogues), some SSRIs (fluoxetine, paroxetine), other antidepressants (nefazodone), protease inhibitors (saquinavir), opioids (fentanyl), calcium channel blockers (diltiazem, verapamil), and disulfiram also compete for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Fluoxetine

The possible pharmacokinetic and pharmacodynamic interactions of repeated nightly zolpidem dosing with fluoxetine were evaluated in 29 healthy women. There were no clinically significant pharmacokinetic or pharmacodynamic interactions (34).

Rifampicin

Rifampicin, and presumably other CYP3A inducers, reduces concentrations of zolpidem (SEDA-22, 42).

Ritonavir

The inhibitory effect of ritonavir on the biotransformation of triazolam and zolpidem has been investigated (35). Short-term, low-dose ritonavir produced a large and significant impairment of triazolam clearance and enhancement of its clinical effects. In contrast, ritonavir produced small and clinically unimportant reductions in zolpidem clearance. The findings are consistent with the complete dependence of triazolam clearance on CYP3A activity, compared with the partial dependence of zolpidem clearance on CYP3A.

Sertraline

Interactions between zolpidem and sertraline have been studied in 28 healthy women, who took a single dose of zolpidem alone and five consecutive doses of zolpidem 10 mg while taking chronic doses of sertraline 50 mg (36). Co-administration of sertraline 50 mg and zolpidem 10 mg was safe but could result in a shortened onset of action and increased effect of zolpidem.

Zomepirac

See also Non-steroidal anti-inflammatory drugs

General Information

Although zomepirac is a pyrrole-acetic acid compound closely related to tolmetin, it was originally claimed to be a new type of analgesic drug. Its history is not unlike that of benoxaprofen. In 1982, because of the severity and frequency of hypersensitivity reactions, it was withdrawn voluntarily by the manufacturers worldwide on a temporary basis (1). It has not been relaunched.

The overall incidence of its adverse effects, according to numerous reviews (SEDA-7, 114), is similar to or somewhat higher than with other NSAIDs. After single oral doses 36% of 496 patients had some adverse effects. The percentage was even higher (43%; 458 of

© 2006 Elsevier B.V. All rights reserved.

1079 patients) during short-term therapy (2 weeks). Owing to adverse reactions, 3.5% of patients dropped out. When it was given over 2–3 weeks, 65–70% patients had adverse effects, but the discontinuation rate was similar to or lower than that of other NSAIDs (2,3). Only the most important adverse effects are presented here.

Organs and Systems

Gastrointestinal

Adverse effects of zomepirac on the gastrointestinal tract were the most frequent reason for interruption of treatment. They increase with duration of administration. Nausea, vomiting, dyspepsia, discomfort, abdominal pain, and diarrhea or constipation have been recorded, as have stomatitis and tongue pain (4). Zomepirac 300 mg/day increases fecal blood loss, but less than aspirin.

Urinary tract

In five patients with prior normal renal function, zomepirac caused acute renal insufficiency, with varying degrees of uremia, proteinuria, and oliguria (5). All recovered either after withdrawal or with prednisone therapy. In another case renal biopsy showed a tubulointerstitial nephritis (6).

Immunologic

The manufacturers received 1100 reports of allergic reactions in the first 2 years after launch. Fatal anaphylactic and anaphylactoid reactions have been reported: 10% of all reports on anaphylactic reactions in the USA named zomepirac, making it second only to the much older drug tolmetin. Hypersensitivity reactions are characterized by hypotension, bronchospasm, and serious respiratory distress, with or without oropharyngeal edema. Type-III allergic reactions have also been described.

Long-Term Effects

Drug dependence

Suspicions based on cluster reports that zomepirac may be addictive have not been confirmed (7).

Zonisamide

See also Antiepileptic drugs

General Information

Original attempts to market zonisamide in the USA were halted by reports of nephrolithiasis, but successful marketing in Japan resulted in renewed interest elsewhere (1). Zonisamide has a broad spectrum of efficacy in the treatment of seizures, including infantile spasms and myoclonic seizures. It may also have neuroprotective and antimanic effects. Its mechanism of action is not known, but it blocks sodium channels and T-type calcium channels and scavenges free radicals.

In a large Japanese survey, adverse effects occurred in 51% of patients treated with zonisamide and led to drug withdrawal in 18%. The most common were drowsiness, ataxia, anorexia, mental slowing, and gastrointestinal symptoms (2). Other adverse effects include dizziness, nystagmus, dysarthria, diplopia, asterixis, tremor, confusion, anorexia, and weight loss. Some of these may be related to the rate of dosage escalation.

In a double-blind, placebo-controlled, add-on, randomized trial of zonisamide 400 mg/day in 203 patients over 14 years of age with refractory partial-onset seizures, the response rate was 42% (3). The most common treatment-emergent adverse events were somnolence, anorexia, rhinitis, dizziness, nausea or vomiting, ataxia, fatigue, and headache. With zonisamide, 22% of the patients lost over 2.3 kg compared with 10% on placebo.

In a Cochrane Collaboration meta-analysis of trials of zonisamide, levetiracetam, oxcarbazepine, and remacemide, there were no significant differences in efficacy among the four drugs (4). The relative risks for treatment withdrawal were also not significantly different.

Organs and Systems

Psychological, psychiatric

Behavioral problems and acute mania have been described (SEDA-16, 75) (SEDA-19, 76).

Of 74 epileptic patients who had taken zonisamide 14 had psychotic episodes, diagnosed retrospectively (5). The authors estimated that the incidence of psychotic episodes during zonisamide treatment was several times higher than the previously reported prevalence of epileptic psychosis, and that the risk was higher in young patients. In 13 patients, psychotic episodes occurred within a few years of starting zonisamide. In children, obsessive-compulsive symptoms were related to psychotic episodes.

© 2006 Elsevier B.V. All rights reserved.

A unique form of paramnesia has been attributed to zonisamide (6).

- After an episode of zonisamide-induced psychosis, a 28-year-old man with epilepsy consistently mistook people who were unknown to him, such as hospital staff, for people whom he had met long ago. However, he did not misidentify their names or other attributes, such as their occupations.

The authors could not fit this extraordinary form of misidentification into any known subcategory of misidentification syndromes, but rather thought that it fitted Kraepelin's description of "assoziierende Erinnerungsfälschungen".

Acid–base balance

Metabolic acidosis has been reported in patients taking zonisamide (7). Zonisamide inhibits carbonic anhydrase (8), which might have contributed, as has been suggested by another case of metabolic acidosis in a 7-year-old boy, in which the mechanism was renal tubular acidosis.

Ammonium chloride, bicarbonate, and furosemide loading tests in an epileptic man with metabolic acidosis and episodic hypokalemia taking zonisamide showed evidence of distal renal tubular acidosis (9). On re-examination 7 weeks after zonisamide had been replaced with phenytoin, the renal tubular acidosis had resolved.

Urinary tract

Zonisamide inhibits carbonic anhydrase, but the risk of nephrolithiasis seems to be lower than initially suspected (SEDA-21, 80). Further cases have been reported (10).

- A 13-year-old boy who had taken zonisamide and acetazolamide for 2 months developed abdominal pain due to left-sided hydronephrosis, which resolved after the passage of a stone. He had an alkaline urine, and acetazolamide was withdrawn. However, 2 months later he formed another stone. Zonisamide was withdrawn and he formed no more stones.
- A 7-year-old boy took zonisamide for 3 months and then formed a thick sludge of calcium phosphate in the bladder when dehydrated because of pneumonia.
- A 15-year-old girl, who had a history of recurrent urinary obstruction, formed a thick sludge of calcium oxalate in the bladder.

In all three patients the urine was alkaline and there was hypercalciuria.

Sweat glands

Zonisamide can cause lack of sweating (11).

- A 10-year-old boy who had taken zonisamide for about 9 months noticed that he had a dry skin and that he seldom sweated. His zonisamide blood concentration was very high. He discontinued zonisamide and became able to sweat.

The authors suggested that this effect was due to ion channel blockade.

In 16 patients taking zonisamide, acetylcholine stimulation testing after about 1 month was normal in four cases and reduced in 12 (12). There was reduced sweating in four of the 12 who had a reduced test response, but not in the four with a normal response.

Children have a higher risk of zonisamide-associated oligohidrosis and hyperthermia (13). Elan Pharma issued a "Dear Doctor" letter reporting this adverse event in June 2002. During the zonisamide development program in Japan one case of oligohidrosis was reported among 403 children (an incidence of 1/285 patient-years of exposure). There were no cases reported in the US or European development programs, although under 100 children were included in those programs. In the first 11 years of marketing in Japan, 38 cases have been reported (about 1 per 10 000 patient-years). In the first year in the USA, two cases were reported (an estimated reporting rate of 12/10 000 patient-years). This rate might be an underestimate, owing to under-reporting.

There have been reports of heat stroke associated with reduced sweating in young patients.

- A 2-year-old mentally retarded boy with frontal lobe epilepsy developed hyperpyrexia with oligohidrosis and central neurological symptoms, including chorea-like involuntary movements, resting tremor, and cogwheel rigidity, while receiving zonisamide (14). A sweat test using pilocarpine iontophoresis showed a marked reduction in the sweat response, which suggested a postganglionic sweating dysfunction. A skin biopsy showed no morphological abnormality in the sweat glands. He regained the ability to sweat within 2 weeks of withdrawal.

Children receiving zonisamide should be monitored closely for evidence of reduced sweating and increased body temperature, especially in warm or hot weather and when taking other drugs that predispose to this (carbonic anhydrase inhibitors, anticholinergic drugs, topiramate).

Immunologic

Zonisamide-induced lupus erythematosus has been reported in a 5-year-old child taking zonisamide and ethosuximide (15). He had raised titers of antinuclear antibodies and anti-DNA antibodies and presented with fever, pericarditis, pleurisy, and arthralgia. Clinical recovery and a reduction in the anti-DNA-antibody titer promptly followed withdrawal. A lymphocyte transformation test against zonisamide was positive.

Second-Generation Effects

Lactation

Zonisamide concentrations in plasma and breast milk were measured, in order to investigate the transfer of zonisamide through the placenta and breast milk in two neonates (16). The transfer rates were 92% via the placenta and 41–57% via breast milk.

Drug–Drug Interactions

Carbamazepine

Evidence that zonisamide reduces serum carbamazepine concentrations is conflicting (SEDA-19, 61). Zonisamide

© 2006 Elsevier B.V. All rights reserved.

can reduce carbamazepine-10,11-epoxide to carbamazepine ratios, possibly by reducing the rate of epoxidation.

CYP3A4 inhibitors

In vitro data suggest that the CYP3A4 inhibitors ketoconazole, ciclosporin, and miconazole reduce zonisamide clearance by 31%, 23%, and 17% respectively (SEDA-22, 93).

Enzyme-inducing anticonvulsants

Serum zonisamide concentrations are reduced by enzyme-inducing anticonvulsants (17).

Lamotrigine

Preliminary evidence suggests that serum zonisamide concentrations can be increased by lamotrigine (17).

Diagnosis of Adverse Drug Reactions

The recommended target plasma zonisamide concentration is 10–20 μg/ml.

Zopiclone

General Information

Although it is chemically distinct to the benzodiazepines, zopiclone, a cyclopyrrolone, has similar pharmacology, binding close to the same site of the GABA receptor–chloride channel complex.

Zopiclone has been widely used as a hypnotic, comparable to estazolam (1), and appears to be relatively safe in overdose. It has no adverse effects that would not be expected from its pharmacological and pharmacokinetic properties, with three exceptions: bitter taste (in 3.6% of 20 513 patients) and, like zolpidem, increased risks of gastrointestinal disturbances and visual hallucinations (2,3). Subchronic zopiclone produces minimal changes in the sleep electroencephalogram (4), a potential advantage over benzodiazepines, and in direct comparisons was at least as effective as triazolam or flunitrazepam, with no rebound insomnia after 1 month (SEDA-19, 37). On the other hand, longer administration of zopiclone can cause physical dependence (5), emphasizing the importance of restricting treatment duration. Likewise, its potential for abuse and release of aggression (6) is similar to that of the benzodiazepines (SEDA-17, 47).

Organs and Systems

Nervous system

In a two-part, placebo-controlled, crossover comparison of the effects of zopiclone and zaleplon on car driving, memory, and psychomotor performance, zaleplon 10 mg had no residual effect on driving when taken at bedtime, 10 hours before driving (7). In contrast, zopiclone 7.5 mg caused marked residual impairment. Patients should be advised to avoid driving the morning after taking zopiclone.

Further concern that zolpidem can impair performance comes from a Chinese study (8). Zopiclone 7.5 mg, but not triazolam 2.5 mg, impaired simulated flight performance 2 hours and 3 hours after a dose at midday and sleeping for 1 hour; performance recovered after 4 hours.

© 2006 Elsevier B.V. All rights reserved.

Endocrine

The syndrome of inappropriate secretion of antidiuretic hormone has been attributed to zopiclone (9).

- A woman with a 2-week history of insomnia took zopiclone 7.5 mg nightly and over the next 9 days became confused, lethargic, and depressed, culminating in an overdose of six zopiclone tablets. Her previous medical history included hypertension and two episodes of diuretic-induced SIADH. Her serum sodium was 129 mmol/l and 4 days later fell to 113 mmol/l. Her serum osmolality was low (240 mmol/kg) and her urine sodium was 20 mmol/l. The serum sodium returned to normal 12 days after withdrawal of zopiclone.

The rapid resolution of symptoms and correction of the hyponatremia after withdrawal was consistent with an effect of zopiclone.

Long-Term Effects

Drug withdrawal

The acute polysomnographic effects of withdrawal of standard doses of zopiclone ($n = 11$), zolpidem ($n = 11$), triazolam ($n = 10$), and placebo ($n = 7$) have been studied in healthy men (10). They took zopiclone 7.5 mg, zolpidem 10 mg, triazolam 0.25 mg, or placebo for 4 weeks in double-blind, randomized order. Sleep EEG was performed. Total sleep time and sleep efficiency were lower in the first night after withdrawal of triazolam. After withdrawal from zopiclone or zolpidem there were slight but not significant rebound effects. Self-rating scales showed minimal rebound insomnia after withdrawal of all three hypnotics. In the placebo group there were no changes in sleep. These results suggest that the risks of tolerance and dependency are low after short-term zopiclone or zolpidem in the recommended doses.

Drug Administration

Drug overdose

- A 72-year-old with respiratory debilitation due to bronchogenic carcinoma died after taking zopiclone about 200–350 mg (11).

Drug–Drug Interactions

Nefazodone

An 86-year-old white woman taking nefazodone for depression started to take zopiclone for insomnia, but subsequently had morning drowsiness (12). The plasma concentration of zopiclone was measured 8 hours after administration on two occasions, during and after nefazodone therapy. After withdrawal of nefazodone, the plasma concentration of the *S*-enantiomer of zopiclone fell from 107 to 17 ng/ml, while the plasma concentration of the *R*-enantiomer fell from 21 to 1.5 ng/ml.

The substantial fall in plasma zopiclone concentration after withdrawal of nefazodone probably reflected a drug interaction due to inhibition of CYP3A4 by nefazodone (13). Despite the normally short half-life of zopiclone, the residual sedation initially observed in this case suggests that the interaction had clinical significance.

Zotepine

See also Neuroleptic drugs

General Information

Zotepine is a dibenzothiepine neuroleptic drug, an antagonist at D_1 dopamine receptors and at 5-HT_1 and 5-HT_2 receptors (1). It rarely causes extrapyramidal disturbances, and when they do occur they are usually mild.

The efficacy and safety of zotepine have been explored in a 1-year open study in 253 patients with schizophrenia

© 2006 Elsevier B.V. All rights reserved.

(mean age 38 years, range 18–65) who took zotepine 75–450 mg/day (2). The mean total BPRS score was reduced from 52 at baseline to 41. Since concomitant treatment was allowed, 173 patients reported 205 ongoing and 448 new neuroleptic medicaments during the study. A total of 826 adverse events were reported by 220 patients; 50 had serious adverse events and 5 died during the study, 2 taking zotepine; one death was a suicide and the other was due to a ventricular dysrhythmia. In all, 138 patients (55%) withdrew from the study; 60 withdrawals were due to adverse events. The most frequently reported adverse events were weight gain (28%; mean weight gain 4.3 kg), somnolence (15%), and weakness (13%). There were adverse events that could be related to extrapyramidal effects in 5%. In 14 patients with normal baseline electrocardiography there were abnormalities at the end of the study, most commonly sinus tachycardia; there were no reports of torsade de pointes. No clinically important hematological abnormalities have been reported to date.

Zuclopenthixol

See also Neuroleptic drugs

General Information

Zuclopenthixol is a thioxanthene neuroleptic drug.

Organs and Systems

Hematologic

Neutropenia has been associated with zuclopenthixol (1).

- A 66-year-old man with schizophrenia took zuclopenthixol 10 mg tds for 18 days and developed a mild leukopenia (2.9×10^9/l) and thrombocytopenia (109×10^9/l). He was asymptomatic, with no evidence of infection or a bleeding tendency. Zuclopenthixol was withdrawn, without any change in the rest of his drug therapy (glibenclamide 5 mg tds, biperiden 2 mg bd, oxazepam 10 mg tds, dipyridamole 75 mg tds, and ranitidine 150 mg/day). The leukocyte and platelet counts rose over the next 5 days.

Sexual function

Priapism, although infrequent, can occur during treatment with neuroleptic drugs and necessitates prompt urological consultation and sometimes even surgical intervention (SEDA-14, 149). A case has been associated with zuclopenthixol (2).

- A 31-year-old man developed priapism after taking zuclopenthixol 30 mg/day for 8 days, the dose having been increased to 75 mg the day before, while he was still taking oral carbamazepine 600 mg/day and clorazepate dipotassium 30 mg/day. He had a history of perinatal anoxic encephalopathy with severe motor sequelae and dyslalia, alcohol dependence, and a personality disorder. On the day before the priapism occurred, he had been physically restrained and given an extra dose of intramuscular clorazepate dipotassium 50 mg. When priapism occurred, all drugs except clorazepate were withdrawn and about 6 hours later the corpora cavernosa were washed and infused with noradrenaline in glucose (8 doses of 40 μg), after which the priapism resolved.

Zygophyllaceae

See also Herbal medicines

General Information

The family of Zygophyllaceae (Table 1) contains nine genera.

Larrea tridentata

The major phenolic component of *Larrea tridentata* (chaparral, creosote bush) is a catechol lignan called nordihydroguaiaretic acid. It causes lymphatic and renal lesions when given chronically in high doses to rodents.

Table 1 The genera of Zygophyllaceae

Balanites (balanites)
Bulnesia (lignum vitae)
Fagonia (fagon bush)
Guajacum (lignum vitae)
Kallstroemia (caltrop)
Larrea (creosote bush)
Peganum (peganum)
Tribulus (punturevine)
Zygophyllum (bean caper)

© 2006 Elsevier B.V. All rights reserved.

Adverse effects

There have been several reports of hepatotoxicity attributed to herbal medicines containing *L. tridentata* leaves (1,2). Of 18 reports of illnesses associated with the ingestion of chaparral, there was evidence of hepatotoxicity in 13 cases (3). The presentation was characterized by jaundice with a marked increase in serum liver enzymes at 3–52 weeks after ingestion, and it resolved 1–17 weeks after withdrawal. The predominant pattern of liver damage was cholestatic; in four cases there was progression to cirrhosis and in two there was acute fulminant liver failure that required liver transplantation.

Chaparral-induced hepatotoxicity in 16 published cases has been summarized in the light of a further report (4).

- A 27-year-old Hispanic man presented with nausea and vomiting, diarrhea, and upper abdominal pain 12 months after starting to take chaparral capsules. A liver biopsy showed hepatocellular injury with necrosis and periportal inflammation. His liver function stabilized after withdrawal of chaparral.

However, in four patients who were given topical chaparral tincture there was no evidence of liver damage (5).

Contact dermatitis has been attributed to *L. tridentata* (6).

A cystic renal cell carcinoma and acquired renal cystic disease associated with consumption of chaparral tea has been reported (7).
