- Severe thrombocytopenia occurred in a 75-year-old woman taking simvastatin 5 mg/day and was resistant to therapy until she developed pneumonia. Recovery from the thrombocytopenia coincided with an increased interleukin concentration in the blood (10).
- There was a close temporal association with thrombotic thrombocytopenic purpura in a 43-year-old man after his second dose of simvastatin (11).

Other cases have been reported (12–15).

Liver

Cholestatic hepatitis occurred in a man with cirrhosis of the liver given simvastatin 20 mg/day (16).

Pancreas

Pancreatitis has been reported with simvastatin (17–22).

Urinary tract

It has been claimed that physicians should bear in mind the nephrotoxic potential of this drug (23), but there is no definite evidence that simvastatin is associated with the development of proteinuria (24).

Skin

- A 66-year-old man had persistent photosensitivity after using simvastatin intermittently (25). The clinical, histopathological, and photobiological features met the criteria for chronic actinic dermatitis.

Musculoskeletal

Rhabdomyolysis has been reported in patients taking simvastatin (26,27). Of 66 patients who took simvastatin for 1 year, two had myalgia and weakness with creatine kinase activity above 3000 (normally less than 100) (28).

- Simvastatin 5 mg/day caused rhabdomyolysis in a 61-year-old man not taking interacting drugs (29).

In a meta-analysis of megatrials with simvastatin, the overall incidence of myopathy was 0.025% (30). The authors suggested that potent inhibitors of CYP3A4 greatly increase the risk, but that weak inhibitors do not. Episodes of gout occurred in three of nine patients with chronic renal insufficiency who took simvastatin (31).

Immunologic

Lupus-like syndrome has been associated with simvastatin, with antibodies to double-stranded DNA in the serum (32).

- Simvastatin-induced lupus erythematosus was suspected in a 79-year-old white man after 3 months (33). He had signs of pleuropericarditis that resolved within 2 weeks of withdrawal.

Second-Generation Effects

Teratogenicity

Of 169 women exposed to simvastatin during pregnancy, three delivered babies with malformations and there were two fetal deaths (34). These results are comparable to what would be expected in the general population. However, based on a general consideration of risk, statins should not be used during pregnancy and only in exceptional circumstances should they be given to any woman of childbearing age.

Drug–Drug Interactions

Calcium channel blockers

In a meta-analysis of megatrials of simvastatin, the overall incidence of myopathy was 0.025%; the same proportion of those with myositis had used calcium channel blockers as the proportion overall, suggesting that there is no important interaction between these two groups of drugs (30).

However, diltiazem interacts with lovastatin although not with pravastatin (SEDA-24, 511), and an interaction has also been observed with simvastatin in a 75-year-old

© 2006 Elsevier B.V. All rights reserved.

man who developed impaired renal function (35). He had extreme weakness and muscle pain.

Ciclosporin

In a patient with glucocorticoid-resistant nephrotic syndrome taking simvastatin and ciclosporin, there was an increase in lactic dehydrogenase activity, suggesting tissue injury, in the absence of an increase in creatine kinase (36).

Clarithromycin

Lovastatin has been reported to interact with clarithromycin (SEDA-14, 1531) (37), and a similar reaction has been observed with simvastatin (38).

- A 64-year-old African-American man developed worsening renal insufficiency, raised creatine kinase activity, diffuse muscle pain, and severe muscle weakness. He had been taking simvastatin for about 6 months and clarithromycin for sinusitis for about 3 weeks. He was treated aggressively with intravenous hydration, sodium bicarbonate, and hemodialysis. A muscle biopsy showed necrotizing myopathy secondary to a toxin. He continued to receive intermittent hemodialysis until he died from infectious complications 3 months after admission.

Gemfibrozil

- Severe rhabdomyolysis occurred in a 52-year-old woman taking a combination of gemfibrozil and simvastatin (39).

Grapefruit juice

Simvastatin should be avoided in patients using grapefruit juice (40).

Itraconazole

Itraconazole probably inhibits simvastatin metabolism (SEDA 21, 459).

Rifamycins

Rifampicin greatly reduced the plasma concentrations of simvastatin and simvastatin acid in 10 healthy volunteers in a randomized, crossover study (41). Because the half-life of simvastatin was not affected by rifampicin, induction of CYP3A4-mediated first-pass metabolism of simvastatin in the intestine and liver probably explains this interaction.

Warfarin

An interaction with warfarin with resulting acute rhabdomyolysis has been observed in a patient taking simvastatin (42). This has not been observed with other statins.

Sirolimus

General Information

Sirolimus is a macrocyclic lactone immunosuppressant that has anti-rejection activity through inhibition of T cell activation. In contrast to tacrolimus and ciclosporin, sirolimus has no effect on calcineurin activity.

Sirolimus is being investigated for the prophylaxis of renal rejection in combination with ciclosporin and glucocorticoids (1).

Comparative studies

In a 12-month study in 719 patients with renal transplants, the combination of sirolimus, ciclosporin, and prednisone in 558 patients (284 taking sirolimus 2 mg/day and 274 taking 5 mg/day) produced significantly more acne, diarrhea, dyslipidemia, headache, hirsutism, hyperkalemia, hypertension, lymphocele formation, and thrombocytopenia compared with 161 patients who took azathioprine, ciclosporin, and prednisone (2). Serum creatinine concentrations were significantly higher at 6 and 12 months in those who took sirolimus. Most of these adverse effects were thought to represent exacerbations of ciclosporin adverse effects, except for diarrhea (8–32%), dyslipidemia (30–42%), lymphocele formation (12–15%), and thrombocytopenia (9–18%), which were more probably related to sirolimus.

That the adverse events profile of sirolimus is different from that of ciclosporin has been further suggested in 83 patients taking primary immunosuppressant regimens containing sirolimus (41 patients) or ciclosporin (42 patients) (3). Arthralgia (20%), hypercholesterolemia (44%), hypertriglyceridemia (51%), leukopenia (39%), thrombocytopenia (37%), and pneumonia (17%) were significantly more frequent in patients taking sirolimus, particularly during the first 2 months of treatment, that is until sirolimus trough concentrations were carefully monitored. Serum creatinine concentrations were lower in the sirolimus group, confirming that sirolimus probably has no direct nephrotoxic effect.

Organs and Systems

Respiratory

Progressive diffuse interstitial pneumonitis has been reported as a possible adverse effect of sirolimus (4), and by 2000 the FDA was aware of at least 34 cases (5). Although the reports were insufficient to conclude that sirolimus was responsible in most cases, eight patients recovered after sirolimus withdrawal.

Bronchiolitis obliterans with organizing pneumonia has been attributed to sirolimus in two renal transplant patients (6). Both improved rapidly after sirolimus withdrawal or dosage reduction.

Metabolism

The most striking consequence of treatment with sirolimus is dose-dependent hyperlipidemia with significant increases in both cholesterol and triglyceride serum concentrations, which resolve after dosage reduction or sirolimus withdrawal (7).

In a 1-year follow-up of 40 renal transplant patients treated with various dosages of sirolimus (0.5–7 mg/m^2/day) in addition to a ciclosporin-based regimen, there were significant increases in serum cholesterol and triglycerides, and significant falls in white blood cell and platelet counts, compared with historical controls (1). These effects correlated with sirolimus trough concentrations but not dosages. One patient had to discontinue sirolimus because of hyperlipidemia refractory to treatment.

© 2006 Elsevier B.V. All rights reserved.

In six patients with renal transplants treated with sirolimus, mean total plasma cholesterol, triglyceride, and apolipoprotein concentrations increased (8). The authors suggested that sirolimus increases lipase activity in adipose tissue and reduces lipoprotein lipase activity, resulting in increased hepatic synthesis of triglycerides, increased secretion of VLDL, and increased hypertriglyceridemia.

Hematologic

Thrombocytopenia, probably related to sirolimus, as well as significant reversible reductions in platelet and white blood cell counts have been found (SEDA-20, 346).

In 119 patients taking sirolimus, thrombocytopenia (defined as a platelet count below 150×10^9/l) and leukopenia (white blood cell count below 5.0×10^9/l) occurred in 78 and 63% respectively (9). The incidence, but not the severity, of these effects correlated with sirolimus whole-blood trough concentrations. Most cases occurred within the first 4 weeks of treatment and the severity was usually limited. There was spontaneous resolution in 89% of the patients and sirolimus dosage reduction or temporary withdrawal was necessary in only 7% and 4% of the patients respectively. None of the patients required permanent withdrawal.

Immunologic

Two reports have recently suggested that sirolimus can produce features of the capillary leak syndrome in patients with psoriasis (10).

- A 53-year-old woman with severe psoriasis for 3 years, who had previously taken ciclosporin, sulfasalazine, and topical glucocorticoids, was given sirolimus 8 mg/m^2/day, and 3 days later had fever, leg edema, dyspnea, weight gain, anemia, and hypotension. A chest X-ray showed pulmonary congestion and cardiomegaly. Empirical antibiotics were unsuccessful, and all symptoms progressively disappeared after sirolimus withdrawal.
- A 58-year-old man took sirolimus 8 mg/m^2/day for severe psoriasis with arthritis. He also took ibuprofen, co-trimoxazole, and paracetamol. Within 1 month he developed nocturnal fever, dizziness, orthostatic hypotension, leg edema, and anemia. All his symptoms subsided after sirolimus withdrawal, furosemide treatment, and erythrocyte transfusion.

No other causes were found, and the authors noted that of 34 psoriatic patients given sirolimus, three had leg edema and a reduced hematocrit. Based on limited in vitro findings, they suggested that sirolimus might enhance apoptosis of activated lymphocytes and thereby cytokine release.

Drug–Drug Interactions

Ciclosporin

Combination of sirolimus with ciclosporin virtually eliminates acute rejection. However, the adverse effects of both drugs are potentiated, increasing the nephrotoxicity of ciclosporin (11).

In a single-dose, open, crossover study in 15 men and six women, the systemic availability of sirolimus 10 mg was markedly increased by concomitant ciclosporin 300 mg, C_{max}, t_{max}, and AUC being increased by 116, 92, and 230% respectively (12,13). However, when sirolimus was given 4 hours after ciclosporin, the increases were only 37, 58, and 80%. Ciclosporin did not affect the half-life or mean residence time of sirolimus. Sirolimus did not significantly affect the systemic availability of ciclosporin.

Diltiazem

In 18 healthy subjects, in a randomized, crossover study of the pharmacokinetics of a single oral dose of sirolimus 10 mg, a single dose of diltiazem 120 mg, and the combination, diltiazem increased exposure to sirolimus, presumably by inhibiting its first-pass metabolism (13).

Tacrolimus

Combination of sirolimus with tacrolimus virtually eliminates acute rejection. However, the adverse effects of both drugs are potentiated, increasing the nephrotoxicity of tacrolimus (11).

Sitafloxacin

See also Fluoroquinolones

General Information

Sitafloxacin is a quinolone antibiotic that is effective against methicillin-resistant *Staphylococcus aureus*.

Organs and Systems

Liver

In a phase II, open, multicenter, randomized study sitafloxacin 400 mg/day caused mild transient increases in alanine transaminase and alkaline phosphatase in 69 patients but no effects on other enzymes (1).

Skin

Data obtained in albino mice have suggested that the phototoxic potential of sitafloxacin is milder than that of lomefloxacin or sparfloxacin (2).

Drug Administration

Drug formulations

After oral administration sitafloxacin 500 mg is rapidly absorbed, with a systemic availability of 89% (3). By 48 hours, about 61% is excreted unchanged in the urine after oral administration and about 75% after intravenous administration. For both routes, the high renal clearance of sitafloxacin implies active tubular secretion.

Sitamaquine

General Information

Sitamaquine (1) is an 8-aminoquinoline that has been used to treat kala-azar (visceral leishmaniasis) (2) and is being tested for activity against *Pneumocystis jiroveci* (1).

In a phase-II, open, dose-escalating safety and efficacy study in 22 Brazilian patients with kala-azar, five groups were given different oral regimens, containing 1.0–3.25 mg of sitamaquine, for 28 days (3). There was nephrotoxicity with 2.5 mg/kg/day in two patients and in the single patient who took 3.25 mg/kg/day. Interstitial nephritis with acute tubular necrosis was proven by biopsy in two patients. Headache and gastrointestinal adverse effects occurred in under 5%. Methemoglobinemia of less than 6% after 7 days was common.

Smallpox vaccine

See also Vaccines

General Information

The last case of smallpox occurred in 1977, and the eradication of smallpox was declared complete by the World Health Assembly in 1980. Since then, routine smallpox vaccination has ceased in all countries, because it is no longer required and because serious adverse reactions sometimes occur after both primary vaccination and revaccination (SED-8, 709) (SED-11, 685) (SEDA-1, 247) (SEDA-3, 262) (SEDA-4, 227) (SEDA-6, 289) (SEDA-13, 289) (SEDA-15, 357) (1–5). However, the threat of bioterrorism has made it necessary to consider prevention and control

© 2006 Elsevier B.V. All rights reserved.

Table 1 Frequencies of some complications per 1 000 000 smallpox vaccinations

Complication	Primarily vaccinated	Revaccinated
Vaccinia gangrenosa	0.9	0.7
Eczema vaccinatum	10.0	0.9
Generalized vaccinia	23.4	1.2
Accidental infections	25.3	0.8

strategies through vaccination and the potential hazards associated with the administration of smallpox vaccine.

Adverse reactions to smallpox vaccination vary from what may be called a "normal" reaction via anomalous reactions to real complications. These can be divided into two categories (6):

1. complications in which sequelae or a fatal outcome are rare (sensitivity, rashes, generalized vaccinia, and autoinoculation vaccinia);
2. complications that may well be fatal or have permanent sequelae (postvaccinial encephalomyelitis, vaccinia necrosum, eczema vaccinatum).

Both categories of complications are much less common after revaccination than after primary vaccination. *Vaccinia* virus can also spread by contact to other subjects and cause adverse effects (7,8).

In an Australian survey of 5 000 000 vaccinations carried out between 1960 and 1976, the frequency of all complications was 188 per million and the death rate 1.5 per million. The ratio of reactions in women to reactions in men was 1.6, increasing with age. Paradoxically, of eight reports of cardiac complications seven concerned men (9).

The frequencies of some complications in 1968 in the USA per 1 000 000 smallpox vaccinations in primarily vaccinated and revaccinated subjects are shown in Table 1 (7).

Recombinant DNA technology using *Vaccinia* virus

Because of its great genetic potential, *Vaccinia* virus is an ideal medium for recombined genes originating from different organisms. In order to use *Vaccinia* virus, efforts have been made to attenuate it further, either by inactivating the genes responsible for virulence (SEDA-15, 357) or by introducing human lymphokine genes into its genome.

Vaccinia DNA can tolerate large insertions into nonessential regions of the genome, and this opens the door to the making of polyvalent live *Vaccinia* recombinations. A major obstacle to their use as vaccines is that severe complications can occur after vaccination, especially in immunodeficient individuals. On the other hand, there is evidence that recombinant *Vaccinia* viruses have reduced pathogenicity. A genetically engineered *Vaccinia* virus expressing murine interleukin-2 has been described (10), and it has been shown that athymic nude mice infected with the *Vaccinia* virus recover from the virus infection rapidly, whereas mice infected with a control virus develop progressive vaccinia.

One attempt to develop safe and efficacious live recombinant vaccines is the use of low neurovirulent strains of vaccinia virus: LC 16 m O (m O) or LC 16 m 8 (m 8). A recombinant *Vaccinia* virus vaccine (RVV) expressing hepatitis B surface antigen likely to form the basis of a safe live RV vaccine against hepatitis B has been constructed (11).

Little is known of the ways in which orthopoxviruses are maintained in nature (12). There is a possibility that strains of *Vaccinia* used as vaccines may become established in nature, as *Vaccinia* may have become established in Indian buffaloes, and/or undergo genetic hybridization with existing orthopoxviruses (12). Enthusiasm for these new prospects should not be allowed to compromise the requirement for obtaining additional scientific information essential to ensure safety, efficacy, and the exercise of all reasonable caution in mounting field investigations (13).

There have already been accusations that two patients with AIDS, treated with an experimental vaccine prepared using a *Vaccinia* virus that had apparently been inactivated and genetically engineered to express HIV proteins, may have died from vaccinia gangrenosa (14,15). On the other hand, there is evidence that recombinant *Vaccinia* viruses have reduced pathogenicity (SEDA-13, 289).

Protection of laboratory workers exposed to orthopoxviruses

In 1980, the US Public Health Service first recommended the use of *Vaccinia* (smallpox) vaccine to protect laboratory workers occupationally exposed to orthopoxviruses. In 1991, the Centers for Disease Control, Atlanta, Georgia, published recommendations on *Vaccinia* vaccine. From 1983 to 1991, 4649 doses of smallpox vaccine were administered, of which 57% were given in 1989–91. The proportion of primary vaccinations increased from 4% in 1983–88 to 14% in 1989–91. Of vaccinees 93% reported no signs or symptoms after vaccination. Reported adverse reactions were mild: lymphadenopathy, fever or chills, and tenderness at the site of vaccination. No severe adverse effects were reported. However, one vaccinee reported a spontaneous abortion 5 months after primary vaccination (16).

A somewhat different note has been sounded from the Committee on Occupational Medical Practice of the American College of Occupational and Environmental Medicine. The committee pointed out that risks to laboratory workers resulting from spontaneous infection are presumably similar to those involved in vaccination. The positive aspect of immunization is that it renders possible control over the time and initial site of entry of the virus. In the Committee's opinion, it is important for scientists and technicians to understand the US Public Health Service recommendations and to have the opportunity to receive *Vaccinia* immunization. They should also understand the possible drawbacks and have the opportunity to refuse vaccination (17). These different recommendations in the USA are also reflected in different national recommendations in other countries.

Accidental needle-stick inoculation of *Vaccinia* virus has been reported (18).

- A 26-year-old laboratory worker, who had been vaccinated against smallpox in childhood, developed a pustule and erythema on his left thumb 3 days after an accidental needle-stick while working with *Vaccinia* virus. Further pustules occurred on the fourth and fifth fingers of the same hand, accompanied by a large

© 2006 Elsevier B.V. All rights reserved.

erythematous lesion on the left forearm, secondary bacterial infection, and axillary lymphadenopathy. After surgical excision of the necrotic tissue, he improved slowly and the lesions healed in about 3 weeks.

Smallpox and bioterrorism

The threat of bioterrorism has made it necessary to consider again prevention and control strategies through vaccination and the potential hazards associated with the administration of smallpox vaccine. Guidelines for prevention and control of smallpox have been elaborated in many countries. The guidelines distinguish between pre-event vaccination programs (worldwide no re-emergence of smallpox) and postevent vaccination programs (re-emergence of smallpox confirmed). Taking into account the risk of smallpox vaccination, most countries have elaborated plans for postevent vaccination programs. During the US pre-event vaccination program, in 1 per 20 000 members of the military who received primary smallpox vaccination, cardiac inflammation (myocarditis and/or pericarditis), including one death (myocardial infarction), has been reported. Compared with the rate reported in an unvaccinated military population during 1998–2000, the rate of myocarditis/pericarditis was substantially increased. However, there were no cases after revaccination. In 2003, among 38 257 civilian health-care and public health workers vaccinated against smallpox, 17 suspected and 5 probable cases of myocarditis/pericarditis were reported. The other adverse events include one case of suspected encephalitis, three of generalized *Vaccinia*, three of ocular *Vaccinia*, and 21 of inadvertent inoculation.

During the US pre-event smallpox vaccination program, there were no reports of eczema vaccinatum, progressive *Vaccinia*, or fetal *Vaccinia* (19,20).

During a meeting in June 2003, the Global Advisory Committee on Vaccine Safety considered two expert reports on the safety of smallpox vaccination in detail. They concluded that there is a real risk of serious adverse events, including safety issues that have not previously been recognized. Therefore, if the vaccine is being used in mass campaigns, it would be very important to include adverse events monitoring. The committee found that the available data were insufficient to define the risk after primary vaccination compared with the risk of revaccination after a long interval (21).

Organs and Systems

Cardiovascular

Acute myocarditis after vaccination against smallpox has been reported (22). Fatal myocarditis is rare, but electrocardiographic evidence of myocarditis has been found more frequently; this adverse effect is probably not always noticed (23–25). Pericarditis after smallpox vaccination has also been described (26).

All case reports of myocarditis/pericarditis after smallpox vaccination have been carefully evaluated. It was concluded that the data are consistent with a causal relation between myocarditis/pericarditis and smallpox vaccination; however, no causal association between ischemic cardiac events and smallpox has been identified (19,20).

- A 57-year-old woman with a history of hypertension, a transient ischemic attack, and carotid endarterectomy died 22 days after smallpox vaccination. Histopathological evaluation showed no evidence of cardiac inflammation.

Pericarditis after smallpox vaccination has been described (26).

The Advisory Committee on Immunization Practices (ACIP) has recommended that people who have underlying heart disease, with or without symptoms, or who have three or more known major cardiac risk factors (that is hypertension, diabetes, hypercholesterolemia, heart disease at age 50 years in a first-degree relative, and smoking) should be excluded from the pre-event smallpox vaccination program (27).

During the period of routine smallpox vaccination, only rare reports of cardiac inflammation (pericarditis, fatal myocarditis, and electrocardiographic evidence of myocarditis) were published in the world literature (SED-8, 709). To determine the risk of cardiac death after smallpox vaccination, death certificates were analysed from a period in 1947 when 6 million New York City residents were vaccinated after a smallpox outbreak; the incidence of cardiac deaths did not increase after the vaccination campaign (28).

Respiratory

Pneumonia has been observed after smallpox vaccination (2).

Nervous system

Neurological complications of smallpox vaccination can cause paralysis; of 26 patients with such symptoms, most were children under 2 years (29).

The most dreaded complication of smallpox vaccination is postvaccinial encephalitis or encephalomyelitis, which is said to occur even without a cutaneous vaccination reaction (30), although this occurs rarely, if at all (2,31). It is mainly a complication of primary vaccination. There is increased morbidity with increasing age, especially around puberty. It is rare after revaccination.

Two conditions must be distinguished: a histopathological picture characterized by diffuse perivenous focal encephalitis and a condition based on a disturbance of the blood–brain barrier, that is an encephalopathy that characteristically occurs in infants. The incubation period of postvaccinial encephalomyelitis is 9–13 days. Its onset is mostly sudden. The clinical picture varies. Mortality is high (30–50%). Recovery may be complete, but there are often neurological sequelae, such as paresis and extrapyramidal disturbances.

The frequency of postvaccinial encephalomyelitis in different countries has varied considerably. Per million primary vaccinations 68 cases were recorded in Bavaria, 48 in the Netherlands, 15 in the UK, and 1.8 in the USA. The frequency increases with age beyond the first year (5). In 53 034 primarily vaccinated army recruits in the Netherlands there were 11 cases (1:5000) (32). In 1968 the frequency in the USA was 2.8 per million primarily

© 2006 Elsevier B.V. All rights reserved.

vaccinated. There were no cases among 8.5 million revaccinations (8). In very young infants sudden death can occur (33), but information about frequency is difficult to assess, because of the occurrence of sudden unexplained deaths ("cot" deaths).

The risk of postvaccinial encephalomyelitis is reduced by simultaneous administration of hyperimmune *Vaccinia* gamma globulin (32) or by pre-immunization with an antigen from formol-inactivated *Vaccinia* virus (34,35). However, cases of postvaccinial encephalomyelitis have been described even after these procedures (32,36).

- A 13-year-old girl died of neuromyelitis optica. By inoculation of rabbits it was shown that the brain tissue contained *Vaccinia* antigen. Moreover, there were high titres against *Vaccinia* virus in both sera and spinal fluid. In infancy this patient had been vaccinated against smallpox (37).
- Accidental administration of 10 doses of smallpox vaccine to an already vaccinated girl resulted in a clinical picture characterized by neuraxitis with general tonic-clonic convulsions. Complete cure was attained after treatment with hyperimmune antivaccinia globulins and methisazone (38).

Polyneuropathy (39) and bacterial meningitis (40) have been described after smallpox vaccination.

Sensory systems

Ears

Disturbances of hearing and balance are described after smallpox vaccination (41).

Eyes

Vaccinial lesions on the eyelids and the conjunctivae are seen after secondary infection with *Vaccinia* virus by scratching (42,43). From these lesions a keratitis can develop, which sometimes extends to deeper layers of the cornea, with concomitant iridocyclitis. Papillitis with myelitis has been described after revaccination (44).

Metabolism

Diabetes mellitus occurred in a 1-year-old child about 4 weeks after smallpox vaccination (45).

Hematologic

Thrombocytopenic purpura is a rare complication of smallpox vaccination (46). Postvaccinial lymphadenitis can occur (47).

Mouth and teeth

Of 2568 people who were given oral vaccination, five bit open the vaccine-containing capsule or tablet, with release of the virus, and developed vaccinia lesions on the tongue, gums, or nares (48).

Urinary tract

Nephritis is a very rare complication of smallpox vaccination (49).

Skin

A 20-year-old man had active eczematous lesions on both wrists. After vaccination widespread *Vaccinia* developed in non-eczematous skin around the eyes and mouth, while the eczematous regions were unaffected. The possible reason was the use of a glucocorticoid ointment (50).

Skin reactions after smallpox vaccination can cause the following complications (2,3):

- Ectopic pocks near the vaccination site (vaccinia serpiginosa).
- Secondary vaccinia, which is caused by spreading of Vaccinia virus from the vaccination site to other body sites by scratching.
- Generalized vaccinia (vaccinia generalisata). Here the *Vaccinia* virus is spread by the blood stream and vaccinial lesions can develop all over the body some 9–10 days after vaccination.
- Eczema vaccinatum. This serious complication occurs most often in infants with active infantile eczema and occasionally in adults who have eczema or some other skin disease. It is seen after vaccination or contact with vaccinated persons with vaccinial lesions. The first symptoms are observed at the eczematous spots 3–4 days after vaccination. In many cases generalization of the vaccinial lesions follows. The estimated mortality is 25–30%.
- Progressive vaccinia (vaccinia gangrenosa). About 7 days after a normal vaccinial reaction the lesion extends, penetrates the underlying tissue, and becomes necrotic. Ulcers are formed, and the process spreads to adjacent areas of the skin. Secondary bacterial infection is common. This rare complication may be due to some abnormality of serum proteins, interfering with immunity, such as agammaglobulinemia or hypogammaglobulinemia. Mortality is high (51–53).
- Keloid from vaccinial scars.

Abnormal hair growth (54), herpes virus infections (55), and malignant changes in smallpox vaccination scars have also been observed (56,57). Allergic skin reactions sometimes occur, for example urticaria and purpura (58) and possibly photosensitivity reactions.

Musculoskeletal

Osteomyelitis and periosteitis are exceedingly rare sequels to smallpox vaccination (59,60).

Acute arthritis has been described after smallpox vaccination (61).

Death

In France 4 113 109 primary vaccinations during 1968–77 have been surveyed. There were 30 deaths that could have been associated with the vaccine, 23 in the first year of life (62). The relation was considered certain in one case, probable in 5, possible in 6, and doubtful in 18. In the certain case there may have been immunodeficiency. In the second group there were three cases of acute encephalitis. Among the doubtful cases were 12 patients who had neurological symptoms.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Pregnancy

The incidence of abortions is said to be higher in women who have recently received smallpox vaccination; in some cases the aborted fetus showed evidence of *Vaccinia* infection (63).

Fetotoxicity

Although routine smallpox vaccination of infants was discontinued in the UK in 1971, some 20–28 cases of complications of vaccination continue to be reported yearly to the Committee on Safety of Medicines (64), including both cross-infection and fetal infection (64).

Susceptibility Factors

HIV infection is a risk factor for vaccinia generalisata, making it important to have *Vaccinia* immune globulin available for outbreak control (65).

- Vaccinia generalisata developed after smallpox vaccination (co-administrated with other vaccines) of an army recruit with asymptomatic HIV infection (66). After 2–3 weeks he developed cryptococcal meningitis, and a diagnosis of AIDS was made. While being treated for the meningitis he developed generalized vaccinia. He was treated with *Vaccinia* immune globulin and recovered from his vaccinia generalisata.

Snakebite antivenom

See also Vaccines

General Information

Snakebite is an important medical emergency in some parts of the rural tropics. In most tropical countries it is an occupational disease of farmers, plantation workers, herders, and hunters. Every year thousands of people die in Africa, Central America, South Asia, and South-East Asia because of envenomation after snakebite. In India alone, an estimated 15–20 000 people die each year due to snakebite. In Sri Lanka, the overall incidence of snakebite exceeds 400 per 100 000 population per year, one of the highest in the world.

© 2006 Elsevier B.V. All rights reserved.

Antivenom (also known as antivenin, antivenene, and antisnakebite serum) is the concentrated enzyme-refined immunoglobulin of animals, usually horses or sheep, that have been exposed to venom. It is the only specific treatment currently available for the management of snakebite envenoming and has proved effective against many of the lethal and damaging effects of venoms. The most widely used antivenoms are F(ab')2-equine polyspecific antivenoms, raised against the venoms of many poisonous snakes. In the management of snakebite, the most important clinical decision is whether or not to give antivenom, because only some snake-bitten patients need it, it can produce severe reactions, and it is expensive and often in short supply.

Antivenom is most effective by intravenous injection. The range of venoms neutralized by an antivenom is usually stated in the package insert. If the biting species of snake is known, the appropriate monospecific antivenom should be used. In countries where several species produce similar signs, snakebite victims are treated with polyspecific antivenom, which contains a lower concentration of specific antibody to each species than the monospecific antivenom.

Organs and Systems

Immunologic

Antivenom treatment can be complicated by early reactions (anaphylaxis), pyrogenic reactions, or late reactions (serum sickness-type). The incidence and severity of early reactions is proportional to the dose of antivenom and the speed with which it enters the blood stream (1,2). These reactions usually develop within 10–180 minutes of starting antivenom therapy. The reported incidence of early reactions after intravenous antivenom in snakebite patients, which ranges from 43% (3) to 81% (4), appears to increase with the dose and decrease when refined antivenom is used and administration is by intramuscular rather than intravenous injection. Unless patients are watched carefully for 3 hours after treatment, mild reactions can be missed and deaths misattributed to the envenoming itself. In most cases symptoms are mild: urticaria, nausea, vomiting, diarrhea, headache, and fever; however, in up to 40% of cases severe systemic anaphylaxis develops, with bronchospasm, hypotension, or angioedema. However, deaths are rare (5).

Early reactions respond well to adrenaline given by intramuscular injection of 0.5–1 ml of a 0.1% solution (1:1000, 1 mg/ml) in adults (children 0.01 ml/kg) at the first sign of trouble. Antihistamines also should be given by intravenous injection to counteract the effects of histamine released during the reaction.

Pyrogenic reactions result from contamination of antivenom by endotoxin-like compounds. High fever develops 1–2 hours after treatment and is associated with rigors, followed by vasodilatation and a fall in blood pressure. Febrile convulsions can occur in children. Patients should be cooled and given antipyretic drugs by mouth, powdered and washed down a nasogastric tube, or by suppository.

Late (serum sickness-type) reactions develop 5–24 days after treatment. Symptoms include fever, itching, urticaria, arthralgia (which can involve the temporomandibular joint), lymphadenopathy, periarticular swellings, mononeuritis multiplex, albuminuria, and rarely encephalopathy. This is an immune complex disease which responds to antihistamines or, in more severe cases, to glucocorticoids.

Early antivenom reactions are not usually Type I IgE-mediated reactions to equine serum proteins and are not predicted by hypersensitivity tests. Several methods have been used to reduce acute adverse reactions to antivenom. A small test dose of antivenom to detect patients who may develop acute adverse reactions to the antivenom has no predictive value, can itself cause anaphylaxis, and is no longer recommended (5). Prophylactic use of hydrocortisone and antihistamines before infusion with antivenom is also practiced widely, although the theoretical basis for their use is unclear. Antihistamines counter only the effects of histamine after its release and do not prevent further release; one small randomized controlled trial showed no benefit from the routine use of antihistamines (6). Hydrocortisone takes time to act and may be ineffective as a prophylactic against acute adverse reactions that can develop almost immediately after antivenom treatment, which is very often administered urgently to snakebite victims. One study has suggested that intravenous hydrocortisone is ineffective in preventing acute adverse reactions to antivenom, but if given together with intravenous chlorphenamine it can reduce these reactions (7). However, this trial recruited only 52 patients and was not designed to study the efficacy of chlorphenamine alone, making it difficult to give a clear interpretation of the results and recommendations on pretreatment with glucocorticoids and antihistamines to prevent acute reactions to antivenom. In one study of 105 patients, low-dose adrenaline given subcutaneously immediately before administration of antivenom to snakebite victims significantly reduced the incidence of acute adverse reactions to the serum (3). However, this trial did not enroll sufficient participants to establish safety adequately, a major concern regarding the use of adrenaline in a prophylactic role, particularly the risk of intra-cerebral haemorrhage. Therefore, further studies on the safety of this treatment are required before it can be recommended routinely. For the present, the only available alternative to prevention is the early detection of adverse reactions to antivenom and the ready availability of drugs such as adrenaline for their prompt treatment.

Sodium hypochlorite

See also Disinfectants and antiseptics

General Information

Sodium hypochlorite is widely used as a cleaning agent and to deal with blood spillages. Chlorine gas is released during the use of hypochlorite. Alkaline hypochlorite solutions with 0.25% "available chlorine" have been used to clean and disinfect wounds.

Accidental injection

Local injection

A patient developed ulceration and paresthesia of the lip with facial swelling after accidental injection of Milton solution (sodium hypochlorite 1%, sodium chloride 16.5%) into the upper lip when a sharp needle was used for irrigation (1). The ulceration healed within 6 weeks, the paresthesia within 3 months. In similar cases hypochlorite solution (25 mg NaClO) was accidentally injected into periapical tissue (2), and into the mandibular branch of the facial nerve (90 mg NaClO) (3).

Intraperitoneal infusion

Accidental intraperitoneal infusion of hypochlorite solution on two occasions (the first time about 10 ml of a 5% solution the second time more diluted) has been reported (4). After the infusion the patient felt severe abdominal pain accompanied by nausea but not by vomiting. Raised peritoneal solute transport rates and reduced ultrafiltration gradually subsided, but they did not return to pre-infusion values.

Intravenous infusion

Accidental intravenous infusion has been reported (5–7).

- A 68-year-old man received an accidental infusion of a 1% sodium hypochlorite solution. After 1 hour and an infusion volume of 150 ml the infusion was stopped. By this time he had a slow heart rate, mild hypotension, and an increased respiratory rate. The blood cell count, hemoglobin, serum electrolyte, creatinine, and urea concentrations, and transaminase activities were normal and hemolysis did not occur. Treatment with NaCl 0.9% and dextrose at an infusion rate of 300 ml/hour was started immediately with the goal of maintaining an adequate diuresis. Furosemide and dopamine hydrochloride were also administered. His blood pressure and respiratory rate promptly returned to normal, but the bradycardia persisted for 3 days despite atropine sulfate (5).
- During dialysis a patient received an accidental infusion of 30 ml of a 5.25% solution of hypochlorite. This led to cardiorespiratory arrest and massive hemolysis with hyperkalemia, although the patient eventually recovered (7).
- In a third case, intravenous infusion of 60 ml of an oral and 0.3 ml of a parenteral 5.25% solution in a suicide attempt did not result in any serious effects (6).

Organs and Systems

Respiratory

Chlorine gas, released during the use of hypochlorite, can cause mucous membrane irritation, bronchospasm, pneumonia, and pulmonary edema. It is believed that when hypochlorite is used as a cleaning substance in low concentrations it does not cause respiratory damage, but in a comparison of pulmonary function tests in 23 cleaning workers and 14 technical personnel, as a control group, even low concentrations of hypochlorite affected pulmonary function, causing irritation in the airways (8).

Solanaceae

See also Herbal medicines

General Information

The genera in the family of Solanaceae (Table 1) include deadly nightshade, henbane, jimson weed, peppers, petunia, and tobacco.

Anisodus tanguticus

Anisodus tanguticus (Zangqie), a traditional Chinese herbal medicine, contains hyoscyamine and related toxic tropane alkaloids (1). Its active ingredient anisodamine has been used to treat snakebite (2).

Brugmansia species

Brugmansia candida (*Datura candida*, angel's trumpet) and *Brugmansia suaveolens* (*Datura suaveolens*, angel's tears) are ornamental flowers that have been used for hallucinogenic effects. Both contain tropane alkaloids, such as hyoscine, hyoscyamine, meteloidine, and norhyoscine, which have anticholinergic properties.

Table 1 The genera of Solanaceae

Acnistus (acnistus)
Atropa (belladonna)
Bouchetia (bouchetia)
Browallia (browallia)
Brugmansia (brugmansia)
Brunfelsia (rain tree)
Calibrachoa (calibrachoa)
Capsicum (pepper)
Cestrum (jessamine)
Chamaesaracha (five eyes)
Datura (jimson weed)
Goetzea (goetzea)
Hunzikeria (hunzikeria)
Hyoscyamus (henbane)
Jaborosa (jaborosa)
Jaltomata (false holly)
Leucophysalis (leucophysalis)
Lycianthes (lycianthes)
Lycium (desert thorn)
Mandragora (mandrake)
Margaranthus (margaranthus)
Nectouxia (nectouxia)
Nicandra (nicandra)
Nicotiana (tobacco)
Nierembergia (cupflower)
Nothocestrum (aiea)
Oryctes (oryctes)
Petunia (petunia)
Physalis (ground cherry)
Quincula (quincula)
Salpichroa (salpichroa)
Salpiglossis (salpiglossis)
Schizanthus (schizanthus)
Scopolia
Solanum (nightshade)
Solandra (solandra)
Streptosolen (streptosolen)

Adverse effects

Anticholinergic toxicity can result from the alkaloids that *Brugmansia* species contain (3).

- A 53-year-old woman was admitted to hospital with vertigo, blurred vision, palpitation, mydriasis of the right eye, and tachycardia (120/minute) (4). She reported that she had been cutting leaves from an angel's trumpet when a drop of sap had entered her right eye.
- A 76-year-old man drank 3 teaspoons (15 ml) of a homemade wine made from *B. suaveolens* over 1 hour and about 1.5 hours later developed respiratory distress and weakness (5).

There have been reports of young men who had confusion and other signs of central nervous system involvement after taking angel's trumpet (6).

After ocular exposure to sap from *B. suaveolens*, seven patients developed unilateral mydriasis, at least three also had ipsilateral cycloplegia, and one developed transient tachycardia (7).

Capsicum annuum

Capsicum annuum (chili pepper) contains a variety of carotenoids, including capsanthin, capsorubin, beta-carotene, cryptoxanthin, lutein, phytofluene, and xanthophyll, and steroids, including capsicoside. One of the main constituents is capsaicin, which produces an intense burning sensation when it comes into contact with the skin, eyes, or mucous membranes and which gives peppers their burning taste. A hot shower or bath before topical application to the skin intensifies the burning sensation. Capsaicin is used internally for various conditions, including colic and for improving peripheral circulation, and externally for unbroken chilblains. A cream for topical application has been used to relieve the pain of postherpetic neuralgia and other pain syndromes.

Adverse effects

Sensitization to *C. annuum* has been reported in a patient who was allergic to latex (8).

Taken orally in regular high doses capsaicin can act as a carcinogen and could promote gastric cancer, but in low doses it seems to have anticarcinogenic activity (9).

Datura stramonium

Datura stramonium (Jimson weed) is a naturally occurring plant that is ingested to induce hallucinogenic effects. Toxicity after ingestion is due to an atropine-containing alkaloid that is present in all parts of the plant but is particularly concentrated in the seeds.

Adverse effects

Intoxication with *Datura* species is often reported (10–12). Eleven patients aged 13–21 years ingested large quantities of Jimson weed pods and seeds (13). The signs and symptoms were classical of atropine poisoning. In milder cases there was asymptomatic mydriasis and tachycardia and in the more severely affected agitation, disorientation, and hallucinations. Nine of the 11 were admitted for observation. None died and none required pharmacological intervention with physostigmine to reverse the anticholinergic symptoms.

© 2006 Elsevier B.V. All rights reserved.

Lycium barbarum

Lycium barbarum (Chinese wolfberry) contains a variety of steroids. A tea prepared from it is used in China as a general tonic.

Adverse effects

An interaction of *L. barbarum* with warfarin has been described.

- A 61-year-old woman, who had taken warfarin for atrial fibrillation in weekly doses of 18–19 mg for years and had been completely stable, developed a raised INR after she consumed a tea made from Chinese wolfberry (14). Four days after drinking the tea (180 ml/day), she had an INR of 4.1. After withdrawal of the herbal tea her INR returned to within the target range and remained stable.

Although an extract of *L. barbarum* inhibited CYP2C9 in vitro, the effect was weak and the authors thought that another mechanism must have been involved.

Mandragora species

Mandragora (mandrake) species contain toxic tropane alkaloids, such as hyoscyamine and/or scopolamine.

Adverse effects

The tropane alkaloids in *Mandragora* species are powerful anticholinergic agents and can cause peripheral symptoms (for example blurred vision, dry mouth) and central effects (for example drowsiness, delirium) (15). They can potentiate the effects of synthetic drugs with similar pharmacological activity.

In 15 patients anticholinergic effects were due to poisoning by *Mandragora autumnalis* intermingled with leaves of chard (*Beta vulgaris*) and spinach (*Spinacia oleracea*) (16). The latency from the time of ingestion was 1–4 hours. There was no correlation between latency and severity. All had blurred vision and dryness of mouth, nine had difficult in micturition, nine dizziness, nine headache, eight vomiting, two difficulty in swallowing, and two abdominal pain. All had blushing, a reactive mydriasis, and tachycardia. The skin and mucosae were dry in 14. There was hyperactivity/hallucination in 14 and agitation/delirium in nine. One patient developed a florid psychotic episode. Prostigmine (2–6 mg) was given to 11 patients and physostigmine (0.5–2 mg) to six. The time to a definite response was variable (3–36 hours). The patients treated with physostigmine had better reversal of the psychoneurological symptoms.

In some cases of poisoning, formulations of ginseng may have been adulterated with *Mandragora officinarum* (17).

Anaphylaxis has been reported after the administration of a homeopathic preparation of mandragora (18).

Nicotiana tabacum

The leaves of *Nicotiana tabacum* (tobacco) contain the toxic alkaloid, nicotine as a major constituent and several other pyridine alkaloids as minor constituents. Although tobacco enemas have been abandoned in official medicine because of their life-threatening toxicity, unorthodox self-medication with this agent has not completely died out. A case report in the 1970s described nausea and confusion, followed by hypotension and bradycardia, due to an enema apparently prepared from 5 to 10 cigarettes. Transdermal nicotine is now widely used as an aid to smoking cessation. Nicotine is covered in a separate monograph.

Scopolia species

Scopolia species (scopola) contain tropane alkaloids, such as atropine, hyoscine (scopolamine), hyoscyamine, and tropane. They can cause anticholinergic symptoms (19).

Somatostatin and analogues

General Information

Somatostatin was first isolated from the hypothalamus, and was shown to inhibit growth hormone release. It has since been found in neuroendocrine tissues throughout the body. It has multiple effects, via five distinct receptors, and acts as a neurotransmitter, in the regulation of growth hormone and thyrotropin release, as a regulator of gastrointestinal and pancreatic function, and as an immune modulator. Synthetic analogues are selective for receptor subtypes 2 and 5, and have different clinical and adverse effects profiles to the native hormone, as well as having longer half-lives. Analogues of somatostatin include depreotide, edotreotide, ilatreotide, lanreotide, octreotide, pasireotide, pentetreotide, and vapreotide (all rINNs).

Octreotide, an octapeptide somatostatin analogue, is usually given subcutaneously in three divided doses per day. Longer-acting analogues with similar efficacy and adverse effects to octreotide, but which can be given every 14–28 days, have been developed (1,2). The therapeutic indications and adverse effects of octreotide have been reviewed (SEDA-13, 1309) (3).

Organs and Systems

Cardiovascular

Both somatostatin and octreotide cause transient increases in mean arterial pressure and mean pulmonary pressure when given intravenously to patients with cirrhosis, more marked with bolus administration than with continuous infusion (4). This may be either direct or mediated by inhibition of gut vasodilatory peptides (SEDA-24, 505) (5) and is not usually associated with significant clinical effects.

Severe hypertension with associated headache, nausea, and vomiting was reported within 2 weeks of administration of octreotide LAR 20 mg in a 26-year-old diabetic woman with autonomic neuropathy (5). Rechallenge with octreotide 75 µg resulted in a transient hypertensive episode lasting 3 hours.

- Exacerbation of pre-existing hypertension was also reported in a 22-month-old boy during octreotide infusion (6).

There has been one report of acute pulmonary edema during octreotide and intravenous fluid therapy for variceal bleeding (7).

Sinus bradycardia (less than 50/minute) is reported in up to 25% of acromegalic patients taking octreotide, and conduction abnormalities are also commonly reported in these patients. This adverse effect is reported only rarely in other recipients of somatostatin or octreotide, probably reflecting the high rate of cardiac abnormalities due to acromegaly (8).

Nervous system

Dizziness occurred in 7.4% of 68 patients randomized to somatostatin and 8.2% of 73 randomized to octreotide, both by rapid infusion, to control variceal bleeding, in which the effectiveness of somatostatin and its analogues is probably via a transient reduction in heart rate and cardiac output (9).

Metabolism

Somatostatin and its analogues inhibit insulin secretion in the short term, before receptor down-regulation. Mild hyperglycemia occurs during octreotide infusion in up to 23% of adults (10,11), and occasionally in children (12). This is not usually clinically significant (3). However, in an open, retrospective comparison of octreotide and lanreotide in 38 patients with acromegaly, one patient in each group stopped therapy because of worsening glycemic control (13).

In a meta-analysis of trials for variceal bleeding, hyperglycemia occurred in 41 of 310 patients who received somatostatin, octreotide, or vapreotide, compared with 26 of 318 patients who received placebo (14).

Reports of the effects of octreotide on glucose metabolism in acromegaly are inconsistent and are complicated by the high prevalence of insulin resistance and overt diabetes in acromegaly. In 10 patients with acromegaly who used modified-release lanreotide for 19 months followed by modified-release octreotide for 21 months after a 3-month washout period, mean fasting glucose, the glucose response to oral glucose tolerance testing, and glycated hemoglobin all increased after octreotide but not lanreotide (15). However, the study was small and the order of the two medications was not randomized.

In patients with insulinoma, octreotide can cause clinically important hypoglycemia, because of suppression of counter-regulatory hormone secretion (16).

Hematologic

- A 42-year-old woman, treated with octreotide infusion 50 mg/hour for cirrhosis-related gastrointestinal bleeding on two occasions 9 months apart, had an immediate fall in platelet count on both occasions, resolving after octreotide withdrawal (17). The thrombocytopenia was not severe (nadir platelet counts 62 and 55×10^9/l) and did not require specific treatment.

The rapid fall in platelet count in this case suggests an immunological mechanism, although this was not directly demonstrated.

Gastrointestinal

Transient gastrointestinal symptoms (nausea, diarrhea, abdominal discomfort, and flatulence) occur in up to 50% of patients during the first few days of treatment, but usually resolve spontaneously after the first 1–2 weeks of treatment (13,18). Nausea and vomiting occur in up to 25% of patients after somatostatin and are also common

© 2006 Elsevier B.V. All rights reserved.

after octreotide (19). Two of 15 patients in a phase I trial of malignant gastrinoma had to stop using long-acting octreotide because of severe nausea (20).

Diarrhea is common soon after starting octreotide but usually resolves within 2 weeks without specific treatment. In a randomized, double-blind, placebo-controlled trial in 203 mostly postmenopausal women with locally recurrent or metastatic breast carcinoma, all of whom were also taking tamoxifen, and who had estrogen-receptor positive and/or progesterone-receptor positive tumors, octreotide was added to the basic treatment in 99 cases (21). The adverse events experienced by 10% or more of the patients and attributed to octreotide were gastrointestinal: diarrhea (53%), nausea (16%), and abdominal pain (11%); diarrhea occurred in only 11% of the controls.

One of 10 patients with rheumatoid arthritis in an open study stopped using long-acting octreotide because of severe diarrhea and weight loss of 3 kg (22). These effects are dose-related and are similar in healthy volunteers, acromegalic patients, and patients with gastrointestinal tumors (3).

Octreotide 100 μg given subcutaneously to five healthy subjects 30 minutes before meals for 7 days increased fecal fat excretion; however, steatorrhea occurred in only two cases; fecal bile acid excretion fell to about 25% (23)

Biliary tract

Biliary sludge and gallstones are frequent adverse effects of both octreotide (2) and its longer acting analogues, compared with 10–25% of the general population (24). Cholelithiasis develops in up to 20% of patients in the long term, secondary to reduced gall-bladder contractility, but only 1% of patients develop symptoms per year of treatment (25). There is prospective evidence that gallstones develop earlier in patients on higher doses of octreotide (24). Rebound gall-bladder hypermotility can occur on withdrawal of octreotide and can be associated with biliary colic or pancreatitis (SEDA-13, 1309) (26,27).

Patients treated with octreotide have impaired meal-stimulated gall-bladder emptying and altered bile chemical composition, similar to spontaneous cholelithiasis. In 16 patients with acromegaly the serum deoxycholic acid concentration increased in proportion to large bowel transit time (28). In 11 patients gall-bladder emptying was slower in patients given octreotide LAR than lanreotide SR, but was impaired in both groups compared with pretreatment values (29).

Fasting gall-bladder volume increased progressively in seven patients with acromegaly treated with once-monthly long-acting octreotide; gallstones formed de novo in six patients within 8 months and one had symptomatic biliary colic (30). Gallstones have also been reported in children receiving prolonged octreotide therapy (12).

Ursodiol appeared to reverse gall-bladder abnormalities in seven of 10 patients. Data from this study also showed earlier development of sludge in recipients of higher doses of octreotide (24).

Hair

Reversible hair loss has been reported in a few patients after both octreotide (31) and lanreotide (32).

Immunologic

Antibodies to somatostatin analogues have been reported only rarely. However, in one study octreotide antibodies were demonstrated in 63 (27%) of 231 patients treated with subcutaneous octreotide for more than 3 years, rising to 57% after 5 years and 72% after 8 years (33). The antibodies did not reduce clinical efficacy.

- A 64-year-old woman, who had had monthly intramuscular injections of long-acting octreotide in the buttocks for 6 years, had increased uptake of ^{111}In-pentetreotide in both buttocks, thought to represent granuloma formation at the injection sites (34). Localized granulomas have previously been described in isolated cases after intramuscular somatostatin analogues, and somatostatin receptors are expressed in high density in activated lymphocytes.

Allergic reactions to somatostatin are rare. Of 97 cirrhotic patients randomized to subcutaneous octreotide, one stopped therapy because of erythematous itchy skin, which then resolved (11).

Second-Generation Effects

Pregnancy

Octreotide is a small peptide that can pass the placental barrier, and it is not recommended for use in pregnant women.

Placental transfer was significant in the first reported pregnancy with long-acting octreotide (35). The dose of octreotide was reduced after an ultrasound suggested intrauterine growth retardation. The female infant had a low birth weight (11th percentile) but caught up to the 50th percentile by 3 months of age. Her development was normal during 18 months of follow-up.

Of seven women who took somatostatin analogues during pregnancy, five stopped taking it when the pregnancy was diagnosed (36). One had a single injection of modified-release lanreotide before pregnancy was diagnosed, with no apparent adverse effects on the infant (37). No fetal malformations or delay in postnatal development have been reported.

Susceptibility Factors

Age

Children are generally not given long-term octreotide because of concerns about its effect on growth. Although growth was reported as normal in a few case series, "catch-up" growth was also described after octreotide was withdrawn (12).

Drug–Drug Interactions

Erythromycin

Pretreatment with octreotide enhanced the gastric prokinetic effects of erythromycin in eight healthy subjects, suggesting that octreotide may be clinically useful

© 2006 Elsevier B.V. All rights reserved.

in patients with tachyphylaxis to this effect of erythromycin (38).

Midodrine

In a controlled study of octreotide and midodrine (an alpha-adrenoceptor agonist) in patients with orthostatic hypotension, the pressor effect of the two drugs was synergistic (39).

Morphine

Somatostatin and its analogues have been reported to be OP_3 (μ) opioid receptor antagonists (40). Somatostatin infusions significantly reduced the effectiveness of morphine analgesia in a case report of three patients with cancer.

Somatropin

General Information

Established indications for somatropin (growth hormone) include growth hormone deficiency in children, Turner's syndrome, Noonan's syndrome, and renal insufficiency in children. Other well-studied indications include idiopathic short stature, adult growth hormone deficiency, osteoporosis, and catabolic states associated with acute and chronic illness and injury. Body composition, respiratory muscle function, physical strength, and height improved in a 12-month trial of somatropin in 54 children with Prader–Willi syndrome (1).

The adverse effects of somatropin differ between adults and children. In adults, adverse effects are commoner in men, in heavier patients, and in adult-onset growth hormone deficiency. Efficacy is no greater in those who develop adverse effects. The higher rate of adverse effects is due to the higher dose of somatropin when calculated according to body weight, and also to lower sensitivity to somatropin in women than in men (2–4). Rapid dose escalation also increases the rate of adverse effects. To minimize adverse effects, it is recommended that treatment be started at a low dosage, that is 0.4–0.8 U/day, and titrated according to the age-specific concentration of IGF-1 (2,3,5).

Adverse effects are commoner in patients using higher doses. Starting at a low dose, increasing the dose gradually, and titrating individual doses against age-specific IGF-I concentrations may minimize adverse events.

Organs and Systems

Cardiovascular

The effect of somatropin on cardiovascular risk is complex, as growth hormone reduces visceral fat and total cholesterol and increases HDL cholesterol concentrations (6–8).

Edema, both generalized and peripheral, is common in adults given somatropin, as is hypertension. Symptoms are usually mild and resolve in many patients despite continuing treatment (9). Increased left ventricular wall thickness has been reported in both adults and children, although in children this is thought to reflect an increase in overall mass and is not thought to be of clinical significance (10,11).

In an open study in five patients with severe dilated cardiomyopathy given high-dose somatropin 4 IU/day (1.3 mg/day) for 3 months, ventricular dysrhythmias worsened in all patients during treatment, from Lown class 2 or 3 to 4A or 4B, and returned to baseline when treatment was stopped (12).

- A 7-year-old boy developed cardiomegaly and edema within a month of starting somatropin, 0.7 IU/kg/week; when the dose was reduced to 0.35 IU/kg/week his heart size returned to normal (13).

This is a reminder that the adverse effects of somatropin are dose-related within the therapeutic range and that dose escalation should be gradual.

Nervous system

Somatropin extracted from cadaveric human pituitaries was used to treat growth hormone-deficient patients until several cases of the fatal degenerative neurological disorder Creutzfeldt–Jakob disease were reported in the mid-1980s. Of 267 cases of iatrogenic Creutzfeldt–Jakob disease, 139 were caused by human cadaver-derived somatropin (SEDA-25, 479).

This disease develops when an abnormal prion protein present in the cadaveric material induces a cascade of conformational changes in host protein. Creutzfeldt–Jakob disease in recipients of somatropin differs from the sporadic form, in that it usually presents with cerebellar signs rather than cognitive impairment, and also in the prominence of prion protein amyloid plaques in nervous tissue (14). In a review, 139 cases of Creutzfeldt–Jakob disease were identified worldwide in people treated with cadaveric somatropin before recombinant human growth hormone became available in the mid-1980s (15). The prevalence of this fatal neurodegenerative condition in recipients of somatropin ranges from 0.3% in the USA

© 2006 Elsevier B.V. All rights reserved.

to 4.4% in France. Creutzfeldt–Jakob disease has been reported to start at 4–30 years after therapy with cadaveric somatropin (14), so that further cases are anticipated and continue to be reported (16).

- A case has been reported in Brazil, 28 years after somatropin therapy (17).
- An 18-year-old man from Qatar presented with a 3-month history of unsteadiness, dysarthria, and left-sided weakness, followed by visual, hearing, and memory loss, 13 years after somatropin therapy (18).

This is the first case from Qatar, but it is possible that other cases there have not been reported.

People exposed to a contaminated batch of somatropin have about a 6% chance of developing Creutzfeldt–Jakob disease (19), although there are no reliable predictors of risk in an individual. The risk varies to some extent with the mode of preparation of the product, but it seems unlikely that it can be entirely eliminated. The natural product was therefore withdrawn from the market in most countries, but was rapidly replaced by biosynthetic somatropin preparations

Carpal tunnel syndrome due to somatropin is probably dose-dependent and was reported in 4.8% of subjects in a double-blind trial (9).

Headache is a common adverse effect of somatropin. It often occurs early in treatment and usually responds to temporary dosage reduction followed by gradual re-escalation (1,20). It can be an early indicator of the rare complication pseudotumor cerebri (idiopathic intracranial hypertension), particularly in high-risk groups, such as children with renal insufficiency, and may require further investigation. Headache was reported in 13% of 75 prepubertal children treated with a modified-release formulation of somatropin over 12 months (21).

Somatropin can cause idiopathic intracranial hypertension (pseudotumor cerebri), characterized by headache, papilledema, visual disturbance, and sometimes nausea and vomiting (22). Less common features include extraocular palsy, present in up to 48% of affected patients (22), mood changes, and somnolence. There have been 30 cases reported worldwide (23); chronic renal insufficiency, Turner's syndrome, obesity, and biochemical growth hormone deficiency are all associated with an increased risk. About half of the reported cases occurred within the first 8 weeks of treatment, and all responded to dose reduction or withdrawal of human growth hormone. Fundoscopy is recommended before starting somatropin and regularly during the first few months, although the absence of papilledema does not exclude the diagnosis. Up to 48% of children with intracranial hypertension due to somatropin also develop a sixth nerve palsy (23).

- A non-obese 6-year-old girl with Ullrich–Turner syndrome developed headache, vomiting, and blurred vision, with papilledema and increased cerebrospinal fluid pressure 5 months after starting somatropin 0.9 IU/kg/week (24). The cerebrospinal fluid pressure normalized after somatropin was withdrawn, and increased again when therapy was restarted. Her visual acuity was reduced to less than 30% in the right eye.

According to the authors there have been 40 cases of pseudotumor cerebri associated with somatropin therapy worldwide, owing to stimulation of cerebrospinal fluid production or reduced drainage.

Sensory systems

Retinal changes, clinically indistinguishable from diabetic retinopathy, were reported in two non-diabetic recipients of somatropin (25).

- An obese 31-year-old man developed non-proliferative retinopathy and macular edema with reduced visual acuity after 14 months' therapy, which improved after somatropin was withdrawn.
- An 11-year-old girl with Turner's syndrome developed unilateral neovascularization after receiving somatropin for 22 months.

These patients improved but did not completely resolve after somatropin was withdrawn.

Somatropin concentrations correlate with retinopathy in patients with diabetes. There are no prospective clinical reports of retinal findings in adult recipients of somatropin, and these are awaited to determine the true frequency of this complication.

Endocrine

Thyroid function tests are often altered by somatropin because of increased conversion of T4 to T3, but this is clinically insignificant at low doses (SEDA-21, 453). One child with Prader–Willi syndrome had a fall in serum thyroxine concentration during somatropin therapy and needed thyroxine replacement (26). Hypothyroidism developed in 11 of 46 growth hormone-deficient children treated with somatropin (27). Prior abnormalities in hypothalamic-pituitary function and alterations in thyroid hormone metabolism, probably both, contributed to the high incidence of hypothyroidism, which was similar to that in previous studies.

Three adolescent boys with chronic renal insufficiency, treated with somatropin during the pubertal growth spurt, developed severe hyperparathyroidism (28). It is unclear whether this was coincidental or whether growth hormone and sex steroid hormones had a synergistic effect.

There have been occasional reports of gynecomastia attributed to somatropin (SEDA-21, 453).

Metabolism

Hyperinsulinemia is common in recipients of somatropin, but the long-term effects are controversial. This issue is becoming increasingly important as more adult patients are treated and the duration of therapy is extended. Growth hormone deficiency is itself associated with insulin resistance (29). Plasma concentrations of glucose and hemoglobin A_{1C} increase, especially in the first 6–12 months, indicating relative insulin resistance (30,31); the increases are often within the reference ranges (4,32).

Plasma glucose is inconsistently described as showing a sustained increase within the reference range, a transient increase, or no change. This reflects both the small non-controlled populations reported and possible selection bias, with exclusion of some patients because of hyperglycemia before the start of a cohort study (32). Hyperglycemia has occasionally been reported in patients

© 2006 Elsevier B.V. All rights reserved.

receiving very high doses of human growth hormone for catabolic conditions, but has usually not required specific treatment (33). In a 6-month randomized study of 74 men and 57 women aged over 65 years, diabetes or glucose intolerance developed in 18 men treated with somatropin compared with seven controls (34).

Diabetes mellitus was previously not thought to be more common in recipients of somatropin than in the general population (SEDA-13, 1308) (35). However, longer-term observations have shown a three-fold incidence compared with predicted rates of type II diabetes, probably representing a younger age of onset rather than an increase in de novo cases (36).

In 78 children treated with somatropin for 7 years the mean fasting glucose concentration increased significantly compared with baseline after both 1 and 6 years of somatropin treatment, but remained the reference range and was not higher at 6 years than at 1 year (30).

In a 5-year study, 67 children treated with somatropin all had a sustained increase in fasting and oral glucose-stimulated insulin concentrations. This was most significant in children on dialysis and with renal transplants (37). In another study, insulin secretion in response to intravenous glucose was increased in 14 children with renal insufficiency, but returned to baseline after 12 months. However, increased insulin concentrations persisted in nine girls with Turner's syndrome (38). Concomitant glucocorticoid and somatropin treatment in children with juvenile arthritis caused a small but significant rise in blood glucose and glycosylated hemoglobin, which returned to pretreatment concentrations after somatropin was withdrawn (39).

Of 21 children, 15 developed hyperglycemia in a study of high-dose somatropin (0.2 mg/kg/day) for burns (40). In another study of 29 children with renal insufficiency (a group known to have insulin resistance), integrated insulin concentrations increased significantly in the first year of somatropin treatment, with no associated change in plasma glucose or glycated hemoglobin (41).

In a retrospective study, the fasting glucose:insulin ratio, a marker of insulin resistance, fell more in girls with Turner syndrome than in children with idiopathic short stature during somatropin therapy. The lower glucose:insulin ratio was due to increased fasting insulin and correlated with increased body mass index (42).

- Diabetes occurred 2 months after somatropin was begun in a 14 year-old girl, with restoration of normoglycemia after it was withdrawn (43).

In a postmarketing review of over 20 000 patients, type II diabetes was three times more common than expected, probably because at-risk individuals became diabetic at an earlier age than predicted (36). In a postmarketing review of 23 333 children and adolescents (52 375 treatment years), the incidence of type I diabetes was not significantly increased. However, type II diabetes occurred in 46 and 28 per 100 000 treatment years in children aged 10–19 and 6–14 years respectively (six times greater in both age groups than published reference values). There was no difference in incidence between boys and girls. A further 42 children developed abnormal glucose tolerance (44). Diabetes and glucose intolerance did not resolve after somatropin was withdrawn. Children who became diabetic were usually pubertal and had received somatropin for a longer period. Obesity, a risk factor for type II diabetes in the general population, was uncommon in these children.

Experience in adults is more limited, and monitoring is essential (45). Studies of somatropin in adults have consistently shown increased plasma concentrations of glucose, glycated hemoglobin, and insulin (46,47). Glucose intolerance and frank diabetes mellitus have been frequently reported in small series (46,48). Hyperglycemia not requiring specific treatment has been reported more often in adult patients (9) and in patients receiving high-dose somatropin to treat wasting associated with burns or HIV infection (33,49), but the overall incidence has not been compared with that in the general population.

In 25 patients a depot formulation of somatropin was associated with a non-sustained increase in glucose and insulin concentrations, more pronounced in men (50).

In a double-blind, placebo-controlled study of 24 growth hormone-deficient adults treated for 4 months with somatropin 2 IU/day, the treated patients had a significant increase in fasting plasma glucose and insulin concentrations, and increased insulin resistance, determined by insulin AUC during oral and intravenous glucose tolerance testing (8). Similarly, a group of 30 adolescents who were not growth hormone-deficient, and who were treated with somatropin for a mean of 7.9 years, had significantly reduced insulin sensitivity and raised plasma glucose concentrations during treatment, returning to control concentrations after somatropin was withdrawn (51). One of these patients developed glucose intolerance.

In a study of high-dose somatropin (0.1 mg/kg/day) in 20 patients with severe burns (a condition that causes insulin resistance), 60% of the treated patients required insulin therapy for hyperglycemia compared with 25% of the controls (52). This study was limited by the fact that the treated patients had more severe burns than the controls.

In a high-dose study in eight HIV-positive men, oral glucose tolerance worsened in the first month of human growth hormone 3 mg/day, then improved toward baseline. Mild glucose intolerance was still present after 6 months, despite a reduction in visceral fat. One man with pre-existing glucose intolerance developed symptomatic diabetes within 2 weeks of starting somatropin (53).

- Acanthosis nigricans, which is characterized by dark velvety thickening of the skin on the nape of the neck and in the groins and axillae, has been described in a non-obese 10-year-old boy with achondroplasia who received somatropin 3–4 IU/week for 7 years (54).

There has been one previous report of acanthosis nigricans in a woman who received human pituitary extract (55). This condition is usually seen in hyperinsulinemic states, including diabetes mellitus and acromegaly; overstimulation at the IGF-I receptor is probably the final common pathway.

Mineral balance

Hypercalcemia, usually mild and not requiring specific treatment, was reported in 43 of 100 patients receiving high-dose somatropin in intensive care (SEDA-13, 1308) (56).

© 2006 Elsevier B.V. All rights reserved.

Fluid balance

Edema is three times more frequent with a dose of somatropin of 0.025 mg/kg/day than 0.0125 mg/kg/day (57). In a randomized, controlled study of 33 obese women, three of nine who received somatropin and two of seven who received somatropin plus insulin-like growth factor-1 withdrew from the study, because of intolerable edema, compared with none in the placebo group. Most patients receiving somatropin required diuretic treatment for edema in this study, in which dose was calculated according to body weight (58). In a randomized, placebo-controlled trial of growth hormone replacement in 166 hormone-deficient adults, 48% of the treated group and 30% of the placebo group reported mild to moderate edema, which resolved in 70% of subjects despite continued treatment (9).

Hematologic

Leukemia has been reported in several patients treated with somatropin. However, when other risk factors are accounted for, there is no current evidence that it increases the risk significantly above population levels (SEDA-23, 468) (59).

- Acute myelogenous leukemia was diagnosed in a 25-year-old man with hypopituitarism, 4 months after he started to use somatropin three times a week (60).

The time interval in this case was too short to implicate somatropin as a definite cause.

Gastrointestinal

Nausea, which did not require specific treatment, occurred within 72 hours after an injection of long-acting somatropin in six of 25 patients (50).

Skin

Injection site reactions to somatropin are common and include nodules, pain, and erythema. They usually resolve spontaneously (21,27). In a 2-year study of once- or twice-monthly injections of a modified-release formulation of somatropin in 56 prepubertal children, injection site reactions were common, especially in the first year of treatment. These included skin nodules in 56% of injections, erythema in 49%, and lipoatrophy in 12% (61).

- A 12-year-old boy developed lipohypertrophy at the site of somatropin injection (62). Site rotation gave partial resolution.
- A 51-year-old woman with both panhypopituitarism and liver disease developed localized abdominal lipohypertrophy during somatropin therapy (63).

The authors of the second report speculated that hepatic IGF-1 secretion was compromised and that peripheral somatropin reached supraphysiological concentrations.

Lipoatrophy, a transient loss of subcutaneous fat identifiable as skin dimpling, occurred in 11% of injections in 75 children who were given modified-release somatropin for 12 months (21) and in one of 68 children in another study (27). Site rotation is recommended to prevent lipodystrophy.

Non-neoplastic pigmented nevi may increase in number in patients treated with somatropin (SEDA-21, 453).

Musculoskeletal

Arthralgia and proximal myalgia are common with somatropin, especially with large doses or rapid dose escalation (3,49,57,58).

A slipped capital femoral epiphysis was reported in 26 of 16 500 patients in one study: it is less common in children with idiopathic short stature than those with a known cause of growth failure (64).

Growth acceleration makes scoliosis more apparent in less than 1% of children treated with somatropin, many of whom also receive spinal irradiation. A causative role for somatropin has not been substantiated (65).

There are conflicting reports on a possible increased risk of fractures in children with osteogenesis imperfecta treated with somatropin, many of whom have a qualitative defect in collagen (66,67).

- A boy with osteogenesis imperfecta, with no previous fractures, who received somatropin from age 5 to 14, had four fractures during his pubertal growth spurt, similar to two previous case reports (68).

Immunologic

Patients treated with recombinant somatropin commonly develop antibodies against growth hormone; the incidence is 22–88% (69). There were low titers of antigrowth hormone antibody, with no reduction in growth response, in 44% of children who used modified-release somatropin once a month and in 68% who used it twice a month (21). Antibodies almost never have clinical significance, but the fourth case of reduced growth due to neutralizing antibodies against growth hormone has been reported in a 9-year-old boy; growth resumed after he was changed to a methionyl-free human formulation of somatropin (69).

Systemic allergic reactions to somatropin are very rare, but can be overcome by desensitization (SEDA-13, 1308) (70). Although early studies suggested a higher rate of renal transplant rejection in recipients of somatropin than in controls (SEDA-21, 452), this was not confirmed in a long-term prospective study (71).

- In a 15-year-old boy with previously quiescent lupus nephritis, laboratory markers of disease activity rose during somatropin treatment and returned to baseline concentrations within 3 months after withdrawal (72).

Long-Term Effects

Tumorigenicity

The incidence of malignancy is increased in acromegaly, in which growth hormone is present in excess. Patients treated with growth hormone have therefore been carefully monitored. The first report of leukemia in Japanese children treated with growth hormone (73) prompted a worldwide survey. There have been reports of 44 new cases of leukemia in growth hormone recipients, of which only 20 were acute lymphoblastic leukemia. This is much less than the expected 80–85% of new childhood leukemia (74).

© 2006 Elsevier B.V. All rights reserved.

A review of Japanese patients found that of the 15 patients who had developed hematological malignancies since 1975, 6 had other risk factors for leukemia, such as Fanconi's syndrome or prior chemotherapy or radiotherapy. The incidence of leukemia in this study was 3 per 100 000, similar to that in the general population of the same age (59). The National Cooperative Growth Study (NCGS—a postmarketing database that includes 19 846 patient-years since the time of growth hormone exposure) similarly reported no increase in the incidence of new leukemia when patients with other risk factors were excluded from the analysis (75).

The recurrence rate of intracranial tumors has been addressed in a number of large observational studies. Reports from the NCGS database (which includes 1262 children with brain tumors) and from England have shown no increase in intracranial tumor recurrence in patients treated with growth hormone (76,77). For patients with craniopharyngioma, postoperative irradiation reduced the recurrence rate, but growth hormone therapy did not increase the risk (78).

In the NCGS study extracranial non-leukemia malignancy rates were similarly not increased in patients treated with growth hormone compared with those who were not (79).

Despite theoretical concerns, there is no evidence that either intracranial or extracranial malignancy, new or recurrent, is increased in subjects treated with growth hormone (76,78,79). Despite this, certain precautions are still recommended for children who have previously been treated for cancer. The diagnosis of growth hormone deficiency should be clearly established (74) and it is recommended that treatment be delayed for at least 1 year after tumor therapy has been completed (36).

In a cohort study in 1848 British patients who received human pituitary-derived growth hormone from 1959 to 1985 (30 000 patient-years), there were two cases of colorectal cancer (0.25 expected) and two cases of Hodgkin's disease (0.85 expected); the standardized mortality ratios were 10.8 and 11.4 respectively (80). However, the number of cancers was small and the doses used were higher than typically today, and these results should be interpreted with caution.

Second-Generation Effects

Teratogenicity

Only a few pregnancies have been reported in women treated with somatropin. Eight women with hypopituitarism were followed prospectively during 12 pregnancies at a mean daily pregestation dose of 0.5 mg/day. The dose of somatropin was gradually reduced during the second trimester and withdrawn at the start of the third trimester. No congenital abnormalities were observed and weight and length at birth were normal (81).

Susceptibility Factors

Age

Most of the information about the long-term safety of somatropin in children has been derived from databases voluntarily maintained by two pharmaceutical companies; thus, there may be under-reporting. Other trials have generally been of short duration, with few participants, and may thus have been subject to type II error. The effectiveness and safety of somatropin in children has been the subject of a systematic review (82).

Sex

Somatropin is being increasingly prescribed for growth hormone-deficient adults. Men have more adverse effects than women, probably because of a greater IGF-1 response (83). This was also seen in 74 elderly men and 57 elderly women in a controlled trial, and was not influenced by concomitant sex steroid therapy (34).

Drug Administration

Drug dosage regimens

One recommended regimen is to start somatropin in a dosage of 0.15 mg/day and titrate upward (SEDA-14, 1521). Very high dosages (0.1–0.2 mg/kg/day, 10–20 times higher than replacement dosages given to adults with growth hormone deficiency) were given to 532 critically ill patients in intensive care units in two placebo-controlled trials (84). Mortality was significantly higher in the treated group than in the placebo group (42 versus 18%). Morbidity was also increased in somatropin recipients, who needed longer ventilator times.

Early studies using doses of somatropin that have been derived from pediatric experience had a high rate of adverse effects, and doses have been progressively reduced. In a 6-month, multicenter, randomized study, 302 adults were given somatropin 3 micrograms/kg/day, increasing to 6 micrograms/kg/day after 3 months, and 293 were given 6 micrograms/kg/day, increasing to 12 micrograms/kg/day (85). The lower dose was associated with significantly fewer adverse events (in particular, arthralgia in 12 versus 20%). However, 78% of women or patients with childhood-onset growth hormone deficiency had subnormal IGF-1 concentrations, suggesting that treatment should be titrated to IGF-1 concentrations and adverse effects.

Drug–Drug Interactions

Ciclosporin

Growth hormone increases the activity and regulates the gene expression of hepatic CYP3A4 (86). Mean blood concentrations of ciclosporin were lower during somatropin therapy in an open study in 16 prepubertal kidney transplant recipients, despite stable weight-related doses, suggesting that the metabolism of ciclosporin was increased by somatropin. Two patients had acute episodes of rejection during somatropin therapy; one of these may have been related to the fall in ciclosporin concentration (87).

Estradiol

In eight postmenopausal growth hormone-deficient women randomized to estradiol, either orally 2 mg/day

© 2006 Elsevier B.V. All rights reserved.

or transdermally 100 micrograms/day, together with incremental doses of somatropin in an 8-week, crossover study, oral but not transdermal estrogen reduced IGF-1 concentrations, protein synthesis, and postprandial lipid oxidation rates (88). This confirms the results of a previous report (89). The mechanism is not known, but high portal estrogen concentrations after oral estrogen administration probably alter hepatic growth hormone metabolism.

Sotalol

See also Beta-adrenoceptor antagonists

General Information

Sotalol is a non-selective beta-adrenoceptor antagonist with no partial agonist or membrane-stabilizing activity. It is also a class III antidysrhythmic drug. The beta-adrenoceptor antagonist properties of D,L-sotalol reside in the L-isomer, the D-isomer having class III antidysrhythmic activity and no clinically significant beta-blocking action (1).

© 2006 Elsevier B.V. All rights reserved.

Quinidine and sotalol have been compared in a prospective multicenter trial of 121 patients after conversion of atrial fibrillation (2). Patients with low left ventricular ejection fractions (below 0.4) or high left atrial diameters (over 5.2 cm) were excluded. After 6 months the percentages of patients remaining in sinus rhythm were similar in the two groups (around 70%), but when the dysrhythmia recurred, it occurred later with sotalol than with quinidine (69 versus 10 days). There was also a difference between patients who had been converted from recent onset atrial fibrillation, in whom sotalol was more effective than quinidine, and in patients who had had chronic atrial fibrillation for more than 3 days, in whom quinidine was more effective. There were significant adverse effects requiring withdrawal of therapy in 17 patients, of whom nine were taking quinidine; three patients had gastrointestinal symptoms, two had central nervous symptoms, two had allergic reactions, one had undefined palpitation, and one had QT interval prolongation. One patient taking quinidine, a 65-year-old man, had frequent episodes of nonsustained ventricular tachycardia.

Organs and Systems

Cardiovascular

Sotalol prolongs the QT interval and can predispose to torsade de pointes (3), sustained ventricular tachycardia, and cardiac arrest, especially in those taking 160 mg/day or more (SEDA-16, 191). Torsade de pointes has been reported in 1.2% of those exposed (data on file, Bristol-Myers Squibb, Princeton, New Jersey). In a review it was concluded that torsade de pointes is also more likely in patients with depressed left ventricular function and a history of sustained ventricular tachydysrhythmias (4).

Several publications involving 962 patients treated with an intravenous infusion of racemic sotalol have been reviewed, with the aim of describing the risk of torsade de pointes (5). Torsade de pointes occurred in only one case (0.1%; 95% CI = 0.003, 0.6), which is less often than with oral sotalol (2–4%). This difference can be explained by the shorter duration of treatment. The other reported complications were hypotension (0.3%), severe bradycardia (0.2%), and atrioventricular block necessitating drug withdrawal (0.03%).

In a survey of 1288 patients taking sotalol, dysrhythmias occurred in 56, in 24 cases torsade de pointes (3). There was no relation between these dysrhythmias and previously associated factors, such as bradycardia, a long QT interval, and hypokalemia, but in patients on hemodialysis even a low dosage (40 mg bd) can be associated with torsade de pointes (6). Similar prodysrhythmic effects have been reported in children (7).

Death

A trial of the efficacy of D-sotalol in patients with left ventricular dysfunction (8) was discontinued early when an interim analysis of 2762 patients showed an overall mortality of 3.9% in the D-sotalol group, compared with 2% in the placebo group (9).

Susceptibility Factors

Some patients with thyrotoxicosis have occult cardiac dysfunction. However, the use of beta-blockers in the treatment of thyrotoxicosis can have severe consequences in terms of severe cardiac dysfunction (10).

- A 52-year-old woman developed atrial fibrillation with a ventricular rate of 220/minute. She had had thyrotoxicosis 20 years before, but was taking no medications. She had an 8-month history of weight loss with a normal appetite. During the previous month she had had excessive sweating, palpitation, and exercise intolerance. The diagnosis was thyroid storm. She was given intravenous sotalol 1 mg/kg over 15 minutes and within 5 minutes sinus rhythm was restored, with improvement of symptoms. However, immediately after the infusion she had an episode of ventricular tachycardia followed by sinus bradycardia, with a resultant fall in blood pressure, followed by an asystolic cardiac arrest. She underwent endotracheal intubation and was treated with inotropes. Right-heart catheterization showed severe cardiac dysfunction (cardiac index 1.2 l/minute). She made an uneventful recovery.

Patients with severe hyperthyroidism can have an occult cardiomyopathy that makes them extremely sensitive to beta-blockers. The long duration of action of sotalol in this case necessitated prolonged inotropic and vasopressor support. A shorter-acting beta-blocker, such as esmolol, could theoretically be safer in such cases.

Sparfloxacin

See also Fluoroquinolones

General Information

Sparfloxacin is a fluoroquinolone with activity against the major respiratory pathogens and atypical pathogens that cause pneumonia. Photosensitivity, nausea, and diarrhea have been the most common adverse events reported in trials, and sparfloxacin is contraindicated in patients with QT interval prolongation (1).

In an in vivo study in rats, endotoxin reduced the biliary excretion of sparfloxacin and its glucuronide, probably owing to impairment of hepatobiliary transport systems and renal handling (2).

Observational studies

The efficacy and safety of sparfloxacin (400 mg loading dose followed by 200 mg/day for 10 days) in the treatment of acute bacterial maxillary sinusitis have been evaluated in 253 patients (3). The overall success rate was 92%. The majority of adverse events were mild or moderate and the most frequent were photosensitivity reactions, headache, nausea, and diarrhea.

Comparative studies

Analysis of safety data from six multicenter phase III trials in 1585 patients comparing sparfloxacin with standard drugs (cefaclor, ciprofloxacin, clarithromycin, erythromycin, and ofloxacin) showed that 25% of patients treated with sparfloxacin and 28% of patients treated with the other drugs had at least one adverse event considered to be related to the study medication (4). Photosensitivity reactions were seen in 7.4% of treatment episodes with sparfloxacin, compared with 0.5% of episodes with the other drugs. Gastrointestinal reactions, insomnia, and alterations in taste were more common in patients taking the comparator drugs. The mean change from baseline QT interval corrected for heart rate (QT_c) was significantly greater with sparfloxacin, but no ventricular dysrhythmias were detected. Study medication was withdrawn in 8.9% of patients taking the comparator drugs and in 6.6% of those taking sparfloxacin.

Organs and Systems

Cardiovascular

Some quinolones can prolong the QT interval, with a risk of cardiac dysrhythmias.

Sparfloxacin causes greater prolongation of the QT interval than other quinolones (5), as has been shown in in vitro comparisons. Compared with grepafloxacin, moxifloxacin, and ciprofloxacin, sparfloxacin caused the greatest prolongation of the action potential duration (6), and in an in vitro comparison of sparfloxacin, ciprofloxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin, moxifloxacin, sitafloxacin, tosufloxacin, and trovafloxacin, sparfloxacin caused the largest increase in QT interval (7). In an in vivo study in conscious dogs with stable idioventricular automaticity and chronic complete atrioventricular block, oral sparfloxacin 60 mg/kg caused torsade de pointes, leading to ventricular fibrillation within 24 hours, while 6 mg/kg did not (8). In halothane-anesthetized dogs, intravenous sparfloxacin 0.3 mg/kg prolonged the effective refractory period, and an extra 3.0 mg/kg reduced the heart rate and prolonged the effective refractory period and ventricular repolarization phase to a similar extent, suggesting that a backward shift of the relative repolarization period during the cardiac cycle may be the mechanism responsible for the dysrhythmogenic effect of sparfloxacin. Data from in vitro electrophysiological studies of the effect of sparfloxacin, ofloxacin, and levofloxacin on repolarization of rabbit Purkinje fibers indicate that the prolongation of the action potential is observed only with sparfloxacin (9).

In a double-blind, randomized, placebo-controlled, crossover study of a single oral dose of sparfloxacin in 15 healthy volunteers, prolongation of the QT interval was about 4% greater with sparfloxacin than with placebo (10). An independent Safety Board concluded from the results of various phase I and phase II studies that the increase in the QT_c interval associated with sparfloxacin is moderate, averaging 3%, and that the few serious adverse cardiovascular events that have been reported during postmarketing surveillance all occurred in patients with underlying heart disease (11).

In 25 patients taking sparfloxacin for multiresistant tuberculosis, there were six cases of moderate prolongation of the electrocardiographic QT interval (30–40 ms compared to baseline) without clinical symptoms (12).

- A 37-year-old woman who was taking sparfloxacin as part of modified antituberculosis drug therapy developed torsade de pointes (13).

Sensory systems

Abnormal taste developed in 17 of 175 patients treated with clarithromycin 250 mg bd for 10 days for community-acquired pneumonia, compared with three of 167 patients treated with sparfloxacin (14). Mild to moderate gastrointestinal disturbances were the most common adverse events and were reported in 13 and 11% respectively.

Skin

During the first 9 months of marketing of sparfloxacin, 371 severe phototoxic reactions were reported to the French pharmacovigilance system or the manufacturers, reporting rate of 0.4 per thousand treated patients (about 4–25 times that reported with other fluoroquinolones) (15).

Phototoxicity occurred in four of nine patients with multidrug-resistant tuberculosis treated with a combination of sparfloxacin (400 mg/day), ethionamide, and kanamycin (initially for 3–4 months) (16). It occurred after several months of treatment and was presumably due to

© 2006 Elsevier B.V. All rights reserved.

the sparfloxacin. Sparfloxacin more commonly causes photosensitivity than ciprofloxacin, levofloxacin, or ofloxacin, which are also effective antituberculosis drugs (15,17). Skin reactions can be severe enough to require withdrawal of sparfloxacin in some patients. In view of this, other fluoroquinolones, particularly ofloxacin, are preferable to sparfloxacin in the management of multidrug-resistant tuberculosis.

In 25 patients taking sparfloxacin for multidrug-resistant tuberculosis, there were five mild phototoxic reactions (12).

Long-Term Effects

Mutagenicity

DNA damage produced by sparfloxacin and UVA in retinal pigment epithelial cells in vitro was remedied by antioxidants, suggesting a possible in vivo strategy for preventing or minimizing retinal damage in humans (18).

Susceptibility Factors

Patients with a history of cardiac disease and patients taking other medications with effects on cardiac repolarization should not be given sparfloxacin, in order to prevent any cumulative inhibitory effect on cardiac repolarization.

Drug–Drug Interactions

Antacids

The absorption of sparfloxacin is impaired by antacids containing aluminium or magnesium (19). In an open, single-dose (400 mg), randomized, four-way crossover study in 20 male volunteers (aged 18–38 years), Maalox (30 ml) given 4 hours after sparfloxacin did not cause a statistically significant reduction in the rate and extent of sparfloxacin absorption. In contrast, Maalox given 2 hours before or 2 hours after sparfloxacin did reduce its absorption: AUC fell by 23 and 17% respectively and mean C_{max} by 29 and 13% (20).

Cisapride

Concomitant administration of cisapride increased the rate of absorption and increased the peak concentration of sparfloxacin without having a significant effect on systemic availability (21,22).

Sucralfate

Co-administration of sucralfate leads to a 44% reduction in the systemic availability of sparfloxacin (22). In eight healthy Japanese, the absorption of sparfloxacin (300 mg orally) was reduced when sucralfate (1.5 g orally) was administered concurrently or 2 hours after sparfloxacin, but not 4 hours after sparfloxacin (23).

Sparteine

General Information

Sparteine is a major quinolizidine alkaloid found in a variety of plants:

- *Ammodendron conollyi*
- *Anagyris fetida*
- *Baptisia australis*
- *Baptisia tinctoria*
- *Chelidonium majus*
- *Cytisus scoparius*
- *Genista lucida*
- *Lupinus argentus*
- *Lupinus laxus*
- *Lupinus luteus*
- *Lupinus niger*
- *Lupinus polyphyllus*
- *Sarothamnus scoparius*
- *Sophora pachycarpa*
- *Sophora secundiflora*
- *Spartium junceum*
- *Spartium scoparium.*

Sparteine has been used as a marker of the metabolic activity of CYP2D6 (1). Pharmacokinetic studies have shown that its metabolic oxidation exhibits genetic polymorphism and that about 6–9% of the Caucasian population are poor metabolizers. Quinidine, haloperidol, and moclobemide are all potent inhibitors of the oxidative metabolism of sparteine (2).

Among the reported effects of sparteine are reduced cardiac conductivity, stimulation of uterine motility, circulatory collapse, and respiratory arrest. Sparteine was contained in a slimming aid ("Herbal Slimming Aid," UK). It was formerly used to induce labor; at the very least it should be considered contraindicated during pregnancy.

Spectinomycin

General Information

Spectinomycin is an aminocyclitol antibiotic, distinct from the aminoglycosides. It has been used mainly in single-dose treatment of gonorrhea (2 g intramuscularly), and for treating organisms with multiple antibiotic resistance (1–3). Apart from induration at the site of injection, tolerance in otherwise healthy individuals has been good, even with doses of 8 g/day for 21 days. Allergic reactions have been observed, but are rare. Spectinomycin-resistant gonococci have been found (4,5).

Long-Term Effects

Drug tolerance

Aminoglycoside adenylyltransferase (aadA) genes mediate resistance to streptomycin and spectinomycin. In a pathogenic porcine *Escherichia coli*, the novel aaA5 has now been described integrated with a trimethoprim resistance gene (6). The aadA6 gene has been sequenced from *Pseudomonas aeruginosa* and can confer high-level resistance to spectinomycin in *E. coli* (7). All strains of multidrug resistant *Vibrio cholerae* O1 El Tor isolated in Albania were resistant to spectinomycin, and resistance to this antibiotic was mediated by the aadA1 gene cassette located in the bacterial chromosome within a class 1 integron (8). Another class 1 integron that contained aadA2 was found in pathogenic *Salmonella typhimurium* isolates from France and was also chromosomally located (9). An aadA gene has also been described in *Enterococcus faecalis* (10).

Resistance of *E. coli* isolates from chicken in Saudia Arabia was 96% compared with 71% among human isolates (11). Serotyping showed an overlap between human and chicken strains, suggesting that these animals may serve as a resistance pool for humans.

Spiramycin

See also Macrolide antibiotics

General Information

Spiramycin is a macrolide antibiotic with activity primarily against *Staphylococcus aureus*, beta-hemolytic streptococci, and viridans streptococci. Since spiramycin is retained in bone and the salivary glands and reaches prolonged high concentrations in the saliva, it is used mainly by dentists and otorhinolaryngologists. Because of high concentration in the tonsillar lymphoid tissue it has been proposed that spiramycin be used in the prevention of meningococcal infections. It does not reach the cerebrospinal fluid. Its toxicity is relatively low. Adverse effects include nausea, vomiting, diarrhea, and skin rashes (1).

Organs and Systems

Cardiovascular

QT interval prolongation (2) and torsade de pointes (3) occur rarely in patients taking spiramycin.

Hematologic

Hematological toxicity, including bone marrow suppression (4) and hemolysis (5), has been observed, especially during combined treatment with spiramycin and pyrimethamine for toxoplasmosis.

Liver

Cholestatic hepatitis occurred in a patient taking spiramycin (6).

Immunologic

A peculiar hypersensitivity reaction was reported in an employee of a pharmaceutical company who developed attacks of sneezing, coughing, and breathlessness while working with spiramycin; he had immediate positive skin prick tests to spiramycin and developed blood eosinophilia during asthma attacks (7).

Henoch–Schönlein purpura occurred in a patient taking spiramycin (8).

Drug–Drug Interactions

Neuroleptic drugs

Acute dystonia was observed during spiramycin therapy in a patient who was being treated with neuroleptic drugs (9).

Spironolactone

See also Diuretics

General Information

Spironolactone is a competitive antagonist at aldosterone receptors. It acts through its active metabolite, canrenone. Canrenone itself has also been used as a potassium-sparing diuretic for intravenous use and its potassium salt has been used orally, in the hope of avoiding the hormonal adverse effects of spironolactone.

Spironolactone has been used as a potassium-sparing diuretic in cardiac failure and in the management of ascites and edema associated with hepatic cirrhosis with secondary hyperaldosteronism. It is also used to treat hyperaldosteronism due to adrenal tumors or adrenal hyperplasia. It has a weak positive inotropic effect and a modest antihypertensive effect, in keeping with its natriuretic action.

Although spironolactone has been available for more than 30 years, its efficacy and safety in patients with heart failure have only recently been recognized in the Randomized Aldosterone Evaluation Study (RALES), in which it reduced mortality (1). Based on this and numerous smaller trials, the use of spironolactone, in conjunction with ACE inhibitors, other diuretics, and possibly beta-blockers or digoxin, represents a promising strategy for patients with severe heart failure. Its main adverse effects are hyperkalemia and antiadrenergic complications (SED-14, 675).

General adverse effects

The major limitation to the use of spironolactone is its liability to cause (sometimes lethal) hyperkalemia, particularly in the elderly, in patients with reduced renal function, and in patients who simultaneously take potassium supplements or ACE inhibitors. As with other diuretics, hyponatremia and dehydration can occur. Other less frequent adverse effects are gastrointestinal intolerance, neurological symptoms, and skin rashes. Hypersensitivity rashes and a lupus–like syndrome have been reported rarely. A few cases of mammary carcinoma have been reported and potential human metabolic products of spironolactone are carcinogenic in rodents. Second-generation effects have not been reported.

Organs and Systems

Nervous system

Central nervous system effects, such as weakness, drowsiness, and confusion, have been reported in patients taking spironolactone. Because most patients with such adverse effects were taking spironolactone for edema and ascites in hepatic cirrhosis, it is not yet clear whether they were caused by the drug itself or by hepatic encephalopathy. The incidence of these complaints in such patients is quite high (9.8%) (SED-9, 357).

Electrolyte balance

The beneficial effects of spironolactone in congestive cardiac failure and hypertension are additive to those of ACE inhibitors. In the RALES, patients taking an ACE inhibitor who were randomized to spironolactone 25–50 mg/day had only a 0.3 mmol/l increase in median potassium concentration (1). Although the difference between the spironolactone and placebo groups was statistically significant, the mean increase was not clinically important, and the incidence of serious hyperkalemia was minimal in both groups of patients.

However, since the publication of RALES the incidence of hyperkalemia attributable to spironolactone has increased. Trends in the rate of spironolactone prescriptions and the rate of hospitalization for hyperkalemia in ambulatory patients before and after the publication of RALES have been examined in a population time-based series analysis (2). Among patients treated with ACE inhibitors who had recently been hospitalized for heart failure, the spironolactone prescription rate increased immediately after the publication of RALES, from 3.4% in 1994 to 15% in late 2001. The rate of hospitalization for hyperkalemia rose from 0.2% in 1994 to 11% and the associated mortality rose from 0.3 to 2.0 per 1000 patients. These increases were particularly marked in elderly people.

It is essential to identify patients who are likely to develop serious hyperkalemia during combined treatment and to evaluate the associated morbidity and mortality. Spironolactone is used in patients with end-stage renal disease undergoing either peritoneal (3) or maintenance hemodialysis (4), although there is scant experimental evidence to support such use in advanced dialysis-dependent renal disease. Carefully selected dialysis patients exposed to doses of spironolactone ranging from 25 mg three times a week to 25 mg/day appeared not to have an increased frequency of hyperkalemia. However, these studies were preliminary and the results should not be extrapolated to the general dialysis population. If spironolactone is contemplated in patients with end-stage renal disease, periodic surveillance is necessary and other causes of hyperkalemia, such as ACE inhibitor therapy and/or a high potassium intake, should be controlled.

Close laboratory monitoring and judicious use of spironolactone is needed to reduce the risk of hyperkalemia. The excess of hyperkalemia in clinical practice compared with RALES can be explained largely by the use of higher doses of spironolactone and the inclusion of patients with lower glomerular filtration rates and whose aldosterone-mediated compensatory distal tubular potassium excretion is already attenuated (5). Such patients include elderly people, people with diabetes, and those taking beta-blockers, non-steroidal anti-inflammatory drugs, potassium salts, potassium-sparing diuretics, or trimethoprim.

Hematologic

Rare cases of agranulocytosis have been reported in patients taking spironolactone (SEDA-22, 239).

- Agranulocytosis occurred in an 87-year-old man with congestive heart failure who took spironolactone 25 mg/day for 3 weeks (6). The agranulocytosis rapidly

© 2006 Elsevier B.V. All rights reserved.

reversed after withdrawal of spironolactone and a short course of granulocyte-colony-stimulating-factor.
- A 43-year-old woman with cirrhosis and hepatocellular carcinoma took spironolactone for 7 days before leukopenia was detected (7). The leukocyte count returned to normal 8 days after withdrawal of spironolactone.

In general, the onset of agranulocytosis with spironolactone ranges from 4 days to 5 weeks and it takes 5–7 days to resolve without the aid of a growth factor.

Gastrointestinal

Nausea and vomiting are more common with spironolactone than with other diuretics (SED-9, 358) and were reported in 11% of patients in the Boston Collaborative Drug Surveillance Program (8). These symptoms can be reduced in patients taking high doses by spreading the dose out during the day.

Liver

Two cases of spironolactone-induced parenchymal hepatitis have been reported. The patients recovered uneventfully (SEDA-20, 205).

- A 50-year-old woman taking spironolactone for androgenic alopecia developed hepatitis with minimal cholestasis 6 weeks after starting therapy (9). After withdrawal of spironolactone, her symptoms resolved and liver function tests improved. She was not rechallenged.

Skin

Rashes (sometimes with eosinophilia), lichen planus (SED-9, 358), and a lupus–like syndrome with a positive rechallenge (SEDA-5, 230) have been reported, but on the whole skin reactions seem to be rare.

Cutaneous vasculitis has been attributed to spironolactone (SED-11, 430). It is unclear whether a patient presenting with erythema annulare centrifugum while taking spironolactone (10) had a similar reaction.

Other reported adverse effects of spironolactone include urticaria, alopecia, and chloasma (SEDA-14, 185).

- A 76-year-old patient developed eczema-like lesions and severe pruritus; histological and immunological investigations showed pemphigoid (11). The skin lesions regressed spontaneously within 15 days of spironolactone withdrawal and no relapse was noted over the next 30 months.

Sexual function

Because of its antiandrogenic action, spironolactone causes gynecomastia, reduced libido, and erectile failure in 4–30% of men. These effects seem to be both dose- and time-dependent.

Reproductive system

Spironolactone causes breast tenderness and enlargement, mastodynia, infertility, chloasma, altered vaginal lubrication, and reduced libido in women, probably because of estrogenic effects on target tissue. Menstrual irregularities were experienced by almost all women taking spironolactone 400 mg/day and most developed amenorrhea at doses of 100–200 mg/day. Normal menstruation was resumed within 2 months of withdrawal.

Very high doses of spironolactone (over 450 mg/day) can cause infertility, but such doses are rarely used. As with other diuretics, studies with spironolactone have mostly been small, not placebo-controlled, and often anecdotal (SEDA-18, 235).

In patients with hepatic cirrhosis, gynecomastia was twice as common during treatment with spironolactone than with potassium canrenoate (42 versus 20%) at equiactive doses (12). This difference may be related to structural characteristics unique to metabolites of spironolactone, namely a thiol group at the 7-alpha position (SEDA-11, 200).

Long-Term Effects

Tumorigenicity

Spironolactone is antiandrogenic and increases the peripheral metabolism of testosterone to estradiol (13). It often causes gynecomastia in men and breast enlargement and soreness in women. Five cases of mammary carcinoma have been reported. Potential human metabolic products of spironolactone are carcinogenic in rodents, and the UK Committee on Safety of Medicines in 1988 restricted the approved indications for the drug, removing the indications of essential hypertension and idiopathic edema (14).

Susceptibility Factors

Age

It has been argued that potassium-sparing diuretics present a real risk of renal insufficiency when they are used in elderly people (15). In large-scale studies in elderly hypertensive patients there is indeed some slight increase in the incidence of renal insufficiency when combinations including potassium-sparing diuretics are used. Although the overall incidence of nephrotoxicity is quite low, elderly patients and those with prior renal dysfunction are at particular risk. Special care is necessary in these circumstances.

Renal disease

In patients with renal insufficiency there is an increased risk of hyperkalemia with spironolactone; serum potassium should be monitored regularly.

Hepatic disease

Hepatic failure carries an unwarranted risk unless serum potassium is regularly monitored (16).

Drug–Drug Interactions

ACE inhibitors

Co-administration of potassium-sparing diuretics with ACE inhibitors can cause severe hyperkalemia (SED-14, 674).

The effects of ACE inhibitors plus spironolactone have been evaluated in 25 patients (11 men, 14 women, mean age 74 years, five with diabetes mellitus) with a mean serum potassium concentration of 7.7 mmol/l (17). The mean

© 2006 Elsevier B.V. All rights reserved.

serum creatinine was 336 μmol/l, the mean arterial pH 7.3, and the mean plasma bicarbonate 18 mmol/l. The main causes of acute renal insufficiency were dehydration ($n = 12$) and worsening heart failure ($n = 9$). The mean dose of spironolactone was 57 mg/day and 12 patients were also taking other drugs that can cause hyperkalemia. Two patients died and two were resuscitated and survived. Hemodialysis was necessary in 17 patients. The mean duration of hospitalization was 12 days. The combination of ACE inhibitors and spironolactone should be used cautiously in patients with chronic renal insufficiency, diabetes, older age, worsening cardiac failure, a risk of dehydration (for example diarrhea), and in those who are taking other drugs that can cause hyperkalemia (18). A dose of spironolactone of 25 mg/day should be exceeded only with caution. In four similar elderly patients with underlying renal insufficiency taking spironolactone there was an increased risk of hyperkalemia associated with diarrhea (19).

In a population-based, nested, case-control study, all patients aged 66 years or over who were taking an ACE inhibitor and who had been hospitalized for hyperkalemia were evaluated for interacting medications (20). Compared with controls taking ACE inhibitors who did not have hyperkalemia, before adjusting for confounding variables, the patients were 27 times more likely to have received a prescription for a potassium-sparing diuretic (type not specified) in the week before hospitalization. There was no such association between hospital admission for hyperkalemia and the use of indapamide in patients taking ACE inhibitors.

Angiotensin receptor antagonists

In eight healthy subjects, treatment with spironolactone and losartan increased mean plasma potassium concentration by 0.8 mmol/l (up to 5.0 mmol/l) and reduced mean urinary potassium excretion from 108 to 87 mmol/l (21). Until more data are available, it is prudent to consider angiotensin II receptor antagonists similar to ACE inhibitors as risk factors for hyperkalemia in patients taking potassium-sparing diuretics.

Antipyrine

Spironolactone has a weak enzyme-inducing effect and enhances the metabolic breakdown of phenazone (antipyrine) (SED-9, 358).

Aspirin

The renal tubular secretion of canrenone, the main metabolite of spironolactone, is blocked by aspirin (22), abolishing the diuretic response, although the antihypertensive effect is apparently not affected (23).

Carbenoxolone

Spironolactone abolishes the ulcer-healing properties of carbenoxolone (24).

Colestyramine

Colestyramine in combination with spironolactone has been reported to cause severe hyperkalemia (25), presumably because it causes exchange of chloride for bicarbonate in the small bowel, predisposing to hyperchloremic acidosis.

Digitoxin

Spironolactone has a weak enzyme-inducing effect and enhances the metabolic breakdown of digitoxin (SED-9, 358) (26). However, this effect may not be significant, because in six healthy subjects spironolactone prolonged the half-life of digitoxin from 142 to 192 hours (27).

Digoxin

Spironolactone increases steady-state digoxin concentrations by about 30%, probably by inhibiting the renal tubular secretion of digoxin by P glycoprotein. There may also be a pharmacodynamic interaction with digoxin. The clinical importance of these observations is uncertain (SEDA-9, 209).

NSAIDs

Some non-steroidal anti-inflammatory drugs, notably indometacin and mefenamic acid, inhibit the excretion of canrenone (28).

Warfarin

It has been suggested that spironolactone may reduce the anticoagulant effect of warfarin (SED-11, 430).

Interference with Diagnostic Tests

Radioimmunoassay of digoxin

Overestimation of the digoxin concentration

Spironolactone can alter the results of some digoxin radioimmunoassays, because it and its metabolites, such as canrenone and 7-alpha-thiomethylspironolactone, are immunoreactive with some forms of antidigoxin antibody (29–31). This results in an overestimate of the true digoxin concentration, because the assay reads the interfering substances as digoxin.

In a study of the use of the TDx II assay in 80 children and adults, there was apparent digoxin immunoreactivity in 3.7% of healthy subjects ($n = 80$), 3.6% of pregnant women ($n = 28$), 10% of patients with renal transplants ($n = 31$), and 23% of immature infants ($n = 40$) (32).

Underestimation of the digoxin concentration

In contrast to this, it has also been reported that spironolactone and its metabolite canrenone caused falsely low readings in a common assay for digoxin (AXSym MEIA) because of negative cross-reactivity (33). Misleading subtarget concentrations were repeatedly reported, and falsely guided increases in drug doses, resulting in digoxin intoxication.

In another study canrenoate interfered with the immunoassay of digoxin (33), reducing the apparent digoxin concentration. The effect was largest with the AxSym MEIA II assay, and there was also some interference with the EMIT assay. However, the TDx assay was not affected. Spironolactone also caused some interference in the AxSym assay but less than canrenoate. In this case the failure to measure high digoxin concentrations resulted in

© 2006 Elsevier B.V. All rights reserved.

clinical toxicity in a 71-year-old man who was given 3.8 mg over 11 days.

In nine assays (AxSYM, IMx, TDx, Emit, Dimension, aca, TinaQuant, Elecsys, and Vitros) interference by spironolactone, canrenone, and three metabolites was sought in vitro, and all routine digoxin measurements using the AxSYM system over 16.5 months ($n = 3089$) were reviewed (34). There was a reduction in the expected concentrations by canrenone (3125 ng/ml) in the following assays: AxSYM (42% of expected), IMx (51%), and Dimension (78%). There was positive bias in aca (0.7 ng/ml), TDx (0.62 ng/ml), and Elecsys (>0.58 ng/ml). Of 669 routinely monitored patients, 25 had falsely low results and 19 of them actually had potentially toxic digoxin concentrations; this was attributable to concurrent therapy with spironolactone, canrenone, hydrocortisone, or prednisolone. However, standard doses of spironolactone (up to 50 mg/day) in patients with heart failure produced less than 11% inhibition.

Although several modern digoxin assays suffer from potentially negative interference from spironolactone and canrenone (34), there are assays that are less susceptible to interference by spironolactone (35). Laboratories should determine the false negative potential of the analytical method that they use.

Stavudine

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Stavudine is a nucleoside analogue reverse transcriptase inhibitor. Its most important adverse effects are peripheral neuropathy and increases in hepatic transaminases, both of which usually resolve on withdrawal.

Organs and Systems

Nervous system

The principal toxic effect of stavudine is a peripheral neuropathy, with symptoms similar to the neuropathy associated with didanosine and zalcitabine (1,2). The development of this neuropathy depends on the duration of treatment, with an increasing risk after 12 weeks of treatment. A prior history of neuropathy increases the risk of stavudine-induced neuropathy. After withdrawal, the symptoms usually improve within 2 weeks, although they can persist for several months.

Metabolism

Lipodystrophy, a syndrome characterized by fat redistribution, hyperglycemia/insulin resistance, and dyslipidemia, can be associated with long-term HIV infection or with highly active antiretroviral therapy (HAART). In 1035 patients, those who took stavudine were 1.35 times more likely to report lipodystrophy (3). However, the study was retrospective, and other factors unrelated to specific drug therapy may have had a greater effect on the adjusted odds ratio.

Hematologic

A modest dose-related macrocytosis without an associated anemia can occur during treatment with stavudine (1,2).

Liver

Asymptomatic increases in hepatic transaminases, which are not clearly dose-related, can occur during treatment with stavudine, requiring dosage modification because of moderate or severe toxicity in about 10% of patients (1,2).

Urinary tract

Renal tubular dysfunction and hypophosphatemia occurred in a patient who was taking both stavudine and lamivudine (4).

Sexual function

Painful bilateral gynecomastia and hypersexuality, possibly related to the use of stavudine, have been reported (5).

- A 25-year-old HIV-infected man reported hot flushes and headaches during the first days of treatment with stavudine (40 mg bd), followed by swelling and tenderness under both nipples. He also reported increased libido, premature ejaculation, and persistent erections. He denied illicit drug use. He had bilateral gynecomastia. Luteinizing hormone and testosterone concentrations were within the reference ranges, excluding primary causes of gynecomastia. One month after withdrawal of stavudine, the swelling and tenderness had abated and his sexual symptoms had resolved. He was not rechallenged with the drug.

The authors argued that although idiopathic gynecomastia could not be ruled out, the temporal relation between withdrawal of the drug and improvement in his symptoms suggested a causative role of stavudine.

In a Swiss case-control study gynecomastia was associated with stavudine in 47 cases. Blood concentrations of luteinizing hormone were above the reference range in 40% of the cases and 29% had reduced testosterone concentrations (6).

Drug–Drug Interactions

Isoniazid

A distal sensory neuropathy is the commonest neurological complication in HIV-infected individuals, and has been documented in up to 30% of patients with AIDS. There is evidence from a retrospective case-note review in 30 individuals that co-administration of stavudine and isoniazid increases the incidence of distal sensory neuropathy. Of 22 patients taking stavudine in combination with other drugs, all took isoniazid for tuberculosis and 12 developed a distal sensory neuropathy, with a median time to onset of 5 months (7). Those taking stavudine alone had an incidence of 11%.

Stem cell factor

General Information

Stem cell factor amplifies the proliferation and mobilization of myeloid, erythroid, and megakaryocyte colonies when combined with a lineage-specific hemopoietic growth factor (for example G-CSF, IL-3). Stem cell factor, added to other recombinant hemopoietic cytokines, is used to increase the mobilization of peripheral blood progenitor cells.

In preliminary trials, transient allergic-type reactions, that is urticaria, respiratory symptoms, and injection-site reactions, resulting from dose-dependent mast cell degranulation, were easily prevented by classical premedication (1).

In 102 patients with multiple myeloma, stem cell factor plus G-CSF produced more frequent injection site reactions and more frequent skin reactions (25 versus 2%), namely rash, erythema, urticaria, pruritus, and abnormal pigmentation, compared with G-CSF alone (2). These reactions occurred despite systemic prophylactic antihistamines. Other adverse effects occurred with similar frequency in the two groups of patients.

Organs and Systems

Immunologic

Stem cell factor produces direct mast cell stimulation with subsequent allergic-type reactions. Despite careful premedication with diphenhydramine, ranitidine, inhaled salbutamol, and pseudoephedrine, such reactions were still observed in 3% of patients (3).

Stepronin

General Information

The adverse effects of stepronin, a sulfhydryl compound, which is used in rheumatoid arthritis, are similar to those of penicillamine. In a long-term open study, treatment had to be interrupted in 30% of 36 patients because of severe adverse effects (1). Seven patients had mucocutaneous reactions (dermatitis, pruritus, stomatitis, glossitis, ageusia), three proteinuria, and one thrombocytopenia and leukopenia.

Stiripentol

See also Antiepileptic drugs

General Information

The clinical pharmacology and adverse effects of stiripentol have been reviewed (1).

The effects of stiripentol have been studied in 41 children with severe myoclonic epilepsy in infancy in a randomized, placebo-controlled, add-on trial (2). There were adverse effects in 21 patients taking stiripentol (drowsiness and loss of appetite) compared with five taking placebo, and the adverse effects disappeared when the doses of other antiepileptic drugs were reduced in 12 of the 21 cases.

Drug–Drug Interactions

Clobazam

When stiripentol 50 mg/kg was given to 20 children taking clobazam, mean serum clobazam and norclobazam concentrations increased about two-fold and three-fold respectively; a mean 25% reduction in clobazam dose was required because of adverse effects (3).

Valproic acid

Serum concentrations of concomitantly administered valproic acid rose by about 20% (3). These findings are in agreement with evidence that stiripentol is a potent metabolic inhibitor.

Streptogramins

General Information

Pristinamycin (rINN) is a synergistic combination of streptogramin A (pristinamycin IIA) and streptogramin B (pristinamycin IB). It is active against the main bacteria that cause respiratory tract infections and could be useful in the treatment of acute or recurrent sinusitis, community-acquired pneumonia, or periodontal infection with *Actinobacillus actinomycetemcomitans* (1–5).

Quinupristin (rINN) and dalfopristin (rINN) are two semisynthetic pristinamycin derivatives that are given in combination parenterally. The combination has a broad spectrum of activity against Gram-positive bacteria, including multidrug resistant bacilli. A comprehensive review has been published (6). Quinupristin + dalfopristin can be used to treat macrolide-resistant streptococci, staphylococcal infections after failure of conventional therapy, or vancomycin-resistant *Enterococcus faecium* (and probably *Enterococcus raffinosus*), but not vancomycin-resistant *Enterococcus faecalis*, *Enterococcus avium*, *Enterococcus casseliflavus*, or *Enterococcus gallinarum* (7–19). Adverse effects include arthralgia, myalgia, and pain at the infusion site (20).

Observational studies

In a small, open, phase II pilot study, low-dose quinupristin + dalfopristin (5 mg/kg intravenously every 8 hours; $n = 11$) and high-dose quinupristin + dalfopristin (7.5 mg/kg intravenously every 8 hours; $n = 15$) were compared with vancomycin (1 g intravenously every 12 hours; $n = 13$) in the treatment of catheter-related staphylococcal bacteremia (21). In patients with a baseline pathogen, the outcome was comparable in all groups. Adverse clinical events in the quinupristin + dalfopristin group consisted of arm and chest pain, chills, fever, arthritis, and phlebitis or pain at the injection site; quinupristin + dalfopristin was withdrawn in 12% of patients (compared with 15% of vancomycin-treated patients).

In healthy volunteers receiving quinupristin + dalfopristin, 7.5 mg/kg infused over 1 hour bd, mean fecal antibiotic concentrations were 291 and 42 µg/g of feces for quinupristin and dalfopristin respectively by the fifth day of treatment (22).

Comparative studies

The pooled results of two multicenter, phase III, randomized comparisons of quinupristin + dalfopristin (7.5 mg/kg intravenously every 12 hours; $n = 450$) with established comparators (cefazolin, oxacillin, vancomycin; $n = 443$) for complicated skin and skin structure infections have been reported (23). The success rate was equivalent in the two groups: 63% of patients given quinupristin + dalfopristin (versus 54%) reported at least one adverse event, most commonly nausea, vomiting, rash, pain, or pruritus. Although most of the adverse events were mild to moderate, the drug was withdrawn in 19% of patients treated with quinupristin + dalfopristin (versus 4.7%) owing to an untoward event. Adverse venous events (atrophy, edema, hemorrhage, hypersensitivity, inflammation, thrombophlebitis, pain) were reported by 66% of patients treated with quinupristin + dalfopristin (versus 28%) and required withdrawal of the drug in 12% of these patients (versus 2%).

General adverse effects

The adverse effects of quinupristin + dalfopristin include arthralgia, myalgias, reversible rises in serum alkaline phosphatase, itching, diarrhea, vomiting, and pain at the infusion site; adverse effects occurred in 2.5–4.6% of patients (24–31).

Organs and Systems

Electrolyte balance

The combination of quinupristin + dalfopristin has been associated with hyponatremia, probably secondary to inappropriate secretion of antidiuretic hormone (32).

- A 67-year-old woman with peripheral neuropathy, IgM paraproteinemia, and chronic obstructive pulmonary disease developed dyspnea and hyponatremia, and a small-cell lung cancer was diagnosed. She was given 3 cycles of chemotherapy (etoposide, cyclophosphamide, and doxorubicin). Her serum sodium concentrations normalized. On day 103, she was given quinupristin + dalfopristin (7.5 mg/kg every 8 hours) because of septicemia with vancomycin-resistant *E. faecium*. The serum sodium concentration thereafter fell (day 110: 117 mmol/l; serum osmolarity: 268 mosm/l; urine osmolarity: 426 mosm/l). Therapy was withdrawn on day 111, and the sodium concentration gradually returned to normal.

Gastrointestinal

In a multicenter, open, randomized trial in 204 patients with erysipelas treated with either oral pristinamycin 1 g tds or intravenous then oral penicillin, adverse events related to treatment were significantly more common with pristinamycin; they were mostly mild or moderate and mainly involved the gastrointestinal tract (33).

Pristinamycin can cause pseudomembranous colitis.

- An 85-year-old woman developed a severe illness (severe diarrhea and vomiting, abdominal tenderness, peritoneal irritation, and systemic toxicity) 8 days after receiving pristinamycin 3 g/day for 10 days (34). An assay for *Clostridium difficile* was positive. She was treated with metronidazole and her symptoms resolved after 72 hours.

Liver

In 25 liver transplant recipients who received intravenous quinupristin + dalfopristin 7.5 mg/kg 8-hourly for vancomycin-resistant *E. faecium* infection, hyperbilirubinemia developed, but there was no evidence of drug-specific histological injury (35).

Skin

In a retrospective study of children taking quinupristin + dalfopristin, rash (2%) was the most frequent adverse event, but only one patient with rash discontinued quinupristin + dalfopristin because of it (31).

Patch tests can be used to confirm pristinamycin-induced drug eruptions. In 11 patients with cutaneous drug reactions after oral pristinamycin, patch tests (with pristinamycin diluted to 20% aqueous and 20% petrolatum) were performed 1–3 months after treatment with pristinamycin (36). There were positive patch tests in nine, and there was no relapse of the drug eruption during patch-testing; 30 control patients had negative tests.

Mean antibiotic concentrations of pristinamycin in dermal interstitial fluid (from suction bullae) are low; nevertheless, the concentrations achieved should theoretically inhibit the growth of group A streptococci (37).

Musculoskeletal

Of seven patients with end-stage renal insufficiency who received quinupristin + dalfopristin, two developed myalgias (38).

Of 32 patients who received quinupristin + dalfopristin, at least 15 developed arthralgias and/or myalgias (39).

Immunologic

The combination of quinupristin + dalfopristin reduces cytokine production in stimulated monocytes from healthy volunteers, suggesting significant immunomodulatory activity (40).

Long-Term Effects

Drug resistance

The relative frequency of resistance to macrolides, lincosamides, and streptogramins (MLS resistance) has been assessed in a series of 2091 staphylococcus isolates collected during a 3-week period in 1995 in 32 French hospitals. A total of 294 strains (144 *Staphylococcus aureus*, 150 coagulase-negative staphylococci) exhibited resistance to at least one of these groups of antibiotics. Resistance to pristinamycin was phenotypically detected in ten *S. aureus* strains (seven isolates from the same hospital and possibly of the same clone) and three coagulase-negative staphylococcus isolates. It was associated with resistance to type A streptogramins encoded by vat or vatB genes and was associated with the erm genes (41).

A short report demonstrated the absence of a reliable correlation between killing kinetics and normal laboratory tests for pristinamycin susceptibility testing of some pneumococci (42). Eight selected multiresistant clinical isolates and two reference pristinamycin-resistant *Streptococcus pneumoniae* strains were studied. Disk diffusion susceptibility and MICs were determined by the agar dilution method, and all clinical isolates appeared to be susceptible to pristinamycin, whereas the two reference strains were not. In contrast, time-kill experiments identified a limited bactericidal effect of pristinamycin in three clinical and both reference strains. These three strains had been classified as pristinamycin-resistant by the Vitek-II system, which uses a kinetic turbidimetric measurement of bacterial growth. Epidemiological information is hindered by the use of highly selected strains for the study.

The in vitro activity of pristinamycin has been evaluated in 200 isolates of *S. pneumoniae* strains with various degrees of susceptibility to penicillin G and erythromycin (43). All the strains were susceptible to pristinamycin, irrespective of their susceptibility to penicillin G or erythromycin.

After 5 days administration of quinupristin + dalfopristin 7.5 mg/kg infused over 1 hour bd, the fecal microflora in 20 healthy volunteers increased significantly during treatment and returned within 12 weeks to baseline concentrations after the end of treatment. There were anerobes and enterococci resistant to erythromycin or to quinupristin + dalfopristin, but glycopeptide-resistant enterococci did not emerge (22).

The relevance of resistance to virginiamycin

Virginiamycin is a streptogramin that has been used in animals as a growth-promoter. Increasing use of virginiamycin has been associated with a high rate of resistance to quinupristin + dalfopristin (44). Acquired resistance to virginiamycin, which is active against Gram-positive lactic acid-producing bacteria, can be detected in *E. faecium* and *E. faecalis* strains isolated from animals and food (45), including strains from poultry, in which high resistance against virginiamycin was found in Belgium (46). Streptogramin resistance is associated with the resistance genes vatA and vatG in *E. faecium* of both animals and man (44). Because virginiamycin has been used in animals and streptogramins have been used infrequently in man, an animal origin of resistance has been suggested, and spread of resistance via the food chain to humans is probable (47).

Susceptibility Factors

Renal disease

The disposition of quinupristin, dalfopristin, and their primary metabolites was similar in eight non-infected patients on peritoneal dialysis compared with eight matched healthy volunteers after the administration of quinupristin + dalfopristin 7.5 mg/kg (48). Since dialysis clearance was insignificant, the combination was thought to be inadequate for the therapy of dialysis-associated peritonitis.

The pharmacokinetics of a single intravenous injection of quinupristin + dalfopristin (7.5 mg/kg over 1 hour) have been assessed in 13 patients with severe chronic renal insufficiency (creatinine clearance 6–28 ml/minute/1.73 m^2) (49). Although the mean peak plasma drug concentration and AUC of quinupristin plus its active derivatives and of both unchanged dalfopristin and dalfopristin plus its active derivatives were about 1.3–1.4 times higher than in healthy volunteers, the authors concluded that no formal reduction in the dosage of quinupristin + dalfopristin is necessary in patients with chronic renal insufficiency.

Drug–Drug Interactions

CYP3A4

Quinupristin + dalfopristin can inhibit the metabolism of agents that are metabolized by CYP3A4 (50).

Strychnine

General Information

Strychnine is an alkaloid that is found in *Nux vomica*. It causes excitation of all parts of the central nervous system, with a characteristic motor pattern. Strychnine is a competitive antagonist at inhibitory neurotransmitter glycine receptors in the spinal cord, brain stem, and higher centers. It thus increases neuronal activity and excitability, leading to increased muscular activity. Since strychnine convulsions also occur in decerebrate animals, the convulsion is termed a "spinal convulsion," but other parts of the central nervous system are also stimulated

© 2006 Elsevier B.V. All rights reserved.

by doses that produce motor manifestations in a decerebrate animal. Strychnine does not selectively stimulate the medulla and cannot therefore be regarded as a useful analeptic drug (1).

The features of strychnine poisoning occur at 15–30 minutes after ingestion. They include heightened awareness, muscle twitches and spasms, and hypersensitivity to stimuli. In severe toxicity, painful generalized convulsions can occur without loss of consciousness. Respiratory arrest secondary to respiratory muscle spasm also occurs and is the usual mode of death. Prolonged muscular spasm can lead to hyperthermia, lactic acidosis, rhabdomyolysis, and acute renal insufficiency due to myoglobinuria.

Drug Administration

Drug overdose

Two cases of strychnine poisoning with characteristic signs and symptoms have been described (2,3). Management included gastric lavage, the administration of activated charcoal, sedation with midazolam and phenobarbital, and paralysis with vecuronium, along with respiratory support and forced hydration. In some countries strychnine is available as a pest control agent, resulting in occasional poisoning. Early diagnosis and prompt management can save the patient, despite the consumption of a large dose of strychnine.

- A 33-year-old man attempted suicide by self-injection of strychnine intramuscularly (4). A few seconds after the first injection he developed dizziness and light-headedness. Ten minutes after the second injection he had seizures, opisthotonos, and tetany. He was rescued with a benzodiazepine and ventilatory support.

A case of fatal poisoning due to strychnine has been described, and the concentrations of strychnine in various body fluids and organs have been detailed (5). The half-life of strychnine in a case of poisoning in a 42-year-old man who survived was 12 hours (6).

Substances that affect the skin: Contact allergy

General Information

Contact allergy is the most frequently described adverse effect of topical drugs and cosmetics; the diagnosis can be established by patch-testing (1–4) and review articles (5).

In allergic contact dermatitis due to topical medicaments (6), any constituent of the formulation can be responsible for the adverse event—the vehicle, preservative, emulsifier, perfume, or the active drug. Hence, patch tests should be carried out with all active and supposedly inactive ingredients of the incriminated topical drug.

When cosmetic allergy is suspected (SEDA-11, 142) (SEDA-13, 117) (7), the patient should be tested with the suspected products. Skin care products can be tested as the marketed formulation. However, some cosmetics, notably those that contain detergents such as soaps, shampoos, and bath foams, can cause false-negative and false-positive patch test reactions. Their ingredients should therefore preferably be tested separately when contact allergy to such products is strongly suspected (8). Natural botanical extracts are being increasingly used in cosmetics. Consumers tend to regard these natural substances as safe. However, patients with positive patch tests to *Aloe vera*, arnica, *Centella asiatica*, chamomile, cucumber, lavender oil, peppermint, rosemary, sage, St John's wort (photosensitivity), tea tree oil, and witch hazel have been reported (9).

Ingredient labeling, which has been mandatory in the European Union since 1 January, 1997, has greatly facilitated the investigation of patients with suspected cosmetic dermatitis (SEDA-22, 159) (10).

There have been useful review articles on cosmetic allergy (8), preservatives (11), fragrances (SEDA-20, 149) (12), topical drugs (6), glucocorticoids (13), and antihistamines (14).

Table 1 lists alphabetically a large number of ingredients of cosmetics and topical drugs that can act as sensitizers; some drugs are accidental contactants, for example in the pharmaceutical industry or in health personnel. For each compound, the concentration and vehicle for patch-testing, known or generally held to be adequate, are mentioned.

Substances that are not listed in any standard table should be patch-tested with great caution; control tests are mandatory when positive reactions are obtained, so as to exclude false-positive irritant patch test reactions.

We have attempted to estimate the sensitizing potential of each particular drug using the following scale:

1—sensitization is common;
2—sensitization can occur;
3—sensitization is unusual;
4—sensitization is rare.

These estimates are based on literature data and personal experience (4).

Table 1 Patch test concentrations and vehicles for skin testing of ingredients of topical drugs and cosmetics

[1] For allergy to preservatives, see (11,134,135).
[2] For glucocorticoid allergy, see (13,81,82) and (SEDA-21, 158). For patch-testing glucocorticoids, a 1% concentration in 70% alcohol can be adequate. However, as alcoholic solutions can only be kept in storage for 1–2 months and can cause irritation, petrolatum is the usual choice of vehicle (SEDA-21, 159).
[3] For allergy to ophthalmic drugs, see (136).
[4] For allergy to fragrances, see (12) (SEDA-20, 149).
[5] For allergy to antihistamines, see (14).

In the column "Frequency of sensitization" the following scale for the occurrence of sensitization is used:

1 = common;
2 = can occur;
3 = unusual;
4 = rare.

In the column "Comment" the following symbols are used:

a = photosensitivity reported;
b = immediate contact reactions reported;
c = accidental contactant;
d = see also separate monograph;
e = has also caused irritant dermatitis;
f = systemic contact dermatitis reported.

Contact allergy in the anogenital region

Allergic contact dermatitis is a common anogenital disease. The predominant complaints are itching and burning. Scratching, mainly at night, and lichenification can lead to painful erosions. Topical medicaments, body care products, popular remedies, and sanitary products are the main sources of contact allergens in the anogenital area.

Epidemiology

During 1992–1997, 1008 patients with anogenital complaints (2% of the whole test population of 54 500 patients) were patch-tested in the Departments of Dermatology of the Information Network of Dermatological Clinics (IVDK). The standard series recommended by the German Contact Dermatitis Research Group (DKG) was tested in 978 of these patients. Other specific allergens were tested according to each patient's history. In most cases topical drugs, ointment bases, and preservatives were included, and in 466 cases patients' own products were also patch-tested. In 351 patients (35%), the final diagnosis of allergic contact dermatitis was confirmed (15). Similar numbers were reported from the UK, where anogenital dermatosis was diagnosed in 201 women in a contact dermatitis clinic over 14 years. In 79 cases (39%) the diagnosis of allergic contact dermatitis was confirmed by patch tests with the European standard series, a medicament series, a glucocorticoid series, and the patients' own medicaments, if necessary. In another UK study, 39 of 135 patients tested (29%) with persisting vulval symptoms had contact hypersensitivity (16). There is evidence that the vulval region and the perianal region should be considered separately, since patients with dermatosis that only involves the vulva have positive patch tests less often than patients with dermatosis of the vulva and the perianal area or patients who have only perianal involvement (17).

Allergens and sources

The most frequent allergens in the study of the IVDK are listed in Table 2, and Table 3 gives information about the patch test results obtained with topical drugs, ointment bases, and preservatives.

All allergens that led to positive reactions in at least 1% of the patients tested are listed (15).

Although the spectrum is comparable to that of all patients tested between 1992 and 1997, there are some allergens of pronounced significance for the anogenital region. Cinchocaine HCl ranked fourth among contact allergens

Table 2 The most frequent allergens among patients with anogenital complaints

Allergen	Number tested	Number with a positive reaction (%)[1]	Number with a positive reaction (%)[2]	IVDK total 1992–7 (%)[3]
Nickel sulfate	962	86 (8.9)	12.6	16–17

Table 3 Patch test results obtained with topical drugs, ointment bases, and preservatives

Allergen	Test formulation	Number tested	Number with a positive reaction (%)
Bufexamac	5% petrolatum	534	9 (1.7)
Framycetin sulfate	20% petrolatum	268	7 (2.6)
Lidocaine HCl	15% petrolatum	524	6 (1.1)
Tincture of *Arnica montana*	20% petrolatum	241	5 (1.2)
Clotrimazole	5% petrolatum	272	5 (1.8)
Iodochlorhydroxyquin (clioquinol)	5% petrolatum	303	5 (1.7)
Chamomile extract	2.5% petrolatum	173	5 (2.9)
Tetracaine HCl (amethocaine HCl)	1% petrolatum	306	4 (1.3)
Panthenol	5% petrolatum	323	4 (1.2)
Chloramphenicol	10% petrolatum	244	3 (1.2)
Mafenide	10% petrolatum	299	3 (1.0)
tert-Butyl hydroquinone	1% petrolatum	710	8 (1.1)
Benzalkonium chloride	0.1% petrolatum	740	8 (1.1)
Bronopol	0.5% petrolatum	728	7 (1.0)
Chloroacetamide	0.2% petrolatum	743	7 (0.9)

in this region. Furthermore, there were more positive patch test results to (chloro)methylisothiazolinone (CMI/MI) and to benzocaine among patients with anogenital complaints compared with the whole test population (15).

Topical local anesthetics play an important role in anogenital contact allergy (15–19). Cinchocaine is commonly used in topical antihemorrhoidal formulations and is a well-known sensitizer (20). Although benzocaine is not as widely used in topical anesthetic formulations in Germany, patients with anogenital dermatitis were at higher risk of sensitization. Amide-type local anesthetics, like lidocaine HCl and tetracaine, are less potent sensitizers (21). Contact allergy to local anesthetics is more often observed among patients with perianal complaints than patients with perianal and vulval or only vulval dermatitis (17).

Topical antibiotics are often used in the treatment of dermatitis with bacterial superinfection. However, in Germany sensitization to the aminoglycoside antibiotic neomycin was less frequent in patients with anogenital dermatitis (15) compared with the UK, where 15 of 79 patients with positive patch tests and anogenital complaints were positive to neomycin (17). Framycetin contact sensitivity was frequent in the UK, partly through cross-reactivity with neomycin (16).

Another important substance in hemorrhoidal formulations is bufexamac, a non-steroidal anti-inflammatory drug that is a well-known sensitizer and sometimes elicits severe dermatitis (22). Bufexamac should therefore always be included in patch tests for anogenital dermatitis.

Glucocorticoid contact allergy is well known (SEDA-21, 158) and has to be particularly suspected in chronic conditions affecting the perianal area (17), after long-term topical medication, and in cases of failure to ameliorate dermatitis with corticosteroids. Patch tests should then be performed both with the recommended markers, budesonide (0.1% petrolatum) and tixocortol pivalate (1% petrolatum), and with the patient's own formulations.

Antifungal drugs are comparatively rare contact allergens in the anogenital region in relation to their widespread use. Clotrimazole and nystatin are preferred. In the study of the IVDK, patch tests with clotrimazole were performed in only 272 patients, leading to five positive reactions (15). In the UK study on anogenital dermatosis, five women out of 201 patients tested had positive reactions to antifungal drugs, but was unfortunately not specified in the article (17). If sensitization to nystatin is suspected, polyethylene glycol should be used as a vehicle for patch-testing (23). Imidazoles can cross-react with one another (SEDA-20, 156). Most cases of contact allergy occurred with miconazole, econazole, tioconazole, and isoconazole (24).

Moist toilet paper is a rare source of contact allergens. The most important allergens in moist toilet paper are preservatives, such as CMI/MI and dibromoglutaronitril + 2-phenoxyethanol (Euxyl K 400) (25–27). These substances were also incriminated in the study of the IVDK (15) and are also found in body care products. In Germany, when CMI/MI was replaced by iodopropyl butylcarbamate (IPBC) in moist toilet paper, one case of contact allergy to IPBC was soon described (28).

Other sources of preservatives are topical medicaments and body care products. Parabens, chloracetamide, and formaldehyde-releasing preservatives, like diazolidinyl urea, imidazolidinyl urea, bronopol, and quaternium 15, should also be considered (15).

Ointment bases do not seem to cause contact allergy in the anogenital region too often, despite wide use. Wool wax alcohol and amerchol L-101 are the most important (15,17). Contact sensitivity to balsam of Peru and fragrance mix is not infrequent and reflects the ubiquitous presence of these substances (16).

Topical remedies are very popular in self-treatment and patients will often not report this, since they do not regard them as medicaments. Furthermore, patients often do not suspect that "natural" remedies cause adverse effects. Some substances lead to a considerable number of allergic reactions, for example chamomile extract and tincture of *Arnica montana* (15). Propolis also has pronounced sensitizing capacity (29), and sensitization to aged tea tree oil is being reported with increasing frequency (30).

Contact allergy from rubber additives in condoms is sometimes suspected, and there are anecdotal reports (31). However, in the study of the IVDK, condoms were patch-tested in 17 patients without positive results (15).

Although sensitization to nickel sulfate is common in patients with anogenital contact dermatitis and in patients with dermatitis in other body sites, the relevance to

© 2006 Elsevier B.V. All rights reserved.

anogenital complaints of sensitization to nickel sulfate should always be doubted (15,16,32). However, direct transmission of nickel from the hands to the anogenital region has to be taken into account, and food can be a rare source of nickel contact in the anogenital area. In these cases relevance can be proved by oral nickel provocation and a nickel-restricted diet for a limited period may be justified (33).

Prediction of contact allergens

Certain chemical substructures, so-called toxophores, can be associated with an increased risk of skin sensitization. These have been codified in a set of 57 rules known as the DEREK (Deductive Estimation of Risk from Existing Knowledge) knowledge-based computer system (34). This rulebase has been subjected to extensive validation and continues to be refined. The predictive ability of the sensitization rule set was assessed by processing the structures of the first 84 chemical substances in the list of contact allergens issued by the German Federal Institute for Health Protection of Consumers (BgVV). The rules identified toxophores for skin sensitization in the structures of 71 of the 84 chemicals. After refinement, by extension of the scope of the existing rules and by generation of new rules with a sound mechanistic rationale for the biological activity, the rules identified toxophores for skin sensitization for 82 of the 84 chemicals.

Conclusions

Contact allergy should always be suspected in patients with anogenital dermatitis, especially if the perianal area is involved. In patients with other chronic inflammatory diseases of the anogenital region, for example lichen sclerosus, contact allergy should also be excluded, since long-term use of topical medicaments on compromised skin carries an increased risk of sensitization.

Patch tests in patients with anogenital eczema should include the standard series: cinchocaine HCl, propolis, bufexamac, and other ingredients of topical formulations according to the patient's history. In cases of doubt, the repeated open application test (ROAT) is recommended. Patients should be advised to apply the suspected product three times a day for 3 days to an area of healthy skin on measuring 5 cm × 5 cm the flexural site of the forearm (35).

Substances that affect the skin: Contact urticaria

Contact urticaria (1–4) refers to a wheal-and-flare response to the application of chemicals to the intact skin. Various cutaneous and extracutaneous symptoms and signs have been described, justifying the term "contact urticaria syndrome." The broad spectrum of clinical manifestations is classified in Table 1. The symptoms usually develop within 20–30 minutes after contact with the offending chemical, but later reactions after several hours have also been recorded.

Most cases of contact urticaria are of non-immunological origin, presumably due to the direct release of histamine, slow-reacting substance of anaphylaxis (SRS-A), bradykinin, or other vasoactive substances. Topical drugs and ingredients of cosmetics that have caused non-immunological contact urticaria are listed in Table 2.

Contact urticaria of immunological origin is less common, although many topical drugs have caused it in previously sensitized individuals. In several reports, passive-transfer tests were positive, and specific antibodies have occasionally been demonstrated, indicating an immunological phenomenon. Topical drugs and ingredients of cosmetics that have caused immunological contact urticaria are listed in Table 3; in most of these cases, the contact urticaria was of probable immunological origin.

Some cases of contact urticarial reactions cannot be ascribed with certainty to either immunological or non-immunological mechanisms; the classical example of this category of contact urticaria of uncertain mechanism is that caused by the bleaching agent ammonium persulfate. Also belonging to this category are several topical substances that have caused contact urticaria on patch-testing, the clinical significance of which is uncertain, for example nickel sulfate, butylated hydroxyanisole (BHA),

Table 2 Agents that have caused non-immunological contact urticaria (1,4)

Alcohols	Eugenol
Balsam of Peru	Formaldehyde
Benzaldehyde	Iodine
Benzocaine	Methyl green
Benzoic acid/benzoin tincture	Methyl salicylate
Camphor	Monoethyl fumarate (SEDA-16, 153)
Cantharides	Nicotinic acid esters (SEDA-17, 187)
Capsaicin	Parabens
Chlorocresol	Phenol
Cinnamic acid	Propylene glycol (SEDA-19, 159)
Cinnamic aldehyde (SED-9, 249)	Resorcinol
Cinnamon oil	Sodium benzoate
Diethyl fumarate (SEDA-16, 153)	Sorbic acid
Dimethylsulfoxide (SED-9, 249)	Sulfur

Table 1 Staging and symptoms of the contact urticaria syndrome (3,4)

Cutaneous reactions only		Extracutaneous reactions	
Stage 1	Localized urticaria Dermatitis/dermatosis Non-specific symptoms (itching, tingling, burning, etc.)	Stage 3	Bronchial asthma Rhinoconjunctivitis Otolaryngeal symptoms Gastrointestinal symptoms
Stage 2	Generalized urticaria	Stage 4	Anaphylactoid reactions

Table 3 Agents known or believed to have caused immunological contact urticaria (1–4)

Acetylsalicylic acid
Acrylic acid (SEDA-18, 175)
Albendazole
Aminophenazone (aminopyrine)
Ampicillin
Amyl alcohol
Bacitracin
Balsam of Peru
Basic blue 99
Benzocaine
Benzoic acid
Benzophenone
Benzoyl peroxide
Benzyl alcohol
Buserelin acetate
Butyl alcohol
Butylated hydroxyanisole (BHA)
Butylated hydroxytoluene (BHT)
Caraway seed oil
Cefotiam hydrochloride (SEDA-19, 163)
Cephalosporins
Cetyl alcohol
Chamomile
Chloramine
Chloramphenicol
Chlorhexidine (SEDA-21, 166)
Chlorocresol (SEDA-12, 137)
Chlorproethazine (SEDA-17, 187)
Chlorpromazine (6)
Clioquinol (iodochlorhydroxyquinoline) (SEDA-5, 152)
Clobetasol 17-propionate (SEDA-8, 153)
Colophony
Corn starch
Denatonium benzoate
Diethyl fumarate
Diethyl toluamide (SEDA-8, 153)
1,3-Diiodo-2-hydroxypropane
Dinitrochlorobenzene
Diphenylcyclopropenone (SEDA-14, 132)
Dipyrone
Disodium cromoglicate (SEDA-12, 137)
Emulgade F
Estrogen cream
Ethyl alcohol
Ethylenediamine dihydrochloride
Etofenamate
Formaldehyde (SEDA-8, 153)
Gelatine
Gentamicin (SEDA-12, 139)
Gentian violet
Glyceryl trinitrate
Hamamelis
Henna
Hexanetriol
Hydrolysed protein (SEDA-21, 166)
Isopropyl alcohol
Isopropyl dibenzoylmethane
Labetalol
Lanolin alcohol (SEDA-5, 152)
Latex
Lidocaine (SEDA-15, 149)
Lindane
Mechlorethamine hydrochloride (SEDA-22, 172)
Menthol
Merbromin
Mercurochrome (SEDA-19, 163)
Metamizole
Methotrimeprazine
Methylethylketone
Mexiletine hydrochloride (SEDA-18, 175)
Mezlocillin (SEDA-15, 149)
Monoamylamine
Myrrh
Neomycin
Nickel sulfate
Nicotine
Nicotinyl alcohol
Nifuroxime
Orthophenylphenate
Oxyphenbutazone
Para-aminodiphenylamine (SEDA-5, 152)
Parabens
Parahydroxybenzoic acid
Paraphenylenediamine derivatives (SEDA-21, 166)
Penicillin
Pentamidine isethionate
Phenylmercuric salts
Polyethylene glycol
Polypropylene (Polysorbate 60)
Povidone iodine (SEDA-20, 157)
Pristinamycin
Procaine hydrochloride
Promethazine hydrochloride
Propipocaine hydrochloride (SEDA-15, 149)
Propyl alcohol
Propylene glycol
Protein hydrolysate (SEDA-15, 149)
Pyrazolone derivatives (SEDA-9, 139)
Pyrethrin (SEDA-15, 149)
Rifamycin (SEDA-17, 191)
Salicylic acid
Sisomycin (SEDA-12, 139)
Sodium hypochlorite
Sodium sulfite
Sorbitan laurate (SEDA-9, 139)
Squaric acid dibutyl ester
Steartrimonium hydrolysed animal protein (SEDA-21, 166)
Stearyl alcohol
Streptomycin
Sulfur
Tetracycline (SEDA-9, 139)
Thiomersal
Thuja
α-Tocopherol
Tropicamide
Vanillin
Virginiamycin

butylated hydroxytoluene (BHT), ethyl vanillin, potassium bichromate, parabens, and ethylenediamine (5).

The diagnosis of contact urticaria can usually be confirmed by an open test. However, such tests should be performed with great caution, since anaphylactoid reactions due to the testing procedure have been described (3,4).

Reports of contact urticaria to ingredients of drugs and cosmetics are listed in Table 4 and Table 5 (7–11).

© 2006 Elsevier B.V. All rights reserved.

Table 4 Contact urticaria to ingredients of topical drugs and cosmetics

Allergen	Allergen-containing product	20-minute patch test	Skin prick test	Reference
Cyclopentolate hydrochloride	Eye drops (Colircursi cicloplejico 1%)	Eye drops +	Not performed	(12)
Di(2-ethylhexyl) phthalate (DOP)	PVC grip cotton gloves	Rubbing with PVC grip+	Gas chromatography extracts + DOP + Di-*n*-butylmaleate +	(13)
Glyceryl thioglycolate	Hair permanent fluid	1% in petrolatum +	Not performed	(14)
Panthenol	Hair conditioner	Hair conditioner Panthenol 30% in petrolatum	Hair conditioner + Panthenol +++	(15)
Wheat hydrolysate	Body cream	Body cream ++	Wheat hydrolysate ++	(16)

Table 5 Contact urticaria to relatively rare antigens in drugs and cosmetics

Allergen	Allergen-containing product	Patch tests	Skin prick tests	Reference
Benzophenone 3	Sunscreens	Benzophenone 3 + (concentration not stated)	Not done	(17)
Benzyl alcohol	Bacteriostatic saline	10 cm wheal after 24 hours (concentration not stated)	Not done	(18)
Cyclopentolate hydrochloride	Eye drops	Eye drops 1% +	Not done	(12)
Di-(2-ethylhexyl) phthalate (DOP)	PVC grip cotton gloves	Rubbing with PVC +	Gas chromatography extracts + DOP + Di-*n*-butylmaleate	(13)
Geraniol	Various cosmetics	Geraniol + (concentration not stated)	Not done	(19)
Glyceryl thioglycolate	Hair permanent fluid	1% in petrolatum +	Not done	(14)
Panthenol	Hair conditioner	Panthenol 30% in petrolatum –	Hair conditioner + Panthenol +++	(15)
Phenoxyethanol	Body lotion	Phenoxyethanol 1% pet + Euxyl K 400 1.5% + Own cosmetics + Not done	Phenoxyethanol 1%+ Euxyl K 400 1.5%+ Body lotion +++ Euxyl K 400 ++ Phenoxyethanol 1%+, 5%+,10%++	(20) (21)
Potassium persulfate	Hair dye	Nickel sulfate	Potassium persulfate (dilution not stated) 5 mm wheal	(22)
Wheat hydrolysate	Body cream	Body cream ++	Wheat hydrolysate ++	(16)

+, ++, +++ indicate increasing intensity of reaction.

Substances that affect the skin: Discoloration, necrosis, and miscellaneous adverse effects

Drugs that cause discoloration of the skin, nails, and mucous membranes are listed in Table 1. Pigmented contact dermatitis has been reviewed (1).

Drugs that cause necrosis of the skin and mucous membranes are listed in Table 2.

Other adverse effects of topical drugs and cosmetics are listed in Table 3.

Table 2 Drugs that have caused necrosis of skin and mucous membranes

Substances that affect the skin: Photocontact dermatitis

Photocontact dermatitis can be toxic or allergic in nature (1–4). Phototoxicity can occur in anybody if enough light energy and photosensitizer are present in the skin. Photoallergy is due to a cell-mediated hypersensitivity response, and therefore occurs in sensitized individuals only.

Compared with contact allergy, photocontact allergy is uncommon, although many chemicals have been responsible for photoallergic reactions.

The British Photodermatology Group has provided a summary of the methods and clinical use of photopatch-testing. The following potential photoallergens have been suggested as standard series for routine testing in all patients suspected of photosensitivity:

(a) benzophenone-3;
(b) butyl methoxydibenzoylmethane;
(c) 2-ethylhexyl-para-methoxycinnamate;
(d) musk ambrette;
(e) octyl dimethyl para-aminobenzoic acid;
(f) para-aminobenzoic acid (PABA).

Patients' own products, diluted as appropriate, should be tested as well (5). Currently, UV filters (and to a lesser extent fragrances) are the main photosensitizers, notably benzophenone-3. Sunscreen photosensitization occurs especially in patients with photodermatoses and photoaggravated dermatoses (3). The UV filter isopropyl dibenzoylmethane caused so many cases of photosensitization that it was withdrawn.

In a review of photopatch-testing in 2390 patients with rashes that were confined to sun-exposed areas, about 70% of 4374 positive reactions were classified as photoinduced reactions, of which 222 (5%) were photoallergic reactions (6). NSAIDs, disinfectants, and phenothiazines were the main photoallergens. Photosensitive reactions to antimicrobial drugs, including topical agents, have been reviewed (7).

Topical photosensitizers are listed in Table 1 (1–4,8).

Table 1 Topical photosensitizers

Aceclofenac (9)	A
6-Acetoxy-2,4-dimethyl-m-dioxane (SEDA-10, 131)	T
Amyl dimethyl PABA (SEDA-10, 131)	T
Balsam of Peru (SEDA-19, 162)	T
Benoxaprofen (10)	A
Benzocaine (11)	A, T
Benzophenone-3 (oxybenzone) (SEDA-22, 170, 172)	A
Benzophenone-4 (sulizobenzone) (SEDA-19, 162)	A
Benzophenone-10 (mexenone) (SEDA-22, 170)	A
Benzydamine (SEDA-18, 164)	A
Bithionol (12)	A
Brilliant lake red	A, T
5-Bromo-4′-chlorsalicylanilide	A
Buclosamide (Jadit)	A, T
Butyl methoxydibenzoylmethane (SEDA-22, 170, 172)	A
Cadmium sulfide	A
Carbimazole (SEDA-10, 131)	A
β-Carotene (SEDA-5, 153)	A
Chloramphenicol (13)	T
Chlorhexidine (14)	A
Chlormercaptodicarboximide	A
Chloro-2-phenylphenol	A
Cinchocaine (dibucaine) (SEDA-5, 155) (SEDA-23, 167)	A
Cinnamates (15)	A
Cinnamic aldehyde (SEDA-8, 153)	A, T
Cinoxate (2-ethoxyethyl-para-methoxycinnamate)	A, T
Clarithromycin (16)	T
Clindamycin (13)	T
Coal tar derivatives (SEDA-8, 160)	A
Coumarin derivatives (SEDA-4, 106)	T
Desoximetasone (SEDA-14, 130)	T
Dibenzthione (sulbentine)	A
Dibromsalan	A
Dichlorophene	A, T
Diclofenac (17)	A
Digalloyl trioleate	A
Dimethoxane	A
Dimethoxydibenzoylmethane	A, T
Diphenhydramine hydrochloride (18,19)	A, T
Doxepin (SEDA-19, 159)	A
Dyes, for example methylthioninium chloride, fluorescein (SEDA-15, 150), rose Bengal, acridine orange, acriflavin, neutral red	A
Erythromycin (13)	T
Essential oils: bergamot oil, cedar oil, citron oil, lavender oil, lime oil, neroli oil, petitgrain oil, sandalwood oil (SEDA-10, 131) (SEDA-12, 134)	A
Fenofibrate (SEDA-22, 170)	A, T
Fenticlor (SEDA-14, 130)	A
Fepradinol (SEDA-23, 167)	T?
Fluorouracil	A
Formaldehyde (SEDA-19, 162)	T
Furocoumarins (20)	A
Glyceryl para-aminobenzoic acid (SEDA-10, 131)	A
Hexachlorophene (21)	A
Homosalate (homomenthyl salicylate) (22)	A
Hydrocortisone (23)	A
Isoamyl-para-methoxycimamate (SEDA-22, 172)	A
Isobutyl para-aminobenzoic acid	A, T
Isopropyl dibenzoylmethane (SEDA-22, 172)	A, T
Ketoprofen (SEDA-22, 170) (24)	A
Lithiol red-CA (D and C Red No. 11)	T
5-Methoxypsoralen (SEDA-23, 167)	A, T
8-Methoxypsoralen (methoxsalen) (SEDA-15, 150) (SEDA-17, 187)	A, T
4-Methylbenzylidene camphor (SEDA-22, 172)	A
6-Methylcoumarin (SEDA-17, 187)	A
Minoxidil (SEDA-11, 139)	A, T
Musk ambrette (SEDA-15, 150)	A
Musk moskene (25)	A
Musk xylene (26)	A
Mycanodin (27)	A
Octyl dimethyl PABA (SEDA-19, 161)	A
Octyl methoxycinnamate (SEDA-22, 172)	A
PABA (para-aminobenzoic acid and derivatives) (SEDA-22, 172)	A
Paraphenylenediamine (18)	A, T
Permanent orange (D and C Orange No. 17)	A
Phenothiazines (28)	A
Phenylbenzimidazole sulfonic acid (SEDA-22, 172)	A
2-Phenyl-5-methylbenzoxazole (Witisol)	A
Piroxicam (SEDA-15, 150) (24)	A
Procaine hydrochloride	A
Selenium disulfide (SEDA-16, 157)	?
Sulfanilamide (29)	A, T
Sulfisoxasole (30)	T
Suprofen (SEDA-18, 164) (24)	A
Tar (31)	T
Tetrachlorosalicylanilide (12)	A, T
Tetracyclines (13)	T
Tiaprofenic acid (SEDA-15, 150) (24)	A, T
Thiocolchicoside (32)	A
Toluidine red (D and C Red No. 35)	A
Tribromsalan (12)	A, T
Triclocarban (14)	A, T
Triclosan (12)	A, T
Zinc pyrithione	A?

A = photoallergy; T = phototoxicity

Succimer

General Information

Succimer is the meso isomer of 2,3-dimethylmercaptosuccinic acid (DMSA). It is used as a lead chelator for oral administration (1). Nausea, vomiting, diarrhea, and anorexia are common. Rashes, sometimes necessitating withdrawal, have been reported in up to 10% of adults and 5% of children, and mild transient rises in serum transaminase activity in 6–10% (mostly adults) (2,3). Life-threatening hyperthermia occurred on two occasions in one subject, but no details were given. Iron can be safely and effectively given to patients taking succimer, which (unlike dimercaprol) does not appear to deplete iron stores or to form a toxic chelate that would preclude the parenteral administration of iron (3).

The manufacturers have accumulated data on about 200 children treated with succimer, of whom about 10% had an adverse event (1). Gastrointestinal symptoms and raised serum transaminases were most frequently observed.

In a UK study, single oral doses of succimer or dimercaptopropane sulfonic acid in different combinations with or without acetylcysteine and potassium citrate were given to 191 patients considered to have mercury toxicity from amalgam dental fillings (4). After a single dose, about 5% of patients complained of mild gastrointestinal discomfort, fatigue, mental fuzziness, headache, and diuresis. These usually cleared within 6 hours of the dose and were considered to be due to heavy metal mobilization. There were no cases of hypersensitivity.

Organs and Systems

Hematologic

Mild to moderate neutropenia (5) and episodes of granulocytopenia, possibly related to succimer, have been reported (1,6).

In animals thrombocytopenia has occurred (7).

Sucralfate

General Information

Sucralfate, a basic aluminium salt of sucrose octasulfate, probably acts by binding to inflamed surfaces; it is possible, however, that its binding properties are more generalized, and it has been used as an intra-alimentary phosphate-binding agent in uremic patients.

Organs and Systems

Metal metabolism

Plasma aluminium concentrations rise in patients with renal insufficiency and one might expect aluminium to accumulate with long-term use of sucralfate (1); it is therefore unwise to use sucralfate in such patients (2).

Gastrointestinal

Bezoar formation has been recorded more than once in patients taking sucralfate, with esophageal obstruction by inspissated drug (SEDA-17, 421) (SEDA-18, 374) (3), and a gastric bezoar can be formed when tube feeds include sucralfate; the formation of bezoars reflects the binding of sucralfate to protein in the food. The French System of Pharmacovigilance on sucralfate has reported bezoars in 16 adults and five neonates (4). All the children were of low birth weights and developed bezoars in the stomach. The adults developed esophageal bezoars around nasogastric tubes. The risk factors for bezoar formation were severe illness, gut hypomotility, dehydration, overdosage with sucralfate, and nasogastric tube feeding. At a pH below 4, there is extensive polymerization of sucralfate, and a sticky viscid gel is formed, which may lead to the formation of a bezoar. In view of this, it has been recommended that sucralfate be used with caution in premature babies and in adults in intensive care who are being fed via a nasogastric tube.

Drug–Drug Interactions

Digoxin

Sucralfate may reduce the absorption of digoxin (5).

Fluoroquinolone antibiotics

The absorption of all fluoroquinolones is significantly impaired when they are co-administered with sucralfate (6).

In a man with prostatitis, co-administration of ciprofloxacin and sucralfate resulted in treatment failure, presumably because of impaired absorption of ciprofloxacin (7).

In an open, randomized, crossover study in 127 healthy volunteers, sucralfate 2 g reduced the AUC of a single oral dose of gemifloxacin 320 mg by 53% and the C_{max} by 69% (8). However, sucralfate had no effect when it was given 2 hours after gemifloxacin.

In two separate crossover studies in eight healthy volunteers sucralfate 1 g reduced the systemic availability of both norfloxacin 400 mg and ofloxacin 400 mg (9). However, sucralfate had no effect when it was given 2 hours after the antibiotics.

Phenytoin

In nine healthy subjects sucralfate reduced the AUC of a single oral dose of phenytoin 500 mg by 10% (10), and in another study it reduced the AUC of a single dose of phenytoin 300 mg by 20% (11). However, in six healthy volunteers sucralfate 1 g qds for 7 days had no effect on steady-state serum phenytoin concentrations (12).

Quinidine

Sucralfate may reduce the absorption of quinidine (5).

Warfarin

Concurrent sucralfate treatment has been claimed to reduce warfarin systemic availability (SEDA-12, 945) (5).

Sufentanil

General Information

Sufentanil, a fentanyl analogue, is a highly lipid-soluble synthetic opioid with high affinity for OP_3 (μ) opioid receptors and a potency some 5–10 times that of fentanyl. It is a short-acting analgesic.

Its adverse effects include pruritus, sedation, nausea and vomiting, dizziness, urinary retention, lightheadedness, miosis, and shivering (SEDA-16, 86). Respiratory depression also occurs (SEDA-21, 89). Motor neuron blockade, acute hypotension, and muscle weakness are rare, affecting under 1% of patients (SEDA-16, 86).

Drug studies

Placebo-controlled studies

In 41 patients undergoing abdominal hysterectomy randomly allocated in a double-blind, controlled study to sufentanil 50 micrograms for 8–16 hours via a lumbar epidural catheter before or at the end of surgery, the pre-emptive group ($n = 20$) used less sufentanil than the control group ($n = 21$) (1). The frequency of adverse effects was similar in the two groups; nine patients in the pre-emptive group and ten in the control group complained of nausea or vomiting and four patients in the pre-emptive group and five patients in the control group complained of mild pruritus.

Comparative studies

Bupivacaine

Intrathecal sufentanil and epidural bupivacaine were compared individually and in combination to establish dose-responsiveness for analgesia in labor in 100 women (2). There was no dose-responsiveness for doses of sufentanil between 2 and 10 micrograms. The ED_{50} for sufentanil was 2.3 micrograms alone (higher than that reported above (3)) and 0.85 micrograms in combination with epidural bupivacaine. Adverse effects included pruritus (incidence 70–90%), nausea, and mild somnolence (10–30%). Transient fetal bradycardia was reported in two cases.

In a double-blind, randomized, placebo-controlled study in 80 patients of the analgesic efficacy of different subarachnoid applications of sufentanil and/or bupivacaine using a microcatheter for easy postoperative pain relief, sufentanil 10 micrograms, bupivacaine 5 mg, or a combination of sufentanil 2.5 micrograms and bupivacaine 2.5 mg provided immediate and adequate postoperative analgesia for 2–3 hours (4). The group who received only sufentanil had the highest incidence of pruritus and respiratory depression. The limitations of this study were highlighted in a letter, which questioned the value of the above procedure when other tried and tested perioperative pain management methods are available (5).

Clonidine

In a double-blind study of the effect of clonidine on intrathecal sufentanil, 53 nulliparous women received sufentanil 5 micrograms intrathecally either alone or with clonidine 30 micrograms (6). The addition of clonidine increased the incidence of hypotension (12% with sufentanil alone, 63% with clonidine) and sedation (23% with sufentanil alone and 46% with clonidine). There was no significant difference in the incidence of pruritus (88%). Again, no motor blockade was observed.

In another randomized, double-blind study in 40 primiparous women in labor at less than 5 cm cervical dilatation who requested epidural analgesia, the addition of clonidine 75 micrograms to epidural sufentanil 20 micrograms did not provide any advantages in analgesic efficacy or adverse effects (7).

Dextrose

The addition of 3.5% dextrose to sufentanil 10 micrograms given intrathecally in a randomized, double-blind study of 48 women in early labor produced a significant reduction in the incidence of clinically important pruritus (8). Dextrose did not compromise the quality and duration of analgesia.

Lidocaine

The analgesic efficacy of intrathecal sufentanil with or without lidocaine has been examined in two groups of outpatients undergoing lithotripsy or gynecological laparoscopy in order to determine optimal analgesia with rapid recovery and discharge (9,10). In a retrospective case-record study of 62 shock-wave lithotripsy procedures, the 25 cases performed using intrathecal sufentanil alone had better outcomes, significantly shorter postanesthesia care unit time, and time for ambulation compared with 37 procedures performed with intrathecal lidocaine; pruritus was significantly more common with sufentanil (9). A double-blind, randomized study in 13 patients undergoing gynecological laparoscopy, who received either lidocaine 10 mg with sufentanil 10 micrograms or intrathecal sufentanil 20 micrograms, was terminated early owing to unacceptably frequent adverse

© 2006 Elsevier B.V. All rights reserved.

effects and inferior analgesia in those given intrathecal sufentanil (10).

Piritramide
Sufentanil 1 microgram/ml plus 0.1% ropivacaine by epidural infusion has been compared with intravenous patient-controlled analgesia with piritramide in a double-blind, randomized study in 24 patients undergoing elective total hip replacement (11). The PCA group had significantly more adverse effects than the epidural group, including hypotension, nausea, and vomiting. There were no cases of respiratory depression, pruritus, hypertension, or dysrhythmias in either group. Epidural sufentanil was a better analgesic.

Combination studies
Adrenaline
In a randomized, double-blind, controlled study, the addition of adrenaline (100 micrograms/ml) significantly reduced the incidence of sedation and light-headedness after epidural sufentanil (40 micrograms) in 43 women who received epidural analgesia during early labor (12). However, adrenaline did not help in preventing maternal oxygen desaturation.

Bupivacaine
In a prospective dose-finding study, 170 women with cervical dilatation of 3–5 cm were randomized to receive intrathecal sufentanil 0, 2.5, 5.0, 7.5, or 10 micrograms combined with bupivacaine 5 mg (13). Bupivacaine combined with 2.5 micrograms sufentanil provided analgesia comparable to higher doses with a lower incidence of nausea and vomiting and less severe pruritus.

Bupivacaine and adrenaline
In a randomized, double-blind study in 243 parturients who received three doses of sufentanil (0.5, 0.75, and 1 microgram/ml) in combination with bupivacaine 0.625 mg/ml and adrenaline 1.25 micrograms/ml by continuous epidural infusion there were no differences in analgesic effects, but there was significantly more pruritus in those who received the highest dose of sufentanil (14). The authors suggested using the lowest dose of sufentanil (0.5 micrograms/ml) with bupivacaine solution to minimize the risk of adverse effects on the mother and neonate, with optimal analgesia.

Ropivacaine
In a randomized, double-blind study in 120 patients undergoing major abdominal surgery the combination of sufentanil 0.75 micrograms/ml with ropivacaine 0.2% provided optimal postoperative patient-controlled epidural analgesia with the fewest adverse effects of the regimens used (ropivacaine alone, ropivacaine and sufentanil 0.5, 0.75, or 1.00 microgram/ml) (15).

Organs and Systems

Cardiovascular

The incidence of hypotension with sufentanil is 7% and that of hypertension 3%. In a double-blind comparison of morphine, pethidine, fentanyl, and sufentanil in balanced anesthesia, patients who received sufentanil had the least hemodynamic disturbances. In high doses, adverse effects such as bradycardia and hypotension can lead to complications in some patients (SEDA-16, 85). Sudden hypotension occurred on induction of anesthesia with sufentanil in four patients, in whom the dose was 8.4–22.7 micrograms/kg (16). Other workers noted similar findings at doses of 1 and 1.5 micrograms/kg.

Clinically significant bradycardia or asystole occurred on induction when sufentanil was used in conjunction with vecuronium (17,18).

The effect of sufentanil was examined in 10 healthy men to find out whether it has the same hemodynamic and sensory effects as when it is used in women in labor. Details of the method of recruitment of volunteers for this double-blind study were not provided, but they received either saline or sufentanil 10 micrograms intrathecally (19), and blood pressure, heart rates, oxyhemoglobin saturation, cold and pinprick sensation, motor block, and visual analogue scales for sedation pruritus and nausea were all measured. Pruritus and sensory changes to pinprick and cold occurred only in the sufentanil group and there were no significant hemodynamic changes in either group. In view of the frequency and severity of pruritus when sufentanil is used in labor, it is interesting that all five of the male volunteers experienced this symptom, three of them severely. These findings suggested that the hypotension observed with the use of intrathecal sufentanil during labor and the sensory changes may not be mediated by the same pathway. The authors proposed that the hypotension observed in such studies is a direct result of pain relief, which is not an issue in the pain-free men in this investigation.

Respiratory

Apneic episodes have been reported in patients given sufentanil (SEDA-20, 81) (SEDA-21, 89). Respiratory arrest occurred 55 minutes after epidural and intrathecal sufentanil and bupivacaine (SEDA-18, 82).

- A healthy 22-year-old woman at 41 weeks gestation presented for urgent cesarean section following fetal heart rate deceleration (20). She was given sufentanil 10 micrograms plus 0.1% bupivacaine 10 mg intrathecally and 8 minutes later became unrousable and apneic. After 3 minutes spontaneous ventilation resumed.

The authors suggested that giving the local anesthesia first and then the sufentanil later might have contributed to this presentation of spontaneous reversal of short-lived early-onset respiratory arrest.

When nasal sufentanil was used to induce anesthesia in children, ventilatory compliance was mildly or markedly reduced and one child required suxamethonium, oxygen, and positive pressure ventilation (SEDA-16, 86).

Respiratory depression has also been described after intrathecal sufentanil 5 micrograms (21).

- An 83-year-old woman scheduled for bilateral knee replacement surgery received midazolam 7.5 mg preoperatively. Continuous spinal anesthesia was planned, with combined general anesthesia.

© 2006 Elsevier B.V. All rights reserved.

Anesthesia was maintained with 0.3–0.5% of inspired isoflurane in 36% oxygen and 70% nitrous oxide while 5 mg of 0.5% bupivacaine was introduced into the subarachnoid space via an insertion at L3–4. Anesthesia extended to T11. During the procedure two top-up doses of bupivacaine 2.5 mg were administered. Postoperatively she was extubated immediately and was fully conscious on transfer to the recovery room, but 75 minutes later she had violent pain in both knees and received sufentanil 5 micrograms intrathecally. Analgesia was achieved in 10 minutes. At 15 minutes pruritus occurred and at 30 minutes she became unresponsive to verbal and painful stimuli and stopped breathing. Blood pressure was 120/60 mmHg, heart rate 72/minute, and oxygen saturation 97%. Ventilation with 100% oxygen via a facemask started immediately and naloxone 160 micrograms was injected intravenously, with full recovery of consciousness and respiration in 10 minutes.

This report is the first of respiratory depression after intrathecal sufentanil in a non-obstetric patient. Previous obstetric cases had occurred earlier and with larger doses of sufentanil. The site of action of sufentanil in this case is likely to have been supraspinal, by either direct cephalad migration in the CSF or through a systemic effect after vascular absorption.

Respiratory arrest has been reported in labor (22).

- A 20-year-old parturient received sufentanil 10 micrograms and bupivacaine 2.5 mg intrathecally as part of combined spinal-epidural analgesia and developed pruritus 15 minutes after the injection, followed by a sleepy feeling at 20 minutes. After 25 minutes she became unresponsive and apneic; her systolic blood pressure was 130 mmHg and her heart rate 60. The fetal heart rate was 86. She was ventilated manually with 100% oxygen and naloxone 0.4 mg was given with prompt recovery of consciousness and respiratory effort. Drowsiness persisted, and a naloxone infusion was initiated after top-up doses of naloxone had failed to relieve it. Subsequent analgesia was with bupivacaine alone. A vacuum-assisted vaginal delivery was performed after 3 hours. The infant's Apgar score was 8 at 1 minute and 9 at 5 minutes. The mother and baby were subsequently well.

This case highlights the low doses at which arrest may occur.

Violent coughing in young children and adolescents exposed to small doses of sufentanil (1 microgram/kg or less) has been reported (23). Specific cases were not alluded to and the literature remains divided on the significance and mechanism of this age-related effect.

Nervous system

An unexpected transient neurological deficit has been described in neurosurgical patients (SEDA-16, 85).

There have been three reports of neurological changes after the intrathecal administration of sufentanil plus bupivacaine (24,25).

- A 40-year-old pregnant woman developed acute confusion, aphasia, increased salivation, and difficulty in swallowing 15 minutes after intrathecal administration of sufentanil 10 micrograms with bupivacaine 2.5 mg (25). There was spontaneous resolution 1 hour later with no need for pharmacological intervention.
- An 18-year-old nulliparous woman with an uncomplicated pregnancy developed difficulty in swallowing, respiratory abnormalities, and excessive tiredness 13 minutes after receiving sufentanil 5 micrograms with bupivacaine 1.25 mg as a spinal analgesic and disappearing over 20 minutes (24).
- A 36-year-old nulliparous woman complained of dyspnea and sensory block extending to the face 15 minutes after an intrathecal injection of sufentanil 5 micrograms with bupivacaine 1.25 mg (24).

In neither of the last two cases was there motor blockade or neonatal sequelae. Such adverse effects can be caused by sufentanil, bupivacaine, or both. Regardless of which drug caused these events, the intrathecal administration of a hypobaric solution to a patient in the sitting position might have contributed, since rostral spread of intrathecal drugs is accelerated in this setting. The use of smaller doses of sufentanil (2.5 or 5 micrograms) will also prevent such adverse effects.

Musculoskeletal

There have been isolated reports of chest wall rigidity after sufentanil (26).

Second-Generation Effects

Pregnancy

The effects of intrathecal and epidural sufentanil as an analgesic during labor have been described in 50 nulliparous patients in a randomized double-blind study, in which they received sufentanil 1–10 micrograms in preservative-free saline (27). The ED_{50} was 1.8 micrograms, based on those who requested further analgesia after 30 minutes. The incidence of adverse effects was similar in all groups (that is was not dose-related in this dosage range) and included pruritus of a similar intensity in all groups. There was no respiratory depression, but blood pressure and oxygen saturation fell. Other adverse effects included changes in temperature sensitivity at 30 minutes in 19 of the 50 subjects. One woman who received 5 micrograms of sufentanil had a fall in oxygen saturation to 90–92% with a respiratory rate of 16 breaths/minute 10–15 minutes after injection, but recovered spontaneously at 20 minutes. Fetal monitoring showed no significant bradycardia and there were no significant differences in 5-minute Apgar scores. It was suggested that hypotension was due to the effect of intrathecal opioid rather than to an effect on the autonomic nervous system and that the temperature sensitivity changes were due to a concentration-dependent local anesthetic effect of opioids. A drop in oxygen saturation in one subject indicated the need for observation for respiratory changes when sufentanil is given intrathecally.

Combined spinal epidural analgesia has been associated with reports of increased operative deliveries, possibly due to reduced perineal sensation and motor weakness. In a comparison of combined spinal epidural

© 2006 Elsevier B.V. All rights reserved.

analgesia (intrathecal sufentanil 10 micrograms followed by epidural bupivacaine and fentanyl at their next request for analgesia) with intravenous pethidine analgesia (50 mg intravenously on demand up to a maximum of 200 mg in 4 hours) in 1223 randomly assigned healthy parturients there was no significant difference in the rates of cesarean delivery for dystocia (28). Maternal hypotension and pruritus requiring treatment occurred in 14% and 17% respectively of patients who received combined spinal epidural analgesia. Fetal heart rate deceleration occurred in 21% of patients who received pethidine compared with 18% of patients who received combined spinal epidural analgesia, and in each group most cases resolved spontaneously. However, profound fetal bradycardia (fetal heart rate of less than 60/minute, lasting 60 seconds or more), necessitating emergency cesarean section, occurred within 1 hour of administration of sufentanil in 8 of 400 mothers, while no such events occurred with pethidine. None of the cases responded to conservative management and none was associated with maternal hypotension. Immediate postnatal neonatal outcomes were similar between the two groups, as judged by Apgar scores and umbilical artery blood gases. These findings are significant, in that an increase in cesarean deliveries due to fetal bradycardia has not previously been reported, but findings in this study must be regarded with an element of caution, as fetal monitoring was more extensive in those given combined spinal epidural analgesia. The authors suggested that fetal bradycardia might have been due to uterine hyperstimulation, associated with intrathecal opioids (although they did not consistently monitor for this), and that fetal bradycardia resulted from reduced placental perfusion secondary to uterine tetany. Alternatively, since sufentanil is highly lipid soluble, it can be detectable in plasma within 39 minutes of intrathecal administration of 15 micrograms. Once in the plasma, transplacental transfer can occur and the drug can have a direct vagotonic effect on the fetus. However, they believed that the most probable explanation for the bradycardia was a direct consequence of hypoperfusion of the placenta secondary to maternal hypotension, although they pointed out that none of their cases was associated with this hemodynamic change in the mother.

In a double-blind, randomized study the analgesic efficacy of sufentanil 0.25 micrograms/ml with 0.125% bupivacaine was compared with fentanyl 2 micrograms/ml with 0.125% bupivacaine in 226 patients in labor with a patient-controlled epidural analgesic device (29). Overall analgesia was good, with no observed difference between the two groups. There was a significant difference in the occurrence of mild pruritus, with 10 cases in the fentanyl group ($n = 105$) and only two in the sufentanil group ($n = 101$). There were no gastrointestinal adverse effects. Sufentanil was deemed preferable owing to a lower incidence of adverse effects for equal analgesic potency.

An epidural mixture of sufentanil with ropivacaine has been used in a double-blind, randomized study in 100 women in the first stage of labor (30). They were randomized to receive 0.2% ropivacaine 12 mg either alone or with sufentanil 5, 10, or 15 micrograms. With combined sufentanil plus ropivacaine the duration of analgesia was about 40 minutes longer than with ropivacaine alone. There were no differences in analgesic efficacy or the incidence of opioid-related adverse effects in the three sufentanil groups. Sufentanil 5 micrograms plus ropivacaine 0.2% was therefore recommended.

Fetotoxicity

When epidural sufentanil is used for labor and delivery, the neonates can have subtle neurological signs of drug depression, including mild hypotonia, poor primary reflexes, and poor habituation to repeated stimuli at 1 and 4 hours of life (SEDA-16, 86).

The absence of motor block associated with combined spinal epidural analgesia using sufentanil has also been reported in an investigation in which intrathecal sufentanil 10 micrograms was compared with epidural lidocaine, adrenaline, and sufentanil 40 micrograms in early labor (31). Adverse effects were not significantly different between the groups, except for more frequent and severe pruritus in the intrathecal group. Although three subjects in each group had transient changes in fetal heart rate within 30 minutes of medication, no intervention was necessary.

Drug Administration

Drug dosage regimens

In a dose-finding, prospective, double-blind study, 60 men scheduled for unilateral extracorporeal shock-wave lithotripsy were randomized to receive 12.5, 15, 17.5, or 20 micrograms of intrathecal sufentanil (32). The results suggested that 15 micrograms of sufentanil may be the optimal intrathecal dose, since 20 micrograms produced significantly more pruritus than the lower doses and those who were given 12.5 micrograms needed significantly more supplementary analgesia.

Drug administration route

Serious consequences (respiratory arrest and hypotension) related to the use of intrathecal sufentanil have been described in parturients (SEDA-22, 101).

Sulfamazone

See also Non-steroidal anti-inflammatory drugs

General Information

Sulfamazone is a pyrazolone derivative. It causes benign intracranial hypertension in children (SEDA-5, 100) (1).

Sulfinpyrazone

General Information

Sulfinpyrazone, a pyrazolone derivative, is used both as a uricosuric agent and as an anti-platelet drug. It has similar adverse effects to those of phenylbutazone when taken for long term (SEDA-6, 104). In a large number of patients who took the drug for secondary prevention of myocardial infarction (an indication that was not subsequently accepted), the incidence of adverse effects was not high (1).

Organs and Systems

Respiratory

Sulfinpyrazone can precipitate bronchoconstriction in some aspirin-sensitive patients (2). There is no cross-sensitivity with dipyrone.

Hematologic

Prolonged treatment with sulfinpyrazone produces a high incidence of thrombocytopenia and granulocytopenia. After withdrawal, these effects are completely reversible (SED-9, 157) (3). Sulfinpyrazone also inhibits platelet aggregation (4).

Sulfinpyrazone has been implicated in the development of myelomonocytic leukemia and multiple myeloma when given with colchicine (3).

Urinary tract

Impairment of renal function and even acute renal insufficiency can follow sulfinpyrazone treatment, by various mechanisms: immunoallergic-induced acute interstitial nephritis, inhibition of renal prostaglandins, and precipitation of uric acid stones. These changes are probably reversible, since there have been cases in which renal impairment spontaneously normalized on withdrawal (5).

Susceptibility Factors

The antinatriuretic effects of sulfinpyrazone could be dangerous in patients with impaired cardiac function (6).

Drug–Drug Interactions

Aspirin

In low dosages (up to 2 g/day), aspirin reduces urate excretion and blocks the effects of sulfinpyrazone. In higher dosages (over 5 g/day), salicylates increase urate excretion.

Beta-blockers

Sulfinpyrazone interferes with the antihypertensive action of beta-blockers (7).

Phenylbutazone

Sulfinpyrazone has a biphasic interaction with phenylbutazone (enhancement followed by antagonism).

Warfarin

By reducing the metabolic clearance of warfarin, sulfinpyrazone enhances its hypoprothrombinemic effect, with life-threatening consequences (8).

Sulfites and bisulfites

See also Disinfectants and antiseptics

General Information

Sulfites and bisulfites have been used extensively as preservatives in the food industry and also in drugs and bronchodilator inhalant solutions (1,2) as preservatives. Sodium metabisulfite is used commonly as an antioxidant in foods and drugs. As an additive in various pharmaceutical products, metabisulfite can cause unpleasant adverse reactions.

Organs and Systems

Respiratory

Status asthmaticus and acute bronchospasm have been linked to the use of metabisulfites (3).

Hematologic

Preservatives in subconjunctival gentamicin were identified as the cause of conjunctival chemosis and capillary closure (4). Patients undergoing cataract surgery were

© 2006 Elsevier B.V. All rights reserved.

divided into three groups: one was given a subconjunctival injection of a preservative-free solution of gentamicin at the end of the cataract procedure, another received a subconjunctival injection of gentamicin containing sodium metabisulfite and disodium edetate as preservatives, and the third was the control group not given a subconjunctival injection. There was a significant difference in the severity of conjunctival chemosis between patients who received gentamicin with and without preservatives (4).

Immunologic

The major symptoms of an adverse reaction to a sulfite are flushing, acute bronchospasm, and hypotension (SED-11, 492) (SEDA-10, 232) (SEDA-11, 221) (5). The incidence of sulfite sensitivity in an asthmatic population is estimated at about 10%. Sulfites have therefore been withdrawn from the composition of several medicines intended for asthmatic patients.

Metabisulfite-induced anaphylaxis through an IgE-mediated mechanism has been described in a patient who developed urticaria, angioedema, and nasal congestion following provocative challenge with sodium metabisulfite (6).

The presence of sodium metabisulfite as an antioxidant in commercial lidocaine with adrenaline significantly increased discomfort during injection (7).

Anaphylactic shock occurring during epidural anesthesia for cesarean section has been attributed to sodium metabisulfite (8).

Reports of contact allergy to topical medicaments containing sodium metabisulfite are rare (9). In two cases, a topical corticosteroid formulation that contained sodium metabisulfite (Trimovate cream) caused contact allergy; patch tests were positive with both sodium metabisulfite and Trimovate cream (10).

Sulfonamides

General Information

The term "sulfonamide" is generic for derivatives of para-aminobenzenesulfonamide (sulfanilamide), which is similar in structure to para-aminobenzoic acid (PABA), a co-factor required by bacteria for folic acid synthesis. The sulfonamides act by competitive inhibition of the incorporation of PABA into tetrahydropteroic acid. Sulfonamides have a higher affinity for the microbial enzyme tetrahydropteroic acid synthetase than the natural substrate PABA. Sulfonamides have a wide range of antimicrobial activity against both Gram-positive and Gram-negative organisms (1). In therapeutic dosages they have only a bacteriostatic effect, and as single agents therefore have a limited role in drug therapy (1). Sulfonamides have been combined with trimethoprim or trimethoprim analogues, since such combinations result in a bactericidal effect (2). Adverse reactions during the administration of sulfamethoxazole + trimethoprim (co-trimoxazole, BAN) can be due to either compound. Although sulfonamides are thought to cause adverse reactions more often than trimethoprim, the culprit in the individual patient can only be determined by re-exposure to the individual agents.

Based on their pharmacological properties and clinical uses, sulfonamides can be classified into four groups (1):

1. short- or medium-acting sulfonamides;
2. long-acting sulfonamides;
3. topical sulfonamides;
4. sulfonamide derivatives used for inflammatory bowel disease.

Short- or medium-acting sulfonamides include the earliest varieties of azosulfonamides (Prontosil, Neoprontosil), sulfapyridine (Dagenan), sulfathiazole (Cibazol), sulfanilamide, and sulfadiazine. With the exception of sulfadiazine, these compounds are no longer used. Sulfadiazine and more recent compounds, including sulfafurazole (sulfisoxazole), sulfamethoxazole, sulfametrole, sulfacitine, and sulfamethizole, are rapidly absorbed and rapidly eliminated. Compared with the older generation they are more soluble, less toxic, and probably less allergenic. Sulfamethoxazole is a medium-acting sulfonamide that is often combined with trimethoprim (as co-trimoxazole). Long-acting sulfonamides include sulfametoxydiazine, sulfadimethoxine, and other compounds, of which many are no longer available, as they were associated with severe hypersensitivity reactions. Although these compounds have the advantage of long administration intervals, their long half-lives (over 100 hours) can be deleterious

© 2006 Elsevier B.V. All rights reserved.

in case of adverse reactions. A long-acting drug that is still widely used is sulfadoxine (*N*-(5,6-dimethoxy-4-pyrimidinyl)-sulfanilamide). It is primarily used in combination with pyrimethamine (Fansidar) for the treatment and prophylaxis of malaria.

The topical use of sulfonamides has been discouraged, because of the high risk of sensitization. Nevertheless, sulfacetamide and sulfadicramide are still used topically for eye infections. Topical silver sulfadiazine (see monograph on Silver) is widely and successfully used in treating burns and leg ulcers (3,4). Since sulfonamides are easily absorbed through skin lesions, the same adverse reactions can occur as after systemic use.

A sulfonamide derivative with special use is sulfasalazine (salicylazosulfapyridine), which has been widely used to treat ulcerative colitis and regional ileitis (Crohn's disease). It is a compound of sulfapyridine and 5-aminosalicylate, linked by a diazo bond. Sulfasalazine is broken down in the large bowel to sulfapyridine, which is absorbed systemically, and 5-aminosalicylate, which reaches high concentrations in the feces (5). Sulfasalazine is not used for the antibacterial properties of the sulfapyridine, but for the local anti-inflammatory effect of 5-aminosalicylate in the gut. Because most of the adverse reactions are thought to be due to the absorbed sulfapyridine, the combination has largely been replaced in clinical practice by newer drugs that contain only 5-aminosalicylic acid (mesalazine), such as mesalazine itself and diazosalicylate (olsalazine) (5). The aminosalicylates are covered in a separate monograph.

Observational studies

In an open trial in 25 patients treated with sulfamethoxypyridazine (1 g/day) for mucous membrane pemphigoid unresponsive to topical steroid treatment, 12% of patients were withdrawn, 4% because of allergic reactions, the others because of significant hemolysis (6).

In children with acute uncomplicated *Plasmodium falciparum* malaria, pyrimethamine + sulfadoxine (25 mg + 500 mg) and artesunate (4 mg/kg) were well tolerated, and no adverse reactions attributable to treatment were recorded (7).

Comparative studies

In a randomized, open, multicenter study in 46 patients with sight-threatening ocular toxoplasmosis, those who took pyrimethamine + sulfadiazine had significantly more adverse events, especially malaise, than those who took pyrimethamine + azithromycin (8).

General adverse effects

The frequency and severity of the adverse effects of sulfonamides correspond to those seen with other antibacterial agents (2–5%). Dose-related effects, which tend to be more troublesome than serious, include gastrointestinal symptoms, headache, and drowsiness. Crystalluria can occur, but urinary obstruction is rare. Hematological adverse effects due to folic acid antagonism occur primarily in combination with trimethoprim. Hemolytic anemia occurs in patients with enzyme deficiencies and abnormal hemoglobins. Hypersensitivity is thought to be the mechanism of many adverse effects of the sulfonamides. They can be life-threatening, and immediate withdrawal is recommended. The most important reactions include anaphylactic shock, a serum sickness-like syndrome, systemic vasculitis, severe skin reactions (Stevens–Johnson syndrome and toxic epidermal necrolysis), pneumonitis, hepatitis, and pancytopenia. Sulfonamides should not be used in the third trimester of pregnancy. In premature infants, they displace bilirubin from plasma albumin and can cause kernicterus. Carcinogenicity has not been reported with the use of sulfonamides.

Sulfanilamide and the history of adverse drug reactions

The first major drug catastrophe in the 20th century history of the public control of drugs occurred in 1937 in the USA. A pharmacist introduced Elixir Sulfanilamide, which consisted of sulfanilamide dissolved in diethylene glycol. It had been tested for flavor, appearance, and fragrance, but not for safety. After taking the drug, over 100 patients died in severe pain; many were children, who were given Elixir Sulfanilamide for sore throats and coughs. Public outrage created support for proposed legislation to reinforce the public control of drugs that was pending in the US Congress (9). This led to the US 1938 Food, Drug, and Cosmetic Act, which is still the country's legal foundation for the public control of drugs and devices intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in humans or animals. It has been a model for similar legislation in many other countries.

The 1938 Food, Drug, and Cosmetic Act prohibited traffic in new drugs, unless they were safe for use under the conditions of use prescribed on their labels. The Act also explicitly required the labeling of drug products with adequate directions for use.

The burden of proof of harm of new drugs was laid on the Federal Food and Drug Agency (FDA). Companies that wanted to manufacture and sell new drugs in interstate commerce had to investigate their safety and report to the FDA. Unless the FDA, within a specified period of time, found that the safety of a drug had not been established, the company could proceed with its marketing. The FDA was also authorized to remove from the market any drug it could prove to be unsafe (10).

The US Supreme Court also established in 1941, in a legal case over drug adulteration, that responsible individuals in a company can be held personally accountable for the quality of the products manufactured by the company, and that distributors of pharmaceuticals are responsible for the quality of their products, even if they are manufactured elsewhere (11).

After World War II, the pharmaceuticals market changed radically, as many companies started industrial production of drugs that had previously been manufactured in pharmacies. Announcements of new industrially produced drugs were hailed as part of technological advancement, as significant a sign of progress as the launching of satellites and putting a man on the moon. However, public safeguards against the risks

© 2006 Elsevier B.V. All rights reserved.

of drugs remained unchanged in most countries. Thus, control of the effects of drugs largely lay in the hands of the manufacturers, even though the responsibility for taking precautions rested with pharmacists and doctors.

Organs and Systems

Cardiovascular

Of 98 patients with drug-induced long QT interval, one taking sulfamethoxazole carried a single-nucleotide polymorphism (SNP; found in about 1.6% of the general population) in KCNE2, which encodes MinK-related peptide 1 (MiRP1), a subunit of the cardiac potassium channel I_{Kr} (12). Channels with the SNP were normal at baseline but were inhibited by sulfamethoxazole at therapeutic concentrations, which did not affect wild-type channels.

Cardiovascular reactions can be due to sulfonamide myocarditis or systemic vascular collapse, owing to severe adverse events such as widespread skin disease. Sulfonamide myocarditis has been described in relation to earlier sulfonamides and occurs in combination with other hypersensitivity reactions (13).

Respiratory

Respiratory reactions to sulfonamides include migratory pulmonary infiltrates, chronic pneumonia, asthma, and pulmonary angiitis. These reactions are thought to be mainly due to hypersensitivity, although the precise mechanisms are not well understood (14–16). The link to the drug has been proven in most cases by recurrence after re-exposure to the same sulfonamide or to co-trimoxazole.

Pulmonary reactions have been described with most sulfonamides. Pyrimethamine + sulfadoxine, used in malaria prophylaxis and treatment, also rarely causes pulmonary reactions (17–19). The sulfapyridine moiety of sulfasalazine, used in inflammatory bowel disease, can produce adverse pulmonary reactions (20).

The time between the last drug exposure and the first clinical symptoms varies from hours to a few days, and the lung pathology disappears in most patients within a few days after withdrawal. Most commonly, pulmonary involvement presents with fever, dyspnea, cough, and shortness of breath. Clinical examination reveals râles in the lungs, and there may be pulmonary infiltrates in the chest X-ray. Pulmonary function tests may show bronchial obstruction (18–21), and arterial blood gases show hypoxemia (19,20). Whereas bronchial obstruction is probably an immediate reaction (type I), pulmonary infiltrates may correspond to a type III reaction, similar to the mechanism responsible for extrinsic allergic alveolitis (20,21). Eosinophilia is present in 8–58% of cases (14,16,18,19,21,22). Histologically, the lung tissue is infiltrated by inflammatory cells, and in most cases the alveoli contain numerous macrophages and eosinophils in a protein-rich edema fluid.

Based on the predominant symptoms and their duration, four categories of sulfonamide-related pulmonary hypersensitivity reactions can be distinguished (23–25):

1. transient or migratory pulmonary infiltrations associated with eosinophilia (Loeffler's syndrome) (22,26–28)
2. chronic eosinophilic pneumonia (23,27)
3. asthma with pulmonary eosinophilia (14–16,21)
4. allergic angiitis with pulmonary involvement (25).

In the first three of these, the adverse reaction is limited to the lung, whereas in the fourth the lung involvement is part of a systemic reaction. Syndromes such as allergic granulomatosis and angiitis (Churg–Strauss syndrome) or Wegener's granulomatosis are not associated with the use of sulfonamides (25).

Nervous system

Neurological disturbances that have been attributed to sulfonamides include polyneuritis, neuritis, and optic neuritis (29,30). Tremor and ataxia have been described with co-trimoxazole (31,32). Aseptic meningitis can be separately caused by sulfonamides and trimethoprim. The occurrence of meningitis has been verified in most patients, with recurrence on re-exposure (33–42).

Sensory systems

Eyes

Drug induced uveitis is rare. Antibiotics that have been implicated include rifabutin and sulfonamides. Furthermore, nearly all antibiotics injected intracamerally have been reported to produce uveitis (43). Topical administration of a corticosteroid and a cycloplegic (such as atropine) is suitable as initial treatment. Withdrawal of causative drugs is not always necessary (44).

Transient myopia can be caused by topical or systematic sulfonamides (45–47).

Corneal ring formation has been described simultaneously with an erythematous skin rash in a patient known to have skin hypersensitivity (48).

Taste

In unmedicated young and elderly volunteers and HIV-infected patients, sulfamethoxazole applied to the tongue was described as sour by young subjects but bitter by elderly subjects (49).

Psychological, psychiatric

Headache, drowsiness, lowered mental acuity, and other psychiatric effects can be caused by sulfonamides (50). However, these adverse effects are rare, and the causative role of the drug is usually not clearly established.

Metabolism

Several sulfonamides, including co-trimoxazole in high doses, can produce hyperchloremic metabolic acidosis. This has even been seen in patients with extensive burns receiving topical mafenide (51). Mafenide (Sulfamylon) and its metabolite *para*-sulfamoylbenzoic acid inhibit carbonic acid anhydrase, resulting in reduced reabsorption of bicarbonate and thus bicarbonate wasting.

© 2006 Elsevier B.V. All rights reserved.

Electrolyte balance

Although co-trimoxazole in therapeutic doses can cause hyperkalemia (52), it is thought to be caused by the potassium-sparing effects of trimethoprim (53).

Hematologic

Sulfonamides have adverse effects on all bone marrow–derived cell lines. The resulting disturbances include hemolytic anemia, folate deficiency anemia, neutropenia, thrombocytopenia, and pancytopenia. While adverse effects on erythrocytes are rare, the rates of leukopenia, neutropenia, and thrombocytopenia are highly variable. In a hospital drug monitoring program, leukopenia or neutropenia occurred in 0.4% of 1809 patients treated with co-trimoxazole (54), and thrombocytopenia of mild-to-moderate degree in 0.1% (54,55), similar to figures recorded in other studies (56,57). Pancytopenia is an extremely rare form of adverse reaction to sulfonamides (58).

There were similar findings in children (59). It is generally believed that trimethoprim is primarily responsible for neutropenia due to co-trimoxazole.

Severe neutropenia often occurs in HIV-infected patients taking co-trimoxazole (60). It seems to be due to either folic acid deficiency or immunological mechanisms.

Erythrocytes

Sulfonamides rarely have adverse effects on erythrocytes. However, there are various mechanisms by which sulfonamide-induced hemolytic anemia can occur (61):

- abnormally high blood concentrations, due to large doses or reduced excretion of the drug in patients with renal disease (62)
- acquired hypersusceptibility, as reflected by the development of a positive Coombs' test (63,64)
- genetically determined abnormalities of erythrocyte metabolism, for example deficiency of glucose-6-phosphate dehydrogenase or of diaphorase (65,66)
- the presence of an abnormal, so-called "unstable", hemoglobin in the erythrocyte, for example hemoglobin Zürich (67,68), hemoglobin Torino (69), hemoglobin Hasharon (70), and hemoglobins H and M (66).

Simple and readily available in vitro methods have been used to demonstrate the pathogenetic mechanisms, including Coombs' test, Harris's test (71), a quantitative assay or screening for glucose-6-phosphate dehydrogenase activity after recovery (72,73), a test for Heinz bodies, the buffered isopropanol technique (74) to detect abnormal hemoglobins, and hemoglobin electrophoresis (61,66). The direct antiglobulin (Coombs') test can be negative in spite of an immune mechanism. If such a mechanism is suspected and the direct Coombs' test is negative, the indirect Coombs' test on the patient's serum with the addition of the suspected sensitizing agent can be of diagnostic value (75). Heinz bodies in the erythrocytes can be important for early differentiation of a sulfonamide-induced reaction, which could further progress to hemolytic anemia (76). This result can also be of help in distinguishing this from other kinds of anemia.

Sulfonamides are not directly associated with folate deficiency and megaloblastic anemias. Sulfasalazine can affect the absorption of folates, but inflammatory bowel disease can also be responsible for reduced folate absorption. Only in combination with trimethoprim are sulfonamides thought to deplete folate stores in patients with pre-existing deficiency of folate or vitamin B_{12} (77).

Leukocytes

Since the days when chloramphenicol was more commonly used, it has been recognized that many antimicrobial drug are associated with severe blood dyscrasias, such as aplastic anemia, neutropenia, agranulocytosis, thrombocytopenia, and hemolytic anemia. Information on this association has come predominantly from case series and hospital surveys (78–80). Some evidence can be extracted from population-based studies that have focused on aplastic anemia and agranulocytosis and their association with many drugs, including antimicrobial drugs (81,82). The incidence rates of blood dyscrasias in the general population have been estimated in a cohort study with a nested case-control analysis, using data from a General Practice Research Database in Spain (83). The study population consisted of 822 048 patients aged 5–69 years who received at least one prescription (in all 1 507 307 prescriptions) for an antimicrobial drug during January 1994 to September 1998. The main outcome measure was a diagnosis of neutropenia, agranulocytosis, hemolytic anemia, thrombocytopenia, pancytopenia, or aplastic anemia. The incidence was 3.3 per 100 000 person-years in the general population. Users of antimicrobial drugs had a relative risk (RR), adjusted for age and sex, of 4.4, and patients who took more than one class of antimicrobial drug had a relative risk of 29. Among individual antimicrobial drugs, the greatest risk was with cephalosporins (RR = 14), followed by the sulfonamides (RR = 7.6) and penicillins (RR = 3.1).

Agranulocytosis was not infrequent in the early sulfonamide era. The first cases were observed in association with sulfanilamide (84,85), Prontosil (84), sulfapyridine (85,86), sulfathiazole (87), sulfadiazine (87), and sulfasalazine (88). Even with topical silver sulfadiazine, agranulocytosis as a consequence of systemic absorption has been reported (89).

Special observations in patients with agranulocytosis favor an immunological/allergic mechanism rather than a toxic one. Several points justify this view:

1. the sulfonamide is well tolerated by most patients during the initial phase of treatment
2. sulfonamide concentrations in the serum, when determined, are not particularly high in patients with hematological complications
3. in some patients, skin rash, fever, and arthritis start concomitantly with or even before the appearance of leukopenia or agranulocytosis
4. re-exposure to a single dose can be followed by a second episode of severe agranulocytosis
5. an agglutinin for leukocytes has been identified in patients' serum shortly after withdrawal of the drug (86)
6. using in vitro techniques, positive reactions to the drug with the lymphocyte transformation test or inhibition of colony growth in bone marrow have been found (90,91); however, the results of lymphocyte transformation tests must be interpreted with caution—sometimes they are positive in patients who have been exposed to the drug without any evidence of a hypersensitivity reaction.

Platelets

Reports of drug-induced thrombocytopenia have been systematically reviewed (78). Among the 98 different drugs described in 561 articles the following antibiotics were found with level I (definite) evidence: co-trimoxazole, rifampicin, vancomycin, sulfisoxazole, cefalotin, piperacillin, methicillin, novobiocin. Drugs with level II (probable) evidence were oxytetracycline and ampicillin.

In another retrospective analysis of drug-induced thrombocytopenia reported to the Danish Committee on Adverse Drug Reactions, 192 cases caused by the most frequently reported drugs were included and analysed (92). There were pronounced drug-specific differences in the clinical appearance. Early thrombocytopenia was characteristic of cases caused by sulfonamides and co-trimoxazole. These drugs also often caused hemorrhage. Accompanying leukopenia was observed in some cases associated with co-trimoxazole. There were no patient-specific factors responsible for the heterogeneity of the clinical appearance, and factors related to the physician seemed to be of little significance.

Acute thrombocytopenia is rarely associated with the newer sulfonamides (4,93,94). The structurally related sulfonylureas and thiazide diuretics can also cause allergic thrombocytopenia (95). Although some in vitro tests have been reported to predict the occurrence of thrombocytopenia, none of these has been used routinely (96,97). Furthermore, a negative test result with a drug does not definitely exclude it as the responsible allergen.

Mouth

Salivary gland enlargement on repeated exposure to sulfafurazole (sulfisoxazole) has been described (98).

Gastrointestinal

Nausea, vomiting, and anorexia occur in a few patients taking sulfonamides (1). They are usually related to dosage, the disposition of the individual patient, and how the question concerning adverse effects is asked.

Liver

Increased activities of alanine transaminase and aspartate transaminase to over five times the upper limit of the reference range were reported in a randomized trial of sulfadiazine in toxoplasmic encephalitis (99).

Co-trimoxazole-induced hepatitis has been repeatedly reported. However, trimethoprim alone can also cause acute liver injury (100). Three forms of liver injury may be related to sulfonamides:

1. hepatitis of the hepatocellular type (101–105)
2. hepatitis of the mixed hepatocellular type accompanied by cholestatic features (106)
3. chronic active hepatitis, possibly leading to cirrhosis (107).

The number of cases of sulfonamide hepatitis published annually fell markedly after 1947, with the introduction of the newer short-acting derivatives (106).

Children can also be affected by drug-induced liver disease (108).

Hitherto, the connection with a sulfonamide has always been investigated by administering a test dose. Immunological in vitro methods that show sensitization to the drug, for example the lymphocyte transformation test, are of limited value. In some patients the hepatic injury develops in connection with a general reaction, such as serum sickness-like syndrome, generalized vasculitis, or rash (109,110). In patients with hypersensitivity, re-exposure can result in generalized malaise, nausea, back pain, and chills within one to several hours (103,107). However, symptoms can be delayed for as long as several days (106). Daily monitoring of liver function on re-exposure seems to be important, since subjective signs can be absent despite rising activities of serum transaminases and alkaline phosphatase (102).

Even in patients with chronic active hepatitis, the histopathology of the liver damage was indistinguishable from non-drug-induced pathology. The degree of piecemeal necrosis usually varies from one area to another. Antinuclear factor and lupus erythematosus factor were positive in some cases (107). Early recognition of drug-induced liver disease is of great importance, since liver injury can be completely reversible after withdrawal.

Pancreas

Pancreatitis has been attributed to sulfonamides. Sulfamethizole (34) and sulfasalazine (111) have been implicated by re-exposure. The 5-aminosalicylic acid moiety of sulfasalazine may also be responsible (112,113).

Urinary tract

Renal complications that occur in relation to sulfonamide administration include crystalluria, tubular necrosis, interstitial nephritis, and glomerular lesions as part of a vasculitis syndrome.

Sulfonamides and their metabolites are excreted in large amounts in the urine. They are relatively insoluble in the acid environment and tend to precipitate in the collecting tubules, calyces, and pelvis of the kidney, and possibly in the ureters. The course is typically benign but adequate hydration and alkalinization may be required (114). Nephrocalcinosis can cause hematuria, renal colic, or acute renal insufficiency (115). Urinary obstruction with anuria/oliguria was seen primarily with the earlier, less soluble sulfonamides. With the newer and more soluble sulfonamides crystal formation is rare, as is acute renal insufficiency due to other mechanisms. During recent years renal complications have been seen more often in patients with AIDS, because of the use of large doses of sulfonamides combined with trimethoprim against infection with *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) or *Toxoplasma* encephalitis. Reduced fluid intake and low urinary pH favor crystal formation, and so both adequate fluid intake (about 2 l/day for adults) and urine alkalinization are encouraged when larger doses of sulfonamides are used (60,115–120). For the diagnosis of sulfonamide crystalluria, the Lignin test is recommended. At room temperature crystals can even be found in the urine of patients taking sulfamethoxazole, which is readily soluble (121).

© 2006 Elsevier B.V. All rights reserved.

Other renal complications reported with sulfonamides are:

- acute tubular necrosis or tubulointerstitial nephritis (117,122);
- interstitial nephritis (123), in some cases combined with granulomatous lesions (124,125);
- acute vasculitis (126);
- acute renal insufficiency in association with a serum sickness-like syndrome, generalized vasculitis, or rashes in combination with hepatic damage (109).

Acute anuria or oliguria is often the first symptom, not only in patients with tubular necrosis or tubulointerstitial nephritis, but also in those with allergic vasculitis. Non-oliguric renal insufficiency can also occur. It is not yet clear whether tubular necrosis in association with sulfonamides is a toxic, collateral, or hypersusceptibility reaction. The unstable hydroxylamine metabolites of some sulfonamides can act as direct renal toxins.

In a French analysis of 22 510 urinary calculi performed by infrared spectroscopy, drug-induced urolithiasis was divided into two categories: first, stones with drugs physically embedded ($n = 238$; 1.0%), notably indinavir monohydrate ($n = 126$; 53%), followed by triamterene ($n = 43$; 18%), sulfonamides ($n = 29$; 12%), and amorphous silica ($n = 24$; 10%); secondly, metabolic nephrolithiasis induced by drugs ($n = 140$; 0.6%), involving mainly calcium/vitamin D supplementation ($n = 56$; 40%) and carbonic anhydrase inhibitors ($n = 33$; 24%) (127). Drug-induced stones are responsible for about 1.6% of all calculi in France. Physical analysis and a thorough drug history are important elements in the diagnosis.

Skin

Rashes are common during sulfonamide administration, and the rate increases with duration of therapy. Maculopapular reactions are most common and occur in about 1–3% of patients (128–132). In a survey of 5923 pediatric records, 3.46% of prescriptions for sulfonamides were followed by the development of a rash, although none was severe enough to require hospitalization (133).

Urticaria, fixed drug eruptions (131,134–137), erythema nodosum (138), photosensitivity reactions (139), and generalized skin reactions involving light-exposed areas (139–141) are less common. Topical silver sulfadiazine cause local reactions, consisting of rash, pruritus, or a burning sensation in 2.5% of patients (4,51).

- Fixed drug eruption has been described in a patient treated with the non-thiazide sulfonamide diuretic indapamide; an oral challenge test showed cross-reactivity to sulfamethoxazole and sulfadiazine (142).

Generalized cutaneous depigmentation after sulfamide therapy occurred in a 41-year-old man (143). Melanocytes were not seen on electron microscopy, but there were clear cells with the characteristics of Langerhans cells along the basal layer.

Other skin eruptions seen with sulfonamides include erythema multiforme, vesicular and bullous rashes, and exfoliative dermatitis (144). In erythema multiforme, linear depositions of IgA at the dermoepidermal junction have been suggested to play a pathogenic role (132).

- Linear IgA dermatosis with erythema multiforme-like clinical features has been reported in a 19-year-old man several days after completion of a 5-day-course treatment with sulfadimethoxine (500 mg bd) for a flu-like syndrome (134). Treatment with methylprednisolone (150 mg) with gradual dosage reduction was started. Slow improvement was followed by a flare-up after reduction to 80 mg/day. Therapy was changed to dapsone 100 mg/day, and there was a dramatic improvement.

The most severe skin reactions associated with sulfonamides are the severe forms of erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis (144–152). In a study from Cameroon, eight of ten patients with toxic epidermal necrolysis had taken sulfonamides (five sulfadoxine, three sulfamethoxazole); two patients died after taking sulfadoxine (153).

Mortality in drug-induced toxic epidermal necrolysis has been estimated to be about 20–30% (154,155), and in Stevens–Johnson syndrome 1–10% (33,146–148,151). Some severe skin reactions start with a maculopapular rash or generalized erythema. The culprit drug is often either a long-acting formulation or a short-acting drug that has been continued over a long period. In both toxic epidermal necrolysis and Stevens–Johnson syndrome immediate withdrawal of the sulfonamide and all other non-essential drugs is required, as well as adequate supportive therapy with fluids, proteins, and electrolytes, in order to prevent renal insufficiency and respiratory distress syndrome (154,155). Occasionally, toxic epidermal necrolysis must be distinguished from staphylococcal scalded skin syndrome (Lyell's syndrome) by histology. In toxic epidermal necrolysis, there is subepidermal cleavage of the skin at the level of the basal cells, resulting in full-thickness denudation, whereas in scalded skin syndrome the split occurs in the upper epidermis near the granular layer just beneath the stratum corneum (156).

The role of sulfonamides as an etiological factor in the Stevens–Johnson syndrome is extremely difficult to evaluate, except for patients with re-exposure or in situations where the drug was given prophylactically for meningitis (146) or pneumonia (147,148,151,152). In the first epidemiological study in 1968, 100 000 individuals were given prophylactic sulfadoxine (Fanasil) and 997 (1.0%) had skin reactions (146). Of these, about 100 had severe reactions, such as erythroderma with jaundice, Stevens–Johnson syndrome, or toxic epidermal necrolysis; 11 died from these complications, that is about one in 10 000 patients treated with the probably causative drug. It is not known how many would have had similar skin reactions unrelated to the drug. However, the benefit to risk balance of meningitis prophylaxis clearly favored the use of sulfonamides (146). A second report (147) showed an incidence of three cases of Stevens–Johnson syndrome in 480 healthy, newly recruited Bantu mineworkers treated prophylactically with sulfadimethoxine. In a third epidemiological study in Mozambique in 1981, 149 000 inhabitants in one town were given a single dose of sulfadoxine as mass prophylaxis in an attempt to stem an outbreak of cholera (148); 22 patients with typical Stevens–Johnson syndrome were admitted to hospital over 18 days; three died.

© 2006 Elsevier B.V. All rights reserved.

In one case toxic epidermal necrolysis caused by cotrimoxazole improved with high-dose methylprednisolone (157). However, previous studies of the use of glucocorticoids in toxic epidermal necrolysis have given contradictory results.

The combination of pyrimethamine and sulfadoxine, used for prophylaxis of chloroquine-resistant malaria (*Plasmodium falciparum*), causes severe skin reactions in one per 5000–8000 users, with fatal reactions in one per 11 000–25 000 users (158). Even at the stage of early rash or generalized erythema, this therapy should be withdrawn (129).

In an open prospective study in 95 HIV-infected patients with successfully treated *Pneumocystis jiroveci* pneumonia, pyrimethamine + sulfadoxine (25/500 mg) was given twice weekly to prevent relapse (159). There were allergic skin reactions in 16 patients, resulting in permanent withdrawal in six. Two patients developed serious adverse reactions (Stevens–Johnson syndrome), both of whom had continued to take prophylaxis despite progressive hypersensitivity reactions.

Most of the cutaneous adverse reactions to sulfonamides are associated with increased in vitro reactivity to sulfonamide metabolites, such as unstable hydroxylamines (160,161). In some cases glutathione deficiency has been proposed as a major mechanism. This seems to be important in patients with AIDS, in whom glutathione deficiency is frequent, and in whom skin rashes are much more common than in other patients (160,162). A predominance of slow acetylator phenotype has also been observed among patients with sulfonamide hypersensitivity reactions, and an association with the phenotypes HLA-A29, B-12, and DR-7 in patients with bullous cutaneous reactions (161,163–165).

A mechanism for generalized drug-induced delayed skin reactions to sulfamethoxazole may be perforin-mediated killing of keratinocytes by drug-specific CD4+ lymphocytes (166). The requirement of interferon gamma pretreatment of keratinocytes for efficient specific killing might explain the increased frequency of drug allergies in generalized viral infections such as HIV, when interferon gamma concentrations are raised.

Immunologic

Sulfa allergy refers to a specific hypersensitivity response to a group of chemicals containing a sulfonamide moiety covalently bound to a benzene ring; drugs structurally similar to sulfonamides may cross-react, for example sulfonylureas, thiazides, and furosemide (167). Sulfa allergy is most consistent with an immune-mediated reaction with delayed onset, 7–14 days after the start of therapy, characterized by fever, rash, and eosinophilia. IgG antibodies may be present and directed against proteins in the endoplasmic reticulum (about 80% of patients) or against the drug covalently bound to protein (about 5% of patients). High-dose methylprednisolone sodium succinate (250 mg every 6 hours for 48 hours) may not only alleviate the signs but also markedly attenuate the antibody response, as reported in a 19-year-old man (168).

Hypersusceptibility to sulfonamides has been proposed to be the mechanism for many adverse reactions, including anaphylactic shock, serum sickness-like syndrome, systemic allergic vasculitis, drug fever (up to 1–2% in some series), lupus-like syndrome, myocarditis, pulmonary infiltrates, interstitial nephritis, aseptic meningitis, hepatotoxicity, blood dyscrasias (agranulocytosis, thrombocytopenia, eosinophilia, pancytopenia), and a wide variety of skin reactions (urticaria, erythema nodosum, erythema multiforme, erythroderma, toxic epidermal necrolysis, and photosensitivity).

Urticarial and maculopapular rashes are the most frequent adverse reactions to sulfonamides after gastrointestinal symptoms. Although hypersusceptibility is suspected to be the mechanism for these adverse effects, type I allergic reactions, which are induced by IgE antibodies, have been confirmed only rarely. It appears that with the older sulfonamides severe reactions were more frequent. In some patients who have immediate hypersensitivity reactions to sulfonamides, IgE has been found that can bind to an N4-sulfonamidoyl determinant (N4-SM) (169).

Prediction

It is desirable to predict hypersusceptibility reactions to sulfonamides. IgE-induced in vitro reactions to sulfonamides have mainly been studied in the last 15 years (169–171). A lymphocyte toxicity assay showed a positive result in about 70% of patients with a maculopapular rash, an urticarial reaction, or erythema multiforme (172). This biochemical test determines the percent of cell death due to toxic metabolites. The same in vitro reaction using the hydroxylamine metabolite of sulfamethoxazole gave significantly different results in six patients with fever and skin rash with or without hepatitis than in control patients (160). Unfortunately, in most adverse reactions it is not known whether the reaction is dose-related or allergic. Individual differences in metabolism predispose to idiosyncratic reactions, for example sulfonamides are metabolized by *N*-acetylation (mediated by a genetically determined polymorphic enzyme) and oxidation to potentially toxic metabolites (164,165). Fever and rash were observed significantly more often in slow than in fast acetylators (164,165). Systemic glutathione deficiency, with a consequently reduced capacity to scavenge such toxic metabolites, might contribute to these adverse reactions, particularly in patients with AIDS (173,174). In a child with dihydropteridine reductase deficiency, a variant of phenylketonuria, adverse drug reactions occurred to cotrimoxazole (175). Unfortunately, there are no reliable in vitro tests to predict idiosyncratic reactions in vivo (160,161,164,165,174).

Cross-reactivity

The immunogenicity of sulfonamide antimicrobials may be due to the presence of an arylamine group at the N4 position of the sulfonamide molecule. Thus, allergic cross-reactions between different sulfonamides can occur. Therefore, in cases of known hypersusceptibility to a specific sulfonamide exposure to other sulfonamides should be avoided. Cross-reactions can even occur with *para*-aminosalicylic acid and local anesthetics of the procaine type; however, the real frequency of these cross-sensitivities is not known and their significance is undetermined. It should be noted that as many as 50% of

© 2006 Elsevier B.V. All rights reserved.

patients with rash have recovered in spite of continued treatment with the same drug (176), and even agranulocytosis did not occur after later re-exposures to the causative agent (162).

Susceptibility factors

In an in vitro study, plasma from HIV-positive patients was less able to detoxify nitrososulfamethoxazole than control plasma, suggesting that a disturbance in redox balance in HIV-positive patients may alter metabolic detoxification capacity, thereby predisposing to sulfamethoxazole hypersensitivity (177).

Types of reaction

Type I reactions

Anaphylactic shock occurs rarely with sulfonamides (160,169,170,178,179). Anaphylaxis to a central venous catheter (ARROWg+ard Blue Catheter) coated with chlorhexidine and sulfadiazine has been reported in a 50-year-old man (180).

Type III reactions

A serum sickness-like syndrome has been observed during sulfonamide administration. This diagnosis should be limited to patients with at least three of the symptoms of classical serum sickness, that is fever, rash, allergic arthritis, lymphadenopathy, and possibly leukopenia or neutropenia. Histologically, severe serum sickness-like syndrome seems to correspond to an allergic vasculitis (126,181). Most of the descriptions of serum sickness-like syndrome with histopathological documentation have been associated with older sulfonamides that are no longer used (182). In some severe forms of serum sickness-like syndrome, the reaction can be complicated by a number of unusual organ manifestations, including plasmacytosis, lymphocytosis, monoclonal gammopathy (183,184), interstitial myocarditis (13,33), allergic pneumonitis, nephropathy, liver damage, and nervous system disorders (126,181).

Lupus-like syndromes

Sulfonamides can cause three different clinical and biological syndromes similar or identical to systemic lupus erythematosus (185,186):

1. exacerbation of pre-existing lupus erythematosus
2. triggering of lupus erythematosus in a susceptible patient
3. serum sickness-like syndrome resembling lupus erythematosus clinically and serologically.

There may be positive LE cells and antinuclear factors. In exacerbation or triggering of lupus erythematosus, two pathogenetic mechanisms may be involved:

1. a reaction to the pharmacological properties of the drug, such as occurs with other drugs, such as hydralazine, diphenylhydantoin, procainamide, isoniazid, and practolol (185–190);
2. a hypersensitivity reaction (186,191,192).

In type I reactions, exposure time, and especially re-exposure time, are usually longer than 1–2 months. In type II reactions, exposure is more variable, lasting from hours to days or up to 1–2 months (185–187). Some patients with ulcerative colitis have developed arthropathy, possibly polyserositis, hematological abnormalities, and even loss of consciousness with positive LE cell and antinuclear antibody tests during treatment with sulfasalazine (187,189).

Diagnosis

No diagnostic tests are available to confirm sulfonamide hypersensitivity, and while avoidance of the drug is generally appropriate when a previous hypersensitivity reaction is suspected, desensitization protocols are available for use in HIV patients in whom *Pneumocystis jiroveci* pneumonia prophylaxis or treatment is indicated (193).

Desensitization

Desensitization has been tried with sulfonamides and especially co-trimoxazole. Desensitization with the combination seems to be essential in patients with AIDS, since co-trimoxazole is the first choice against *Pneumocystis jiroveci* pneumonia and toxoplasmosis. Desensitization is successful in 75% of patients with AIDS (194–196). However, the procedure is not completely safe and even anaphylactic shock can occur (170).

Body temperature

Drug fever due to sulfonamides is usually accompanied by a skin reaction; however, fever without other manifestations can occur (164,165).

Long-Term Effects

Drug resistance

Salmonella typhimurium DT104 is usually resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. An outbreak of 25 culture-confirmed cases of multidrug-resistant *S. typhimurium* DT104 has been identified in Denmark (197). The strain was resistant to the abovementioned antibiotics and nalidixic acid and had reduced susceptibility to fluoroquinolones. A swineherd was identified as the primary source (197). The DT104 strain was also found in cases of salmonellosis in Washington State, and soft cheese made with unpasteurized milk was identified as an important vehicle of its transmission (198).

Second-Generation Effects

Fertility

Male infertility with oligospermia has been reported during treatment with sulfasalazine (199,200). However, inflammatory bowel disease can also affect the maturation of spermatozoa (201).

Teratogenicity

The sulfonamides appear to have little if any effect on early human development. This is indicated by the absence of case reports or epidemiological survey data

© 2006 Elsevier B.V. All rights reserved.

during pregnancy. In one study of 50 282 mother–child pairs, 1455 were exposed to sulfonamides during the first 4 months; there was no increase in the relative risk of any malformation (202,203).

Malaria during pregnancy is associated with an increased risk of severe anemia and babies of low birth weight. Effective intermittent therapy with pyrimethamine + sulfadoxine reduces parasitemia and severe anemia and improves birth weight in areas in which *Plasmodium falciparum* is sensitive to this combination. In an open, prospective trial in 287 pregnant women in the Gambia who were exposed to a single dose of a combination of artesunate and pyrimethamine + sulfadoxine there was no evidence of a teratogenic or otherwise harmful effect (204).

Fetotoxicity

Sulfonamides should not be given to pregnant women in the third trimester of pregnancy. They can displace bilirubin from plasma albumin and cause kernicterus (bilirubin encephalopathy) (205–208). For the same reason, the administration of sulfonamides to lactating women or premature infants should be avoided. Successful treatment of neonatal hyperbilirubinemia with higher bilirubin concentrations has been established using exchange transfusion and phototherapy.

Susceptibility Factors

Genetic factors

The acetylator phenotype of a patient can affect the frequency and severity of adverse reactions to drugs that are metabolized by acetylation (66,164,165).

In patients with porphyria, sulfonamides should not be used (209).

Other features of the patient

Although patients with HIV infection are more likely to develop generalized skin reactions to sulfonamides, they can be used for prophylaxis and therapy.

Relative contraindications to sulfonamides are systemic lupus erythematosus and a known predisposition to lupus-like reactions. Allergic reactions to antimicrobials are frequent in patients with Sjögren's syndrome. They are especially susceptible to reactions to penicillins, cephalosporins, and sulfonamides, but reactions to macrolides and tetracyclines also seem to be over-represented in these patients (210).

Drug Administration

Drug administration route

Sulfacetamide sodium (Albucid) in solutions stronger than 5% can cause burning and stinging when applied to the eyes, but this brief discomfort is usually tolerated without serious complaints. Sulfacetamide still compares favorably with newer antibiotics since it is effective against superficial ocular infections caused by a variety of microorganisms. However, serious allergic reactions can develop after ocular treatment (211).

The sulfonamides have a bacteriostatic rather than a bactericidal action. Many local anesthetics used in the eye are esters of *para*-aminobenzoic acid, and such drugs will interfere with the action of sulfonamides. Thus, to obtain the maximum effect from instillation of sulfonamide eye-drops, these drugs should not be used until the effect of the local anesthesia disappears.

Drug–Drug Interactions

Alkalis

Urine alkalinization increases the urinary excretion of sulfonamides (212,213).

Barbiturates

Sulfafurazole enhances the anesthetic effect of short-acting intravenous barbiturates, by competitive displacement from binding sites on plasma albumin (214).

CYP2C9

The inhibitory effect of sulfonamides on tolbutamide metabolism is mediated by CYP2C9, and therefore other drugs with narrow therapeutic ranges that are metabolized by CYP2C9, such as phenytoin and warfarin, deserve attention when certain sulfonamides (for example sulfaphenazole, sulfadiazine, sulfamethizole, and sulfafurazole) are co-administered (215).

Phenytoin

Attention is warranted when certain sulfonamides (for example sulfaphenazole, sulfadiazine, sulfamethizole, and sulfafurazole) are co-administered with CYP2C9 substrates with narrow therapeutic ranges, such as phenytoin.

Sulfonylureas

Hypoglycemia, often during the first hours of combining the two drugs, is the result of an important interaction between sulfonylureas and sulfonamides (216–219). For example, the half-life of tolbutamide was increased from 9.5 to 29 hours by chronic sulfaphenazole and from 9.2 to 26 hours by a single dose of sulfaphenazole (220). Interference by sulfonamides with the protein binding of sulfonylureas may contribute.

Most reports of this interaction have described hypoglycemia with tolbutamide in combination with sulfaphenazole (216,217,220,221), sulfafurazole (217), or co-trimoxazole (219,222). The inhibitory effect of sulfonamides on tolbutamide metabolism is mediated by CYP2C9 (215).

Chlorpropamide produces the same interaction (223).

The combination of gliclazide, fluconazole, and sulfamethoxazole can cause severe hypoglycemia (224).

Warfarin

Attention is warranted when certain sulfonamides (for example sulfaphenazole, sulfadiazine, sulfamethizole, and sulfafurazole) are co-administered with CYP2C9 substrates with narrow therapeutic ranges, such as warfarin (215).

© 2006 Elsevier B.V. All rights reserved.

Interference with Diagnostic Tests

Folate measurement

Sulfonamides, in contrast to trimethoprim, do not interfere with the microbiological assay of folate (77).

Theophylline

Sulfamethoxazole distorts the results of high performance liquid chromatography used for detection of theophylline plasma concentrations; the antibiotic should be withdrawn 24 hours before the procedure (SEDA-6, 7).

Sulfonylureas

General Information

Sulfonylureas act by inhibiting ATP-sensitive potassium channels (K_{ATP} channels) in pancreatic beta cells, increasing the amount of insulin released. The beta cells of patients taking these drugs are chronically stimulated. Changes in the pattern of insulin secretion and increased peripheral resistance to insulin both result in increased output of glucose from the liver. A rise in the number of insulin receptors, amelioration of the postbinding defect, and inhibition of the increased glucose output from the liver have been described (SEDA-5, 391), mostly in in vitro or animal experiments of short duration. The K_{ATP} channels in the beta cells and other tissues have been reviewed, including a discussion of the effects of various sulfonylureas (1). Enhanced action on beta cells by the addition of ADP suggests that the action of sulfonylureas varies with the metabolic state of the islet. Chlorpropamide and glibenclamide have high islet- binding specificity, while glibenclamide also binds with high affinity to extra-pancreatic binding sites.

Increased insulin release reduces blood glucose and glycosuria and contributes to a reduction in energy loss. This leads to increased storage of body fat when more is eaten than is necessary to meet daily energy needs and provokes feelings of hunger. Traditionally therefore, the sulfonylureas have been regarded as being unsuitable for overweight diabetics, who primarily need to lose weight. However, the results of the Diabetes Control and Complications Trial (DCCT) (2) and the UK Prospective Diabetes Study (UKPDS) (3) have shown that a sustained increase in the blood glucose concentration accelerates the development of secondary complications of diabetes mellitus. Being overweight may therefore be the price to be paid for normalization of blood glucose. However, not all secondary changes, such as macroangiopathy, seem to depend directly on the blood glucose concentration.

The potencies and the durations of action of oral hypoglycemic drugs vary (see Table 1). Oral drugs may make the cell more sensitive to insulin, and it is difficult to predict how long the hypoglycemic effect will last. The blood concentration does not always determine the duration of action. When the concentration is falling, stimulation of insulin secretion can continue for some time.

There have been reviews of oral hypoglycemic drugs (4–8).

Maturity-onset diabetes of the young (MODY) is characterized by type 2 diabetes at or before adolescence. It is a genetically heterogeneous disease, for which at least five different genes have been identified. MODY3, one of the most common forms, is characterized by a mutation in the hepatocyte nuclear factor (HNF)-1α gene. MODY3 can be very sensitive to sulfonylureas (SEDA-22, 475) (9,10).

Table 1 Doses, durations of action, and half-lives of sulfonylureas

RINN	Dose (mg)		Duration of action (hours)	Half-life (hours)	
				Renal function	
	Mean/day	Maximum/day		Normal	Anuric
Acetohexamide	250–1000	1500	12–24	16	48
Carbutamide[a]	500–1500	2500			
Chlorpropamide	100–500	1000	20–60	35	200
Glibenclamide (glyburide)	2.5–10	20	12–18	5–8	11
Glibornuride	12.5–100		10–15		
Gliclazide	40–240	240	12–18	8–11	
Glimepiride	1–4	6	12–20	5–8	
Glipizide	2.5–20	30	6–12	3–5	Unchanged[b]
Gliquidone	15–90	120	6–12	6–10	Unchanged[b]
Glisoxepide	2–12	15	5–10		
Glymidine (glycodiazine)	500–1500	3000	6–12		
Tolazamide	100–500	1000	12–16	8–10	
Tolbutamide	500–2000	3000	6–12	3–5	48

[a] Obsolete
[b] Hypoglycemia occurs despite the unchanged half-life

Three new cases have been presented, all with a mutation in the HNF-1α gene; low-dose glibenclamide was the best treatment in all cases (11).

The UK Prospective Diabetes Study (3) has shown that timely treatment, by reducing blood glucose concentrations before subjective complaints develop, reduces secondary complications in type 2 diabetes mellitus.

Combinations of oral hypoglycemic drugs

The different mechanisms of action of the various classes of hypoglycemic drugs makes combined therapy feasible: the sulfonylureas and meglitinides stimulate insulin production by different mechanisms, the biguanides reduce glucose production by the liver and excretion from the liver, acarbose reduces the absorption of glucose from the gut, and the thiazolidinediones reduce insulin resistance in fat. It is not necessary to wait until the maximal dose of one drug has been reached before starting another. However, sulfonylureas and meglitinides should no longer be used when endogenous insulin production is minimal. Combinations of insulin with sulfonylureas or meglitinides should only be used while the patient is changing to insulin, except when long-acting insulin is given at night in order to give the islets a rest and to stimulate daytime insulin secretion.

Large studies of the effects of lifestyle changes, the effects of drugs in preventing or postponing the complications of diabetes, or the usefulness of various combinations are regularly published. The different mechanisms of action of the various classes give different metabolic effects and different adverse effects profiles (12). Comparative costs of the various therapies in the USA have been presented (13).

This subject has been reviewed in relation to combined oral therapy. In a systematic review of 63 studies with a duration of at least 3 months and involving at least 10 patients at the end of the study, and in which HbA_{1c} was reported, five different classes of oral drugs were almost equally effective in lowering blood glucose concentrations (14). HbA_{1c} was reduced by about 1–2% in all cases. Combination therapy gave additive effects. However, long-term vascular risk reduction was demonstrated only with sulfonylureas and metformin.

The adverse effects of combined drug therapy are attributable to adverse effects of the individual drugs. Increased adverse effects or new adverse effects in patients taking combinations have not been reported.

Sulfonylureas + meglitinides

Glipizide, nateglinide, and their combination have been compared in a double-blind, randomized, placebo-controlled study in 20 patients with type 2 diabetes not requiring insulin (15). Before a standardized breakfast they took glipizide 10 mg, nateglinide 120 mg, both, or placebo; 4 hours after the meal blood glucose concentrations were significantly higher after nateglinide, but peak and integrated glucose concentrations did not differ. Integrated insulin concentrations were higher with glipizide. There were three episodes of hypoglycemia in the glipizide alone group and three in the combined group; three required treatment with glucose.

Sulfonylureas + thiazolidinediones

Troglitazone 100 or 200 mg/day or placebo was given for 16 weeks to 259 patients already taking sulfonylurea therapy (16). HbA_{1c} was 0.4 and 0.7% lower and blood glucose concentrations fell. The most common event was hypoglycemia, but this did not occur more often when troglitazone was added. Liver enzymes increased to the same extent in the three groups and never rose above normal. No patients withdrew because of drug-related effects.

Organs and Systems

Cardiovascular

Early studies suggested that tolbutamide caused excessive cardiovascular deaths (17) as reported in the University Group Diabetes Program (UGDP) (SEDA-4, 301), but

© 2006 Elsevier B.V. All rights reserved.

the UK Prospective Diabetes Study did not find different mortality in patients treated with insulin, glibenclamide, or chlorpropamide (3).

This effect of tolbutamide has been attributed to prevention of ischemic preconditioning, a protective manoeuvre that reduces myocardial damage after temporary stoppage of coronary blood flow (18). Transient myocardial ischemia augments post-ischemic myocardial function and prevents dysrhythmias. K_{ATP} channels play a role in this so-called ischemic preconditioning. In 48 atrial trabeculae, obtained during catheterization, the recovery of the developed muscle force in patients treated with a sulfonylurea was only half of what was found in non-diabetics or diabetics treated with insulin. This suggests that inhibition of K_{ATP} channels by oral sulfonylureas might contribute to increased cardiovascular mortality (19). The question of whether the findings obtained mainly with glibenclamide can be generalized to all sulfonylureas has been discussed, since sulfonylureas differ greatly in their ability to interfere with vascular or cardiac K_{ATP} channels (20). Both glimepiride and glibenclamide (21) improved glycemia in 29 patients in a randomized, double-blind, placebo-controlled, crossover study of a number of susceptibility factors for ischemic heart disease (plasminogen activator inhibitor activity, plasminogen activator inhibitor antigen, LDL cholesterol, C peptide, proinsulin, des-31,32 proinsulin, etc.), but K_{ATP} channels were not investigated.

Glibenclamide prevented the increase in tolerance to myocardial ischemia normally observed during the second of two sequential exercise tests (22).

Respiratory

- A 76-year-old man who had taken glibenclamide for 2 weeks, having switched from voglibose, developed pneumonitis; a lymphocyte stimulation test was positive for glibenclamide (23).

Sensory systems

A change in taste sensation has been reported with glipizide (24).

Metabolism

In 36 Japanese patients who were relatively lean but had excess abdominal fat, glibenclamide and voglibose caused loss of weight and abdominal fat (25). The loss of abdominal fat was related to glycemic control. The ratio of subcutaneous to abdominal fat shifted toward subcutaneous fat only in those who took voglibose. Both voglibose and glibenclamide improved insulin sensitivity and the acute response to insulin.

Hypoglycemia

DoTS classification (BMJ 2003;327:1222–5)
Adverse effect: Hypoglycemia due to sulfonylureas
Dose-relation: toxic effect
Time-course: time-independent
Susceptibility factors: disease (impaired liver or kidney function, alcoholism); drug interactions; reduced food intake; exercise

Hypoglycemia is the most frequent complication in patients with diabetes taking oral hypoglycemic drugs (26–28).

Presentation

In general, hypoglycemia caused by oral hypoglycemic drugs is more dangerous and of longer duration than hypoglycemia caused by insulin (29), and the most dangerous hypoglycemic attacks are those that result from long-acting drugs, such as chlorpropamide, and later sulfonylureas, such as glibenclamide (SEDA-4, 303). Sulfonylureas are mostly used by elderly people, and the characteristic warning symptoms of hypoglycemia (dizziness, breathlessness, sweating, and a feeling of hunger) are often absent or not well-interpreted.

Neurological symptoms are common and hypoglycemia can cause hemiplegia, which can be confused with neurological symptoms of other origin (transient ischemic attack, stroke, etc.). A bilateral case has been reported (30).

- A 68-year-old man started to take glibenclamide and 1 week later developed a blurred voice and right-sided hemiplegia with a blood glucose of 1.4 mmol/l. Ten minutes after intravenous glucose 50 g his motor function returned to normal. Six hours later he developed slurred speech and left-sided hemiplegia; his blood glucose was 1.9 mmol/l. During glucose administration his deficit resolved.
- A 75-year-old man taking gliclazide 80 mg bd and metformin 850 mg tds became hypoglycemic and was treated successfully (31). All hypoglycemic drugs were withdrawn, but he received more through his doctor's prescription computer and again became hypoglycemic on two occasions. On the second he became unconscious for 4.5 hours and his plasma glucose was 1.2 mmol/l. After resuscitation his abbreviated mental test was 5/10 and did not improve. He later became very aggressive and died of bronchopneumonia.

Three patients became comatose due to hypoglycemia (32):

- an 83-year-old woman who took two times 5 mg glibenclamide bd;
- a 61-year-old man who took 2 mg glimepiride bd and 500 mg metformin bd;
- a 79-year-old woman who took 5 mg glibenclamide tds and metformin 850 mg bd.

All of these patients had general malaise, reduced food intake, and vomiting; glucose had to be given for a long time and one patient died with pneumonia.

Frequent attacks of hypoglycemia can result in encephalopathy, and after withdrawal of the hypoglycemic drug cerebral injury can persist. It is not exceptional for prolonged hypoglycemic coma to end fatally (33,34). In 494 cases of severe hypoglycemia, 10% of the patients died and 9% had permanent sequelae (35).

Factitious hypoglycemia can take a long time to diagnose.

- A 20-year-old woman with unexplained hypoglycemia had an exploratory laparotomy with pancreatic biopsy, which showed a histological picture compatible with hyperplasia (36). Glipizide was detected in the blood at a concentration of 0.72 (usual target

© 2006 Elsevier B.V. All rights reserved.

range 0.1–0.49) μg/ml. The diagnosis was factitious hypoglycemia.

- A 33-year-old nurse with unexplained hypoglycemia had only small increases in insulin and C-peptide, and glibenclamide was found in her serum (37). However, she denied using it and did not want psychiatric therapy.

Reported cases again illustrate that hypoglycemia induced by tablets tends to relapse and that long-term observation after normalizing the blood glucose concentration is necessary.

Hypoglycemia has been reported in a worker, not wearing a mask, working with a machine preparing ultrafine sulfonylurea powder (38).

Incidence

In 13 963 sulfonylurea users over 65 years of age, there were 255 severe attacks of hypoglycemia during 20 715 patient-years of use (39).

In an open comparative study in 57 patients acarbose and gliclazide had the same effects on HbA_{1c}, blood glucose, and lipids, although the ratio of HDL:LDL cholesterol increased during acarbose therapy (40). Of those who took gliclazide 10% reported at least one mild hypoglycemic reaction.

In an 8-week, non-interventional cohort study in 22 045 patients with type 2 diabetes, of whom 4.9% discontinued therapy, adverse advents occurred in 2.3% (41). There were attacks of hypoglycemia in 0.3%. Of the 6547 patients taking glimepiride, 2.5% had adverse reactions and 0.4% had hypoglycemic reactions.

In an open, multicenter study, 849 patients with poorly controlled diabetes were treated with glimepiride monotherapy for 6 months in doses that were titrated from 1 to 6 mg (42). The authors tried to identify factors that could predict the response to glimepiride. Patients who achieved a fasting blood glucose below 7.7 mmol/l and HbA_{1c} below 7.5% or a reduction in fasting blood glucose of over 20% and/or in HbA_{1c} of at least 10% were defined as responders (57% of the 849 patients). Earlier treatment with other oral hypoglycemic drugs or long-standing diabetes increased the rate of non-responders. In 9.2% of the patients there were episodes of hypoglycemia, 1.4 per patient, and third-party or medical assistance was required five times as often. A family history of type 2 diabetes doubled the risk; a high HbA_{1c} reduced the risk.

In a retrospective study in Hong Kong, drug-induced hypoglycemia accounted for 0.5% of admissions; 50% of the episodes were related to sulfonylureas (43). These patients were older, predominantly female, in poorer general health, and needing assistance in daily activities, including feeding. Co-morbidities, such as macrovascular complications, renal insufficiency, and concurrent infections, were common. Low plasma albumin concentrations probably reflected poor nutritional status. Of those who had recurrent admissions, 67% lived in old peoples' homes, compared with 22% in those without previous admissions. The prognosis in this group was poor: 23% died within 1 year. Patients taking gliclazide ($n = 13$) or glipizide ($n = 10$) accounted for 37% of the episodes. They had more vascular complications than patients who used glibenclamide or chlorpropamide. They had a higher frequency of previous admissions (47 versus 19%) and a higher mortality rate (1 year, 47 versus 10%; 5 years, 72 versus 34%).

In a period of 12 months 23 episodes of severe hypoglycemia were recorded in those taking a sulfonylurea in a district with a population of 367 051 (8655 with diabetes) (44). The total cost of emergency treatment was estimated to be up to $92 078/year.

Causes and susceptibility factors

Most sulfonylureas are at least partly metabolized in the liver (SEDA-9, 709) (45), and hence liver insufficiency, liver disease, and liver enzyme inhibition (alcohol) or induction (drugs) can alter the half-life of the drug and its duration of action.

Renal dysfunction is another cause of hypoglycemia (46). Some sulfonylureas, such as chlorpropamide (30%) and tolbutamide (50%), are excreted by the kidney. Other drugs, such as acetohexamide, glibenclamide (glyburide), glibornuride, and glymidine, are mainly metabolized, but some of their metabolites also have a hypoglycemic effect and are excreted by the kidneys, so that renal insufficiency can prolong their hypoglycemic actions. The reduction in insulin metabolism in diseased kidneys (nephropathy) can contribute to hypoglycemia, since it increases the half-life of insulin.

Hypoglycemia can also result from drug interactions, with the simultaneous use of drugs that have glucose-lowering effects or that inhibit the clearance of oral hypoglycemic drugs.

The conclusion (SEDA-22, 475) (47) that fasting is well tolerated and that old age is no contraindication to sulfonylurea therapy has not been accepted by others (48,49), as the previous study included only a small number of relatively healthy patients with type 2 diabetes.

Hypoglycemia can result from overdosage of sulfonylureas (50,51). Factitious hypoglycemia induced by tablets is difficult to diagnose, since C peptide concentrations will be high and not suppressed. Reduced intake of food or alcohol can also play a role (52).

Severe hypoglycemia induced by long-acting and short-acting sulfonylureas in Basel, Switzerland (200 000 inhabitants), has been analysed in a retrospective study in 28 patients (median age 73 years) (53); 11 men and 5 women (2.24 per 1000 person-years) were taking long-acting sulfonylureas (15 glibenclamide, 1 chlorpropamide) and 2 men and 10 women (0.75 per 1000 person-years) short-acting sulfonylureas (10 glibornuride, 2 gliclazide). Metformin was only involved when combined with a sulfonylurea. There were no deaths. Reduced food intake ($n = 9$), increased activity ($n = 2$), impaired renal function ($n = 2$), alcohol ($n = 2$), too many tablets ($n = 3$), and no obvious factor ($n = 10$) were the causes.

Drug-induced hypoglycemia in 102 non-alcoholic, non-epileptic patients has been reviewed (54). There were susceptibility factors for hypoglycemia in 94; 84 were over 60 years old, of whom 70 were over 70 years; 66 had renal impairment, of whom 28 also had reduced energy intake, 10 had reduced energy intake, 30 had infections, 5 had liver cirrhosis, and 10 had malignant neoplasia; 14 had used hypoglycemia-potentiating drugs, such as beta-blockers ($n = 8$), cimetidine ($n = 2$),

© 2006 Elsevier B.V. All rights reserved.

co-trimoxazole ($n=2$), and aspirin ($n=2$). Forty patients had protracted hypoglycemia lasting 12–72 hours. Head trauma ($n=4$), skeletal injury ($n=3$), seizures ($n=8$), transient asymptomatic myocardial ischemia ($n=2$), and transient right hemiplegia ($n=1$) were seen. Five patients died. Ten used glibenclamide + metformin, 14 used glibenclamide + insulin, and 53 used only glibenclamide.

To study the impact of Munchausen's syndrome, 129 patients with unexplained hypoglycemia in France had blood tests for sulfonylureas, which were found in 22 cases—glibenclamide in 19 patients and gliclazide in 3 (55). The concentrations were usually higher than the usual target concentration: in seven cases they were five times higher and the highest value was 18 times higher. In most cases an insulinoma was suggested and pancreatectomy was planned.

Management

Treatment of sulfonylurea-induced hypoglycemia and of overdose with sulfonylureas has been reviewed (56). If intravenous dextrose is insufficient, octreotide is recommended (57) but not diazoxide. In patients with insulin reserve, dextrose can stimulate insulin secretion and paradoxically worsen the condition. Patients with drug-induced hypoglycemia should not be given glucagon, since it will stimulate insulin secretion. Hypoglycemia can last for up to 5 days. Continued observation is important, because recurrence after temporary recovery is common.

Nutrition

In patients taking maximal doses of sulfonylureas, plasma homocysteine concentrations were raised during secondary failure with poor metabolic control, which may indicate increased vascular risk (58). The concentrations correlated inversely with endogenous insulin concentrations.

Electrolyte balance

Mild hyponatremia has been reported with sulfonylureas, most commonly with chlorpropamide (59,60). The mechanism with chlorpropamide is secretion of ADH (61).

In 70 non-insulin-dependent patients with diabetes, taking one of five different oral hypoglycemic drugs, 21% of prescriptions were associated with a low plasma sodium concentration, but it was lower than 129 mmol/l in only 8% (62). Every oral hypoglycemic agent was associated with a low plasma sodium concentration, which normalized on withdrawal. Extreme hyponatremia was only seen with chlorpropamide and, in one case, with glibenclamide.

Fluid balance

Water retention with oliguria, uremia, and edema has been reported with gliclazide (63). Resistance to diuretics can be caused by chlorpropamide (64) or, to a lesser extent, tolbutamide. Changing to a sulfonylurea without an antidiuretic effect (glibenclamide) or to one that enhances water excretion (acetohexamide, glipizide, or tolazamide) (65) may be advisable.

Hematologic

The most dangerous adverse reaction of sulfonylureas is agranulocytosis. Aplastic anemia (66), red cell aplasia (67), pure white cell aplasia (68), bone marrow aplasia, and hemolytic anemia have been described during treatment with chlorpropamide (69), glibenclamide (70), or tolbutamide (71).

Thrombocytopenia has been described with chlorpropamide (72), tolbutamide (73), glibenclamide (74), and glimepiride (75).

- A 68-year-old man, who had taken pipotiazine and trihexyphenidyl for 12 years for chronic psychosis, took glimepiride for hyperglycemia. No platelet counts were performed before or during this. He had no symptoms of bleeding. He developed a petechial rash and hematomas on his trunk, legs, and face, hemorrhagic bullae in his mouth, and gingival bleeding. There was thrombocytopenia (1×10^9/l), with no malignant cells in a bone marrow aspirate and no serological evidence of recent viral infection. All medications were withdrawn and he was given prednisone and human immunoglobulin. After 7 days the hemorrhagic syndrome abated, although his platelet count was still 2×10^9/l. After four weeks the platelet count was 23×10^9/l and the prednisone was gradually withdrawn. After 6 months the platelet count was normal (346×10^9/l).

Glibenclamide can cause hemolysis by a non-immune mechanism (76).

- A 68-year-old man with a long history of type 2 diabetes and a slowly progressive myelodysplastic syndrome for 2 years took glibenclamide 5 mg/day for more than a year, buformin 150 mg/day, and voglibose 0.6 mg/day. His hemoglobin was 8.4 g/dl. No other cause of hemolysis was found and glibenclamide was withdrawn. His hemoglobin rose to 11.1 g/dl.

Eosinophilic infiltrations have been described with tolbutamide (SEDA-8, 917) (77), and chronic eosinophilic pneumonia has been described with chlorpropamide (78) and tolazamide (79).

Gastrointestinal

Gastrointestinal tract disturbances are frequent with sulfonylureas. They comprise nausea, vomiting, heartburn, dyspepsia, a metallic taste, and abdominal pain (80). They are less troublesome when the drug is taken after meals.

Liver

The risk of hepatotoxicity with the sulfonylureas varies with both the drug and the dosage. It has been described with chlorpropamide (81), tolazamide (82), tolbutamide (83), glipizide (84), and glibenclamide (85). Anicteric, cytolytic hepatitis has been described after glibenclamide (86).

Hepatic granulomas have been reported as a hypersensitivity reaction to chlorpropamide (87). Cholestatic jaundice from sulfonylureas is also probably of allergic origin; it is rare and has been described with glibenclamide (88), also in combination with hepatorenal syndrome (89), acetohexamide (90), chlorpropamide (91), gliclazide (92), and tolazamide (93).

© 2006 Elsevier B.V. All rights reserved.

- A 64-year-old man who had taken glibenclamide 10 mg/day for 4 years developed cholestasis (94). There was no extrahepatic obstruction on ERCP and serological tests for hepatitis A, B, and C, *Helicobacter pylori*, and antimitochondrial or antinuclear antibodies were all negative. Liver biopsy showed portal and periportal inflammation, edema, and prominent centrilobular hepatocanalicular cholestasis. When glibenclamide was withdrawn and insulin given, the laboratory values normalized within 8 weeks. Rechallenge was considered unethical.

Hepatitis has been described with glibenclamide (95) and gliclazide (96).

- A 60-year-old woman with normal liver function tests developed acute hepatitis 6 weeks after starting to take gliclazide. No viruses, autoimmune factors, or metabolic factors that could have caused hepatitis could be found. A lymphocyte transformation test was not performed. A liver biopsy was compatible with drug-related acute hepatitis. When gliclazide was withdrawn she improved. She took glibenclamide and recovered fully within 6 weeks.
- A 64-year-old man who took gliclazide 160 mg bd for 3 months developed hepatitis (97). No other cause could be detected. Gliclazide was withdrawn. A liver biopsy after 2 weeks showed resolving acute hepatitis, consistent with a drug reaction, and 3 months later the liver profile was normal.
- A 42-year-old woman with newly diagnosed diabetes and no other known diseases developed a slightly abnormal liver profile (98). Good glycemic control was obtained with metformin 850 mg bd and gliclazide 80 mg bd. After 4 weeks she developed a pruritic skin rash, which resolved after 4 days of treatment with fexofenadine. A liver profile 2 weeks later was abnormal. Metformin was withdrawn, but 3 days later she was icteric and gliclazide was withdrawn. A liver biopsy was consistent with cirrhosis and there were moderate inflammatory infiltrates. The liver function tests improved and after 3 weeks she was rechallenged with metformin without exacerbation.

In the last case cirrhosis may have contributed to the adverse effect of gliclazide.

Pancreas

A possible relation between 2 years of treatment with a sulfonylurea and damage to the islets of Langerhans has been reported (99). A fatal case of pancreatitis has been attributed to glibenclamide (100).

In a case-control study in 1.4 million people in Sweden, 462 who were hospitalized for pancreatitis without gallbladder disease were compared with 1781 randomly selected controls; 6% of the cases and 3% of the controls had diabetes (101). Diet and insulin therapy were not associated with an increased risk, but the risk of pancreatitis with glibenclamide had a crude odds ratio of 3.2 and was higher in people aged over 70 years and in those taking beta-blockers.

Urinary tract

Nephrotic syndrome and immune complex glomerulonephritis have been attributed to chlorpropamide (102).

Skin

Photosensitization has been described with carbutamide (103), tolbutamide (104), chlorpropamide (105), and glibenclamide (106), sometimes combined with porphyrinuria.

Allergic skin reactions have been described with all sulfonylureas. They include pruritic rashes, erythema nodosum, urticaria, blisters (86), erythema multiforme, exfoliative dermatitis, Quincke's edema, erythroderma, and itching, while lichenoid drug reactions with ulceration have occurred after chlorpropamide and tolazamide (107). More generalized hypersensitivity reactions may prove fatal, but rarely.

Erythema multiforme has been attributed to glibenclamide (108).

- A 69-year-old woman, who had taken gliclazide 40 mg/day for 3 months, was switched to glibenclamide 2.5 mg/day. She had malaise for 2 days, followed by anorexia, fever, and 2 days later erythema multiforme over her whole body. She also had liver dysfunction, renal impairment, and rhabdomyolysis. A lymphocyte stimulation test was positive for glibenclamide, which was withdrawn; the rash improved and the laboratory tests normalized within 4 days.

Pigmented purpuric dermatosis has been attributed to glipizide (109).

- A 66-year-old man took glipizide for 4 weeks and developed brownish, non-pruritic, purpuric, scaling patches on his upper legs and buttocks. Biopsy showed dilated capillaries with surrounding extravasated erythrocytes, perivascular lymphocytic infiltrates, and areas of hemosiderin deposition. After withdrawal of glipizide the rash cleared.

Immunologic

Hypersensitivity vasculitis has been described with glibenclamide (110). Glibenclamide contains a sulfa moiety and can cause allergic reactions in someone who is allergic to sulfonamides.

- A 57-year-old man with a previously undocumented sulfa allergy used atenolol 100 mg/day, hydrochlorothiazide 25 mg/day, docusate sodium 100 mg/day, and ranitidine 300 mg bd for several months (111). He started to take celecoxib 200 mg/day, and 1 month later developed erythema multiforme and difficulty in breathing caused by swelling of the throat. He improved after withdrawal of his drugs and further treatment. He was then instructed to reintroduce his previous drugs one a day. One day later, after taking glibenclamide 5 mg, he developed new lesions and dyspnea. After 3 weeks he had another relapse when he reintroduced hydrochlorothiazide. He omitted glibenclamide, celecoxib, and hydrochlorothiazide, but continued to use insulin, metformin, ranitidine, and psyllium. The urticarial lesions disappeared.

Celecoxib and hydrochlorothiazide also have sulfa moieties and could have contributed in this case.

Death

Of 2275 diabetic patients aged 45–74 years with proven coronary artery disease, followed for 7.7 years, 990 were

© 2006 Elsevier B.V. All rights reserved.

treated with diet alone, 79 with metformin, 953 with glibenclamide, and 253 with a combination of metformin and glibenclamide (112). They were compared with 9047 non-diabetics. Mortality was lowest in the non-diabetics; death rates in the others were: diet alone 26%, metformin 32%, glibenclamide 34%, and combined therapy 44%.

Second-Generation Effects

Pregnancy

Sulfonylureas ($n = 68$) and metformin ($n = 50$) have been compared retrospectively with insulin ($n = 42$) in pregnancy (113). There were no severe attacks of hypoglycemia, no jaundice, and no differences in neonatal morbidity. However, in those who took metformin, pre-eclampsia and perinatal deaths were more common. Since metformin was given to obese women, and since obesity contributes to pre-eclampsia and perinatal mortality, this may have been an effect of obesity.

In 404 pregnant women at 11–33 weeks of gestation, with a fasting blood glucose of 5.3–7.8 mmol/l, randomly assigned to insulin or glibenclamide, there were no differences in perinatal outcome (114). Glibenclamide was not found in cord blood. The data were analysed separately for women with mean glucose concentrations at home above and below 5.8 mmol/l. In the high blood glucose group there were large children for gestational age in 19% (insulin) and 17% (glibenclamide), compared with 10% (insulin) and 11% (glibenclamide) in the low glucose group; it is not clear whether these differences were significant. There were no other differences (for example macrosomia, insulin in cord blood) between the groups.

Teratogenicity

There is anecdotal evidence of a risk of teratogenicity of sulfonylureas, and on theoretical grounds it is inadvisable to give sulfonylureas to women of fertile age. In women using self-administered hypoglycemic drugs during pregnancy, chlorpropamide, glibenclamide, and tolbutamide were associated with serious malformations, such as microtia, deafness, facial deformities, ventricular septal defect (with or without aortic rotation), atrial septal defect, and a single umbilical artery (115). Of 332 children of women using a sulfonylurea during the first week of pregnancy, 12% had major and 5% had minor abnormalities, related to the increase in HbA_{1c} (116). An effect of high blood glucose could not be excluded. Chromosomal damage is described with chlorpropamide (117), which may have contributed to the development of a cleft palate in another case (118). The choice for pregnant women with diabetes is between insulin given frequently in a short-acting form to avoid overdosage, or a continuous insulin infusion system, since overdosage of insulin can harm the developing fetus.

Fetotoxicity

Hypoglycemia has been reported in a neonate whose mother had taken tolbutamide (119).

- A woman with pre-existing hypertension took labetalol 600 mg/day and tolbutamide for gestational diabetes and had long-standing hypoglycemia. She had started to take tolbutamide 500 mg/day in week 23 and increased the dosage to 1500 mg/day in week 29. Her HbA_{1c} concentration was 5.0–5.8%. She felt no intrauterine movements during week 34 and an emergency cesarean section was performed. The baby had diabetic fetopathy (details not specified) and a blood glucose concentration of 0.8 mmol/l. Despite the administration of 20% glucose 10 ml as a bolus and then 8 ml/hour, the blood glucose remained below 1 mmol/l, and 10 hours after birth octreotide, a somatostatin analogue, was given. Intravenous glucose was discontinued after 3 days and octreotide on day 9. There were no signs of encephalopathy. C peptide, proinsulin, and insulin concentrations in the child were inappropriately high. Serum tolbutamide in the child was 141 μmol/l at 3 hours and the half-life was 46 hours.

The half-life of tolbutamide in this case was much longer than the reported half-life in adults of 7 hours, but the normal half-life in neonates is not known. The activity of CYP2C9, which metabolizes tolbutamide, may be reduced in the first 2 days of life.

Transient diabetes insipidus was seen in a child born to a mother who took chlorpropamide during pregnancy (120).

Neonatal thrombocytopenia and congenital malformations have been associated with administration of tolbutamide to the mother (121).

Susceptibility Factors

Age

Old age increases sensitivity to sulfonylureas and the frail elderly are at greatest risk (122).

Renal disease

Glimepiride (6), which is metabolized in the liver, was given for 3 months to two groups of diabetic patients with renal impairment: those with creatinine clearances of 30–60 ml and 10–30 ml (123). The goal was to reach a fasting blood glucose concentration below 10 mmol/l. There was recurrent hypoglycemia in one patient who did not need further drug therapy. There was one "silent" myocardial infarct. There were no other adverse effects. Serum insulin and C peptide concentrations did not change. There was increased clearance of glimepiride in the group with low creatinine clearances, probably caused by altered protein binding, increasing the unbound fraction available for hepatic metabolism.

Other features of the patient

Hypopituitarism, hypoadrenalism, and hypothyroidism all increase sensitivity to sulfonylureas because of reduced secretion of counter-regulatory hormones.

In insuloma, sensitivity to sulfonylureas is increased because insulin secretion from the tumor cells is greater than from normal islet cells.

Exercise training can force a reduction in the dose of various drugs in the treatment of diabetes (124). The hypoglycemic action of exercise in combination with

© 2006 Elsevier B.V. All rights reserved.

sulfonylurea on postabsorptive glucose concentration is mainly caused by greater inhibition of glucose production in the liver (125).

Prolonged hypoglycemia in patients with end-stage renal disease prompted a search for predisposing factors in such patients with type 2 diabetes taking oral therapy only (126). Seven patients with and 31 without prolonged attacks of hypoglycemia, all on hemodialysis, were studied. All were using glibenclamide, except for three controls who took tolbutamide. The hypoglycemic episodes lasted 28–256 hours and glucose 83–2000 g was given for each episode. A recent fall in food intake, previous hypoglycemic episodes, longer duration of episodes, and a history of cerebrovascular disease were associated with prolonged hypoglycemia. There were no relations to age, sex, beta-blockers, ACE inhibitors, or drug doses. There were no cases of liver disease or alcohol abuse. Glibenclamide is seven times more highly concentrated in the pancreatic islets than other sulfonylureas, it has a long half-life, and its degradation products have hypoglycemic activity (SEDA-14, 1510).

Drug Administration

Drug formulations

New formulations of some sulfonylureas offer the possibility of once-daily therapy. They include gliclazide MR (SEDA-25, 511) and glipizide GITS (SEDA-22, 444) (SEDA-23, 475).

Gliclazide is available in various formulations with different kinetics in vivo and in vitro (127). Gliclazide MR is a modified-release formulation that allows once-a-day dosing. In a double-blind study 800 patients were randomized to gliclazide or gliclazide MR; there were no differences in adverse reactions or hypoglycemia (128). When comparing identical doses of Diamicron™ and Diabrezide™ in an open, crossover study, Diabrezide had a larger acute and mid-term hypoglycemic effect than Diamicron (129).

In a small study, gliclazide MR 30–120 mg/day had similar efficacy to 80–320 mg/day of the immediate-release formulation. The most commonly observed adverse events were arthralgia, arthritis, back pain, and bronchitis, which may not all have been directly related to the drug, as they also occurred with placebo. There was symptomatic hypoglycemia in about 5%.

Glipizide GITS was also studied in 19 patients with type 2 diabetes in an open, randomized, two-way, crossover study for 5 days, comparing 20 mg/day and 10 mg bd (130). Despite lower serum concentrations with glipizide GITS, the effects on serum concentrations of glucose, insulin, and C-peptide were the same. This may explain the low overall rate of hypoglycemia and lack of weight gain with glipizide GITS.

From time to time, drug names are confused and the wrong drug is prescribed or dispensed instead of the one intended. Of all the errors that occur, sulfonylureas are often implicated (131). Examples include chlorpropamide instead of chlorpromazine, chloroquine or etodolac instead of chlorpropamide, glyburide instead of thyroxine, and oxybutynin hydrochloride or acetohexamide instead of acetazolamide (SEDA-16, 490) (SEDA-17, 495) (SEDA-18, 414) (SEDA-19, 395) (SEDA-21, 443).

Drug dosage regimens

There were no differences in episodes of hypoglycemia, concentrations of glucose, insulin, HbA1c, or lipids, or body weight when glibenclamide was given in one daily dose instead of divided doses (132).

Drug overdose

A suicide attempt with chlorpropamide has been reported (50).

- A 23-year-old woman took chlorpropamide 5–10 g. She needed assisted respiration and cardiac pacing for bradycardia (probably due to blockade of potassium channels), fluid infusion, and forced diuresis for 3 days. Notwithstanding continuous glucose infusion and glucose boluses she relapsed into severe hypoglycemia with convulsions. Only on day 27 was her urine free of chlorpropamide and her blood glucose normal.

Chlorpropamide is the longest-acting sulfonylurea. The high doses of glucose this patient was given may have stimulated further insulin secretion, thus contributing to the long period of fluctuating hypoglycemia. In the preceding 5 years 12 fatal cases of chlorpropamide poisoning with 3–15 g were seen in the same institution.

- Glibenclamide self-poisoning has been reported in a 48-year-old man with von Willebrand disease, Prinzmetal angina, hepatitis C, and depression (51). He had frequent hypoglycemic attacks, which were not reduced by reducing the dose of glibenclamide. Laparotomy for an insulinoma was considered until a glibenclamide concentration of 0.32 μg/ml was found, although glibenclamide was supposed to have been withdrawn.

Permanent right-sided hemiplegia, dysphasia, and hepatitis occurred after a suicide attempt with gliclazide (133).

- A 14-year-old non-diabetic girl took 15 tablets of gliclazide (1200 mg) and had gastric lavage 6 hours later. She developed lethargy, vomiting, and generalized tonic-clonic convulsions. Her blood glucose concentration was 0.8 mmol/l, aspartate transaminase 147 U/l (2.45 μkat/l), alanine transaminase 102 U/l (1.07 μkat/l), bilirubin 78 μmol/l (direct 31 μmol/l), and alkaline phosphatase 63 U/l. Electroencephalography showed voltage suppression in the left hemisphere and generalized slow-wave activity. A CT scan showed cerebral edema. Hypoglycemia was controlled within 24 hours with intravenous glucose. The convulsions could not be controlled with phenytoin, dexamethasone, or mannitol, given for cerebral edema, but they stopped on day 9. After 3.5 months of follow-up she could perceive words but could not speak and was severely hemiplegic.

Drug–Drug Interactions

General

Drug mechanisms that result in potentiation of the hypoglycemic effects of the sulfonylureas include:

- prolongation of the half-life by inhibition of metabolism or excretion (phenylbutazone, coumarins, chloramphenicol, doxycycline, bezafibrate, probenecid, sulfaphenazole, naproxen, fenyramidol);
- competition with plasma protein binding sites (NSAIDs, salicylates, and sulfonamides);
- potentiation of their hypoglycemic action by inhibition of gluconeogenesis, enhancement of oxidation of glucose, or stimulation of insulin secretion (beta-adrenoceptor antagonists, monoamine oxidase inhibitors, salicylates).

Examples are given in Table 2.

ACE inhibitors

In a retrospective case-control study, a primary diagnosis of hypoglycemia was identified in 413 patients registered as diabetic in 1993 (134). Five controls of the same age and sex, without hypoglycemia, were selected for each case from the same cohort. The relative risks of hypoglycemia with ACE inhibitors, beta-blockers, calcium antagonists, and salicylates were determined. There was an association between enalapril and sulfonylureas. However, other ACE inhibitors could not be identified as a risk factor. There was no interaction with beta-blockers, calcium channel blockers, or salicylates.

The interaction of ACE inhibitors with sulfonylureas has also been illustrated in case reports (135,136).

- A 67-year-old man using glucocorticoids for asthma, ranitidine 300 mg/day, and enalapril 5 mg/day developed a low blood glucose (1.2 mmol/l) within 48 hours of starting to take glibenclamide 5–10 mg/day.
- A 64-year-old man, who used, amongst other drugs, glibenclamide 2.5 mg/day and metformin 850 mg bd, lost consciousness after a week of dwindling appetite and loose stools. His blood glucose was 2.2 mmol/l. He had renal impairment (creatinine 362 μmol/l). He also used ranitidine and ramipril 2.5 mg/day, which could have contributed to both the hypoglycemic effect and renal insufficiency.

In the second case, renal insufficiency could have reduced the clearance of the active metabolites of glibenclamide.

Table 2 Drug interactions with oral hypoglycemic drugs

Interactions	Mechanisms
Enhanced hypoglycemia	
ACE inhibitors	7
Alcohol	3
Allopurinol	1 or 6
Azapropazone	2
Beta-adrenoceptor antagonists	3
Bezafibrate	7
Chloramphenicol	1
Cimetidine	7
Coumarin anticoagulants	7
Isoniazid	7
Levodopa	3
Naproxen	2
Perhexiline	3
Probenecid	1, 2, or 6
Pyrazolones	1, 2, or 6
Salicylates	2 or 6
Sulfonamides	1, 2 or 6
Reduced hypoglycemia	
Acetazolamide	7
Furosemide	7
Glucocorticoids	5
Oral contraceptives	5
Phenothiazines	7
Rifampicin	4
Sulfamethoxydiazine	7
Thiazide diuretics	5

Key to mechanisms:
[1]—Inhibition of drug-metabolizing enzymes
[2]—Displacement of drug from protein-binding sites
[3]—Impairment of glucose homeostatic mechanism
[4]—Induction of metabolizing enzymes
[5]—Increased insulin resistance
[6]—Reduced renal secretion
[7]—Unknown

Alcohol

A disulfiram-like effect after use of alcohol has been described with chlorpropamide, but also with gliclazide, glipizide, and acetohexamide. However, the hepatic effects of sulfonylureas include inhibition of the enzymatic degradation of ethanol, an effect that is only partly comparable with the action of disulfiram, which blocks the degradation of aldehyde but not that of ethanol itself. This interaction results in a vasomotor reaction, with giddiness, tachycardia, headache, angina pectoris, and skin reactions. The most prominent drug to elicit these effects is chlorpropamide, but tolbutamide and other drugs can also do it. The specific effect of alcohol and chlorpropamide has been propagated to be of use as a genetic marker, but this has not been confirmed (SEDA-7, 407).

Excessive use of alcohol, sometimes found in older persons living alone, may also contribute to changes in sensitivity to oral hypoglycemic drugs. Low doses of alcohol (4.35 mmol/l/kg, comparable to one or two drinks) in fasting diabetics taking glibenclamide 20 mg/day in a randomized, double-blind, placebo-controlled study caused a greater fall in blood glucose concentrations than saline and increased counter-regulatory hormone concentrations (137).

Clarithromycin

Two men aged 82 and 72 years with impaired renal function and taking glibenclamide 5 mg/day and glipizide 15 mg/day, respectively, became comatose due to hypoglycemia within 48 hours of starting to take clarithromycin (138). Clarithromycin inhibits cytochrome CYP3A4. It should be used carefully in patients with diabetes and reduced renal function taking oral drugs.

Diltiazem

The interaction of tolbutamide with diltiazem has been studied in eight healthy men (139). Tolbutamide had no

© 2006 Elsevier B.V. All rights reserved.

effect on diltiazem, but diltiazem increased the AUC of tolbutamide by 10% without an effect on blood glucose concentrations.

Hydroxychloroquine

The addition of hydroxychloroquine to sulfonylureas has been investigated in a placebo-controlled study in 125 adipose patients whose diabetes was not well enough controlled with a sulfonylurea alone (140). During the first six months HbA_{1c} was significantly reduced by 1.02%. There were no significant differences in adverse effects, but those who took hydroxychloroquine had a greater incidence of minor corneal changes.

Rifampicin

Reduced efficacy of gliclazide has been attributed to induction of CYP2C9 by rifampicin (141).

- A 65-year-old man who had taken gliclazide 80 mg/day for 2 years took rifampicin for an infection with *Mycobacterium gordonae*, after which the dose of gliclazide had to be increased to 120 mg/day and later to 160 mg/day. After 75 days of combined therapy, gliclazide 80 mg/day gave a plasma concentration of 1.4 μg/ml; 7 months after stopping rifampicin it increased to 4.7 μg/ml. Gliclazide was then reduced to 80 mg/day.

It is important to check the blood glucose concentration if rifampicin is given in combination with oral hypoglycemic drugs.

Sulfonamides

Tolbutamide is mainly metabolized by CYP2C9, which also has a role in the metabolism of sulfonamides. Of various sulfonamides, sulfaphenazole had the largest inhibitory effect on the metabolism of tolbutamide in vitro (142). This gives a theoretical basis for being careful when tolbutamide and sulfonamides are co-administered.

Sulindac

See also Non-steroidal anti-inflammatory drugs

General Information

There is still no firm evidence that by acting through an active metabolite, sulindac has any distinct advantage over other members of the group of NSAIDs that are

© 2006 Elsevier B.V. All rights reserved.

related to indometacin. However, its good tolerance in elderly patients has been stressed (1). Its pattern of adverse effects is similar to that of indometacin (2), with an incidence ranging from 17 (3) to 50% (4). Sulindac causes fewer gastrointestinal adverse effects than aspirin, but in some studies the incidence equalled that of ibuprofen (5), fenoprofen (6), and indometacin (7).

Organs and Systems

Cardiovascular

Several cardiac abnormalities have been reported, including congestive heart failure, dysrhythmias, and palpitation (8).

Respiratory

Pulmonary infiltrates were described in a woman with osteoarthritis who had been taking sulindac for 6 months (9).

Nervous system

Adverse effects on the nervous system were found in 2.5–6.5% of patients in one study (4). Dizziness, drowsiness and headache, somnolence, vertigo, insomnia, and blurred vision, that is all adverse effects described with indometacin, have been observed. Acute reversible encephalopathy with rash and fever has been described.

Like other NSAIDs, sulindac can cause aseptic meningitis in patients with systemic lupus erythematosus (SEDA-7, 109). Recurrent aseptic meningitis, described in a patient with no underlying connective tissue disease who had tolerated other NSAIDs, suggested immunological hypersensitivity to sulindac (10).

Psychological, psychiatric

Psychiatric symptoms, bizarre behavior, and paranoia have been attributed to sulindac (11).

Electrolyte balance

The risk of severe hyperkalemia with sulindac has been documented in a series of four cases (12).

Hematologic

Agranulocytosis (probably due to toxicity rather than hypersusceptibility) can be caused by sulindac (13), as can bone marrow aplasia (14) and severe thrombocytopenia (15,16), which may be the consequence of autoimmune platelet destruction in the presence of sulindac or its metabolite (SEDA-7, 109). Immune-mediated hemolytic anemia with a positive direct antiglobulin test has been reported (SEDA-18, 103).

Aplastic anemia in a woman with osteoarthritis taking sulindac relapsed 3 years later during therapy with fenbufen, suggesting that extreme caution should be exercised before giving NSAIDs to a patient with a history of NSAID-related aplastic anemia (17).

Gastrointestinal

Sulindac can cause all of the gastrointestinal adverse effects that are associated with indometacin, from dyspepsia to peptic ulcer. Nausea and abdominal pain are the most frequent, followed by constipation (18). Surprisingly, a study in healthy volunteers showed no gastroscopic mucosal damage after 7 days (19). This recalls past papers showing a lack of mucosal damage in short-term therapy, even with NSAIDs known to be gastrotoxic. A giant esophageal ulcer has been described (20). A preterm neonate developed fatal hemorrhagic gastritis with oral sulindac (21).

Ulcers in an ileal pouch with chronic bleeding have been described (22).

Sulindac reduces the number and size of rectal and colon polyps (23) and colon-mucosal synthesis of prostaglandin E_2 and 6-keto-prostaglandin $F_{1\alpha}$ is markedly reduced in patients taking sulindac. As this occurs concomitantly with the regression of polyps, it supports the hypothesis that prostaglandins are implicated in the regulation of colonic polyp growth (24). These observations have been confirmed in two other studies. Low-dose rectal sulindac produced complete adenoma remission in 87% of 15 colectomized patients with familial adenomatous polyposis. Polyp number and size fell significantly in 22 patients who took sulindac 150 mg bd for 3 months (25). After rectal administration of sulindac two patients had histologically proven mild gastritis (26).

Liver

Sulindac can cause toxic hepatitis, and several cases, some with positive rechallenge, have been described (27,28). A retrospective cohort study with secondary case-control analysis suggested that sulindac has a higher incidence of acute liver damage than all other NSAIDs, although the calculated risk is very low (27 per 100 000 prescriptions) (29). Liver function impairment is generally mild and reversible. Analysis of spontaneous reports to the FDA and the Danish Committee on ADRs (SEDA-18, 103) has confirmed these data.

Abdominal pain, nausea, high fever with chills, icterus, high liver enzyme activities, and hepatomegaly are characteristic and are probably caused by hypersensitivity. The occurrence of fever, rash, and/or eosinophilia in 35–55% of patients seems to confirm a hypersensitivity mechanism (SEDA-18, 103).

Cholestatic jaundice (30) and acute cholangitis in combination with acute pancreatitis (SEDA-13, 79) have been described.

Pancreas

There are several reports of pancreatitis associated with sulindac (SEDA-4, 66) (SEDA-7, 109). Symptoms resembling acute pancreatitis appeared after 3–90 days. Rechallenge was positive in one case (31). Acute cholangitis in combination with acute pancreatitis has been described (SEDA-13, 79).

Urinary tract

Sulindac may be less likely to cause renal toxicity than other NSAIDs (32), at least when it is used in low dosages, but there is some disagreement on this point (33–35), and five cases of nephrotic syndrome and renal insufficiency have been described (36,37).

© 2006 Elsevier B.V. All rights reserved.

Analysis of small renal and biliary stones has shown that sulindac or its metabolite was present in the material (SEDA-15, 99), and the labeling of sulindac was revised in 1989 to warn physicians of this phenomenon. However, despite the presence of sulindac or its metabolites in some renal stones, patients taking long-term sulindac are not at risk of an increased incidence of renal stone formation compared with those taking other NSAIDs (38).

Skin

The Stevens–Johnson syndrome has been reported in women who all recovered after the drug was withdrawn and corticosteroids given (SEDA-6, 95). Toxic epidermal necrolysis has also been reported (39–41).

A reaction like lupus pernio, with purple discoloration, swelling, red papules, and desquamation of the distal parts of several toes, which resolved after drug suspension and recurred after resumption, has been observed (42), as have subcutaneous fat necrosis (SEDA-11, 92), and fixed drug reaction (SEDA-12, 84).

Immunologic

Several types of proven or suspected hypersensitivity have already been mentioned, for example in connection with the liver, but the exact mechanism of a particular adverse effect has not always been clear. One case of fever, pharyngitis, cervical lymphadenopathy, leukopenia, liver abnormalities, proteinuria, pulmonary infiltrates, and abdominal pain has been described. Another patient who previously took sulindac without problems developed pruritus, dyspnea, perioral edema, and lethargy after taking a single dose of sulindac 150 mg.

Pneumonitis is probably part of a general hypersensitivity reaction (SEDA-6, 94) (9,43).

An anaphylactic reaction has been described (44). Sulindac is also thought to have been responsible for a severe multisystem reaction (possibly again anaphylactic) involving the cardiovascular, hepatic, pulmonary, and hematological systems in a patient with quiescent systemic lupus erythematosus (45).

Second-Generation Effects

Fetotoxicity

The use of oral sulindac for closure of patent ductus arteriosus has been evaluated in a prospective comparison with intravenous indometacin. Sulindac promoted ductal constriction without compromising renal function in preterm infants, but its use was associated with severe gastrointestinal complications (46).

Susceptibility Factors

Patients with sodium depletion are at risk of developing hyponatremia with all NSAIDs. Sulindac also provoked hyponatremia in an elderly patient taking a salt-restricted diet (47).

Drug Administration

Drug overdose

Agranulocytosis of short duration was described after an overdose of sulindac 12 g (48). Eight cases of sulindac overdose have been reported to the UK National Poisons Information Service; all the patients remained asymptomatic (SEDA-9, 89).

Drug–Drug Interactions

Furosemide

Data on sulindac inhibition of the diuretic effect of furosemide are contradictory (49).

Lithium

Unlike other NSAIDs, sulindac does not seem to interact with lithium (SEDA-10, 82). However, in one case it may have increased serum lithium concentrations (50).

Propranolol

Like indometacin, sulindac interacted with propranolol and a thiazide diuretic in a hypertensive patient (SEDA-6, 95).

Thiazide diuretics

Like indometacin, sulindac interacted with propranolol and a thiazide diuretic in a hypertensive patient (SEDA-6, 95).

Topical dimethylsulfoxide

Two cases of peripheral neuropathy attributed to a combination of oral sulindac and topical dimethylsulfoxide have been reported (SEDA-9, 89).

Warfarin

Potentiation of warfarin effects by sulindac has been reported (51).

Sulmazole

See also Phosphodiesterase type III, selective inhibitors of

General Information

Sulmazole is an inhibitor of phosphodiesterase type III.

Sulmazole commonly causes adverse gastrointestinal effects; dose-related anorexia, nausea, and vomiting have been reported in about 50% of patients given an intravenous infusion (1,2) and also after single oral doses (3). Cardiac dysrhythmias, mostly ventricular, have been reported occasionally with sulmazole (4). Other reported adverse effects in small numbers of patients include headache (1), temporary visual disturbances (2,5), discoloration of the urine (attributed to a metabolite) (2,6), and a small reduction in platelet count (1).

Sulpiride and levosulpiride

General Information

Sulpiride and its levorotatory isomer levosulpiride are dopamine receptor antagonists. The pharmacology, efficacy, and tolerability of levosulpiride for dyspepsia and emesis have been reviewed (1).

Levosulpiride has been evaluated in 15 double-blind, randomized trials in patients with dyspepsia (1818 patients in all, of whom 676 were treated with levosulpiride) and in 11 trials in patients with emesis (718 patients in all, of whom 383 were treated with levosulpiride) (1). Levosulpiride was effective in the treatment of dyspepsia and emesis. The incidence of adverse effects was 11% in 840 patients with dyspepsia. Most of them were mild and resulted in treatment withdrawal in only 0.9% of cases. The common adverse effects were drowsiness, breast tenderness, and hoarseness.

Sulprostone

See also Prostaglandins

General Information

Sulprostone is a synthetic prostaglandin analogue of PGE_2 used for inducing uterine contraction.

In large series, sulprostone has had good tolerability with a very low complication rate. The most severe complication is myocardial infarction secondary to coronary spasm, with a frequency of one in 20 000, usually in smokers and women over 35 years of age with cardiovascular disease (SEDA-23, 436).

Organs and Systems

Cardiovascular

Several experimental studies have provided support for the hypothesis that coronary spasm plays a major role in the pathophysiology of myocardial infarction during the administration of sulprostone. However, the possibility of myocardial infarction is not mentioned in the product information.

- Two cases of myocardial infarction (one fatal) have been reported in patients receiving sulprostone with mifepristone (1,2).
- Myocardial infarction has been reported in a woman aged 35 years with normal coronary arteries and good left ventricular function (3).
- A 30-year-old woman developed uterine atony and bleeding after induced abortion because of fetal death at 17 weeks of gestation (4). Sulprostone was given intravenously at a rate of 500 micrograms/hour. When additional sulprostone was injected into the uterine cervix, the patient sustained a myocardial infarction, with ventricular fibrillation and cardiocirculatory arrest, most probably due to coronary artery spasm. She was resuscitated and recovered completely.

Sulprostone should be used with care, particularly in patients with cardiac risk factors, and only in settings equipped to manage complications.

Cardiac dysrhythmias have been reported after the administration of misoprostol.

© 2006 Elsevier B.V. All rights reserved.

- A 38-year-old woman developed complete heart block, ventricular fibrillation, and subsequent asystole about 7 minutes after intravenous sulprostone 30 micrograms over 5 minutes, after she had previously been given a total dose of intramyometrial sulprostone 500 micrograms at seven different points for postpartum hemorrhage after cesarean section (5).

The time-course suggested that the most likely cause of the arrest was the intravenous sulprostone. Contributory causes may have been hemorrhagic shock, electrolyte abnormalities, and hypothermia (from massive blood transfusion).

- Cardiac arrest occurred in a 39-year-old woman 3.5 hours after the administration of sulprostone 250 micrograms directly into the uterine wall for postpartum hemorrhage after manual removal of the placenta (6). She had specific contraindications to sulprostone, as formulated by the French authorities: age over 35 years, heavy cigarette smoking, and cardiovascular risk factors.

In the Netherlands, sulprostone is registered for intravenous administration only. The authors strongly advised against administration directly into the uterine wall.

Nervous system

Seizures have been described during pregnancy termination induced by sulprostone (7).

Liver

Sulprostone has been associated with minor abnormalities of liver function (8).

Urinary tract

Sulprostone has been associated with minor abnormalities of kidney function (8).

Reproductive system

Sulprostone can cause rupture of the uterine cervix (9).

- A 43-year-old woman, who had previously had a first trimester miscarriage that required evacuation of the uterus and a normal vaginal delivery at term 4 years before, was admitted for an abortion at 16 weeks. Ripening of the cervix was started with a pessary of gemeprost 1 mg. After 3 hours, when the cervix was 1 cm dilated, an intramuscular injection of sulprostone 500 mg was given. After 30 minutes she developed persistent abdominal pain, which became a continuous cramping and then a shooting pain; a male fetus of 170 g was aborted. There was a 3 cm longitudinal cervical rupture located posteriorly that reached the posterior fornix.

Sultiame

See also Antiepileptic drugs

General Information

Sultiame is a carbonic anhydrase inhibitor that has been used as an antiepileptic agent in most forms of epilepsy except absence seizures.

In 86 patients there was a good correlation between the weight-related dose of sultiame and the sultiame serum concentration (1). The half-life was 8.7 hours. In children the half-life was shorter and the clearance higher than in adults, and sultiame concentrations in children were lower than in adults, dose for dose.

Sultiame as monotherapy has been studied in a double-blind, placebo-controlled trial for 6 months in 66 children with benign childhood epilepsy with centrotemporal spikes (2). The number of adverse events per day of exposure was similar with sultiame and placebo, and no patient withdrew because of adverse effects.

The most common adverse effects of sultiame are gastrointestinal disturbances, ataxia, dizziness, headache, paresthesia, anorexia, weight loss, sedation, behavioral disorders, and metabolic acidosis (SEDA-21, 74) (3). There have been rare reports of neuropathy and acute tubular necrosis (3).

Organs and Systems

Psychological, psychiatric

- A 9-year-old boy with rolandic epilepsy developed impaired vigilance, depressed mood, fatigue, loss of drive, and listlessness when given sultiame 5 mg/kg/day

(4). All his symptoms disappeared within a few days of withdrawal.

Sunscreens, substances used in

General Information

Solar UV rays are classified into three groups: UVA rays have the longest wavelength and account for 90% of the total; UVB rays have higher energy and are the most damaging; UVC rays are filtered out by the ozone layer.

Topical sunscreens

Topical sunscreens are made up of constituents that either absorb or reflect incident radiation; absorbents are organic chemicals, reflectants are inorganic chemicals.

The commonest absorbents are *para*-aminobenzoic acid (PABA) and its derivatives, cinnamates, benzophenones, and salicylates, none of which offers significant protection against UVA. Dibenzoylmethane derivatives and anthranilates, which also work by absorbing radiation, are more effective UVA filters.

Reflectant inorganic components, such as zinc oxide and titanium dioxide, provide significant UVA protection, as well as good UVB protection. However, they are opaque and can leave a visible white film, despite the use of "microfined" particles in most products, and some users find them cosmetically less acceptable.

The Sun Protection Factor (SPF) is the ratio of the amount of UVB radiation that is just enough to produce sunburn on protected skin to the amount that will produce the same effect on unprotected skin. For example, skin protected by a sunscreen with an SPF of 10 should be able to withstand a given intensity of UVB rays for 10 times as long as unprotected skin before burning. As no assessment of UVA protection is included, the SPF should not be used as the basis for recommending a sunscreen to a patient who is sensitive to UVA.

Some products also carry a star rating system to indicate UVA protection, four stars representing the greatest; this rating is not an absolute measure, but indicates UVA protection relative to UVB, and its usefulness is controversial. Objective testing of widely available sunscreen agents has shown UVA protection to be significantly less than for UVB.

People vary in their susceptibility to sunburn, as follows:

I— Always burns, never tans
II— Burns easily, sometimes tans
III— Tans easily, burns rarely
IV— Always tans, never burns

Those who burn easily (types I and II) should be advised to choose a preparation with a high SPF (15 or more) that will provide good protection against UVB and adequate protection against UVA. Darker subjects (skin types III and IV) can safely use sunscreens with a lower SPF (around 10).

General adverse effects

Ultraviolet-absorbent organic sun filters, particularly derivatives of PABA, dibenzoylmethane, and anthranilates, can cause both allergic and photoallergic contact dermatitis. PABA-containing formulations can stain clothing yellow and cause stinging or drying of the skin.

Organs and Systems

Immunologic

Photopatch-testing with sunscreens in Sweden has been reviewed (1). Between 1990 and 1996, 355 patients with suspected photosensitivity were photopatch-tested with seven sunscreens (benzophenone-3 (Eusolex 4360), isopropyldibenzoylmethane (Eusolex 8020), butylmethoydibenzoylmethane (Parsol 1789), octylmethoxycinnamate (Parsol MCX), PABA, phenylbenzimidazole sulfonic acid (Eusolex 232), 4-methylbenzylidene camphor (Eusolex 6300); 2% petrolatum). There were 42 allergic reactions in 28 patients. The most common allergen was benzophenone-3 (Eusolex 4360), with 15 photocontact and one contact allergic reaction, followed by eight photocontact and four allergic contact reactions to isopropyl dibenzoylmethane (Eusolex 8020). In six cases, photocontact reactions were due to butylmethoxydibenzoylmethane (Parsol 1789). Phenylbenzimidazole sulfonic acid (Eusolex 232) caused two cases of photocontact allergy, and benzophenone-3 caused contact urticaria in one patient (1). There was a similar frequency of photocontact dermatitis to Eusolex 4360, Eusolex 8020, and Parsol 1789 in an Italian study, in which nine of 36 patients had positive reactions when photopatch-tested with sunscreens (UVA 10 J/m^2) (2).

In 19 patients with positive photopatch tests to sunscreens among all the patients that were photopatch-tested between 1992 and 1999 (total not stated) there were 21 positive photopatch tests to sunscreen agents (3). Nine patients reacted to oxybenzone, eight to butylmethoxydibenzoylmethane, three to methoxycinnamate, and one to benzophenone. There were no reactions to *para*-aminobenzoic acid (PABA), reflecting the increased use of PABA-free sunscreens. Six patients also had positive patch tests to components of the

© 2006 Elsevier B.V. All rights reserved.

sunscreen base, such as fragrances, which can complicate the diagnosis.

Oxybenzone is the most frequently used benzophenone in sunscreens, estimated to be present in 20–30% of commercial products. Phototoxicity and allergic contact dermatitis have been described, but reports of immediate-type hypersensitivity are scarce.

- A 22-year-old woman with a history of atopy had anaphylaxis 10 minutes after widespread application of an oxybenzone-containing sunscreen (4). Blinded patch tests with the sunscreen and its ingredients yielded wheal and flare reactions after 15 minutes to the sunscreen and to oxybenzone. Some days before skin testing the woman had had contact urticaria on the face after kissing a friend who had applied the same sunscreen.

A positive patch test to polyvinylpyrrolidone/eicosene (10% in petrolatum on days 2 and 4) was found in a patient who had used a sun block (5).

Photo-induced contact urticaria to benzophenone-3 and benzophenone-10, possibly in combination with delayed hypersensitivity, has been described (6). Urticaria occurred within minutes of UVA irradiation (10 J), 24 hours after the application of the benzophenones.

Octyl triazone is a UVB absorber structurally unrelated to the benzophenones. Photocontact allergy to this agent in a sunscreen has been described (7).

Suprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Suprofen, alpha-methyl-4-(2-thienylcarbonyl)-phenylacetic acid, was specifically promoted as a non-narcotic analgesic for many painful conditions, and was withdrawn from the market worldwide in 1987. It caused an unusual clinical syndrome of acute flank pain and nephrotoxicity (SEDA-12, 89). It is still available as a 1% ointment in some countries.

Organs and Systems

Urinary tract

The pathogenesis of suprofen nephrotoxicity in young healthy volunteers involved a transient reduction in renal plasma flow and glomerular filtration rate, possibly due to intratubular precipitation of uric acid (1).

Skin

Suprofen ointment can cause photodermatitis (SEDA-17, 113).

Susceptibility Factors

A case-control study identified as susceptibility factors for adverse effects of suprofen male sex, hay fever and asthma, exercise, and alcohol consumption (2).

Suramin

General Information

Suramin is a trypanocide that has been used in the treatment of African trypanosomiasis and onchocerciasis, and has been studied in AIDS (SEDA-10, 277) (SEDA-15, 335). However, the high doses that are required for a worthwhile effect are extraordinarily toxic. It is particularly likely to cause adverse effects in the malnourished and has therefore largely been abandoned for the treatment of trypanosomiasis and onchocerciasis, but it still seems uniquely capable of killing the adult onchocerciasis worm, although results are sometimes incomplete even in that respect (SEDA-20, 283).

Suramin is mainly used now in the treatment of hormone-refractory prostate cancer, in which it has shown some antitumor effect, although accompanied by extensive and sometimes severe adverse effects (1), and in the treatment of high-grade glioma. Since it suppresses adrenocortical function it is usually given in conjunction with glucocorticoids. The concomitant use of glucocorticoids and anti-androgen withdrawal usually makes it difficult to establish the true response to suramin.

© 2006 Elsevier B.V. All rights reserved.

Observational studies

AIDS

For a time, unsuccessful attempts were made to treat AIDS with suramin (2), because of its proven ability to impair the in vitro infectivity (and inhibit the cytopathic effect) of human T cell lymphotropic virus type III (HTLV-III) or lymphadenopathy-associated virus (LAV). However, it is no longer used for this indication. Its adverse effects were more severe and numerous than in its traditional field of use: two-thirds of patients had malaise, fever, and raised transaminases, and a quarter had adrenal insufficiency. Erythematous drug eruptions (particularly on sun-exposed surfaces) were common; some patients had a burning sensation of the skin, particularly on the limbs. The most common laboratory abnormalities were proteinuria, microscopic pyuria, trace hemoglobinuria, and occasional granular casts. There were rises in hepatic transaminase activities in some patients, usually during the second and third weeks, and others had eosinophilia (maximum 14%) during a drug eruption. There was a high incidence of keratopathy (SEDA-14, 263).

Hormone-refractory prostate cancer

Much work relating to the use of suramin in prostatic cancer involves drug combinations, including aminoglutethimide, epirubicin, and hydrocortisone, with or without androgen deprivation, and in these studies it is hardly possible to determine which drug was responsible for a given adverse effect.

The adverse effects of suramin that were reported in a group of 69 patients with hormone-refractory prostate cancer were anorexia (19%), malaise and fatigue (40%), paresthesia (10%), weakness (9%), and skin rash (6%). In another group of patients there were higher frequencies of adverse effects: fatigue occurred in 70% and neuropathy in 16%. Hematological abnormalities occurred often, but were mostly mild and consisted of neutropenia (30%), anemia (74%), thrombocytopenia (26%), and coagulopathy (30%). Other common adverse effects have included uremia (21%), increased serum transaminase activities (19%), nausea and vomiting (30%), constipation (9%), edema (33%), dysrhythmias (7%), mild hyperglycemia (86%), and rash (60%) (SEDA-20, 283).

In 81 patients intravenous suramin (peak plasma concentration 300 μg/ml trough concentration 175 μg/ml) combined with aminoglutethimide 250 mg qds in patients with progressive androgen-refractory prostate cancer after antiandrogen treatment had been withdrawn, effectiveness was limited, whereas most adverse effects were attributed to suramin (3). There were 38 episodes of grade 3 and 4 toxic effects in 29 patients. Severe thrombocytopenia occurred in four patients. There were four episodes of atrial fibrillation. One patient developed uremia which required dialysis. One patient developed grade 3 neurosensory changes, but none had neuromotor changes. There was one episode of grade 4 rash, which was probably attributable to aminoglutethimide, consisting of diffuse erythematous exfoliating papules over the chest, back, arms, and face. All adverse effects were reversible.

The efficacy and adverse effects of treatment with suramin for hormone-refractory prostate cancer have been evaluated in 27 patients (4). The treatment regimen consisted of a loading phase, targeted to reach suramin serum concentrations of 180–250 μg/ml using a dose of 1.4 g/m^2 at 3-day intervals. Constant suramin concentrations were obtained with a dose of 0.5–1 g/m^2 every 7–10 days. Six patients did not complete the suramin loading phase because of adverse effects and were withdrawn. About one-third of the assessable patients had a more than 50% reduction in prostate specific antigen and/or serum alkaline phosphatase. Two of these also had a reduction in metastases on bone scan. Another 48% of the patients had unchanged prostate specific antigen or serum alkaline phosphatase during treatment with suramin, suggesting stable disease. The mean survival time was 41 weeks. Responders had a survival of 70 weeks compared with 12 weeks among non-responders. However, the adverse effects were substantial. The most common adverse effects were renal impairment (18 patients), 10 of whom had a mild increase in serum creatinine and seven had a moderate increase. One patient died of multiorgan failure, including renal shutdown. Suramin treatment was interrupted for 7–14 days when the creatinine clearance was under 40 ml/minute, which resulted in improvement in renal function. A sensimotor polyneuropathy occurred in 18 patients and typically presented as paresthesia involving the limbs, combined with reduced nerve conducting velocity. Mild and moderate sensorimotor polyneuropathy occurred in 14 patients. Severe polyneuropathy occurred in two cases and led to the withdrawal of suramin. These effects were only partially reversible. Eleven patients had no neurotoxic symptoms. Allergic rashes occurred in 30% of patients and consisted of a moderate, diffuse, morbilliform rash during the loading phase of suramin treatment, usually disappearing within a few days without further therapy. Two patients with more severe and prolonged rashes were treated with high-dose corticosteroids with a beneficial effect. Hematological toxicity consisted of anemia in 22% of the patients, who all needed blood transfusions, leukopenia in 15%, of whom one with a severe leukopenia was successfully treated by granulocyte-macrophage colony stimulating factor, and thrombocytopenia, which occurred in 15% of patients and led to spontaneous bleeding in two. The platelet count returned to normal in both cases after the withdrawal of suramin. Vortex keratopathy occurred in 15% of the patients. Corneal changes were always minimal and vision was not affected. One patient had a retinal bleed, which led to withdrawal. Severe infections occurred in 26% of the patients, and also led to the withdrawal of suramin and required intravenous antibiotics. These results have further confirmed that suramin has a limited but statistically significant effect in the treatment of hormone-refractory prostate cancer. Although the severity of adverse effects were somewhat less than in previous studies they were still substantial. The toxicity of suramin seems to be closely related to the cumulative dose, peak concentration, and treatment regimen, and toxicity may be reduced by reducing daily doses and giving additional treatment-free intervals.

Suramin has been combined with epirubicin in 26 patients with hormone-refractory prostate cancer (5). No additional therapeutic effect was found compared with

© 2006 Elsevier B.V. All rights reserved.

suramin or epirubicin alone. Suramin was given in an initial daily dose of 350 mg/m^2, with weekly infusions thereafter, targeted to maintain suramin plasma concentrations at 200–250 μg/ml for a maximum of 6 months. Cortisone acetate was added after 4 weeks in order to prevent adrenal insufficiency. Epirubicin was given as a weekly intravenous bolus from the start, also for a maximum of 6 months. The median duration of therapy with suramin and epirubicin was 9 (2–29) weeks. The toxic effects of this combined treatment included grade 1–2 nausea and vomiting (54%), fatigue (54%), anorexia (58%), stomatitis (52%), diarrhea (8%), mild rash (11%), neutropenia, usually mild (65%), low-grade fever (26%), mild increases in serum creatinine concentrations (27%), proteinuria (58%), and peripheral neurotoxicity (mild 23%, severe 4%); alopecia was caused by the epirubicin in 58%.

The use of suramin plus hydrocortisone and androgen deprivation and the use of multiple courses of suramin have been assessed in 59 patients with newly diagnosed metastatic prostate cancer (6). Suramin (doses aimed at plasma concentrations between a trough of 150 μg/ml and a peak of 250 μg/ml) was given in a 78-day fixed dosage schedule (one cycle) and suramin treatment cycles were repeated every 6 months to a total of four cycles. There was significant broad-spectrum toxicity throughout the study, leading to withdrawal of treatment in 33 patients. Cardiovascular events (dysrhythmias, hypotension, and congestive heart failure), neurotoxic effects, and respiratory effects were more frequent than expected. In consequence, repeated courses of suramin could be given in a minority of cases only. The authors felt that in the light of the relatively non-toxic palliation achieved with standard hormonal therapy, suramin in this dosage schedule has only limited use in patients with newly diagnosed metastatic prostate cancer.

The effects of fixed-dose suramin plus hydrocortisone have been studied in 50 patients with hormone-refractory prostate cancer (7). Suramin was initially given as a 30-minute test infusion of 200 mg. In the absence of allergic reactions, additional 24-hour intravenous infusions of 500 mg/m^2 were given daily for the next 5 days. Thereafter, 2-hour intravenous infusions (350 mg/m^2) were given weekly on an outpatient basis for 12 weeks or until disease progression. The median duration of response was 16 weeks and the median time to disease progression 13 weeks. Fatigue and lymphopenia were the most commonly reported adverse effects, in 27 patients (54%) and 39 patients (78%) respectively. Skin rash occurred in 12 patients (24%). Suramin was withdrawn in three patients because of acute renal insufficiency ($n = 2$) and Stevens–Johnson syndrome ($n = 1$).

In a randomized study in 390 patients suramin has been given in a fixed low dose (3.192 g/m^2), intermediate dose (5.320 g/m^2), or high dose (7.661 g/m^2) to determine whether its efficacy and toxicity in the treatment of patients with hormone-refractory prostate cancer is dose-dependent (8). There was no clear dose–response relation for survival or progression-free survival, but toxicity increased especially with the higher dose. There were neurological adverse effects in 40% of the patients and cardiac adverse effects in 15%. This raises questions about the usefulness of suramin, particularly in high doses, in advanced prostate cancer. However, in another phase I study of suramin with once- or twice-monthly dosing in patients with advanced cancer, suramin was relatively safely administered without using plasma concentrations to guide dosing (9). Dose-limiting toxic effects included fatigue, neuropathy, anorexia, and renal toxicity. Diffuse colitis, erythema multiforme, and hemolytic anemia were reported as unusual effects.

High-grade glioma

The efficacy, toxicity, and pharmacology of suramin have been studied in 12 patients with recurrent or progressive recurrent high-grade gliomas aged 26–67 years (10). Suramin was given in doses similar to those used in patients with hormone-refractory prostate cancer. Treatment-related adverse effects were usually mild and reversible. Three patients developed transient grade 3–4 toxicity (leukopenia, a rise in serum creatinine, and diarrhea). There was no coagulopathy or central nervous system bleeding. All patients reached target suramin concentrations. The pharmacology of suramin was not affected by anticonvulsant therapy. Median time to progression was 55 days (range 17–242) and median survival was 191 days (range 42–811). There were no partial or complete remissions at 12 weeks. However, the clinical outcome in three patients suggested that effect of suramin may be delayed. One patient who progressed after 12 weeks had a subsequent marked reduction in tumor size and maintained an excellent partial response for over 2 years without other therapy. The two others had disease stabilization and lived for 16 and 27 months respectively. Based on these observations, suramin and radiotherapy are now being used concurrently in patients with newly diagnosed glioblastoma multiforme to study survival as the primary outcome.

Renal cell carcinoma

Suramin was not effective in one phase II study in advanced renal cell carcinoma, in which it was given in a fixed dose plus hydrocortisone to 22 patients (19 men, three women, aged 30–74 years) (11). Three patients had grade 4 toxicity (hypersensitivity, urethral obstruction, hypotension, and neutropenic sepsis). Eleven developed grade 3 toxicity, mainly abdominal pain, anemia, diarrhea, erythema, dyspnea, fatigue, and fever.

Placebo-controlled studies

The antitumor effect of suramin has been evaluated in a prospective randomized trial in 458 patients with hormone-refractory prostate cancer and significant opioid analgesic-dependent pain (12). Reduction of pain and opioid requirements served as surrogates for tumor responsiveness. The patients were given either suramin (aiming at sustained plasma concentrations of 100–300 μg/ml) plus hydrocortisone (40 mg/day) or placebo plus hydrocortisone. Patients treated with suramin plus hydrocortisone had greater reductions in combined pain and opioid analgesic intake. Suramin did not reduce the quality of life or performance status. However, overall survival was similar. Most of the adverse events were mild or moderate and were easily managed medically.

© 2006 Elsevier B.V. All rights reserved.

Frequent adverse effects of suramin were rash, chills, fever, and taste disturbance. In contrast to the results of earlier studies, in which different suramin dosage regimens were used, neurological, renal, hepatic, and coagulation abnormalities were rare.

Organs and Systems

Nervous system

The neurological adverse effects of suramin have been reviewed in the context of a broad review of neuropathies associated with malignancy and chemotherapy (13).

Neurotoxicity is a dose-limiting adverse effect of suramin and there are two distinct types of neuropathy: a mild, length-dependent, axonal polyneuropathy, and a more serious subacute demyelinating, Guillain–Barré-like polyneuropathy. The reported incidence of neuropathy is 25–90% with a mean of about 50%. Various neuropathies were noted in four of 38 patients infused with suramin for various malignancies (14).

The milder axonal polyneuropathy is the most common neurological adverse effect of suramin and causes distal paresthesia, reduced pain and vibration sensation in the feet, weak toe extensors, and absent ankle jerks; this neuropathy is largely reversible. Milder neuropathies occurred in 50–70% of patients with plasma concentrations below 300 μg/ml, and severe motor neuropathy was rare in this category of patients.

The more severe demyelinating neuropathies appear to be dose-related and occur when peak suramin plasma concentrations are maintained above 350 μg/ml; the effective serum concentration in cancers is about 250 μg/ml (SEDA-20, 283) (15,16). A Guillain–Barré-like polyradiculoneuropathy occurs in 10–20% of patients after 1–5 months of treatment, with a maximum at 2–9 weeks after the start of treatment. The first symptoms are distal limb and or facial paresthesia, followed by diffuse, symmetrical, proximal weakness and areflexia. About 25% of these patients eventually require ventilation. The CSF protein content may be raised.

In 24 patients with hormone-refractory prostate cancer given suramin twice weekly intravenously targeted to reach plasma concentrations of 50–100, 101–150, 151–200, or 201–250 μg/ml plus doxorubicin, fatigue occurred in 18 and was dose-limiting in two (17). Eight developed neurological symptoms, of whom three, all receiving the highest dose, developed grade 3 toxicity. There were five cases of neuropathies. Two patients had evidence of a demyelinating neuropathy, one of whom developed a Guillain–Barré-like syndrome and inflammatory myopathy. A further patient had a mixed axonal and demyelinating peripheral neuropathy. Two patients developed a motor neuropathy that exacerbated pre-existing neurological defects. Other frequent adverse events were proteinuria, leukopenia, and alopecia. However, the respective roles of suramin and doxorubicin in causing these adverse effects were uncertain.

Evidence of an underlying distal axonal polyneuropathy can be detected by electromyelography (18). Electroencephalography shows slow motor conduction velocities and electromyography shows reduced recruitment in both proximal and distal muscles. In the more severe cases denervation emerges. Sural nerve biopsies have shown a reduced density of the large and small myelinated fibers, occasional axonal degeneration, and demyelination. Epineural and endoneural mononuclear inflammatory cell infiltrates are sometimes seen. After withdrawal of treatment symptoms may deteriorate further for several weeks with recovery, sometimes incomplete, after 1–2 months.

The precise mechanism of the neurotoxicity of suramin is unknown, although both inhibition of the effects of nerve growth factors and a possible immune-mediated effect, consistent with the many immunomodulating effects, have been suggested. In a recent experimental study in dorsal root ganglion cell cultures suramin disrupted the transport and metabolism of glycolipids, with accumulation of the GM1 ganglioside and ceramide, leading to cell death (19).

Sensory systems

Photophobia, lacrimation, and palpebral edema are recognized late effects of suramin, and there is evidence of a late optic atrophy of suramin (20).

High-dose treatments for cancers seem to produce changes in most patients consistent with a vortex keratopathy (SEDA-21, 320), although it can be entirely symptomless. Other cases have a hyperoptic refractory shift leading to blurred vision. Of 114 patients, 19 developed ocular symptoms and signs while taking suramin sodium for metastatic cancer of the prostate (21). Of these, 13 developed bilateral corneal epithelial whorl-like deposits, in 10 cases associated with a foreign body sensation and lacrimation. Symptoms in all cases resolved with topical lubricants. Three patients developed asymptomatic corneal deposits. Seven had blurred vision and had a mean hyperopic shift in refractive error of 1.13 (range 0.75–2.00) diopters, which persisted throughout treatment. None of these patients had a reduction in best-corrected visual acuity. At the very least, ophthalmological surveillance is necessary when suramin is used.

Suramin has been used in the treatment of AIDS and adrenal carcinoma, in both of which there was a high incidence of keratopathy (SED-13, 836).

Endocrine

The adrenal glands are sensitive to the toxic effects of suramin; both glucocorticoid and mineralocorticoid functions can be impaired at doses normally used, necessitating replacement therapy (22).

Hematologic

Occasional cases of hemolytic anemia and agranulocytosis have been reported in patients taking suramin (SED-13, 836). Severe neutropenia has been attributed to suramin in six cases (23). Plasma concentrations of platelet-derived growth factor-AB (PDGF-AB) and fibroblast growth factor basic correlated with the time-course of the neutropenia, which was unpredictable and occurred both during and after withdrawal of suramin. Plasma concentrations of suramin and G-CSF did not correlate

© 2006 Elsevier B.V. All rights reserved.

with the neutropenia, but there was a rapid response to G-CSF.

Blood coagulation can be altered by suramin, which causes accumulation of glycosaminoglycans, which have heparin-like properties (24). In patients who had received suramin intravenously for 2 weeks there was inhibition of factors V, VIII, IX, X, XI, and XII, while thrombin, prothrombin, and factor VII were unaffected (25). The inhibition of factor V was virtually irreversible, although the effect of suramin on the other factors is readily reversed by dilution.

In one patient with cancer, immunological complement-mediated destruction of circulating platelets was induced by suramin, demanding urgent treatment (26).

Gastrointestinal

Suramin can cause vomiting (27).

Liver

In three men with severe chronic active hepatitis, suramin treatment prolonged the prothrombin time in all three, caused a rise in bilirubin in two, and may have led to hemorrhage from esophageal varices in one patient and to hepatic encephalopathy in another (28).

Urinary tract

Suramin can cause acute renal failure (29,30).

Skin

Skin effects were prominent in patients treated with the high doses needed in malignancies, including morbilliform rashes in 67%, UV recall in 35%, urticaria in 18%, and keratotic papules in 12% (31). Late reactions include various skin eruptions, hyperesthesia and paresthesia (particularly affecting the palms and soles of the feet); erythema multiforme as part of a generalized skin reaction has been well documented in some individual cases (32) and toxic epidermal necrolysis has been reported (33).

A single dose of intravenous hydrocortisone 200 mg was protective against skin complications in another small group of patients.

Second-Generation Effects

Teratogenicity

Suramin has generally been avoided in pregnancy because its safety is uncertain; it is teratogenic in experimental animals (34–36).

Drug–Drug Interactions

Furosemide

In 26 patients treated with suramin for hormone-refractory prostate cancer, furosemide reduced the total body clearance of suramin by 36% (37). In view of the increased risk of severe adverse effects after treatment with higher plasma concentrations of suramin, it would be prudent to alter dosage schemes in patients treated with both suramin and furosemide.

Warfarin

In 13 men with advanced hormone-refractory prostate cancer the interaction between suramin and warfarin was studied because of potential worries that suramin may affect blood coagulation (38). After initial stabilization to an International Normalized Ratio (INR) of about 2.0 suramin plus hydrocortisone was started, after which warfarin requirements fell by 0.50–0.78 mg/day. The difference did not reach statistical significance. There were no bleeding problems. These results suggest that suramin and warfarin can be safely co-administered, provided that coagulation status is monitored.

Suriclone

General Information

Suriclone, a cyclopyrrolone analogue of zopiclone, has similar pharmacology to the benzodiazepines, binding close to the same site of the GABA receptor–chloride channel complex. It is effective as an anxiolytic and has the notable advantages of minimal sedation and cognitive toxicity, and milder withdrawal effects than those of diazepam or lorazepam (1). Its withdrawal from further development is a mystery.

Suxamethonium

See also Neuromuscular blocking drugs

General Information

Suxamethonium consists of two acetylcholine molecules linked together. Initially, it acts like acetylcholine by depolarizing the motor end-plate. However, unlike acetylcholine, which on dissociation from the receptor is immediately destroyed by acetylcholinesterase present in the neuromuscular junction, suxamethonium is hydrolysed by a (pseudo)cholinesterase present in the plasma but not at the neuromuscular junction. Most of an injected dose of suxamethonium is normally destroyed before it reaches the neuromuscular junction. If the activity of plasma cholinesterase in a particular patient is reduced, more of the suxamethonium reaches the neuromuscular junction and its action is proportionately prolonged. The molecules of suxamethonium that reach the acetylcholine receptor sites interact repeatedly with them, producing prolonged depolarization of the motor end-plate, which becomes surrounded by an electrically inactive zone. The end-result is flaccid paralysis. The action of suxamethonium is terminated by diffusion away from the neuromuscular junction. Hydrolysis results in choline and succinylmonocholine, which has a very weak competitive blocking action and is further slowly hydrolysed by plasma cholinesterase to choline and succinic acid.

About 10% of an intravenous dose of suxamethonium is excreted unchanged in the urine with a half-life of 1–2 minutes (1). The half-life is prolonged in patients with pseudocholinesterase deficiency or an abnormal pseudocholinesterase.

The usual adult dose of suxamethonium chloride is 0.5–1.5 mg/kg, which provides clinical relaxation for some 4–9 minutes. However, the normal response is highly variable and relaxation for up to 15 minutes can result from normal doses. Suxamethonium iodide has about two-thirds the potency of the chloride.

General adverse effects

Suxamethonium has several unwanted and potentially dangerous adverse effects. Generalized muscle fasciculations are associated, to a varying degree, with muscle pain, an acute rise in serum potassium, which under certain conditions can result in dysrhythmias and cardiac arrest, raised intraocular and intragastric pressures, and rhabdomyolysis and myoglobinuria with a rare risk of renal insufficiency. Bradycardia and junctional rhythms are relatively common. Normal doses can cause prolonged paralysis (on rare occasions for several hours) in patients with congenital or acquired plasma cholinesterase abnormality or deficiency.

Anaphylactoid reactions have been documented, and signs suggestive of histamine release are not uncommon. These are mostly mild such as flushing of the skin. Occasionally bronchospasm and/or hypotension can lead to circulatory arrest. Suxamethonium is the relaxant most commonly associated with the syndrome of malignant hyperthermia.

Tumor-inducing effects have not been reported.

Tachyphylaxis and resistance

Tachyphylaxis to the neuromuscular blocking effects of suxamethonium is associated with repeated doses. Prolonged exposure of the neuromuscular junction to suxamethonium (resulting from repeated bolus injections or during an infusion of the drug, or as a consequence of delayed hydrolysis subsequent to genetic or acquired plasma cholinesterase deficiency) is accompanied by the development of a phase II block, with non-depolarizing characteristics and a variably prolonged recovery. This depends on both the dose and the duration of exposure to suxamethonium. A cumulative dose of 3–4 mg/kg and an exposure time of 20–30 minutes can be sufficient during halothane anesthesia (2). However, there is wide variation between patients (3), and monitoring of neuromuscular transmission (train-of-four or post-tetanic count) is advisable with cumulative doses greater than 3 mg/kg.

Resistance to suxamethonium has been seen in von Recklinghausen's disease (4) and nemaline myopathy (5).

Organs and Systems

Cardiovascular

Bradycardia and other dysrhythmias are common (80% in some series) and occur after the first and subsequent injections of suxamethonium in infants and children. In adults, these effects are seen more commonly after second or later injections, particularly when the interval between the doses is 2–5 minutes. However, it has been suggested that bradycardia and asystole may now be more frequently seen than previously in adults after a single injection of suxamethonium, as a result of the increased use of fentanyl or the omission of atropine beforehand (6). Nodal rhythm and wandering pacemaker are frequent. The bradycardia is sometimes extreme (asystolic periods of 15–30 seconds duration have been reported). Usually these minor dysrhythmias revert to normal after a few minutes. Halothane can prolong their presence. The incidence of bradycardic asystole is not known, as atropine (the effective therapy) is usually quickly given.

Over the years cardiac arrest in apparently healthy children has occurred unexpectedly, most cases having been attributed to suxamethonium-induced hyperkalemia in patients with previously undetected myopathies (7–17). Several children have died of this complication. A diagnosis of Duchenne dystrophy or another unspecified progressive myopathy was made in 80% of the patients reported to the American Malignant Hyperthermia Registry who were subsequently tested for myopathies (18). Pointing out that hyperkalemia was detected in 72% of the patients from whom blood samples were taken, the authors suggested that calcium, sodium bicarbonate, hyperventilation, and glucose and insulin should be considered for the treatment of anesthesia-related cardiac arrest in children. This is certainly good advice. Standard resuscitative efforts in such cases are often ineffective, as severe hyperkalemia prevents the restoration of a stable cardiac rhythm. It should be stressed that resuscitative efforts should not be stopped until hyperkalemia has been aggressively treated. Excessive doses of adrenaline, calcium, sodium bicarbonate, and glucose/

© 2006 Elsevier B.V. All rights reserved.

insulin may be required. Peritoneal dialysis (19), hemodialysis (20), and cardiopulmonary bypass (21) have been used successfully to treat suxamethonium-induced hyperkalemic cardiac arrest.

Regarding the risk of this rare but life-threatening complication in children with undetected myopathy or muscular dystrophy, it has been suggested that the routine use of suxamethonium in pediatric anesthesia be abandoned. It should be reserved for emergency intubation or when immediate securing of the airway is necessary.

Tachycardia and a rise in blood pressure are occasionally seen. Other supraventricular and ventricular dysrhythmias are much less common. Ventricular fibrillation associated with suxamethonium is usually the result of hyperkalemia, but has also been reported in hypercalcemia (22) and is often seen in the course of malignant hyperthermia. Atropine, especially when given intravenously just before suxamethonium, is the most effective agent for the prevention of dysrhythmias. Hexafluorenium, D-tubocurarine, pancuronium, and other non-depolarizer blockers have also been reported as being effective in prevention. Severe hypotension can occur in patients with anaphylactoid reactions.

On theoretical grounds, suxamethonium, being akin to acetylcholine, should produce effects not only at the neuromuscular junction, but also at autonomic ganglia, at muscarinic receptors, and at postganglionic parasympathetic receptors. However, these other types of cholinoceptors are not so sensitive to its action. Nevertheless, stimulation of sympathetic ganglia has been invoked as being possibly responsible for the tachycardia and rise in blood pressure that sometimes occur transiently after its use. Likewise, stimulation of parasympathetic ganglia or direct stimulation of cardiac muscarinic receptors may be responsible for bradycardia. Differences in resting sympathetic and vagal tone have been said to account for the more frequent occurrence of tachycardia in "vagotonic" adults and bradycardia in "sympathotonic" children. The transient mild rise in blood pressure is possibly the result of the initial fasciculation, inducing an increase in venous return, which may also reflexly result in a slowing of the heart rate. Stimulation of afferent receptors in the carotid sinus has also been claimed to cause reflex bradycardia. Small doses (20–25 mg) are said to convert nodal to sinus rhythm, and larger doses to depress the sinoatrial node and so to cause bradycardia and nodal rhythm. Fasciculation probably produces an increase in afferent discharge from muscle spindles, which may account for the reported arousal pattern on the electroencephalogram; this in turn is postulated as a cause of tachycardia and a rise in blood pressure.

It has been hypothesized that suxamethonium modulates noradrenaline release from postganglionic sympathetic nerve terminals by presynaptic nicotine (+) and muscarinic (−) receptors on these nerve terminals (23). The refractory period of these presynaptic nicotinic receptors is postulated as being longer than that of the muscarinic receptors, which results in a net muscarinic effect (bradycardia) after a second injection of suxamethonium within 4–5 minutes of the first. To explain the occurrence of bradycardia after an initial injection of suxamethonium in young children, it is postulated that sympathetic nerve terminals mature later, so that muscarinic (bradycardic) effects are unopposed by noradrenaline secretion in younger patients.

Some controversial correspondence has followed the report of four cases of fatal cardiac arrest among 150 patients who were given suxamethonium by paramedics in out-of-hospital emergencies (24). The authors suggested that this might militate against suxamethonium-facilitated endotracheal intubation in this setting. Others, however, have argued that there was no evidence for a causal role of suxamethonium in those cases (25). Patients with critical conditions, such as respiratory failure requiring endotracheal intubation, may have a cardiac arrest without being given suxamethonium. Furthermore, undetected esophageal intubation was considered to be an alternative explanation of cardiac arrest. Indeed, when endotracheal intubation is attempted in these often dramatic and stressful circumstances by health-care providers who have no routine experience in this, there may be a high rate of esophageal intubation. In one study 18 of 108 patients who had been intubated by paramedics were found to have the tube in their esophagus (26). So the role of suxamethonium in the above report is questionable. On the other hand, suxamethonium is part of the protocol for emergency intubation in many centers worldwide and suxamethonium-associated cardiac arrest, apart from anecdotal instances, has not been reported to be a relevant problem (27). Suxamethonium may increase the success rate of emergency intubations while reducing the incidence of traumatic intubations (28). Therefore, rapid-sequence intubation with an induction agent such as etomidate and suxamethonium is probably still the technique of choice for airway management in emergencies. Whoever uses this technique must be aware of contraindications to suxamethonium and must have frequent practice in endotracheal intubation.

Respiratory

Apnea of variable duration results from muscle paralysis. The return of spontaneous respiration is normally rapid, but it may be delayed if phase II block develops. This will only be of consequence if it is not detected and spontaneous respiration is permitted before it is adequate. Exacerbation of muscle weakness in Duchenne muscular dystrophy after injection of suxamethonium can lead to delayed respiratory failure postoperatively (29).

Bronchospasm is a feature of about one-third of anaphylactoid reactions to suxamethonium and laryngeal edema can also occur, producing intubation problems (30) or respiratory distress and cyanosis after extubation (31).

Nervous system

An arousal pattern can occur on the electroencephalogram, possibly as a result of increased afferent traffic from muscle spindles. This has been speculated as the cause of perioperative dreaming in children in whom an intermittent-suxamethonium technique has been used during light anesthesia (SEDA-13, 102) (32). Suxamethonium must be used with caution in neurological disease and is better avoided altogether when there is a risk of a dangerous rise in serum potassium. A transient rise in intracranial pressure has been observed after injection of

© 2006 Elsevier B.V. All rights reserved.

suxamethonium, probably as a result of increased cerebral blood volume (33,34). This might be regarded as noxious in patients with intracranial lesions. However, when suxamethonium was given to patients with markedly raised intracranial pressure who received artificial ventilation on the intensive care unit, no adverse effects were observed (35).

Patients with severe head injuries require endotracheal intubation and controlled ventilation. Rapid-sequence intubation using an intravenous anesthetic plus suxamethonium is the standard technique for this, as the patient may have a full stomach. However, suxamethonium has been suggested by some to have a negative effect by causing increased intracranial pressure. The literature on this has been reviewed (36). The authors found only two studies that specifically addressed the effects of suxamethonium on intracranial pressure in patients with head injuries (35,37). In both studies suxamethonium was given to patients who were already being ventilated in the intensive care unit. There were no adverse effects of suxamethonium on intracranial pressure or cerebral perfusion pressure. However, when suxamethonium was given to lightly anesthetized patients undergoing resection of intracranial tumors, there were significant increases in intracranial pressure (38,39). These could be prevented by pretreatment with a small dose of a non-depolarizing muscle relaxant (39). The importance of an adequate level of anesthesia for intubating patients at risk of intracranial hypertension should be stressed. A lightly anesthetized patient will have large increases in intracranial pressure during intubation, no matter which muscle relaxant is used, because of a stress response that includes venous vasoconstriction and a massive increase in central venous pressure, resulting in impaired venous outflow from the cranium and thereby increased intracranial blood volume.

Neuromuscular function

Muscle pain

The depolarization of the motor end-plate receptors produced by suxamethonium (either directly or via repetitive discharge generation by the motor nerve terminals) (40) results in generalized and desynchronized contraction of skeletal muscle fibers. These fasciculations result in aching muscle pain (in up to 90% of patients), most commonly in the neck, pectoral region, shoulders, and back. The pain is most often experienced the day after operation and is worse in ambulatory patients. It is more common in women than in men. Children, elderly patients, athletes, and pregnant women (41) complain less often. Africans also seem to be less susceptible (42).

Mechanism

The cause of the pain is unknown, although there are many hypotheses such as damage to muscle (43,44) resulting from asynchronous contractions of adjacent muscle fibers (45), irreversible damage to muscle spindles (46), potassium flux (47), lactic acid (48), serotonin (49), calcium influx-associated damage to muscle spindles (50), and prostaglandins (51,52). The pain appears not to be related to the extent or intensity of the observed fasciculations.

Prevention

Various preventive measures have been recommended, but none is effective in all cases. One reliable method is the injection of a small non-paralysing dose of a non-depolarizing neuromuscular blocker 2–3 minutes before the injection of suxamethonium (53–57) in preventing fasciculations, but the patient must be carefully observed, since an unexpected degree of paralysis occasionally ensues (SEDA-6, 130).

Other measures, much disputed, include the prior injection of diazepam (58,59), procaine or lidocaine (57), vitamin C, suxamethonium itself (10 mg), and aspirin (51,52). The combined use of atracurium 0.05 mg/kg and lidocaine 1.5 mg/kg reduced the incidence of postoperative myalgia to 5% compared with 75% in controls (57). Thiopental, injected immediately beforehand, is also said to have some effect, as is giving the suxamethonium slowly.

Myotonic reactions

Rarely, on injecting suxamethonium, contracture, instead of the usual relaxation, of skeletal muscles ensues. In denervated muscles the postulated mechanism is direct activation of the contractile mechanism by suxamethonium because of the widespread chemosensitivity of the muscle fiber membranes.

Paradoxical contracture is most often associated with myotonia dystrophica and myotonia congenita. A myotonic reaction has also been reported in a patient with hyperkalemic periodic paralysis (60). Suxamethonium is therefore contraindicated in these conditions, even though normal responses are sometimes seen. Contracture has also been reported as a result of denervation in Pancoast's syndrome and after plexus injuries and, rarely, in patients with amyotrophic lateral sclerosis or multiple sclerosis (61–63).

Failure of relaxation and generalized muscular rigidity after suxamethonium is sometimes also seen in patients who develop the syndrome of malignant hyperthermia. Isolated masseter muscle rigidity can occur after the administration of suxamethonium, being reported particularly in children given both suxamethonium and halothane. Most experts define masseter muscle rigidity as a major increase in masseter muscle tone severe enough to make mouth opening impossible and to prevent laryngoscopy and endotracheal intubation. Referring to the high incidence of positive results with halothane-caffeine contracture testing, some believe that up to 50% of patients with masseter muscle rigidity are susceptible to malignant hyperthermia (64–67). Others are not convinced of such a high degree of correlation (68) and hold that divers other factors are responsible for the majority of cases (69–71). While severe masseter muscle rigidity is rare (72), smaller increases in jaw tension of about 60 seconds duration occur almost invariably after suxamethonium administration (73,74). Such increases in masseter muscle tone can be attenuated by using propofol as an induction agent and by precurarization, that is pretreatment with a small dose of a non-depolarizing muscle relaxant (74) This might be important during rapid sequence induction of anesthesia.

A hypothesis has been offered to explain muscle hyperexcitability in response to suxamethonium (75). Voltage clamp experiments on alpha subunits of human muscle

© 2006 Elsevier B.V. All rights reserved.

sodium channels, heterologously expressed in HEK 293 cells, showed that succinic acid, a metabolite of suxamethonium, shifted steady-state activation in the direction of more negative membrane potentials. The EC_{50} for this effect was 0.39 mmol/l. This might lead to muscle hyperexcitability in vivo. Clearly, it is not currently possible to claim any direct clinical implications of this study, but two facts should be considered. After the administration of a routine dose of suxamethonium, blood concentrations of 0.17 mmol/l have been reported (76) Thus, equimolar concentrations of succinic acid are to be expected, given that cholinesterase activity is not impaired. Moreover, succinic acid is a citric acid cycle intermediate, ubiquitous in body tissues. In conditions of ischemia and hypoxia, tissue and serum concentrations of succinic acid increase up to 0.2 mmol/l (77,78). Thus, the administration of suxamethonium to a hypoxic patient may well lead to succinic acid concentrations that affect muscle sodium channel excitability in vitro.

Rhabdomyolysis

Myoglobinuria (79) and raised serum creatine kinase activity (44) have been reported after suxamethonium and appear to be evidence of muscle damage, probably resulting from fasciculation. Repeated bolus doses of suxamethonium result in higher plasma myoglobin concentrations (80) and creatine kinase activities (44). Myoglobinemia seems to be much more common in children than in adults (SEDA-10, 107) (SEDA-11, 121) (81) and is more marked when halothane is used (82). On occasion, myoglobinuria results in renal insufficiency (83–88).

There is an association between (latent) muscular dystrophy (usually of the Duchenne or Becker type) and the production of rhabdomyolysis by suxamethonium (84,85,89,90). Suxamethonium can cause excessive muscle damage in these patients, as manifested not only by severe myoglobinemia and raised serum creatine kinase activity but also by acute exacerbation of muscle weakness postoperatively (SEDA-11, 121) (7,29,84,91,92). Massive potassium release can result in hyperkalemic cardiac arrest. Such patients may also develop features suggestive of the syndrome of malignant hyperthermia (93,94). Suxamethonium should not be used in patients with Duchenne muscular dystrophy or who have a family history suspect for the condition.

Prolonged paralysis

Prolonged paralysis can result from idiosyncrasy, overdose, or reduced or abnormal plasma cholinesterase activity. There are geographical and racial differences in sensitivity to suxamethonium (SEDA-6, 129) (95,96); some of these differences arise from dietary and other environmental factors and others result from variations in plasma cholinesterase genotypes. Genotypically normal patients may be paralysed by a usual (1 mg/kg) dose of suxamethonium for as short a time as 2 minutes or (rarely) as long as 20 minutes, and the duration in general inversely reflects plasma cholinesterase activity (97).

Prolonged paralysis after suxamethonium has also been reported in von Recklinghausen's disease (98), but resistance to suxamethonium has also been seen (4).

Sensory systems

Shortly after the introduction of suxamethonium it was noted that it can increase intraocular pressure (99), an observation that has subsequently been confirmed in several other studies (100–114). The increase in intraocular pressure occurs promptly after intravenous injection of suxamethonium, peaks at 1–2 minutes, and returns to baseline after 6–10 minutes (102,109). The mean increase is about 4–8 mmHg, with a range of 5–15 mmHg.

Mechanism

Several mechanisms have been suggested to explain the effect of suxamethonium on intraocular pressure. One of the first ideas was to blame fasciculation and contraction of the extraocular muscles of the eye (115). However, a study in humans undergoing enucleation showed that suxamethonium produces an increase in intraocular pressure even after detachment of the extraocular muscles (116). So activity of the extraocular muscles may increase intraocular pressure, but there must be other factors. Observing that suxamethonium administration was almost invariably followed by retraction of the eyeball, some investigators suggested increased tone of intraorbital smooth muscles as a mechanism (117), but in fact there is very little intraorbital extraocular smooth muscle in humans. This idea has therefore not been widely accepted. There appears to be some effect of suxamethonium on the intraocular smooth muscles, as indicated by the observation that there is a rapid rise in anterior chamber thickness and a diminution of lens thickness after suxamethonium administration (118). These changes could be explained by a relaxing effect of suxamethonium on the ciliary muscle, which would in turn result in increased aqueous humor outflow resistance and a consequent increase in intraocular pressure (116). However, this mechanism would not be expected to produce pressure increases of the magnitude observed after suxamethonium injection. A vasodilatory effect on conjunctival vessels has been observed (119), and this has been interpreted as indirect evidence of choroidal vasodilatation (120). On the other hand, an increase in ocular blood flow has not been detected after suxamethonium administration but after subsequent endotracheal intubation (121). In conclusion, there is no satisfactory explanation for the suxamethonium-associated increase in intraocular pressure, but increased tone of extraocular muscles, increased aqueous humor outflow resistance, and increased choroidal blood volume are probably important elements.

Prevention

Many efforts have been made to find a technique to prevent the suxamethonium-associated increase in intraocular pressure. Some attenuation of the pressure response has been demonstrated with defasciculation doses of non-depolarizing muscle relaxants (122), but this could not be reproduced in subsequent studies (100–102,123). The same is true for self-taming, that is

© 2006 Elsevier B.V. All rights reserved.

pretreatment with a small dose of suxamethonium (124,125). Other drugs that have been used with some effect are diazepam (105,126,127), lidocaine (107,114,121,128,129), glyceryl trinitrate (130), nifedipine (131), and beta-blockers (132), but none of these completely prevented increases in intraocular pressure.

The most effective method of attenuating the intraocular pressure response to suxamethonium plus endotracheal intubation is to provide a deep level of anesthesia by using intravenous anesthetics and opiates (133–137). In 60 patients who received thiopental/suxamethonium, propofol/suxamethonium, or propofol/alfentanil/suxamethonium for anesthesia induction, the increase in intraocular pressure after suxamethonium plus endotracheal intubation was completely blocked by propofol plus alfentanil (137). Combining an intravenous anesthetic with a rapid-onset opioid, such as alfentanil, prevents increases in intraocular pressure (137). When the ultra-short-acting opioid remifentanil (1 microgram/kg) was given in combination with propofol (2 mg/kg) and suxamethonium (1 mg/kg) for endotracheal intubation during induction of anesthesia the highest intraocular pressure recorded was 18 mmHg, whereas peak values up to 35 mmHg occurred in the control group without remifentanil (138).

Implications for surgery

A particular problem is the clinical impact of a rise in intraocular pressure during operation in cases of penetrating eye injury, which is usually performed as an emergency, when it is often not clear whether the patient has eaten recently. While it is commonly accepted that anesthesia in these patients should be induced in a rapid-sequence technique, that is by giving an hypnotic and suxamethonium followed rapidly by endotracheal intubation, in order to reduce the risk of pulmonary aspiration of gastric contents, there is considerable controversy about what to do in the case of penetrating eye injuries. As suxamethonium provokes an increase in intraocular pressure in intact eyes, there is concern that its use could result in loss of intraocular contents and damage to the eye if the eyeball is opened. This, however, has not hitherto been observed, either in clinical studies or in animal experiments (139–141). Several experts regard suxamethonium as being appropriate for rapid-sequence intubation in patients with penetrating eye injuries (142–146).

Similarly, there are difficulties in strabismus surgery, which is commonly performed in children, with the goal of correcting the optical axes of the eyes by shortening certain extraocular muscles. The "forced duction test" can be used to differentiate between a paretic muscle and a restrictive force that prevents ocular movement. Suxamethonium, by increasing the tone of the extraocular muscles, can produce considerable alterations in the results of that test, sometimes lasting as long as 20 minutes (147). Suxamethonium should therefore be avoided in strabismus surgery. Furthermore, in a retrospective study there was an increased incidence of masseter muscle rigidity in patients with strabismus (148). A positive halothane-caffeine contracture test was subsequently found in 25% of the adults and 50% of the children in whom masseter rigidity had occurred (64–67). In line with that, there were more patients with strabismus in a group of patients who had experienced an episode of malignant hyperthermia than in the general surgical population in the USA (149). Based on these observations, it has been assumed that patients with strabismus might have an increased risk of malignant hyperthermia (146,150), which has been regarded as another reason for avoiding suxamethonium in strabismus surgery (151). On the other hand, the incidence of strabismus was not different in two groups of patients, with or without a positive halothane–caffeine contracture test (152). In conclusion, there are some indirect clues to an increased risk of malignant hyperthermia in patients with strabismus, but for the time being there is not enough evidence to contraindicate suxamethonium. However, there are reasons for reserving its use for special circumstances, such as rapid-sequence induction in patients with an increased risk of pulmonary aspiration. First, the surgical procedure can be impaired by increased tone in the extraocular muscles. Secondly, patients with strabismus may have a higher risk of suxamethonium-associated masseter muscle rigidity. Thirdly, most patients with strabismus are children, in whom the suxamethonium is best avoided (SEDA-19, 139).

Electrolyte balance

An immediate rise in serum potassium occurs after the administration of suxamethonium. The rise is normally small, 0.5 mmol/l or less (4). However, in some cases it can be larger, and cases of cardiac arrest associated with hyperkalemia have been reported in critically ill patients after prolonged immobilization (153–161). Cardiac arrest also occurred in a patient with wound botulism (162).

- A 28-year-old previously healthy man was admitted with a 4-week history of progressive symmetrical muscle weakness that had started in his neck and descended to both arms and legs. He also complained of diplopia, dysphonia, and dysphagia. On the day of admission, he noted difficulty in breathing. He had a history of intermittent diamorphine abuse, and had been injecting "black tar" heroin subcutaneously for the past month. Several hours after admission he had to be intubated, and was given etomidate 20 mg plus suxamethonium 80 mg. Within 60 seconds he developed a wide complex tachycardia, which degenerated into ventricular fibrillation refractory to electrical countershock and standard resuscitative measures. His serum potassium concentration 10–12 minutes after the onset of cardiocirculatory arrest was 6.8 mmol/l, having been 4.7 mmol/l several hours before. Calcium chloride, sodium bicarbonate, and glucose/insulin were given, and 25 minutes after the arrest began the heart rhythm converted to sinus tachycardia. The electrocardiogram subsequently showed no structural abnormalities. A serological test taken on the day of admission was positive for botulinum toxin type A. He eventually survived without any residual deficits and was discharged from hospital after 63 days.

The authors suggested that suxamethonium should be avoided in patients with suspected botulism and in patients with muscle weakness of unknown origin. Wound botulism had been observed before in drug users

© 2006 Elsevier B.V. All rights reserved.

who have injected black tar heroin (163). Botulinum toxin inhibits presynaptic acetylcholine release, resulting in muscle weakness. In animals chronic administration of botulinum toxin caused an increase in the number of postsynaptic acetylcholine receptors with distribution across the muscle surface (164) and postsynaptic acetylcholine receptors converted into the immature type with prolonged channel opening times (165). With huge numbers of muscle fibers altered in that way, suxamethonium may cause hyperkalemic cardiac arrest by producing massive potassium efflux.

One major concern for anesthetists is suxamethonium-associated hyperkalemia in apparently fit patients without obvious risk factors. Life-threatening hyperkalemia occurred in three Japanese women who underwent cesarean section (166).

- Cardiac arrest occurred in a 34-year-old woman who was given suxamethonium 120 mg. She had been immobilized and treated with high-dose magnesium sulfate and ritodrine for 5 weeks before the event because of preterm uterine contractions. Her preoperative creatine kinase activity was 4050 IU/l. After rapid-sequence induction of anesthesia and injection of suxamethonium she became cyanotic and pulseless and the electrocardiogram showed ventricular fibrillation. The serum potassium concentration after 25 minutes of cardiopulmonary resuscitation, which included the administration of adrenaline, sodium bicarbonate, and calcium chloride, was 5.7 mmol/l. During resuscitation vaginal vacuum delivery was performed. Finally, she was defibrillated successfully and made a full recovery.
- Two other patients had been immobilized and treated with magnesium and ritodrine for several weeks. Preoperative creatine kinase activities were 2120 IU/l and 630 IU/l. In both cases, serum potassium increased by 2.3 mmol/l within 2–3 minutes after suxamethonium injection (from 4.0 to 6.3 mmol/l and from 4.9 to 7.2 mmol/l). This was accompanied by tall peaked T waves and a short period of ventricular tachycardia in one case and by tall peaked T waves and widened QRS complexes in the other.

The authors suggested that the combined effects of immobilization and prolonged magnesium administration might have resulted in a denervation-like state of large groups of skeletal muscles. The drawback of that explanation is that an awake and healthy person will always move normally even when confined to bed. As long as muscle cells receive physiological stimulation via the neuromuscular junction in patients without muscle weakness, denervation-like changes should not occur to a significant extent. In addition, denervation alone is not known to be associated with an increase in plasma creatine kinase activity, a strong indicator of muscle cell damage, which was found in all the patients reported here. Unfortunately, the authors did not document creatine kinase activities or myoglobin concentrations after suxamethonium, which might have given some idea about additional suxamethonium-induced rhabdomyolysis.

It can be assumed that these three patients had some form of myopathy, either acquired during their previous course or pre-existing. It would have been interesting to know if they had any clinical symptoms, such as muscle pain or weakness. Pre-existing myopathy would be unlikely if plasma creatine kinase activities had been normal before. However, this information was not given in the paper. On the other hand, myopathy could have been acquired during the course of pregnancy and hospital treatment. Various drugs and toxins have been associated with myopathies (167). Hypermagnesemia can produce muscle weakness but magnesium sulfate has not so far been reported to cause myopathy. Therefore, the role of ritodrine in these cases should be questioned. This selective beta$_2$-adrenoceptor agonist has previously been linked to myopathic changes in a patient treated for preterm labor (168). In addition, glucocorticoid treatment, probably used to promote fetal lung development, might be a contributory factor. Long-term glucocorticoid treatment is associated with myopathic changes (167).

In the end, the exact mechanism of suxamethonium-associated hyperkalemia in these cases cannot be determined. Given the huge numbers of patients who receive suxamethonium during rapid-sequence induction of anesthesia for cesarean section, even after some time of treatment for preterm labor without adverse effects, it would be overzealous to call for a restricted use of suxamethonium in these patients. Rather, this report is in support of preoperative screening of plasma creatine kinase activity. Probably suxamethonium should not be used in patients with raised plasma creatine kinase activity. It is a good idea to check creatine kinase activity preoperatively in women due to undergo cesarean section after prolonged immobilization and pretreatment with magnesium sulfate and a beta$_2$-adrenoceptor agonist such as ritodrine.

Mechanism

The underlying mechanisms of and mortality from suxamethonium-associated hyperkalemic cardiac arrest have been reviewed (169). The rise in serum potassium probably results from repetitive opening of receptor-linked ion channels and suxamethonium-induced fasciculation, although it can occur in the absence of visible fasciculation. Muscle injury with excessive leakage of potassium is postulated as a cause of the hyperkalemia. Reuptake of potassium into muscle cells may also be hindered. It has been shown that denervation results in a spread of the normally small receptor area of the motor end-plate over the entire muscle fiber membrane, so that eventually the whole membrane surface is directly excitable by depolarizing agents such as acetylcholine or suxamethonium (170). The immature extrajunctional receptor-linked ion channels so formed remain open for a longer time than those at normal motor end-plates. Depolarization by suxamethonium thereby results in an excessive efflux of potassium from ion channels spread over the entire muscle fiber membrane and not just, as normally occurs, from the circumscribed motor end-plate region (171–173). Prolonged immobilization can also result in extrajunctional receptor spread (174) and a greater increase in serum potassium than usual after suxamethonium.

Rhabdomyolysis is also a mechanism for hyperkalemia, and it has been said that almost all reported cases of hyperkalemic cardiac arrest considered to have resulted from rhabdomyolysis occurred in children and

© 2006 Elsevier B.V. All rights reserved.

adolescents with underlying muscular dystrophies (169). Hyperkalemia during rapid acute rhabdomyolysis is more likely to result in unsuccessful resuscitation than hyperkalemia due to the potassium efflux that results from upregulation of acetylcholine receptors.

Susceptibility factors

The rise in serum potassium can be prolonged (SEDA-11, 122) (175) and exaggerated (SEDA-10, 108) (176) in patients taking beta-blockers. In renal insufficiency the rise after suxamethonium is similar to that in healthy patients (177) and is only dangerous if the serum potassium is already high (above 5.5 mmol/l). However, several conditions can lead to a massive rise in serum potassium, resulting in ventricular fibrillation and cardiac arrest. These include burns (178,179), massive trauma (180,181), and neurological diseases or injuries, especially when denervation is a feature, such as spinal cord injury (182), hemiplegia, multiple sclerosis, or muscular dystrophy (183), peripheral nerve injuries (62,184) and polyneuropathy (185,186). Hyperkalemia has also been reported after suxamethonium in patients with tetanus (187), encephalitis (188), Parkinson's disease (SEDA-6, 129) (189), muscle wasting secondary to chronic arterial insufficiency (190), metastatic embryonal rhabdomyosarcoma (SEDA-14, 114) (191), ruptured cerebral aneurysms (SEDA-5, 134) (192), hyperparathyroidism (22), and in patients with severe and long-lasting sepsis (193,194).

There are times when patients are most susceptible to hyperkalemia. In patients with burns or trauma this is generally between 10 and 60 days after the injury, or longer if there is persistent infection and delayed healing. In neurological diseases or injuries the danger period is usually from 3 weeks to 6 months after onset. However, in some cases, such as patients with transverse spinal lesions and tetraplegia, dangerous hyperkalemia has been reported as early as 24–48 hours after the injury, and likewise severe potassium rises have been reported more than 6 months after injury or onset of disease, particularly in patients with progressive lesions (SEDA-6, 128) (183).

Extrajunctional spread of acetylcholine receptors and expression of the immature type of these receptors with prolonged channel opening times have been shown after burns, which may be why there can be massive potassium release after suxamethonium administration. As the increase in acetylcholine receptor density on the muscle surface takes some time to develop, there should be an interval after the accident during which suxamethonium can be safely given. However, the length of this interval is controversial. Referring to a lack of reports of hyperkalemic complications during the first week after the injury, it has been suggested that suxamethonium can be given safely during the first 6–7 days after major thermal injury (195). However, based on the results of animal experiments, suxamethonium might be safe for up to 48 hours after the injury only (195).

The use of suxamethonium in intensive care units has been critically reviewed (196). Several cases of hyperkalemic cardiac arrest after suxamethonium have occurred in intensive care patients (153,155–157,159,160). Of particular concern is the risk of hyperkalemic cardiac arrest when suxamethonium is given to critically ill patients after a period of immobilization (154). The exact mechanism is not known, but extrajunctional spread of acetylcholine receptors is believed to play a major role. It is strongly recommended that suxamethonium should not be given to patients who have been immobilized in the intensive care unit for more than a few days.

In yet another report of suxamethonium-induced fatal hyperkalemic cardiac arrest in an intensive care unit it was assumed that severe mucositis after cancer chemotherapy might have contributed to the hyperkalemic response (197).

- A 37-year-old woman with acute myelogenous leukemia was admitted to an intensive care unit (ICU) with mental status changes and progressive dyspnea due to pneumonia. Intubation was performed before ICU admission using a sedative without neuromuscular blockade. She had received chemotherapy with cytarabine, daunorubicin, and intrathecal methotrexate for brain metastases. After chemotherapy and before ICU admission her course was complicated by continuous neutropenic fevers and by painful mucositis causing dysphagia and bleeding. After 10 days of ventilator treatment in the ICU and treatment with ceftazidime, gentamicin, metronidazole, vancomycin, amphotericin, and aciclovir, her condition improved, allowing withdrawal of ventilator support and extubation. A few hours later, however, she gradually developed severe respiratory distress and required reintubation. The serum potassium concentration before intubation was 4.3 mmol/l. For endotracheal intubation she received intravenous etomidate 14 mg and suxamethonium 100 mg. Immediately after intubation she developed a broad-complex tachycardia and her blood pressure could not be measured. Chest compression and advanced cardiac life support were started. Her serum potassium concentration was 13.1 mmol/l. Intravenous calcium chloride, sodium bicarbonate, and insulin/glucose were therefore given. The serum potassium fell to 6.5 mmol/l but rose to 7.4 mmol/l 15 minutes later, despite additional antihyperkalemic treatment. She finally died.

Despite this having been a case of suxamethonium-induced hyperkalemic cardiac arrest after several days of ventilator treatment on the intensive care unit, the authors did not believe that upregulation and extrajunctional spread of acetylcholine receptors were the underlying mechanisms. They implied that mobilization and daily physiotherapy would have both prevented these typical denervation-like changes and ruled out a neuromuscular disorder. Rather they suggested that severe generalized mucositis had resulted in a state that they compared to an "internal burns injury." However, these speculations were not substantiated by additional data. In particular, they gave no information on the presuxamethonium neuromuscular state of the patient. Some form of polyneuropathy and/or myopathy could have been present, and this was not ruled out by the fact that the patient could breathe spontaneously and sit in a chair. While it is true that severe mucositis represents a state of widespread cellular damage similar to severe burn injuries, it is not clear why this itself should result in hyperkalemia after suxamethonium. To our knowledge suxamethonium only has effects on excitable cells. Even in patients with severe thermal injuries, no case of hyperkalemia after suxamethonium has been

© 2006 Elsevier B.V. All rights reserved.

reported within the first 48 hours after the accident, and suxamethonium-induced hyperkalemia in burned patients is believed to result from upregulation of acetylcholine receptors, owing to thermal damage of nerve fibers (structural denervation) and immobilization (functional denervation) (170). Apart from immobilization due to the severity of the illness it is very unlikely that mucositis should have similar effects. Mucositis itself should therefore not be regarded as a risk factor for suxamethonium-associated hyperkalemia.

In a survey of intensive care units in the UK, more than two-thirds of the respondents would have chosen suxamethonium in a clinical scenario requiring re-intubation in a patient with abdominal sepsis and weaning failure after 20 days of ICU stay (198). The authors concluded that there is a lack of appreciation of the dangers of suxamethonium in critically ill patients in intensive care units.

The use of suxamethonium in patients with renal insufficiency was controversial in the 1970s, after some cases of hyperkalemic cardiac arrest in such patients. As several studies did not show exaggerated potassium release, suxamethonium is now considered safe for patients with renal insufficiency, if preoperative hyperkalemia is excluded. The observation of some cases of postoperative hyperkalemia recently prompted a review of the literature (199). The authors found sufficient evidence to support the current consensus: suxamethonium can be used in patients with renal insufficiency, but it should not be given if there is pre-existing hyperkalemia; doses of suxamethonium should not be given repeatedly, as this can result in sinus bradycardia.

Suxamethonium is said to be contraindicated in patients with hyperkalemia (that is a serum potassium concentration over 5.5 mmol/l). This, however, has been questioned (200). In an analysis of their anesthetic database, the authors identified 38 patients with a preoperative serum potassium concentration over 5.5 mmol/l who subsequently received suxamethonium. In no case were dysrhythmias or any complications documented and there were no deaths. While they admitted that minor complications might not have found their way into the database, the authors felt that major problems caused by suxamethonium in these patients were unlikely. They suggested that the use of suxamethonium in patients with serum potassium concentrations above 5.5 mmol/l may be acceptable when other muscle relaxants have inappropriate profiles. As their analysis included only a few patients with serum potassium concentrations above 6.0 mmol/l they recommended the use of antihyperkalemic treatment before suxamethonium in these patients.

Prevention

It has been claimed that non-depolarizing drugs given before suxamethonium attenuate the rise in potassium, but this has been repeatedly shown to be unreliable. It seems advisable to avoid the use of suxamethonium completely in such patients. This subject has been extensively reviewed (201,202).

Gastrointestinal

Suxamethonium can increase intragastric pressure. This is probably a result of fasciculation of the abdominal muscles (203), although a vagal effect can also contribute. The rise is highly variable, ranging from zero to more than 85 cm H_2O according to many different investigations (204–207). The intragastric pressure at which the lower esophageal sphincter opens is also variable, with a mean of about 28 cm H_2O, depending partly on the angle between the esophagus and the cardia of the stomach (208,209). There is therefore a danger that the suxamethonium-induced rise in intragastric pressure may produce incompetence of the lower esophageal sphincter and result in regurgitation. This risk is likely to be increased in patients with hiatus hernia, gastric and intestinal dilatation, ascites, and intra-abdominal tumors. Pregnant patients are especially susceptible, as the tonus of the lower esophageal sphincter can also be reduced in pregnancy. It has been suggested, however, that suxamethonium causes, either by a direct action on the lower esophageal sphincter or indirectly through a pinch action of the diaphragm, increased resistance to opening of the lower esophagus, which counteracts the increased intragastric pressure (210). Attenuating fasciculation by giving small doses of non-depolarizing blockers reduces the rise in gastric pressure (203,206,211).

Urinary tract

In severe renal disease, suxamethonium should only be given if the serum potassium is below 5.5 mmol/l. The excretion of neostigmine and pyridostigmine can be impaired in renal insufficiency, and this has been reported to have resulted in prolongation of the action of suxamethonium given some hours later (212).

Myoglobinuria resulting from suxamethonium administration can cause acute renal insufficiency (83,84,213).

Musculoskeletal

The problem of suxamethonium-associated postoperative myalgia has been reviewed (214). Key statements are:

- there is no correlation between the severity of muscle fasciculation, changes in serum creatine phosphokinase or serum potassium, and postoperative myalgia;
- although not proven, mechanical muscle damage is still assumed to be an underlying mechanism;
- several classes of pretreatment drugs reduce the incidence and severity of myalgia; combining two agents may be the most useful method;
- so far, the lowest incidence of post-suxamethonium myalgia has been reported when a small dose of a non-depolarizing neuromuscular blocking agent was given together with lidocaine as pretreatment.

In addition, there was a reduced incidence and intensity of post-suxamethonium myalgia when anesthesia had been maintained by propofol infusion compared with isoflurane (215).

Immunologic

From the results of intradermal injections, suxamethonium has only 1% of the histamine-releasing activity of D-tubocurarine (216). However, through the years there have been many reports of reactions, varying from flushing and urticaria to bronchospasm (217,218) and severe

© 2006 Elsevier B.V. All rights reserved.

shock (219–222). That suxamethonium was responsible was suggested in some cases by the fact that the patients reacted on different occasions with raised plasma histamine and catecholamine concentrations (223–225). The association was confirmed in other cases by repeatedly injecting the drug, thereby producing bronchospasm several times in the course of the one anesthetic (226,227). Skin testing has also yielded confirmation, although this can be dangerous (220). Analysis of large series of patients (228–233) who have had severe anaphylactoid reactions during anesthesia, using more sophisticated laboratory and immunological investigations in addition to intradermal skin tests, suggests that suxamethonium may be much more commonly associated with such reactions than was previously believed. In 18 cases (234) cardiovascular collapse was the predominant feature in 72% and bronchospasm in 33%; cardiac arrest occurred in five patients. In addition, two reports (235,236) of anaphylactic reactions involving both thiopental and suxamethonium have raised the question of "aggregate"-induced reactions (235) occurring when drugs are given in such a way that they can interact in the injection system.

Body temperature

The syndrome of malignant hyperthermia can be triggered by suxamethonium. Mortality is more than 60% in untreated patients. This syndrome is reported as occurring once in every 15 000–150 000 anesthetics. It may be more common in the Japanese. However, there are also abortive forms of malignant hyperthermia, and many of the typical signs may be produced by other conditions, so that it is difficult to ascertain the precise incidence. Autosomal dominant inheritance, with reduced penetrance and variable expressivity, is the proposed genetic basis. The cause is unknown, but it is thought to be associated with a rise in free ionized myoplasmic calcium, possibly owing to a failure of the sarcoplasmic reticulum to bind calcium. As a result, aerobic and anaerobic metabolism are increased, resulting in the typical features of the syndrome. Halothane and suxamethonium are the most frequent triggers, although almost all of the inhalational anesthetic agents have been incriminated. While other muscle relaxants (pancuronium, D-tubocurarine) have been suggested as triggers in a few cases, and many other drugs used in anesthetized patients also, convincing evidence is lacking. It has been suggested that stress plays a role in the development of malignant hyperthermia (237).

Dantrolene (238,239) is the agent of choice for treatment of malignant hyperthermia and greatly reduces the mortality to under 10% if given in time (240) together with general supportive measures. Dantrolene itself has adverse effects that are mostly minor in nature, such as nausea and vomiting, when it is used acutely. However, a report has suggested that it may have contributed to uterine atony, with resulting excessive hemorrhage when given prophylactically after a cesarean section (241), and muscle weakness associated with its oral prophylactic use in a patient with compromised respiratory function is reported to have exacerbated postoperative respiratory depression to such an extent that artificial ventilation was required (SEDA-14, 114) (242). The combination with calcium channel blockers, such as verapamil, may result in severe cardiovascular depression and hyperkalemia (SEDA-12, 113) (243,244), so that extreme care is required.

Second-Generation Effects

Pregnancy

Maternal doses of suxamethonium up to 200 mg have been reported as not resulting in detectable concentrations in neonates. Very large bolus doses (300–500 mg) have produced umbilical vein concentrations up to 2 micrograms/ml, but the neonates showed no adverse effects (245,246). Extreme reduction in plasma cholinesterase activity, either caused by organophosphorus poisoning (247) or genetically determined (SEDA-15, 123) (248,249), has resulted in weakness and respiratory depression in neonates after normal or small (247) maternal doses.

Susceptibility Factors

Genetic factors

Plasma cholinesterase deficiency can be hereditary or acquired. The hereditary form is believed to account for two-thirds of suxamethonium-sensitive patients. Genetically determined plasma cholinesterase variants hydrolyse suxamethonium much more slowly. About 96% of the population are homozygotes for the normal "typical" gene, one in 25 are heterozygotes ("typical"/"atypical") and have a slightly prolonged (about 2–4 times normal) response to suxamethonium, and one in 2000–3000 are homozygotes for the "atypical" gene and have a markedly prolonged response (2–3 hours). The "silent" gene is much rarer and homozygotes (about 0.0006% of the population) have virtually no plasma cholinesterase activity; in them complete paralysis after suxamethonium lasts many hours.

Acquired plasma cholinesterase deficiency is clinically less important, since paralysis from suxamethonium seldom lasts for more than 20–30 minutes. However, this can be avoided by not using suxamethonium in patients known to be at risk. Clinically important prolongation of suxamethonium-paralysis is only to be expected, with the exception of some drug-induced effects, in patients with more than one cause for a reduction in pseudocholinesterase activity. In malnutrition and liver disease (250,251) the synthesis of plasma cholinesterase in the liver is reduced. Neonates have about 50% of normal adult plasma cholinesterase activity. In pregnancy there is a rapid fall in plasma cholinesterase activity of about 25% in the first trimester, which only returns to normal some 6–8 weeks postpartum (252–254). Occasionally much larger falls occur. The lowest average values have been reported during the first week of the puerperium (SEDA-5, 135) (255,256). Similar changes have been reported in gestational trophoblastic disease (hydatidiform mole) (257). Cancer is sometimes associated with lower plasma cholinesterase activity (SEDA-5, 136) (258). There is also a report of multiple esterase

© 2006 Elsevier B.V. All rights reserved.

deficiencies in Hodgkin's disease (259). Plasma cholinesterase activity has also been reported to be reduced by up to 70–80% in patients with renal disease and burns. Plasmapheresis (SEDA-5, 135) (260,261) removes cholinesterase, along with other proteins, from the plasma.

Numerous drugs also reduce plasma cholinesterase synthesis or activity, for example estrogens, glucocorticoids, phenelzine, organophosphorus compounds (such as ecothiopate eye-drops, insecticides), carbamates (insecticides, bambuterol), cytotoxic drugs, metoclopramide, the ester-type local anesthetic drugs, and pancuronium. Anticholinesterases also prolong the action of suxamethonium. Several reviews are recommended for detailed information about plasma cholinesterase and its relevance in anesthetic practice (96,262–264).

Hepatic disease

In severe liver dysfunction the synthesis of plasma cholinesterase may be reduced to such an extent that the action of suxamethonium can be prolonged (SED-8, 282). This is usually not more than 2 or 3 times the normal duration.

Other features of the patient

Suxamethonium-induced fasciculation or increased muscle tone can be dangerous in patients with fractures or dislocations (especially vertebral, when the drug is relatively contraindicated), in patients with open-eye injuries or after the eyeball is opened surgically, when an increase in abdominal pressure must be avoided (pheochromocytoma, aortic aneurysm, full stomach, ileus), and in patients in whom a rise in arterial pressure may be catastrophic (cerebral aneurysm, raised intracranial pressure). Prolonged paralysis, occasionally lasting hours, is a risk if the patient is, or has been, taking certain drugs.

Pregnancy

In pregnancy the risk of regurgitation has to be weighed against the advantage of rapid intubation. The use of "precurarization" with small doses of non-depolarizing drugs may reduce the intensity of the fasciculation, but is by no means reliable. If possible, relaxation is better achieved by using a non-depolarizing agent alone.

Muscle disorders

Patients with muscle disorders (dystrophia myotonica, myotonia congenita, myasthenia gravis, and hyperkalemic periodic paralysis) tend to react unpredictably to suxamethonium. In myasthenia gravis, small doses of suxamethonium may be tried and the resulting effect monitored. In the other diseases listed non-depolarizers, cautiously used, are preferable. Cardiac arrest has been reported in patients with pseudohypertrophic muscular dystrophy (Duchenne type) and excessive muscle damage may be produced by suxamethonium in this condition.

Myasthenic syndromes

In myasthenia gravis responses to suxamethonium are unpredictable (265–268). Resistance has been reported and the development of a phase II block can occur more readily, occasionally leading to prolonged paralysis. The measures used to treat the condition, for example plasmapheresis or anticholinesterases, further complicate the picture. Patients with the Eaton–Lambert syndrome are very sensitive to all relaxants.

Asthma or allergic reactions

In patients with asthma or a history of previous allergy, suxamethonium should be used with caution, in view of its potential for causing allergic reactions and bronchospasm. When a patient or a relative has had a previous adverse reaction to an anesthetic, the possibilities of an atypical cholinesterase genotype or malignant hyperthermia should also be considered. Patients with certain musculoskeletal and developmental abnormalities, such as a tendency to joint dislocations, squint, ptosis, hernias, some forms of cryptorchidism, pectus excavatum, kyphosis, foot deformities, and myopathic features, and also those who have reacted to a previous injection of suxamethonium with generalized muscle rigidity or masseter spasm, may be more prone to malignant hyperthermia. Dantrolene should be available to every area where anesthetic agents are used.

Patients at risk of aspiration

The choice of muscle relaxants for rapid sequence induction of anesthesia in patients at risk of aspiration has been controversial for many years. Suxamethonium has been used for decades, because it has a fast onset and a short duration of action, although it can have severe adverse effects. Alternatives have been suggested, all of which have their own pros and cons, but suxamethonium has withstood the test of time and is still widely used. On this background, the use of rocuronium versus suxamethonium has been subjected to a Cochrane review, in which 40 studies addressing the issue were identified, 26 of which were combined for analysis (269). For rocuronium, the relative risk of excellent intubating conditions was 0.87 (95% CI = 0.81, 0.94) compared with suxamethonium. In a subgroup of patients who had been given propofol as an induction agent, there was no difference between rocuronium and suxamethonium. The reviewers concluded that overall suxamethonium creates excellent intubation conditions more reliably than rocuronium and should still be used as a first-line muscle relaxant for rapid sequence intubation. Rocuronium, when used with propofol, reliably created excellent intubation conditions and was consequently suggested as a second-line alternative to suxamethonium. In addition, some have suggested that intubating under deep anesthesia without a neuromuscular blocker is an acceptable third-line alternative if neither suxamethonium nor rocuronium is considered appropriate. To allow rapid-sequence intubation of the trachea without a muscle relaxant, adequate doses of propofol (2.0–2.5 mg/kg) or etomidate (0.3 mg/kg) and a fast-onset opioid, such as alfentanil (50 micrograms/kg) or remifentanil (4 micrograms/kg) are required (270–275).

Drug–Drug Interactions

Antidysrhythmic drugs

Quinidine potentiates not only non-depolarizing muscle relaxants but also depolarizing drugs (276).

© 2006 Elsevier B.V. All rights reserved.

Verapamil can potentiate the block produced by both types of neuromuscular blocking agent (277).

Beta-blockers can prolong and possibly exaggerate the rise in serum potassium resulting from the injection of suxamethonium (SEDA-10, 108) (SEDA-11, 122) (175,176).

Aprotinin (Trasylol)

Aprotinin (Trasylol) slightly reduces plasma cholinesterase activity and would only be expected to prolong the action of suxamethonium in combination with other factors. However, re-paralysis has been reported when this agent was used after operations during which suxamethonium had been given alone or in combination with normal doses of D-tubocurarine (278).

Bambuterol

Bambuterol, a $beta_2$-adrenoceptor agonist that is used to relieve bronchospasm, approximately doubles the duration of action of suxamethonium (SEDA-14, 114) (279). Plasma cholinesterase activity was reduced significantly even 10–12.5 hours after a single dose of 30 mg had been given to patients. The interaction is due to the binding of carbamate groups to plasma cholinesterase.

Cardiac glycosides

Cardiac glycosides and suxamethonium can interact, resulting in an increased risk of dysrhythmias (280), perhaps through alterations in intracellular calcium (22). In 24 patients with ischemic heart disease taking digoxin who underwent abdominal surgery ventricular extra beats with bigemini or severe bradycardia were recorded in two patients and episodes of torsade de pointes occurred in two others during endotracheal intubation (281). The authors suggested that endotracheal intubation in digitalized patients should be performed without suxamethonium. However, considering the frequency with which digitalized patients receive suxamethonium and the paucity of reports of clinical problems, this interaction is probably of minor importance.

Cytotoxic and immunosuppressive drugs

Nitrogen mustard and related alkylating agents, such as cyclophosphamide, chlorambucil, triethylmelamine, and thiophosphoramide, prolong the action of suxamethonium (282,283). Plasma cholinesterase activity is reduced, possibly by alkylation of the enzyme. It has been suggested that azathioprine may potentiate suxamethonium by inhibition of phosphodiesterase activity (SEDA-4, 87) (284).

Donepezil

Donepezil acts primarily as a reversible inhibitor of acetylcholinesterase with a half-life of over 70 hours. Prolonged paralysis lasting several hours and requiring postoperative mechanical ventilation in the intensive care unit has been reported after the use of suxamethonium in a patient taking long-term donepezil (285).

- An 85-year-old woman with a history of mild Alzheimer's disease and hypertension underwent abdominal hysterectomy. Anesthesia was induced with suxamethonium 100 mg and 40 minutes later pancuronium 2 mg. After 2 hours, when surgery was finished, train-of-four stimulation elicited three twitches, and neostigmine 5 mg plus glycopyrrolate 1 mg was given to reverse neuromuscular block. She was subsequently able to follow commands and was breathing adequately; four twitches were observed during train-of-four stimulation. Several minutes after extubation she became apneic and had to be reintubated. Further neostigmine 1 mg was given, but neuromuscular block persisted without any response to peripheral nerve stimulation. In a blood sample taken 60 minutes after the second dose of neostigmine plasma cholinesterase activity was 2.1 (reference range 7.1–19) U/ml. The dibucaine number was 45 (reference range 81–87)%, and the fluoride number was 84 (44–54)%.

The authors of this report subsequently tested the effect of donepezil on plasma cholinesterase activity in vitro. Supratherapeutic concentrations (0.02 mg/ml) reduced plasma cholinesterase activity to 53% of baseline. Dibucaine and fluoride numbers were not affected by neostigmine or donepezil. Others have shown previously that therapeutic doses of donepezil inhibit acetylcholinesterase by 64% (286). Prolonged paralysis in this case may have been due to the combined effects of atypical plasma cholinesterase and additional inhibition of plasma cholinesterase activity by donepezil. Unfortunately, preoperative plasma cholinesterase activity was not known and low cholinesterase activity was detected under the influence of neostigmine, which inhibits both plasma cholinesterase and acetylcholinesterase. Because a very high dose of neostigmine resulted in intensification rather than reversal of neuromuscular block, overdose of neostigmine may have caused paradoxical neuromuscular block (287). Hypothetically, paradoxical block is a combination of desensitization and open channel block (SEDA-13, 298). So the additional dose of neostigmine should have been omitted. In addition, an excess of acetylcholine at the end-plate might have been the result of combined inhibition of acetylcholinesterase by both donepezil and neostigmine. Until more is known, neostigmine and other cholinesterase inhibitors should be used with caution in patients taking donepezil.

- A 72-year-old woman with a symptomatic hiatus hernia, osteoarthritis, and Alzheimer's disease was taking fluoxetine 20 mg/day, donepezil hydrochloride 10 mg/day, nimesulide 12.5 mg/day, and omeprazole 20 mg/day (288). There still was no twitch response to peripheral nerve stimulation 20 minutes after rapid-sequence induction of anesthesia with propofol 2.5 mg/kg and suxamethonium 1 mg/kg. She then gradually developed a weak twitch response, and 50 minutes after induction of anesthesia four twitches with a fade were elicited by train-of-four stimulation. No additional medication was given and after the end of the procedure 10 minutes later she was extubated uneventfully. She refused further blood testing and so her plasma cholinesterase activity at that time is not known. However, her anesthetic notes from a previous operation did not reveal any problems with prolonged paralysis after suxamethonium.

© 2006 Elsevier B.V. All rights reserved.

It is not proven that donepezil was the cause of the prolonged duration of action of suxamethonium in this case. However, a case with some similarities has been reported before (285). In addition, there has been another report linking donepezil therapy to both prolonged duration of action of suxamethonium and reduced sensitivity to atracurium (289). Recovery of neuromuscular function should therefore be monitored when suxamethonium is given to patients taking donepezil. The withdrawal of donepezil 2–3 weeks before an operation cannot be supported, because this might have adverse effects on cognitive function. The issue has been highlighted in a recent letter, and the author concluded that "a brief prolongation of muscle relaxation is very rarely a problem (although its mismanagement may be)" (290).

Ecothiopate

Ecothiopate eye-drops, used in the treatment of glaucoma, prolong the action of suxamethonium considerably (291,292). Ecothiopate is a long-acting anticholinesterase that inhibits the activity of both acetylcholinesterase and plasma cholinesterase. Plasma cholinesterase activity may be reduced to 5% or less and on withdrawal requires 1–2 months for recovery to normal values (293,294). The prolonged anticholinesterase effect is due to conversion of the enzyme to its stable phosphoryl derivative. If a patient has used ecothiopate eye-drops in the previous 2 months or so, suxamethonium should not be given, unless normal plasma cholinesterase activity can be demonstrated. Various organophosphorus insecticides, such as parathion and malathion, may also result in prolonged paralysis after suxamethonium due to reduced free cholinesterase activity (247,295), produced in a similar manner to that in the case of ecothiopate.

Estrogens and estrogen-containing contraceptives

Estrogens and estrogen-containing contraceptives prolong the action of suxamethonium. Plasma cholinesterase activity is reduced, possibly by estrogenic inhibition of the hepatic synthesis of plasma cholinesterase, and its isozymes are modified (262,296,297). Diethylstilbestrol, included in this group, is reported to have caused paralysis for 3 hours in a patient with other aggravating factors (SEDA-4, 89) (298). One would, however, expect little prolongation of suxamethonium paralysis since the decrease in plasma cholinesterase activity (after contraceptives, at least) averages only about 20%. Prednisone, cortisol, and dexamethasone also reduce plasma cholinesterase activity to a mild or moderate degree (SEDA-15, 122) (299–301).

General anesthetics

When mixed in solution, thiopental will hydrolyse suxamethonium, owing to a pH effect. Ketamine may prolong the action of suxamethonium slightly (302,303); a phase II block might be prolonged more significantly (303), although there is no clinical experience reported. Decreased presynaptic acetylcholine synthesis or release has been postulated as the mechanism (304). In another study there was no significant shift in the dose–response curve for suxamethonium with ketamine (305). Inhalational agents potentiate muscle relaxants, which is of more clinical importance with regard to non-depolarizing agents. Tachyphylaxis and phase II block develop earlier and after smaller total doses of suxamethonium when volatile agents such as halothane, enflurane, or isoflurane (306,307) are used instead of balanced anesthesia. Halothane can increase the incidence of cardiac dysrhythmias, especially bradycardia and nodal rhythm, after suxamethonium. Atropine and glycopyrrolate, particularly when given intravenously just before, afford some protection (SEDA-5, 136) (308).

Lithium carbonate

Lithium carbonate delays the onset and prolongs the action of depolarizing relaxants (309,310). The principal mechanism of action is disputed. Factors suggested have been the development of dual block, reduced sensitivity of the end-plate for suxamethonium, diminished synthesis or release of acetylcholine, and plasma cholinesterase inhibition (310–312). The clinical importance is also disputed.

Local anesthetics

Procaine and cocaine are esters that are hydrolysed by plasma cholinesterase and can therefore competitively enhance the action of suxamethonium (313). Chloroprocaine may have a similar action. Lidocaine also interacts, although the mechanism is not clear unless very high doses are used (314).

Magnesium sulfate

Magnesium sulfate is used mostly in the treatment of toxemia of pregnancy. Serum magnesium concentrations may be raised and, as magnesium inhibits the release of acetylcholine and reduces the sensitivity of the postjunctional membrane, the action of non-depolarizing agents will be prolonged. It is not so clear, however, why the action of suxamethonium is also prolonged (315–318). Suxamethonium-induced fasciculation are reportedly prevented (SEDA-5, 135) (319). It has been suggested that the administration of intravenous magnesium sulfate should be stopped 20–30 minutes before muscle relaxants are given. Monitoring with a nerve stimulator is advisable.

Metoclopramide

Metoclopramide inhibits the activity of plasma cholinesterase and can prolong the action of suxamethonium (SEDA-14, 115) (320–322).

Neostigmine

Neostigmine inhibits both plasma cholinesterase and acetylcholinesterase, so that if any suxamethonium is still circulating, its action will be prolonged (by about a factor of two). This may present problems when neostigmine is administered to antagonize phase II block (323) (in which hypothetical desensitization block and open channel block elements may also be intensified) or shortly after suxamethonium is given. In renal insufficiency both neostigmine and pyridostigmine can cause prolongation (by 1–2 hours) of the action of suxamethonium given several hours after renal transplant operations.

Non-depolarizing muscle relaxants

Non-depolarizing muscle relaxants and suxamethonium are mutually antagonistic. These agents are often given in small non-paralysing doses before suxamethonium to reduce fasciculation and other adverse effects. Gallamine is slightly more effective than D-tubocurarine, and both are more effective than pancuronium. This precurarization tends to prolong the onset of action of (probably by direct antagonism) and to shorten (D-tubocurarine) or lengthen (pancuronium) its duration of action (324). The latter effect may well be due to inhibition of plasma cholinesterase by pancuronium. When compared with pancuronium, pretreatment with either atracurium or vecuronium was associated with a significantly shorter time to 90% twitch recovery after a standard dose of suxamethonium (325). When non-depolarizing agents are given after suxamethonium, even more than 30 minutes later, their action is considerably potentiated and prolonged (89,326,327). This effect (and also the production of a phase II block when suxamethonium is used alone in high or frequently repeated doses) may be the result of inhibition of transmitter release through a prejunctional action of suxamethonium (328). Suxamethonium given some time after a paralysing dose of a non-depolarizing agent (for example for peritoneal closure) produces varying effects depending on the depth of residual curarization and on the dosage of suxamethonium (SEDA-21, 141) (329–331). As it is uncertain what type of block results, this practice cannot be recommended, although few problems with subsequent reversal have been reported.

Phenelzine

Phenelzine, a monoamine oxidase inhibitor, has been reported to cause significant prolongation of suxamethonium paralysis due to depressed plasma cholinesterase levels (to about 10% of normal). Recovery of plasma cholinesterase activity took 2 weeks (332).

Tacrine (tetrahydroaminoacridine) and hexafluorenium

Tacrine (tetrahydroaminoacridine) and hexafluorenium, used sometimes to potentiate and prolong the action of suxamethonium (333,334), inhibit plasma cholinesterase. Hexafluorenium also inhibits acetylcholinesterase and has a weak neuromuscular blocking action of the non-depolarizing type; a phase II block develops fairly rapidly when repeated injections of even small doses (0.2–0.3 mg/kg) of suxamethonium are given in combination with hexafluorenium (335). Fasciculation is reportedly reduced and hyperkalemia prevented (336), as is the increase in intraocular pressure (337), when hexafluorenium is given before suxamethonium. Because of a lack of consistency of successful results from various investigators, this method is not recommended for patients who are especially at risk from hyperkalemia or increased intraocular pressure. Simultaneous injection of hexafluorenium and suxamethonium can cause severe bronchospasm.

Trimetaphan

Trimetaphan can double the duration of suxamethonium block (338–340). The mechanism is not clear, but may be a competitive effect at the neuromuscular junction. Blockade of end-plate ionic channels has also been suggested (341).

Suxibuzone

See also Non-steroidal anti-inflammatory drugs

General Information

Suxibuzone, a derivative of phenylbutazone, is an NSAID that has been used topically. Skin reactions, gastrotoxicity, nephrotoxicity, headache, and vertigo have been noted. The carcinogenic potential of suxibuzone in animals has attracted attention (1) and put an end to sales in some countries.

Tacrine

General Information

Tacrine (tetrahydroaminoacridine) was one of the first drugs to be widely marketed for the loss of memory and intellectual decline in Alzheimer's disease. However, its efficacy is controversial. A Cochrane review of the use of tacrine in Alzheimer's disease produced results that were compatible with improvement, no change, or even harm (1). For measures of overall clinical improvement, the intention-to-treat analyses did not detect any difference between tacrine and placebo (OR = 0.87; 95%CI = 0.61, 1.23). There was no effect on behavioral disturbance (SMD = 0.04; 95%CI = –0.52, 0.43) or cognitive function (SMD = 0.14; 95%CI = –0.02, 0.30). The odds ratio for withdrawal due to an adverse event was significantly different from 1, the control group experiencing fewer events (OR = 0.7; 95%CI = 4.1, 7.9). Raised serum liver enzymes caused the most withdrawals. Gastrointestinal adverse effects (diarrhea, anorexia, dyspepsia, and abdominal pain) were the other major adverse events and the odds ratio for withdrawal was also in favor of the control group (OR = 3.8; 95%CI = 2.8, 5.1). No deaths were reported in any of the studies, which lasted up to 6 months.

In a prospective randomized, double blind, parallel-group, multicenter comparison of idebenone 360 mg/day ($n = 104$) and tacrine up to 160 mg/day ($n = 99$) for 60 weeks in 203 patients with mild-to-moderate dementia of the Alzheimer's type, idebenone produced more benefit than tacrine (2). The benefit : harm balance was favorable for idebenone compared with tacrine. More patients taking tacrine (65%) reported adverse events than those taking idebenone (50%). The dropout rate in those taking tacrine was also higher. There were statistically significant differences between tacrine and idebenone for gastrointestinal adverse events (nausea, vomiting) and hepatobiliary toxicity (raised serum transaminase activity).

Organs and Systems

Nervous system

Myoclonus has been attributed to tacrine (3).

- A 68-year-old woman, who had had dementia of probable Alzheimer's type for 4 years, was given tacrine 40 mg/day and 24 hours later progressively developed generalized uncontrolled abnormal movements affecting all her limbs and her mouth, suggestive of myoclonus and controlled by clonazepam. The myoclonus disappeared 24 hours after tacrine was withdrawn. Causation was established a few months later by rechallenge: myoclonus occurred during the next 48 hours.

Liver

Hepatic failure associated with tacrine occurred outside the usual time of onset (within 9 months) and resulted in the death of a 75-year-old woman with Alzheimer's disease who had taken tacrine for 14 months (4). Thus, the potential for delayed, life-threatening hepatotoxicity with tacrine, although unusual, should not be overlooked.

The presence of the combined alleles M1 and T1, which mark deficiencies in glutathione-*S*-transferase genes, increases susceptibility to tacrine hepatotoxicity (5). It would be interesting to use this molecular epidemiological approach to identify the role of combinations of glutathione-*S*-transferase genotypes in other adverse drug reactions.

Tacrine-induced hepatotoxicity was reduced by ursodeoxycholic acid (13 mg/kg/day for 105 days) in a pilot study in 14 patients with Alzheimer's disease (6). Serum activity of alanine transaminase in 100 patients taking ursodeoxycholic acid was normal in 93% of cases, compared with 69% of patients who had taken tacrine alone.

Authors evaluating the adverse effects of tacrine in Alzheimer's disease recommend regular monitoring for hepatotoxicity (SEDA-15, 136).

Tacrolimus

General Information

Tacrolimus, a macrolide derivative, has similar immunosuppressive properties to ciclosporin and has effects on T lymphocytes by inhibiting interleukin-2 production. On a weight basis, tacrolimus is about 100 times more potent than ciclosporin. In view of the outcome of several multicenter trials, it has been used as an alternative to ciclosporin as a baseline regimen for the prophylaxis of renal and liver transplant rejection and in the treatment of acute rejection (SED-13, 1130) (SEDA-21, 390) (1). The clinical pharmacology, clinical use, and adverse effects profile of tacrolimus in organ transplantation have been extensively reviewed (2).

© 2006 Elsevier B.V. All rights reserved.

General adverse effects

The incidence of adverse effects (for example neurotoxicity, nephrotoxicity, and hyperglycemia), particularly those requiring drug withdrawal, was initially found to be higher in tacrolimus-treated liver transplant patients, but subsequently fell after the initial tacrolimus dose was reduced. This was in accordance with the results of very early trials, which showed that the initially proposed dose of tacrolimus was too high (3). In subsequent studies, tacrolimus and ciclosporin had a similar spectrum of adverse effects for nephrotoxicity, infectious complications, and lymphoproliferative disorders, and long-term adverse effects occurred at comparable rates, that is less than 2% (SED-13, 1130) (SEDA-21, 390).

Even though the glucocorticoid-sparing effect of tacrolimus is greater than that of ciclosporin, the initial hope that tacrolimus might prove less toxic than ciclosporin has not been realized. In trials in renal transplant patients, increased serum creatinine concentrations, tremor, paresthesia, gastrointestinal disorders, hyperglycemia, diabetes mellitus, pruritus, and angina pectoris occurred more often with tacrolimus, whereas there was a higher incidence of dysrhythmias, hyperkalemia, gingival hyperplasia, acne, alopecia, and hirsutism with ciclosporin (SEDA-21, 390). In the European Tacrolimus Multicenter Liver Trial, there was some evidence of possible advantages for tacrolimus over ciclosporin in terms of hypertension, cytomegalovirus infection, hirsutism, and gum hyperplasia (SEDA-21, 390). The safety profile of tacrolimus is very similar in children to that in adults, but in sharp contrast to ciclosporin, gingival hyperplasia, hirsutism, and coarsening of facial features have not been observed (4,5).

As the adverse effects of tacrolimus and ciclosporin are not strictly comparable, switching a patient from one to the other can sometimes be beneficial. Severe or persistent tacrolimus-related adverse effects, for example neurotoxicity, gastrointestinal disorders, or diabetes mellitus, can abate after replacement by ciclosporin (SEDA-20, 347) (6). Conversely, the change from ciclosporin to tacrolimus has been safely and successfully undertaken in patients with adverse effects from ciclosporin, such as nephrotoxicity, hemolytic–uremic syndrome, hypertension, neurological disorders, gingival hyperplasia, hypertrichosis, and dyslipidemia (SED-13, 1130) (SEDA-20, 347) (7,8). Replacing one drug by another is not always advantageous; in two patients switched to tacrolimus for ciclosporin-induced cortical blindness, visual abnormalities promptly resolved, but both patients rapidly developed thrombotic thrombocytopenic purpura and severe graft-versus-host disease, and finally died 33 days after bone marrow transplantation (9).

Long-term follow-up (mean of 93 months) of tacrolimus-based immunosuppression has been reported in 121 adult patients with liver transplants (10). Infections were the most common causes of deaths (17 patients out of 42), and half of them occurred during the first year after transplantation. Cardiovascular events (seven patients) or de novo malignancies (three patients) were also important causes of death. End-stage renal disease related to tacrolimus nephrotoxicity was noted in two patients who required renal transplantation. At 7 years, other important adverse effects included hyperkalemia (30%) or hypertension (31%) requiring treatment, and insulin-dependent diabetes mellitus (13%). Seven patients developed de novo malignancies and six had post-transplant lymphoproliferative disorders. The risks of tacrolimus in renal transplantation have been discussed (11).

Organs and Systems

Cardiovascular

The incidence of hypertension and the prevalence of antihypertensive drug use are lower with tacrolimus than with ciclosporin (5,12).

Severe recurrent, but usually reversible hypertrophic cardiomyopathy has been infrequently reported, both in adults and children (SEDA-19, 352) (SEDA-20, 346). Based on experimental data and one additional case report, the interaction of tacrolimus with calcium channel blockers in the cardiac muscle has been suggested as a possible mechanism (SEDA-21, 390). However, the role of tacrolimus in the development of cardiomyopathy is still hypothetical. Echocardiographic abnormalities were relatively common before and after liver transplantation in 12 adult patients, and there was no clear evidence that oral tacrolimus specifically alters cardiac function (13). Other investigators did not show differences in heart weight, ventricular thickness, or valve circumferences between 67 liver transplant recipients treated with tacrolimus and 72 non-transplanted patients who died from end-stage liver disease (14). In addition, more than 80% of patients in both groups had left ventricular hypertrophy.

Other isolated reports and preliminary studies have suggested a possible risk of life-threatening dysrhythmias, including sinus bradycardia or sinus arrest, asymptomatic but significant mean QT/QT_c interval prolongation in 33 patients (over 500 msec in seven patients), and recurrent episodes of ventricular tachycardia or torsade de pointes in two patients (SEDA-21, 391) (SEDA-22, 390) (15,16).

Several reports have previously focused on the possible occurrence of cardiomyopathy in tacrolimus-treated transplant patients, particularly children. In two further liver transplant children aged 2.5 and 14 years who died from multiorgan system failure due to sepsis and end-stage liver failure, pathological examination showed prominent concentric left ventricular hypertrophy (17). Although tacrolimus was regarded as a possible cause of asymptomatic hypertrophic cardiomyopathy in these patients, a direct causal relation was difficult to establish. The cause is probably multifactorial, and potential confounding factors (for example hypertension, glucocorticoids) are numerous in this population. In a retrospective review of 89 pediatric heart transplant patients who had survived for at least 6 months, repeated echocardiography showed signs of cardiac hypertrophy, particularly early after transplantation and in very young infants (18). However, there was no evidence of progressive hypertrophy on follow-up examinations, and no significant differences in the degree of cardiac hypertrophy between patients aged over 1 year at the time of transplantation who received ciclosporin ($n = 26$) or tacrolimus ($n = 41$).

In a retrospective study, the prevalence of hypertension 2 years after adult liver transplantation was significantly

© 2006 Elsevier B.V. All rights reserved.

lower in patients treated with tacrolimus (64% of 28 patients) than in patients treated with ciclosporin (82% of 131 patients) (19). In addition, hypertension occurred later with tacrolimus. A similar benefit of tacrolimus over ciclosporin was found in a randomized, comparative trial in 85 heart transplant patients, and 41% of 39 tacrolimus-treated patients developed new-onset hypertension requiring treatment, compared with 71% of 46 ciclosporin-treated patients (20).

In 37 patients with liver transplants there was no difference between the pre- and post-transplant QT interval in the 25 taking oral ciclosporin and the 12 taking oral tacrolimus (21).

Cardiac symptoms manifesting as myocardial ischemia are uncommon, but can occur through tacrolimus toxicity (22).

- A 20-year-old woman with chest pain, dyspnea, and protracted electrocardiographic ST depression had very high blood tacrolimus concentrations (45 ng/ml). Subsequent coronary angiography ruled out any significant organic lesions, but showed vasospastic coronary arteries. She had no other cardiac symptoms when tacrolimus was restarted with careful surveillance of serum concentrations.

Nervous system

Tacrolimus mostly produces mild to moderate neurotoxic effects that are usually not treatment-limiting and rarely clinically relevant, at least in children (23). The occurrence of neurological symptoms, sometimes severe, is a well-known complication in the early post-transplant period, particularly in liver transplant recipients. It is therefore in most cases difficult to attribute these disorders to a particular immunosuppressive regimen.

When neurological symptoms occur in patients taking tacrolimus they are very similar to those seen in patients taking ciclosporin, with more frequent insomnia, tremor, and headaches, but a similar rate of severe neurological adverse effects, such as acute psychosis, peripheral neuropathy, seizures, encephalopathy, coma, and paralysis. Persistent speech disorders (dysarthria, apraxia, expressive aphasia, akinetic mutism), and visual blurring can also occur (SEDA-21, 391) (SEDA-22, 420) (24).

The higher incidence of moderate or severe late neurotoxicity from tacrolimus compared with ciclosporin was strongly associated with severe postoperative infections, multiple organ failure, and an increased bilirubin, creatinine, and transaminases (25).

It has been suggested that anxiety rather than akathisia can account for several symptoms caused by tacrolimus, such as restlessness (SEDA-21, 391).

Posterior leukoencephalopathy, with clinical, radiological, and neuropathological features resembling those previously described with ciclosporin has been reported in several patients (SEDA-22, 420) (26). Cortical blindness, generalized tonic-clonic seizures ($n = 2$), and diffuse MRI abnormalities were found in three of 50 patients taking tacrolimus after bone marrow transplantation (SEDA-20, 347); these findings have also been observed in patients taking ciclosporin. Acute neurotoxicity was fatal in one patient despite changing from tacrolimus to ciclosporin, and autopsy showed multiple cerebral hemispheric infarcts due to cerebral vasculitis (SEDA-22, 420).

Six patients taking tacrolimus (including five children) developed signs of encephalopathy with generalized or focal seizures, reduced visual acuity or cortical blindness, altered mental status, and white matter lesions on MRI scan, particularly in the parieto-occipital regions (27–29). Three patients had tacrolimus blood concentrations above the target range before the neurological adverse event. Although there was complete resolution after tacrolimus withdrawal or reduction in dosage in four patients, two children still had persistent brain imaging abnormalities and recurrent episodes of seizures.

- A chronic inflammatory demyelinating polyneuropathy was considered to have been caused by tacrolimus in a 62-year-old patient (30).
- The presence of significant tacrolimus concentrations (5.2 and 1.3 ng/ml at 8 and 72 hours after the last dose) in the cerebrospinal fluid of a 64-year-old woman with a renal transplant, who developed an extremely severe form of encephalopathy after 21 months of treatment, suggested that tacrolimus can cross the blood–brain barrier (31).

Complete resolution of tacrolimus-induced neurotoxicity does not occur after tacrolimus withdrawal or dosage reduction (32).

- A 48-year-old man developed acute loss of speech and swallowing apraxia shortly after liver transplantation. Tacrolimus serum concentrations were very high. Although there was progressive improvement after tacrolimus withdrawal, residual speech deficits were still present 3 weeks later. A PET scan showed a marked reduction in metabolic rate in the temporal lobes and the adjacent parieto-occipital region bilaterally.

Other cases of severe neurotoxicity have been seen during tacrolimus treatment for graft-versus-host disease after allogeneic bone marrow transplantation.

- A 16-year-old girl had hypertension and generalized convulsions, which recurred after tacrolimus readministration; she subsequently died from cerebral hemorrhage and respiratory failure (33).

Based on this report and a review of previously published cases, concomitant hypertension and the use of high-dose methylprednisolone were discussed as precipitating factors of tacrolimus neurotoxicity. In two other patients aged 4 and 15 years who had prolonged leukoencephalopathy, the underlying chronic graft-versus-host disease was thought to be a risk factor (34).

In children one advantage of tacrolimus is that it can reduce the dose of glucocorticoids required for immunosuppression. This in turn improves growth. When in one center the immunosuppression protocol was changed to tacrolimus plus mycophenolate mofetil and prednisone, two patients developed transient encephalopathy associated with tacrolimus (35). In both cases, the encephalopathy was managed by treating the associated hypertension and fluid overload; tacrolimus was not withdrawn.

Both tacrolimus and ciclosporin are hydrophobic and can alter the properties of the cell membrane. They bind to an intracellular peptidylprolyl isomerase that regulates

© 2006 Elsevier B.V. All rights reserved.

T cell activation and can interfere with cytoskeletal components that prevent interleukin-2 synthesis and release. Cytotoxic edema caused by acute cerebral ischemia is associated with reduced diffusion, reflecting the failure of membrane sodium pumps. Altered electrolyte or fluid balance can precede the onset of encephalopathy. This can be shown by fluid-attenuated inversion recovery and diffusion-weighted MRI images (36).

A polymorphism of the ABCB1 gene may be associated with a risk of tacrolimus-induced neurotoxicity after liver transplantation. In six patients with neurotoxicity and 11 without neurotoxicity, high tacrolimus concentration, liver dysfunction, and a mutation in position 2677 in exon 21 were positive predictive factors for tacrolimus-induced neurotoxicity (37).

Sensory systems

Eyes

- Optic neuropathy has been reported in a 58-year-old liver transplant patient who had taken tacrolimus for 2 months (38). Further deterioration of vision occurred despite withdrawal.

Ears

Sudden hearing loss has been attributed to tacrolimus (39).

- A 38-year-old woman was switched from ciclosporin to tacrolimus 44 days after kidney and pancreas transplantation and 17 days later had sudden hearing loss with tinnitus. Her tacrolimus blood concentration 3 days later was 28 ng/ml and peaked at 35 ng/ml 8 days later. Audiograms showed bilateral hearing loss—80% for speech perception and mild to moderate sensorineural hearing loss. Her hearing improved on tacrolimus dosage reduction and after the tacrolimus blood concentration reached 15 ng/ml.

Although she was taking many other drugs, including muromonab, which was withdrawn 1 month before the hearing loss occurred, the role of tacrolimus was supported by its chemical similarity to erythromycin, which is ototoxic when given intravenously.

Endocrine

The risk of post-transplant diabetes mellitus is greater with tacrolimus than with ciclosporin, but this was mostly true in black patients and during the initial months after transplantation (40). In one study, insulin sensitivity, alpha and beta cell function, and beta cell reserve were studied in 14 hepatitis C-positive patients with liver transplants, who took tacrolimus or ciclosporin maintenance for 1 year (41). The patients were matched for low prednisolone dosage (1.1 mg/day versus 1.3 mg/day), body mass index, lean body mass, and sex, and compared with eight controls. Insulin sensitivity and insulin secretory reserve were significantly different from controls, but there was no significant difference between ciclosporin and tacrolimus.

The incidence, mechanism, and risk factors of tacrolimus-associated diabetes mellitus are still debated. In 58 patients investigated 1–3 years after liver transplantation there was a significantly higher incidence of diabetes mellitus with tacrolimus ($n = 32$) compared with ciclosporin ($n = 26$) (42). Newly-diagnosed diabetes occurred in nine of 28 tacrolimus-treated patients, of whom six required insulin, and in none of 25 ciclosporin-treated patients. Five patients taking tacrolimus also had islet cell-specific autoantibodies that correlated significantly with HLA risk haplotypes.

- A 32-year-old woman with previous autoimmune disorders and a susceptible HLA haplotype developed diabetes with newly positive glutamic acid decarboxylase antibody after taking tacrolimus for 5 months (43).

Together, these reports suggest that tacrolimus does not suppress the production of autoantibodies in patients genetically prone to develop autoimmune diabetes, with induction of an autoimmune phenomenon. This also suggests that tacrolimus treatment should be undertaken cautiously in predisposed patients.

Metabolism

Of 834 primary adult liver transplant recipients, of whom 499 were alive and taking tacrolimus, 70% were glucocorticoid-free after 1 year; this did not change over the next 5 years (44). However, glucocorticoid-associated adverse effects, such as hypertension, diabetes, and hyperlipidemia, were not statistically significantly less common in patients not taking glucocorticoids. This may have been because of the diabetogenic effect of tacrolimus.

Diabetes mellitus

Altered glucose metabolism and subsequent hyperglycemia or even insulin-dependent diabetes mellitus is an important issue in transplant patients, particularly in adults or patients taking high doses. In animals, high-dose tacrolimus causes glucose intolerance and reduced insulin release (45). This resolves after withdrawal. Diabetes mellitus after transplantation is a relatively common complication in pediatric thoracic organ recipients taking tacrolimus (46). Specific risk factors have not been identified. A switch from tacrolimus to ciclosporin for other reasons in two patients did not resolve the problem.

The incidence of hyperglycemia or diabetes mellitus requiring insulin at some point during treatment was 10–20% in adults (2% in children), an incidence about 2–3 times higher than with ciclosporin (SEDA-20, 347). However, more recent studies and case reports have shown that children could be also very sensitive to the diabetogenic effects of tacrolimus, with an incidence possibly higher than previously thought (47,48). While the diabetes mellitus tends to improve or abate after the dose of tacrolimus or glucocorticoid has been reduced, glucose intolerance was more frequent in the tacrolimus group after a median of 23 months (49). However, post-transplant diabetes mellitus requiring permanent insulin treatment was as frequent in patients with liver grafts taking ciclosporin or tacrolimus after 1 year (50). Finally, there was a possible correlation between impaired glucose tolerance or a diabetic pattern detected by a pretransplant 75 g oral glucose tolerance test and the later development of post-transplant diabetes mellitus (51).

© 2006 Elsevier B.V. All rights reserved.

In a pooled analysis of four randomized trials of tacrolimus versus ciclosporin after renal transplantation, the prevalence of post-transplant diabetes mellitus at 1 year (two studies, 532 patients) was five times higher with tacrolimus than with ciclosporin (OR = 5.0; 95% CI = 2.0, 12.4) (52). In the opinion of the US FDA, diabetes mellitus after transplantation was a significant hazard in tacrolimus-treated patients, even though about half of the patients were no longer taking insulin at 2 years after transplantation (53).

The exact mechanisms of tacrolimus-induced diabetes are unknown. In one renal transplant patient with genetic susceptibility, tacrolimus was associated with insulin-dependent diabetes mellitus and the simultaneous occurrence of anti-glutamic acid decarboxylase antibody (54). Within 2 months after conversion from tacrolimus to ciclosporin, the antibody was no longer detected and the patient's insulin requirements fell dramatically. Tacrolimus-induced direct beta cell toxicity, with subsequent development of beta cell autoimmunity, was therefore suggested as a possible mechanism in patients with genetic susceptibility for type I diabetes.

Hepatitis C virus infection has been associated with diabetes and is a significant risk in patients with renal transplants. In 427 patients with renal transplants and no previous diabetes mellitus, diabetes after transplantation occurred more often in hepatitis C virus-positive than hepatitis C virus-negative patients (39 versus 9.8%) (55). Diabetes mellitus after transplantation occurred more often in hepatitis C virus-positive patients taking tacrolimus than in those taking ciclosporin (58 versus 7.7%). In hepatitis C virus-negative patients, the rates of diabetes mellitus were similar. The authors concluded that hepatitis C is strongly associated with diabetes mellitus after renal transplantation because of the greater diabetogenicity of tacrolimus.

In 17 patients, in whom fasting blood samples were taken immediately before transplantation and at 1 and 3 months after transplantation for measurement of HbA, insulin, C-peptide, free fatty aids, lipids, urea, and creatinine, the incidence of diabetes mellitus was high (47%) (56). Diabetes was more common in black patients, but owing to the small number of patients the difference was not statistically significant. Insulin resistance seems to be the main pathogenic mechanism involved.

Lipid metabolism

In contrast to its effects on glucose metabolism, tacrolimus offers potential advantages over ciclosporin for lipid disorders (57). Compared with ciclosporin-based immunosuppressive regimens, total cholesterol and LDL cholesterol serum concentrations were lower in patients taking tacrolimus for 1 year (58). Both findings were considered to result from a significant glucocorticoid-sparing effect of tacrolimus.

Hematologic

Acute hemolysis occurred in eight of 1400 patients (59). Although multiple other causal factors could have been relevant, further hematological investigations suggested that tacrolimus can cause or promote hemolysis, particularly in patients with acquired anti-erythrocyte antibodies.

Pure red cell aplasia is an occasional complication of treatment (SED-13, 1131) (SEDA-20, 347) (60). In one case, tacrolimus was thought to have caused reversible pancytopenia with severely reduced granulopoiesis and megakaryocytopoiesis on bone marrow examination (SEDA-21, 391).

- The prothrombin time was prolonged to 36 seconds, with isolated factor V deficiency (5%), 2 weeks after a 46-year-old patient with a liver transplant was given tacrolimus and oxacillin (61). Factor V antigen was lower than 5%. In vitro investigations of the patient's plasma showed dose-dependent factor V inhibitory activity in the presence of tacrolimus. Factor V activity and the coagulation profile returned to normal after withdrawal.

The development of this transiently acquired inhibitor of coagulation factor V may have been due to either tacrolimus or oxacillin.

Microangiopathy and the resulting thrombotic thrombocytopenic purpura-like syndrome has been reported in three transplant patients taking tacrolimus, including one with a severe form (62). Microangiopathy was associated with high trough tacrolimus concentrations (over 24 ng/ml) and raised concentrations of endothelin and various cytokines, namely interleukin-8, interleukin-10, interleukin-12, tumor necrosis factor alfa, and interferon gamma.

Mouth and teeth

A brief case report has suggested that tacrolimus can cause gingival hyperplasia (63).

Gastrointestinal

Severe gastrointestinal toxicity with anorexia and weight loss is sometimes observed in patients taking tacrolilmus (SEDA-19, 352).

Tacrolimus-associated *Clostridium difficile* diarrhea has been reported (64).

- A 29-year-old man was given mycophenolate and tacrolimus for an episode of renal transplant rejection that occurred 6.5 years after transplantation. Four weeks after tacrolimus was begun, he had diarrhea, nausea, and malaise. There was *C. difficile* toxin in the stools, and his symptoms abated with metronidazole. About 1 month later, he developed diarrhea, fever, and severe dehydration. *Clostridium difficile* toxin was again detected in the stools, and his symptoms completely resolved with oral vancomycin and withdrawal of tacrolimus.

Similar cases have been reported to the manufacturers. A possible relation between the macrolide molecular structure of tacrolimus and the development of *C. difficile* colitis remains to be established.

Liver

In children 0.1% tacrolimus ointment has been used daily without major adverse effects.

- In a 3-year-old African-American boy with moderate atopic dermatitis, tacrolimus caused raised transaminase and lactate dehydrogenase activities. Tacrolimus was withdrawn on day 29, but no further information was given about their liver function tests (65).

© 2006 Elsevier B.V. All rights reserved.

The finding of mild to moderate liver function test abnormalities that normalized on dosage reduction or withdrawal of tacrolimus has suggested possible dose-related hepatotoxicity (66). In liver transplant patients, liver biopsy showed a centrilobular hepatocellular drop-out with sinusoidal dilatation and congestion, and no features of cellular rejection or acute hepatitis.

Pancreas

Acute pancreatitis has rarely been reported in clinical trials, but no detailed cases were available before the following report (67).

- A 28-year-old woman was switched from ciclosporin to tacrolimus for prophylaxis of graft-versus-host disease after allogeneic stem cell transplantation for chronic myelogenous leukemia. She also took methylprednisolone and inhaled pentamidine. After 2 weeks she developed acute abdominal pain, tachypnea, hypoxia, and oliguria. Amylase and lipase peaked at about four and five times the upper limits of the reference ranges, and urinary analysis was consistent with acute tubular necrosis. An abdominal CT scan showed an enlarged edematous pancreas with a peripancreatic inflammatory exudate. There was no biliary obstruction or dyslipidemia. Shortly after tacrolimus withdrawal, she became anuric and had an episode of acute respiratory distress, but then improved over the next few days.

Although treatment with methylprednisolone, pentamidine, and total parenteral nutrition could have contributed in this patient, they were either continued or readministered without ill effect.

Urinary tract

Tacrolimus nephrotoxicity has been reviewed (68) and is considered to be very similar to that described with ciclosporin. The clinical and histological characteristics of acute tacrolimus nephrotoxicity have been described from a retrospective analysis of 67 patients with renal transplants, of whom 27 developed acute nephrotoxicity, in seven of whom underlying moderate-to-severe renal arteriosclerosis might have predisposed to tacrolimus nephrotoxicity (69).

Tacrolimus-induced chronic nephrotoxicity has clinical and histopathological features very similar to those induced by ciclosporin, that is tubular lesions, hyaline arteriolopathy, and hemolytic–uremic syndrome-like changes in glomeruli and vessels (70). Isolated glomerular microthrombosis has also been described (71). Although tacrolimus was successfully used in several patients suffering from ciclosporin-induced hemolytic–uremic syndrome, thrombocytopenic purpura and hemolytic–uremic syndrome, including one fatal case, have also been reported in patients taking tacrolimus (SED-13, 1131) (SEDA-20, 347). In addition, ciclosporin and tacrolimus were significant risk factors for recurrence of hemolytic–uremic syndrome in patients who had undergone renal transplantation for end-stage renal disease (72). Late nephrotoxicity evaluated by the mean serum creatinine concentration and/or glomerular filtration rate at 1 year was similar in patients taking ciclosporin or tacrolimus (73,74). However, compared with ciclosporin, tacrolimus appears to be associated with more frequent and severe proximal or distal tubular acidosis 6 months after renal transplantation, although this conclusion is based on work with only a few patients in each group (SEDA-19, 352) (75). Overall, the reported incidence of tacrolimus-associated nephrotoxicity varies from 18 to 42% in liver transplant patients; among 128 patients who had early and late episodes of renal allograft dysfunction (1–156 weeks after transplantation) requiring biopsy, tacrolimus nephrotoxicity was estimated to account for only 17% of cases (76). There were higher than expected serum tacrolimus concentrations in most patients, and the highest concentrations were detected 1.6 days before the peak serum creatinine. However, renal histological lesions were independent of tacrolimus dosage or blood concentrations (77).

The nephrotoxic adverse effects of tacrolimus and ciclosporin are clinically indistinguishable. The pathological features of renal biopsies at 2 years of treatment in patients enrolled in a large multicenter comparison of tacrolimus and ciclosporin in renal transplantation have been reported (78). Of 412 patients initially randomized, renal biopsies were available from 79 taking tacrolimus and 65 taking ciclosporin. There were features of tacrolimus or ciclosporin nephrotoxicity (hyaline arteriolar change, tubular vacuolization) in 19 and 11 patients respectively. There were no differences in the rates of biopsy-proven acute rejection (8.9 versus 9.2%) or chronic allograft nephropathy (62 and 72%). In addition, the histological features of chronic allograft nephropathy were very similar. An older age of the donor, acute rejection, cytomegalovirus infection, and ciclosporin- and tacrolimus-associated nephrotoxicity during the first year of transplantation were the most significant factors associated with the occurrence of chronic nephropathy.

As with ciclosporin, tacrolimus used as a primary immunosuppressant has sometimes been associated with de novo thrombotic microangiopathy/hemolytic–uremic syndrome. Its role has been clearly confirmed in a 52-year-old heart transplant patient in whom hemolytic–uremic syndrome recurred 6 days after tacrolimus readministration (79). From a report of two additional cases and a review of 19 other reported cases, the incidence of tacrolimus-associated thrombotic microangiopathy has been suggested to be 1.0–4.7%; 15 cases were reported in renal transplant patients (80). The mean time to diagnosis was 9 months (4 days to 31 months), and the tacrolimus trough concentrations were usually within the target range. Most patients had the clinical features of hemolytic–uremic syndrome. Final outcomes were known in 18 patients: 10 had tacrolimus dosage reduction only (six recovered, three had an acute cellular rejection, one lost his renal graft); one stopped taking tacrolimus and recovered; seven had tacrolimus dosage reduction or withdrawal and underwent plasmapheresis, fresh-frozen plasma exchange, high-dose glucocorticoids, or anticoagulation (three died of sepsis and multiorgan failure, one lost her renal graft, and three recovered). Furthermore, and in contrast to previous reports (SEDA-19, 353), a change from ciclosporin to tacrolimus in patients with ciclosporin-associated hemolytic–uremic syndrome is not always successful.

- Two renal transplant patients developed resistant late acute rejection while taking ciclosporin (81). After a

© 2006 Elsevier B.V. All rights reserved.

switch to tacrolimus, they had clinical and histological features of hemolytic–uremic syndrome, with biopsy-proven thrombotic microangiopathy within 2 and 12 days after conversion. Both finally required explantation of their renal allografts.

Skin

The long-term safety of topical tacrolimus ointment 0.1% for 6–12 months has been assessed in 316 patients with atopic dermatitis (82). The most common adverse effects clearly attributed to tacrolimus were a local burning sensation (47%), pruritus (24%), and erythema (12%); the incidences fell with time. The observed incidence of infections did not exceed the expected incidence in patients with atopic dermatitis, and there were no effects on circulating cell-mediated immunity.

In 631 adult patients with moderate to severe atopic dermatitis enrolled in a randomized, double-blind, multicenter comparison of tacrolimus (0.03% or 0.1%) with a vehicle applied twice-daily for 12 weeks, the most common adverse events were skin burning, erythema, and pruritus (83). Others were flu-like symptoms and headache. Withdrawal was required in 50 patients because of adverse events, twice as many as in the vehicle group. There was pruritus in 30 patients, skin burning in 19, skin erythema in 12, and skin infections in two. Skin burning and pruritus have consistently been observed with tacrolimus ointment, typically during the first days of treatment, reducing in incidence within the first week; they tend to be mild or moderate.

In 255 children with atopic dermatitis, tacrolimus 0.1% ointment caused transient skin burning and itching as the most common adverse events (65). Two patients required hospital admittance to control skin infections. A flu-like syndrome was the major non-topical adverse event.

- A diffuse, follicular, erythematous eruption has been reported in a 45-year-old patient with a previous history of allergies to multiple medications, including clarithromycin (84). It resolved after tacrolimus withdrawal.

The authors speculated on possible cross-sensitivity between tacrolimus and clarithromycin, which are both macrolides, but confirmatory skin-testing was not performed. In addition, the patient had taken many other drugs that might have been responsible.

Hair

In several studies, alopecia has been found more often with tacrolimus than ciclosporin, and severe alopecia has sometimes followed replacement of ciclosporin by tacrolimus. However, in the light of one detailed case report, and bearing in mind the minimal effect of tacrolimus on hair growth, it is not unlikely that alopecia has sometimes been mistakenly attributed to tacrolimus rather than to concomitant glucocorticoid-induced hair loss in the absence of the counteracting effects of ciclosporin (SEDA-21, 391).

Musculoskeletal

Severe acute rhabomyolysis with subsequent fatal acute renal insufficiency has been reported in an 18-month-old girl (SEDA-19, 353).

Like ciclosporin, tacrolimus has been thought to reduce bone mineral density, but this conclusion was based on a series of seven patients, all of whom had also taken azathioprine and glucocorticoids (85).

- Severe bone pain, previously reported in ciclosporin-treated patients (SED-14, 1291), also occurred as a possible consequence of tacrolimus treatment in a 50-year-old woman (86). Bilateral knee pain occurred within 2 months after renal transplantation and bone scintigraphy showed increased uptake in both knees. Calcitonin was ineffective, and she improved only after the dose of tacrolimus was reduced.

Sexual function

Priapism has been described in a patient with a liver transplant (87).

- One month after transplantation, a 19-year-old man who was taking tacrolimus, azathioprine, and prednisone, developed nausea and vomiting. He reported a 2-week history of painful spontaneous penile erections lasting 2–3 minutes and had had no previous episodes of priapism. An episode of spontaneous erection was confirmed during a medical examination that found no physical abnormalities. The tacrolimus blood concentration was 28 ng/ml. The digestive symptoms and priapism resolved after the tacrolimus concentration had fallen. Sickle cell disease was ruled out.

The authors discussed several mechanisms, including tacrolimus-induced vasodilatation, platelet aggregation, an increase in serotonin, or a fall in endothelin concentrations, based on in vitro data only.

Immunologic

Tacrolimus reduces IgE antibody synthesis, with a subsequent dramatic increase in IgE serum concentrations. This phenomenon has been reported in one asymptomatic patient but has also been advanced as an explanation for a case in which an infant girl treated with tacrolimus had milk hypersensitivity (SEDA-21, 391).

Fish allergy with increased IgE total concentrations and specific IgE antibodies against various fish products have been reported in two children with liver transplants (88). Even though both patients had a personal or familial history of allery, this again suggested a possible relation between tacrolimus and food allergy.

An increasing blood eosinophil count was associated with *Pneumocystis jiroveci* pneumonia in patients taking tacrolimus (89). The mean absolute eosinophil count was significantly higher and absolute eosinophilia (over 350×10^6/l) was more frequent in six patients who developed *P. jiroveci* pneumonia while taking tacrolimus compared with six patients with *P. jiroveci* pneumonia who were taking ciclosporin and eight patients without *P. jiroveci* pneumonia who were taking tacrolimus. A retrospective analysis also showed that the increase in eosinophil count preceded the diagnosis of *P. jiroveci* pneumonia.

Infection risk

Tacrolimus-based immunosuppression may be associated with a lower incidence of major infectious complications,

© 2006 Elsevier B.V. All rights reserved.

namely CMV and pneumonia compared with other drugs (90). However, this hypothesis is based on a single paper, and other studies have been unable to find significant differences in the incidence of major infections between tacrolimus and ciclosporin (5,91). In addition, and as a direct consequence of excessive immunosuppression, a further retrospective study found an increased incidence of symptomatic Epstein–Barr virus infections and related lymphoproliferative disorders in children under 5 years of age who had taken tacrolimus rather than ciclosporin (92).

An unexplained change in the pattern of microbial causes of pneumonia has been noted in liver transplant patients taking tacrolimus, with an unexpectedly high incidence of *Legionella* and fungal pneumonia, the latter being involved in all deaths directly due to pneumonia (93).

In a randomized, double-blind, placebo-controlled study at 23 centers in the USA, children with moderate to severe atopic dermatitis applied the vehicle, tacrolimus ointment 0.03%, or tacrolimus ointment 0.1% for 12 weeks (94). Burning and pruritus were the main adverse effects. *Varicella* infection and vesiculobullous rashes on non-application areas occurred, but with a low incidence (below 5%). Since they occurred in those who used tacrolimus 0.03%, it is likely that they were random events rather than drug-related. Regardless of dose, there were some age-related differences in the incidence of individual adverse events. For example, otitis media was more common in younger children (2–6 years). Tacrolimus ointment had no age-selective effect that was not also observed with the vehicle. Each of the adverse events resolved without sequelae.

Long-Term Effects

Tumorigenicity

It has generally been considered that the incidence and pathological features of tacrolimus-induced cancers after transplantation are similar to those observed with other immunosuppressive agents, in particular ciclosporin (95). However, in a retrospective study in 392 children, who survived for more than 6 months after liver transplantation and were followed for a mean of 4.3 years, there was a five-fold higher rate of lymphoproliferative disease after transplantation in children who took tacrolimus ($n = 141$) than in those who took ciclosporin ($n = 251$) (96). As a result, the incidence density rate of lymphoproliferative disease was 4.8 per 100 person-years in tacrolimus-treated patients, with no difference among age groups. In addition, the mean time to lymphoproliferative disease (12.6 months) was five-fold shorter with tacrolimus than with ciclosporin. Most of the patients with lymphoproliferative disease had a primary Epstein–Barr virus infection after transplantation. The authors suggested that the 10-fold higher in vivo immunosuppressive effect of tacrolimus might have accounted for these findings.

Tacrolimus-induced post-transplant lymphoproliferative diseases are similar to those of the conditions induced by other immunosuppressants, particularly ciclosporin (SED-13, 1131). However, additional data from prolonged follow-up are still awaited. In children who are frequently Epstein–Barr virus-negative, the incidence of post-transplant lymphoproliferative disease varies from 6–11% to 22% after liver transplantation (97). In 89 children, the incidence of post-transplant lymphoproliferative disease at 1 year was 20% (possibly related to Epstein–Barr virus in 89% of patients) (98). Excessive immunosuppression, for example as a result of prior muromonab or antithymocyte globulin administration and high tacrolimus blood concentrations during the period preceding Epstein–Barr virus infection are regarded as significant risk factors, emphasizing the need to secure low trough tacrolimus concentrations after the first post-transplant month. An increase in total gammaglobulin and the development of oligoclonal or polyclonal immunoglobulins were thought to be preliminary signs of this syndrome.

Second-Generation Effects

Pregnancy

Among 25 infants born after 27 pregnancies in tacrolimus-treated liver transplant patients there was an unexpectedly low incidence of hypertension, pre-eclampsia, and allograft function abnormalities, whereas preterm delivery, low birth weight, and transient mild renal impairment with hyperkalemia in neonates occurred at a similar rate (99).

It has been suggested that tacrolimus may be less likely than ciclosporin to cause maternal renal dysfunction or pre-eclampsia, but this hypothesis is based only on retrospective work in a small number of patients (100).

- Congestive heart failure with dilated cardiomyopathy occurred in twin boys born to a woman with a renal transplant who had taken tacrolimus throughout her pregnancy (101). One twin died from irreversible cardiac failure, and autopsy findings showed thrombogenic cardiomyopathy and degeneration of cardiac muscle. The other twin was more actively treated and had only mild tricuspid insufficiency on follow-up.

This report is in keeping with the possible and debated role of tacrolimus in the development of cardiomyopathy in children.

Teratogenicity

In the National Transplantation Pregnancy Registry, there was no evidence of an increased incidence of congenital malformations among 25 infants born after 27 pregnancies in tacrolimus-treated liver transplant patients (99).

Fetotoxicity

Among 25 infants born after 27 pregnancies in tacrolimus-treated liver transplant patients, there were two neonatal deaths whose conception had been close to the time of transplantation, and very high tacrolimus cord levels were found in one child who presented with neonatal anuria (99).

Drug Administration

Drug overdose

Acute tacrolimus overdosage usually produces only moderate toxicity or none at all. From the data available in 16 children or adults, overdosage up to 30 times the intended

© 2006 Elsevier B.V. All rights reserved.

dose produced no symptoms in seven patients and reversible moderate increases in serum creatinine concentrations, or transaminase activities, nausea, and mild tremors in eight patients who underwent gastric decontamination and conservative measures only (102,103). An additional patient on maintenance treatment developed renal insufficiency, histoplasmosis, and sepsis within two days of overdosage. Continuous hemofiltration dramatically increased the rate of elimination of tacrolimus in two other patients who experienced acute renal and liver failure with high plasma tacrolimus blood concentrations (104).

Even large accidental overdosage of tacrolimus does not result in marked acute toxicity (105).

- The inadvertent administration of 25 times the intended dose in a 22-month-old infant produced minimal consequences, with only a five-fold reversible increase in serum amylase activity.

Drug–Drug Interactions

Antimicrobial agents

The hepatic metabolism of tacrolimus is primarily mediated by CYP3A, and experimental evidence suggests a theoretical potential for numerous interactions with drugs that induce or inhibit CYP3A. However, very few formal drug interaction studies have been carried out, and most of our current knowledge is based on case reports and small series of patients, or is derived from experience accumulated with ciclosporin. Among antimicrobial agents, erythromycin, chloramphenicol, clarithromycin, clotrimazole, danazol, oral (but not intravenous) fluconazole, itraconazole, and ketoconazole increase tacrolimus serum concentrations and can cause subsequent nephrotoxicity, whereas rifampicin reduces tacrolimus concentrations (SED-13, 1131) (SEDA-20, 348) (SEDA-22, 419) (106–109).

- A potential interaction with pristinamycin has been described in a 41-year-old renal transplant patient who had an approximate five-fold increase in tacrolimus trough concentrations within 4 days of pristinamycin treatment (110).
- A 10-fold increase in tacrolimus dosage was required in a 61-year-old patient with a renal transplant who took concomitant rifampicin (111).

The interaction of tacrolimus with rifampicin has been convincingly confirmed in six healthy volunteers who took a single oral or intravenous dose of tacrolimus (112). Rifampicin 600 mg/day for 18 days produced a significant 47% increase in tacrolimus clearance after intravenous administration and a 51% reduction in its oral systemic availability, consistent with induction by rifampicin of both hepatic and intestinal metabolism of tacrolimus.

Calcium channel blockers

A 3-day course of diltiazem 90 mg/day produced a four-fold increase in tacrolimus trough concentrations in a 68-year-old patient with a liver transplant (113).

In a non-randomized, pharmacokinetic study, four patients taking tacrolimus after kidney and liver transplantation were given diltiazem in seven incremental dosages of 0–180 mg at 2-week intervals (114). The mean tacrolimus-sparing effect was similar to the ciclosporin-sparing effect previously reported. This effect occurred at a lower dose of diltiazem in renal transplant patients than in liver transplant patients. Tacrolimus is metabolized by CYP3A4 and is also a substrate for P glycoprotein, and this interaction could have occurred by inhibition of these mechanisms.

A retrospective study has shown a significant improvement in kidney function and a 38% reduction in tacrolimus dosage requirements in patients taking both nifedipine and tacrolimus compared to patients not taking nifedipine (115).

Ibuprofen

Acute renal insufficiency in association with the use of ibuprofen and tacrolimus has been reported in two liver transplant recipients (116), and the relevance of this interaction is probably similar to that reported with ciclosporin.

Metronidazole

Metronidazole can produce a two-fold increase in blood concentrations of ciclosporin and tacrolimus, with a subsequent increase in serum creatinine in both cases (117).

Mibefradil

Mibefradil, a potent inhibitor of CYP3A, increased tacrolimus blood concentrations dramatically (118).

Nefazodone

Nefazodone may inhibit the metabolism of tacrolimus (119).

- A 16-year-old boy had a five-fold increase in tacrolimus blood concentrations and a two-fold increase in creatinine concentrations within 4 weeks of nefazodone treatment. Complete normalization occurred after replacement with paroxetine and a transient reduction in tacrolimus dosage.

Protease inhibitors

Various protease inhibitors are metabolic inhibitors and are predicted to have deleterious effects on tacrolimus metabolism.

- In a 52-year-old liver transplant patient with HIV infection, successive treatment with various antiretroviral combinations containing nelfinavir, ritonavir, or saquinavir increased tacrolimus blood concentrations and caused severe prolonged neurological symptoms suggestive of tacrolimus toxicity (120). The patient was finally stabilized with a regimen containing nelfinavir, stavudine, and lamivudine, and a more than 95% reduction in the dosage of tacrolimus.
- An acute drug interaction with nelfinavir has been described in a 49-year-old liver transplant man with HIV and hepatitis C infections (121). The patient had three consecutive episodes of increased blood tacrolimus concentrations during nelfinavir administration. Both drugs were finally continued, but the dose of tacrolimus was only one-seventieth of the usual dose.

Theophylline

An increase in tacrolimus trough blood concentrations has been attributed to concomitant theophylline therapy in a 33-year-old man with a renal transplant (122). A subsequent pharmacokinetic study showed that theophylline increased the AUC of oral tacrolimus six-fold.

Voriconazole

In a patient who took tacrolimus after liver transplant, co-administration of voriconazole resulted in raised trough tacrolimus concentrations (nearly 10-fold); there were no changes in another patient, who took a placebo (123). Voriconazole inhibits the metabolism of tacrolimus in liver microsomes by 50% in vitro.

Monitoring Therapy

In 14 patients with renal transplants, there was a closed relation between individual tacrolimus whole blood trough concentrations and the occurrence of adverse effects (124). The incidence of tacrolimus adverse effects was 76% with tacrolimus concentrations above 30 ng/ml and only 5.3% with concentrations below 10 ng/ml. This relation was found in all separate groups of adverse effects analysed, that is nephrotoxicity, neurotoxicity, infections, and others. In contrast, there was no relation between tacrolimus concentrations and rejection episodes. Accordingly, the authors stressed that tacrolimus whole blood trough concentrations should be strictly kept under 20 ng/ml.

There is no relation between tacrolimus blood concentrations and the occurrence of major neurotoxicity (125).

Tafenoquine

General Information

Tafenoquine is an 8-aminoquinoline derivative that is more active than primaquine (SEDA-13, 811). It is active against all human forms of malaria. In animals, tafenoquine is several times more potent than primaquine and is effective against both blood and liver stages of the malaria parasite. It has a half-life of 14 days, which makes it a good candidate for prophylaxis, with the

© 2006 Elsevier B.V. All rights reserved.

possibility of monthly dosing. It was effective and safe in early trials (1).

In a randomized, double-blind, placebo-controlled trial, in a single oral dose of 4–600 mg (base) in 48 men it was well tolerated, apart from minor gastrointestinal disturbances; the half-life was 14 days (2). However, although tafenoquine may well be safer than primaquine, patients were also excluded from this trial if they had glucose-6-phosphate dehydrogenase (G6PD) deficiency, so it remains to be seen whether tafenoquine can overcome the most important practical problem with primaquine. Further widespread use will be needed before rare adverse effects, if any, emerge (SEDA-14, 958) (SEDA-21, 296) (SEDA-22, 305) (SEDA-23, 306).

There has been a randomized placebo-controlled study of tafenoquine as chemoprophylaxis for malaria in 426 Gabonese schoolchildren aged 12–20 years (1). Children with G6PD deficiency were excluded. Radical cure of malaria was achieved with halofantrine followed by placebo or tafenoquine in the following daily doses: 250 mg, 125 mg, 62.5 mg, or 31.25 mg given for 3 days. Follow-up was for 77 days. Tafenoquine was highly effective in dosages over 62.5 mg/day. There were 180 adverse events thought to be related to the study drug. All were mild and self-limiting and none was considered to be serious. They included headache, fever, and abdominal pain. However, none was significantly more common with tafenoquine than with placebo. On day 28, but at no other time, there was a small (0.4 g/dl) but significant fall in hemoglobin concentration with tafenoquine 250 mg/day.

Susceptibility Factors

Age

In 104 healthy men (mean age 29 years, weight 60 kg) who took tafenoquine for malaria prophylaxis (loading dose 400 mg/day for 3 days followed by 400 mg/month in 5 consecutive months) age and weight affected the apparent volume of distribution, and subjects who contracted malaria had higher clearance rates (3). The population estimate of the first-order absorption half-life was 1.0 hour, clearance was 3.20 l/hour, volume of distribution was 1820 liters, and half-life was 16.4 days.

Talc

General Information

Talc is a three-layered magnesium sheet with lubricant properties; it is rarely found as a pure entity in nature. The particle size varies considerably (1) depending on the manufacturing process, and may be an important factor in the development of adverse effects. Talc is principally used as inert filler material in medicinal tablets or as a drying ingredient in baby powders. The adverse effects of talc include empyema, dysrhythmias, and respiratory failure (2).

Use of talc in pleurodesis

Intrapleural therapy in humans was first reported by Bethune in 1935, when he described the dusting of pleural surfaces with talc before lobectomy to promote pleurodesis (3). Since this initial description, many different agents have been used intrapleurally to produce pleurodesis, both in patients with pleural effusion and in patients with pneumothorax. Some of these agents, talc in particular, have been associated with potentially serious adverse events. Over the last 25 years the role of intrapleural therapy has expanded and now includes the instillation of thrombolytic agents intrapleurally to hasten the resolution of complicated pleural space infections (empyema); both streptokinase and urokinase have been used for this purpose. Malignant pleural effusions represent 25–50% of all pleural effusions seen in a general hospital (4). Lung, breast, ovarian, genitourinary, and gastrointestinal tract malignancies are often associated with pleural effusions, and malignant effusion is often the first manifestation of malignancy (5,6).

The aim of pleurodesis is to produce fusion between the visceral and parietal pleural surfaces and so prevent the accumulation of air or fluid in the pleural space. In a chemical pleurodesis, this fusion is generally achieved by the instillation of agents that induce an inflammatory response on the pleural surfaces. These agents can be introduced into the pleural space through a chest tube at the bedside or during thoracoscopy/thoracotomy.

Mechanism of action

The mechanism of action of talc in pleurodesis has not been fully elucidated, although it is thought to stimulate a typical local inflammatory response, with reduced fibrinolytic activity, mesothelial cell injury, and fibroblast proliferation. Pneumonitis or respiratory failure can be secondary to downstream inflammatory mediators from more proximal talc injury (7). This acute-phase inflammatory response is dose-related (8,9) and is inhibited by glucocorticoids (10). Talc may also have an adhesion stimulating quality, since empyema alone stimulates a typical inflammatory response but does not lead to pleurodesis (11). In fact, talc stimulates intercellular adhesion molecule-1 in mesothelial cells (12). The mechanism of chronic fibrosis may involve continuous fibroblast activation by foreign body giant cell released mediators or macrophages.

Administration

Talc can be insufflated into the pleural space in a powder form, usually at thoracoscopy or thoracotomy (talc poudrage), or can be mixed with normal saline and instilled through a standard chest tube as talc slurry.

Comparative studies

The use of talc, one of the most common agents for chemical pleurodesis, has been documented in more than 3000 patients, largely in the form of case series (13). The intrapleural use of talc has been the subject of a number of recent comprehensive reviews (11,14,15).

Of 51 patients with malignant pleural effusions, 14 underwent slurry talc pleurodesis via a chest tube, 14 had talc poudrage during Video-Assisted Thoracoscopic exploration of the pleural cavity for suspected malignant effusion, and 24 underwent chemical pleurodesis with bleomycin via a chest tube (16). The most common adverse effects were chest pain and fever. The duration of adverse effects after talc pleurodesis was longer (2–3 days) than after bleomycin. There was chest pain in 15 of the 28 patients who received talc, with a duration of 18–52 (median 31) hours. There was fever in 22 of those who received talc, with a duration of 5–34 (median 12.5) hours. Complications were more common in those who received talc, such as thoracic empyema ($n = 1$), wound infection ($n = 2$), and respiratory distress ($n = 5$).

Adverse effects

Adverse events related to agents used in pleurodesis have been rare. However, almost any agent introduced into the pleural space can reach the circulation through inflamed pleural surfaces, with potential adverse effects (17). A case of fulminant pneumonitis following talc pleurodesis prompted a review of the existing experience (18). Of 78 patients with recurrent pleural effusions or pneumothorax treated by pleurodesis, five had bilateral pleural effusions, resulting in a total of 89 procedures. In 19 procedures talc was administered by poudrage and in 70 procedures it was given as a slurry with 50–500 ml of isotonic saline and 20–30 ml of 1% lidocaine. The dose was 5 g in 85 procedures, and 2.5 and 10 g each in two procedures. Of the patients who presented with malignant effusions, 18 had a primary carcinoma in the lung, 12 in the ovary, and 10 in the breast; there were six cases of lymphoma; 13 patients had less common primaries. Nine patients had benign or undiagnosed effusions and nine had spontaneous pneumothorax.

Of the procedures evaluated, 19 involved only minor complications, including fever over 38.1°C within 12 hours of pleurodesis in 13, asymptomatic hypoxemia in 19, dyspnea relieved by oxygen in six, and an increased need for narcotics in five. Subcutaneous emphysema, local infection, and asymptomatic hypotension each occurred after one procedure. There were major complications in 11 patients, including one patient with pulmonary embolism, three with unilateral pulmonary edema, eight who developed bilateral pulmonary edema, and one who died within 24 hours after bilateral talc administration. Patients developed respiratory complications after 24 of 28 talc pleurodesis procedures. The most significant respiratory complication was adult respiratory distress syndrome, defined by bilateral diffuse infiltrates on chest X-ray and hypoxemia requiring mechanical ventilation, which occurred after eight procedures in seven patients. This figure includes one patient who died after simultaneous bilateral talc poudrage.

Minor adverse effects related to talc pleurodesis are common: chest pain occurs in about 7% of patients and fever in 16–69%. Fever characteristically starts within 4–12 hours of pleurodesis and rarely lasts more than 72 hours. Chest pain is usually only mild (11,13,14).

Respiratory complications

The most serious adverse effect of talc is a possible association between talc pleurodesis and the development of acute respiratory failure (usually in the form of ARDS); over 30 cases have been described (13) after intrapleural talc either as a slurry (8) or insufflated (18,19). The literature on acute respiratory failure after intrapleural talc has been reviewed, with recommendations on whether talc should continue to be used to produce pleurodesis (20). Some believe that intrapleural talc should not be used to produce a pleurodesis, since there are effective alternatives for producing pleurodesis (mechanical abrasion if thoracoscopy is performed, tetracycline derivatives or bleomycin if chest tubes are used).

Most cases of ARDS have occurred in patients with malignant pleural effusions, not all were clearly talc-related, and there is not enough information in some case reports to be certain of the role of talc. For example, in 1980, respiratory failure/pneumonia in seven of 197 patients who underwent talc poudrage for malignant pleural effusion was described in an abstract, but no further information regarding the clinical course of these patients is available (9). In 1983, Rinaldo et al. were the first to carefully document the development of ARDS after intrapleural talc instillation (8). They described three patients who developed progressive dyspnea and acute respiratory failure, characterized by bilateral diffuse pulmonary infiltrates, within 72 hours of the instillation of talc 10 g through a chest tube. All three had underlying malignancies and all required intubation and ventilation for respiratory failure. One patient died after 1 month of intensive care support. No other cause for ARDS was found in these patients and the authors were confident that talc had been responsible by unknown mechanisms. They recommended that other sclerosants be used for chemical pleurodesis. At around the same time, a patient who developed acute pneumonitis after chemical pleurodesis with talc 2 g was described (21). The clinical course of this patient was different to that described above: breathlessness occurred within 3 hours of pleurodesis, but the patient did not require intensive care support until 10 days later, when bilateral pulmonary infiltrates developed. At bronchoalveolar lavage 12 days after pleurodesis, talc particles were seen in the lavage fluid. No other cause for the pulmonary infiltrates was found and the patient recovered with oxygen and corticosteroid therapy alone. The authors suggested that systemic absorption of talc, with subsequent embolization to the

© 2006 Elsevier B.V. All rights reserved.

lung, had produced this picture and they also suggested that pleural biopsies performed just before pleurodesis might have aided the systemic absorption of talc.

Three large case series were published after these reports. In two series (15,22) there were no episodes of respiratory distress after talc pleurodesis in 299 and 360 patients respectively. However, respiratory failure occurred in five of 58 patients treated with talc pleurodesis (23). Excess narcotic analgesia and infective pneumonia were considered causative in two patients, and two other patients recovered with oxygen and corticosteroids. No more information on these two patients was provided. The remaining patients developed bilateral pulmonary infiltrates and severe hypoxia consistent with ARDS, but recovered after intubation and ventilation for 5 days. This patient had undergone simultaneous bilateral talc pleurodesis and the authors thought that the higher dose of talc that this patient had received might have contributed to the development of ARDS. Again, the mechanism by which talc produced ARDS was unknown.

The possibility that talc can cause respiratory failure was explored further in 1997 (24). ARDS occurred in four of 338 patients treated with talc poudrage (2 g) via thoracoscopy. All four had malignant effusions and all developed bilateral pulmonary infiltrates, hypoxia, and hypotension within 24–48 hours of talc insufflation. All four required mechanical ventilation and three died. Bronchoalveolar lavage was performed in all four and talc crystals were recovered from lavage fluid in each case. Furthermore, at autopsy in one patient, talc crystals were found in almost every organ, showing that systemic distribution of talc did occur after pleurodesis. However, as the authors acknowledged, it was not possible to definitely attribute the symptoms in these patients to the talc pleurodesis. Studies in animals have shown systemic distribution of talc after pleurodesis (25). However, systemic dissemination may occur in all patients treated with pleurodesis and does not confirm that this is the cause of respiratory failure documented in a small number of patients.

The highest incidence of respiratory complications after talc pleurodesis was reported in 1999 in a retrospective review of 89 procedures in 78 patients (18). ARDS occurred in 9% (that is after eight procedures in seven patients). All seven patients had increased oxygen requirements, respiratory distress, and bilateral infiltrates on chest X-ray, and required a mean of 38 hours of mechanical ventilation. Six patients had malignant effusions. The other had AIDS, had undergone bilateral pleurodesis for pneumothoraces secondary to *Pneumocystis jiroveci* (*Pneumocystis carinii*) pneumonia, and died within 24 hours of the procedure. No more clinical information was given about the other six patients, particularly regarding the time-course of symptoms and investigations to exclude other diseases.

Since the literature on this topic largely comprises case reports and retrospective reviews, it is possible that complications may have been under-reported. In addition, there is marked variability in the reported incidence of respiratory complications from series to series, and there is the additional confounding factor that malignant pleural effusion, a condition with a poor short-term survival and significant associated morbidity, is often the indication for talc pleurodesis. Respiratory complications are common in these patients, and talc pleurodesis may be coincidental rather than causative. Other possible causes for respiratory distress in these patients include re-expansion pulmonary edema, sepsis related to the chest-tube, and bacterial contamination of talc. The presence of talc crystals in bronchoalveolar lavage fluid indicates systemic distribution but not necessarily causation of ARDS, and is likely to occur in all patients treated with talc. There is significant variability in the talc preparations available for pleurodesis, and it has been suggested that smaller particle size poses a higher risk for ARDS, although this is unproven. It has also been suggested that pleural biopsy before pleurodesis may increase the risk of ARDS (also unproven).

Organs and Systems

Respiratory

Intravenous injection of "solubilized" psychoactive pills containing talc can produce microemboli in small pulmonary vessels, leading to talc granulomatosis, a common finding in drug abusers. Medications intended for oral use can be injected or sniffed, together with talc particles. Pulmonary hypertension due to talc microemboli is a well-known cause of respiratory failure in heroin addicts.

- A heroin addicted patient, who had been followed up for 6 months for increasing dyspnea due to chronic cor pulmonale, was admitted to an intensive care unit. She died shortly after. Postmortem lung biopsies showed talc particles within alveolar walls and alveolar macrophages, as well as alterations in blood vessels (26).

Talc granulomatosis has been ascribed to sniffing cocaine (27).

Overzealous application of baby powder can cause severe pulmonary complications if the infant inhales the powder (28).

Formation of umbilical granulomas has been described as an adverse effect of talc in a newborn infant (29).

A group of patients underwent lung function testing 22–35 years after they were treated for idiopathic spontaneous pneumothorax either with talc poudrage or by simple drainage. The former caused mild restrictive impairment of lung function with a mean total lung capacity 89% of predicted, compared with a mean total lung capacity of 96% in subjects who had been treated by simple drainage. None of the subjects had developed a mesothelioma (30).

Although described in association with conglomerate masses and bullous disease in end-stage talc granulomatosis, spontaneous pneumothorax can also occur earlier in the course of talc-induced lung disease (31).

Gastrointestinal

An experimental animal study undertaken to determine whether cornstarch powder suspended in physiological saline causes intraperitoneal adhesions after laparotomy showed a significantly higher incidence of adhesions than in the control group two weeks after surgery. It was recommended that powder-free surgical gloves should

© 2006 Elsevier B.V. All rights reserved.

be used to prevent adhesion formation after abdominal surgery (32).

Long-Term Effects

Tumorigenicity

Ovarian cancer has been increasing in frequency over the past 40 years, and a role for environmental factors in its etiology has been inferred from its higher incidence in industrialized countries. Cosmetic talc, deposited in the vagina after direct application to the perineum or to undergarments, sanitary napkins, or diaphragms, or through use of a talc-dusted condom during intercourse, may play an important role. In a case-control study of the use of talc in genital hygiene the risk of ovarian cancer was significantly increased in women who applied talc directly as a body powder, on a daily basis, for more than 10 years (33). The greatest risk of ovarian cancer was in the subgroup of women estimated to have made more than 10 000 talc applications during years when they were ovulating. However, this exposure was found in only 14% of women with ovarian cancer. The authors concluded that a life-time pattern of perineal talc use may increase the risk of epithelial ovarian cancer, but that it is unlikely to be the cause of most cases of epithelial ovarian cancers.

Talipexole

General Information

Talipexole is a dopamine receptor agonist.

Long-term evaluations have indicated that no new adverse effects appear after the first 8 weeks of treatment and that overall adverse effects may abate with time.

Organs and Systems

Cardiovascular

Sinus bradycardia and hypotension have been attributed to talipexole (1).

- About 4 hours after a 65-year-old man with Parkinson's disease took talipexole hydrochloride 0.8 mg, he acutely developed sleepiness, delusion, akinesia, and faintness associated with hypotension and sinus bradycardia. A similar episode occurred when he took talipexole hydrochloride 1.2 mg/day in combination with co-careldopa (levodopa 200 mg/day plus carbidopa 20 mg/day). These symptoms persisted for 12 hours and abated gradually without any specific treatment.

The authors suggested that talipexole had caused bradycardia and hypotension by stimulating both D_2 dopamine receptors and alpha$_2$-adrenoceptors.

Nervous system

Frequent nervous system adverse effects of talipexole are drowsiness, dizziness, and fatigue (2); headache and confusion have also been reported. Talipexole can improve the negative symptoms of schizophrenia but exacerbate the positive symptoms (3).

Extrapyramidal reactions to talipexole are uncommon.

- A 60-year-old man with a 12-year history of Parkinson's disease was given talipexole for the wearing-off phenomenon 3 years after starting levodopa (4). His parkinsonism deteriorated and his serum creatine phosphokinase activity rose to 1875 IU/l. The talipexole was withdrawn after gradual dosage reduction and he gradually improved.

The authors suggested that talipexole had caused an incomplete form of the neuroleptic malignant syndrome.

Talniflumate

See also Non-steroidal anti-inflammatory drugs

General Information

Talniflumate is an inhibitor of calcium-activated chloride channels, which has been developed to treat mucous hypersecretion (1). It is a phthalidyl ester of pyridinecarboxylic acid, related to niflumic acid.

Organs and Systems

Gastrointestinal

Gastrointestinal effects are the most frequent adverse effects of talniflumate (2).

Tamoxifen

General Information

Tamoxifen is an estrogen receptor partial agonist with antiestrogenic properties in the breast and estrogenic effects in tissues such as bone and the cardiovascular system. In most cases there is endometrial thickening on ultrasonography, and additional tests, such as hydrosonography or hysteroscopy, are required to confirm the presence of an empty atrophic uterus, as seen in most asymptomatic women taking tamoxifen.

Tamoxifen is commonly used in the treatment of breast carcinoma (1); the overall rates published for adverse effects vary very greatly, between 1 and 60% (2,3). It has also been used as a form of HRT to reduce bone loss and the incidence of fractures in high-risk cases (4). A combination of tamoxifen with ovarian suppression is as effective as the use of cytostatic drugs, and has been claimed to be better tolerated (5–7).

The use of tamoxifen to prevent breast cancer has been reviewed (8). The merits of using tamoxifen to prevent mammary carcinoma in women who have never had the disease but are believed to be at high risk have been disputed (9), but it is clear that it would involve very long treatment and that one's view of the adverse effects might need to be revised for this class of users. The available data after 5, 10, and 15 years of follow up confirmed an increase in the incidence of endometrial cancer and of thromboembolic complications and suggested ocular toxicity, but these effects were not common and should be more than balanced by the reduced risk of coronary heart disease and osteoporosis (8).

© 2006 Elsevier B.V. All rights reserved.

Tamoxifen also has beneficial side effects: it protects the myocardium, reduces the incidence of ischemic heart disease, reduces the loss of bone mineral density, and has beneficial effects on lipids (10).

Observational studies

The effect of high-dose tamoxifen as an adjunct to postoperative brain irradiation has been studied for 40 weeks in 12 patients with glioblastoma multiforme, but without controls (11). Two weeks after surgery, the patients were given high-dose oral tamoxifen (120 mg/m^2 bd for 3 months) and 2 weeks later external beam radiotherapy (59.4 Gy, three daily fractions every 6.5 weeks). In one patient tamoxifen was associated with severe vomiting, necessitating dosage reduction and subsequent withdrawal; another patient had bilateral deep venous thrombosis after 51 weeks, but a causal relation was not firmly established. The authors concluded that adjuvant high-dose tamoxifen is relatively well tolerated, although in this series it did not appear to improve the prognosis.

Placebo-controlled studies

In the Breast Cancer Prevention Trial (P-1), initiated by the National Surgical Adjuvant Breast and Bowel Project (NSABP) in 1992, more than 13 000 eligible women were randomized to tamoxifen 20 mg/day or placebo for 5 years (12). During 69 months of follow-up tamoxifen reduced the risk of both invasive and non-invasive cancer and reduced fractures of the hip, radius, and spine; however, the rate of endometrial cancer increased (RR = 2.53; 95% CI = 1.35, 4.97), as did the frequency of vascular events.

General adverse effects

The adverse effects of tamoxifen are largely those that one would expect to be associated with a reduction in estrogenic activity, that is hot flushes (which can be severe), dry skin, mental or nervous system effects (such as mild depression, headache, fatigue, nervousness, and tremor), oligomenorrhea and amenorrhea, loss of libido, vaginal discharge, and rare events, such as pruritus, migraine, and edema (SED-12, 1034) (13). Nausea and vomiting are not uncommon. There are also reports of hirsutism, weight gain, rashes, thrombocytopenia, and leukopenia (SED-12, 1034); the hirsutism could reflect a relative dominance of endogenous androgen activity as the degree of estrogenic activity declines. The most specific and dangerous complication of tamoxifen is hypercalcemia, a direct consequence of the successful treatment of mammary carcinoma with bony metastases; the incidence varies greatly. Liver dysfunction and peliosis hepatis have been incidentally reported.

When tamoxifen is used in men (14), common adverse effects have included weight gain (25%), mood alterations (21%), hot flushes (21%), reduced libido (29%), and deep vein thrombosis (4%). The hot flushes respond well to oral clonidine 0.1 mg/day (15).

One expert in the USA (16) has publicly defended the safety of tamoxifen on the grounds that some of its supposed adverse effects may in fact have other causes. It is a difficult argument to follow, since she postulates that several of the unwanted effects referred to are in fact menopausal. However, these are largely likely to be inevitable consequences of the very changes that treatment with tamoxifen is intended to induce, that is suppression of estrogenic effects. Virtually the opposite belief can be derived from a Canadian study, which showed that 25 women taking tamoxifen were diffident about attributing adverse events to the drug, and therefore tended to under-report adverse effects (17). Menopause-like problems with these drugs are clearly likely to persist unless or until more selective SERMs become available, for example substances that act exclusively on the breast tumor.

Organs and Systems

Cardiovascular

Both deep vein thrombosis and pulmonary embolism have been described with tamoxifen.

- Cerebral sinus thrombosis, progressing to hemorrhagic cerebral infarction, occurred in a 52-year-old woman (18).

Although the authors pointed to the absence of risk factors other than the drug, it must be remembered that cerebral venous thrombosis is a recognized complication of various malignancies. In this case the breast tumor had been treated with various cytostatic drugs and stem cell transplantation, and tamoxifen had been given as an adjuvant, and it was believed that the tumor had been eliminated. Nevertheless, in this complex case one should perhaps be hesitant in attributing the complication solely to the drug.

In the light of three further cases of thrombosis, it has been suggested that there may be a particular predisposition to this complication in patients with high circulating concentrations of homocysteine, and that these should be checked for in advance of treatment (19).

In one case tamoxifen was associated with myocardial infarction (20).

Respiratory

An important synergistic reaction between radiation-related pulmonary fibrosis and tamoxifen has been described in 196 women followed for a minimum of 5 years, with a relative risk of 2.0 (21). However, others have shown that tamoxifen did not increase the pulmonary toxicity of agents such as carmustine and dacarbazine (22).

Nervous system

A short supplementary report on the US NSABP, originally published in 1999, later corrected the original data on adverse effects: among women who had used tamoxifen for an average of 29 months to complement irradiation after lumpectomy for intraductal carcinoma; there were five cases of stroke, compared with only one among the women who had not used tamoxifen (23). In a parallel study of breast cancer prevention there was also a slight but non-significant increase in the incidence of stroke in those taking tamoxifen. It may be wise to regard a history of stroke, transient ischemic attacks, uncontrolled

© 2006 Elsevier B.V. All rights reserved.

hypertension, diabetes mellitus, or atrial fibrillation as relative contraindications to tamoxifen.

Sensory systems

There have been repeated reports of ophthalmic complications from tamoxifen, including irreversible retinopathy with seriously reduced visual acuity, refractile opacities, cystoid macular edema, retinal yellow-white dots, and keratopathy (SEDA-6, 356) (SEDA-7, 391) (SEDA-16, 466).

- Bilateral optic neuritis developed in a woman with breast cancer who was treated for 6 months with tamoxifen (24).

In a prospective study even in low doses (for example 10 mg/day or lower) tamoxifen caused ocular toxicity if given for a sufficiently long period; most of the changes were reversible but they justify very close monitoring (25). A related compound, MER-29 (triparanol), causes cataract and has various other adverse reactions in common with tamoxifen.

Metabolism

Steatosis and adipose tissue distribution has been evaluated using CT scanning in a cross-sectional study of 32 women taking tamoxifen for breast cancer and a similar control group (26). Tamoxifen users generally had more visceral adipose tissue and more liver fat than controls, and had a higher risk of diabetes. It is still unclear whether tamoxifen causes long-term metabolic abnormalities in obese patients, or whether patients with the metabolic syndrome X of obesity are at increased risk of the complications of tamoxifen. In view of this finding, and earlier results pointing in the same direction, it would be wise in future studies of tamoxifen to monitor metabolic changes in obese women with or without breast cancer.

Hematologic

Thrombosis and pulmonary embolism have been described with tamoxifen (27,28); the number of cases is small, but the association would not be unexpected in view of what is known about the effects of other sex hormones. The primary condition might be responsible, at least in part, for the occurrence of such complications. Tamoxifen does reduce antithrombin III but not to a degree at which a major risk would be expected, and other measurable effects on the coagulation process seem to be slight.

When tamoxifen 20 mg/day was compared with equieffective doses of anastrozole in 668 patients with advanced breast tumors that were hormone receptor-positive or of unknown receptor status, tamoxifen produced too high a rate of thromboembolism and vaginal bleeding to be considered the treatment of choice (29,30).

Liver

Liver dysfunction and peliosis hepatis are occasional complications of tamoxifen. There have also been reports of cirrhosis with fatty liver in women taking tamoxifen after surgery for breast cancer (31). The condition is reversible, and liver tests are advisable so that the tamoxifen can be promptly withdrawn if necessary.

- An elderly woman with a history of breast cancer developed multifocal steatohepatitis, but after tamoxifen was withdrawn the CT features improved dramatically, and the hepatic transaminases normalized (32).

Skin

Tamoxifen has several adverse effects on the skin, including edema, flushing, rashes, hyperhidrosis, urticaria, alopecia, and hypertrichosis. Radiation recall dermatitis, a severe painful inflammatory skin reaction in sites that have previously been exposed to ionized radiation, can occur in patients taking tamoxifen (33). In one case the tamoxifen was withdrawn and the skin healed spontaneously in 7 weeks (34). Toremifene, a tamoxifen analogue, was well tolerated: during 18 months of continuous treatment no signs of radiation recall developed.

Hair

Effects of hormonal or antihormonal products on the hair are reported sporadically.

- A woman taking tamoxifen for metastatic cancer (presumably from the breast) developed alopecia; she began to lose her hair within 3 months and was entirely bald after 13 months of treatment (35).

The authors did not make it clear whether cytostatic drugs, which can cause alopecia, were also used, but it is striking that there have been several earlier reports of baldness with tamoxifen.

Musculoskeletal

In principle an anti-estrogen might precipitate osteoporosis, but tamoxifen has not been shown to do so; indeed, there is reason to believe that it protects the skeleton against steroid-induced bone loss (36), and in some studies of the state of the bones during treatment with tamoxifen there was actually a higher bone density than in controls.

Sexual function

Tamoxifen can cause loss of libido (37). In 57 patients sexual desire, arousal, and the ability to achieve orgasm were unaffected by tamoxifen (38). There was a 54% incidence of dyspareunia, but this seemed to be a consequence of co-administration of chemotherapy, which can cause vaginal dryness and loss of libido, rather than an effect of tamoxifen.

Reproductive system

Breasts

Tamoxifen can cause a sudden rapid increase in the growth rate of uterine leiomyomas (39).

- A leiomyoma of the breast occurred in a 50-year-old woman taking tamoxifen. It appeared as a discrete mass and had a microscopic pattern akin to leiomyomas at other sites (40).

Ovaries

In premenopausal women, tamoxifen has complex effects on ovarian function, compatible with accelerated development of multiple follicles, with ovarian enlargement and cyst formation (41,42); this might be expected in

© 2006 Elsevier B.V. All rights reserved.

view of its similarity to clomiphene. Ovarian cysts have also been seen in postmenopausal patients with breast cancer during long-term adjuvant therapy with tamoxifen. Some premenopausal women with breast cancer had very marked increase in estrogen concentrations as a result of increased ovarian estrogen synthesis caused by tamoxifen. All premenopausal women with breast cancer taking tamoxifen should be under close gynecological and ultrasonographic surveillance to detect such effects as soon as they occur.

Dutch workers concluded that patients who were still having a menstrual cycle had a high chance (81%) of developing ovarian cysts during tamoxifen treatment, but that postmenopausal women taking tamoxifen only developed ovarian cysts if their ovaries were able to respond to FSH stimulation, as shown by serum estradiol production (43). Differences in patient populations might explain why some workers (44) still find no association in their patients between tamoxifen and ovarian pathology.

Macroscopically visible cystic endosalpingiosis in the paraovarian region has been described in a woman who had been taking tamoxifen for breast cancer (45).

- A 2.5 cm multicystic lesion was seen on the external surface of the right ovary, and histological examination showed a mass of dilated glands lined by ciliated tubal-type epithelium and set in a fibrovascular stroma. Cystic endosalpingiosis resulting in a tumor-like mass is rarely described and is probably not well recognized by histopathologists.

Although unlikely to be mistaken for malignancy, this kind of lesion can result in diagnostic confusion. The role of tamoxifen in the development of the lesion in this case is not clear, but the estrogenic effects of tamoxifen may have contributed.

In one case, a complex cyst, thought to be due to ovarian hyperstimulation, resolved after monthly administration of a depot gonadorelin (GnRH) receptor agonist without abandoning tamoxifen (46). One might expect some patients to react to tamoxifen with ovarian hyperstimulation, since another non-steroidal antiestrogen (that is clomiphene) is used for ovarian stimulation and also on occasion produces cysts.

In one case reported from Japan, there was torsion of an ovarian cyst (47).

In a study of the mechanism and frequency of this complication, hormone concentrations in 20 premenopausal women taking tamoxifen (20 mg/day) were compared with those in untreated controls (48). Ovarian cysts were found in 80% of the treated patients but only in 8% of controls, and 17-beta-estradiol concentrations were significantly raised.

Uterus

Intermenstrual bleeding is a practical problem during tamoxifen therapy, particularly since it obliges the physician to undertake repeated endometrial investigations to exclude malignancy. Monitoring the uterine cavity in women taking tamoxifen is mandatory, especially when there is postmenopausal bleeding.

Some preliminary but well-designed work has suggested that by inserting a levonorgestrel-releasing intrauterine system it may be possible to limit considerably the problems posed by unscheduled uterine bleeding (49).

Benign thickening of the endometrium is common during tamoxifen treatment, but appears to be fully reversible within a few months of withdrawal (50,51).

Uterine polyps are not uncommon during postmenopausal treatment with tamoxifen (52), and up to 3% can show malignant changes. There has been an attempt to identify risk factors for the development of these polyps, by analysing the histories of 54 women in whom they occurred, as well as the histories of a larger control group without polyps (53). The women who developed polyps had a later menopause, had breast cancer for a longer period, and weighed more.

The pathology of tamoxifen-associated cases of myometrial adenomyosis has been compared with that in five cases of postmenopausal adenomyosis not associated with tamoxifen. The tumors were not identical: morphological features more often present in the tamoxifen-associated cases were cystic dilatation of glands (which sometimes resulted in grossly visible intramural cystic lesions), fibrosis of the stroma, and various forms of epithelial metaplasia. The proliferative activity in the adenomyosis, as determined by MIB1 staining, was higher in the tamoxifen group (54), and this could be another mechanism of postmenopausal bleeding among tamoxifen users.

Tamoxifen can be associated with the formation of endometrial polyps and polypoid endometriosis; these polyps ("basilomas") can become malignant (55,56), perhaps because they lack progesterone receptors and are exposed to unopposed estrogen (57).

Whether one should routinely screen patients for endometrial changes is disputed; there seems to be no correlation between endometrial thickness and endometrial pathology, and complications could be easily overlooked (58).

The gynecological consequences of antiestrogens (tamoxifen and toremifene) have been evaluated in 167 postmenopausal breast cancer patients in a 3-year prospective study. There was a proliferative endometrium more often in the tamoxifen group than in the toremifene group, but this did not translate into an increase in the rate of endometrial cancer. The authors did not recommend routine surveillance of the endometrium.

Immunologic

An acute inflammatory polyarthritis resembling rheumatoid arthritis has been reported in three women temporally related to the use of tamoxifen (59).

Long-Term Effects

Tumorigenicity

Several authors (60,61) have described a variety of cases, seven in all, of malignancies secondary to therapeutic dosages of tamoxifen given for 6 months to 10 years.

Uterine fibroids and endometrial polyps (sometimes with bleeding) have been reported in menopausal women who had taken tamoxifen for periods of months or years (SEDA-16, 466) (62,63). In view of this, the question of whether tamoxifen increases the risk of

© 2006 Elsevier B.V. All rights reserved.

endometrial cancer has been widely discussed. The authors of a 1993 review of the outcome of six major trials tended strongly to the conclusion that tamoxifen can cause both endometrial hyperplasia and endometrial cancer proportional to the total dose (64); the figures pointed to an overall incidence of endometrial cancer of 0.5% in tamoxifen users and 0.1% in controls. Another major review up to 1992 concluded that in the world literature there were 70 cases of uterine malignancies with tamoxifen, including 61 cases of adenocarcinoma of the endometrium and four cases of uterine sarcoma (65).

Six cases of endometrial carcinoma were subsequently reported from France (66), and 36 cases in all had been reported up to that time (67). Although the effect can be caused by tamoxifen alone in women aged over 55, in younger women it is more likely to be an additive one, attributable to use of both tamoxifen and pelvic irradiation in the same subject.

Two distinct patterns of uterine cancer have been shown using magnetic resonance imaging of the tamoxifen-exposed uterus in 35 women (68). Patients with pattern 1 had homogeneous high signal intensity of the endometrium on T2-weighted images and enhancement of the endometrial–myometrial interface and a signal void in the lumen on gadolinium-enhanced images (18 patients). Patients with pattern 2 had heterogeneous endometrial signal intensity on T2-weighted images with enhancement of the endometrial–myometrial interface and lattice-like enhancement traversing the endometrial canal on gadolinium-enhanced images (17 patients).

Although the endometrial cancers associated with tamoxifen are usually pure adenocarcinomas, other types of rare tumors have also been reported. A pure uterine rhabdomyosarcoma has been reported (69), and a mesodermal mixed tumor of the endometrium occurred 5 years after 5 years of tamoxifen therapy (70). The tumor responded only to combined treatment with doxorubicin, cyclophosphamide, 5-fluorouracil, and carboplatin. It is possible that this type of tumor arises later than adenocarcinomas and should be looked for during long-term use of tamoxifen.

- Two well-documented cases of uterine carcinosarcoma have been reported in elderly women after 6 and 7 years of tamoxifen treatment (71). At laparotomy, a heterologous malignant mixed Mullerian tumor with peritoneal spread was found in each case and rapidly proved fatal; large uterine polyps with special histological features may represent an intermediate step in the formation of such tumors (72).

Ten similar cases have been described before.

When assessing the risk of endometrial malignancy in women with breast cancer taking tamoxifen, it is worth taking into account evidence that patients with breast cancer may at the outset have some endometrial pathology. In women with breast cancer scheduled for tamoxifen there were endometrial polyps in 9.3%, endometrial cysts in 16%, and synechiae in 12% at the outset. Tamoxifen significantly increased the incidence of these benign endometrial lesions, usually after less than 1 year of treatment. There were no cases of endometrial carcinoma in 34 patients who had taken tamoxifen for 12–24 months, and only one in 78 patients who had taken it for 5–72 months (73).

The risk that tamoxifen may cause endometrial cancer has been the subject of lively correspondence in the Lancet (74), fired by the paper published in 2000 by Bergman and her colleagues, who had concluded that the endometrial cancers seen with tamoxifen are unusually aggressive (75). Concern was expressed that such a conclusion could lead to even wider hesitation to use tamoxifen in breast cancer, despite the fact that it is already used very selectively, for example in women with positive estrogen receptors. A contradiction between Bergman's results and those of the NSABP P-1 were also highlighted, and doubts expressed whether Bergman's findings justify restricting the use of tamoxifen as a preventive agent. However, a Canadian group adduced its own work to support Bergman's findings, while French workers suggested that her unfavorable results, which were not seen in their own patients, could have been due to selection bias. It was also argued that a progestogen-releasing intrauterine contraceptive device might be used to counter the undesirable effects of tamoxifen on the endometrium. Clearly the issue raised by Bergman is still subject to debate, but it is obvious that physicians who use tamoxifen in advanced breast cancer or as a preventive agent should continue to do so selectively and that ways of protecting the endometrium during tamoxifen therapy need to be found.

The effects of norethisterone on endometrial abnormalities have been studied in 463 postmenopausal women taking tamoxifen or placebo (76). As in other studies, the results showed that any increased risk of endometrial cancer caused by tamoxifen is low and that transvaginal ultrasound screening is probably not justified for asymptomatic women taking tamoxifen. The authors found that 26% of women taking tamoxifen have endometrial thickening of 8 mm or more. It is possible to identify cysts in 7% of these women, polyps in 3%, and both cysts and polyps in 8%. These changes are characteristic of tamoxifen and unlike those seen with estrogen replacement therapy.

The usefulness of transvaginal ultrasound in detecting serious uterine changes in tamoxifen users has been disputed. According to one group it is a dependable diagnostic method (77), whereas others found it disappointing, with a high proportion of false positive results, even when the assessment criteria were chosen so as to exclude mild endometrial thickening (78). Setting these two papers beside one another it seems that one can detect marked endometrial changes but that ultrasound is not a dependable means of determining whether there is malignancy.

Second-Generation Effects

Teratogenicity

Since animal studies suggested the possibility of fetal and neonatal malformations it has for a long time been customary to exclude pregnancy before giving tamoxifen. However, there is currently reason to believe that the risk presented by tamoxifen to the human fetus is very slight or non-existent.

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Genetic factors

Certain women have a genetic predisposition to develop an endometrial malignancy during tamoxifen treatment. There were significant amounts of tamoxifen-DNA adducts in the endometrium in eight of 16 women who took the drug but none at all in others, suggesting that a genotoxic mechanism may be responsible for tamoxifen-induced endometrial cancer (79). However, there is biochemical and histological evidence that tamoxifen-associated endometrial carcinoma is likely to be similar to type I and will therefore have a relatively favorable prognosis (80).

Drug–Drug Interactions

Cytotoxic drugs

An unusual case of rapidly fatal renal failure reported in 1993 could reflect an interaction between tamoxifen and one or more cytostatic agents, with mitomycin C a prime suspect; in a series of breast cancer patients some 10% of those treated both with tamoxifen and a cytostatic agent developed abnormal renal function, progressing towards various stages of hemolytic-uremic syndrome (81).

Tamsulosin

See also Alpha-adrenoceptor antagonists

General Information

Tamsulosin is an alpha$_1$-adrenoceptor antagonist that was specially designed for the treatment of benign prostatic hyperplasia, since it is highly selective for the urinary tract alpha$_{1A}$-adrenoceptors (1). Indeed, it produces little or no cardiovascular effects, no first-dose effect, and much less dizziness. In clinical trials, adverse effects included dizziness, weakness, headache, and nasal congestion. Abnormal ejaculation was the most frequent adverse effect, in 8% of the patients at 0.4 mg/day, and in 18% at 0.8 mg/day (2,3).

Taxaceae

See also Herbal medicines

General Information

The family of Taxaceae contains two genera:

1. *Taxus* (yew)
2. *Torreya* (torreya).

Taxus species

Taxus (yew) trees contain alkaloids called taxanes that have anticancer activity and are the basis of the semi-synthetic anticancer drugs paclitaxel and docetaxel (see separate monographs), which are based on taxol, from *Taxus brevifolia*.

Taxus baccata has been used as a means of suicide (1–3), successfully, because of cardiac dysrhythmias (4).

© 2006 Elsevier B.V. All rights reserved.

Taxoids from *Taxus cuspidata* (the Japanese yew) inhibit P glycoprotein and are candidates for reversing multidrug resistance in cancer cells (5).

Taxus celebica, which contains the flavonoid sciadopitysin, is traditionally used in China as an herbal treatment of diabetes mellitus.

Adverse effects

Hematologic

Thrombocytopenia has been attributed to the Chinese herbal mixture Jui, prepared from *T. cuspidata* (Japanese yew) (6).

- A 51-year-old Japanese woman developed gingival bleeding and petechiae. The only medication she had taken was Jui. She had thrombocytopenia and the causal relation was demonstrated by rechallenge. She recovered on withdrawal of the product.

Immunologic

Of 18 patients with seasonal allergic rhinitis, suffering mainly in April and May, five were sensitized to the pollen of *T. cuspidata* (7).

Drug overdose

In two cases the ingestion of a massive dose of *T. celebica* was followed by acute renal insufficiency; both patients initially presented with gastrointestinal upset and fever (8).

- A 40-year-old patient attempted suicide by drinking an extract made from 120 g of yew needles (*T. baccata*); recurrent episodes of ventricular tachycardia were successfully treated with high doses of lidocaine (9).
- Lethal intoxication with yew leaves (*T. baccata*) presented with dizziness 1 hour after ingestion, nausea, diffuse abdominal pain, unconsciousness, weak breathing, tachycardia, brief ventricular flutter followed by bradycardia, and finally death by respiratory arrest and cardiac standstill; the electrocardiogram showed atypical bundle branch block and absent P waves (10).
- A 14-year-old boy cut leaves from a yew tree (*T. baccata*), crushed them, and ingested them; he died soon afterwards (11). At autopsy pieces of partially crushed, partially preserved yew leaves were found in the stomach. The histological findings were non-specific.

Four prisoners drank a decoction of yew needles (*T. baccata*) (12). Two died in prison with cardiac arrest. One went into deep coma, and had several episodes of ventricular fibrillation, controlled by defibrillation; after return of consciousness his general condition deteriorated suddenly, he lost consciousness again, his circulation stopped, and he died on the fourth day. The other patient drank a much smaller amount of the decoction; he was conscious, had bradycardia requiring transient pacemaking, and had a mild ventricular dysrhythmia; he recovered after 10 days. In both cases there was excessive diuresis and severe hypokalemia and atropine was effective for a short time in the control of bradycardia.

Of 11 197 exposures to the berries of *Taxus* species children under 12 years of age were involved in 96% (under 6 years 93%; 6–12 years 3.7%) (13). When the final outcome of the exposure was documented ($n = 7269$), there were no adverse effects in 93% and minor effects in 7.0%. There were moderate (more pronounced, but not life-threatening) effects in 30 individuals and major (life-threatening) effects in four. There were no deaths. Decontamination therapy had no impact on outcome compared with no therapy. When symptoms occurred after exposure to *Taxus*, the most frequent were gastrointestinal (66%), followed by skin reactions (8.3%), nervous system effects (6.0%), and cardiovascular effects (6.0%).

Tea tree oil

General Information

Tea tree oil is extracted from *Melaleuca alternifolia*, a plant that is native to Australia. It is considered to have antibacterial properties, including an effect on methicillin-resistant *Staphylococcus aureus* (MRSA), while the commensal flora of the skin seem to be less susceptible (1). In addition, it is said to have antifungal, antiviral, anti-inflammatory, and analgesic properties, and has been increasingly incorporated into cosmetics for aromatherapy.

Organs and Systems

Nervous system

The systemic toxicity of tea tree oil is comparable to that of eucalyptus oil, and ingestion of 10–25 ml has resulted in ataxia, drowsiness, disorientation, or coma for 2 days; recovery was full without complications (2).

- A 4-year-old boy took a small quantity of tea tree oil and within 30 minutes became ataxic and shortly thereafter progressed to unresponsiveness; he was endotracheally intubated and his neurological status improved gradually over 10 hours (3).

Immunologic

Since the beginning of the 1990s, several case reports of allergic contact dermatitis to tea tree oil have been published (4,5). Most of these adverse effects emerged after the application of aged tea tree oil, and patients who are allergic to tea tree oil do not react to patch tests with freshly distilled tea tree oil (6). In a review of tea tree oil focussing on the allergic compounds in detail, the authors concluded that *d*-limonen, alpha-terpenes, and the aromadendrens are important allergens, whereas 1,8-cineole was not believed to be important, as has been previously stated (7). Tea tree oil undergoes photo-oxidation within a few days to several months, leading to degradation products, such as peroxides, epoxides, and endoperoxides, which are moderate to strong sensitizers. Experimental sensitization in guinea pigs was followed by patch tests with 15 constituents of oxidized tea tree oil in 11 patients with tea tree oil contact dermatitis (6). All the patients reacted to alpha-terpinene, terpinolene, and ascaridol, the latter being a deterioration product of alpha-terpinene.

Many people who are allergic to tea tree oil also react to turpentine, colophony, fragrances, balsam of Peru, and plant extracts of Compositae (8).

- A 46-year-old Chinese man developed an allergic contact dermatitis to tea tree oil, colophony, balsam of Peru, and abitol. He had used the tea tree oil under an occlusive dressing on a superficial abrasion on his left shin for 2 weeks, after which the treated area became red and itchy. During the next week, skin lesions appeared on his trunk and extremities, and were diagnosed as an erythema multiforme-like id reaction.
- A 38-year-old man developed an immediate hypersensitivity reaction, characterized by pruritus, throat constriction, and light-headedness, after topical application of tea tree oil (9). An intradermal test with tea tree oil gave a wheal and flare reaction. Specific IgG and IgE were not detected.

Teicoplanin

General Information

Teicoplanin has been used in the treatment of Gram-positive infections. Its pharmacological properties allow once-daily dosing. Its safety profile has been thoroughly investigated, and it is generally well tolerated. It diffuses well into bone tissue (1).

Teicoplanin is more effectively administered once daily than vancomycin and it can be given intramuscularly or intravenously; it is not absorbed after oral administration. It is 90% bound to plasma proteins and its elimination is primarily by renal excretion, allowing dosage adjustments to be made on the basis of the measured creatinine clearance. A dosing regimen of 12 mg/kg on day 1 followed by 6 mg/kg/day most often results in efficacious serum concentrations but premature neonates and children require higher dosages. However, doses of 10 mg/kg/day are required to achieve adequate bone concentrations, and there is little penetration into cerebrospinal fluid or aqueous or vitreous humors. In fat, concentrations can be subtherapeutic after a dose of 400 mg. Unlike vancomycin, routine drug monitoring is not required, although it may sometimes be useful for predicting the therapeutic effect of the drug.

© 2006 Elsevier B.V. All rights reserved.

Observational studies

In a study of the effects of teicoplanin (6–12 mg/day intravenously), 166 of 342 patients reported one or more adverse events, and in 119 they were thought to be associated with teicoplanin (2). Most had some form of hypersensitivity response (fever, rash, chills, or pruritus), and treatment was withdrawn in 59 patients. There was a clinically significant abnormality of liver function tests in 123 patients, but in only 33 was it judged to be possibly associated with teicoplanin. There was a rise in serum creatinine in 28 patients, in five of whom an association with teicoplanin was suggested.

Cell wall agents, such as glycopeptides, have concentration-independent bactericidal activity, and the time over which the antibiotic serum concentration persists over the minimal inhibitory concentration of the pathogen is a main pharmacodynamic determination of the outcome. In a two-way, randomized, open, two-period, crossover study in 10 healthy adults, teicoplanin given in two 200 mg doses intramuscularly produced steady-state trough concentrations even higher than those after once-daily intravenous administration of 400 mg (3). Conversion from intravenous to intramuscular administration may therefore allow better compliance with preserved efficacy. Intramuscular teicoplanin was well tolerated. Adverse effects reported were mild local pain for 2–3 hours, headache, and backache.

In 76 patients receiving long-term teicoplanin for chronic osteomyelitis due to oxacillin-resistant *Staphylococcus aureus*, teicoplanin had to be withdrawn in only one subject because of low-grade fever, muscular pain, and sleeplessness; these adverse effects abated after withdrawal (4).

Comparative studies

In a prospective study 56 patients with suspected or proven severe Gram-positive infections were randomized to receive vancomycin (1 g 12-hourly intravenously) or teicoplanin (200–400 mg/day intravenously or intramuscularly) (5). Clinical and bacteriological cure rates were similar, but vancomycin was associated with significantly greater toxicity (16 vancomycin, 7 teicoplanin), predominantly histamine-associated reactions (15, including two cases of red man syndrome) (SEDA-17, 312), and nephrotoxicity (five with vancomycin compared with one with teicoplanin). Four of the five vancomycin patients who developed nephrotoxicity were receiving netilmicin at the time, some with amphotericin as well.

The overall rate of adverse reactions in comparative trials was 19%, which is comparable with the rate observed with beta-lactams, but lower than the corresponding rate (39%) associated with vancomycin (6).

Only three of 422 patients treated with a single dose of teicoplanin for antimicrobial prophylaxis during hip or knee arthroplasty (400 mg by intravenous bolus at the time of anesthesia) reported adverse events compared with nine of 424 patients treated with five doses of cefazoline: one had nausea and two had erythema (7). Six patients given teicoplanin had surgical wound infections, and 57 had proven or suspected infections involving other body systems.

In another study, a single dose of teicoplanin (6 mg/kg intravenously) was compared with three doses of cefradine plus metronidazole as prophylaxis for vascular surgery. Efficacy was similar with the two regimens. Adverse events were reported by 40 of 136 patients treated with teicoplanin (versus 39 of 139 treated with cefradine plus metronidazole), and 19 (versus 15) were considered to be related to the study drug; however, none was considered definitely related (8).

In a prospective, randomized trial in 34 drug abusers a short course of a combination of a glycopeptide (vancomycin or teicoplanin) with gentamicin was significantly less effective in right-sided endocarditis caused by *S. aureus* than a combination of cloxacillin and gentamicin (9).

Pharmacoeconomics

In a randomized, prospective, cost-effectiveness study both teicoplanin and vancomycin were assessed as second-line therapy in 66 neutropenic patients after the failure of empirical treatment with a combination of piperacillin + tazobactam and amikacin (10). The primary success of second-line therapy was equivalent, and the direct total costs were similar. Acquisition costs per dose were in favor of vancomycin, but costs derived from administering vancomycin and serum concentration monitoring led to similar costs for both regimens. With the exception of the red man syndrome, which occurred in 10% of vancomycin-treated patients but none of the teicoplanin-treated patients, toxicity (renal, liver, and ear toxicity, diarrhea, phlebitis) was also similar.

In a retrospective cost analysis, the records of 527 patients with acute leukemia were studied (11). They had been treated in a multicenter, randomized trial for febrile neutropenia with ceftazidime and amikacin plus either teicoplanin (6 mg/kg in a single dose; $n = 275$) or vancomycin (30 mg/kg/day in 2 doses; $n = 252$). Clinical responses were equivalent. Again the higher acquisition costs for teicoplanin were counterbalanced by the lower incidence of adverse events and easier administration, resulting in overall similar costs for both regimens. A total of 8% of patients treated with vancomycin reported adverse events compared with 3.2% of patients treated with teicoplanin. Rashes occurred in 6.0 versus 1.4% respectively. Nephrotoxicity, ototoxicity, fever, and hypotension occurred in very few patients.

General adverse effects

The most common adverse events associated with teicoplanin are hypersensitivity, fever, rash, diarrhea, nephrotoxicity, and thrombocytopenia (12,13). Local reactions at the injection site include pain, redness, or discomfort after intramuscular injection, or phlebitis after intravenous injection. Erythroderma has occurred during infusion of teicoplanin with fever and hypotension. Allergic reactions have been reported with teicoplanin, with cross-reactivity between teicoplanin and vancomycin documented by in vitro studies showing IgE release by basophils in response to stimulation by both vancomycin and teicoplanin. However, known hypersensitivity to vancomycin is not a contraindication to teicoplanin. Tumor-inducing effects have not been reported.

© 2006 Elsevier B.V. All rights reserved.

Red man syndrome

The red man syndrome associated with rapid infusion of vancomycin, resulting in histamine release, is very rarely seen with teicoplanin. Teicoplanin can usually be safely administered to patients with a history of red man syndrome due to vancomycin, as has been confirmed in six children treated with teicoplanin for febrile neutropenia and Gram-positive bacteremia (14).

However, case reports have suggested that there can be cross-reactivity between vancomycin and teicoplanin in the induction of this syndrome, although the underlying mechanism remains elusive (15).

- A swinging pyrexia (peaking at 39–40°C during the day but settling overnight) developed after the fifth day of teicoplanin treatment in a 35-year-old man with infective endocarditis due to *Streptococcus mitis*. Two days after stopping the drug he became apyrexial. Therapy with vancomycin had previously had to be interrupted because of an extensive purpuric rash and erythema, which progressed to exfoliative dermatitis and was subsequently identified as red man syndrome secondary to vancomycin.

Organs and Systems

Cardiovascular

Hypotension has been observed as part of the manifestations of a hypersensitivity reaction to teicoplanin (16).

Respiratory

Bronchospasm required withdrawal of teicoplanin in two of 310 patients (17).

Sensory systems

Ototoxicity has been reported during treatment with teicoplanin (18). A fall in high-frequency auditory threshold was observed in one patient treated with teicoplanin for a serious Gram-positive infection (19). However, the causal relation between teicoplanin and alterations in auditory function has not been established in controlled clinical studies (20). Guinea pigs treated for 28 days with a maximum dose of 75 mg/kg/day remained without any evidence of functional, morphological, or histological changes indicative of ototoxicity (21). There were 11 cases of ototoxicity among 3377 patients treated with teicoplanin (20). It can be concluded that teicoplanin-associated ototoxicity is rare.

Hematologic

The overall rate of hematological adverse effects of teicoplanin was 2.2% in 1431 patients participating in a large non-comparative multicenter study (22).

Hemophagocytosis after vancomycin and teicoplanin occurred in a 45-year-old woman (23).

Leukocytes

The incidence of teicoplanin-induced leukopenia is low (0.33%) and the leukopenia is usually reversible.

- A 10-year-old Malay boy with G6PD deficiency received teicoplanin (300 mg/day) for an epidural abscess and 14 days later developed an erythematous, maculopapular, non-pruritic rash over his trunk and upper limbs and a mild fever with chills (24). He had a leukocyte count of 2×10^9/l. Teicoplanin was withdrawn and by 3 days the rash had almost completely subsided. After rechallenge with a single intravenous dose of teicoplanin 300 mg, he developed a fever (39.3°C), chills, and worsening of the rash on his arms. Teicoplanin was again withdrawn. His fever resolved after 4 days and his leukocyte count normalized by 7 days.
- Neutropenia developed in a patient after 20 days of treatment with teicoplanin (25).

In patients undergoing bone marrow transplantation receiving teicoplanin for the treatment of severe sepsis, the duration of neutropenia was not prolonged by teicoplanin (26).

Teicoplanin rarely causes eosinophilia (27).

Platelets

Thrombocytopenia was associated on two consecutive occasions with teicoplanin in a patient with acute myeloid leukemia (28). The exact mechanism for this adverse event is unknown. Teicoplanin does not alter platelet function or blood coagulation (29).

- Severe thrombocytopenia occurred in a 46-year-old white man treated with teicoplanin 6 mg/kg/day for methicillin-resistant *S. aureus* bacteremia (30). The platelet count fell to 25×10^9/l on day 8 (baseline 110). After drug withdrawal the platelet count improved within 4 days. The trough teicoplanin concentrations were 17 μg/ml on day 4 and 15.4 μg/ml on day 9.

Teicoplanin caused thrombocytopenia in one of 17 children (31).

In trials in the USA, thrombocytopenia occurred more commonly with teicoplanin than with vancomycin, but this was almost exclusively in patients who received much larger doses than are now recommended.

Gastrointestinal

Adverse events involving the gastrointestinal system are rare with teicoplanin. Diarrhea has been listed among non-specific events observed in 5.1% of patients (22).

Liver

In one study transient rises in liver enzymes occurred in 2.3% of patients taking teicoplanin (17). Other authors have reported abnormal liver enzymes (19,32–34).

Urinary tract

Teicoplanin can be nephrotoxic, but less often than vancomycin (6). However, concomitant aminoglycoside therapy in some patients makes the contribution of the glycopeptide antibiotic difficult to assess. Renal toxicity was observed more often in patients receiving the combination of netilmicin plus vancomycin than in patients treated with netilmicin plus teicoplanin (35). Similar differences in nephrotoxicity between vancomycin and

© 2006 Elsevier B.V. All rights reserved.

teicoplanin were observed in febrile neutropenic patients receiving tobramycin plus piperacillin (36). There was significant deterioration of renal function when vancomycin and ciclosporin, but not teicoplanin and ciclosporin, were used together; the mechanism responsible for this interaction is unknown (36).

In two of 76 patients receiving long-term teicoplanin a reduction in dosage was required because of reduced renal function, which recovered within 30 days (4).

There was a fall in residual renal function during episodes of peritonitis in a prospective multicenter study in 152 children with peritoneal dialysis-associated peritonitis (37). The study evaluated the efficacy, safety, and clinical acceptance of combination treatment, including a glycopeptide (teicoplanin or vancomycin) and ceftazidime, each given either intermittently or continuously. Irreversible anuria developed in 19% of the patients with residual diuresis. In patients who retained residual renal function, there was a strong trend toward a decreased residual glomerular filtration rate (−11%). There was no difference with respect to the type of glycopeptide or the mode of use. Aminoglycosides were used concomitantly in only 12 patients and did not seem to affect the evolution of residual renal function. Underdosing/non-adherence or overdosing occurred in 8.2% of continuously treated versus 4.9% of intermittently treated patients. Intermittent and continuous intraperitoneal treatment with glycopeptides and ceftazidime were equally efficacious and safe when measured by objective clinical criteria.

In children with febrile neutropenia and Gram-positive bacteremia associated with antineoplastic drug therapy, teicoplanin was significantly less nephrotoxic than vancomycin (14).

The effect of co-administration of fosfomycin on glycopeptide antibiotic-induced nephrotoxicity for 3 days has been investigated in rats (38). Fosfomycin reduced glycopeptide antibiotic-induced nephrotoxicity, as shown by reduced urinary excretion of *N*-acetyl-beta-D-glucosaminidase and fewer histological signs of nephrotoxicity in those treated with a combination of glycopeptide and fosfomycin compared with a glycopeptide alone. In addition, the higher the dose of fosfomycin, the more it reduced urinary *N*-acetyl-beta-D-glucosaminidase activity, suggesting that the role of fosfomycin in alleviating nephrotoxicity is dose-dependent. There was significantly less accumulation of teicoplanin and vancomycin in the renal cortex of rats treated with glycopeptide antibiotics plus fosfomycin compared with the glycopeptide antibiotics alone.

Skin

A pustular skin eruption occurred in a 60-year-old woman who was given teicoplanin 400 mg as a loading dose followed by 200 mg/day (39). Following the sixth injection of teicoplanin she developed a pruritic eruption on her chest, which evolved into a widespread maculopapular eruption with tiny pustules and occasional vesicles on an erythematous base over the face, trunk, and limbs within 2 days. Teicoplanin was withdrawn and she was given prednisolone 60 mg/day. This resulted in improvement of the eruption and relieved the discomfort over the next 7 days. In other cases teicoplanin caused an acute generalized rash and exanthematous pustulosis (24,40).

Vancomycin reportedly caused a severe delayed skin reaction with allergic cross-reactivity between vancomycin and teicoplanin requiring steroid therapy (41).

- A 68-year-old woman who was being treated with vancomycin for *Staphylococcus epidermidis* bacteremia developed pruritus and a generalized maculopapular skin rash after 2 weeks. After a short course of prednisolone, she was given teicoplanin and developed general malaise, fever, conjunctival injection, an extensive rash, and later blisters on the legs, again requiring treatment with steroids.

Musculoskeletal

Teicoplanin has been successfully used to treat bone and joint infections without any adverse reactions affecting bones or joints (42).

Immunologic

Allergic reactions have been reported with teicoplanin. Erythroderma during infusion of teicoplanin with fever and hypotension was described in a single patient. Re-exposure elicited the same reaction (16). Allergic cross-reactivity between teicoplanin and vancomycin has been reported (43,44). This cross-reactivity was documented by in vitro studies showing IgE release by basophils in response to stimulation by both vancomycin and teicoplanin in a further patient who had an allergic reaction to vancomycin (45). In other studies the second drug did not elicit allergic reactions in patients known to be allergic to one of the two compounds (46–48). Based on these small studies and individual case reports one can conclude that allergic reactions to teicoplanin can occur in patients with known allergic reactions to vancomycin, but the frequency of occurrence of this type of cross-reaction appears to be low. Therefore, known hypersensitivity to vancomycin is not a contraindication to the use of teicoplanin.

Local reactions at the injection site, including pain, redness, or discomfort after intramuscular injection, and phlebitis after intravenous injection, occur in about 3% of patients (6).

Long-Term Effects

Drug tolerance

In a study of antibiotic resistance in enterococci from raw meat, there was a high prevalence of glycopeptide-resistant strains (49). Resistance to vancomycin was significantly associated with resistance to teicoplanin, erythromycin, tetracycline, and chloramphenicol.

Susceptibility Factors

Renal disease

The administration of 5 and 10 mg/kg of teicoplanin to seven anuric patients immediately after the end of hemodialysis gave mean values of C_{max} of 63 and 122 μg/ml,

© 2006 Elsevier B.V. All rights reserved.

mean AUCs of 526 and 1104 hours.μg/ml, mean half-lives of 109 and 107 hours, mean clearance rates of 13 and 12 ml/minute, mean apparent volumes of distribution of 1.68 and 1.68 l/kg, and mean volumes of distribution at steady state of 0.31 and 0.28 l/kg (50). Trough serum concentrations were above 10 μg/ml for 24 hours after the 5 mg/kg dose and for 48 hours after the 10 mg/kg dose. Teicoplanin was not detected in the dialysate. Its concentrations in the arterial and the venous lines of the fistulae were similar.

Drug Administration

Drug overdose

- A 10-day-old girl with a history of postasphyxia acute renal failure, which recovered within 7 days, was given teicoplanin for sepsis due to *Staphylococcus hominis* (51). The dosage used was erroneously high (20 mg/kg 12-hourly instead of an initial dose of 16 mg/kg followed by 6–8 mg/kg/day), and therapy was suspended after 5 days. She improved, and blood cultures were negative. Serum creatinine concentrations and cystatin C (as an early marker of glomerular damage) remained in the reference ranges. Urinary parameters for tubulotoxicity (*N*-acetyl-beta-D-glucosaminidase, $beta_1$-microglobulin) were higher than in the following days, but remained in the reference ranges. Urinary concentrations of epithelial growth factor were also higher during therapy than afterwards, probably indicating repair activity. Serum concentrations of teicoplanin were not determined.

Drug–Drug Interactions

Aminoglycosides

The risk of nephrotoxicity increases with the concomitant use of other nephrotoxic drugs, especially aminoglycosides (36).

Ciprofloxacin

Teicoplanin should be administered separately from ciprofloxacin, since precipitation has been provoked by concomitant parenteral administration (52).

Colestyramine

Since colestyramine binds teicoplanin in vitro and reduces its activity against *Clostridium difficile* almost completely, there is potential for a clinically important interaction (53).

Enalapril

A possible drug interaction with enalapril has been reported; a patient with diabetes receiving teicoplanin for osteomyelitis developed renal insufficiency requiring dialysis after the addition of enalapril (54).

Monitoring Therapy

There is evidence that predose concentrations of teicoplanin are related to clinical outcome; the evidence is less conclusive for vancomycin. Predose concentrations can be linked to some toxic effects (nephrotoxicity for vancomycin and thrombocytopenia to teicoplanin) (55,56). In severe infections monitoring serum teicoplanin concentrations is indicated to assure adequate trough concentrations (over 10 μg/ml) (57). For the treatment of *S. aureus* endocarditis trough concentrations should exceed 20 μg/ml (57). Inadequately low serum concentrations of teicoplanin may have been responsible for the high failure rate in intravenous drug users treated with teicoplanin for right-sided endocarditis (58). The fact that teicoplanin pharmacokinetics are unpredictably variable in intravenous drug users adds further weight to the importance of monitoring serum drug concentrations in this population during the treatment of severe infections such as endocarditis (59). Since the half-life of teicoplanin also varies greatly in patients with various degrees of renal insufficiency, monitoring serum concentrations can be helpful in guiding therapy in some patients with markedly reduced creatinine clearance (60).

Telenzepine

General Information

Telenzepine is a muscarinic M_1 receptor antagonist, like pirenzepine. On a weight-for-weight basis it is 25–50 times more potent than pirenzepine, but dose for dose it is, if anything, more likely to have undesired anticholinergic effects (1).

In 163 patients with endoscopically proven benign gastric ulcers randomly allocated to telenzepine 3 mg/day or ranitidine 300 mg/day for up to 8 weeks in a prospective, double-blind study, anticholinergic events occurred significantly more often in patients taking telenzepine, dry mouth being the most frequent adverse effect (2).

Telmisartan

See also Angiotensin II receptor antagonists

General Information

Telmisartan is a highly selective antagonist at type 1 angiotensin II (AT_1) receptors.

Organs and Systems

Respiratory

The incidence of cough with telmisartan has been assessed in a multicenter, randomized, parallel-group, double-blind, placebo-controlled study, for 8 weeks using a visual analogue scale in 88 patients with hypertension who had previously had ACE inhibitor-related cough (1). Cough was reported in 60% of the patients taking lisinopril 20 mg/day, 16% of those taking telmisartan 80 mg/day, and 9.7% with placebo.

Drug–Drug Interactions

Digoxin

Multiple-dose telmisartan 120 mg od administered with digoxin 0.25 mg od resulted in higher serum digoxin concentrations (2). Digoxin AUC and C_{max} rose by 22% and 50% respectively; the rise in C_{min} (13%) was not significant. These results suggest that telmisartan reduces the clearance of digoxin. The magnitude of this effect is comparable to that observed with calcium channel blockers, carvedilol, captopril, amiodarone, quinidine, and propafenone. Monitoring serum digoxin concentrations should be considered when patients first receive telmisartan and in the event of any changes in the dosage of telmisartan.

© 2006 Elsevier B.V. All rights reserved.

Paracetamol or ibuprofen

The single-dose pharmacokinetics of telmisartan 120 mg were not affected by a concurrent single dose of paracetamol 1 g or ibuprofen 400 mg tds for 7 days (3).

Temazepam

See also Benzodiazepines

General Information

Temazepam is a benzodiazepine that was first discovered as a metabolite of diazepam. It is relatively short-acting, having a half-life of about 10 hours.

Temazepam has favorable kinetics for use as a hypnotic (1) and is widely prescribed for this purpose. Rather surprisingly, both 10 and 20 mg caused discernible and comparable psychomotor impairment the following morning (SEDA-20, 32), at a time when the subjective effects had virtually disappeared. This result emphasizes the often subtle but pervasive insight-impairing effects of benzodiazepines. Temazepam in soft capsules is more rapidly absorbed than from tablets. However, drug users have abused temazepam capsules by heating them to liquefaction and injecting the resultant fluid intravenously, often together with other substances; the resulting medical problems are varied and often serious.

Organs and Systems

Psychological, psychiatric

Temazepam produces a variety of adverse nervous system effects, including restlessness, agitation, irritability, aggression, rage, and psychosis. Perhaps because it is likely to be used recreationally, temazepam has also been used to facilitate crime, particularly in the UK (2).

The effects of oral temazepam 5, 10, and 30 mg on memory have been studied in healthy volunteers subjected to a battery of cognitive tests and analogue mood ratings (3). The lowest dose had no effect and 10 mg significantly increased only self-ratings of well-being. Temazepam 30 mg significantly improved recall of items learned before drug administration, but impaired recall and recognition of word lists acquired after drug administration. There was no impairment of retrieval, suggesting that automatic information processing was unaffected. Temazepam 30 mg significantly reduced self-ratings of anxiety and increased self-ratings of sedation. It also significantly impaired performance in symbol copying, digit-symbol substitution, and number cancellation tasks. It is striking that at a dose that was sedative and impaired many aspects of performance, temazepam nevertheless improved retrieval of items learned before drug administration. In a randomized, crossover study, psychomotor performance and memory were tested and mood assessed for 3 hours after single doses of placebo, temazepam 20 mg, or temazepam 30 mg in six healthy women aged 21–23 years (4). Psychomotor speed and explicit memory showed dose-dependent slowing and impairment, but there was no change in short-term memory.

Drug Administration

Drug dosage regimens

Benzodiazepine prescribing for sleep induction in an elderly medical inpatient population has been examined, to determine if hospital prescribing increases the use of benzodiazepines after discharge (5). The secondary objectives included monitoring for adverse effects and assessment of the quality of sleep in hospital compared with the quality of sleep at home. Inpatient and outpatient prescribing of benzodiazepines used for insomnia was recorded over 3 months. Benzodiazepines were prescribed for 20% of patients, and 94% of the prescriptions were for temazepam. Of the 57 patients who were given benzodiazepines during a hospital admission, 57% had not taken a benzodiazepine at home before admission. Benzodiazepines were effective in the short-term for inducing sleep in hospital, with little evidence of adverse effects.

Drug administration route

Inadvertent intra-arterial injection of temazepam can cause tissue damage.

- A 29-year-old unemployed man developed pain and swelling of the right hand following inadvertent intra-arterial injection of temazepam capsules (6). Over 10 days, necrotic areas involving the index, middle, and little fingers developed and the fingers had to be amputated. He reported episodes of intravenous drug use during the previous 3 days—a single heroin dose followed by temazepam four times (10 mg gel capsules dissolved in hot water). He had injected the drugs into a superficial blood vessel on the back of the right hand.

Drug overdose

In a retrospective analysis of 352 consecutive cases of fatal overdose, temazepam accounted for 65% of all deaths from benzodiazepine overdose (7). Acute rhabdomyolysis, usually associated with intravascular injection, has been seen after an oral overdose of temazepam (SEDA-17, 45).

- An 83-year-old woman developed coma, respiratory depression, hypotonia with generalized hyporeflexia, bilateral extensor plantar responses, and bullous eruptions containing serous fluid over the medial aspects of the knees after taking seven temazepam tablets (8).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Oral contraceptives

The clearance of temazepam was increased when oral contraceptives were co-administered (9). It is unlikely that this is an interaction of clinical importance.

Temocapril

See also Angiotensin converting enzyme inhibitors

General Information

Temocapril is an ACE inhibitor, a prodrug that is converted to the active metabolite temocaprilat after absorption.

Drug–Drug Interactions

Warfarin

Temocapril had no effect on the pharmacokinetics or pharmacodynamics of multiple-dose warfarin in 24 healthy subjects (1). There have been similar negative interaction studies with other ACE inhibitors and oral anticoagulants.

Reference

1. Lankhaar G, Eckenberger P, Ouwerkerk MJA, Dingemanse J. Pharmacokinetic–pharmacodynamic investigation of a possible interaction between steady-state temocapril and warfarin in healthy subjects. Clin Drug Invest 1999;17:399–405.

Tenidap sodium

See also Non-steroidal anti-inflammatory drugs

General Information

Tenidap sodium, an antirheumatic drug, combines the clinical and pharmacological properties of NSAIDs with those of a disease-modifying agent. Data from clinical studies have been reviewed (SEDA-19, 100).

Pfizer abandoned tenidap sodium for use in rheumatoid arthritis after a non-approval letter from the FDA was issued because of unresolved questions about its safety. The decision related only to the 120 mg dose. The FDA's Arthritis Drugs Advisory Committee also voted against approving tenidap sodium for osteoarthritis.

Organs and Systems

Nervous system

The adverse effects of tenidap sodium include headache (3.8%) (1).

Hematologic

Acute eosinophilic pneumonia has been described in a man with osteoarthritis taking tenidap sodium (2).

Gastrointestinal

As expected with a cyclo-oxygenase inhibitor, the adverse effects most frequently reported by patients taking tenidap sodium were gastrointestinal; serious gastrointestinal events occurred in 2.1% (1).

Liver

Increases in serum transaminases can occur, and severe abnormalities in liver function tests have been reported (1,3–5).

Urinary tract

Proteinuria, by an unknown mechanism, is a frequent adverse effect of tenidap sodium (13%), but is reversible and non-progressive in the long term, and with no evidence of deteriorating renal function (1,6).

Skin

The adverse effects of tenidap sodium include alopecia (3.2%) (1).

Drug–Drug Interactions

ACE inhibitors

Tenidap sodium reduces the antihypertensive effects of ACE inhibitors (7).

© 2006 Elsevier B.V. All rights reserved.

Diuretics

Tenidap sodium reduces the antihypertensive effects of diuretics (7).

Lithium

Tenidap sodium interacts with lithium, reducing its renal clearance and increasing steady-state lithium concentrations; the dosage of lithium should be reduced to avoid toxicity (7,8).

Phenytoin

Tenidap sodium displaces phenytoin from plasma albumin binding sites by about 25% (9).

Warfarin

Tenidap sodium interacts with warfarin by displacing it from plasma albumin, although there may be another mechanism; the dosage of warfarin may need to be reduced to avoid toxicity (7,10).

Tenofovir

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Tenofovir is a nucleotide (nucleoside monophosphate) analogue reverse transcriptase inhibitor, given as a prodrug, tenofovir disoproxil fumarate. In contrast to the other members of this class, it only needs to be phosphorylated twice intracellularly before it is pharmacologically active. Adverse effects have been reported as flatulence, raised transaminases, raised creatine kinase activity, and rarely a raised serum creatinine (1). Tenofovir does not currently appear to be nephrotoxic.

Reference

Phase I/II trial of the pharmacokinetics, safety, and antiretroviral activity of tenofovir disoproxil fumarate in human immunodeficiency virus-infected adults. Antimicrob Agents Chemother 2001;45(10):2733–9.

Tenoxicam

See also Non-steroidal anti-inflammatory drugs

General Information

Tenoxicam is a piroxicam analogue with a half-life of 75 hours. Whether the differences in pharmacokinetics in elderly patients have any clinical significance is unknown (SEDA-12, 93).

The pattern of adverse effects is similar to that of piroxicam, but tenoxicam causes slightly fewer serious gastrointestinal effects (1). Fecal blood loss is lower than with aspirin (SEDA-8, 111). A large, multicenter, hospital-based study confirmed that tenoxicam and piroxicam had similar tolerance ratings: 13% of patients had severe adverse effects, most often gastrointestinal (melena, hematemesis, rectal bleeding, exacerbation of ulcerative colitis) and serious rashes (SEDA-15, 103). Gastrointestinal adverse effects are more frequent with higher doses (2).

In an open, non-comparative study in 1267 patients, performed to test tenoxicam safety in general practice, the most common adverse reactions were gastrointestinal (11%), central and peripheral nervous system disorders (2.8%), and skin reactions (2.5%) (3). Patients who take long-term tenoxicam are at low risk of nephrotoxicity. The prevalence of urinary system adverse effects was 0.07% in trials that included 67 000 patients (4).

Other adverse effects include phototoxic dermatitis, thrombocytopenia, edema of the legs, pruritus, and hypersalivation (SEDA-12, 93).

Organs and Systems

Respiratory

Tenoxicam can provoke severe bronchoconstriction and nasal obstruction in aspirin-sensitive asthmatic patients (SEDA-12, 93).

Liver

Mild chronic drug-induced hepatitis has been attributed to tenoxicam (SEDA-21, 108).

Skin

Three cases of toxic epidermal necrolysis (Lyell's syndrome) have been described in patients taking tenoxicam (SEDA-17, 114).

A fixed drug eruption with cross-sensitivity to droxicam and tenoxicam has been reported (SEDA-18, 107), but tenoxicam may not cross-react in patients with photosensitivity to piroxicam (SEDA-18, 107).

Drug Administration

Drug administration route

Tenoxicam can be given intravenously, but phlebitis and pain at the injection site occur, albeit rarely (SEDA-19, 99).

Terazosin

See also Alpha-adrenoceptor antagonists

General Information

The alpha$_1$-adrenoceptor antagonist terazosin has similar adverse effects to those of prazosin. The long-term efficacy and safety of terazosin have been reviewed, in both monotherapy and combination therapy in whites and blacks (1,2).

In order to investigate the mechanisms of adverse events associated with alpha$_1$-adrenoceptor antagonists, the Veterans Affairs Cooperative Study database was analysed with respect to the relation between adverse events and hypotension in 1229 men with benign prostate hyperplasia. Treatment with terazosin produced the following rates of adverse events: dizziness 19%, weakness 6%, postural hypotension 6%, and syncope 1%. Of these adverse events only postural hypotension was associated with orthostatic blood pressure changes. Weakness, dizziness, and postural hypotension occurred to the same extent in patients with falls in systolic blood pressure of 5 mmHg or more or less than 5 mmHg. Thus, dizziness and weakness do not seem to be associated with changes in blood pressure, suggesting that these adverse events associated with alpha-blockers are not related to vascular effects. Designing a subtype selective alpha$_1$-antagonist that has less effect on blood pressure may not result in marked improvement in tolerability over currently available alpha$_1$-antagonists (3).

Organs and Systems

Skin

Terazosin has reportedly caused a rash (4).

- A 59-year-old man developed a generalized rash 3 days after starting to take terazosin 2 mg/day for benign prostatic hyperplasia. He had mild fever, weakness, intense pruritus, and a widespread eruption of scaling erythematous plaques with a violaceous hue on the trunk and extremities. The clinical examination was otherwise unremarkable and laboratory and serological test were negative. A skin biopsy was suggestive of a drug reaction. Terazosin was stopped, and treatment with oral prednisolone and emollients resulted in complete recovery in 2 weeks.

Sexual function

Priapism is rare with alpha-blockers (5).

- A 20-year-old man with a cervical spinal cord injury and a neuropathic bladder was given terazosin 1 mg at night increasing 5 days later to 2 mg. He developed a full erection of his penis, which lasted 5 hours and subsided spontaneously. Terazosin was stopped and the patient experienced no further priapism.

Terbinafine

General Information

The allylamine derivative terbinafine can be used orally or topically. It is active against a broad range of fungi, including filamentous fungi and, to a lesser extent, yeast-like fungi. However, probably because of irreversible protein binding, its clinical usefulness is limited to the treatment of dermatophyte infections and perhaps lymphocutaneous sporotrichosis.

Terbinafine acts by inhibiting the synthesis of fungal ergosterol at the level of squalene oxidase, leading to depletion of ergosterol and accumulation of toxic squalenes in the fungal cell membrane.

Pharmacokinetics

Numerous reviews and studies of the pharmacokinetics of terbinafine have appeared (1–13). Independent of food, its oral availability is 70–80%. With a single dose of 250 mg, plasma concentrations reach around 0.97 μg/ml after two hours. Apparent steady-state plasma concentrations are reached after 10–14 days after only two-fold accumulation, although the half-life is up to 3 weeks and microbiologically active concentrations can be measured in plasma for weeks to months after the last dose, which is consistent with slow redistribution from the peripheral tissues and fat. Protein binding is over 99% and the apparent volume of distribution over 2000 liters, high concentrations reaching adipose tissues, the dermis, epidermis, and nails. Less than 0.2% reaches the breast milk. After several weeks, no further accumulation of the compound occurs (14,15). In renal or hepatic failure, elimination is slowed. Terbinafine undergoes extensive and complex hepatic biotransformation involving at least seven CYP450 enzymes (16); none of its metabolites is mycologically active. Urinary excretion accounts for more than 70% and fecal elimination for 10% of total excretion; the extent of enterohepatic recycling is unknown. Children have a shorter half-life, a lower mean AUC, and a higher volume of distribution, reflecting their higher proportion of lipophilic tissues (17,18).

Comparative studies

The safety and efficacy of terbinafine 250 mg/day and itraconazole 200 mg/day given for 12 weeks for toenail onychomycosis have been compared in a randomized, double-blind study in 372 patients (19). Adverse events were reported in 39% of the terbinafine-treated patients and in 35% of the itraconazole-treated patients. The mean values of biochemical parameters of liver and kidney function did not change significantly. Terbinafine produced higher rates of clinical cure (76 versus 58%) and mycological cure (73 versus 46%) than itraconazole.

In a randomized, double-blind comparison of terbinafine 250 mg/day ($n = 146$) with itraconazole 200 mg/day ($n = 146$), administered for 12 weeks for toenail onychomycosis, mycological cure rates at the 36-week follow-up end-point (67 versus 61%) and the proportion of patients with adverse effects (23 versus 22%) were similar in both study arms. However, more patients taking terbinafine stopped treatment permanently because of treatment-related adverse events (8 versus 1%) (20).

In a double-blind, randomized, multicenter comparison of terbinafine (250 mg/day for 12 or 16 weeks) or itraconazole capsules (200 mg bd for 1 week every 4 weeks for 12 or 16 weeks), 236 patients reported at least one adverse event. All were within the known safety profile of both drugs, and there were no significant differences among the four treatment regimens. Continuous terbinafine was significantly more effective than intermittent itraconazole (mycological cure rates at week 72: 76, 81, 38, and 49%; significant for all comparisons between terbinafine and itraconazole) (21,22).

General adverse effects

Terbinafine is usually well tolerated. Gastrointestinal complaints (dyspepsia, nausea, diarrhea) were the most common reasons for withdrawal. Abdominal pain and loss of taste were reported, as well as mild nervous system symptoms (headache and dizziness) (23).

Organs and Systems

Sensory systems

Taste disturbance is a rare adverse effect of terbinafine. It is usually reversible, with a median time to recovery of 42 days. However, a 46-year-old woman had complete loss of taste after taking oral terbinafine, with persistent taste disturbances for 3 years after stopping the drug (24).

Hematologic

The projected rate of all blood dyscrasias associated with terbinafine has been estimated to be 32 per million patient-years (25). Pancytopenia has been reported (26).

Leukocytes

Neutropenia has been reported in patients taking terbinafine (25–28).

- A 55-year-old woman who was taking terbinafine and paroxetine presented with fever, diarrhea, and vomiting. A bone marrow biopsy showed overall reduced cellularity, and the aspirate showed a profound shift toward the production of immature myeloid cells, consistent with maturation arrest. Treatment consisted of withdrawal of all outpatient medications, hydration, intravenous fluids, broad-spectrum antibiotics, and G-CSF 5 μg/kg for 5 days. Mature granulocytes appeared in the peripheral blood on the fifth day in hospital, and she was discharged on the seventh hospital day with an absolute neutrophil count of 6.2×10^9/l. Paroxetine was resumed weeks after discharge from hospital without hematological toxicity over 6 months.
- A 60-year-old man presented with fever, oral mucositis, pedal cellulitis, and bacteremia after a 6-week course of terbinafine 250 mg. He was taking concurrent yohimbine for impotence. Bone marrow examination showed a hypocellular marrow with myeloid maturation arrest. Treatment consisted of withdrawal of outpatient medications, broad-spectrum antibiotics, hydration,

© 2006 Elsevier B.V. All rights reserved.

and G-CSF, and was ultimately successful. Yohimbine was resumed later without any adverse effects.

- A 42-year-old man presented with fever and granulocytopenia (absolute neutrophil count: 340×10^6/l; temperature: 39.5°C) after a 30-day course of oral terbinafine 250 mg/day for presumed onychomycosis (27). The granulocyte count recovered promptly after withdrawal of the drug and administration of G-CSF for 2 days.
- Agranulocytosis occurred in a 15-year-old who took terbinafine 250 mg/day for toenail onychomycosis and tinea pedis (29). This effect was noted 4 weeks after starting terbinafine and resolved within 1 week after its withdrawal.

Platelets

Thrombocytopenia has been attributed to terbinafine (30), and the incidence has been estimated at 1 in 200 000 patients (25).

- A 25-year-old Yemeni woman with familial-ethnic leukopenia developed thrombocytopenia with epistaxis after taking terbinafine 250 mg for 4 weeks (30). The platelet count recovered from a nadir of 63×10^9/l to 314×10^9/l after drug withdrawal.
- A 53-year-old woman developed severe thrombocytopenia after a 6-week course of terbinafine (250 mg/day) for onychomycosis (31). A bone marrow aspirate showed a normocellular marrow. She received a platelet transfusion and recovered after a short course of prednisolone.

Mouth

- A 38-year-old man presented with acute right otitis media and unrelated painless bilateral enlargement of the parotid glands 15 days after taking oral terbinafine for tinea cruris (32). He stopped taking terbinafine and 12 days later the swelling had significantly abated and completely disappeared 4 weeks later.

Liver

Minor abnormalities in liver function tests have been reported in up to 4% of patients taking oral terbinafine (33), but have not generally been considered clinically important (SEDA-16, 297) (SEDA-18, 7) (SEDA-18, 25).

Terbinafine can cause hepatitis, with an estimated rate of about 1 in 50 000 (34). Idiosyncratic reactions can lead to liver cell necrosis as well as cholestasis. Prolonged cholestatic hepatitis and liver failure have been reported (35–39).

- In four patients with cholestatic hepatitis associated with terbinafine, all presented with jaundice and direct hyperbilirubinemia, various other clinical signs of hepatitis, and mild to moderate rises in alkaline phosphatase and hepatic transaminase activities (34,39). Biopsies in two patients showed cellular infiltrates in the portal tracts and hepatocellular and canalicular cholestasis ($n = 1$) and hepatocyte degeneration ($n = 1$). In the two cases with long-term follow-up, hepatitis was reversible after withdrawal of terbinafine and liver tests normalized within 6 months.
- A 41-year-old man developed severe hepatic dysfunction following a 3.5-week course of terbinafine (250 mg/day) (40). He had marked pruritus, jaundice, malaise, anorexia, and loin pain. His serum bilirubin rose to a peak of 718 μmol/l with alkaline phosphatase 569 U/l, alanine transaminase 90 U/l, aspartate transaminase 63 U/l, and a prolonged prothrombin time of 21 seconds, unresponsive to vitamin K. Liver biopsy showed canalicular cholestasis consistent with a drug reaction. His symptoms resolved 11 months after drug withdrawal, and his liver function tests normalized after 15 months.
- A previously healthy 46-year-old man developed acute fulminant hepatitis following treatment with rabeprazole, citalopram hydrobromide, terbinafine, and a multivitamin formulation (41). Liver biopsy showed submassive centrilobular necrosis and intrahepatic cholestasis with florid bile duct proliferation.

In the last case, because of the similarity of the clinical, laboratory, and histological effects of omeprazole and lansoprazole, as previously reported, the authors concluded that the reaction in the second patient might have been caused by the proton pump inhibitor rather than terbinafine.

- A 56-year-old woman developed chronic biliary ductopenia and portal fibrosis 2 years after a course of terbinafine (42). Terbinafine treatment at that time had resulted in jaundice and evidence of cholestasis. After withdrawal of terbinafine, she continued to have pruritus and persistently raised serum alkaline phosphatase activity. Investigations for various types of chronic liver disease were negative and so chronic bile duct loss and periportal fibrosis were attributed to terbinafine.

Because of the rare and unpredictable nature of hepatobiliary reactions to terbinafine, the mechanism of hepatotoxicity has been hypothesized to be either immunological or metabolically mediated. A potentially toxic reactive metabolite of terbinafine, 7,7-dimethylhept-2-ene-4-ynal (TBF-A), the *N*-dealkylation product of terbinafine, has been identified in vitro (43). The authors speculated that this allylic aldehyde metabolite, formed by liver enzymes and conjugated with glutathione, would be transported across the canalicular membrane of hepatocytes and concentrated in the bile. The reactive monoglutathione conjugate could bind to hepatobiliary proteins and cause direct toxicity. Alternatively, it could modify canalicular proteins and lead to an immune-mediated reaction, causing cholestatic dysfunction.

Skin

Cutaneous adverse effects reportedly occur in 1–3% of patients taking terbinafine. The overwhelming majority of these reactions consist of mild to moderate macular exanthemas.

The risk of serious skin disorders has been estimated in 61 858 users of oral antifungal drugs, aged 20–79 years, identified in the UK General Practice Research Database (44). They had received at least one prescription for oral fluconazole, griseofulvin, itraconazole, ketoconazole, or terbinafine. The background rate of serious cutaneous

© 2006 Elsevier B.V. All rights reserved.

adverse reactions (corresponding to non-use of oral antifungal drugs) was 3.9 per 10 000 person-years (95% CI = 2.9, 5.2). Incidence rates for current use were 15 per 10 000 person-years (1.9, 56) for itraconazole, 11.1 (3.0, 29) for terbinafine, 10 (1.3, 38) for fluconazole, and 4.6 (0.1, 26) for griseofulvin. Cutaneous disorders associated with the use of oral antifungal drugs in this study were all mild.

Generalized rashes, fixed drug eruptions, toxic epidermolysis, and erythema exudativum multiforme have all been reported in association with terbinafine (45,46).

Pustular eruptions can occur occasionally (45–49).

- Acute generalized exanthematous pustulosis associated with terbinafine has been described in two patients (47,49). Both presented within 7–10 days after starting to take terbinafine with generalized pustular dermatosis and leukocytosis; fever was a presenting symptom in one patient. Treatment with systemic corticosteroids was successful in both cases.
- A 62-year-old diabetic man on stable oral medication with glibenclamide, metformin, Zestoretic (lisinopril + hydrochlorothiazide), gemfibrozil, and aspirin developed febrile generalized pustular eruptions after 44 days of therapy with oral terbinafine 250 mg/day (50). Withdrawal of terbinafine and symptomatic treatment with hydrotherapy and topical and systemic steroids resulted in complete resolution of fever and pustulosis within 4 days. The erythematous component responded more slowly, and mildly pruritic erythematous plaques persisted for more than 40 days.
- In another case of acute generalized exanthematous pustulosis attributed to terbinafine (250 mg/day), epicutaneous and intracutaneous skin tests were negative, and there was no evidence of viral infection (51).

Terbinafine can cause or exacerbate psoriatic lesions.

- Severe pustular psoriasis provoked de novo by oral terbinafine has been reported in a 65-year-old man 2 weeks after the start of therapy for onychomycosis (52). Treatment of psoriasis was complicated and ultimately required continuous systemic and topical antipsoriatic therapy.
- A 74-year-old woman developed inverse psoriasis after 14 days of therapy with terbinafine 250 mg/day for onychomycosis (53). The lesions resolved almost completely on withdrawal of terbinafine and topical therapy.

Probable psoriatic onychodystrophy, misdiagnosed as onychomycosis and treated with terbinafine, induced inverse psoriasis in the second case, underscoring the importance of mycological confirmation of onychomycosis before therapy.

Ten cases of severe skin reactions probably associated with terbinafine requiring drug withdrawal have been reported: erythema multiforme ($n = 5$), erythroderma ($n = 1$), severe urticaria ($n = 1$), pityriasis rosea ($n = 1$), and worsening of pre-existing psoriasis ($n = 2$) (54). All the patients made an uneventful recovery with appropriate therapy. The authors pointed out that patients should be counselled about discontinuing terbinafine at the onset of a skin eruption and about seeking medical advice about further management.

- Cutaneous lupus erythematosus attributed to terbinafine has been reported in two previously healthy women (55,56). In the first patient, the lesions improved but did not resolve completely; in the second the symptoms resolved completely with appropriate therapy and the patient remained disease-free after withdrawal of all medication.
- Another woman with a previous history suggestive of lupus erythematosus developed a widespread flare in her skin 1 week after starting oral terbinafine (57). The eruption ultimately responded to systemic treatment with corticosteroids.

Baboon syndrome has been attributed to terbinafine (58).

- A 26-year-old man developed a fixed drug eruption on his hands and inguinal and gluteal areas after oral treatment of onychomycosis with terbinafine 250 mg/day. The rash showed the characteristic distribution of the baboon syndrome. Although epicutaneous and intracutaneous tests were negative, the rash recurred 20 hours after oral rechallenge with terbinafine.

The underlying pathogenic mechanism for the baboon syndrome has been suggested to be a systemically induced allergic contact dermatitis.

Hair

Hair loss has been attributed to terbinafine (59).

- A 69-year-old woman took terbinafine 250 mg/day for 112 days for subungual hyperkeratosis and developed hair loss after 3 months. She was also taking hydrochlorothiazide, amiloride hydrochloride, and amlodipine besilate, all in the same dosage for more than 5 years. Clinical and laboratory investigations showed no other obvious causes, and hair loss completely reversed on withdrawal of terbinafine.

Musculoskeletal

Since its introduction, the Netherlands Pharmacovigilance Foundation Lareb has received eight reports of arthralgia in patients taking terbinafine (60). In four cases, skin reactions were also present and in two cases urticaria. Two patients who reported arthralgia also had a fever. Logistic regression modelling showed that both urticaria and arthralgia were statistically significantly associated with reports on terbinafine compared with all other reports in the database. These findings may point toward a clustering of these symptoms in patients using terbinafine, suggesting a shared immunological reaction.

Immunologic

Exacerbation of lupus erythematosus has been reported during terbinafine therapy (55–57,61). Of 21 consecutive patients with subacute cutaneous lupus erythematosus who attended an outpatient dermatology department in Germany during 1 year, 4 had terbinafine-associated disease (62). In addition to high titers of antinuclear antibodies with a homogeneous pattern, anti-Ro(SS-A) antibodies were present; in three of the four women, anti-La(SS-B) antibodies were also found. All the

© 2006 Elsevier B.V. All rights reserved.

patients had antihistone antibodies, as in drug-induced lupus, and showed the characteristic genetic association with the HLA-B8,DR3 haplotype; moreover, in two cases HLA-DR2 was also present. After withdrawal of terbinafine, antinuclear antibody titers fell and antihistone antibodies became undetectable within 4.5 months in three patients.

- A 66-year-old man with giant cell arteritis and hypertension developed a hypersensitivity reaction 4.5 weeks after starting to take terbinafine, with a skin eruption, fever, lymphadenopathy, and hepatic dysfunction (63). Concomitant medications included prednisone, doxazosin, and aspirin. His symptoms and signs resolved within 6 weeks after withdrawal of terbinafine and continuation of all the other medications. The hypersensitivity syndrome reaction in this case was idiosyncratic, with no apparent predisposing factors.

Susceptibility Factors

Age

The pharmacokinetics of terbinafine and five known metabolites have been investigated in 12 children, (mean age 8 years; range 5–11 years), who took terbinafine 125 mg/day for 6–8 weeks for tinea capitis (15). The metabolism of terbinafine was similar to that observed in adults, and there were comparable steady-state plasma concentrations after administration of the same oral dose. Steady state was reached by day 21 with no further accumulation up to day 56. Terbinafine was effective in all patients and safe and well tolerated over 56 days.

In a randomized, double-blind comparison of terbinafine ($n = 27$) with itraconazole ($n = 28$) for 2 weeks for tinea capitis in Pakistani children (mean age 8 years), fever, body ache, and vertigo were seen with terbinafine in one patient each, and urticaria with itraconazole in two patients (64). There were no significant changes in hematological and biochemical profiles.

In an open assessment of the efficacy, safety, and tolerability of oral terbinafine 125–250 mg/day for 1, 2, and 4 weeks for tinea capitis in 132 Brazilian children aged 1–14 years, adverse events were reported in 10 patients (65). The drug was prematurely withdrawn in one patient. In the post-treatment evaluation, two patients had abnormal bilirubin concentrations and eight patients had abnormal alkaline phosphatase activities; none was considered clinically relevant.

In an open, non-comparative study of the use of terbinafine for 14 days to treat tinea capitis in 50 children and adolescents (mean age 7.6 years; range 24 months to 18 years), the clinical and mycological cure rates were 86%. The drug appeared to be well tolerated. Two children had reversible neutropenia, thought to be due to a preceding viral illness; other adverse effects were not observed (18).

In 14 children, aged 1–15 years, with *Microsporum canis* tinea capitis given oral terbinafine for 4 weeks, the recommended daily dose produced no response by week 4; the dose was doubled (to 250 mg/day) for a further 4–8 weeks in six patients and continued at the original dose in six patients (66). Two patients withdrew. Four patients were cured after 8–12 weeks of treatment, and all had taken the doubled dose of terbinafine, except for one who had taken the usual adult dose of 250 mg/day from the start. Oral terbinafine was well tolerated by all but one patient, who had gastrointestinal disturbance and slightly raised transaminase activities during the first 4 weeks of treatment.

In an open, prospective, uncontrolled study in 81 immunocompetent young children (aged 2–13 years) with tinea capitis due to *Microsporum canis*, oral terbinafine was given in dosages based on weight (62.5 mg for those weighing 10–20 kg and 125 mg for 20–40 kg), and applied topically to affected areas (1% cream bd) (67). Treatment lasted for 4 weeks, followed by an 8-week observation (treatment-free) period. All the subjects were assessed for efficacy and tolerability at 12 weeks. At 12 weeks: 32 had completely recovered, with no evidence of relapse during the observation period, and 21 had mycological cure but residual signs of infection. The effective cure rate was 65%. Terbinafine was well tolerated by these children: 75 had no adverse effects; the other six had abdominal pain ($n = 2$), vomiting ($n = 1$), generalized itching ($n = 1$), local itching ($n = 1$), and localized erythema ($n = 1$). Hematological and biochemical parameters remained normal during the study.

Drug–Drug Interactions

Rifamycins

Rifampicin 600 mg/day reduced terbinafine concentrations by about 50% by enzyme induction (68).

Theophylline

Theophylline is largely metabolized by CYP1A2 and terbinafine increases its half-life (69). In a randomized, crossover study in 12 healthy volunteers, terbinafine increased theophylline exposure by 16%, with a 14% reduction in clearance and a 24% increase in half-life (69). These pharmacokinetic changes may predispose individuals to accumulation of theophylline and unwanted toxicity. Caution should be taken in prescribing terbinafine for patients taking long-term theophylline.

Tricyclic antidepressants

Desipramine

Inhibition of CYP2D6 by terbinafine has been evaluated by assessing 48-hour concentration-time profiles of the tricyclic antidepressant desipramine in 12 healthy volunteers identified as extensive CYP2D6 metabolizers by genotyping and phenotyping (70). The pharmacokinetics were evaluated at baseline (50 mg oral desipramine given alone), steady state (after 250 mg oral terbinafine for 21 days), and 2 and 4 weeks after terbinafine withdrawal. The pharmacodynamics were evaluated before and 2 hours after each dose of desipramine, using Mini-Mental Status Examination and electroencephalography. Terbinafine inhibited CYP2D6 metabolism, as indicated by significant increases in desipramine C_{max} and AUC and reductions in the C_{max} and AUC of the CYP2D6-mediated metabolite, 2-hydroxydesipramine, both of which were still altered 4 weeks after terbinafine withdrawal. Caution should be exercised when

co-prescribing terbinafine and drugs that are metabolized by CYP2D6, particularly those with a narrow therapeutic index.

Imipramine

- A 51-year-old patient developed imipramine toxicity and increased plasma concentrations associated with the introduction of terbinafine, possibly due to inhibition of CYP2D6 (71).

Nortriptyline

Metabolism by CYP2D6 is of major importance for the hydroxylation of nortriptyline, making it susceptible to competitive inhibition by terbinafine. Nortriptyline intoxication provoked by terbinafine has been reported (72).

- A 74-year-old man taking a stable dose of nortriptyline for depression developed signs of nortriptyline intoxication 14 days after he started to take terbinafine (72). Nortriptyline serum concentrations were several times higher than the usual target range and fell to baseline after withdrawal of terbinafine. Re-challenge led to the same clinical and laboratory findings.
- Nortriptyline intoxication secondary to terbinafine has been observed in a woman with a major depressive disorder (73). After rechallenge her serum nortriptyline concentration rose and the serum concentrations of its two hydroxylated metabolites fell. She had a normal genotype for CYP2D6, suggesting that this interaction can occur even in people without reduced CYP2D6 activity.

Warfarin

While terbinafine had no effect on warfarin in healthy volunteers, it can prolong the prothrombin time in some individuals (74–77), prompting intensification of laboratory control during terbinafine therapy.

- A 71-year-old woman taking a stable dose of warfarin and cimetidine was treated with terbinafine, and 32 days later developed profuse intestinal bleeding associated with a prothrombin time of 120 seconds, suggestive of an interaction between warfarin and terbinafine, either directly or through the mediation of cimetidine (which can reduce terbinafine clearance by 33%) (74).

However, a contrasting case has also been reported.

- A 68-year-old woman taking warfarin, glibenclamide, metformin, furosemide, and spironolactone was given terbinafine 250 mg/day and 4 weeks later required progressive increases in the warfarin dosage to maintain a therapeutic INR; after withdrawal of terbinafine, her warfarin requirements returned to baseline over 4 weeks, supporting enzyme induction with gradual onset and offset (75).

Since a pharmacokinetic study of a single dose of warfarin in 26 healthy volunteers treated with terbinafine showed no significant interaction, and since a large postmarketing study of terbinafine did not find any cases of interaction of warfarin with terbinafine, the manufacturers (78) and others (77) have cautioned about any generalization regarding an interaction between terbinafine and warfarin.

Terbutaline

See also Beta$_2$-adrenoceptor agonists

General Information

Terbutaline is a selective beta$_2$-adrenoceptor agonist, with a similar profile to salbutamol, and its adverse effects profile is similar to that of salbutamol at equivalent doses (SEDA-21, 186) (SEDA-22, 193).

Nebulized terbutaline 5 mg has been compared with injected adrenaline (0.01 ml/kg of 1:1000 adrenaline to a maximum of 0.3 ml) in children with acute asthma. Those who received adrenaline had a significantly higher rate of adverse effects, 47 versus 11% (SEDA-21, 186).

Organs and Systems

Respiratory

The possibility of paradoxical bronchospasm due to terbutaline must be taken into consideration (SEDA-8, 145).

Nervous system

With terbutaline, somnolence has been reported in some studies, and may be characteristic of this drug, apparently occurring in some 25% of patients (SEDA-8, 145).

Acute paraparesis occurred after an injection of terbutaline sulfate for premature labor in a 26-year-old woman (1).

Metabolism

The effect of terbutaline on glucose metabolism has been studied in six healthy, pregnant women, with normal glucose tolerance, between the 30th and 34th weeks of pregnancy (2). The women took either oral terbutaline 5 mg every 6 hours for 24 hours or no medication. The study was repeated after 1 week and each subject acted as her own control. With terbutaline fasting blood glucose increased in each subject, the mean rising from 4.6 to 5.2 mmol/l (82 to 94 mg/dl). Basal serum insulin increased significantly, from 18 to 27 μU/ml. Glucagon fell from a mean of 166 to 144 pg/ml. There was a 12% rise in basal hepatic glucose production. The glucose infusion rate to maintain euglycemia fell by 33% while subjects were taking oral terbutaline. Indirect calorimetry showed that terbutaline caused a significant increase in energy expenditure. Oxygen consumption increased by 9% (270 to 294 ml/minute) and basal caloric expenditure increased by 14% (from 1.32 to 1.5 kcal/minute). Thus, oral terbutaline given for 24 hours is associated with a significant reduction in peripheral insulin sensitivity and an increase in energy expenditure. Increases in basal hepatic glucose metabolism and a reduced ability of insulin to suppress hepatic glucose output are consistent with an effect of terbutaline on maternal hepatic glucose metabolism.

Second-Generation Effects

Pregnancy

In pregnant women with a history of migraine or vascular headache the use of terbutaline (and its congeners) should be avoided because of the risk of cerebral ischemia (SEDA-8, 145). One pregnant woman with asthma suffered a hypotensive episode after treatment with subcutaneous terbutaline (SEDA-12, 123).

A severe and life-threatening hypotensive reaction in patients with quadriplegia after terbutaline medication warrants a warning against indiscriminate use of beta-adrenoceptor agonists in the absence of autonomic spinal function (SEDA-8, 145).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Phenylephrine

Sweating, tachycardia, and headache have been reported when terbutaline was added to phenylephrine (SEDA-18, 16).

Toloxatone

Sweating, tachycardia, and headache have been reported when terbutaline was added to toloxatone (SEDA-18, 16).

Terfenadine

See also Antihistamines

General Information

Launched as a peripherally acting antihistamine with little sedative activity, terfenadine largely fulfilled this promise, but proved to have cardiotoxic properties, which led to restrictions on its use (SEDA-17, 196) (SEDA-18, 182) (SEDA-18, 186) (SEDA-19, 176) (SEDA-20, 163) (SEDA-21, 177) (SEDA-22, 179).

Inhibitors of CYP3A4 can lead to accumulation of unchanged terfenadine, causing prolongation of the QT interval and ventricular dysrhythmias. However, little is known about the effects of terfenadine on the pharmacokinetics of other drugs, even though it is known that terfenadine itself inhibits CYP3A4 activity in human liver microsomes. In view of its mode of metabolism, interactions with many other drugs are likely.

Organs and Systems

Cardiovascular

Terfenadine can cause prolongation of the QT interval in overdose or during interactions with drugs that inhibit its metabolism, such as erythromycin (1), ketoconazole (2), and grapefruit juice (3). Torsade de pointes can result (4).

Nervous system

Terfenadine has been investigated in several thousands of patients and found to have a sedation rate comparable to placebo (5). It has not been shown to impair driving performance (6).

Liver

There have been reports of cholestatic hepatitis induced by terfenadine (SEDA-21, 177), but quantitative information has been lacking on the risk of acute liver disease among users of this drug. In a population-based cohort study using general practice data in the UK carried out by the Boston Collaborative Drug Surveillance Program, a causal connection to terfenadine could not be ruled out in only three cases of acute liver disease among 210 683 recipients (7). However, the three individuals were also taking other drugs known to cause liver toxicity.

Skin

Terfenadine has been reported to cause skin reactions, notably urticaria and rashes in a number of cases (SEDA-11, 148) (SEDA-13, 132). A photoallergic reaction to terfenadine has also been reported (SEDA-12, 143), and so have severe exacerbations of psoriasis (SEDA-14, 137).

Stevens–Johnson syndrome has been reported both with terfenadine (SEDA-21, 177).

Drug–Drug Interactions

Atorvastatin

Terfenadine is normally metabolized by CYP3A4 to fexofenadine, which has negligible cardiac effects. Atorvastatin is also a CYP3A4 substrate, and its effects on the pharmacokinetics of terfenadine have been studied in healthy volunteers who took atorvastatin 80 mg/day from 7 days before to 2 days after terfenadine 120 mg (8). Concentrations of terfenadine and fexofenadine were measured for 72 hours. There were no alterations in the pharmacokinetics of the parent compound or of its metabolite and there were no alterations in QT_c intervals after terfenadine alone or with atorvastatin.

Buspirone

Ten healthy volunteers took oral terfenadine 120 mg/day for 3 days and then took buspirone 10 mg; terfenadine had no significant effects on the pharmacokinetics of buspirone (9).

Erythromycin

Torsade de pointes has been reported in patients taking erythromycin and terfenadine (1).

Grapefruit juice

Grapefruit juice substantially increased the AUC and C_{max} of terfenadine (3).

Ketoconazole

Terfenadine can cause prolongation of the QT interval in overdose or during interactions with drugs that inhibit its metabolism, such as ketoconazole.

- Torsade de pointes occurred in a patient who was taking the recommended prescribed dose of terfenadine in addition to cefaclor, ketoconazole, and medroxyprogesterone (2). Measured serum concentrations of terfenadine and its main metabolite showed excessive levels of

© 2006 Elsevier B.V. All rights reserved.

parent terfenadine and proportionately reduced concentrations of its metabolite, suggesting inhibition of terfenadine metabolism.

Nefazodone

Nefazodone is a phenylpiperazine antidepressant that is predominantly metabolized by CYP3A. In a randomized, double-blind, double-dummy, parallel-group, multiple-dose study in healthy men and women who were given terfenadine 60 mg every 12 hours or nefazodone 300 mg every 12 hours, the plasma concentrations of terfenadine were significantly increased by co-administration of nefazodone (10). The mean QT_c interval was unchanged by terfenadine alone, but was markedly prolonged with co-administration of nefazodone, and the extent of prolongation correlated with the plasma terfenadine concentration.

Norfluoxetine

A possible interaction with norfluoxetine, a metabolite of fluoxetine, has been reported (SEDA-20, 164).

Sertindole

Sertindole 30 mg/day had no effects on the pharmacokinetics of a single dose of terfenadine 120 mg or of its metabolite (11). The authors concluded that sertindole at this dose does not inhibit the metabolism of terfenadine.

Sparfloxacin

The effect of the concomitant administration of terfenadine and sparfloxacin on the QT_C interval has been studied in healthy men aged 18–49 years (12). Sparfloxacin was given in a dose of 400 mg on the first day and 200 mg/day thereafter for 3 days with terfenadine 60 mg bd. Terfenadine had no effect on the pharmacokinetics of sparfloxacin and there were no apparent effects on the QT_C interval.

Venlafaxine

Drugs used in the treatment of depression and psychosis can alter the metabolism of terfenadine. When the antidepressant venlafaxine was given to steady state (37.5 mg bd for 3 days and then 75 mg bd for 5 days), the pharmacokinetics of a single dose of terfenadine 120 mg were not altered and there were no changes in the electrocardiogram (13). The authors concluded that cardiotoxicity is unlikely to arise with co-administration of terfenadine and venlafaxine.

Terguride

General Information

Terguride is an ergot derivative, a partial dopamine agonist with properties similar to those of bromocriptine. It has been used in the treatment of Parkinson's disease and hyperprolactinaemia.

In 21 patients with parkinsonism, terguride 0.25–0.5 mg caused improvement for periods of up to 6 hours, although eight of 21 subjects showed no improvement or deterioration with doses of 0.5–1.0 mg (1). In three patients the addition of terguride 0.75 mg/day for 5–10 days did not affect levodopa-induced psychosis. In three patients with levodopa-induced dyskinesias, the addition of terguride 0.75 mg/day for 14 days resulted in a slight increase in the severity of the involuntary movements. The adverse effects of terguride, nausea and hypotension, were similar to those of levodopa. Terguride caused prolonged inhibition of prolactin release, but unlike levodopa did not increase plasma growth hormone concentrations. Additionally, terguride caused considerable sedation. These results may have been due to the combined effects of terguride on both non-dopamine and dopamine neurotransmitter systems, rather than to partial or incomplete dopamine agonist effects.

In 32 women with ovarian dysfunction due to hyperprolactinemia treated with terguride for 2–33 months, increased prolactin concentrations were successfully normalized in 21 (2). Regular periods reappeared in 14, 13 became pregnant, 7 gave birth to healthy babies, and 2

© 2006 Elsevier B.V. All rights reserved.

aborted in the first trimester. Galactorrhea disappeared in 18 patients and was markedly inhibited in the others. There were adverse effects in 11 of the patients. They were mostly mild and included in most cases nausea, headache, and stomachache. The complaints were transient and abated after prolonged treatment.

Terodiline

See also Anticholinergic drugs

General Information

Terodiline, an anticholinergic drug that was originally used for urinary incontinence (1), but was withdrawn in most countries in 1991 because of multiple reports of drug-related cardiac dysrhythmias (SEDA-17, 174).

Organs and Systems

Cardiovascular

A retrospective analysis of data from 19 patients has shown that the effect of terodiline on the QT interval is dose-related. The authors commented that terodiline has structural similarities to prenylamine, an antianginal drug that was previously shown to have prodysrhythmic properties, so that such problems should really not have been unexpected (SEDA-20, 147).

Tetanus toxoid

See also Vaccines

General Information

Tetanus toxoid is prepared from *Clostridium tetani* and can be given either in a fluid form (plain) or an adsorbed form. The slight local reactions that tend to occur (induration, erythema, tenderness) are more common with the adsorbed type. Intramuscular injection of tetanus toxoid is generally the route of choice, and the vaccine is best injected into a large muscle.

General adverse effects

Data on adverse events after tetanus immunization have been collected by Behringwerke, Germany (SED-12, 826) and in the framework of the US Monitoring System for Adverse Events Following Immunization (MSAEFI) (SEDA-13, 274). Some figures for particular types of complication are cited below.

Isolated reports of adverse effects have included: abscess formation (SEDA-11, 288); dermatomyositis, neuralgic amyotrophy, polyradiculoneuritis with paresis of the urinary bladder and bowel (SEDA-9, 283); asymmetrical polyneuropathy, demyelinating polyneuropathy, and Guillain–Barré syndrome (SEDA-14, 281); and subcutaneous nodules. Polyvinylpyrrolidone thesaurismosis, revealed by inflammatory manifestations after tetanus booster injection, has also been reported (SEDA-10, 288).

Combined diphtheria + tetanus + pertussis vaccination

An overview of clinical trials with a special diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine has been published (1). The vaccine contains as pertussis components purified filamentous hemagglutinin, pertactin, and genetically engineered pertussis toxin. The vaccine induces high and long-lasting immunity and is at least as efficacious as most whole-cell pertussis vaccines and similar in efficacy to the most efficacious acellular pertussis vaccines that contain three pertussis antigens. The vaccine is better tolerated than whole cell vaccines and has a similar reactogenicity profile to other acellular vaccines.

A vaccine containing diphtheria and tetanus toxoids and acellular pertussis with reduced antigen content for diphtheria and pertussis (TdaP) has been compared with a licensed reduced adult-type diphtheria–tetanus (Td) vaccine and with an experimental candidate monovalent acellular pertussis vaccine with reduced antigen content (ap) (2). A total of 299 healthy adults (mean age 30 years) were randomized into three groups to receive one dose of the study vaccines. The antibody responses (anti-diphtheria, anti-tetanus, anti-pertussis toxin, anti-pertactin, anti-filamentous hemagglutinin) were similar in all groups. The most frequently reported local symptom was pain at the injection site (62–94%), but there were no reports of severe pain; redness and swelling with a diameter of 5 cm or more occurred in up to 13%. The incidence of local symptoms was similar after TdaP and Td immunization. The most frequently reported general symptoms were headache and fatigue (20–50%). The incidence of general symptoms was similar in the TdaP and Td groups. There were no reports of fever over 39°C. No serious adverse events were reported.

Data from the Third National Health and Nutrition Survey (1988–94) have been used to analyse the possible effects of DTP or tetanus immunization on allergies and allergy-related symptoms among 13 944 infants, children, and adolescents aged 2 months to 16 years in the USA (3). The authors concluded that DTP or

© 2006 Elsevier B.V. All rights reserved.

tetanus immunization increases the risk of allergies and related respiratory symptoms in children and adolescents. However, the small number of non-immunized individuals and the study design limited their ability to make firm causal inferences about the true magnitude of effect.

Tetravalent, pentavalent, and hexavalent immunization

DTaP or DTwP vaccine can be combined with other antigens, such as *Haemophilus influenzae* type b (Hib), inactivated poliovirus (IPV), and hepatitis B vaccine. In children DTaP or DTwP vaccines are the basis for such combinations, while in adults it is mostly Td vaccine, Current safety concerns regarding combination vaccines have been defined and reviewed (4). The author concluded that there is no evidence that adding vaccines to combination products increases the burden on the immune system, which can respond to many millions of antigens. Combining antigens usually does not increase adverse effects, but it can lead to an overall reduction in adverse events. Before licensure, combination vaccines undergo extensive testing to assure that the new products are safe and effective.

The frequency, severity, and types of adverse reactions after DTP-Hib immunization in very preterm babies have been studied (5). Adverse reactions were noted in 17 of 45 babies: nine had major events (apnea, bradycardia, or desaturation) and eight had minor reactions (increased oxygen requirements, temperature instability, poor handling, and feeding intolerance). Babies who had major adverse reactions were significantly younger at the time of immunization than the babies who did not have major reactions. Of 27 babies immunized at 70 days or less, 9 developed major reactions compared with none of those who were immunized at over 70 days.

The Hexavalent Study Group has compared the immunogenicity and safety of a new liquid hexavalent vaccine against diphtheria, tetanus, pertussis, poliomyelitis, hepatitis B and *H. influenzae* type b (DTP + IPV + HB + Hib vaccine, manufactured by Aventis Pasteur MSD, Lyon, France) with two reference vaccines, the pentavalent DTP + IPV + Hib vaccine and the monovalent hepatitis B vaccine, administrated separately at the same visit (6). Infants were randomized to receive either the hexavalent vaccine ($n = 423$) or (administered at different local sites) the pentavalent and the HB vaccine ($n = 425$) at 2, 4, and 6 months of age. The hexavalent vaccine was well tolerated (for details see the monograph on Pertussis vaccines). At least one local reaction was reported in 20% of injections with hexavalent vaccine compared with 16% after the receipt of pentavalent vaccine or 3.8% after the receipt of hepatitis B vaccine. These reactions were generally mild and transient. At least one systemic reaction was reported in 46% of injections with hexavalent vaccine, whereas the respective rate for the recipients of pentavalent and HB vaccine was 42%. No vaccine-related serious adverse event occurred during the study. The hexavalent vaccine provided immune responses adequate for protection against the six diseases.

Organs and Systems

Cardiovascular

Myopericarditis has been attributed to Td-IPV vaccine (7).

- A 31-year-old man developed arthralgia and chest pain 2 days after Td-IPV immunization and had an acute myopericarditis. He recovered within a few days with high-dose aspirin.

The authors discussed two possible causal mechanisms, natural infection or an immune complex-mediated mechanism. Infection was excluded by negative bacterial and viral serology and a favorable outcome occurred within a few days without antimicrobial treatment.

Nervous system

Reports of neurological adverse effects after tetanus immunization have appeared (8). The most common reported complication is a polyneuropathy. In the majority of cases the onset occurred within 14 days of the last injection, and ranged in severity from a single nerve palsy to profound sensorimotor involvement of the nervous system, including cord and cortex. Recovery was usually complete (eight of 10 patients with onset at less than 14 days after injection) but three patients with onset at more than 14 days from injection had only partial recovery.

Mononeuritis and polyneuritis after tetanus immunization during 1970 and 1977 have been reviewed (9). The frequency of this adverse effect was 0.4 per one million distributed vaccine doses.

Sensory systems

Optic neuritis has been attributed to Td-IPV vaccine (10).

- Ten days after receiving Td-IPV vaccine a 56-year-old woman developed acute unilateral optic neuritis. Complete remission occurred within 6 weeks of prednisolone treatment. No other causes were found.

Skin

Bullous pemphigoid has been attributed to DTP-IPV vaccine (11).

- A previous healthy 3.5-month-old infant developed bullous pemphigoid 3 days after receiving a first dose of DTP-IPV vaccine. *Staphylococcus aureus* was isolated from purulent bullae. The lesions resolved rapidly after treatment with antibiotics and methylprednisolone.

The authors mentioned 12 other cases of bullous pemphigoid, reported during the last 5 years, that had possibly been triggered by vaccines (influenza, tetanus toxoid booster, and DTP-IPV vaccine).

- About 2 weeks after receiving a second dose of adsorbed tetanus toxoid a 50-year-old woman developed generalized morphea, a rare condition, in which multiple patches of skin sclerosis occur over much larger areas than in the localized variant. The patient denied taking any drugs. After prednisone therapy, a month later the lesions had dramatically improved (12).

© 2006 Elsevier B.V. All rights reserved.

The cause of this condition is unknown, but an autoimmune mechanism triggered by endogenous and exogenous factors has been suggested.

Immunologic

Allergic reactions to reinforcing doses of tetanus toxoid have been described by different investigators (SEDA-8, 300) (SEDA-11, 288). The association between high titers of antitoxin produced by active immunization and reactions is well established (13,14). Booster doses of tetanus toxoid are being given with unnecessary and indeed excessive frequency. Continuing to do this will produce a more highly toxoid-sensitive population without adding significantly to the already high protection that this immunized population has against tetanus. It is therefore recommended that routine boosters in individuals known to have had primary immunization including a reinforcing dose be given only at 10-year intervals, and that emergency boosters be given no less than 1 year apart (15). Allergic reactions may be due to an allergy to the toxoid or the proteins of *C. tetani* that co-purify with toxoid during the precipitation process used in its conventional preparation (16).

Susceptibility Factors

Age

In children aged 15–16 years receiving routine reinforcement tetanus immunization, adsorbed vaccine caused more intense and more frequent local reactions than did plain tetanus toxoid, and a higher incidence of pyrexia. The incidence of swelling and erythema at the inoculation site increased with serum antitoxin titre at the time of administration, whereas pain and tenderness were related to the presence of the aluminium hydroxide adjuvant (17). Based on similar experiences it has been widely recommended that plain and not adsorbed tetanus toxoid should be used when reinforcement of immunity to tetanus alone is desired.

Other features of the patient

The only contraindication to tetanus toxoid is a history of a severe allergic or neurological reaction after a previous dose. AIDS and HIV infections are not contraindications. Data on the immune response to tetanus in children with AIDS showed defective responses (18).

Tetracaine

See also Local anesthetics

General Information

Tetracaine is a highly lipid-soluble, potent aminoester. It is primarily used as a constituent of many different topical formulations and for spinal anesthesia. It is four times as potent as lidocaine, and unless great caution is taken in dosage, serious systemic adverse effects can develop,

© 2006 Elsevier B.V. All rights reserved.

owing to rapid absorption after topical use (for example in a 0.5% gargle) (1) or use in endoscopy. It is more effective than Emla in reducing the pain of venous cannulation in children.

Tetracaine can cause local reactions when applied to the skin, but because it is rapidly metabolized by plasma cholinesterase systemic reactions are unlikely (2).

Organs and Systems

Cardiovascular

- An 18-month-old child undergoing cardiac surgery developed discoloration of the hand, consistent with severe bruising, after application of 4% tetracaine gel, which was inadvertently left under an occlusive dressing for about 24 hours (3). There were no long-term sequelae and no treatment was required.

The authors blamed a combination of the vasodilatory properties of tetracaine and the fact that the child was heparinized for surgery, causing capillary leak at the area of application.

Hematologic

Adult cases of methemoglobinemia have been reported with Cetacaine (a proprietary mixture of 14% benzocaine, 2% tetracaine, and 2% butylaminobenzoate) (4–6).

Cetacaine spray used to anesthetize the oropharynx before endoscopy led to dyspnea, central cyanosis, and an oxygen saturation of 80%; methemoglobinemia was diagnosed, and the patient recovered rapidly with methylthioninium chloride 1 mg/kg over 5 minutes.

- A 77-year-old woman received two sprays of Cetacaine for an attempted emergency nasotracheal intubation. After intubation, she became cyanosed. The arterial blood was chocolate brown and the SaO_2 by CO oximetry was 54–58%, despite a high PaO_2. The methemoglobin concentration was 39% and she was treated with methylthioninium chloride. Three weeks later, Cetacaine again caused cyanosis with a drop in SpO_2 to 76% and a methemoglobin concentration of 24%, which resolved spontaneously.
- A 74-year-old man received Cetacaine spray to his oropharynx for transesophageal echocardiography. His SpO_2 fell to 85%, he became drowsy, then unresponsive, cyanotic, and apneic, and required intubation. His PaO_2 was 37 kPa (280 mmHg), SaO_2 40%, and methemoglobin concentration 60%. Intravenous methylthioninium chloride produced an immediate improvement in the cyanosis and the methemoglobin concentration fell to 0.6%.

Skin

Reported local adverse effects of tetracaine include itch and a high incidence of erythema as a consequence of vasodilatation, which may actually be an advantage. There was no evidence of dermatitis (SEDA-20, 127) (7).

In 272 children who required topical local anesthesia for venepuncture, there was no association between the duration of application of 4% tetracaine gel and the development of adverse skin reactions (8). However, two reports discussed by the same authors highlighted rare adverse reactions.

- A 4-year-old child with no previous exposure complained of severe pain, erythema, and blistering 5 minutes after the application of 4% tetracaine gel.
- An anesthetist who was suspected of occupational exposure developed redness and blistering after applying a test dose of tetracaine.

The authors recommended minimizing occupational contact and quickly removing the cream in patients who report pain after application of tetracaine.

There may be a higher incidence of skin sensitization from tetracaine gel than Emla. At one hospital, in a 3-month period, there were seven site reactions to tetracaine (9). While the Summary of Product Characteristics says that significant skin reactions are rare, the authors estimated that seven reactions in their hospital represented a higher rate than 0.01–0.1% (usually regarded as the frequency of rare events). Indeed, the reported incidence of moderate to severe local skin reactions in clinical trials is 0.6–8.8%, compared with 0–1.7% with Emla. According to the Summary of Product Characteristics there is also a risk of sensitization with repeated exposure (four of the seven children who had reactions to tetracaine had had prior exposure to it), which is not known to happen with Emla.

Immunologic

Anaphylactic shock has been reported after spinal anesthesia (SED-12, 257) (10).

Tetrachloroethylene

General Information

Tetrachloroethylene is a chlorinated derivative of a simple hydrocarbon, $H_2C{=}CH_2$, in which each of the four hydrogen atoms is replaced by chlorine, $Cl_2C{=}CCl_2$. It is a heavy liquid that has been used to treat hookworm infection. It is given orally in a dose of 0.1 ml/kg up to a maximum of 5 ml as a single dose on an empty stomach. Usually formulated as capsules or emulsion, it is unstable, especially if exposed to light. Concurrent *Ascaris* infection should be treated first to avoid migration of worms and the risk of peritonitis.

General adverse effects

The adverse effects of tetrachloroethylene are similar to those of carbon tetrachloride (CCl_4), but less severe. Tetrachloroethylene is hepatotoxic and neurotoxic, but gastrointestinal disturbance is the only common adverse effect when it is used carefully. There is some risk of addiction to the inhaled vapor: inhalation can result in vascular reactions, loss of consciousness, pulmonary edema, and fatal hepatic and renal damage. Alcohol and fatty foods increase absorption and hepatic toxicity. Exposure to tetrachloroethylene has been known to lead to vinyl chloride disease. Allergic reactions have not been reported.

It is highly unlikely that single-dose use of tetrachloroethylene could have a tumorigenic effect; however, animal studies conducted in connection with exposure to tetrachloroethylene in the course of industrial use showed an increased occurrence of liver tumors.

Organs and Systems

Cardiovascular

In cases of poisoning with tetrachloroethylene, hypotension can occur; sympathomimetic drugs should not be used to treat it, since ventricular fibrillation can be precipitated.

Respiratory

Hypersensitivity pneumonitis has been attributed to occupational exposure to tetrachloroethylene in a 42-year-old dry cleaner; the diagnosis was confirmed by lung biopsy (1).

Nervous system

Headache and vertigo are common with tetrachloroethylene (2,3). Patients should remain at rest for 3 hours after administration and take only water.

Inhalation of tetrachloroethylene vapor can cause stupor (4).

Psychological, psychiatric

Reversible neuropsychiatric symptoms, readily resembling alcoholic intoxication, have occurred after a single dose of 5 ml. Sleep apnea causing neuropsychiatric abnormalities has been attributed to exposure to high concentrations of tetrachloroethylene and *N*-butanol vapors; however, the patient was obese and the association with the solvents was not clear (5).

Gastrointestinal

Nausea, vomiting, colicky abdominal pain, and diarrhea are common with tetrachloroethylene (2).

Liver

Hepatotoxicity from tetrachloroethylene is similar to that caused by carbon tetrachloride and can occur after oral treatment or even inhalation of the vapor (6).

Urinary tract

Tetrachloroethylene can cause renal damage, especially after inhalation (7).

Skin

If tetrachloroethylene comes into contact with the skin, either directly or after vomiting, burn-like reactions can occur (8).

Erythema multiforme has followed oral administration of tetrachloroethylene (9).

Second-Generation Effects

Pregnancy

It is unwise to use tetrachloroethylene in pregnancy in view of its potential for hepatotoxicity, but there is no specific information on the risks to the fetus as a result of therapeutic use; however, work relating to industrial use (exposure of women in the dry-cleaning industry) suggests the need for caution (10).

Susceptibility Factors

Age

It is dangerous to use tetrachloroethylene in young children (11).

Tetracyclines

See also Individual agents

General Information

The tetracyclines are a closely related group of antibiotics with comparable pharmacological properties but different pharmacokinetic characteristics. They have both the advantages and disadvantages of broad-spectrum antibiotics. Tetracyclines are effective not only against bacteria and spirochetes, but also against some forms of *Mycoplasma*, *Chlamydia*, and *Rickettsia*, as well as protozoa. They affect multiplying microorganisms by inhibiting ribosomal protein synthesis. Their effect is therefore primarily bacteriostatic rather than bactericidal, depending on the kind of microorganism.

Most of the adverse effects of the tetracyclines depend on the concentration of the antibiotic in the affected organ. The more lipophilic drugs are more potent with regard to their bacteriostatic efficacy and hence usually require daily doses below 1 g.

Use in non-infective conditions

Tetracyclines have many effects on non-infective inflammatory processes (SEDA-24, 278). They have been tried, and claimed to be of some value, in the treatment of rheumatoid arthritis, periodontal disease, myocardial infections, gastric disorders, and experimentally in the treatment of cancers. In all of these disorders, the proposed mechanisms for effects are on the host rather than the microbial side.

Tetracyclines have many effects on cells involved in inflammatory reactions, including inhibition of neutrophilic functions, such as migration, phagocytosis, degranulation, and the production of free oxygen radical (1). Most of these effects are supposed to be due to chelation of divalent ions and can be partly reversed by the addition of calcium ions or zinc ions. Their ability to inhibit synthesis of mitochondrial proteins may be the background for their effects on lymphocytes, such as inhibition of lymphocyte proliferation in response to mitogens, inhibition of interferon gamma production, and inhibition of immunoglobulin production. Enzyme inactivation caused by tetracyclines has been studied in several models. Tetracyclines inhibited gingival collagenolytic activity in diabetic mice and in humans with periodontal disease (2). Subsequent studies showed that tetracyclines inactivated collagenases found in several places in the body (3,4). Most probably, the inhibitory effects of tetracyclines on collagenases are exerted through inactivation of metalloproteases, rather than serine proteases. Tetracycline also has radical-scavenging properties, which may be partly related to the ulcer-healing effect observed in a rat model of gastric mucosal injury (5).

As is to be expected, modified cycline molecules devoid of antibacterial effects are as effective as non-modified molecules. New derivatives with refined anti-inflammatory and enzyme inhibitory (and reduced antimicrobial) effects are being studied in experimental laboratories (6).

Tetracyclines and metalloproteinases

A major target for non-infective indications of the tetracyclines is inhibition of metalloproteinases. The following is a brief summary of what is known about tetracyclines and metalloproteinases, followed by some comments about possible adverse effects.

The matrix metalloproteinases (MMPs) are a family of calcium- and/or zinc-dependent endopeptidases involved in degradation of extracellular matrix and tissue remodelling (7). At least 21 mammalian MMPs have been described. They participate in various biological processes, such as embryonic development, ovulation, angiogenesis, apoptosis, wound healing, and nerve growth.

Under normal conditions, the activity of MMPs is very low and is strongly regulated by natural tissue inhibitors (TIMPs). The TIMPS are a family of four structurally related proteins (TIMP-1, 2, 3, and 4), exerting dual control of the MMPs by inhibiting both their active forms and their activation. In addition, the proteolytic activity of MMPs is inhibited by non-specific protease inhibitors, such as alpha$_2$-macroglobulin and alpha$_1$-antiprotease.

In the presence of specific stimuli, exemplified by cytokines and growth factors, MMPs can be up-regulated. Chronic activation of MMPs, due to an imbalance between the activity of MMPs and TIMPs, can result in excessive degradation of the extracellular matrix and is believed to contribute to the pathogenesis of several diseases, such as rheumatoid arthritis, osteoarthritis, periodontal disease, emphysema, atherosclerosis, skin ulceration, and cancer.

The physiological and pathophysiological roles of MMPs and TIMPs have been extensively studied in knockout mice (7). For most of the MMPs and TIMPs there seem to be significant overlaps in functions, and a deficiency of one enzyme can be compensated for by the presence of others (7,8). Each MMP is encoded by a distinct gene, and about half of the human MMP genes so far discovered are on chromosome 11 (7).

The mere fact that MMPs might be involved in the pathogenesis of several chronic disorders has made this field attractive to numerous pharmaceutical companies.

© 2006 Elsevier B.V. All rights reserved.

One major approach for controlling abnormal MMP activity has been the use of small molecular weight inhibitors, and several excellent reviews of the design of such inhibitors have been published (7).

Rheumatoid arthritis

In 1942, the Swedish doctor Nana Svartz introduced sulfasalazine into therapy and suggested that it might be useful in rheumatoid arthritis because of its antibacterial activity. Since then, many antimicrobial agents have been tried in the treatment of rheumatoid arthritis, based on the assumption that the disease may be due to an infectious agent. Interest has focused on tetracyclines for the treatment of rheumatoid arthritis (9), reactive arthritis (10), and osteoarthritis (11) and the state of the art has been reviewed (12). The theory that rheumatoid arthritis is due to an infectious agent has been refined to a statement that it may be a gene transfer disease in which some viruses act as vectors (13), thereby excluding a direct effect of antibacterial agents on the disease.

Two further perspectives on the use of tetracyclines in rheumatoid arthritis have been published (14,15). In addition to an effect on matrix metalloproteinases, the authors focused on a potential antiarthritic action of tetracyclines by their effects in the interaction between the generation of nitric oxide, matrix metalloproteinase release, and chondrocyte apoptosis. Both minocycline and doxycycline inhibit the production of nitric oxide from human cartilage and murine macrophages (16) in concentrations that are achieved in vivo. The authors suggested that tetracyclines may have several potential chondroprotective effects: direct inhibition of matrix metalloproteinase activity and, by inhibition of nitric oxide production, further reduction of matrix metalloproteinase activity, reversal of reduced matrix synthesis, and reduced chondrocyte apoptosis.

In double-blind, placebo-controlled studies, minocycline relieved clinical symptoms and reduced some laboratory measures of disease activity in patients with rheumatoid arthritis (17–19). However, the progression of radiographic damage was not significantly reduced and minocycline caused several adverse effects. This led to investigations of the therapeutic effects of doxycycline in patients with rheumatoid arthritis. In 13 patients with moderate rheumatoid arthritis, low-dose doxycycline 20 mg bd reduced the urinary excretion of pyridinoline (20). Pyridinolines are collagen cross-links that are released from joints during cartilage and bone resorption and correlate with the severity of joint destruction (21). In a later study, doxycycline produced a significant reduction in the number of tender joints and significant improvements in disability and behavior in 12 patients with rheumatoid arthritis (22).

However, these studies were not placebo-controlled, and it was possible that the observed effects were due to factors other than doxycycline. Two double-blind, placebo-controlled trials have since been reported (23,24).

In a crossover study, 66 patients took 50 mg doxycycline or placebo twice a day for 12, 24, or 36 weeks (23). Patients' assessments, swollen and tender joint counts, duration of morning stiffness, erythrocyte sedimentation rate, and the so-called modified disease activity score (25) were used as measures of disease activity. Doxycycline had no significant effects on clinical and laboratory measures of disease activity, pyridinoline excretion, or progression of radiographic joint damage. Furthermore, there were adverse effects during treatment with doxycycline and not with placebo. The authors concluded that doxycycline 50 mg bd provided no therapeutic benefit in patients with rheumatoid arthritis.

In another study, a 16-week, randomized, double-blind, placebo-controlled trial, eligible subjects with active seropositive or erosive rheumatoid arthritis were randomly allocated to three treatment groups: doxycycline 200 mg intravenously, azithromycin 250 mg orally, or placebo (24). The primary end-points were changes between baseline and week 4 in the tender joint count, erythrocyte sedimentation rate, and urinary excretion of pyridinoline. The trial was stopped prematurely after 31 patients had been enrolled. Three subjects were withdrawn because of worsening arthritis. There were no significant differences across the groups in any of the three primary clinical endpoints. The authors concluded that doxycycline did not reduce disease activity or collagen cross-link production.

Ten chemically modified tetracyclines (CMTs), minocycline, and doxycycline have been tested for their capacity to inhibit cartilage degradation in vitro (26). CMT-8 was the most active. The authors concluded that by carefully selecting a tetracycline-based MMP inhibitor and controlling dosages it should be possible to inhibit pathologically excessive MMP-8 and/or MMP-13 activity, especially that which causes bone erosion, without affecting the constitutive activity of MMP-1 needed for tissue remodelling and normal host function. They thought that of the CMTs, CMT-8 and to a lesser extent CMT-3 and CMT-7 were the most effective. However, the effects of these CMTs in a full-scale trial in rheumatoid arthritis have not been reported.

Reactive arthritis

It is well established that a number of microorganisms found in the gastrointestinal tract are associated with reactive arthritis and that most of these organisms might be susceptible to tetracyclines. Several investigations have shown clinical effects of tetracyclines in the treatment of reactive arthritis (12). In these cases, a more direct antibacterial effect of the triggering organism (if still present in the patient) might be the mechanism involved.

Osteoarthritis

Tetracyclines have been investigated in experimental osteoarthritis, because metalloproteases are involved in the breakdown of cartilage matrix seen in this condition. Doxycycline reduced the severity of knee osteoarthritis induced in dogs by ligamentous section (27) and also reduced the degradation of type XI collagen exposed to extract of human arthritic cartilage (28).

Periodontal disease

Periodontal disease is caused by microorganisms, but host responses are in large part responsible for destruction of the periodontal support structures. In these patients, pathological activity of host-derived matrix metalloproteinases occurs in response to the bacterial infection in the

© 2006 Elsevier B.V. All rights reserved.

periodontal tissues, causing destruction of collagen, the primary structural component of periodontal matrix. This in turn leads to gingival recession, pocket formation, and increased tooth mobility. The final outcome is loss of the tooth.

Tetracyclines inhibit collagenolytic activity in gingival tissue (SEDA-23, 256) (29–31). Based on these findings, a large clinical development program was initiated to demonstrate the potential of a sub-antimicrobial dose of doxycycline to augment and maintain the beneficial effects afforded by conventional non-surgical periodontal therapy in adult periodontitis. A summary of these studies has been published (32). Several different dosage regimens and placebo were compared in patients who had had a variety of adjunctive non-surgical procedures. Of the various parameters studied, the following are worthy of mention: collagenase activity in gingival crevicular fluid and gingival specimens, so-called clinical attachment levels, probing pockets depths, bleeding on probing, and subtraction radiographic measurements of alveolar bone height.

Sub-antimicrobial doses of doxycycline reduced collagenase activity in both gingival crevicular fluid and gingival biopsies, augmented and maintained gains in clinical attachment levels and reductions in pockets depths, reduced bleeding on probing, and prevented loss of alveolar bone height. These clinical effects occurred in the absence of any significant effects on the subgingival microflora and without evidence of an increase in the incidence or severity of adverse reactions relative to the controls. The authors proposed that the main mechanism underlying these effects is inhibition of pathologically high matrix metalloproteinase activity in neutrophils (MMP-8) and bone cells (MMP-13).

Acne

Over the years, various tetracyclines have been used in the treatment of acne. Their mechanism of action is not clear, but appears to be not purely antimicrobial, since they reduce chemotaxis of polymorphonuclear leukocytes, modify complement pathways, and inhibit the polymorphonuclear leukocyte chemotactic factor and lipase production in *Propionibacterium acnes* (33). They may also have a direct effect on sebum secretion (34), for example by modification of free fatty acids (35).

Adult respiratory distress syndrome

Adult respiratory distress syndrome (ARDS) has many causes, is associated with severe lung damage, and is characterized by pulmonary edema and hypoxemia. It has a high mortality. The current method of treatment is supportive and there is no specific therapy. This was the background to a thorough review of the anti-inflammatory properties of tetracyclines in the prevention of acute lung injury (36). The authors ended with an optimistic forecast, that targeting the proteases that cause ARDS with chemically modified tetracyclines may be useful in prevention and treatment. They ended by suggesting that strategies to prevent ARDS should focus on targets downstream from the initial inflammatory signals that provoke the cascade of events.

Glaucoma

Tetracyclines, especially demeclocycline, are among the most effective ocular hypotensive agents, according to studies in rabbits and cats. The biochemical mechanism of this effect is unknown. The prolonged effect and apparent lack of adverse ocular adverse effects suggest their possible usefulness for treating glaucoma in man (SEDA-15, 260).

General adverse effects

Mild gastrointestinal disturbances are common. A common and nearly unique feature of all tetracyclines is the formation of drug–melanin complexes, resulting in pigment deposition at various sites. Except for enamel defects and presumable disturbances of osteogenesis these deposits do not give rise to abnormalities of organ function. In view of tooth discoloration and enamel hypoplasia, with a tendency to caries formation, tetracyclines should be avoided in children under 8 years of age and in women after the third month of pregnancy. The risk of photosensitivity reactions largely depends on the dose of the drug and the degree of exposure to sunlight. It may be increased in long-term treatment. Skin, nail, and other organ pigmentation often occur, even with low-dose long-term treatment. The syndrome of fatty liver degeneration is rarely encountered today, because risk factors such as pregnancy are respected, and formulations with lower doses are available. Adverse effects can occur with most tetracyclines if the dosage is not altered in patients with renal insufficiency.

Allergic reactions to tetracyclines are less than half as common as allergic reactions to penicillin. For this reason, tetracyclines are alternatives in patients with allergic reactions to other antibiotics. Exceptional observations of anaphylactic shock have been reported (37,38). In a few cases tetracyclines were assumed to be the cause of hypersensitivity myocarditis (39). Pneumonitis with eosinophilia has been described in association with tetracyclines (40). A serum sickness-like syndrome was probably associated with minocycline in a 19-year-old man treated for acne (41). Allergic and toxic reactions may in some cases have been caused by degraded formulations or additives (42). Tumor-inducing effects have not been reported.

Jarisch–Herxheimer reaction

The Jarisch–Herxheimer reaction is common in patients treated with tetracyclines for louse-borne relapsing fever (43). Two forms of reaction are described at the start of tetracycline therapy: (a) fever, rigor, increased respiratory and heart rates, and occasional delirium and coma (44); (b) fever and disseminated intravascular coagulation (45). At about the time the temperature reaches its peak, spirochetes disappear from the peripheral blood (44). Meptazinol, a partial opioid antagonist, reduces the Jarisch–Herxheimer reaction in relapsing fever (46).

Bleeding with thrombocytopenia and signs of intravascular coagulation in patients treated for louse-borne relapsing fever may be due to a Jarisch–Herxheimer reaction mediated by the release of endotoxins from disintegrating spirochetes (43).

© 2006 Elsevier B.V. All rights reserved.

Comparisons of individual tetracyclines

The spectra of bacterial effectiveness of the various tetracyclines are fairly similar. However, metabolism and excretion vary. In general, preference is currently given to drugs that can be given in relatively low doses (not above 1.0 g/day).

Tetracycline (chlortetracycline) and oxytetracycline

These tetracyclines are incompletely absorbed from the gastrointestinal tract. Plasma concentrations fall with half-lives of 6–12 hours. They are predominantly excreted by the kidney, extrarenal elimination amounting at most to 10–20%. They have a lower affinity for fat and membranes, which means that higher dosages to achieve therapeutic effectiveness. However, higher dosages can contribute to an increased risk of systemic toxic effects and, as absorption from oral administration is incomplete, also to an increased risk of gastrointestinal adverse reactions.

Demeclocycline (demethylchlortetracycline)

Demeclocycline produces a significantly higher rate of phototoxic skin reactions than other tetracyclines, presumably owing to its long half-life (about 16 hours), resulting in therapeutic plasma concentrations lasting 24–48 hours, and an even longer-lasting accumulation of the drug in membranes and fatty tissues. Demeclocycline is eliminated about 20–40% by glomerular filtration. In patients with liver cirrhosis, cardiac failure, or impaired renal function, it should be used cautiously, because of its pronounced effect on electrolyte and fluid balance (47).

Doxycycline and minocycline

Doxycycline and minocycline are more lipophilic tetracyclines. They are well absorbed after oral administration. Their half-lives are 16–18 hours. Their higher affinity for fatty tissues improves their effectiveness and changes their adverse effects profile. Local gastrointestinal irritation and disturbance of the intestinal bacterial flora occur less often than with the more hydrophilic drugs, which have to be given in higher oral doses for sufficient absorption.

Nevertheless, their toxic effects are similar to those of other tetracyclines and arise from accumulation in fatty tissues. Accumulation in a third compartment and the resulting long half-life may contribute to an increased incidence of various toxic adverse effects during long-term treatment, even if lower daily doses are used. This seems also to be the case for pigmentation disorders and possibly for neurological disturbances (48).

Minocycline and doxycycline are predominantly eliminated by the liver and biliary tract (70–90%). Therefore, no change in dose is needed in patients with impaired renal function. However, it should be considered that hepatic elimination of doxycycline or minocycline might be accelerated by co-administration of agents that induce hepatic enzymes.

Methacycline

Methacycline is rarely used. It has similar efficacy to ampicillin in acute exacerbations of chronic bronchitis.

Chemically modified tetracyclines

As early as the 1960s it was recognized that tetracyclines might inhibit bone growth, supposedly by interference with calcium metabolism. It was not until collagenase was discovered in 1983 (50) that intensive interest in the non-antimicrobial properties of tetracycline-based antibiotics developed. Most of the initial studies were done with doxycycline and minocycline, that is semi-synthetic tetracyclines with widespread medical and dental uses. However, in 1987, a non-antibacterial chemically modified tetracycline (CMT) that inhibited mammalian collagenase activity was described (51). At present, the CMTs (also known as COLs, from their having been introduced by CollaGenes Pharmaceuticals Inc, Newton, PA, USA) comprise a group of at least 10 analogues compounds (CMT-1 to CMT-10) that differ in their specificity and potency in inhibiting MMP. Comparative pharmacokinetic data, obtained from animals, have recently been published, as has a bibliography covering more than 75 papers and abstracts related to the basic biological properties of these compounds (52). Chemically modified tetracyclines are more active in interfering with mammalian processes than the classical tetracyclines, which is the main justification for their use in non-infective problems (52,53). From a qualitative point of view, it might be reasonable to assume similar host-related adverse effects as the classical tetracyclines, while from a quantitative point of view, dosages, duration of therapy, etc., will influence the number of adverse effects. However, the risks might be quite high.

Hematologic

Sideroblastic anemia is characterized by the accumulation of iron in the mitochondria of erythroblasts. In a Phase I study in 35 patients with refractory tumors, eight taking CMT-3 developed anemia without leukopenia or thrombocytopenia (54). Three of these patients underwent bone-marrow examination and each had ringed sideroblasts. The authors referred to several cases of aplastic anemia, megaloblastic anemia, and hemolytic anemia in which members of the tetracycline family have been implicated. However, they stated that there has been no previous reports of sideroblastic anemia associated with any tetracycline derivative and that the molecular mechanisms by which CMT-3 might cause sideroblastic anemia are unclear.

Immunologic

Based on the strategy that inhibition of angiogenesis is of importance in anticancer therapy, CMT-3 (COL-3) was used in a phase 1 study in 35 patients at the National Institutes of Health in the USA in patients with refractory metastatic cancer (55). The patients received a test dose of CMT-3, followed by pharmacokinetic testing during daily dosing for 7 days. After a few doses, three patients developed symptoms of drug-induced lupus, and the diagnoses were verified after a few days or weeks. CMT-3 was withdrawn and there was improvement.

Bacterial resistance

Prolonged treatment with the classical antibacterial tetracyclines results in bacterial resistance and/or

© 2006 Elsevier B.V. All rights reserved.

opportunistic fungal infections. It has therefore been forecast, but not so far proven, that chemically modified tetracyclines without antibacterial activity may not cause microbial resistance. However, accepting that the major mechanism by which bacteria get rid of tetracyclines intracellularly is by increasing their efflux via P glycoprotein, the chemically modified tetracyclines might also trigger that mechanism, thereby causing reduced sensitivity of the exposed bacterial population to all types of tetracyclines. Before this possibility has been ruled out, the new chemically modified tetracyclines should be introduced with great care.

Organs and Systems

Cardiovascular

Cardiovascular reactions to tetracyclines have often been associated with other symptoms of hypersensitivity, such as urticaria, angioedema, bronchial obstruction, and arterial hypotension (37,56). Such reactions occurred in patients who had tolerated tetracyclines previously and were therefore considered as anaphylactic.

Respiratory

There have been a few cases of acute bronchial obstruction after the administration of a tetracycline (57).

Pneumonitis with eosinophilia has also been described (40,58).

When pleural tetracycline instillation is used to produce local inflammation for pleurodesis in spontaneous pneumothorax, there are no severe short-term or long-term adverse effects (59).

Nervous system

Tetracyclines rarely cause benign intracranial hypertension. This syndrome has primarily involved children (60,61), although it has also been observed in adults (48,62–69). Re-exposure can result in recurrence (59). As a rule, the symptoms develop within days or occasionally several months after the start of therapy, in one case only after 18 months of tetracycline therapy for acne (48). The syndrome includes headache, nausea and vomiting, dizziness, tinnitus, papilledema, and visual disturbances caused by scotoma or optic nerve damage. Intracranial pressure can be raised up to three-fold. Distinct intracerebral lesions are not visible on CT scan or angiography and the ventricular spaces are not enlarged (62). With the exception of raised intracranial pressure, all findings, including the cell count and protein concentration of the cerebrospinal fluid, are normal. After withdrawal, symptoms resolve over a period of hours to days or occasionally weeks. Increased use of long-term therapy with tetracyclines for acne may contribute to a higher prevalence of this syndrome (70).

Early studies showed that curare blockade was increased by tetracyclines (71–73). This effect can be antagonized by calcium ions (74). There was a short-term increase in muscular weakness in patients with myasthenia gravis after intravenous tetracycline. The mechanism may be a calcium-antagonizing effect of magnesium ions present in the tetracycline solvent, as the symptoms could be provoked by similar amounts of magnesium alone. The formation of calcium complexes with non-protein-bound tetracycline, thus lowering the serum concentration of free calcium, may also be involved (75).

Sensory systems

Acute transitory myopia was described as an effect of tetracycline therapy, probably due to changes in refractive power (76).

Endocrine

Hormone production in patients with "black thyroid," who had taken a tetracycline for prolonged periods, was normal (77,78).

Metabolism

Tetracyclines can increase blood urea nitrogen or serum urea concentrations without a corresponding increase in serum creatinine (that is without accompanying renal damage). The mechanism is an excess nitrogen load of metabolic origin accompanied by negative nitrogen balance. This effect is termed "anti-anabolic" (79,80), but is in fact the result of inhibition of protein synthesis, which affects not only microorganisms but to some degree mammalian cells also. Sodium and water depletion, due to the diuretic effect of some tetracyclines, can further enhance uremia (80).

Tetracyclines have been associated with hypoglycemia (81). Insulin doses may have to be reduced (82).

Hematologic

Hematological changes with tetracyclines are extremely rare. However, in individual cases, hemolytic anemia (83), neutropenia or slight leukopenia, thrombocytopenia (84), and even aplastic anemia have all been described. In the light of the fact that such blood changes are often reported without a clear description of their cause, the relation to the drug often remains doubtful, especially if reactions are listed in tabular form and information on specific details or concomitant drug therapy is lacking.

Bleeding with thrombocytopenia and signs of intravascular coagulation in patients treated for louse-borne relapsing fever may be due to a Jarisch–Herxheimer reaction mediated by the release of endotoxins from disintegrating spirochetes (43).

Mouth and teeth

The long-term esthetic results of treating severely stained teeth due to tetracyclines by endodontics and internal bleaching have been assessed in 20 patients and found to be excellent (85). A therapeutic strategy may be bleaching after the preparation for porcelain laminate veneers or night-guard vital bleaching (86,87).

Stomatitis, other signs of irritation of the oropharynx, and a rash in and around the orifices have been described in patients taking tetracyclines. This may partly be considered as mucous membrane manifestations of allergic or toxic origin. Secondary infections by pathogenic organisms, such as *C. albicans*, viruses, or bacteria, should always be considered (88).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Nausea, vomiting, and epigastric burning are the most common adverse effects of tetracyclines. This is also true for the lower-dose formulations. The symptoms are usually mild and seldom necessitate withdrawal. Nausea occurs in 8–15% of patients.

Esophageal damage

Esophageal ulcers have been described in association with oral doxycycline or tetracycline. Acute onset of substernal burning pain and dysphagia was noted within hours of taking the drug (89–93). Remaining parts of the ingested capsule were identified by esophagoscopy.

Thirty centers for pharmacovigilance in France have reported 81 cases of esophageal damage after treatment with tetracyclines collected between 1985 and 1992 (94). There were 64 ulcers, eight cases of dysphagia, and nine of esophagitis. Most (96%) of the cases were caused by doxycycline and 73% of the patients were female, mean age 29 years. Prescriptions were for dermatological (54%), urogenital (23%), and ENT diseases. In one patient, a 71-year-old man, an esophagobronchial fistulation required esophagectomy. In 92% the drugs were not taken correctly, that is at bedtime or without a sufficient quantity of fluid. Treatment with sucralfate 1 g tds did not change the outcome of tetracycline-induced esophageal ulcers (95).

In three studies of more than 600 children with chest pain, none had tetracycline-induced esophagitis as a cause of their pain (96–98).

Patients should not lie down immediately after taking a tetracycline capsule and the formulation should be swallowed with generous quantities of water (89,99).

Liver

A clinical syndrome, often with fatal outcome, has been recognized as a complication of high doses of tetracycline. It is characterized by nausea, vomiting, and spiking fever. Jaundice, acidosis, and uremia are also often present, while hematemesis and melena are only occasionally observed. Some patients die because of refractory hypotension. The histopathological findings are those of diffuse fatty liver degeneration (100–102). Although the syndrome was primarily described in pregnant women, it is not restricted to them. Impaired renal function, and thus reduced renal elimination of tetracyclines, as well as serious infections, increases the risk of this complication (100,103). Since the introduction of lower doses of tetracycline (under 1 g/day), the syndrome of fatty liver degeneration with severe hepatic insufficiency has become rare (101). However, a few reports have described liver reactions in previously healthy individuals with no pre-existing conditions and given usual oral doses of tetracyclines (104,105). Liver enzymes and renal function should be monitored, especially in patients at risk.

A personally experienced case of likely tetracycline-induced liver injury after low-dose tetracycline has been reported (106). The patient took oral doxycycline 200 mg/day for 8 days and had markedly altered liver function. The liver enzyme activities normalized only 109 days after withdrawal. The authors also reviewed all reports of liver damage to Swedish Adverse Drug Reactions Advisory Committee (SADRAC) in the period 1965–95. There were 23 liver reactions with a suspected causal relation to oral low-dose tetracycline derivatives. A causal relation was considered likely in three cases and possible in eight, giving an incidence of roughly one in 18 million defined daily doses. There were no deaths from these liver reactions, and liver enzyme activities normalized in all cases without any serious clinical consequences. The authors remarked that the frequency of liver reactions resulting from tetracyclines may be somewhat higher, as previous studies in Sweden suggest that only 20–50% of severe adverse reactions are reported to SADRAC (106).

Pancreas

Pancreatitis is a common feature of the clinical syndrome of fatty liver due to tetracyclines, although it has also been observed without overt liver disease in a patient after two separate exposures (107).

Urinary tract

Tetracyclines not uncommonly cause a raised serum urea concentration due to impaired protein synthesis rather than renal damage, However, renal insufficiency can occur, and patients with pre-existing renal insufficiency are particularly likely to develop raised blood urea nitrogen, serum phosphate, and serum sulfate concentrations during treatment with most tetracyclines. These changes may be associated with acidosis and even symptoms of uremia. Renal dysfunction can be missed if diuresis alone is monitored, since non-oliguric renal insufficiency has been reported (108). Interstitial nephritis is extremely rare (109–111).

Uremia, which may at least in part be due to a reduction in renal function, has been observed in patients with liver cirrhosis (112–114), cardiac failure, or interstitial nephritis (115), which is extremely rare (109–111).

Most observations suggest that a determining factor for the risk of renal insufficiency is a relative overdose of the drug in patients with pre-existing renal damage (113,114), particularly in those who are already dehydrated (for example due to diuretic therapy). The half-life of tetracyclines is prolonged several-fold in patients with renal dysfunction (116). With normal renal function, 20–70% of an intravenous dose of tetracycline is eliminated by glomerular filtration. Maintenance therapy must be adjusted to the degree of renal impairment.

Acquired Lignac–De Toni–Fanconi syndrome, with polyuria, polydipsia, glycosuria, aminoaciduria, hyperphosphaturia, and hypercalciuria, was described in a number of patients treated with outdated tetracycline formulations. The degeneration products responsible for the toxic action are probably epitetracycline, anhydro-4-epitetracycline, and anhydrotetracycline (117), as similar renal damage was produced in rats with anhydro-4-epitetracycline (118).

A few observations of a nephrogenic diabetes insipidus-like syndrome with demeclocycline (demethylchlortetracycline hydrochloride) and resistance to exogenous vasopressin suggested impairment of renal concentrating function by tubular damage (47). Demeclocycline has therefore been proposed for the treatment of inappropriate secretion of antidiuretic hormone (119–123).

© 2006 Elsevier B.V. All rights reserved.

Acute interstitial nephritis leading to acute renal insufficiency has been reported after a single repeated dose of tetracycline (124).

Skin

Pronounced responsiveness of the skin and nails to light is a complication of systemic therapy with tetracyclines. In general, the pathogenesis of skin reactions promoted by sunlight exposure is mediated by phototoxicity, as suggested by the high occurrence rate (up to 9 out of 10 patients), depending on sun exposure and drug dosage. Experimental studies identified a wavelength close to 320 nm within the ultraviolet spectrum as the most potent area for the induction of phototoxic reactions (125). It has been described with various tetracyclines and presumably occurs with all of them. The skin changes resemble those of minor to severe sunburn, with erythema, edema, papules, blisters, and urticaria (126,127). In some circumstances they resemble cutaneous porphyria and have therefore been described as "porphyria-like cutaneous changes" (128).

Pigmentation due to tetracyclines occurs, but the exact frequency is not known. It has been observed with newer and lower-dose formulations as well as with older drugs, and presumably occurs with all tetracyclines. In contrast to phototoxic reactions, pigmentation can appear without light exposure and without inflammation. Pigment deposits were observed in light-exposed and non-exposed skin, the conjunctivae, the oral mucosa, the tongue, and internal organs, such as the thyroid and heart valve endothelium (77,78,129,130). The pigment is presumed to be a drug–melanin–calcium complex and depends on the chelating properties of the tetracycline molecule. Although pigmentation usually tends to persist after withdrawal, it does not provoke any symptoms or organ dysfunction, except for cosmetic problems. A number of cases occurred in patients treated for acne, and may possibly have been due to more common use of long-term treatments (131), although there is no evidence that the risk is increased in these patients.

Allergic skin and mucous membrane reactions occur with a very low incidence of 0.3%, which is about 10-fold lower than the incidence of such reactions in patients treated with other antibiotics (132). A generalized rash can occur during tetracycline treatment. Various forms have been described, including generalized urticaria, maculopapular rash, erythema exudativum, multiforme-like eruptions, and rare cases of Stevens–Johnson syndrome (133–136). Even acute generalized exanthematous pustulosis has been described (137). Fixed drug eruptions due to systemic administration are rare (138–140), as is a serum sickness-like syndrome (41,141). Allergic contact dermatitis induced by local application of a tetracycline is an exception (133,142–144).

Antimicrobial drugs, especially co-trimoxazole, ampicillin, and tetracyclines, can cause fixed drug eruptions (145).

Nails

Pronounced photosensitivity of the skin and nails is a complication of systemic therapy with tetracyclines. Onycholysis is associated with nail discoloration. Dystrophy is usually preceded by photosensitivity reactions of the skin (133). Depending on the degree and area of light exposure, onycholysis may also affect the toe nails (126). In contrast to idiopathic onycholysis, it not only affects women (146).

Musculoskeletal

Deposition of tetracyclines in bone tissue has been demonstrated in animals (147) and man (148). However, whereas osseous tissue in adult patients treated with tetracycline has shown deposits only in areas of repair or remodelling, children's bones contain extensive areas of deposition. Tetracycline deposition in bone has been reported to have an effect on longitudinal bone growth (149). In experimental tissue cultures, osteogenesis was impaired by tetracyclines in concentrations similar to serum concentrations that are associated with a therapeutic effect (that is 1 μg/ml) (150). The deposition of tetracyclines in human bone begins in utero as early as in the first trimester of pregnancy (148). With regular tissue turnover, the deposits disappear.

Infection risk

Monilial infections of the vulva and vagina in temporal association with tetracycline use can occur, even without other predisposing factors such as diabetes, pregnancy, immunodeficiency, and therapy with oral contraceptives and glucocorticoids. They also occur in patients treated with other antibiotics (151). *C. albicans* is not always the cause of vaginitis. The same is true for balanitis in men (152). If symptoms persist or change in patients with urethritis or adnexitis, this may be due to treatment failure, because of resistance of the causative pathogen (153).

Long-Term Effects

Drug resistance

Resistance to tetracyclines shows marked inter-regional variations and changes rapidly with time. The selection of resistant bacterial strains may be favored by widespread, often prophylactic, use in veterinary medicine and by long-term therapy for acne, periodontal disease, or symptomatic *Borrelia* infections. Many of the documented cases of resistance are of limited practical significance, since the tetracyclines are merely one of a number of therapeutic alternatives. The problem may be different when these drugs are the chemotherapeutic agents of first choice, that is in chronic *Borrelia* infections, especially arthritis due to Lyme disease and pulmonary or bubonic plague due to *Yersinia pestis* (154).

For infections with *Chlamydia* or *Mycoplasma*, effective alternative antibiotics are available. Increased rates of resistant strains of genital *Mycoplasma* may explain treatment failures (153,155).

A rather high resistance rate of 25–50% is reported for *Hemophilus* species (156), and this has to be taken into consideration if tetracyclines are given to patients with chronic pulmonary diseases or for the treatment of acute respiratory infections.

For infections with *Neisseria gonorrhoea*, tetracyclines are not indicated, owing to the higher prevalence of

© 2006 Elsevier B.V. All rights reserved.

resistance, especially among penicillinase-producing strains (157). For these patients, better alternatives are usually available.

Second-Generation Effects

Teratogenicity

Teratogenic effects of tetracyclines have been demonstrated (158–160), as evidenced by increased rates of intrauterine death, congenital anomalies in general (161), and congenital cataracts (162) in fetuses exposed to tetracyclines. However, it is often impossible to distinguish between the drug and an underlying unidentified viral infection as a cause of the observed abnormalities.

Of 38 151 pregnant women who had babies without any defects (controls), 214 (0.6%) had taken oral oxytetracycline; in contrast, of 22 865 pregnant women who had offspring with congenital abnormalities, 216 (0.9%) had taken oxytetracycline (OR = 1.7; 95% CI = 1.4, 2.0) (163). More women whose babies had congenital abnormalities had taken oxytetracycline in the second month of pregnancy:

- neural-tube defects (OR = 9.7; CI = 2.0, 47);
- cleft palate (OR = 17; CI = 3.5, 84);
- multiple congenital abnormalities (particularly the combination of neural-tube defects and cardiovascular malformations) (OR = 13; CI = 3.8, 44).

The authors mentioned that their previous study had not shown a teratogenic potential of doxycycline (164), but concluded, far more prudently, that all tetracyclines are contraindicated during pregnancy.

Fetotoxicity

Discoloration of the first teeth is particularly likely if a tetracycline is given to the mother after the third month of pregnancy (165). Tetracyclines pass across the placenta and reach therapeutic concentrations in the fetal circulation (166,167).

Tooth discoloration is due to deposition of tetracyclines in the form of calcium complexes in the mineralizing zones of the teeth, and seems to be pathogenically related to the pigmentation of other organs. It occurs when tetracyclines are used during tooth formation. Tetracyclines pass through the placenta and are also found in high concentrations in the breast milk (168). As mineralization of the deciduous teeth takes place from the fourth month of intrauterine life until 1 year after birth and continues for the permanent teeth up to the age of 7–8 years (166), pregnant women after the third month of pregnancy, nursing women, and children under the age of 8 years should not be treated with tetracyclines. Discoloration of the teeth after intrauterine exposure to tetracyclines was observed in up to 50% of children at risk and was especially high when tetracyclines were used during the last trimester (166). Besides its merely cosmetic aspect, tooth discoloration in children is associated with enamel defects and hypoplasia in severe cases (169). Adult-onset tooth discoloration coincident with minocycline administration occurred in four of 72 patients (170).

Susceptibility Factors

Age

Pregnant women after the third month of pregnancy, nursing women, and children under the age of 8 years should not be treated with tetracyclines, because of the risk of discoloration of the teeth. Besides its merely cosmetic aspect, tooth discoloration in children is associated with enamel defects and hypoplasia in severe cases (169).

Renal disease

Tetracyclines are removed by hemodialysis, but significantly less than creatinine or urea (100,116). Severe adverse effects of tetracyclines occur almost exclusively with doses over 1.0 g/day (101) or in the treatment of pyelonephritis with concomitant renal insufficiency.

Drug Administration

Drug administration route

The intravenous formulation of tetracycline was instilled intrapleurally to produce chemical pleurodesis, with good effect, from the 1970s to the 1990s. The adverse effect most commonly seen with tetracycline was chest pain, which was often severe (171,172). In a comprehensive review of intrapleural therapy published in 1994 (173) the incidence of chest pain was estimated at 14%, and fever occurred in 10% of patients. However, the intravenous form of tetracycline has been withdrawn by the manufacturer and so this agent is no longer available for pleurodesis.

Drug–Drug Interactions

Antacids

Co-administration of tetracyclines with antacids or other drugs containing divalent or trivalent cations, such as calcium, magnesium, or iron, is contraindicated. Tetracyclines form complexes with such cations, which are very poorly or not at all absorbed (75,174,175).

To avoid this interaction, delay of 2–3 hours between the ingestion of tetracycline and the cation is recommended (175). Similarly, reduced systemic availability results from simultaneous intake of abundant quantities of milk or milk products.

Antidiarrheal drugs

Antidiarrheal drugs, such as kaolin-pectin and bismuth products (176,177), impair the absorption of tetracyclines by chelation (see the interaction with antacids in this monograph).

Coumarin anticoagulants

Although antibiotics can inhibit the production of vitamin K in the gut by intestinal bacteria, they do not thereby interfere with the actions of coumarin anticoagulation, since vitamin K that is produced by intestinal bacteria is of less importance than vitamin K that is obtained from dietary sources (178). Nevertheless, there have been

© 2006 Elsevier B.V. All rights reserved.

sporadic reports that tetracyclines can enhance the effects of coumarin anticoagulants (179–182). The mechanism is not known, but evidence that tetracyclines can reduce the activity of prothrombin (183) suggests an additive pharmacodynamic interaction.

Diuretics

The combination of tetracyclines with diuretics is particularly detrimental to renal function (184). Tetracyclines accumulate in patients with pre-existing renal insufficiency (for example elderly people, even if the serum creatinine is in the reference range) and can cause nausea and vomiting, which causes dehydration and worsens renal function. This is exacerbated by the effects of diuretics.

Iron

See antacids above (174,175).

Methoxyflurane

In patients taking oral or parenteral tetracyclines who undergo methoxyflurane anesthesia, renal insufficiency and oxalate crystal formation in renal tissue was attributed to an interaction between these drugs (185–187). Tetracyclines are therefore not recommended preoperatively.

Risperidone and/or sertraline

An interaction of tetracycline with risperidone and/or sertraline has been described (188).

- A 15-year-old youth with Asperger's syndrome, Tourette's syndrome, and obsessive-compulsive disorder was stabilized on risperidone 1.5 mg bd and sertraline 100 mg od and had marked improvement in his social skills and tics, until he was given tetracycline 250 mg bd for acne. Within 2 weeks his tics were acutely exacerbated with pronounced neck jerking and guttural sounds. The sertraline was increased to 150 mg/day, but the tics did not resolve. The tetracycline was withdrawn after 1 month, and the tics improved within a few weeks.

The authors reviewed the major metabolic pathways of the three drugs used in this case. Tetracycline may have accelerated the hepatic metabolism of risperidone, but tetracycline has not been shown to induce CYP2D6, the major hepatic enzyme involved in the metabolism of risperidone. The authors claimed that it was more likely that tetracycline binds to risperidone or its active metabolite, making them inactive. They supported this suggestion by citing evidence that clozapine, which has similar pharmacology to risperidone, interacts with tetracycline in vitro (189). They also commented on the possibility that the effect could have come from increased concentrations of sertraline, which can increase tics (190). Tetracycline may inhibit the hepatic enzymes that metabolize sertraline; however, adequate evidence is lacking. Another possibility is a protein binding interaction, because all three drugs are highly protein bound. However, the observation that the tics were not worsened by an increase in sertraline dosage makes this possibility less likely. The mere fact that the withdrawal of tetracycline resulted in an improvement in the tics supports an interaction between tetracycline and risperidone.

Tetryzoline

General Information

Tetryzoline, an alpha-adrenoceptor agonist with vasoconstrictor and decongestant properties, is widely available without prescription for symptomatic relief of "pink eye" and is found in various products in a concentration of 0.05%.

Susceptibility Factors

Age

Tetryzoline eye-drops are considered to be safe when used appropriately. However, relatively small amounts can produce profound central nervous depression and can lead to serious toxicity, especially in children under 2 years of age. A Poison Center reported 64 cases of tetryzoline poisoning over a period of 3 years; ingestions accounted for 59 cases, but three were attributable to administration into the eye, ear, or nose (1).

Tezosentan

See also Endothelin receptor antagonists

General Information

Tezosentan is a dual endothelin-A and endothelin-B receptor antagonist. Its common adverse effects include headaches, nausea, and hypotension compared with placebo (1).

Organs and Systems

Nervous system

Tezosentan has been studied in single intravenous doses of 5, 20, 50, 100, 200, 400, and 600 mg for 1 hour in sequential groups of six men in a randomized, placebo-controlled, double-blind design (2). Headache was the most frequently reported adverse event and it was more common than with placebo at doses of 100 mg and over. There were no clinically important changes in vital signs, electrocardiography, or clinical laboratory tests. The volume of distribution at steady state, about 16 liters, and the clearance, 30 l/hour, were independent of dose. Endothelin-1 concentrations increased dose- and concentration-dependently and returned slowly to baseline after the end of the infusion.

During chronic double-blind, placebo-controlled infusion in healthy men, tezosentan 100 mg/hour for 6 hours in six subjects (total dose 600 mg) and 5 mg/hour for 72 hours in eight subjects (total dose 360 mg), headache was the most common adverse event (75–100% with tezosentan and 50% with placebo) (3).

Thalidomide

General Information

Thalidomide was synthesized in 1953 by Wilhelm Kunz and Herbert Keller, working for Chemie Grünenthal. Kunz was preparing a series of peptides for antibiotic synthesis and in doing so isolated a non-peptide by-product, which Keller recognized as an analogue of the hypnotic glutethimide. They prepared a series of further analogues, one of which was thalidomide. It was introduced as a hypnotic in the late 1950s, as a supposedly safe sedative for children and pregnant women. Besides West Germany, Great Britain was the only country in which formulations containing thalidomide were sold on a large scale during the period 1959–60 inclusive. Following the discovery of its major teratogenic effects, thalidomide was withdrawn from the market in the early 1960s.

Modern uses

Since its withdrawal, thalidomide has been found to be effective in the treatment of erythema nodosum leprosum, and in 1997 it was marketed in the USA for this indication. The mechanism of action of thalidomide is still unclear (1,2), but it has many anti-inflammatory and immunomodulatory actions in vitro and in vivo (3,4).

In dermatological practice, thalidomide has also been used to treat patients with various diseases that are unresponsive to conventional therapy. Among these are aphthous stomatitis, Behçet's disease, discoid and systemic lupus erythematosus, uremic pruritus, actinic prurigo, prurigo nodularis, sarcoidosis, adult Langerhans cell histiocytosis, erosive lichen planus, and pyoderma gangrenosum (5). There has also been research on a possible antineoplastic action of thalidomide (6), which may be produced via antiangiogenic effects or direct effects on tumor cells, such as induction of apoptosis or G1 arrest of the cell cycle, inhibition of growth factor

© 2006 Elsevier B.V. All rights reserved.

production, regulation of interactions between tumor and stromal cells, modulation of tumor immunity, modulation of adhesion molecules, and inhibition of cyclooxygenase type 2 (7,8). The malignancies in which thalidomide has been used include multiple myeloma, glioblastoma multiforme, renal cell carcinoma, and malignant melanoma.

The use of thalidomide in dermatology is based on its immunomodulatory properties. In vitro it inhibits leukocyte chemotaxis and reduces phagocytosis by monocytes and polymorphonuclear leukocytes, without signs of cytotoxicity (9,10). The production of TNF-alpha in human monocytes is selectively inhibited by enhanced degradation of TNF-alpha messenger RNA (11). In phytohemagglutinin-activated cultures of peripheral blood mononuclear cells the production of interleukin-4 and interleukin-5 (cytokines for type 2 T helper cells) is enhanced, while interferon-gamma production is inhibited by thalidomide (12). Its antiangiogenic activity is probably the cause of its teratogenic effects (13). There is evidence that angiogenesis is increased in multiple myeloma and that thalidomide is active in refractory myeloma (14). In organ bath experiments thalidomide antagonizes the actions of histamine, 5-hydroxytryptamine, acetylcholine, and prostaglandins; neither the mechanisms nor the clinical relevance of these effects is known (15).

Stereopharmacology of thalidomide

Thalidomide is given in a racemic mixture of its two enantiomers, *R*-thalidomide and *S*-thalidomide; the former is responsible for its hypnotic effects and the latter for its immunomodulatory and teratogenic effects (16).

Formulations

The full chemical name of thalidomide is α-(*N*-phthalimido)glutarimide or *N*-(2,6-dioxopiperid-3-yl)phthalimide. It has been marketed under a wide variety of brand names, including Contergan, Distaval, Glutanon, Hippuzon, Isomin, Kedavon, Kevadon, Neurosedine, Neurosedyn, Proban M, Sedalis, Softenon, Telagan, and Telargon. It has also been used in combination with various other drugs, for example in the proprietary combinations Tensival, Valgraine (with ergotamine tartrate), and Asmaval (with ephedrine).

The development of an intravenous formulation of racthalidomide is problematic, because of its poor solubility and rapid degradation in aqueous media (17). However, a chemically stable solution of the separate enantiomers of thalidomide for intravenous infusion has been described.

Pharmacokinetics

Thalidomide is slowly absorbed after oral administration; after an oral dose of 100 mg the t_{max} is 2–4 hours and the C_{max} is around 1 μg/ml (16). At larger doses its poor solubility in intestinal fluids reduces its rate of absorption even further. Co-administration with a high-fat meal causes small (<10%) changes in the AUC and C_{max} but prolongs the t_{max} markedly, to about 6 hours (18).

Thalidomide is slowly and variably absorbed after rectal administration (19). The mean availability of several formulations relative to oral administration was less than 40%.

The two enantiomers of thalidomide, *R* and *S*, undergo fast chiral interconversion at physiological pH (16). The apparent clearance rates in adults are 10 l/hour for *R*-thalidomide and 21 l/hour for *S*-thalidomide; however, each has a half-life of about 5 hours, implying different volumes of distribution (70 liters for the *R*-enantiomer and 150 liters for the *S*-enantiomer). Because of rapid interconversion, administration of *R*-thalidomide alone as a hypnotic would not avoid the teratogenic affects of *S*-thalidomide. Thalidomide does not induce its own metabolism. Its plasma protein binding is low.

The clearance of thalidomide is not altered in hepatic disease or in renal insufficiency, but hemodialysis increases it two-fold (20). Very small amounts of hydroxylated metabolites are detected in the blood and urine.

General adverse effects

Aside from teratogenicity, the main adverse effects of thalidomide include somnolence, dizziness, fatigue, tremor, rash, constipation, and edema. Although these adverse effects are generally mild and reversible, more severe adverse effects, such as peripheral neuropathy, deep vein thrombosis, and neutropenia, have occasionally been reported.

Organs and Systems

Cardiovascular

Bradycardia, hypotension, orthostatic hypotension, and dizziness have been reported with thalidomide; these effects may have been due to its central sedative effects or to vasovagal activation (21).

Of 96 patients taking thalidomide 52 had a heart rate below 60/minute at some time during follow-up and 10 developed symptomatic bradycardia; the symptoms abated with reduction of the dose in most cases (22).

Diabetic microvascular disease has been attributed to thalidomide (23).

- A 57-year-old man with type I diabetes mellitus started taking thalidomide after failed stem cell transplantation for multiple myeloma and after 10 months developed a sensory neuropathy with loss of pain sensation and ischemic changes in the legs.

The authors suggested that the antiangiogenic properties of thalidomide were implicated in the pathogenesis of diabetic foot disease in this patient.

Thromboembolic disease

DoTS classification (BMJ 2003;327:1222–5)

Adverse effect: Deep venous thrombosis with thalidomide
Dose-relation: collateral effect
Time-course: intermediate
Susceptibility factors: genetic; diseases (multiple myeloma, lupus erythematosus); drugs (chemotherapy, especially doxorubicin; darbepoetin)

Deep venous thrombosis is a common complication of thalidomide, especially when it is used in combination

© 2006 Elsevier B.V. All rights reserved.

with chemotherapy and in patients with multiple myeloma (24–26).

Arterial thrombosis has also been reported. Of 23 patients with myeloma who took thalidomide 150 mg/day for 142 patient-months there were seven cases of thrombosis, five venous and two arterial; in a historical control group of 18 similar patients who did not take thalidomide there was only one case over 289 months (26,27).

Incidence

Of 50 patients with multiple myeloma, 14 developed a deep venous thrombosis after taking thalidomide 400 mg/day, compared with two of 50 patients who did not take it (24) All the episodes occurred during the first 3 cycles of therapy. One patient taking thalidomide had a pulmonary embolus. Most of the patients continued to take thalidomide with the addition of low molecular weight heparin followed by warfarin and there was no progression of deep venous thrombosis.

Of 23 men with advanced androgen-dependent prostatic cancer who received docetaxel alone, none developed a venous thrombosis, compared with nine of 47 men who received docetaxel + thalidomide (28).

Susceptibility factors

The risk of thrombosis from thalidomide may be increased in certain conditions, such as malignancies, cicatricial pemphigoid (29), and systemic lupus erythematosus. Four episodes of thrombosis (two arterial, two venous) occurred in three patients with systemic lupus erythematosus and one with severe atopic dermatitis within 10 weeks of starting treatment with thalidomide 50–100 mg/day (30). All four had at least one risk factor for thrombosis, but none had thrombosis before or after treatment with thalidomide.

The incidence of deep venous thrombosis is increased by the co-administration of doxorubicin, as suggested by a study in 232 patients with multiple myeloma who received a combination of thalidomide and chemotherapy in two protocols that differed only by the inclusion of doxorubicin in one: DT-PACE (dexamethasone + thalidomide + cisplatin + doxorubicin + cyclophosphamide + etoposide) and DCEP-T (dexamethasone + cyclophosphamide + etoposide + cisplatin + thalidomide) (25). There was an increased risk of deep venous thrombosis in those who received DT-PACE but not in those who received DCEP-T. Multivariate analysis confirmed that those who received thalidomide + doxorubicin had an increased risk of deep venous thrombosis. In two separate trials in patients taking thalidomide for multiple myeloma, deep venous thrombosis occurred in four of 15 patients who received concomitant treatment with doxorubicin + dexamethasone compared with three of 45 who received dexamethasone only (26).

Of 535 patients who received thalidomide with or without cytostatic chemotherapy, 82 developed a deep venous thrombosis (31). Multivariate analysis showed that the combination of thalidomide with chemotherapy that contained doxorubicin was associated with the highest odds ratio (OR = 4.3). Newly diagnosed disease (OR = 2.5) and chromosome 11 abnormalities (OR = 1.8) were also independent predictors. After a median period of 2.9 years, survival was worse in those with chromosome 13 abnormalities, aged over 60 years, with a raised lactate dehydrogenase activity, and a raised serum creatinine concentration.

Three episodes of thrombosis occurred in patients who had taken thalidomide (25–100 mg/day) for up to 2 years (32). However, all had other risk factors (heterozygous protein C resistance in one and surgical intervention or trauma in the others), so a causal role of thalidomide was debatable.

In a trial of thalidomide in Behçet's disease there was superficial thrombophlebitis in 10 of 32 patients taking thalidomide 100 mg/day, two of 31 patients taking thalidomide 300 mg/day, and three of 32 patients taking placebo (33). The fact that this apparent increase in the incidence of thrombophlebitis in those taking 100 mg/day was not reproduced at the higher dosage suggests that the effect occurred by chance.

Management

Of 256 patients with myeloma randomized to thalidomide or not, 221 received no prophylactic anticoagulation and 35 received low-dose warfarin 1 mg/day (31). The incidence of deep venous thrombosis was higher in those who took thalidomide (hazard ratio 4.5). Warfarin did not reduce the risk, and prophylactic subcutaneous enoxaparin 40 mg/day was therefore introduced in 68 patients of a subsequent group of 130 patients who received thalidomide. This intervention eliminated the difference in the incidence of deep venous thrombosis between those who took thalidomide and those who did not.

Pulmonary hypertension

Pulmonary hypertension has been reported in one patient taking thalidomide (34).

- A 51-year-old man with multiple myeloma and a history of cardiovascular disease took thalidomide 100 mg/day and developed reversible pulmonary hypertension (pulmonary artery pressure 70 mmHg) with normal mitral valve and left ventricular function. After withdrawal of thalidomide for 2 months the pulmonary artery pressure fell to 47 mmHg. Rechallenge with a lower dose of thalidomide was again associated with a rise in pulmonary artery pressure.

Respiratory

In some early cases an increased incidence of asthmatic attacks was reported by asthmatic patients (35).

- A 65-year-old man with IgG multiple myeloma was given thalidomide and after 37 days developed acute cough, sweating, general malaise, and dyspnea at rest (36). There was an interstitial and alveolar pattern on the right side of a chest X-ray and arterial blood gases showed partial respiratory insufficiency (pH 7.40, $PaCO_2$ 40 mmHg, PaO_2 47 mmHg). Microbiology was negative (sputum and blood cultures and urinary antigen detection for *Streptococcus pneumoniae* and *Legionella pneumophila*). He recovered when thalidomide was withdrawn and oxygen and intravenous

© 2006 Elsevier B.V. All rights reserved.

glucocorticoids were given. A chest X-ray and arterial blood gases were normal 4 days later.

Nervous system

Somnolence is very common in patients taking thalidomide, and headache, dizziness, paresthesia, and peripheral neuropathy are common. Stupor, coma, and seizures have also been reported (21). The sedative effect possibly occurs through activation of the sleep center in the brainstem. However, even when it is taken in large doses, thalidomide is not associated with lack of coordination or respiratory depression (3).

In patients with leprosy, HIV infection, and multiple myeloma, the incidences of somnolence, fatigue, and weakness were 36–43%, 48%, and 6–22% respectively (21). Administration of thalidomide at bedtime minimizes appreciation of the drowsiness that it produces, and daytime drowsiness usually abates over several weeks.

Stupor has been reported in six patients with advanced refractory malignancies, complicated by severe weakness, anemia, nausea, vomiting, and dehydration, or tumor lysis syndrome with renal insufficiency; three developed fever, neutropenia, sepsis, and/or pneumonia, but the contribution of thalidomide was uncertain (21).

Seizures, including generalized tonic-clonic seizures, have been reported in patients taking thalidomide, 18 during the first 18 months of its availability in the USA; there was a past history of seizures or pre-existing nervous system disease in 11 (21).

Polyneuropathy

DoTS classification (BMJ 2003;327:1222–5)
Adverse effect: Polyneuropathy with thalidomide
Dose-relation: Collateral reaction
Time-course: Long-term
Susceptibility factors: sex (women more susceptible); age (elderly people more susceptible)

A chronic polyneuropathy was described soon after thalidomide was introduced. It is predominantly sensory, affecting distal nerves. Anatomically the lesion is a degeneration of the axis cylinder (37).

Mechanism

In six patients with multiple myeloma who developed a thalidomide-induced sensory polyneuropathy, spinal cord MRI showed high-signal intensity in the posterior columns in only one patient, with abnormal central conduction time at somatosensory-evoked potentials (38). These results suggest that thalidomide can induce either an axonal length-dependent neuropathy or, less often, a ganglionopathy.

Clinical features

The common symptoms are tingling of the hands, gradually increasing sensory disturbances, and finally motor disturbances, usually of the hands, although only after thalidomide has been taken over a lengthy period. A positive Babinsky reflex and disturbed vibration sense have also been reported (39). Unless the drug is discontinued promptly at the start of symptoms the polyneuropathy can be irreversible (40,41).

In 35 patients with polyneuropathy, mostly of the sensory type, which occurred after about 9 months of ingestion of thalidomide 100–200 mg/day, the principal symptoms were paresthesia and distal sensory disturbances in the feet. Withdrawal of the drug led to partial improvement, but complete resolution was not observed (42–45).

In 114 patients with thalidomide polyneuropathy other features included toxic psychosis, amnesic and aphasic symptoms, cerebellar syndromes, and autonomic dysfunction. An attempt was made to relate thalidomide toxicity to daily or total dose and duration of therapy but no association was found. The severity of the polyneuropathy was related to the age of the patient (46).

In 22 patients with thalidomide polyneuropathy, who were followed for 4–6 years after withdrawal, the symptoms and signs remained unchanged in 50% and improved in 25%; the rest recovered. Improvement was usually slow, and in some patients did not begin for 3 years (47).

- A 68-year-old woman took 20 tablets of thalidomide per month for 6 months and developed a severe peripheral neuropathy, which persisted for 3 years. Electromyography showed irreversible damage to several nerve trunks (48).

The distinguishing features of thalidomide polyneuropathy and of leprous polyneuropathy have been described. In thalidomide polyneuropathy the longest nerve fibers are affected first and the condition progressively involves fibers of decreasing length. Thus, the upper border of sensory loss in the limbs is roughly the same distance from the dorsal root ganglion cells; this can be estimated using a tape measure. Loss of tendon reflexes is also characteristic. In leprous polyneuropathy, the cells first affected are those in the coolest tissues, as *Mycobacterium leprae* is temperature-sensitive. This leads to the early involvement of the lobes of the ears, the nose, and the digits. Typically, deep reflexes are preserved (49).

Restlessness, agitation, queer sensations, difficulty in memorizing (40), and vertigo and convulsions (50) have also been reported. In nearly all cases there was a concomitant polyneuropathy. Muscle weakness or cramps, mild ataxia, carpal tunnel syndrome, and signs of pyramidal tract involvement have also been described (51).

Deterioration of the sensory nerve action potentials more than 40% from baseline may predict the development of neuropathy (51).

After withdrawal of thalidomide, symptoms are usually slow to recover, if they eventually do (3). The first symptoms of peripheral neuropathy can develop even after the withdrawal of thalidomide (33).

Incidence and susceptibility factors

The incidence of peripheral neuropathy, with symmetrical painful paresthesia of the hands and feet often accompanied by sensory loss in the legs, seems to vary with the condition that is being treated, and ranges from under 1% in patients with leprosy to over 70% in patients with prurigo nodularis (41,52). The symptoms do not correlate with either the duration of treatment or the dose. Women and elderly people seem to have an increased risk of neuropathy (53).

© 2006 Elsevier B.V. All rights reserved.

Incidences of 21–100% have been reported after treatment for up to 5 years (38,54–57).

Some have found no correlation between the occurrence of neuropathy and the cumulative dose (56); while others have found correlations with total dose (41,57) or daily dose. In 135 patients treated with thalidomide for various skin diseases, there were no cases in those who took daily doses of 25 mg/day or less, but the relative risk of neuropathy was 8.2 at a daily dose of 50–75 mg/day, and 20 at a daily dose of over 75 mg/day (54). It has been suggested that the risk increases at total doses over 20 g (58). Below this dose the risk of neuropathy is about 10% (57).

The incidence and susceptibility factors for thalidomide neuropathy have been studied in a prospective cohort study in 135 patients (54). Structured questionnaires were administered, standardized neurological and electrophysiological examinations were performed, and neuropathic signs and symptoms were classified by investigators who did not know the dose of thalidomide or the treatment duration. Definite thalidomide neuropathy occurred in 25% of patients, and another 30% developed atypical neuropathy, discordant clinical and electrophysiological features, or typical clinical signs without electrophysiological investigation. The only significant susceptibility factor was the daily dose: neuropathy did not develop at dosages below 25 mg/day.

Diagnosis and monitoring

Changes in nerve conductivity are frequent and predictable in thalidomide-induced neuropathy. Nerve conduction studies are required before and during therapy, irrespective of dose (55).

In 135 patients treated with thalidomide for various skin diseases who were prospectively monitored for 2 years there was clinical and electrophysiological evidence of a thalidomide-induced neuropathy in 25%; however, the neuropathy was subclinical in nearly a quarter of patients and when all potential cases were included, the rate was 56% (54). The incidence was maximal during the first year of treatment (20%).

Peripheral nerve function should be monitored by reviewing symptoms, regular neurological examination, and periodic screening of sensory nerve electrophysiology (58). If there is evidence of neuropathy, withdrawal of thalidomide should be considered; the decision should be made on an individual basis and should take into account the seriousness and severity of the underlying condition and the severity of the neuropathy.

Psychological, psychiatric

Mood changes are common with thalidomide (3). Three cases of paranoid reactions have been reported in patients with multiple myeloma taking thalidomide; however, causality was not proved (21).

- Reversible dementia occurred in a patient with multiple myeloma taking thalidomide 200 mg/day plus dexamethasone (59). Memory deficit and mania occurred about 2 months after the start of therapy and did not resolve on withdrawal of dexamethasone and administration of risperidone. The memory loss worsened and proceeded to disorientation, apraxia, and tremor 4 months after the start of therapy. The dementia resolved completely within 48 hours after withdrawal of thalidomide.

Endocrine

Hypothyroidism has occasionally been reported in patients taking thalidomide (60,61).

- A 44-year-old man with an initial TSH concentration within the reference range took thalidomide 400 mg/day for multiple myeloma and within 4 weeks developed cold intolerance, fatigue, depression, dizziness, and bradycardia, and had a markedly raised TSH (62). He was given levothyroxine and the dose of thalidomide was reduced to 200 mg/day, after which he became euthyroid.

This case prompted further investigation of thyroid function in patients with multiple myeloma. TSH concentrations were measured in 174 patients who had been randomly assigned to chemotherapy plus thalidomide 400 mg/day ($n = 92$) or chemotherapy alone ($n = 82$). After 3–4 months 18 of the patients taking thalidomide had a serum TSH concentration over 5 IU/ml, including six with a concentration over 10 IU/ml (range 12–114 IU/ml), while seven receiving chemotherapy alone had a serum TSH concentration over 5 IU/ml and none had a concentration over 10 IU/ml. In 169 patients with relapsing multiple myeloma who took thalidomide 200–800 mg/day, of those with a serum TSH concentration in the reference range to begin with, 61 had increases after 2–6 months.

Metabolism

In a placebo-controlled study in six patients with type 2 diabetes mellitus thalidomide 150 mg/day for 3 weeks reduced insulin-stimulated glucose uptake by 31% and glycogen synthesis by 48% (63). However, it had no effect on rates of glycolysis, carbohydrate oxidation, non-oxidative glycolysis, lipolysis, free fatty acid oxidation, or re-esterification. The authors concluded that thalidomide increases insulin resistance in obese patients with type 2 diabetes.

This effect can have clinical consequences. For example, in patients with prostate cancer, reducing the dose of thalidomide improved hyperglycemia, suggesting that thalidomide may have exacerbated it in the first place (64).

- A 70-year-old man with no family history of diabetes or known diabetes took thalidomide 400 mg/day for refractory multiple myeloma. He developed hyperglycemia, which had to be treated with insulin and later with glipizide GITS 5 mg/day and which responded despite continuation of thalidomide (65).

Weight gain and edema have been reported in patients taking thalidomide (3). In 13 patients with minimally symptomatic HIV disease thalidomide for 14 days caused an increase in weight of 3.6% (66).

Electrolyte balance

Severe hyperkalemia occurred in six of eight patients with multiple myeloma and moderate to severe renal insufficiency who took thalidomide 100–200 mg/day for up to

© 2006 Elsevier B.V. All rights reserved.

12 days; three died and one recovered after withdrawal of thalidomide (67). Hyperkalemia occurred despite the fact that most of the patients also took dexamethasone.

Fluid balance

Thalidomide can cause painful edema of the legs, which is transitory and disappears as treatment continues (68). Peripheral edema was reported in 4.2% of patients with erythema nodosum leprosum, in patients with HIV infection (3.1% of those taking 100 mg/day and 8.3% of those taking 200 mg/day), and in up to 22% of patients with refractory multiple myeloma (21).

Hematologic

Thalidomide can cause leukopenia. In controlled trials in patients with HIV infection the incidences of neutropenia were 9%, 17%, and 25% in those who took placebo, thalidomide 100 mg/day, and thalidomide 200 mg/day respectively (21).

Neutropenia occurred in 14 of 80 patients treated with thalidomide for refractory chronic graft-versus-host disease (69). The median thalidomide dose at which neutropenia developed was 200 mg qds. Erythrocyte and platelet counts were not affected. After withdrawal of thalidomide the neutropenia resolved within a month (except in three patients, who died with refractory graft-versus-host disease). Six patients were rechallenged with thalidomide and again became neutropenic.

Of 44 patients who took thalidomide for refractory multiple myeloma, 10 developed grade 3 or 4 neutropenia, usually in the first or second week of treatment (70). There was concomitant progression of thrombocytopenia in five cases and bone marrow hypoplasia without a significant increase in myeloma cell numbers in five. Neutropenia was more common in patients with low neutrophil and platelet counts, anemia, or a high percentage of plasma cells in the bone marrow before thalidomide treatment.

Of 50 Taiwanese patients with relapsed and/or refractory multiple myeloma who took thalidomide on a dose-escalation schedule, 100–800 mg/day, 18 of 22 responders had reduced leukocyte counts before there was significant reduction in M proteins, compared with only four of the 28 non-responders (71). The median time from the start of thalidomide treatment to the minimum leukocyte count was 28 (range 7–150) days, with a mean cell count of 2.19 (range 0.96–3.35) $\times 10^9$/l. The leukopenia was generally transient, with rapid recovery despite continuation of thalidomide.

Myeloproliferative reactions have been reported in three patients with myelofibrosis taking thalidomide 200 mg/day (72). Thalidomide-associated leukemic transformation has also been reported in five patients with multiple myeloma (73).

Mouth and teeth

Xerostomia is common in patients taking thalidomide (2,3).

- An oral lichenoid eruption occurred in a 33-year-old woman after she had taken thalidomide 200 mg/day for a few days for graft-versus-host disease after bone marrow transplantation for chronic myeloid leukemia (74).

Gastrointestinal

Constipation is common in patients taking thalidomide (2,3).

Liver

Severe hepatotoxicity has been attributed to thalidomide in multiple myeloma (75) and hepatic failure can occur (21,76,77).

Four post-marketing reports of hepatic failure have been reported; one patient with multiple myeloma developed severe jaundice, hepatic failure, and coma, and died 1 month after the start of thalidomide therapy; three other patients had pre-existing liver disease, and hepatic failure and death were probably not drug-related (21).

- A 50-year-old man with history of chronic hepatitis B had transient rises in serum transaminases after two successive episodes of autologous stem cell transplantation, with spontaneous resolution; at that time PCR for hepatitis B virus was negative (76). Later he was given thalidomide and after 5 months suddenly experienced dizziness and jaundice. The concentration of hepatitis B virus DNA was 1641 pg/ml and serological tests for other viruses were negative. Despite conventional supportive care, he died of septicemic shock caused by *Klebsiella* pneumonia. Other hepatotoxic agents were excluded.
- A 58-year-old woman, with a history of chronic stable hepatitis C infection, was given thalidomide 200 mg/day for end-stage plasma cell leukemia (77). Within 1 week she developed jaundice, light-coloured stools, and marked rises in serum transaminases, which had been stable before the introduction of thalidomide. The jaundice resolved promptly on withdrawal of all drugs; other drugs besides thalidomide that might have been implicated were reintroduced without ill effects.

Skin

Rash due to thalidomide is commonly described as erythematous, macular, and pruritic; it occurs over the back, trunk, and limbs and most commonly occurs 10–14 days after the start of treatment (21). In trials of thalidomide in patients with erythema nodosum leprosum the incidence of rash was 25%, in patients with HIV infection it was 42%, and in patients with myeloma it was up to 26%.

Other skin reactions to thalidomide include pustuloderma, exfoliative reactions, and hypersensitivity reactions, including toxic epidermal necrolysis (3). The frequency of erythema nodosum was increased compared with placebo during the first 8 weeks of thalidomide therapy for Behçet's syndrome, but not thereafter (33).

Redness of the palms was observed in four of 13 patients treated with thalidomide (43). Erythroderma and peripheral eosinophilia occurred in two patients with chronic renal insufficiency who were taking thalidomide for prurigo nodularis (78).

© 2006 Elsevier B.V. All rights reserved.

Three of forty patients taking thalidomide for leprosy developed dermatitis herpetiformis, which was thought to have been caused by the treatment (79).

In 87 patients with multiple myeloma in an open trial given thalidomide alone ($n = 50$) or thalidomide + dexamethasone ($n = 37$), there were minor to moderate skin eruptions in 23 patients taking thalidomide alone and in 16 of those taking thalidomide + dexamethasone (80). These included morbilliform, seborrheic, maculopapular, and non-specific dermatitis. Three patients taking thalidomide + dexamethasone had severe skin reactions (exfoliative erythroderma, erythema multiforme, and toxic epidermal necrolysis) that required hospitalization and withdrawal of thalidomide.

Worsening of psoriasis has been reported in a 46-year-old woman taking thalidomide for Behçet's disease (81).

Nails

Brittle nails occurred in three patients who took thalidomide (43), and in another case brittleness was accompanied by marked ridging of the nails (82). This last patient also had amenorrhea. She was taking 50–100 mg nightly at the time.

Sexual function

Erectile dysfunction and loss of libido have occasionally been attributed to thalidomide (83).

Reproductive system

Amenorrhea

In women taking thalidomide there have been occasional reports of amenorrhea (84–89).

Four of 13 women with cutaneous lupus erythematosus (either discoid or associated with systemic disease) treated with thalidomide 100–300 mg/day had amenorrhea during the first 4–5 months of treatment (85). They had high serum concentrations of pituitary gonadotrophins, normal prolactin concentrations, and low estradiol concentrations; antiovary antibodies were not detected. In one woman an ovarian biopsy showed severe ovarian atrophy and absence of ova or follicles. In all four women menstruation resumed 2–3 months after withdrawal of thalidomide. In two women thalidomide was reintroduced: one developed oligomenorrhea again after 5 months, with high concentrations of pituitary gonadotrophins; withdrawal of thalidomide resulted in remission. Other cases of ovarian failure in women taking thalidomide for aphthous ulcers have been described (87).

Among 21 women who took thalidomide, secondary amenorrhea occurred in four who took it for refractory cutaneous lupus erythematosus and in one who took it for aphthous ulcers (84). Menstruation resumed 2–3 months after withdrawal of thalidomide, and in one case amenorrhea recurred after reintroduction, in association with raised serum concentrations of pituitary gonadotrophins.

Four of thirteen women who took thalidomide for cutaneous lupus erythematosus developed amenorrhea (85). In one case a biopsy showed severe ovarian atrophy and absence of ova or follicles. In another case rechallenge with thalidomide 50 mg/day resulted in amenorrhea, which resolved on withdrawal.

Two young women with discoid lupus erythematosus developed amenorrhea after taking thalidomide 100–150 mg/day (86). In one patient the menstrual cycle returned to normal within 5 months after withdrawal of thalidomide; in another the dosage was reduced to 50 mg on alternate days but menstruation had not returned 6 months later.

Of seven women who took thalidomide for aphthous ulcers three developed amenorrhea (87).

- A 28-year-old woman took thalidomide 100 mg/day for Behçet's disease and after 3 months developed amenorrhea (89). She took an oral contraceptive for 8 months, but then had a deep vein thrombosis in association with a factor V Leiden mutation; the oral contraceptive was withdrawn and she was given warfarin. She remained amenorrheic. She had a raised serum concentration of follicle-stimulating hormone but all other laboratory tests were normal. Ultrasonography showed a normal uterus and an endometrial lining of 4 mm. The amenorrhea was attributed to thalidomide, which she decided to continue taking; she remained amenorrheic.

Thalidomide may destroy follicular cells by an action at follicle stimulating hormone receptors, either by directly inhibiting the binding of follicle stimulating hormone or by a post-receptor mechanism (87).

Gynecomastia

In men taking thalidomide there have been occasional reports of gynecomastia.

- A 69-year-old man developed right-sided gynecomastia after taking thalidomide 200 mg/day for 2 years (90). Mammography showed diffuse dense glandular right breast tissue in the retroareolar area with no discrete masses or microcalcification. He had taken no other drugs and had serum concentrations of prolactin, estradiol, and testosterone in the reference ranges. Thalidomide was withdrawn but the gynecomastia did not change during the following 3 months.
- A 55-year-old man developed unlilateral gynecomastia after taking thalidomide 200 mg/day for 2 weeks (91). Mammography and ultrasonography showed an enlarged but otherwise normal mammary gland. He continued to take thalidomide for 4 months and the gynecomastia persisted.

Immunologic

Leukocytoclastic vasculitis has been reported in one of 260 patients (92).

Of 54 patients randomized to either placebo ($n = 26$) or thalidomide 200 mg/day ($n = 28$) starting 80 days after allogeneic bone marrow transplantation chronic graft-versus-host disease was significantly more common in those who took thalidomide; there was also a significant overall survival advantage in those who took placebo (93). These results suggest that while thalidomide is effective in treating chronic graft-versus-host disease, its use to prevent chronic graft-versus-host disease results in a paradoxical outcome.

Tumor lysis syndrome has been attributed to thalidomide in a 59-year-old woman with myeloma (94).

© 2006 Elsevier B.V. All rights reserved.

Infection risk

Disseminated infection with *Herpes simplex* virus and *Varicella zoster* virus occurred in a patient taking thalidomide for relapsed multiple myeloma (95).

Body temperature

Febrile reactions are common in patients taking thalidomide. In one study of 56 patients with HIV infection who took thalidomide for 14–21 days, 24 discontinued therapy owing to adverse reactions. Cutaneous and/or febrile reactions, which occurred in 20 patients, were the most frequent adverse effects (96).

Death

A randomized, placebo-controlled study of thalidomide in toxic epidermal necrolysis, undertaken because of the potent in vitro TNF-alpha-inhibitory properties of thalidomide, was stopped because of excess mortality in the thalidomide group (10 of 12 patients died compared with three of 10 in the placebo group) (97). There was an insignificant increase in plasma TNF-alpha in the thalidomide-treated patients on day 2.

Second-Generation Effects

Teratogenicity

Thalidomide should not be used during pregnancy because of its teratogenic effects (61,98–109). In 46 examined cases of malformations, 41 of the mothers had taken thalidomide, while in the other five cases the possibility could not be ruled out, while among 300 normal controls none of the mothers had taken thalidomide (110).

History

In the late 1950s and early 1960s thalidomide was used as a sedative in pregnant women in several countries in Europe and also distributed for trials in the USA, but was then identified as a cause of severe congenital limb malformations in many of the babies whose mothers had taken it while pregnant. The thalidomide disaster produced deep distrust in the way the public control of the effects of drugs was carried out. Suddenly, the edifices for the public control of drugs were in many countries perceived as gravely deficient and barely adapted to their purposes. People realized that drugs that were not safe could be produced by respected pharmaceutical companies, prescribed by trusted doctors, and sold by authorized pharmacies. It also became widely known that many marketed drugs were not providing their purported benefits and that claims of efficacy were barely checked by the drug regulatory authorities.

The outrage over thalidomide stimulated considerable reinforcement of the public control of drugs. In the USA, an amendment of the Food, Drug, and Cosmetic Act was approved by Congress in 1962 (111). Not only the safety but also the efficacy of drugs would henceforth be part of the criteria that the FDA used as benchmarks in decisions over whether drugs should be allowed on to the market. Since then pharmaceutical companies have had to show premarketing proof of both the safety and the efficacy of any new drug they want to introduce. Moreover, manufacturers of drugs in the USA have since 1962 had a duty to report to the FDA any information on adverse effects of their products.

At that time, existing drugs on the US market also came under scrutiny, and a review of their efficacy conducted by the US National Academy of Sciences (112) led to the voluntary withdrawal by pharmaceutical manufacturers of about two-thirds of the approximately 7100 products that the FDA had previously approved (113).

Similar legislative changes were called for in other countries, with a strong emphasis on applying the principle of premarket testing of drugs, rather than relying on random, more or less voluntary, postmarket surveillance and monitoring.

In Britain the thalidomide tragedy led to calls for a revision of the existing drug safety regulations. However, the government's position was ambiguous. It expressed a belief in the value of premarket testing of all new drugs, but did not want to move against the interests of the pharmaceutical industry. The "goose which has laid so many golden therapeutic eggs" (114) was important for the economy. Instead of creating new legislation with far-reaching requirements on the testing of new drugs, a Committee on Safety of Drugs (CSD) was appointed in 1964, expecting voluntary cooperation from the pharmaceutical industry, and its chairman asserted that it was not going to impose unnecessary restraints on the industry. Moreover, a flexible approach was to be taken regarding the efficacy of medicines. The CSD would invite reports on the toxicological testing of drugs, consider whether clinical trials should be undertaken, and assess the results in terms of safety and efficacy. It pledged that information submitted to it by the manufacturers of new drugs would be kept confidential. In its first year the CSD received 600 submissions for new drugs from pharmaceutical manufacturers. Its reviews were rapid and it rejected only a small proportion of the submissions (115).

In 1967 the Association of the British Pharmaceutical Industry (ABPI) was facing radical political proposals to abolish brand names of drugs and introduce mandatory labeling with therapeutic classifications on all medicines. To avoid legislation with mandatory rules, the ABPI revised its Code of Practice to cover the inclusion in promotional material of information on adverse effects, precautions, and contraindications (116). When the Medicines Commission was established in 1969, under the 1968 Medicines Act, to regulate the quality, safety, efficacy, and promotion of drugs, the rules of confidentiality regarding data on the effects of drugs remained in place. The Medicines Commission saw its task as integrating consideration of the pharmaceutical industry's interests with the interest of public safety (115).

In Sweden, public outrage eased the acceptance of proposals for new legislation on drug control that were pending in the Riksdag (the Swedish Parliament). A new law in 1962 (115), and subsequent regulations issued in 1963 (117), stressed the importance of controlling drug safety and efficacy. Mandatory premarket testing, with results examined by the Swedish national drug control agency, was to be the main instrument in controlling the drug market.

The thalidomide disaster led to other initiatives in many countries to create mechanisms by which doctors

© 2006 Elsevier B.V. All rights reserved.

could easily alert colleagues to illnesses that they suspected were due to drug exposure. Such national schemes eventually led to the establishment in 1968 of the WHO Collaborating Center for International Drug Monitoring, which receives national data on adverse drug reactions and uses them to issue warnings about hazards to the medical community.

Features

Birth defects associated with the use of thalidomide during the first trimester include phocomelia, duodenal stenosis, esophageal fistula, neural tube defects, microphthalmia, deformities of the pinnae of the ears, and mid-line hemangiomas (118). A simple nevus extending from the forehead over the nose down to the upper lip is a characteristic feature. Before the introduction of thalidomide, phocomelia was a rare malformation (119).

A summary of the types of malformations that can occur is given in Table 1, based on 14 necropsies at the Pathological Institute, University of Hamburg (120).

Table 1 A summary of the malformations caused by thalidomide

Abnormality	Number
Cardiovascular	
Anomalies of the heart and arteries	10
Fallot's tetralogy	5
Ventricular septal defect	4
Respiratory	
Bilobed right lung	5
Ear, nose, and throat	
Anomalies of the external ear	7
Sensory systems	
Microphthalmia	2
Gastrointestinal	
Duodenal atresia	4
Agenesis of appendix and cecum	5
Malrotation	7
Imperforate anus	1
Liver	
Abnormal lobulation of the right lobe of the liver	5
Biliary tract	
Absent gallbladder	8
Atresia of the common bile duct	3
Urinary tract	
Anomalies of the urinary tract	10
Skin	
Facial nevus	1
Musculoskeletal	
Hypogenesis or agenesis of long bones	5
Phocomelia	4
Defects of metacarpal and phalanges only	3
Amelia	2
Reproductive function	
Bicornuate uterus	5 (of 8 female children)
Atresia or absence of the vagina	3

The commonest abnormalities are agenesis or malformations of the upper and lower limbs; the eyes, ears, and internal organs can also be involved (108). Of 285 cases, 251 had upper-limb defects and 146 upper-limb defects alone. In 92 cases both the upper and lower limbs were affected and in five cases only the lower limbs were involved. Syndactyly and polydactyly were common. In some cases the hands and feet were attached directly to the trunk. Occasionally all four limbs are virtually absent. In 21 cases the ears were imperfectly developed without impaired hearing. In another series, in 50% of cases only the arms were involved; in 25% both arms and legs; in 16% the external ear was absent (121). In 303 cases, 37 other defects were observed, the biggest single group being cardiac abnormalities; congenital anomalies of the gut were also noted (119,122).

Of 96 children with congenital limb deformities who were born in 1962–63, 68 had a history of thalidomide administration during the first trimester (123). The results are summarized in Table 2. In addition, electroencephalographic examination of 71 of the children showed abnormalities in 32 of 48 cases with a history of thalidomide administration, and 12 of 23 in those who had not been exposed to the drug.

In another series of 22 cases there were anomalies of the heart ($n = 5$), anomalies of the external ear ($n = 4$), duodenal atresia ($n = 6$), anomalies of the urinary tract ($n = 5$), and microphthalmia, imperforate anus, and internal hydrocephalus ($n = 1$ each) (102,104).

Three cases of congenital limb deformity after the administration of thalidomide-containing formulations during the first trimester were the first of this kind to be reported from the UAR and Kuwait (124).

Children exposed to thalidomide appear to be shorter than normal children, but growth rates are relatively normal (125).

Duodenal stenosis and left-sided hydronephrosis and hydroureter due to an abnormal opening of the left ureter into the bladder have been reported associated with phocomelia in a 5-month-old male infant. The mother had taken thalidomide in early pregnancy (126).

The differential diagnosis between the Stilling–Türk–Duanesches syndrome and thalidomide embryopathy has been detailed, following a review of the case history of a boy with multiple congenital abnormalities (127).

Table 2 Abnormalities in children with congenital limb deformities

	Thalidomide taken in first trimester	No history of thalidomide exposure
Number of cases	68	28
Limb abnormality alone	13	17
Congenital heart disease	14	1
Abnormality of urogenital system	43	3
Abnormality of alimentary system	18	5
Hydrocephalus and meningocele	4	2

Cardiovascular

- A 29-year-old primipara was delivered of a female infant who died 30 hours later after increasingly severe attacks of cyanosis. Postmortem a cor triloculare was found. The mother had taken thalidomide 25 mg on the day of conception and afterwards on average 3 tablets a week for 5 weeks, the last tablet on the 35th day of pregnancy (128).

Ear, nose, and throat

Ear defects occurred in a child whose mother took a thalidomide-containing formulation in the early months of pregnancy. The abnormalities included absence of both auricles, hypoplasia of the middle ear, deafness, ophthalmoplegia of the right eye, and retarded mental development (129).

Nervous system

In some cases the central nervous system may have been affected (109,130,131), and cranial nerve palsies have been reported (132). In a survey of ear deformities attributed to thalidomide (133) there were also 19 cases of seventh cranial nerve lesions and 18 cases of sixth nerve lesions (134).

Sensory systems

Ocular malformations, including aplasia of the macula, choroidal colobomata, microphthalmos, and extraocular muscle paresis have been attributed to thalidomide taken in early pregnancy (135). Ocular defects have been reported in four of 21 thalidomide children examined in Canada; there was strabismus in two cases, congenital blepharoptosis in one, and ocular muscle palsies associated with other central nervous system damage in one (136).

Hematologic

Panmyelophthisis, with additional features resembling the Fanconi syndrome, has been reported after the administration of thalidomide in the first months of pregnancy (137).

Mouth, teeth

Dental examination of 40 children in Stockholm with thalidomide embryopathy showed hypodontia and disturbances of mineralization. In addition, children with very shortened forelimbs are more susceptible to tooth injury when they fall (138,139).

Cleft deformities of the face are more common in thalidomide children than in other children. Two cases of cleft lip and palate have been attributed to thalidomide taken in early pregnancy (140). There was a cleft lip and/or palate in three of 161 cases in Hamburg and in six of 9l8 cases seen in other centers. These deformities are usually associated with ear deformities, an association that was observed before the introduction of thalidomide (141).

Gastrointestinal

Agenesis of the appendix due to thalidomide can cause acute abdominal pain and tenderness (142,143). In two cases of anal stenosis the malformation was isolated and of the type due to incomplete rupture of the anal membrane; there were no malformations of the extremities (144).

Excessive sweating has been seen in thalidomide-deformed children (143,145). In some patients, small doses of ascorbic acid (50 mg daily) are helpful in this condition (143).

Musculoskeletal

Two cases of Perthe's disease have been reported in children with congenital abnormalities after thalidomide ingestion by the mother during the first trimester (146). Thalidomide can cause growth disturbance at the upper end of the femur.

Frequency

The numbers of babies with phocomelia seen in university clinics in Germany and a few clinics in England are listed in Table 3 (119).

However, it is difficult to calculate how often dysmelic malformations occur in relation to the number of pregnant women who have taken thalidomide (101,103). In Hamburg 0.17% of all neonates had such malformations. Other reports state that about 20% of expectant mothers who had taken thalidomide in the early months gave birth to an abnormal infant (104,147).

The total number of afflicted children in the Rhineland and Westphalia alone before thalidomide was withdrawn was estimated at 1500–2000 (104,119,147). In England and

Table 3 Numbers of babies with phocomelia in Germany and Britain

Place	1949–59	1959	1960	1961	Total (1959–61)

© 2006 Elsevier B.V. All rights reserved.

Wales the number of cases was calculated to be at least 800 (148).

The frequency in Bonn in 1962 was 3.56 per 1000 of all newborn children (200 times the frequency in 1960–61). In Liverpool, the frequency during 1960 and 1961 was lower (0.778 per 1000), but nevertheless considerably higher than in other countries. Cases have been reported from Australia, Scotland, and Sweden (149). The USA was relatively free from this adverse effect, since thalidomide (as Kevadon) failed to pass the Food and Drug Administration because of another adverse effect, namely polyneuropathy (119).

It was estimated that 10 000 deformed children were born in West Germany before thalidomide was withdrawn; of these, 4000 are believed to have survived. In Japan there were believed to be 1000 thalidomide children; in England 400; in the Scandinavian countries 280; in Canada 200; in Belgium 60; and 25 in the Netherlands. From 1958 to 1961, 223 kg of thalidomide were marketed in Austria; during this period 19 children were born showing abnormalities compatible with the dysmelia syndrome.

Dose relation

The actual dose of thalidomide taken is not as important as the fact of its ingestion (103,104,147). Neither the duration of administration of thalidomide nor the total dose was related to the teratogenic risk (77,119). Some cases have been observed after the ingestion of only 1, 2, or 3 tablets (150).

A baby with micromelia of all four limbs was born to a woman who had taken only a single dose of thalidomide 200 mg in the first weeks of pregnancy (151). In two other cases the total dose was less than 125 mg (152).

In one case the question arose as to whether ingestion of thalidomide by the father previous to or at the time of conception could have played a role (153).

- A baby was born with bilateral absence of radii and thumbs. The mother denied having taken thalidomide or any other drug. The father had been receiving thalidomide for some six months before the conception of the child.

However, the taking of a single sleeping tablet by the mother could easily have been forgotten in this case. Nevertheless, in one study in rabbits the effect on the offspring of the administration of thalidomide to the male parent was studied (154). It was concluded that in rabbits of a cross-bred colony of high fertility there was a deleterious effect on the progeny ascribable to paternal treatment with thalidomide.

Time course

During a 1-year period, 10 babies with major limb defects were born in Stirlingshire maternity units. At least eight of the mothers had had thalidomide prescribed in the early weeks of pregnancy (59,98–101).

The critical phase for teratogenic effects of thalidomide is from the 27th to the 40th day after conception or from the 37th to the 54th day after the first day of the last menstrual period (155). In 12 of 86 cases the date of conception was fairly well known and the narrowest interval of time that spanned the taking of thalidomide was from the 27th to the 44th day after conception (150). In 205 cases, the mothers that were able to give precise accounts of the timing of administration of thalidomide had taken it from the 31st to 39th day from the first day of their last menstrual period, and in two cases they had taken only two tablets at 36–39 days (156).

In contrast, one woman gave birth to a baby with typical abnormalities after having taken thalidomide for 2 months before conception but only during the first 3 weeks of pregnancy (157).

Experimental data

Experimental work on thalidomide is complicated by the fact that different species respond in different ways to the drug (158). For example, oral thalidomide 25–200 mg/kg/day in rabbits produced a large number of fetal abnormalities, whereas very few occurred in rats. In contrast, after intravenous injection of thalidomide dissolved in propylene glycol or dimethylsulfoxide, abnormalities were produced in both species with doses as low as 2.5–10 mg/kg/day in rabbits, and 10 mg/kg/day in rats (159).

In vitro experiments

In leukocyte cultures, thalidomide is a potential antimitotic agent (160). There was a reduction in the percentage of lymphocytes transformed into the "blast" and "intermediate" types. The cells showed morphological abnormalities: pyknotic changes, chromatin clumping, and perinuclear pink halo of cytoplasm.

Mesanephric tissue from human embryos is normally capable of producing cartilage in vitro. However, when chondrogenic tissues from human embryos aged 5–8.5 weeks were exposed to thalidomide, it interfered with this process and the authors suggested that it may have a specific effect on similar tissues in vivo, accounting for the types of malformation of the fetus that have been observed (161).

Chickens

When chick eggs were injected with thalidomide, gross malformations were found only in the thalidomide-treated group after breeding; they affected 20% of the chickens and included encephalocele, anencephaly, microphthalmia, beak malformations, deformities of the jaw and legs (128).

In chick embryos, malformations were induced by introducing thalidomide into the amniotic cavity. However, other types of traumatic procedures similarly resulted in abnormalities (162).

Changes in the mitochondria of the endothelial cells of the axial limb bud artery occurred in chick embryos after treatment with thalidomide (163). However, there were no macroscopic abnormalities in chicks after thalidomide administration.

Thalidomide caused profound alterations in the morphogenesis of the encephalon in the developing chick embryo in vitro. Platyneuria occurred in 82% compared with 23% in the control group. Thalidomide has an inhibitory effect on growth, as measured by failure of closure of the neural plate, which can be reversed by the addition of ATP to the cultures (164).

The action of thalidomide on the production of limb abnormalities in the chick are similar to those produced by nitrogen mustard (165). Only mesodermal tissues are affected; differentiation is arrested and the mesodermal cells regroup beneath the ectodermal cap. The latter no longer induces development of the proximal portion of the limb, but only of its terminal part, which explains the occurrence of phocomelia.

Dogs

Of nine dogs treated with thalidomide 100 mg/kg/day in the first 3 weeks of pregnancy, three had no litters at all. Of a total of 30 pups, 19 appeared normal, two were stillborn and four died within 48 hours (of these six, two had malformations), and five survived for some days but had an abnormal tail bone (166).

Mice

In mice treated with thalidomide there was a marked reduction in litter size (167). The young had congenital anomalies, such as cleft lip, microphthalmia and malformation of the tail, in a frequency of 5–10%.

There was a high incidence (17.5%) of abnormal embryos in mice treated during the sixth to eighth days of pregnancy, whilst thalidomide-treated animals had a higher incidence of fetal resorption (168). Others, however, failed to find any malformations or other adverse effects when using doses ranging from 2 mg/kg up to 400 mg/kg (169).

In random-bred Charles River strain albino mice, thalidomide 1000 mg/kg/day given from the first day of mating failed to produce gross malformations of the offspring (170).

Monkeys

In seven pregnancies in monkeys, one normal fetus was obtained, four had deformities, and two had teratomas (171).

Rabbits

In rabbits treated with thalidomide there was a marked reduction in litter size (167). The frequency of malformations (encephalocele, anencephaly) was 30%. Experiments with thalidomide on pregnant rabbits showed that the young invariably showed deformities similar to those seen in humans (172).

In rabbits, malformations were found with doses of 5 mg/kg/day, 150 mg/kg/day, and 500 mg/day, given between the seventh and eleventh days of pregnancy. There were abnormalities of the extremities, skull, nose, and palate, as well as malformations of the kidneys. There seemed to be an increase in frequency with higher doses (173).

When 10 pregnant New Zealand white rabbits were fed thalidomide from the eighth to the eleventh days of pregnancy in doses of 150 mg/kg, 59 fetuses were produced, of which 56 were malformed. The 11 control rabbits gave birth to 94 normal fetuses (174).

In six male rabbits of proven fertility treated with 0.75–2.5 g of thalidomide for 10–21 days before mating, three of forty experimental matings did not result in pregnancies; six litters had five or fewer offspring; there was gross abnormality of one male offspring in each of two different litters fathered by the same male; eight litters showed total loss of young and in another eight litters there was marked loss of young by day 14 of the postnatal period (154).

Rabbits have been found to be very sensitive to the action of thalidomide, but the types of abnormality produced vary with the strain of rabbit. In hybrid rabbits, in which the pregnant doe received thalidomide in a dose of 150 mg/kg on days 7–13, 13% of the young were deformed (175). Apart from the femur, only preaxial structures of both forelimbs and hind limbs were affected. Abnormalities were of both the supernumerary and reduction types. In contrast, only abnormalities of the forelimbs occurred in the New Zealand white strain of rabbits under the same dosage schedule (176). The pattern of these limb defects bore no resemblance to spontaneously occurring deformities, and it is suggested it is a characteristic pattern for the drug.

In Chinchilla and New Zealand white rabbits, thalidomide 150 mg/kg on days 6–15 of pregnancy caused increased incidences of conceptions undergoing resorption and of fetal malformations, and reductions in litter size and body weight of the 28-day fetuses; 22% of fetuses were deformed, with abnormalities affecting the locomotor, nervous, cutaneous, ocular, respiratory, and renal systems (177).

In liver-damaged rabbits, thalidomide 150 mg/kg on days 7–12 of pregnancy produced an 80% rate of fetal abnormalities. The teratogenic activity correlated with high blood and tissue concentrations of thalidomide (178). There was no correlation between the dose of thalidomide and blood thalidomide concentration in healthy rabbits (179).

Experimental work in six strains of rabbit showed that defective evolution of the spiral septum underlay many of the cardiac abnormalities. Incomplete evidence in the literature suggests the same effect may be present in human cardiac deformities (180).

A synthetic analogue of thalidomide, methyl-4-phthalimido-DL-glutamate, was teratogenic in rabbits (181).

Rats

In rats treated with thalidomide, congenital malformations were not seen, but the number of young per litter was reduced by 33% (167).

In rats thalidomide produced abnormalities of the ossification centers of the sternum and cervical vertebrae (182). These changes in ossification centers were more easily found after small doses than with large doses, since in the latter many of the young do not survive until birth.

In Wistar rats that received thalidomide 0.5–1% in the diet for periods from 9 days before mating up to the 20th day of pregnancy, 1% thalidomide produced the greatest number of fetal resorptions and extensive defects of ossification of thoracic centers, sternebrae, and pelvic girdles. Of 170 observed malformations, 150 (82%) occurred in rats treated with thalidomide before mating. The authors suggested that thalidomide may have a gonadal effect (183).

A histochemical study of the development of the sternum in thalidomide-treated rats showed increased storage

© 2006 Elsevier B.V. All rights reserved.

of glycogen and reduced or absent alkaline phosphatase activity. These changes resulted in a delay in calcification of cartilage (184).

There were no macroscopic abnormalities in rats after thalidomide administration, although the number of resorption sites in the latter after 18 days gestation was increased (171).

Mechanisms

The mechanism by which thalidomide causes fetal abnormalities is not known. There is a high incidence of fetal resorption, but the cause of this is not known; it could be secondary to an abnormality of the fetus.

The more marked effect of thalidomide on some systems, for example the nervous system, the fetus, and erythrocytes, may be due to differing membrane permeabilities of different tissues to the drug (185). From a study of five head autopsies, and electroencephalographic and neurological findings in 17 individuals with the thalidomide embryopathy, it has been suggested that the action of thalidomide is not confined to mesoblastic tissue (186). This is especially true in children with an aural embryopathy. Cytogenic examination of mitotic cells in five children with ear deformities showed that the proportion of non-modal chromosomes was not greater than 10% and there were no structural changes in single chromosomes (187).

The abnormality of the ossification centers found in the rat could be connected with abnormal development of long bones. Radiographs of the limbs of 92 children with deformities due to thalidomide showed joint changes similar to those in neuropathic (Charcot's) joints in adults. The authors suggested that thalidomide causes joint changes by causing an embryonic sensory neuropathy. This hypothesis can be extended to explain other visceral and congenital malformations (188).

Thalidomide prolongs the survival time of skin homografts in the mouse, and the mechanism involved is thought to be immunosuppressive, because of the inhibition of the appearance of immunoblasts in the regional lymph nodes (189). The fetus is immunogenetically a homograft, and an early spontaneous abortion is homograft rejection. Thalidomide may therefore act by preventing spontaneous abortions, allowing damaged fetuses to reach term. If this were so, the abortion rate of those women who took thalidomide should be reduced (190). However, thalidomide has a direct toxic action on the pre-implantation blastocyst, especially the embryonic disc, and the immunological theory also cannot be reconciled with the fact that thalidomide produced teratogenic effects when given to the male rabbit before mating (191).

It has been suggested that thalidomide acts by a toxic action on the initial nerve impulses in the organogenetic phase of development due to accumulation of the drug in the nervous system of the embryo (192).

It has been suggested that in some way, thalidomide interferes with the action of certain of the B vitamins, that as a result of this antagonism fetal damage can occur, and that in the adult there may be a link between this effect and the polyneuropathy that thalidomide can cause (193). Thalidomide and its two isoglutamine derivatives caused an increase in sensitivity of intracellular hemoglobin to oxidation by nitrite ions in rats; simultaneous administration of pyridoxine and riboflavin prevented or corrected this change (185).

Prevention

Women of child-bearing age should take steps not to become pregnant while taking thalidomide, for example by using reliable contraception. If a woman taking thalidomide misses a menstrual period, thalidomide should be withdrawn for at least 9 weeks (120). Counseling about therapeutic abortion will be necessary.

Susceptibility Factors

The incidences of polyneuropathy and hypersensitivity reactions seem to be higher in HIV-infected patients (2,93).

Drug–Drug Interactions

Darbepoetin

In a study of the combination of thalidomide 100 mg/day with darbepoetin alfa 2.25 mg/kg/day in patients with myelodysplastic syndromes, there was an unexpectedly high incidence of thromboembolic events (194). Of the first seven patients enrolled, two developed deep vein thromboses and one died of a massive pulmonary embolus. The authors concluded that thalidomide may increase the thromboembolic risk associated with erythropoietic proteins in patients with myelodysplastic syndromes.

Dexamethasone

An interaction of thalidomide with dexamethasone has been postulated (195).

- A 64-year-old man with myeloma took dexamethasone and thalidomide 200 mg/day for 14 days and had no adverse effects. The dosage was increased to 400 mg/day and 10 days later a rash occurred; thalidomide was withdrawn. Within 3 days he developed toxic epidermal necrolysis.

Two other patients of eight who received thalidomide plus dexamethasone for multiple myeloma had unexpected severe skin rashes, including one who became seriously ill with erythroderma. Both recovered fully after thalidomide was withdrawn.

Docetaxel

The increased risk of venous thromboembolism in patients taking thalidomide and docetaxel is discussed in the cardiovascular section.

Sedative drugs

Thalidomide enhances the sedative actions of alcohol, barbiturates, chlorpromazine, and reserpine (118), perhaps by additive effects on their several pharmacodynamic actions (196), although other mechanisms have been described (197).

Sex steroids

Thalidomide does not interact with ethinylestradiol or norethindrone (198).

Theaceae

See also Herbal medicines

General Information

The genera in the family of Theaceae (Table 1) include camellia.

Table 1 The genera of Theaceae

Camellia (camellia)
Cleyera (cleyera)
Eurya (eurya)
Franklinia (Franklin tree)
Gordonia (gordonia)
Laplacea (laplacea)
Stewartia (stewartia)
Ternstroemia (ternstroemia)

Camellia sinensis

Camellia sinensis (green tea) contains caffeine and antioxidant polyphenols. It has been touted as being useful in a wide variety of conditions, including cancer prevention, mostly on relatively slim epidemiological evidence (1), cardiovascular disorders, and AIDS.

Adverse effects

The adverse effects of green tea are those of caffeine, with tremulousness and insomnia and withdrawal symptoms (headache, drowsiness, and fatigue).

Theophylline

General Information

Owing to their ability to relax bronchial muscles, theophylline and related compounds are used chiefly in the maintenance treatment of asthma and chronic obstructive pulmonary disease. However, the availability of other therapeutic agents (for example beta-adrenoceptor agonists or steroid inhalers) with increased efficacy, fewer adverse effects, and greater ease of management has led to reduced use of these agents. Theophylline has also been used in the treatment of apnea associated with prematurity (1), congestive heart failure (2), and life-threatening Cheyne–Stokes respiration (3). In the emergency treatment of acute exacerbations of asthma (status asthmaticus), the controversy concerning the possible benefit of including theophylline or aminophylline has not been resolved (4,5) (and see the section under Drug–Drug Interactions in this monograph). A review has suggested that a combination of high doses of inhaled $beta_2$-adrenoceptor agonists, systemic corticosteroids, and oxygen is the treatment of choice; theophylline adds little to the bronchodilator effect of inhaled beta-agonists in most patients (6).

The bronchodilator effect of theophylline is related to serum concentrations, and begins at 5–8 μg/ml, with virtually no additional effects beyond 20 μg/ml. The relation of relatively minor adverse effects to serum concentration is idiosyncratic below 15 μg/ml; above that concentration, the relation becomes more consistent and more serious adverse effects also are increasingly likely, that is toxic effects; the latter are frequent at about 20 μg/ml. Therefore, the therapeutic range is usually considered to be 10–20 μg/ml; 10–15 μg/ml is optimal. However, there is still controversy. For example, the authors of one study found that the clinical response to theophylline correlated significantly with the log plasma theophylline concentration, while other authors have claimed that clinical aspects are more relevant for dose correction during therapy than the determination of serum concentrations (SEDA-12, 3). Various factors influence the metabolism of these compounds, including pronounced interindividual differences in metabolism, concurrent illnesses, and factors such as smoking, age, and weight. The use of these drugs requires extremely close attention, and many authors have stressed the importance of monitoring serum concentrations, the patient's clinical condition, and adverse effects.

An example of some of the complexity encountered is the initiation of chronic bronchodilator therapy with oral theophylline. Approximate initial daily doses are as follows: 6 mg/kg for adult nonsmokers; 10 mg/kg for adult smokers; 12 mg/kg for children under 12 years. Increases in dosage, if any, are made in small increments after about 3 days, depending on the clinical response and serum theophylline concentration. Proper dosing is complicated by two factors: variable systemic availability among the different products used and elimination kinetics in which saturable kinetics are probable but poorly defined.

Theophylline has been derivatized to produce aminophylline, choline theophyllinate, and other compounds. Several modified-release formulations are available. Maximum serum concentrations occur at 1–3 hours with most of the standard formulations and at up to 6 hours with modified-release formulations. In aminophylline, the most widely used theophylline derivative, theophylline is combined with ethylenediamine to enhance its solubility. Since ethylenediamine is therapeutically inert, all the effects of aminophylline, except for allergic reactions, are considered to stem from the theophylline component.

Among the methylated xanthines, theophylline is the least active cerebral stimulant, its most pronounced features being stimulation of the medullary respiratory center, circulatory system, and smooth muscles of the bronchi. Therapeutic use and untoward responses will derive from these basic pharmacological features, which, apart from the desired actions, can produce untoward effects. Serious adverse reactions are rare with appropriate blood concentrations; however, it is difficult to control theophylline concentrations, especially when it is taken orally, absorption being erratic. When it is given intravenously, slow administration is advised. With both oral and parenteral administration, monitoring of serum theophylline concentrations with individual adjustment of dosage is necessary.

The adverse effects of other theophylline derivatives have been reviewed (SEDA-17, 1). Whether or not newer drugs have similar efficacy and/or better tolerability than the classic theophylline derivatives has not been carefully evaluated.

General adverse effects

Nausea, vomiting, headache, dizziness, tachycardia, dysrhythmias, vascular collapse, tremor, agitation, and convulsions have been described. Although 1% of children and 4% of adults cannot tolerate even low serum concentrations, the incidence of adverse effects during therapeutic use is generally related to the logarithm of the serum concentration. However, the relation between the severity of the symptoms of theophylline poisoning and serum–drug concentration is less clear and may well depend on the chronicity of the overdose (SEDA-9, 78) (see Drug overdose in this monograph).

True allergy to theophylline is rare. Hypersensitivity to aminophylline, when it occurs, is most likely due to the ethylenediamine component. Two immunogenic types of reactions have been described, one of urticaria and general pruritus and the other involving thrombocytopenia and a hemorrhagic diathesis (SED-8, 1). Also reported have been contact dermatitis, exfoliative erythroderma accompanied by bronchospasm and pruritus, generalized dermal reactions (SED-10, 4), severe generalized symptoms with a high fever (7), and aggressive behavior in a child (8).

The observation of excess mortality from cancer of the pancreas among US male veterans admitted to hospital for bronchial asthma and discharged on various bronchodilators has raised the question of a possible connection to the theophylline (see the monograph on Caffeine). Although not fully resolved, chronic use of theophylline does not appear to be associated with an increased risk of esophageal or gastric carcinoma (9).

Organs and Systems

Cardiovascular

The relation between toxicity and excessive serum theophylline concentrations has been confirmed, tachycardia being a frequent indication of toxic symptoms (SED-9, 3). It appears that the cardiac and metabolic effects of theophylline are at least partly related to catecholamine release (SEDA-13, 1). The importance of appropriate dosage has been stressed in several papers, all indicating the particular risk of ventricular fibrillation in subjects with respiratory distress (10). The authors have pointed to the potentially lethal effect of serum theophylline concentrations in excess of 20 μg/ml. In another study, half the patients with serum concentrations greater than 35 μg/ml had life-threatening dysrhythmias (SEDA-7, 7). In one study of the effect of oral aminophylline on cardiac dysrhythmias in 15 patients with chronic obstructive pulmonary disease, aminophylline had both dysrhythmogenic and chronotropic effects but did not change the grade of dysrhythmia (SEDA-7, 7). In another study of 16 patients there was a relation between the use of theophylline and multifocal atrial tachycardia (11). Whereas raised blood theophylline concentrations are likely in themselves to produce cardiovascular complications, patients with pre-existing cardiac disease are at greater risk.

Respiratory

Aminophylline sometimes aggravates bronchial asthma; sensitization to the ethylenediamine component is considered to be responsible (SEDA-6, 5).

Nervous system

In addition to the more common adverse effects of tremor, dizziness, anxiety, agitation, insomnia, visual disturbances, and seizures, depression, confusion (SEDA-6, 1), acute dyskinesias (SEDA-17, 1), and toxic psychosis (SED-10, 5) have also been reported.

Seizures with focal onset have been described during treatment of status asthmaticus in adult patients with no previous history of epilepsy (12). Although, serum theophylline concentrations are an unreliable predictor of seizures, seizures occur most commonly at serum concentrations over 40–50 μg/ml (13). Older patients are more likely to have seizures than younger ones at similar theophylline concentrations (14). Patients with pre-existing central nervous system abnormalities (15) or severe pulmonary disease may also be at increased risk (SEDA-17, 1). Theophylline-induced seizures have been reported in two neonates (SEDA-6, 2); the serum theophylline concentration during seizures was 51 μg/ml.

- A girl aged 3.5 months receiving theophylline had a seizure; in the next few months, she had a mixed seizure disorder and subsequently symptoms of moderately severe right brain damage (16).

Because toxic symptoms before seizures can be absent or undetected, such events underline the need for blood concentration monitoring during therapy.

Theophylline disturbs sleep more profoundly in caffeine-sensitive subjects (SEDA-15, 1). Exacerbation of spasticity has occurred when theophylline was used after a stroke (17).

Psychological, psychiatric

The concern that cognitive function may be impaired in children taking theophylline is still not resolved (SEDA-14, 1) (SEDA-15, 1); a review has suggested that detrimental effects of theophylline on various measures of cognitive function may be measure-specific (18).

Endocrine

The dangers of theophylline toxicity in hypothyroidism have been described (19).

Metabolism

The metabolic effects of intravenous infusions of aminophylline have been studied in a series of healthy young subjects with regard to serum glucose, insulin, glucagon, cortisol, and free fatty acid concentrations. Infusion of aminophylline, which produced theophylline concentrations in the usual target range (10–20 μg/ml) caused only small increases in plasma glucose concentrations but rapid, pronounced, and prolonged rises in free fatty acids. Increases in free fatty acid concentrations paralleled the rise in theophylline concentrations (SEDA-6, 6).

Gastrointestinal

The commonest gastrointestinal adverse effects of aminophylline in adults are nausea and gastrointestinal irritation, which are primarily a function of serum theophylline concentrations, although some additional local irritation may be produced by oral administration. Nausea was reported in six of 20 asthmatic patients with serum theophylline concentrations of 20 μg/ml (SED-9, 4). In a survey of 2766 theophylline-treated patients with cardiac or pulmonary diseases, 11% had adverse effects, most of which were gastrointestinal disturbances (7.8%) (SED-9, 4).

In two elderly patients hematemesis was thought to have been due to both a local irritant action of aminophylline and a susceptibility to systemic toxic effects at lower serum theophylline concentrations (SEDA-5, 5).

Esophageal ulceration can result from tablets that were taken with insufficient fluid and/or while lying down (20,21).

Non-allergic proctitis associated with an aminophylline suppository has been reported in a child (SEDA-17, 1).

Liver

Since about 90% of theophylline is eliminated by hepatic metabolism, liver function is related to toxic effects on other systems (see Susceptibility Factors in this monograph). Hepatitis has been reported in two patients (SEDA-15, 1).

Pancreas

An excess in mortality from pancreatic cancer has been noted among US male veterans admitted to hospital for bronchial asthma and discharged on various bronchodilators, suggesting a possible connection with theophylline

© 2006 Elsevier B.V. All rights reserved.

(SEDA-7, 8). A relation between coffee consumption and pancreatic cancer was reported in a case-control study (SEDA-7, 8), with an unexpected increase in pancreatic cancer associated with an increase in coffee drinking (relative risk in men, 2.6). The same workers studied changes in mortality from pancreatic cancer in different countries in relation to changes in coffee consumption and found a significant relation between increases in coffee consumption and increases in mortality from pancreatic cancer. However, the data on which the findings were based were crude.

Urinary tract

Methylxanthines, especially theophylline, in healthy subjects inhibit solute reabsorption in both the proximal nephron and the diluting segment without changing either glomerular filtration rate or renal blood flow appreciably. Accordingly, an apparent increase in creatinine clearance in a heavy tea drinker has been attributed to a discrepancy between GFR and creatinine clearance (22).

Skin

Three cases of skin eruptions have been reported in patients taking aminophylline who had probably been sensitized by the use of a multiantibiotic cream formulation also containing ethylenediamine (SEDA-12, 4). A case of Stevens–Johnson syndrome after modified-release theophylline has been reported (23).

Immunologic

Salivary IgA was significantly reduced in asthmatic children treated with theophylline compared with healthy controls or unmedicated patients with asthma (24). This finding is in harmony with earlier statements that theophylline reduces the bactericidal capacity of leukocytes and affects suppressor T cells (SEDA-11, 6). Theophylline also interferes with basophil and eosinophil responses; these immunomodulatory effects might participate in its therapeutic efficacy (25,26).

Long-Term Effects

Mutagenicity

Genetic effects of theophylline are not well known. Theophylline suppresses phosphodiesterase and cyclic AMP activity, and increases calcium transport in animals (SEDA-4, 25), suggesting a potential for teratogenicity. An increased rate of sister chromatid exchange rate, an indication of mutagenicity, has also been reported (SEDA-17, 1).

Second-Generation Effects

Pregnancy

Theophylline crosses the placenta, resulting in potentially dangerous serum theophylline concentrations in the neonate (SEDA-5, 3). This is of practical importance, since 1.3% of pregnant women have asthma. Fetal tachycardia has been observed when maternal blood concentration exceeds 20 μg/ml (27). In one neonate the serum theophylline concentration of 14 μg/ml was 3 μg/ml higher than the cord or maternal serum concentrations. The authors concluded that neonates of mothers receiving theophylline products should be monitored for pharmacological effects of theophylline. In another study, women with asthma who used theophylline had a longer average duration of labor than did untreated women, since theophylline inhibited uterine contractions (SEDA-5, 3).

Fetotoxicity

Symptoms of irritability, vomiting, and jitteriness have been described in an infant, possibly related to ingestion of aminophylline during pregnancy by an asthmatic mother (28).

In pregnant women with bronchial asthma, bronchospasm can be exacerbated during labor, necessitating infusion of aminophylline. The placental transport of aminophylline and its effects on the fetus and the neonate are poorly understood. A recent report has highlighted the potential problems (29).

- A 26-year-old primigravida with bronchial asthma developed an acute exacerbation at 40 weeks gestation. She did not respond to salbutamol and was given hydrocortisone and aminophylline 250 mg intravenously, without improvement. She received two more doses of intravenous aminophylline, the last being 2 hours before delivery. At cesarean section she delivered a full-term female neonate weighing 3150 g with Apgar scores of 3 and 5 at 1 and 5 minutes respectively. Within 3 minutes of birth the neonate developed multifocal clonic convulsions, which failed to respond to intravenous glucose, calcium, phenobarbital, and phenytoin. She had a tachycardia, a normal blood pressure, and poor respiratory drive, and was comatose. The serum theophylline concentration was 8.6 μg/ml (47 μmol/l) at 1 hour of life. Despite ventilatory support and anticonvulsant therapy, she continued to have intermittent seizures and died 48 hours after birth. Postmortem showed normal brain structure and no evidence of hemorrhage or asphyxial brain injury.

The toxic concentrations for theophylline in neonates have not been well defined, and can vary from infant to infant. Other pharmacokinetic factors, such as low plasma protein binding and limited capacity for excretion could make neonates prone to aminophylline toxicity. Fetuses and neonates can develop theophylline toxicity even with plasma concentrations in the target range, since they can metabolize theophylline to caffeine, adding to the methylxanthine load.

Lactation

The kinetics of theophylline transfer into breast-milk have been studied in three lactating women given theophylline intravenously (SEDA-6, 2). The data suggested that theophylline accumulation to toxic concentrations should not occur in most breast-fed infants, but that serum theophylline concentrations in the mother should be kept as low as possible and transfer will be minimal if infants are nursed just before the mother takes the theophylline.

Susceptibility Factors

Age

Prematurity

Serious difficulties arise in giving theophylline to premature neonates. These are explained by peculiarities in biotransformation in prematurity. Transformation of theophylline to caffeine in premature neonates is explained by the lack of enzymes for desmethylation and *C*-hydroxylation and by predominant *N*-methylase activity. High serum caffeine concentrations have been found in two studies of premature newborns with respiratory disturbances who had received theophylline (SEDA-4, 3); caffeine and theophylline synergism was incriminated in the development of toxic reactions in these children. In another study, there was clinically significant hyperglycemia in 13% of preterm infants who received theophylline (30). Blood glucose concentrations should be monitored in preterm infants who receive theophylline. There is some evidence (SED-10, 5) that administration of 4.5 mg/kg of theophylline followed by a maintenance dose (1.2–1.52 mg/kg every 8–12 hours) is most likely to correct respiratory disturbances in premature neonates, while avoiding adverse effects. Because of simpler dosing regimens, some pediatricians prefer caffeine as the drug of choice in premature neonates (27,31).

Developmental differences in the balance between metabolic and renal elimination pathways determine the unique toxicokinetics of theophylline in neonates. Three premature neonates received inadvertent intravenous doses of theophylline for apnea of prematurity (32). All had sinus tachycardia and agitation. Maximum serum theophylline concentrations were 55–123 μg/ml; theophylline-derived caffeine concentrations plateaued at 8.4–13 μg/ml and did not fall during the sampling period. The half-life of theophylline was 28–37 hours and the clearance 0.02–0.05 l/kg/hour. This study shows that, in contrast to older children, theophylline elimination remains a first-order process during acute intoxication in premature infants, and that large overdoses of theophylline in neonates, while inducing symptoms and signs of overdose, do not uniformly result in life-threatening sequelae and do not necessarily require invasive treatment. Although the literature is rather scanty, the pharmacokinetics of theophylline in premature neonates do not seem to be different from those in full-term neonates. Furthermore, toxic concentrations in neonates have not been defined. It has been speculated that various factors in neonates, such as low plasma protein binding, metabolic interconversion to caffeine, and limited excretory capacity, make them susceptible to toxicity even at plasma concentrations within the usual adult therapeutic range (SEDA-23, 1)(SEDA-25, 1).

Term infants

Caution has been urged in using theophylline for wheezing in full-term infants under 3 months of age (SEDA-4, 3).

Cerebral blood flow velocity in infants treated with an intravenous bolus dose of aminophylline was reduced, perhaps because of a reduction in PCO_2, due to aminophylline (33).

Children

Convulsions have been attributed to theophylline given for bronchial asthma in the usual recommended dosage, with serum concentrations in the target range of 10–20 μg/ml (SEDA-5, 4). Young children may be more prone to excitement and dehydration due to diuresis and vomiting. Two afebrile children reported visual hallucinations during theophylline toxicity (SEDA-13, 2). Despite the recommendation for higher initial doses in young children, dosage management is more difficult, owing to the greater likelihood of toxicity, which is probably a reflection of more erratic pharmacodynamics.

Based on a retrospective investigation of theophylline-induced convulsions in epileptic children, it was concluded that infants under 1 year of age with epilepsy have a higher risk of theophylline-induced convulsions; theophylline should be avoided in this group (34).

Elderly patients

It is not entirely clear whether the risk of toxicity in the elderly is a function of an age-related reduction in the rate of metabolism, a tendency for systemic toxic effects to develop at relatively lower serum concentrations, or the greater likelihood of conditions that affect the pharmacokinetics of theophylline, for example cardiac failure, liver disease, or chronic obstructive pulmonary disease. In a review of 72 consecutive patients referred to a regional poisons center with chronic theophylline intoxication, stratification of data by chronological age showed a stepwise increase in the frequency of life-threatening events with advancing years; the authors suggested that elderly patients have a much greater risk of such events than younger patients (35).

In an investigation of 510 episodes of raised theophylline concentrations in 214 hospitalized patients, the authors concluded that life-threatening events can occur in critically ill patients or patients with past seizures or dysrhythmias with mildly raised theophylline concentrations (21–40 μg/ml) (36).

One study showed that in order to maintain plasma concentrations in the target range in elderly people, the maintenance dosage should be reduced by about 25% (SEDA-5, 1). Other reports have implicated chronic obstructive pulmonary disease and cardiac failure in elderly patients whose reduced theophylline clearances led to toxic reactions or potentially toxic plasma concentrations (SEDA-7, 6) (SEDA-8, 1). It was suggested that aminophylline dosages be reduced by 50% when there are clinical signs of cardiac failure, in order to avoid excessive drug accumulation.

Hepatic disease

In cirrhosis of the liver, drug clearance falls, the half-life of theophylline increases about threefold, and the incidence of adverse effects increases (SED-10, 6).

Drug Administration

Drug overdose

The effect of theophylline is cumulative, and there is a danger of overdosage if it is given repeatedly. However,

© 2006 Elsevier B.V. All rights reserved.

intoxication has been described in young children after a single suppository (SED-9, 4).

The symptoms of overdosage are nausea, vomiting, headache, dizziness, tachycardia, dysrhythmias, vascular collapse, tremor, agitation, and convulsions. The highly variable interindividual differences in metabolism and disease-related alterations in metabolism of the various formulations can result in iatrogenically induced overdosage. The tendency of patients to increase the dose as their condition deteriorates is a second major source of overdosing.

The amount of drug administered, whether putative or known, is less likely to correlate with untoward reactions than the serum concentration is. Likewise, the serum concentration correlates poorly with relatively minor adverse effects. More reliable is the escalating correlation of serious toxic effects with serum concentrations rising above 15 μg/ml.

The relation between the severity of clinical manifestations of theophylline poisoning and serum drug concentrations is unclear. However, a start has been made in clarifying this, with the finding that patients with theophylline overdose caused by chronic repeated overmedication often develop seizures and dysrhythmias with serum concentrations of 40–70 μg/ml, while those with acute single ingestion are highly unlikely to suffer serious complications unless serum concentrations exceed 100 μg/ml. According to this study, patients who took a single overdose were easily recognized by the presence of hypotension, hypokalemia, and a low serum bicarbonate, features not present in patients with chronic overdose (SEDA-11, 5) (37). These findings could lead to better indicators for more aggressive treatment before the advent of major complications.

In healthy volunteers, theophylline reduced circulating pyridoxal phosphate (vitamin B6) concentrations, presumably by noncompetitive inhibition of pyridoxal kinase. Theophylline concentrations of approximately 10 μg/ml produced only partial inhibition, plasma pyridoxal kinase and pyridoxal concentrations being unaffected. The authors speculated that with theophylline overdose and greater inhibition, vitamin B6 deficiency might contribute to seizures (SEDA-14, 2).

Rhabdomyolysis is a rare complication of theophylline overdose (38).

- A 73-year-old man took an unknown number of theophylline modified-release tablets and furosemide 40 mg tablets. He developed a tachydysrhythmia, vomiting, and restlessness. His maximum theophylline concentration was 67 μg/ml and he had hypokalemia (2.8 mmol/l) and hyponatremia (123 mmol/l). The maximum creatine kinase activity was (32 mol/l [sic]) and the serum myoglobin concentration was 3789 μg/l. He was treated with oral activated charcoal, continuous venovenous hemodialysis, intravenous potassium and sodium chloride, forced diuresis, and continuous intravenous metoprolol, and survived without sequelae.

Management

The use of hemodialysis or hemoperfusion in the management of theophylline toxicity was initially controversial (SEDA-8, 11) (SEDA-9, 10) (SEDA-11, 5). In one study (39) hemoperfusion provided a higher theophylline clearance rate than hemodialysis, but the latter appears to have comparable efficacy in reducing the morbidity of severe theophylline intoxication and is associated with a lower rate of procedural complications. The recommendation that these treatments be considered for patients who fail to respond to supportive care is complicated by findings that, once major complications have occurred, the benefits from these risky procedures are greatly reduced.

However, charcoal hemoperfusion is now regarded as the recommended method for rapid reduction of serum theophylline concentrations, if necessary, although access to this technique is limited in most hospitals. Venovenous hemofiltration, which is readily available in many hospitals, appears to be a realistic and practical alternative to charcoal hemoperfusion, in combination with oral activated charcoal, particularly in the hemodynamically unstable patient with severe theophylline toxicity without anticoagulation (40,41). A higher extraction ratio in neonates than in adults has also been described (41).

Drug–Drug Interactions

General

Both positive and negative drug interactions have been reported with theophylline. The usefulness of combination products has also been discussed (SEDA-6, 2) (SEDA-11, 7). The use of combinations complicates the evaluation of adverse effects, particularly those of theophylline and ephedrine. The likelihood of adverse effects of each component and synergistic effects between components must be evaluated in relation to the patient's clinical condition. A positive feature is the likelihood of greater compliance with an effective combination product.

Pharmacokinetic interactions

In one study, antacids increase the rate of theophylline absorption without a change in total systemic availability (42), although in an earlier study there was no interaction (43).

The concomitant use of drugs that reduce theophylline clearance can produce toxic serum concentrations with therapeutic doses of theophylline. Most of these drugs are believed to have this effect by inhibiting the hepatic microsomal P450-metabolizing enzymes that are responsible for the biotransformation of theophylline. Such drugs include the xanthine oxidase inhibitor allopurinol, some histamine H_2 receptor antagonists (cimetidine in particular), some antidepressants (fluvoxamine), and oral contraceptives. Also included are some antimicrobial drugs, for example tetracycline, the macrolides (erythromycin and troleandomycin), fluoroquinolones (ciprofloxacin, norfloxacin), possibly the cephalosporins, isoniazid, antihelminthic drugs (thiabendazole and possibly pyrantel), and antiviral drugs (influenza vaccine and vidarabine).

Other drugs that reduce theophylline clearance, but by unknown mechanisms, are cardiac medications: the beta-blocker propranolol, the calcium channel blockers

© 2006 Elsevier B.V. All rights reserved.

nifedipine and verapamil, and mexiletine. Considering that increased theophylline concentrations can lead to an increased propensity for central and cardiac stimulation, it is prudent to avoid using a combination of theophylline and cardiac medications, especially antidysrhythmic drugs.

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). These agents can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that interact in this way include theophylline (44).

Conversely, drugs that induce P450 enzymes increase theophylline clearance and lower blood concentrations. These include the barbiturates, phenytoin, carbamazepine, and rifampicin. Increased clearance also occurs with a high-protein diet, marijuana, and tobacco. With phenytoin the interaction is two-sided: the plasma concentrations of both drugs fall. This can result in poor seizure and respiratory control and in drug toxicity.

Recommendations have been presented for correction of theophylline doses during concomitant medication with some of the above drugs (SEDA-8, 130) (45). Concomitant therapy with allopurinol, cimetidine, erythromycin, furosemide, isoprenaline, or propranolol requires a reduction in dose of about 20–30%; for oleandomycin the reduction should be about 50%.

Pharmacodynamic interactions

A debate was triggered by the suggestion some years ago of increased mortality because of greater use of theophylline, and additive toxicity between oral theophylline and inhaled beta-adrenoceptor agonists (SEDA-7, 1). Some authors concluded that a combination of theophylline and beta-adrenoceptor agonists in low doses will give equal and possibly superior results over full doses of either agent and may produce fewer adverse effects (SEDA-7, 2) (SEDA-8, 13). No one has yet documented any serious synergistic toxicity from a combination of theophylline and a beta-adrenoceptor agonist in appropriate doses (SEDA-15, 1), and it seems clear that the patient with severe asthma who is undertreated is much more at risk of dying than one who receives concomitant theophylline and adrenergic drug treatment in appropriate doses and sequence (SEDA-9, 10). At any rate, the most appropriate maintenance therapy continues to be debated. In recent years, it has been customary to use a combination of a beta-adrenoceptor agonist and a nontheophylline formulation, such as a steroid inhaler. However, it should be noted that the finding that theophylline has significant effects on basophils and eosinophils renewed an interest in theophylline.

Adverse reactions to theophylline are more common in patients who are concurrently taking a tetracycline (SED-9, 4).

Adenosine

Theophylline increases the dose of adenosine needed for conversion of supraventricular tachycardia, through competitive inhibition at purine receptors (46).

Caffeine

Caffeine can accumulate to toxic concentrations during treatment with theophylline (47). Likewise, concomitant administration of caffeine and theophylline can significantly increase plasma theophylline concentrations and reduce the clearance rates of theophylline and its metabolites (48).

Calcium channel blockers

Theophylline toxicity has been reported in several patients, apparently stabilized on theophylline, after the introduction of verapamil (49) or nifedipine (50).

Cephalosporins

The interaction between certain cephalosporins (including moxalactam) and the alcohol in theophylline elixir can cause a disulfiram-like reaction (51).

Citalopram

Both theophylline and citalopram are metabolized by CYP1A2. In an open, multiple-dose study in 13 healthy nonsmoking volunteers, steady-state citalopram therapy had no significant effect on theophylline metabolism. The authors suggested that dosage adjustment of theophylline may not be necessary in patients taking concurrent citalopram (52). The most frequent treatment-related adverse effects were fatigue and nausea.

Corticosteroids

In a single-dose study of the interaction of theophylline with prednisolone, the plasma concentrations of both drugs were slightly lower when they were given in combination than when given alone (53).

The kinetic behavior of theophylline given concomitantly with methylprednisolone and auranofin to six women suggested a possible interaction of theophylline with auranofin, although a role of the corticosteroid could not be ruled out. The observed concentrations of theophylline were lower than expected, suggesting the need to measure serum theophylline concentrations in patients who also take steroids and gold salts (54).

Digoxin

Despite the ability of theophylline to reduce blood concentrations of digitalis in digitalis intoxication (55), therapeutic doses of theophylline can cause dysrhythmias in the presence of concentrations of digoxin in the high part of the usual target range (56).

Fluvoxamine

Fluvoxamine is a potent inhibitor of cytochrome CYP1A2, which may lead to interactions with several tricyclic antidepressants and theophylline (57).

Furosemide

Intravenous furosemide reportedly increased steady-state theophylline concentrations by about 20% (SED-11, 428). However, this result has not been confirmed (58).

© 2006 Elsevier B.V. All rights reserved.

GABA receptor antagonists

Carbapenems (imipenem more than meropenem) are believed to increase central nervous system excitation by inhibition of GABA binding to receptors. Combinations with other GABA-inhibiting drugs, such as theophylline or quinolones, have been reported to provoke seizures (59,60).

Gold salts

The kinetic behavior of theophylline given concomitantly with methylprednisolone and auranofin to six women suggested a possible interaction of theophylline with auranofin, although a role of the corticosteroid could not be ruled out. The observed concentrations of theophylline were lower than expected, suggesting the need to measure serum theophylline concentrations in patients who also take steroids and gold salts (54).

Lithium

Theophylline increased the renal clearance of lithium, with resultant lowering of the serum lithium concentration (61).

Macrolides

The most frequently observed effects of macrolides on theophylline pharmacokinetics are increases in half-life and serum theophylline concentrations and reduced clearance (62). The interaction with theophylline is mainly seen with higher doses of macrolides and can result in theophylline toxicity (63).

Ciprofloxacin

Serious theophylline toxicity has been attributed to ciprofloxacin (64).

- A 79-year-old woman presented with a generalized seizure. She had long-standing asthma, and her admission medication included steroid and salbutamol inhalers, oral prednisolone, and oral modified-release aminophylline 450 mg bd. Plasma theophylline concentrations over the previous 3 years had been 8–12 μg/ml (44–66 μmol/l) without apparent toxicity. Seven days before presentation she had developed a fever and cough productive of green sputum, and had been given ciprofloxacin 500 mg bd. Despite adequate gas exchange, she developed repeated episodes of self-terminating supraventricular tachycardia, associated with hypokalemia (serum potassium 3.2 mmol/l), acidosis (pH 7.05), hypotension, and difficulty in breathing. The theophylline concentration was 33 μg/ml (183 μmol/l). Renal function was normal, and no other causes of fits or dysrhythmias were apparent. She was unable to tolerate oral activated charcoal and hemodialysis was started. After 2 hours of dialysis, the plasma theophylline had fallen to 15 μg/ml (177 μmol/l), she was in sinus rhythm, and her serum potassium was 3.8 mmol/l. She made an uneventful recovery.

Erythromycin

Erythromycin can increase the serum concentrations of theophylline by 20–25%. However, patients with an average serum concentration of theophylline under 15 μg/ml will probably have only a small increase in their serum theophylline concentration during erythromycin therapy, whereas patients with steady-state concentrations above 15 μg/ml deserve careful monitoring and close observation for symptoms of theophylline toxicity during treatment with erythromycin (65,66).

Fatal aminophylline toxicity has been described, precipitated by the concomitant administration of erythromycin (64).

- A 55-year-old man with a long history of bronchiectasis and severe obstructive pulmonary disease presented with a chest infection, having been taking oral modified-release aminophylline 450 mg bd for 4 years, with trough concentrations always in the range 6–12 μg/ml (33–66 μmol/l) and no apparent toxicity. Two days before admission, his general practitioner had prescribed trimethoprim 200 mg bd for a suspected urinary tract infection. On the day of admission, he was given cefotaxime 1 g intravenously bd and erythromycin 500 mg orally qds. Other medications included captopril 25 mg tds, furosemide 80 mg bd, ranitidine 150 mg bd, protriptyline 10 mg tds, and inhaled budesonide. He was anxious and had a fine tremor, but his gas exchange was satisfactory. He had chronic renal impairment of uncertain cause and hyperkalemia (5.5 mmol/l). The possibility of aminophylline toxicity was raised, but despite this, he received three doses of erythromycin. The plasma theophylline was 66 μg/ml (363 μmol/l). He had an episode of ventricular tachycardia and fibrillation, was successfully resuscitated, but had a second episode of ventricular tachycardia 30 minutes later, from which he could not be resuscitated. The plasma theophylline concentration at the time of his second cardiac arrest was 58 μg/ml (319 μmol/l).

These cases of interactions of aminophylline with macrolide antibiotics illustrate that serious, even fatal, adverse effects can occur when possible interactions are not considered. In both cases, experienced physicians prescribed appropriate antimicrobial drugs, but omitted to consider the possibility of interactions with aminophylline, and failed to reduce the dose of aminophylline or to measure theophylline concentrations. In the first case the development of tachycardia, hypokalemia, acidosis, vomiting, and convulsions can be explained on the basis of theophylline toxicity caused by ciprofloxacin, while in the second the anxiety, tremor, and cardiac arrests could all have resulted from an interaction of aminophylline and erythromycin. These cases add to an extensive literature that emphasizes the potential for interaction between aminophylline and drugs metabolized by CYP1A2.

Prulifloxacin

Prulifloxacin reduced the elimination of theophylline in healthy volunteers (67) presumably by inhibiting cytochrome CYP1A2.

Mexiletine

Mexiletine reduces the clearance of theophylline, and this combination has been reported to cause ventricular

© 2006 Elsevier B.V. All rights reserved.

tachycardia (68). A similar interaction with caffeine has been reported (69).

Olanzapine

In healthy subjects, olanzapine did not affect theophylline pharmacokinetics (70). These results confirm the earlier reported *in vitro* findings that olanzapine is not a potent inhibitor of CYP1A2 (71).

Pancuronium

Antagonism to pancuronium has been found with theophylline concentrations in excess of the recommended target range (SEDA-5, 4).

Aminophylline appears to facilitate neuromuscular transmission, perhaps by increasing neurotransmitter release through raising cyclic AMP concentrations at the neuromuscular junction by phosphodiesterase inhibition (72). This would account for the antagonism of pancuronium-induced blockade that has been reported to occur in the presence of very high serum concentrations of theophylline (73). A similar effect should theoretically occur with other nondepolarizing relaxants.

Phenobarbital

Co-medication with phenobarbital may require an increase in the theophylline dose by about 30%; concurrent use with phenytoin may require an increase of as much as 75% (45).

Proton pump inhibitors

Co-administration of either lansoprazole or pantoprazole in healthy subjects did not affect the steady-state pharmacokinetics of theophylline in therapeutic doses (74).

Quinine

Quinine increased serum theophylline concentrations in an elderly patient (75).

Quinolones

Levofloxacin has been reported to interact with theophylline.

- A 59-year-old Japanese man taking theophylline for emphysema had stimulation, insomnia, and tachycardia owing to theophylline toxicity after he also took levofloxacin and clarithromycin (76). His theophylline clearance returned to normal and his symptoms resolved after withdrawal of levofloxacin, while clarithromycin was continued.

In a randomized, multiple-dose, period-balanced, three-way, crossover study in healthy nonsmoking male volunteers, moxifloxacin did not alter the pharmacokinetics of theophylline (77).

In seven healthy volunteers taking modified-release theophylline, intravenous pazufloxacin mesilate increased serum theophylline concentrations; analysis of the urinary excretion of theophylline and its metabolites suggested that CYP1A2 had been inhibited (78). Theophylline concentrations need to be monitored if pazufloxacin is co-administered.

Tacrolimus

An interaction of theophylline with tacrolimus has been described (79).

- A 33-year-old man with end-stage renal disease due to diabetic nephropathy received a cadaveric kidney graft. Immunosuppressive therapy after transplantation included tacrolimus (7 mg/day), azathioprine (75 mg/day), and prednisone (7.5 mg/day). He developed erythrocytosis 3 months later and was given drugs that reduce erythropoietin production, first enalapril, without success, and then theophylline (600 mg/day). After 1 month, his serum creatinine and tacrolimus concentrations were raised. The dosage of theophylline was therefore reduced to 300 mg/day four times a week. One month later, his serum creatinine and tacrolimus trough blood concentrations increased further. On withdrawal of theophylline, both renal function and tacrolimus trough blood concentration rapidly normalized. Theophylline was then reintroduced in a lower dose and increased the AUC of tacrolimus.

CYP3A4 is primarily responsible for tacrolimus biotransformation in the liver, but it has only a minor role in theophylline metabolism. It is therefore surprising that this tacrolimus–theophylline interaction occurred. The authors suggested that as long as renal function remains stable, low-dose theophylline can be used in transplant patients with erythrocytosis, provided that tacrolimus concentrations are closely monitored.

Tegaserod

The effect of tegaserod on the single-dose pharmacokinetics and safety profile of theophylline has been determined in a randomized, open, crossover study in 18 subjects (80). Tegaserod did not alter the pharmacokinetics of theophylline and the incidence of adverse events was similar after co-administration. However, since in vitro studies have shown that tegaserod inhibits CYP1A2 (81), more evidence is needed to claim that no dosage adjustment is required when theophylline is co-administered.

Terbinafine

In a randomized crossover study in 12 healthy volunteers, terbinafine increased the AUC of theophylline by 16%, with a 14% reduction in clearance and a 24% prolongation of half-life (82). The clinical impact of these results is difficult to define because of the small sample size in this study and because it is not known what effect terbinafine has on steady-state theophylline concentrations. An earlier study (83) showed that terbinafine reduced the clearance of caffeine, which is metabolized via similar pathways. Until more information is available, clinicians who prescribe terbinafine for patients taking chronic theophylline therapy should be cautious, and serum theophylline concentrations should be monitored.

Tocainide

Tocainide reduces the clearance of theophylline and increases its half-life, but to an extent that is probably clinically insignificant (84).

© 2006 Elsevier B.V. All rights reserved.

Trimethoprim

Two episodes of severe hyponatremia have been described in the same patient, one attributed to theophylline and the other to trimethoprim (85). The evidence to support an interaction is circumstantial, and the patient was taking multiple medications, making interpretations difficult.

Food-Drug Interactions

Food can affect both the absorption and the clearance of theophylline. One study showed that the absorption of a modified-release formulation of theophylline was very slow after an overnight fast, in contrast to absorption after a test meal (86). The effect may be dose-related. More specifically, dietary protein significantly affects theophylline clearance: a low-protein diet reduces theophylline clearance and a high-protein diet increases it. The implications for clinical practice have not been elaborated, but dietary extremes are contraindicated in patients taking theophylline (51).

Thiacetazone

See also Antituberculosis drugs

General Information

Thiacetazone (thioacetazone, thiosemicarbazone) was greeted enthusiastically in 1946 as one of the first synthetic agents against tuberculosis. However, its use rapidly diminished with the increasing observation of untoward effects. It is currently rarely used and then only for economical reasons. Dosages should never exceed 200 mg/day.

Adverse effects of thiacetazone include bone marrow depression and hemolytic anemia. It can also cause serious skin rashes. Continuous laboratory and clinical observations are required (1).

Organs and Systems

Hematologic

Adverse effects of thiacetazone include bone marrow depression, with anemia, leukopenia, agranulocytosis, and thrombocytopenia (2–4). Hemolytic anemia has also been described (5).

Gastrointestinal

Anorexia, nausea, and vomiting are not uncommon with thiacetazone (1).

Urinary tract

Hepatotoxicity with jaundice is frequent with thiacetazone (1).

Skin

Adverse effects of thiacetazone on the skin are of various types, mainly erythematous and maculopapular rashes, angioedema, purpura (6), toxic epidermal necrolysis, Stevens–Johnson syndrome, and pigmentation (7).

Of 50 cases of cutaneous adverse effects of thiacetazone, there were 48 cases of erythema multiforme (25 cases of Stevens–Johnson syndrome and 23 of toxic epidermal necrolysis), one case of erythrodermia, and one case of lichenoid toxidermia; there were 20 deaths, 16 with toxic epidermal necrolysis and four with Stevens–Johnson syndrome (8).

In a retrospective study, 38 cases of toxic epidermal necrolysis were observed in Dakar, and were attributed to thiacetazone in 24 cases; 23 died, mainly because of hypovolemic shock during the first week and septic shock during the second (9). Those who died were generally aged over 50 years, had more than 50% skin involvement, and had evolving tuberculosis at the time of presentation or HIV infection. After-effects were vaginal synechia and two cases of blindness.

Immunologic

Cutaneous allergic reactions to thiacetazone are very common in HIV-positive patients, in the order of 20%. Ethambutol should therefore be used instead of thiacetazone in these patients (10).

Susceptibility Factors

Arguments have been advanced for the abandonment of thiacetazone as an antituberculosis drug (11,12), despite its cheapness, on the grounds that it often causes severe skin reactions, some rapidly fatal, in patients infected with HIV-1 (13). The WHO and IUATLD has recommended careful information and surveillance of possible adverse reactions, particularly cutaneous, in patients treated for tuberculosis in such countries and immediate replacement with ethambutol if there are any prodromal signs of toxicity.

Anergy to tuberculin and lymphopenia have been associated with an increased risk of adverse reactions to thiacetazone. In a randomized study of rifampicin- and thiacetazone-containing regimens in HIV-positive adults with pulmonary tuberculosis, eight of 13 patients who developed adverse reactions were tuberculin-anergic, compared with 12 of 77 patients who did not develop adverse reactions (13). An absolute lymphocyte count below 2.0×10^9/l was also associated with adverse reactions.

Drug–Drug Interactions

Isoniazid

Thiacetazone combined with isoniazid (and possibly thioacetazone alone) has been reported to damage chromosomes in cultured human lymphocytes (14).

Thiamine

See also Vitamins

General Information

The requirement for thiamine depends on the utilization of energy-yielding substrates, and increases with energy expenditure; it is therefore expressed relative to energy intake (here given in mega-Joules, MJ, formerly often given per 1000 kilocalories (kcal) which is a better known but outdated terminology). The Average Requirement is 72 micrograms/MJ/day, the Population Reference Intake is 100 micrograms/MJ/day, and the Lowest Threshold Intake is 50 micrograms/MJ/day. Expressed for average energy expenditure, this would mean an Average Requirement of 0.8 mg/day for men and 0.6 for women, a Population Reference Intake of 1.1 and 0.9 mg/day, and a Lowest Threshold Intake of 0.6 and 0.4 mg/day (1).

Excess thiamine is normally readily cleared by the kidneys. Important adverse reactions are usually associated with parenteral feeding with doses much larger than the Population Reference Intake and over long periods of time. Most common are hypersensitivity reactions, which have been observed mainly after parenteral administration. The symptoms and signs are weakness, precordial pain, palpitation, dyspnea, epigastric pain, vomiting, itching, erythema, scaling of the facial skin, severe rash, tachycardia, hypotension, purpura, semicoma, and even fatal anaphylactic shock.

Despite its favorable safety profile, it cannot be assumed that thiamine is completely innocuous. Thiamine hydrochloride is routinely given to patients with Wernicke's encephalopathy or malnourished states (such as malabsorption, beri-beri, cancer, AIDS, and chronic alcohol abuse). Systemic reactions are rare but deaths can occur.

Organs and Systems

Respiratory

Respiratory failure has been reported after parenteral administration of high doses of thiamine, albeit on only a single occasion (2).

Skin

Thiamine hydrochloride, and possibly its intermediates such as thiothiamide, can cause allergic contact dermatitis (3,4). A prospective study of the toxicity of parenteral thiamine hydrochloride in a large group of patients showed adverse reactions in only 1.1% of the cases, mainly in the form of local irritation. Only one out of the 11 adverse reaction cases was serious (5).

Immunologic

Anaphylactic shock is a major adverse effect of thiamine, and can be life-threatening. It is IgE-mediated (6) and usually occurs after multiple parenteral dosages (6–10) but occasionally also after intramuscular injection. In some cases oral challenge did not produce any reaction (8,11,12).

- A 51-year-old woman with diabetes mellitus, chronic alcoholism, and anxiety disorder became acutely confused and was given 50% dextrose 25 g and thiamine hydrochloride 100 mg intravenously; 20 minutes later she became deeply cyanosed with shallow labored breathing at 28/minute, hypertensive, and tachycardic, with respiratory and metabolic acidosis and a blood alcohol concentration of 124 mg/dl (27 mmol/l) (13). The next morning she was communicative and oriented and her vital signs and blood gases were normal. She was given thiamine hydrochloride intravenously and within moments developed shortness of breath, warmth, and tightness of the throat. She had a tachycardia, hypotension, hypoxia, and central cyanosis. She recovered within 24 hours.

© 2006 Elsevier B.V. All rights reserved.

In 989 consecutive patients (1070 doses) there were 12 adverse reactions (1.1% of doses), comprising local irritation in 11 cases and a major skin reaction in the 12th. The authors concluded that thiamine hydrochloride can safely be given intravenously and that intradermal test doses before administration are not warranted unless patients have had previous allergic reactions (5).

Drug–Drug Interactions

Cancer chemotherapy

In a review it was suggested that thiamine when given to patients with cancer may interfere with chemotherapy in that thiamine may promote nucleic acid ribose synthesis and tumor cell proliferation via the transketolase pathway. The authors suggest that an oversupply of thiamine may actually do harm and may be responsible for the failure of therapeutic attempts to terminate cancer cell proliferation (14). Thiamine is directly involved in ribose synthesis in pancreatic adenocarcinoma cells through transketolase-catalysed non-oxidative pentose phosphate reactions. In addition, the chemically modified co-factor oxythiamine inhibited tumor cell proliferation in vitro and in vivo by 40% and 91% in two distinct tumor models (14). According to a review of thiamine supplementation in patients with cancer this raises serious suspicions that routine thiamine administration may not be warranted and could possibly be harmful (15). Thiamine deficiency in cancer patients is most often observed during or shortly after chemotherapy. Clinical and experimental data have shown increased thiamine utilization by human tumors and its interference with experimental chemotherapy. Current thiamine administration protocols oversupply thiamine by 200–20 000% of the RDA, because it is considered harmless and needed by cancer patients. However, since the thiamine-dependent transketolase pathway is the main reaction that supplies ribose phosphate for nucleic acids in tumors, excessive thiamine supplementation may be responsible for failed therapeutic attempts to terminate cancer cell proliferation. The authors therefore recommended that cancer management should include regular evaluation of thiamine status of the patient, especially during chemotherapy, and that dosages of thiamine should not exceed 1.2 mg/day unless necessary. Future studies should clarify whether oxythiamine as an inhibitor of transketolase is really safe and whether it is especially effective against cancer.

Thiamphenicol

General Information

Thiamphenicol is a semisynthetic derivative of chloramphenicol, an amine derivative of hydrocarbylsulfonylpropandiol. It differs in that the NO_2 group in the para position is replaced by a methylsulfonyl group. The substitution in the para position of the molecule does not influence its effects on either protein or DNA synthesis in any recognizable way. The antibacterial spectrum is almost identical to that of chloramphenicol.

The two drugs are used in similar dosages, although there are large differences in their elimination. Glucuronidation is unimportant for thiamphenicol: over 90% of a therapeutic dose is excreted by the kidneys in unchanged form. The corresponding figure for chloramphenicol is only about 10%. Thus, in contrast to chloramphenicol, the half-life of thiamphenicol is prolonged in patients with reduced renal function in whom accumulation can occur.

Although the mechanism by which chloramphenicol causes aplastic anemia is not fully understood, all the available evidence suggests that the biochemical consequences of thiamphenicol administration and the risk of serious complications differ from those of chloramphenicol (1).

© 2006 Elsevier B.V. All rights reserved.

It does not seem unreasonable, therefore, to use thiamphenicol for wider indications than chloramphenicol, provided that the dosage is adjusted according to renal function. However, thiamphenicol has adverse effects on bone marrow, calling for a degree of caution. It is therefore generally recommended that thiamphenicol should not be given for more than 10–14 days.

The most important adverse effects are an immediate dose-related and reversible disturbance of erythropoiesis (2,3) and peripheral neuropathy. In contrast to chloramphenicol, aplastic anemia and the gray syndrome do not seem to occur with thiamphenicol.

Observational studies

Thiamphenicol has been used to treat 1171 patients with chancroid (4). Each patient was given granulated thiamphenicol 5.0 g orally in a single dose. Only 0.89% did not respond. A few patients had adverse effects, including epigastric pain, headache, nausea, and skin rashes; all were mild and of short duration.

Organs and Systems

Nervous system

Several cases of peripheral neuropathy after the administration of thiamphenicol for 3–5 months have been reported and were thought to be due to a vitamin deficiency. In most cases the sensory function of the nerves of the legs was primarily affected. When discovered early, the damage was reversible, but in other cases it tended to persist (5).

Hematologic

There is evidence that thiamphenicol is more potent than chloramphenicol in causing the early dose-related and therefore predictable type of bone marrow toxicity. Many studies have shown that thiamphenicol in a dose of 1.5 g, and to a much lesser extent 0.75 g/day, causes an immediate disturbance of erythropoiesis in almost every case (6). Alterations in the bone marrow become most evident in patients with renal disease and in elderly subjects (probably because of reduced renal function). Leukocytes and thrombocytes are only slightly affected (7).

Most reviewers have been impressed by the fact that the reported cases of peripheral cytopenia were never accompanied by bone marrow aplasia (8). There have been some doubtful case reports of marrow aplasia, in which factors such as advanced age (predisposing to antibiotic accumulation), neoplasia, concurrent treatment (myelotoxic drugs, anticoagulants), and major surgical interventions have to be mentioned. Even if these cases are to be ascribed to thiamphenicol, they fall within the normal spontaneous incidence of aplastic anemia (9–12).

The most severe hematological changes were reported after treatment of typhoid fever and sepsis with relatively high doses of thiamphenicol. These changes have always been reversible on withdrawal. The serum iron concentration returned to normal within a few days and was rapidly followed by reticulocytosis. Experimental results strongly suggest that the toxic effect of thiamphenicol is temporary and that recovery of the bone marrow after drug-induced suppression is complete, with no subsequent risk of myelodysplasia or leukemic transformation (13).

The occurrence of acute leukemia has been studied in relation to preceding use of drugs (before the 12 months preceding the diagnosis) in a case-control study of 202 patients aged over 15 years with a diagnosis of acute leukemia and age- and sex-matched controls (14). Among users of chloramphenicol or thiamphenicol the odds ratio for any use was 1.1 (0.6–2.2) whereas the odds ratio for high doses was 1.8 (0.6–5.3). Other systemic antibiotics showed no substantial relation with the occurrence of leukemia.

Gastrointestinal

Diarrhea, nausea, or constipation occur in under 10% of cases and are usually mild (15).

Skin

Alopecia has been reported in patients with renal insufficiency taking thiamphenicol, and can lead to complete baldness (6). After withdrawal, normal hair growth will recover. Other skin reactions are rare.

Immunologic

Thiamphenicol has immunosuppressive properties, which are ascribed to an effect on immunocompetent cells, rather than on immunoglobulin synthesis (16). In animals, thiamphenicol prolonged the survival of skin homografts (17).

Second-Generation Effects

Fetotoxicity

Although thiamphenicol penetrates the fetal circulation and is distributed evenly in fetal tissues, no fetal abnormalities have been related to thiamphenicol administration during pregnancy (18). Since mitochondrial protein synthesis in the fetal liver is inhibited by the drug concentrations normally attained, repeated administration of thiamphenicol to pregnant women is not recommended.

Susceptibility Factors

Renal disease

Impaired renal function is an important risk factor for toxic effects of thiamphenicol (19).

Other features of the patient

Pre-existing bone marrow dysfunction and prolonged treatment is an important risk factor for toxic effects of thiamphenicol (20).

Thiamylal sodium

See also General anesthetics

General Information

Thiamylal sodium is a short-acting intravenous barbiturate anesthetic.

Organs and Systems

Electrolyte balance

Severe hypokalemia occurred in a 14-year-old boy undergoing emergency aortic arch replacement under deep hypothermic cardiopulmonary bypass (1). He was treated with thiamylal by infusion, total dose 30 mg/kg, for persistent convulsive waves on his electroencephalogram. This caused his serum potassium concentration to fall to 1.6 mmol/l. The hypokalemia was resistant to potassium chloride infusion 80 mmol/hour, but responded to replacing the thiamylal infusion with midazolam. It was noted that there have also been reports of severe hypokalemia in brain-injured patients undergoing thiopental coma therapy.

Thiazide diuretics

See also Diuretics

General Information

Although one thiazide diuretic may be 100 times more potent than another weight for weight, all these drugs have essentially the same properties. Their mechanism of action (inhibition of sodium and chloride reabsorption in the distal convoluted tubule of the kidney) is identical and they can therefore be dealt with as a group. Thiazide-like diuretics, structurally different from the thiazides, have similar actions. Thiazide and thiazide-like diuretics are listed in Table 1.

Like all diuretics, the thiazides can cause electrolyte abnormalities, such as hypokalemia and hyponatremia, and dehydration. These complications are uncommon in patients with uncomplicated hypertension, but are more common in patients with heart failure or decompensated hepatic cirrhosis with secondary hyperaldosteronism. Until a patient is accustomed to the effect of a diuretic, dizziness may be experienced. Serum lipid concentrations are slightly raised acutely and hyperglycemia can occur during long-term therapy. Rare effects are thrombocytopenia, rashes, drug fever, cholestatic jaundice, pancreatitis, and precipitation of hepatic

encephalopathy in patients with hepatic cirrhosis. Generalized allergic vasculitis has been described occasionally. There is no evidence that the thiazides induce tumors. Second generation effects have not been reported.

Organs and Systems

Cardiovascular

Although dizziness is a fairly frequent complaint at the beginning of diuretic treatment (1), postural hypotension is rarely reported. Ischemic complaints (mesenteric infarction and transient cerebral ischemic attacks) have been observed in elderly patients, but it is not clear whether these resulted from diminished organ perfusion or from an effect of the drug itself. The former is more likely, since similar problems have arisen with any form of antihypertensive treatment in old people who have to some degree become dependent on their hypertension to ensure a blood supply through sclerotic vessels.

Criticism directed against the diuretics in recent years has among other things sought to show that they increase the risk of coronary events, including acute myocardial infarction. However, there is no real basis for such criticism. Properly used in hypertension the diuretics produce a beneficial effect out of all proportion to any incidental adverse cardiac effects.

- A 72-year-old woman had repeated episodes of sudden-onset pulmonary edema, each occurring immediately after she took a dose of hydrochlorothiazide 12.5 mg (2).

The close temporal relation between the ingestion of hydrochlorothiazide and the onset of symptoms, together with rapid and full clinical recovery after withdrawal of therapy, suggested drug-induced pulmonary edema and possible anaphylactoid hypotension.

Respiratory

In the older literature there were various reports of acute allergic interstitial pneumonitis caused by the thiazides, sometimes confirmed by rechallenge. Typically, it presents within an hour of taking the drug and causes chest pain, breathlessness, or both; the chest X-ray is characteristic (3,4). Recovery is rapid, but assisted ventilation may be needed. Most cases in the recent literature relate to hydrochlorothiazide, but that may simply reflect its wide use. A case involving chlorothiazide (5) suggests that this syndrome can arise with any thiazide, although it sometimes occurs after the first dose of hydrochlorothiazide when other thiazides have been well tolerated. The incidence is unknown, but recent work has confirmed that it is rare. No susceptibility factors have been identified. It can occur on initial exposure or subsequent rechallenge. The mechanism is obscure, but an immunological basis has been suggested.

The reason for concern about this adverse effect is that it may easily be mistaken for myocardial infarction or acute left ventricular failure, conditions that are not uncommon in patients requiring diuretics.

Diffuse interstitial pulmonary fibrosis has been reported after treatment with cyclopenthiazide and triamterene (6).

Sensory systems

Visual disturbances caused by dehydration of lens tissue or by retinal edema have been reported, particularly in the first few weeks of treatment. On the whole these effects are innocuous and transient (SED-9, 354). Presenile cataract has been attributed to long-term use of hydrochlorothiazide (7).

Electrolyte balance

Sodium balance

Hyponatremia is the most common electrolyte abnormality in the general hospital population and is associated with a wide range of diseases and a variety of drugs. Acute hyponatremic encephalopathy can develop rapidly with diuretics, particularly thiazides. Women, all patients with hypokalemia, and those with a low sodium and/or solute intake are particularly susceptible to diuretic-induced hyponatremia.

In a hospital-based survey of hypertensive patients with hyponatremia (serum sodium concentration below 135 mmol/l) the odds ratio for hyponatremia was three times higher in women. In those over 65 years there was a 10-fold higher risk. In many instances hyponatremia was insidious in its presentation and did not occur until several months after therapy had begun (8). However, hyponatremia can also develop rapidly.

- A 69-year-old woman with uncontrolled hypertension took two doses of hydrochlorothiazide 25 mg and her serum sodium fell to 115 mmol/l within 24 hours, with accompanying neurological symptoms (9). She recovered fully with the administration of 3% saline.

Potassium balance

The thiazides increase potassium excretion, but rarely to such an extent that total body potassium stores are appreciably affected. In most patients there is no reason to think

© 2006 Elsevier B.V. All rights reserved.

that long-term diuretic treatment will deplete body potassium at all. This is discussed in the monograph on Diuretics.

Mineral balance

Thiazides and related diuretics reduce the renal clearance of calcium by inhibiting the tubular secretion of calcium ions. This is discussed in the monograph on Diuretics.

Metal metabolism

Magnesium

Hypomagnesemia is common with both loop and thiazide diuretics. In 242 patients the frequency was 19% (10). It was corrected with potassium magnesium citrate, whereas potassium citrate or potassium chloride alone had little corrective effect.

Diuretic-induced hypomagnesemia is of particular relevance to patients with congestive heart failure (11). There is a reduced rate of sudden cardiac death in patients who take long-term diuretic therapy when potassium- and magnesium-sparing diuretics and/or magnesium supplements are also used. All potassium-sparing diuretics are also magnesium-sparing, and diuretic-induced hypokalemia is difficult to correct unless underlying magnesium deficiency is also addressed (12).

Zinc

Thiazide diuretics promote zinc loss in the urine and can reduce the zinc content of hair in the long term (13). It has sometimes been suggested that changes in zinc balance could be responsible for the effects of thiazides on sexual potency. There is evidence that diuretics deplete body zinc, which in turn interferes with testosterone production and causes erectile impotence (14).

Hematologic

Thrombocytopenia has been reported, but its incidence is low (SED-8, 484). Even rarer complications are autoimmune hemolytic anemia, granulocytopenia, and agranulocytosis (SED-9, 354).

Acute intravascular hemolysis has been described in a single case, and in this instance there were antibodies to hydrochlorothiazide; methyldopa, which had been given concurrently, might have facilitated antibody formation (15).

Gastrointestinal

Nausea and vomiting have often been reported, but if the incidence is compared to that in a control group taking placebo (1), it seems to be negligible, even in hospital (16), and such complaints rarely necessitate a change of therapy. The high incidence reported in the past (SED-9, 354) was probably related to the sheer size of the chlorothiazide tablets, and it has almost disappeared since the general change to more potent thiazides and related drugs.

Liver

Jaundice has very rarely been attributed to thiazide diuretics (SED-9, 354).

- Rash, lymphadenopathy, splenomegaly, periorbital edema, and hepatitis occurred in an 18-year-old woman who was taking phenobarbital and hydrochlorothiazide (17). Tests for fluorescent antinuclear antibody and hepatitis-associated antigen and antibody were negative. Liver biopsy was not characteristic of viral hepatitis. She recovered within 2 weeks after withdrawal of the drugs and administration of methylprednisolone and diphenhydramine.

Biliary tract

Studies of the relation between diuretic use and cholecystitis have yielded conflicting results. A significant association of thiazide use with acute cholecystitis was reported in a case-control study (18). However, others examined the association between the use of thiazides and cholecystectomy and failed to show a relation between the use of thiazides and gallstone disease, except possibly in women who are not overweight (19).

Pancreas

Pancreatitis has been reported occasionally with thiazides (SED-9, 354) (SEDA-5, 228) (SEDA-17, 263).

Urinary tract

Toxic damage to the kidney has occasionally been reported (20), but is rare, and it is not clear whether nephrotoxicity was due to severe hypokalemia or the drug itself.

Thiazide diuretics cause hyperuricemia and can occasionally precipitate gout (21). They can also cause renal stones (22). Uric acid precipitation is not normally a problem, although it was with the uricosuric drug tienilic acid.

Renal vasculitis due to thiazides is rare (SEDA-18, 234).

Skin

Rashes due to thiazides are common but are only very occasionally severe and disabling (SEDA-11, 198). A state of chronic photosensitivity can persist for many years after drug withdrawal and is difficult to treat (23); it can mimic contact dermatitis, and there can be cross-reactivity with sulfonamides and phenothiazines. Patients who develop photosensitivity to thiazides should never take these drugs again.

Several cases of a reaction resembling systemic lupus erythematosus have been described (24–26). One patient taking hydrochlorothiazide developed unequivocal antinuclear antibody (ANA) positivity, with the homogeneous pattern most commonly found in drug-induced lupus (27). It is uncertain whether thiazides cause a lupus-like syndrome or activate latent disease in predisposed individuals.

Two of nine patients with drug-induced toxic epidermal necrolysis were taking hydrochlorothiazide, one with triamterene and allopurinol, the other with reserpine and hydralazine; both died (28).

In a patient who developed an allergic vasculitis affecting the skin during long-term treatment with hydrochlorothiazide the findings suggested that immediate (Type I) hypersensitivity may be involved in the induction of vasculitis (29).

- A 60-year-old man with a history of renal insufficiency and hypertension, taking hydrochlorothiazide,

© 2006 Elsevier B.V. All rights reserved.

furosemide, and amiloride, developed pellagroid dermatitis involving light-exposed areas (30). The pigmentation disappeared slowly after withdrawal of hydrochlorothiazide and amiloride.

Hydrochlorothiazide, which is a well-known photoallergen, can also cause allergic photodermatitis (31).

- A 77-year-old man developed a florid photosensitive lichenoid eruption, histologically confirmed, while taking thiazide diuretics for heart failure (32). The eruption cleared on withdrawal of the drug. Although thiazide-induced photosensitivity is well documented, there have been no histologically proven cases of a lichenoid eruption in light exposed areas.

Immunologic

It has long been thought that loop and thiazide diuretics pose a theoretical risk of cross-sensitivity in patients with sulfonamide allergy because of their common structures. However, the available literature does not provide sufficient numbers of well-documented cases to support this impression (33). It seems that careful administration of diuretics is permissible in patients with documented sulfonamide allergy, but as always such a drug challenge should not be attempted without careful follow-up. A furosemide rechallenge protocol, based on a method that has been used to rechallenge with a sulfa-containing antimicrobial agent, safely allowed the long-term reinstitution of loop diuretic therapy with furosemide (34).

Second-Generation Effects

Pregnancy

In the past, thiazide diuretics have been considered as being contraindicated in pregnancy, because of risks to the mother and fetus. However, more recent evidence suggests that their use need not be contraindicated (35).

Susceptibility Factors

Age

The risks and benefits of distal tubular diuretics have been assessed in preterm infants under 3 weeks of age with or developing chronic lung disease (36). Acute and chronic administration of distal diuretics improved pulmonary mechanics; adverse effects were not reported. However, additional studies are needed to assess whether thiazide administration improves mortality, duration of oxygen dependency, ventilator dependency, length of hospital stay, and long-term outcome in patients exposed to corticosteroids and bronchodilators, and whether adding spironolactone to thiazides or adding metolazone to furosemide has any beneficial effect.

Other features of the patient

Thiazides should be used with caution in patients with a history of gout.

The use of thiazide diuretics in hepatic cirrhosis is associated with a high incidence of severe hypokalemia, asterixis, and precipitation of encephalopathy (9). Thiazides should not be used in patients with advanced hepatic insufficiency.

Drug–Drug Interactions

ACE inhibitors

Even low dosages of angiotensin-converting enzyme (ACE) inhibitors, such as enalapril, can cause profound first-dose hypotension in hypertensive patients treated with a thiazide (37). This is rare if volume depletion and sodium depletion are avoided.

Angiotensin-converting enzyme inhibitors can cause renal insufficiency in patients with bilateral renal artery stenosis or stenosis of the artery supplying a single functioning kidney. Concomitant diuretic treatment may play a role in this adverse reaction (38).

Allopurinol

Adverse reactions to allopurinol, particularly toxic epidermal necrolysis and a hypersensitivity syndrome, are reputed to be more common in patients taking thiazides, but evidence to support this is hard to find (SEDA-11, 198) (SEDA-13, 188).

Angiotensin-II receptor antagonists

The value of low doses of thiazide diuretics in the management of hypertension is well attested, and low doses of diuretics have synergistic actions with other antihypertensive drug classes, including the angiotensin-II receptor antagonists (39–41). It is still unclear what represents the optimal dose of a thiazide diuretic in combination with either an ACE inhibitor or an angiotensin-II receptor antagonist. The addition of an angiotensin-II receptor antagonist to diuretic therapy seems to blunt the associated electrolyte disturbances. In particular, hydrochlorothiazide-induced hyperuricemia is specifically attenuated by losartan (42).

Beta-blockers

The combination of a thiazide and a beta-blocker can cause hyperglycemia (SEDA-10, 191) (SEDA-19, 192).

Calcium carbonate

Milk-alkali syndrome occurred in a patient who was taking chlorothiazide 500 mg/day for hypertension and calcium carbonate 7.5–10 g/day for heartburn (43).

Ciclosporin

Patients taking diuretics and ciclosporin may be at higher risk of hyperuricemia and gouty complications, perhaps because of tissue breakdown caused by ciclosporin (44).

Lithium

The thiazide diuretics inhibit the tubular excretion of lithium ions and can cause frank lithium intoxication (45). This is a potentially serious and well-documented interaction.

© 2006 Elsevier B.V. All rights reserved.

NSAIDs

Several non-steroidal anti-inflammatory drugs (NSAIDs) have been reported to interfere with the natriuretic effects of thiazides (SED-11, 423). A similar interaction is seen with tenidap, an antiarthritic cytokine modulating drug (46). The salt-retaining properties of the NSAIDs probably play the central role in this interaction.

Non-steroidal anti-inflammatory drugs (NSAIDs) are often reported to interfere with the blood pressure-lowering action of thiazide diuretics (SED-14, 667). In 17 women with arthritis and hypertension taking fosinopril and hydrochlorothiazide, ibuprofen, sulindac, and nabumetone, each for 1 month, had no effect on mean arterial pressure (47). These results suggest that the ACE inhibitor fosinopril may neutralize the tendency of NSAIDs to increase blood pressure in thiazide-treated hypertensive patients. However, the design of this study precluded such a conclusion, since no evidence was provided that any of the NSAIDs increased blood pressure in the absence of fosinopril. Furthermore, the numbers were small and the precision of the comparison is likely to have been low. Careful monitoring of blood pressure is necessary when NSAIDs are introduced in thiazide-treated hypertensive patients, even when ACE inhibitors are co-prescribed.

Oral hypoglycemic drugs and insulin

Thiazide drugs can oppose the blood glucose-lowering effects of oral hypoglycemic drugs and insulin (48) (although this effect is rarely serious).

Potassium-wasting drugs

Thiazide drugs have additive potassium-lowering effects with other drugs that reduce serum potassium, such as corticosteroids and carbenoxolone. Profound hypokalemia due to the latter combination has been reported to cause massive rhabdomyolysis and acute tubular necrosis (49).

Thiazinamium metilsulfate

See also Antihistamines

General Information

Thiazinamium is a first-generation antihistamine (SED-13, 418).

Organs and Systems

Sensory systems

In long-term, double-blind study in 12 men with chronic bronchitis, three who took thiazinamium metilsulfate 900 mg/day had visual disturbances (1).

Gastrointestinal

Thiazinamium can cause attacks of sternal and epigastric pain, perhaps due to esophageal spasm. Esophageal ulceration has been reported (2).

Thiazolidinediones

General Information

The thiazolidinediones include pioglitazone and rosiglitazone; darglitazone is in development; ciglitazone, englitazone, and troglitazone have been withdrawn owing to adverse effects on the liver (all names are rINNs).

The thiazolidinediones reduce insulin resistance and are sometimes designated as insulin sensitizers. They promote glucose utilization in peripheral tissues by stimulating non-oxidative glucose metabolism and suppressing gluconeogenesis. They activate the so-called Peroxisome Proliferator Activated Receptor Gamma (PPARγ), a nuclear hormone receptor that enhances a number of genes encoding enzymes involved in glucose and fat metabolism. PPARγ is essential for normal insulin sensitivity (1–3). They may also intervene directly in the fuel metabolism of skeletal muscle and liver, as suggested by in vitro experiments (4). They can reduce HbA_{1c}, the glucose AUC after a glucose tolerance test, and the glucose AUC after a meal in glucocorticoid-induced diabetes, as has been shown in seven patients taking troglitazone (5). They may ameliorate albuminuria in incipient diabetic nephropathy (6).

© 2006 Elsevier B.V. All rights reserved.

In some systems, troglitazone behaves as a partial agonist, but in fat cells it behaves as a full agonist. The transcriptional activities of troglitazone and rosiglitazone differ (7). The thiazolidinediones promote fat accumulation in subcutaneous tissue (8) rather than in the abdominal region, which plays such a bad role in the insulin resistance syndrome. Troglitazone lowers fasting glucose and postprandial glucose. Its effects persist for 2–3 weeks after withdrawal (9). It is also effective in insulin-resistant glucocorticoid-induced diabetes (10). It has a greater insulin-sparing effect than biguanides when given to patients on continuous subcutaneous insulin infusion (11).

The thiazolidinediones have been frequently reviewed (12–22). They can be prescribed as single drugs or in combination with other hypoglycemic drugs (23). In 12 healthy people, meals did not affect the absorption of rosiglitazone (24).

Comparative studies

In a parallel-group study in patients starting on hypoglycemic therapy with thiazolidinediones, 35 took troglitazone 600 mg/day, 36 took rosiglitazone 8 mg/day, and 30 took pioglitazone 45 mg/day (25). At 2 and 4 months, there was an equal effect on glucose lowering and greater weight gain with pioglitazone; pioglitazone had the largest beneficial effect on lipids and rosiglitazone the least.

In 203 patients, randomly assigned for 1 year to rosiglitazone 4 mg bd or glibenclamide to achieve optimal control, there was significant and sustained reduction in hyperglycemia and a significant reduction in diastolic blood pressure with rosiglitazone (26). There were no differences in adverse effects or in left ventricular mass index.

Placebo-controlled studies

Rosiglitazone monotherapy has been studied double-blind in 493 patients for 26 weeks (27). There was a dose-related fall in hemoglobin. Rosiglitazone caused more mild to moderate edema. One patient had a temporary rise in transaminases, which normalized spontaneously.

In a parallel-group, double-blind, placebo-controlled, dose-ranging study of rosiglitazone 4, 8, and 12 mg/day in 369 patients for 8 weeks after a run-in period, hematocrit and hemoglobin, C peptide, fasting blood glucose, and fructosamine all fell (28). Hepatotoxicity, significant cardiac events, or hypoglycemia were not different from placebo.

In 574 patients taking a sulfonylurea, twice-daily placebo ($n = 192$ patients) was compared with rosiglitazone 1 mg/day ($n = 199$ patients) or rosiglitazone 2 mg/day ($n = 183$ patients) for 26 weeks (29). Rosiglitazone improved HbA_{1c}. With the higher dose of rosiglitazone there were more cases of hypoglycemia and a small increase in mean body weight; some patients complained of headache and upper respiratory tract infections.

In a placebo-controlled study, 959 patients took placebo, rosiglitazone 4 mg od, 2 mg bd, 8 mg od, or 4 mg bd for 26 weeks (30). In the placebo group 38% withdrew and in the rosiglitazone groups 20%. Two patients (one in the placebo and one in the 4 mg bd group) had changes in alanine transaminase of more than three times the upper limit of the reference range. Other adverse events related to edema were seen in 1.6% of the placebo group and in 4.1% of those taking 2 mg bd and 6.6% in those taking 4 mg bd. There were small dose-dependent falls in hemoglobin and hematocrit.

In a multicenter, double-blind, placebo-controlled study, 408 patients took pioglitazone 7.5, 15, 30, or 45 mg/day (31). There was no hepatotoxicity and the overall adverse events profiles did not differ, except for edema in 12 of 329 patients who took pioglitazone. There was a significant fall in triglycerides and a small fall in LDL cholesterol. However, in another study in 150 patients, postprandial triglycerides were not reduced by pioglitazone (32).

In 561 patients with HbA_{1c} concentrations of at least 8.0% on stable treatment with a sulfonylurea, pioglitazone was added for 16 weeks in a double-blind study (33). The incidence of edema increased from 2% in the placebo group to 7%. With pioglitazone there were more episodes of hypoglycemia, a dose-related increase in body weight, and a dose-related fall in hemoglobin. The frequency of adverse cardiovascular effects was the same.

Combinations of oral hypoglycemic drugs

The different mechanisms of action of the various classes of hypoglycemic drugs make combined therapy feasible: the sulfonylureas and meglitinides stimulate insulin production by different mechanisms, the biguanides reduce glucose production by the liver and excretion from the liver, acarbose reduces the absorption of glucose from the gut, and the thiazolidinediones reduce insulin resistance in fat. It is not necessary to wait until the maximal dose of one drug has been reached before starting another. However, sulfonylureas and meglitinides should no longer be used when endogenous insulin production is minimal. Combinations of insulin with sulfonylureas or meglitinides should only be used while the patient is changing to insulin, except when long-acting insulin is given at night in order to give the islets a rest and to stimulate daytime insulin secretion.

Large studies of the effects of lifestyle changes, the effects of drugs in preventing or postponing the complications of diabetes, or the usefulness of various combinations are regularly published. The different mechanisms of action of the various classes give different metabolic effects and different adverse effects profiles (34). Comparative costs of the various therapies in the USA have been presented (35).

This subject has been reviewed in relation to combined oral therapy. In a systematic review of 63 studies with a duration of at least 3 months and involving at least 10 patients at the end of the study, and in which HbA_{1c} was reported, five different classes of oral drugs were almost equally effective in lowering blood glucose concentrations (36). HbA_{1c} was reduced by about 1–2% in all cases. Combination therapy gave additive effects. However, long-term vascular risk reduction was demonstrated only with sulfonylureas and metformin.

The adverse effects of combined drug therapy are attributable to the adverse effects of the single drugs. Increased adverse effects or new adverse effects in patients taking combinations have not been reported.

© 2006 Elsevier B.V. All rights reserved.

Thiazolidinediones + biguanides

In a multicenter, randomized, double-blind study, 116 patients were treated for 26 weeks with metformin plus placebo, 119 with metformin plus rosiglitazone 4 mg/day, and 113 with metformin plus rosiglitazone 8 mg/day (37). In both rosiglitazone groups there were small but statistically significant falls in hemoglobin and hematocrit. Edema was rare but more common in the rosiglitazone groups (2.5% with 4 mg/day and 3.5% with 8 mg/day). Body weight fell by 1.2 kg from baseline with placebo but increased by 0.7 kg with rosiglitazone 4 mg/day and by 1.9 kg with 8 mg/day. No one taking rosiglitazone had an increase in alanine transaminase greater than three times the upper limit of the reference range.

In a placebo-controlled study in 116 patients who responded insufficiently to metformin 2.5 g/day, rosiglitazone 2 or 4 mg bd was added for 26 weeks (38). HbA_{1c} and fasting plasma glucose improved and hemoglobin fell. Edema was reported in 5.2% of the patients who took rosiglitazone and two patients withdrew because of headache.

Thiazolidinediones + meglitinides

In 585 patients in a double-blind, randomized, placebo-controlled, multicenter study lasting 16 weeks, nateglinide 40 mg tds alone, troglitazone 200 mg/day alone, and the combination were compared (39). The combination was most effective in lowering HbA_{1c}. The most frequent adverse effects were mild hypoglycemia, most often in the combination group. Three patients (two in the combination group and one in the troglitazone alone group) withdrew because of hypoglycemia. Most of the withdrawals were related to increased liver enzymes and weight gain, known adverse effects of troglitazone. Twelve patients withdrew because of predefined changes from baseline (transaminases more than 200% and alkaline phosphatase and bilirubin more than 100% over baseline); seven were taking troglitazone alone, four combined therapy, and one placebo.

In an open trial, 256 patients with type 2 diabetes with inadequate hypoglycemic control (HbA_{1c} over 7.0% during previous therapy) took repaglinide (0.5–4 mg at meals), troglitazone (200–600 mg/day), or a combination of the two for 22 weeks (40). Combination therapy was most effective. Repaglinide only was more effective than troglitazone only. Mean body weight increased in both groups. Serious adverse events were chest pain, cerebrovascular disorders, malignancies, dysrhythmias, electrocardiographic changes suggesting myocardial infarction, and increased aspartate transaminase activity (in one patient taking troglitazone). The serious adverse effects were similar in the different groups. Hypoglycemia occurred in 4% of the patients taking combined therapy, in 16% of those taking troglitazone only, and in 27% of those taking repaglinide only; none needed assistance. There were changes in liver function tests in three patients in the combined group and in one patient each in the two other groups; the drugs were withdrawn in the affected patients and liver function normalized. There were no differences in adverse effects in the different groups. Hypoglycemia occurred in 11 patients taking repaglinide, in seven taking combination therapy, and in one taking troglitazone. Anemia occurred in four patients taking combined therapy and in two taking troglitazone only.

Thiazolidinediones + sulfonylureas

Troglitazone 100 or 200 mg/day or placebo was given for 16 weeks to 259 patients already taking sulfonylurea therapy (41). HbA_{1c} was 0.4 and 0.7% lower and blood glucose concentrations fell. The most common event was hypoglycemia, but this did not occur more often when troglitazone was added. Liver enzymes increased to the same extent in the three groups and never rose above normal. No patients withdrew because of drug-related effects.

Insulin + thiazolidinediones

Insulin plus metformin (27 patients, 2000 mg/day) or troglitazone (30 patients, 600 mg/day) in patients with type 2 diabetes using at least 30 U/day was compared with insulin alone (30 patients) for 4 months (42). Body weight increased in the insulin and the insulin plus troglitazone groups. In the insulin plus metformin group there were significantly more gastrointestinal adverse effects but less hypoglycemia than the other groups.

The addition of rosiglitazone to insulin for 26 weeks in a double-blind study in 315 patients with inadequately controlled type 2 diabetes improved glycemic control and was well tolerated (43). There was a significant fall in hemoglobin, and some patients in both the rosiglitazone and placebo groups developed edema.

General adverse effects

The adverse effects of the thiazolidinediones are comparable and include weight gain, upper respiratory tract infections, headache, and hypoglycemia (mostly in combination with other hypoglycemic drugs). Fluid retention sometimes occurs (19,21) and can lead to or exacerbate heart failure and pulmonary and general edema, which was reported in 1.5–12% of patients taking pioglitazone. Small clinically unimportant falls in hematocrit and hemoglobin occur because of hemodilution. Changes in liver enzymes and bilirubin have not been reported with rosiglitazone, and although there have been some reports of hepatic-related adverse effects, they have not been definitive (SEDA-25, 515). However, troglitazone causes liver complications, sometimes fatal, and this has led to its withdrawal from the market. There are no drug interactions with other hypoglycemic agents.

Organs and Systems

Cardiovascular

Reductions in VLDL cholesterol, LDL cholesterol, and chylomicrons may contribute to a reduction in cardiac complications. Pioglitazone reduced both lipoprotein(a) and the remnant particles (cholesterol-rich particles after the release of triglycerides from the chylomicrons), whereas troglitazone caused increases in lipoprotein(a) (44).

Respiratory

A single case of pleuropulmonary disease possibly induced by troglitazone has been reported (45).

© 2006 Elsevier B.V. All rights reserved.

Nervous system

Ataxia has been attributed to troglitazone in two patients aged about 80 years (a man and a woman) (46). The ataxia developed during treatment and disappeared in one case 2–3 days after withdrawal and in the other within 2 weeks. In one, the ataxia was accompanied by a dementia-like syndrome, which completely disappeared within 8 weeks. One of the patients was rechallenged and developed ataxia again.

Metabolism

The thiazolidinediones can cause hypoglycemia both when used alone or in combination with other hypoglycemic drugs (47).

The thiazolidinediones increase body weight. With troglitazone the increase in body weight is accompanied by changed fat distribution, but central fat, in part responsible for the cardiovascular changes seen in diabetes, remains the same; weight gain is accompanied by increased subcutaneous fat (48).

In one study, troglitazone increased body weight, adipocyte size, leptin concentrations, GLUT4 protein expression, basal and insulin-stimulated glucose transport, and insulin-stimulated whole-body glucose disposal rate (49).

In a 24-week study, in which 40 patients taking troglitazone and glibenclamide were compared with patients taking glibenclamide, serum fasting insulin, serum triglycerides, and insulin resistance were reduced when troglitazone was added. Fat deposition in the liver and the visceral fat area were reduced, but deposition in skeletal muscle was not (50).

When patients taking troglitazone were switched to equivalent amounts of rosiglitazone ($n = 60$) or pioglitazone ($n = 60$) there were no changes in HbA_{1c} or other parameters, except that with pioglitazone there was a significant improvement in lipid profile, with an average fall in total cholesterol of 0.5 mmol/l (51).

However, in 23 patients who took pioglitazone for 16 weeks, in whom fasting and mean glucose concentrations and mean free fatty acid concentrations fell, weight gain of 3.6 kg was associated with an increase in peripheral fat without edema (52).

In 38 patients taking metformin 2550 mg/day and glimiperide 6 mg/day, rosiglitazone 4 or 8 mg/day was added for 20 weeks (53). HbA_{1c} and fasting blood glucose fell significantly. There was hypoglycemia in 19% of those who took 4 mg/day and 28% of those who took 8 mg/day, and body weight increased by 4.2 and 4.6 kg respectively. There were no signs or symptoms of liver disease and no changes in liver function tests.

Fluid balance

Two cases of pulmonary and general edema have been reported with rosiglitazone (54).

- A 78-year-old man became short of breath. He had been taking rosiglitazone 8 mg/day for 6 months. He had renal insufficiency, atrial fibrillation, hypertension, and congestive heart failure, with pitting edema and bilateral pleural effusions. He was refractory to intravenous furosemide and metolazone. Withdrawal of rosiglitazone and administration of bumetanide gave a net fluid output of 9.5 litres and the edema resolved.
- A 67-year-old man, who had taken troglitazone 600 mg/day for 4 months and who had renal insufficiency, stroke, and cardiomyopathy, developed pitting edema, hepatomegaly, ascites, and a pleural effusion. The edema was resistant to treatment until troglitazone was changed to glipizide 10 mg/day, when he had a diuresis of 18 litres in 6 days. Later he took rosiglitazone 4 mg bd for 3 weeks and had weight gain of 5 kg and pitting edema. Diuretic therapy failed until rosiglitazone was withdrawn, after which he reached his baseline weight in 4 days.

Pioglitazone also causes fluid retention, possibly because of increased production of vascular endothelial growth factor (55). The safety profile of monotherapy and combined therapy with pioglitazone has been evaluated in 3500 patients over 2500 patient-years, and some data from post-marketing surveillance were included; peripheral edema and hemodilution were common (56).

Hematologic

In 303 patients who took placebo or rosiglitazone for 8 weeks after a run-in period, rosiglitazone 4 mg bd had the same effect as 6 mg bd, but hemoglobin and hematocrit were lower with 6 mg bd (57). In another study troglitazone produced small reductions in hemoglobin, hematocrit, and erythrocyte counts and increases in lactate dehydrogenase and blood urea nitrogen (58).

Liver

The thiazolidinediones are hepatotoxic (59).

Troglitazone

Troglitazone causes liver damage more often than the other members of the family. Hepatotoxicity delayed and finally prevented the registration of troglitazone in Europe. In the US, a patient with diabetes who used troglitazone in a study, developed hepatic failure necessitating liver transplantation and died. Troglitazone was withdrawn from a major National Institutes of Health evaluation of various regimens for preventing type 2 diabetes. In Japan the government recommended in December 1997 that liver function tests should be assessed every month in patients taking troglitazone. In 1998 there were 21 fatal cases of liver failure and three liver transplantations in patients taking troglitazone (60). Monitoring of liver function was intensified and in 1998 troglitazone was withdrawn for monotherapy. In 1999 the FDA received 61 reports of fatal hepatic toxicity and seven cases requiring liver transplantation (61) and in spring 2000 troglitazone was withdrawn in America and in Japan.

- A 58-year-old man developed severe hepatitis after taking troglitazone 400 mg/day and glibenclamide 5 mg/day (62). Glibenclamide was stopped after 6 weeks as his HbA_{1c} was 7.0%. About 2 weeks later he developed malaise and 1 week later jaundice. His bilirubin and transaminases were greatly raised and there was ascites. He had taken about 34 g of troglitazone. Drug-induced lymphocyte stimulation test was strongly positive for

© 2006 Elsevier B.V. All rights reserved.

troglitazone and not for other drugs. Troglitazone was withdrawn and 3 days later the plasma concentration was below the limit of detection. Notwithstanding intensive therapy he died after 5 weeks. At autopsy, the liver showed yellow atrophy and massive hepatocellular coagulation necrosis with moderate neutrophil, monocyte, and eosinophil infiltration.

The positive lymphocyte stimulation test, the eosinophils, and the low blood concentrations 3 days after withdrawal suggest that hypersensitivity to troglitazone was the underlying cause. The authors reported that another patient with hepatitis after troglitazone had had a subacute course after withdrawal of the drug.

Late hepatic damage has also been reported.

- A 62-year-old woman with normal liver function tests took troglitazone 400 mg/day in combination with gliclazide 80 mg/day and pravastatin (63). After 9 months her transaminases were slightly above normal, but the HbA_{1c} was 7.0% and treatment was continued. Her liver enzymes were measured monthly and after 19 months rose abruptly. Troglitazone was withdrawn immediately and she received insulin. Her liver enzymes improved rapidly. A biopsy showed hepatic necrosis round the central vein and a mild inflammatory infiltrate and fibrosis in the portal area compatible with protracted acute hepatitis. A lymphocyte stimulation test and a skin test were negative for troglitazone.
- A 76-year-old man took troglitazone 400 mg in addition to glimepiride 4 mg/day, metformin 1 g/day, aspirin, and pravastatin (64). After 18 months his liver function deteriorated and improved after withdrawal of troglitazone.

There are no differences in outcome between these two patterns of hepatotoxicity, "rapid risers," in whom liver failure takes only a few days to develop, and "slower risers." The estimated death rate is one in 100 000, but the estimate of the FDA advisory committee was one in 15 154 at 8 months of treatment. It is unclear whether hepatotoxicity is a class effect of thiazolidinediones or whether the lipophilic alpha-tocopherol moiety of troglitazone is responsible for this effect. The basic quinone structure of alpha-tocopherol is common to other drugs that can form hepatotoxic free radicals by CYP2E1-mediated oxidation.

The relation of liver disease to oral hypoglycemic drugs has been investigated in 44 406 patients, of whom 605 had liver disease (65). When 185 patients with mild and transient disorders, 249 with a predisposing condition, and 113 with another cause were excluded, 57 cases with possibly drug-induced liver changes were left. Of these, 11 could be attributed to other drugs and eight were attributed to fatty liver disease caused by diabetes. In 51 patients, oral drugs were continued without worsening of the liver enzymes. In two cases (a 58-year-old woman, whose liver function improved after discontinuing metformin, and an 86-year-old woman, who developed jaundice and died shortly after metformin and glibenclamide were prescribed) a causal relation could not be excluded.

There has been a report of hepatic injury with troglitazone but not with rosiglitazone (66).

- A 38-year-old woman was given insulin when glibenclamide and acarbose failed. Troglitazone 400 mg/day was added and increased to 800 mg/day 1 month later. After 2 months her liver function tests were normal, but she developed jaundice after 4 months. Total and direct bilirubin were 127 and 101 μmol/l and alanine transaminase was 34 μkat/l. After withdrawal of troglitazone her symptoms disappeared and her liver function tests normalized within several months. Metformin 1000 mg bd reduced her insulin requirement. Rosiglitazone 4 mg bd was added and her liver function tests remained normal for 10 months.

Pioglitazone

Hepatocellular damage has occasionally been attributed to pioglitazone.

- A 67-year-old man took pioglitazone 30 mg/day after having taken glibenclamide 2.5 mg/day for 10 years and voglibose 0.6 mg/day for 5 years (67). His liver function was normal before and during 6 months of pioglitazone therapy, but at 7 months he had abnormal liver function tests (total bilirubin 10 μmol/l, aspartate transaminase 1.95 μkat/l, alanine transaminase 5.65 μkat/l, alkaline phosphatase 17 μkat/l, gamma-glutamyl transferase 8 μkat/l). He was asymptomatic, with negative viral serology and normal liver ultrasonography. After withdrawal of pioglitazone his liver function normalized within a month.
- A 49-year-old man developed scleral icterus with raised bilirubin and transaminases after using pioglitazone 15-30 mg for 6 months and 45 mg for 1 week (68). No other cause for hepatitis was found. After withdrawal his liver function improved substantially within 14 days.
- A 49-year-old woman developed jaundice after taking pioglitazone 30 mg/day for 6 weeks, and after 3 weeks the alanine transaminase was 131 U/l and aspartate transaminase 79 U/l (69). Tests for viral hepatitis were negative. A liver biopsy showed marked portal edema, patchy chronic inflammation, a cellular infiltrate, and marked bile duct proliferation. There was no fibrosis. The laboratory results worsened after pioglitazone was withdrawn, and 1 month after withdrawal the bilirubin reached a peak of 585 μmol/l. Over the next 8 weeks the symptoms and laboratory tests improved, and after 6 months her condition was the same as when she had started to take pioglitazone.

Rosiglitazone

The frequency of liver damage with rosiglitazone is much lower than with troglitazone and the reported cases seem to have been less serious. No deaths have been reported.

- A 61-year-old man developed hepatotoxicity 8 days after starting to take rosiglitazone 4 mg/day, and it was withdrawn (70). The alanine transaminase was 28 μkat/l, aspartate transaminase 23 μkat/l, alkaline phosphatase 8.7 μkat/l, total bilirubin 14 μmol/l, and direct bilirubin 13 μmol/l. All the tests were normal 5 months later. He had taken troglitazone for 1 week 8 months before this incident but had stopped because of nausea and an upset stomach.
- A 69-year-old man taking rosiglitazone 4 mg/day and metformin 500 mg/day developed hepatic failure within

© 2006 Elsevier B.V. All rights reserved.

a week and both drugs were withdrawn (71). His alanine transaminase was 32 μkat/l, aspartate transaminase 47 μkat/l, total bilirubin 65 μmol/l, and direct bilirubin 41 μmol/l. He became comatose and the aspartate transaminase rose to 185 μkat/l. The enzyme activities were normal 7 weeks after withdrawal.

- A 58-year-old woman started to feel ill 2 weeks after starting to take rosiglitazone 4 mg/day (72). One week later her peak aspartate transaminase was 5.2 μkat/l, alanine transaminase 4.2 μkat/l, and bilirubin 41 μmol/l. Four weeks later all the values had returned to normal.
- In a 47-year-old woman, who took rosiglitazone 4 mg/day for a short, unspecified time, the alkaline phosphatase increased (11 μkat/l) and returned to normal 2 weeks after withdrawal (73).
- An obese 37-year-old man with type 2 diabetes, who used rosiglitazone for 15 months, at first 4 mg/day then 8 mg/day for 6 months, developed granulomatous hepatitis (74). His liver enzymes were normal at 6 and 8 months. After 14 months he developed fatigue, abdominal discomfort, and weight loss and 3 weeks later chills, nausea, vomiting, and diarrhea. No hepatic viruses were found. A liver biopsy showed a periportal mixed cellular infiltrate and granulomas within the portal triad and the parenchyma. There was no evidence of sarcoidosis. After withdrawal of rosiglitazone he improved and the liver enzymes became normal within 2 months.
- A 49-year-old man with pre-existing hepatic pathology took rosiglitazone 4 mg/day for 2 months and 8 mg/day for 5 months (75). He developed a "bull" face and then edema of the eyelids and neck. He had anorexia and nausea. His serum sodium was 110 mmol/l, potassium 3.3 mmol/l, chloride 81 mmol/l, cholesterol 21 mmol/l, triglycerides 33 mmol/l, and his liver enzymes were raised. Rosiglitazone was withdrawn and he was given saline and potassium, acarbose for his diabetes, spironolactone 200 mg/day for edema, and atorvastatin 10 mg/day for hyperlipidemia. He improved over 3 weeks.

Liver function was monitored in patients aged 30–80 years with type 2 diabetes taking rosiglitazone (76). When a patient had transaminase or alkaline phosphatase activities higher than 2.5 times the upper limit of the reference range, they were not included in the studies. In 5006 patients taking rosiglitazone as monotherapy or combined therapy there were no hepatotoxic effects. At entry to the studies, 5.6% of the patients had values between 1.0 and 2.5 times the upper limit. Of the placebo-treated patients, 39% had a fall to normal values and 39% had an increase, but not over three times the upper limit. In 66% of the patients treated with a hypoglycemic drug the values fell (often with a fall in HbA_{1c}); in 13% they increased to below three times the upper limit and in 2.0% to over three times (four patients).

Musculoskeletal

Rhabdomyolysis has been attributed to troglitazone in combination with alcohol (77).

- A 59-year-old man took troglitazone 400 mg/day for 6 months and alcohol about 40 g/day. He developed weakness and muscle pain. He had mild liver damage. His HbA_{1c} concentration was 9.0%. All his muscles were tender, his creatine kinase activity was 10 570 IU/ml, and his myoglobin, aldolase, and aspartate transaminase were raised. Troglitazone was withdrawn. He improved biochemically and clinically.

There was an increase in creatine phosphokinase activity to over 10 times the upper limit of the reference range in seven of 1510 patients taking pioglitazone in the USA; four normalized during treatment, two normalized after withdrawal, and one had fallen but not normalized at follow-up (21).

Immunologic

- Angioedema has been reported in an obese woman after she had taken pioglitazone 30 mg/day for 7 days (78). She developed a sore throat followed by dyspnea and swelling of the lips and tongue. There was no rash. After intravenous glucocorticoids her symptoms rapidly abated.

Susceptibility Factors

Renal disease

Dosage adjustment of rosiglitazone is not necessary when renal function is reduced (79).

Drug–Drug Interactions

Metformin

In 16 healthy men taking metformin 500 mg bd and/or rosiglitazone 2 mg bd for 4 days there were no significant effects on the steady-state pharmacokinetics of either drug (80).

Simvastatin

Troglitazone has been reported to reduce the effect of simvastatin, probably by induction of CYP3A4 (81).

Thionamides

General Information

Several natural or synthetic substances interfere with the synthesis and/or secretion of the thyroid hormones. Two types of thionamides are used in the treatment of hyperthyroidism:

1. derivatives of thiouracil, especially propylthiouracil (rINN); methylthiouracil and iodothiouracil have

© 2006 Elsevier B.V. All rights reserved.

been used in the past, but are not currently used clinically;
2. derivatives of thioimidazole, especially thiamazole (rINN; methimazole) and its carbethoxy derivative carbimazole (rINN), which is converted in the body to thiamazole (1,2).

All of these drugs interfere with the thyroid peroxidase system and inhibit the synthesis of the thyroid hormones, reducing their overproduction in hyperthyroidism. However, if they are used in too high dosages, they can cause hypothyroidism and hypersecretion of thyrotrophin (TSH) which in turn will stimulate thyroid growth and the development of goiter. To avoid these problems, regular dosage adjustment or combination with synthetic thyroid hormones is necessary as soon as the euthyroid state is obtained.

Antithyroid drugs may also suppress lymphocytic infiltration into the thyroid and thereby directly modulate the basic disorder of autoimmune hyperthyroidism (SEDA-6, 364) (SEDA-9, 344). Propylthiouracil, but not the thioimidazoles, also inhibits the conversion of thyroxine to its more active derivative triiodothyronine. This effect is significant during high-dose treatment, and propylthiouracil may therefore be preferred if a more rapid onset of action is desired, for example thyrotoxic crisis, although clear experimental proof of the advantageous effect is still lacking (3).

The antithyroid drugs are well absorbed from the intestinal tract, but the half-life of propylthiouracil is much shorter (2 hours) than that of the thioimidazoles (6 hours). However, the in vivo half-life may be longer due to accumulation and retention of the drug in the thyroid gland (4).

General adverse effects

Both the thiouracils and the thioimidazoles can produce hypothyroidism and goiter. Most of their other adverse effects are allergic rather than toxic. The overall frequency of untoward reactions is 2–14%, but severe reactions occur in less than 1% of patients. Some data suggest that the thioimidazoles have a lower incidence of adverse effects than the thiouracils (5). An association between the dosage of thionamide and the development of untoward reactions has been found in several studies (6). It has therefore been proposed that the initial dose of carbimazole should not exceed 30 mg/day and that of propylthiouracil 300 mg/day (SEDA-17, 474). Allergic reactions include drug fever, lymphadenopathy, arthralgia, agranulocytosis, thrombocytopenia, leukopenia, and skin reactions (1,7). In view of the in vivo conversion of carbimazole to thiamazole, cross-allergy between the two compounds can be expected and has been observed. Cross-allergy between thiouracil and thioimidazoles is rare, but a few cases have been reported. Tumor-inducing effects have not been reported.

Organs and Systems

Nervous system

Neuritis has been described in patients taking thiamazole (8,9).

Sensory systems

Eyes

In contrast to ^{131}I, antithyroid drugs do not seem to increase the risk of new or worse exophthalmos in patients with Graves' disease (10,11).

Retrobulbar neuritis has been reported in a patient taking thiamazole (12).

Ears

Ototoxicity has rarely been attributed to antithyroid drugs (13). In one case progressive bilateral sensorineural hearing loss attributed to propylthiouracil was associated with myeloperoxidase-antineutrophil cytoplasmic antibodies (MPO-ANCA) (14).

Taste

Taste disturbance has been described in patients taking antithyroid drugs and has been attributed to zinc deficiency (SEDA-7, 398) (SEDA-11, 357).

Endocrine

Overtreatment with antithyroid drugs can cause hypothyroidism (15,16).

Metabolism

A specific form of hypoglycemia occurs in Hirata disease, a rare autoimmune syndrome in which large amounts of insulin can be released from autoantibodies. In a Japanese series of 197 cases, 43% of the patients had been taking medications before diagnosis: thiamazole for Graves' disease, alpha-mercaptopropionyl glycine for cataracts, liver disease, or rheumatoid arthritis, or glutathione for liver disease, all of which are sulfhydryl compounds. After these drugs were withdrawn, the hypoglycemic attacks subsided (17).

Hematologic

Neutropenia, agranulocytosis, aplastic anemia, and thrombocytopenia are the most important adverse effects of antithyroid drugs.

Neutropenia and agranulocytosis

There are two different types of neutropenia due to antithyroid drugs: a mild dose-related reduction in leukocyte count and a true allergic agranulocytosis (SEDA-10, 368) (18).

Allergic agranulocytosis

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: hypersusceptibility effect
Time-course: intermediate
Susceptibility factors: genetic (HLA DRB1*08032 allele); age (over 40); sex (women)

Severe agranulocytosis (or more rarely pancytopenia) is usually only observed during the first few months of therapy. Since agranulocytosis can develop very rapidly, periodic leukocyte counts are usually considered to be of little help, but it has been suggested that weekly leukocyte counts during the first month of treatment can detect presymptomatic cases and allow more rapid intervention

© 2006 Elsevier B.V. All rights reserved.

(19). Patients should therefore be warned to seek immediate medical help if a fever or sore throat develops during antithyroid drug treatment. If the drug is withdrawn immediately recovery is the rule, but fatal cases have also been reported (20,21). In one case agranulocytosis unusually occurred after a second exposure to the drug, in this case propylthiouracil (22).

Frequency

The risk of agranulocytosis has been estimated during several surveys. A large European–Israeli study (23) showed a risk of about 3 per 10 000 users. However, the mortality in this survey was small (one in 45 cases) (SEDA-13, 376). In two hospital surveys of agranulocytosis (24,25) there was an increased risk in women aged over 40 years and when the dose of thiamazole (thiamazole) was more than 40 mg/day. In vitro lymphocyte testing can confirm the sensitization of the immune system to the antithyroid drugs and can occasionally indicate cross-sensitivity between thiamazole and propylthiouracil (SEDA-8, 372) (SEDA-9, 344). In a Japanese study, using an adverse drug reactions database, 24 of 91 cases of presumed drug-induced leukopenia were associated with thiamazole (26). The estimated overall risk was 3 per 10 000, largely in the first 3 months (RR = 182, 95% CI = 74, 449).

Mechanism

Laboratory studies have provided insights into the immune mechanisms underlying the hematological complications of antithyroid drugs (27). Sera from five patients taking thiamazole who presented with immune thrombocytopenia showed antibodies to the platelet cell adhesion molecule-1. Similar antibodies were present in the serum of a patient with carbimazole-associated neutropenia and mild thrombocytopenia, together with antibodies to the neutrophil-specific Fc gamma receptor IIIb (28). Antibodies against the rhesus component of erythrocyte proteins have also been described in patients with carbimazole-associated anemia, leading to the conclusion that carbimazole can induce cell lineage-specific drug-dependent antibodies that cause cytopenias.

In 24 patients with Graves' disease with thiamazole-induced agranulocytosis, 68 patients with Graves' disease without agranulocytosis, and 525 healthy controls, there was a strong positive association of the HLA DRB1*08032 allele with susceptibility to methimazole-induced agranulocytosis, suggesting that cellular autoimmunity may be involved in its development (29).

Time-course

In 18 cases of antithyroid drug-induced agranulocytosis in China, previous evidence that most cases occur early in treatment (2–12 weeks in 17 of 18 cases) and in those taking high doses was confirmed (30). This series also confirmed that agranulocytosis develops abruptly, arguing against routine monitoring of white cell count, and that fever and sore throat are the earliest symptoms.

Management

The treatment of this complication is controversial. There have been at least 15 reports of the use of granulocyte colony stimulating factor (G-CSF) in severe cases (granulocyte count under 100×10^6/l) of thionamide-induced agranulocytosis with the objective of shortening the period of neutropenia and hence the risk of infection (31). In another case the use of G-CSF in thionamide-induced agranulocytosis was associated with a number of iatrogenic complications (31). A review of treatment with G-CSF has shown that the average time to recovery from agranulocytosis is 8.2 days, not obviously different from the reported range of 7–14 days without the drug, leading the authors to argue against its routine use in afebrile patients, even in the face of a severe reduction in granulocyte count.

In 24 patients with Graves' disease who developed agranulocytosis during antithyroid drug therapy, randomized to receive G-CSF ($n = 14$) or an antibiotic only, recovery time (defined as the number of days required for neutrophil counts to exceed 0.5×10^9/l) did not differ between the treatments in patients with moderate or severe agranulocytosis, arguing against its routine use (32). These conclusions have been supported by retrospective data from a further 12 patients, four of whom received G-CSF (33). Again, there was no significant difference in terms of the speed of hematological recovery, the number of days of antibiotic treatment, or the duration of hospitalization.

In a retrospective cohort study of 90 cases of drug-induced agranulocytosis in Strasbourg, antithyroid drugs were implicated in 23% of cases, second only to antibiotics in terms of frequency of prescription in the affected cohort (34). The clinical presentation was often severe and included isolated fever (41% of cases), septicemia or septic shock (31%), and pneumonia (10%). The outcome was favorable in 98% of cases. All the patients were treated with broad-spectrum antibiotics and 42 received hemopoietic growth factors; in those given growth factors the mean durations for hematological recovery, antibiotic therapy, and hospitalization were significantly reduced. While patient selection may have contributed to these findings, they do suggest a useful role for such growth factors in supporting patients with this potentially life-threatening complication of thionamide therapy.

Aplastic anemia

Aplastic anemia due to antithyroid drugs is very rare and has been said to occur as an adverse effect of thionamide therapy with about one-tenth of the frequency of agranulocytosis.

- Aplastic anemia developed in a 58-year-old woman taking thiamazole for the third time; she responded well to drug withdrawal and treatment with human granulocyte colony stimulating factor (35).
- A 16-year-old girl who had taken thiamazole for 1 month (30 mg/day) developed a sore throat and dysphagia and had pancytopenia (36). Instead of the expected picture of hypoplasia, bone marrow aspiration showed replacement with plasma cells, a finding suggestive of myeloma and representing a picture not previously described in this context. Thiamazole was withdrawn and she was given antibiotics, dexamethasone, and granulocyte colony stimulating factor. Her

© 2006 Elsevier B.V. All rights reserved.

hematology and bone marrow findings normalized within days and she was well at follow-up at 24 months.

There have been anecdotal reports of the use of G-CSF in cases of thionamide-induced agranulocytosis (37). In a retrospective review (38) the outcomes in 10 severe cases treated with G-CSF and in 10 treated without were reviewed. The time to hematological recovery, the duration of antibiotic use, and the duration of hospitalization were all shorter in those treated with G-CSF, although there were no deaths in either group. These findings are in accord with the results of other non-randomized studies of the use of G-CSF in drug-induced agranulocytosis, but conflict with the results of one randomized study that showed no benefit (32). The latest findings must therefore be interpreted with caution, although it is notable that this study was confined to those with severe suppression of leukocyte counts and clinical evidence of infection.

Liver

Both carbimazole and propylthiouracil can cause liver damage, sometimes as part of a hypersensitivity reaction associated with pruritus, rash, fever, and arthralgia. Severe liver injury is believed to be rare, with only 20 reported cases up to 1993 (39). In contrast, subclinical hepatic dysfunction, characterized by a rise in hepatic enzymes, may be common and does not necessitate drug withdrawal in the absence of symptoms (39).

Of 14 cases of suspected drug-induced liver disease presenting to a gastroenterology department over a 3-year period, one was thought to be related to thiamazole, with a hepatitic pattern of liver function tests in a 39-year-old woman 6 days after the start of therapy; recovery was swift and complete (40). Delayed cholestatic hepatitis without antineutrophil cytoplasmic antibodies has been reported (41), and there have been fatal cases of hepatic necrosis (SEDA-21, 438) (7).

In a retrospective review of 497 patients taking propylthiouracil for hyperthyroidism, clinically overt hepatitis developed in six patients at 12–49 days after starting the drug (42). Jaundice and itching were present in five, fever in two, rash in two, and arthralgia in one. Serum bilirubin, alanine transaminase, and alkaline phosphatase were increased in five, four, and six patients respectively. The type of hepatic injury was cholestatic in three, hepatocellular in one, and mixed in two. There were no differences in age, sex, drug dose, or serum thyroid hormone concentrations at time of diagnosis in those with hepatic injury compared with those without. Liver function normalized in all patients at 16–145 days after withdrawal of propylthiouracil. In addition to these cases of overt liver injury, 14% of the cohort had mild asymptomatic liver enzyme rises at a mean of 75 days after the start of treatment.

The reported incidence of liver injury in this report is higher (at 1.2%) than in previous reports, perhaps reflecting patient selection or ethnic differences in study populations. An association with propylthiouracil in the six cases described was supported by the temporal association with the start of therapy and recovery after withdrawal. This complication is likely to be a hypersusceptibility reaction, given the lack of dose association within the therapeutic range, the unpredictable occurrence, and an association with symptoms of hypersensitivity. The findings of this retrospective study do not indicate the need for regular monitoring of liver function tests in those taking propylthiouracil, but they do highlight the need to consider drug toxicity if overt hepatic injury develops, especially early in the course of propylthiouracil therapy.

Pancreas

Acute pancreatitis and parotitis without antineutrophil cytoplasmic antibodies has been attributed to thiamazole (43).

- A 33-year-old woman developed acute pancreatitis together with mild cholestatic hepatitis and erythema nodosum 1 month after starting carbimazole for Graves' disease; rechallenge with a single dose of carbimazole (10 mg) 7 days after initial recovery led to a further episode of acute pancreatitis, from which she recovered (44).

The temporal association with carbimazole therapy, the response to rechallenge, and the absence of other causes of acute pancreatitis suggested that the drug was causative in this case.

Urinary tract

Chronic tubulointerstitial nephritis with renal insufficiency without antineutrophil cytoplasmic antibodies has been attributed to propylthiouracil (45).

Skin

The most common reaction to antithyroid drugs is a benign skin rash or pruritus without rash. Although such a reaction is usually not serious and can even disappear during continuous treatment, it nevertheless indicates an allergic reaction and requires withdrawal of therapy. Thiouracil can then be replaced by thioimidazoles, but allergy to both products can occasionally occur.

Sexual function

Sexual precocity associated with hypothyroidism has been reported after long-term treatment of children with propylthiouracil, and may reflect relative overdosage (46).

Immunologic

Antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis is a well-described complication, particularly with propylthiouracil and to a lesser extent with carbimazole, and has been most often described in patients with Graves' disease. The possible drug-induced causes of ANCA-positive vasculitis with high titers of antimyeloperoxidase antibodies in 30 new patients have been reviewed (47). The findings illustrated that this type of vasculitis is a predominantly drug-induced disorder. Only 12 of the 30 cases were not related to a drug. The most frequently implicated drug was hydralazine ($n = 10$); the remainder involved propylthiouracil ($n = 3$), penicillamine ($n = 2$), allopurinol ($n = 2$), and sulfasalazine ($n = 1$).

Cutaneous vasculitis is often a feature of such cases, although severe systemic manifestations often also occur.

© 2006 Elsevier B.V. All rights reserved.

Two patients with propylthiouracil hypersensitivity presented with skin manifestations but also had renal, rheumatological, and hematological features (48). A review of the literature showed that the symptoms and signs in patients with ANCA-associated thionamide-induced vasculitis are diverse. Acral purpuric skin lesions are typically seen; recognition of these classical clinical features may allow early diagnosis and limit associated morbidity and the requirement for other therapies, particularly immunosuppression. Several other reports have described cases of MPO-ANCA-positive cases of vasculitis presenting in a variety of ways in both adults and children treated with propylthiouracil (49–52).

There have been reports of propylthiouracil-induced ANCA-associated small vessel vasculitis (53,54), crescentic glomerulonephritis (55), and Wegener's granulomatosis (56). More common, however, may be a condition termed "antithyroid arthritis syndrome," which is a transient migratory polyarthritis occurring within 2 months of starting thionamides and resolving within 4 weeks of stopping therapy (57).

ANCA-positive vasculitis in a patient with multinodular goiter has been described, together with a review of the clinical features in a further 26 cases (58). Renal involvement, typically with crescentic or necrotizing glomerulonephritis on biopsy, and arthralgia were the most common manifestations. A few cases of diffuse proliferative lupus nephritis associated with ANCAs have been reported (SEDA-20, 394). Other cases of ANCA-associated disease in patients have been reported, including subjects presenting with neutrophilic dermatosis (59), pyoderma gangrenosum, secondary sterile pyoarthrosis (60), and purpura fulminans (61). Small vessel vasculitis leading to pulmonary alveolar hemorrhage and crescentic glomerulonephritis has also been described (61).

In 61 patients with Graves' hyperthyroidism, 32 of whom were taking propylthiouracil and 29 methimazole, there was a higher prevalence of antimyeloperoxidase ANCAs in those taking propylthiouracil than in those taking thiamazole (25 versus 3.4%) (62). There were no significant differences in age, duration of therapy, or drug dosage in those who developed antimyeloperoxidase ANCAs compared with those who did not. Two ANCA-positive patients in this study developed rheumatoid arthritis or membranous glomerulonephritis, but none developed classical ANCA-associated vasculitis.

There have been reports of antimyeloperoxidase ANCAs associated with diffuse pulmonary alveolar hemorrhage (63), IgA nephropathy (64), and drug-induced neutropenia (65) in patients who had Graves' hyperthyroidism taking propylthiouracil. Investigation using serum from the last of these patients implicated a complement-mediated mechanism. In another case ANCAs developed in two of three monozygotic triplets, both of whom had Graves' disease treated with propylthiouracil, supporting a genetic role in the development of this drug complication (66).

Long-term outcomes in a series of seven children who developed myeloperoxidase-specific ANCA-positive necrotizing crescentic glomerulonephritis associated with propylthiouracil were studied in Japan (67). Three had nephritis alone and four had extrarenal vasculitis. All had taken glucocorticoids, some with additional drugs, and all had achieved remission. None had progressed to end-stage renal insufficiency or death during a mean period of follow-up of 58 months. This apparently benign course, albeit with a relatively short period of follow-up, is similar to that seen in adult patients with this drug complication and implies a better prognosis than in subjects with non-drug-induced ANCA-positive vasculitic disease.

The size of this problem has been addressed using serum samples from 117 patients with Graves' disease treated either with propylthiouracil or thiamazole, and from untreated patients (68). Myeloperoxidase ANCA and proteinase-3 antineutrophil cytoplasmic antibodies (PR3-ANCA) were tested by enzyme-linked immunosorbent assay. Myeloperoxidase ANCA was negative in all untreated patients and patients taking thiamazole, but positive in 21 of 56 patients taking propylthiouracil. In contrast, PR3-ANCA was not detected in any patient in the study. The proportion of patients who were positive for myeloperoxidase ANCA increased with the duration of propylthiouracil therapy. Of the 21 patients who were positive for myeloperoxidase ANCA, 12 had no symptoms, but nine complained of myalgia, arthralgia, or coryza-like symptoms after the appearance of the antibody; none had abnormal urinary findings. These findings suggest a specific association between propylthiouracil therapy and the development of myeloperoxidase ANCA in patients with Graves' disease.

ANCA-positive microscopic polyangiitis has been associated with propylthiouracil, with a fatal outcome despite treatment with glucocorticoids and cyclophosphamide (69). Another patient presented atypically with acute pericarditis 10 months after starting to take propylthiouracil 100 mg tds (70). Another patient developed ANCA-negative leukocytoclastic vasculitis of the skin (71).

Several cases of "collagen-like" or "lupus-like" disease have been reported (joint pain, skin rash, and positive antinuclear antibodies) during treatment with either propylthiouracil or thiamazole (SEDA-8, 372) (SEDA-10, 368). Some cases of general vasculitis can be fatal, although high-dose glucocorticoid therapy can be helpful (72).

Other reports have described serious immunological complications of propylthiouracil in the absence of ANCA, including interstitial nephritis and fatal Stevens–Johnson syndrome in a 90-year-old woman treated for 5 weeks (73) and disseminated intravascular coagulation and vasculitis 2 weeks after the introduction of propylthiouracil in a 42-year-old woman (74). The latter was treated successfully by drug withdrawal and intravenous methylprednisolone.

Second-Generation Effects

Pregnancy

Both the thiouracils and thioimidazoles readily cross the placenta and can cause fetal hypothyroidism, resulting in a slight delay in neurological or bone maturation. Various degrees of goiter have also been observed, even to the extent of severe tracheal compression and death. Antithyroid drug dosage should therefore be reduced to the minimum required to maintain a euthyroid state without supplementation of levothyroxine (75).

© 2006 Elsevier B.V. All rights reserved.

Teratogenicity

Aplasia cutis congenita has been attributed to carbimazole, or its active metabolite thiamazole, given during early pregnancy (SEDA-14, 367) (76), and a review revealed 16 cases of solitary skin defects associated with intrauterine exposure to thiamazole (76). The defects can be restricted to a region of the body or can be widespread. Several causes have been documented, including chromosomal abnormalities (for example trisomy 13) and single gene mutations, such as Goltz syndrome. A few cases are believed to result from in utero exposure to teratogens, including thionamides. To date, 16 cases of solitary skin defects associated with intrauterine exposure to thiamazole have been reported. Additional cases of aplasia cutis congenita in thionamide-exposed infants associated with other congenital abnormalities, such as bilateral atresia of the nasal choana, esophageal atresia, imperforate anus, and cardiovascular defects have also been reported (76).

Additional cases of aplasia cutis congenita in thionamide-exposed infants associated with other congenital abnormalities, such as choanal atresia, esophageal atresia, imperforate anus, and cardiovascular defects, were also reviewed. This pattern of abnormalities has previously led to the term "methimazole [thiamazole] embryopathy" (77).

- A 3-year-old child, whose mother had been treated for Graves' hyperthyroidism with thiamazole throughout pregnancy, had two scalp lesions and other abnormalities of tissues of ectodermal origin, including dystrophic nails and syndactyly.

The authors suggested that a history of in utero exposure to thiamazole should be sought in all children with aplasia cutis congenita, as well as other ectodermal tissue abnormalities, to allow better definition of the "methimazole embryopathy." However, cautious interpretation of the literature is required, given the small number of thiamazole-associated cases of aplasia cutis congenita compared with the widespread prescription of this drug in pregnant women with hyperthyroidism. On the other hand, the absence of an apparent association with the use of the alternative thionamide, propylthiouracil, argues in favor of using the latter in pregnant patients.

In a prospective study in 241 women referred to a teratology service because of exposure to thiamazole during pregnancy, congenital abnormalities were compared with those found in offspring of 1089 controls referred because of exposure to non-teratogenic drugs or radiography (77). There were no statistically significant differences between the two groups in terms of major abnormalities, gestational age at delivery, neonatal weight, or head circumference, but among the thiamazole-exposed infants two had a major malformation consistent with "methimazole embryopathy." One had choanal atresia (exposed at 4–7 gestational weeks) and the other had esophageal atresia (exposed at 0–16 gestational weeks) (78). These are very rare malformations, and the number of cases in the cohort was insufficient to reach statistical significance, so the possibility of a chance association with thiamazole exposure cannot be excluded. These cases do, however, lend support to the view that thiamazole may be teratogenic, although thyrotoxicosis itself may be the associated factor. Until further data are available, treatment of thyrotoxicosis with propylthiouracil may be preferable in women who are planning a pregnancy.

- Scalp atresia has been described in an infant whose mother had taken carbimazole in a high dose (60 mg/day) during the first 12 weeks of pregnancy and propylthiouracil thereafter (79). The infant had other dysmorphic features (a flat face, low-set ears, upper lip retraction, and a low-set fifth finger) in addition to transient hypothyroidism.
- Choanal atresia has been described in an infant whose mother presented in early pregnancy with Graves' hyperthyroidism and who took carbimazole in doses up to 60 mg/day in the first trimester (80). She was also clinically and biochemically severely hyperthyroid at this time.

Propylthiouracil crosses the placenta as readily as the thioimidazoles, but the rare and probably real association between thioimidazoles and fetal anomalies makes the thioimidazoles less attractive first-line alternatives (81–83). When propylthiouracil is used cautiously in minimal amounts and with frequent dose adjustments, it is probably the safest form of treatment of hyperthyroidism during pregnancy (SEDA-8, 373) (SEDA-11, 357).

Fetotoxicity

Neonatal hypothyroidism has been reported after maternal use of antithyroid drugs (84,85). Transient neonatal hyperthyroidism in a female child born to a mother who had been treated with potassium iodide and carbimazole during pregnancy was followed by sexual precocity (86).

Lactation

The antithyroid drugs appear in human milk, and breastfeeding has therefore been considered contraindicated during such treatment. However, the amount of drug transferred in human milk is too small to affect thyroid function in the breastfed infant (87,88).

Susceptibility Factors

The antithyroid drugs should not be used in patients with a large intrathoracic goiter, which can further increase in size (89).

In severe hepatic disease, the dosages of antithyroid drugs should be very cautiously determined.

Drug Administration

Drug dosage regimens

There are two general patterns of use of antithyroid drugs: monotherapy with progressive reduction in dosage during recovery from hyperthyroidism and a higher dosage of antithyroid drugs complemented by thyroid replacement therapy to avoid hypothyroidism. There is no convincing evidence for a better short-term or long-term control of Graves' disease with either form of therapy, but combination therapy followed by monotherapy with levothyroxine increased the remission rate

© 2006 Elsevier B.V. All rights reserved.

substantially. The administration of levothyroxine during antithyroid drug treatment reduces both the production of antibodies to TSH receptors and the frequency of recurrence of hyperthyroidism (90). During combination therapy with propylthiouracil and levothyroxine in normal therapeutic doses the inhibition of the conversion of T4 to T3 is of no importance. A single daily dose of antithyroid drugs cannot completely block iodine organification but can nevertheless control most cases of hyperthyroidism. Such therapy can therefore be used in some patients to improve compliance. The duration of therapy is also controversial, but a more prolonged duration of therapy is usually associated with a higher remission rate (SEDA-12, 354).

Drug overdose

Acute overdose of 13 g of propylthiouracil had no serious adverse effects, except for a temporary reduction in serum triiodothyronine (SEDA-5, 382).

Drug–Drug Interactions

Iodine

Since thionamides block the organification of iodine and incorporation of iodine into iodotyrosines, they inhibit the uptake of ^{131}I used therapeutically in hyperthyroidism. For this reason, thionamides are generally withdrawn for a period of up to a week before ^{131}I therapy is planned, and re-introduction is similarly delayed until several days after ^{131}I therapy. The effect of treatment with either thiamazole or propylthiouracil before ^{131}I has been studied retrospectively (91), the thionamide being withdrawn 5–55 days before ^{131}I administration. The findings confirmed the view that propylthiouracil, but not thiamazole, significantly reduced the cure rate after ^{131}I compared with that found in subjects not pretreated with propylthiouracil, and that discontinuation for 4 months was required for the cure rates to be similar. These findings highlight the fact that thionamides cause a relative "radio-resistance," and prolonged drug withdrawal or an increased dose of ^{131}I may be required to produce an acceptable cure rate.

Thiopental sodium

See also General anesthetics

General Information

Thiopental sodium, a barbiturate and one of the oldest anesthetics, still remains the first-choice induction drug for cesarean section (1).

Organs and Systems

Cardiovascular

Cardiovascular depression is a well-documented complication of thiopental. However, the plasma concentrations necessary to produce loss of corneal reflex and trapezius muscle tone were only minimally depressant to the heart

© 2006 Elsevier B.V. All rights reserved.

(2). Problems can in any case be reduced or avoided by proper fluid administration before induction of anesthesia, as well as by cautious choice of dosage and administration in patients with uncompensated cardiac failure.

Surgery for cerebral artery aneurysms sometimes requires cardiopulmonary bypass and deep hypothermic circulatory arrest if they are to be operated on safely. During such bypass procedures patients with such aneurysms often receive large doses of thiopental, in the hope of providing additional cerebral protection. In 42 non-cardiac patients thiopental loading to the point of suppressing electroencephalographic bursts caused only negligible cardiac impairment and did not impede withdrawal of cardiopulmonary bypass; however, there were no data on patients with cardiac disease (3).

Sensory systems

Patients sometimes notice a taste of onions or garlic before they lose consciousness; the incidence of this sensation was 42% in 113 adult patients (4).

Endocrine

Thiopental given for cerebral protection after cardiac arrest to patients in intensive care caused altered thyroid function (5). Five patients received 5 mg/kg as a bolus followed by 3 mg/kg/hour for 48–72 hours. Free T3 concentrations fell dramatically in three of them and remained near normal in the other two. In those in whom T3 concentrations fell they returned to near normal on withdrawal of thiopental. Reverse T3 concentrations increased in these patients. Although the study was not controlled, the authors speculated that thiopental causes conversion of T3 to reverse T3, and that this can intensify the sick euthyroid syndrome that can occur after cardiac arrest.

Electrolyte balance

Life-threatening hyperkalemia after therapeutic barbiturate coma with thiopental has been described in three patients; it was fatal in one (6). All the episodes occurred after the withdrawal of thiopental. Hypokalemia that is resistant to potassium replacement is common during thiopental coma and clinicians may choose to manage asymptomatic barbiturate-induced hypokalemia expectantly in an attempt to avoid rebound hyperkalemia.

Hematologic

- Immune hemolytic anemia with acute renal insufficiency has been reported in a 55-year-old patient after induction of anesthesia with thiopental 450 mg; a specific thiopental antibody was detected; the patient recovered fully (7).

Gastrointestinal

Vomiting is common during many types of anesthesia (8). By reducing upper esophageal sphincter pressure during induction, thiopental can contribute to this complication (9).

Skin

Fixed drug eruptions after thiopental administration have been reported (10).

Immunologic

Anaphylaxis has been repeatedly reported after thiopental (SED-10, 190) (SED-11, 211), but is rare, with an estimated incidence of one in 30 000.

- An extreme example reported in 1993 involved a 55-year-old obese man with no history of allergy to penicillin, who had on earlier occasions received sodium thiopental without reaction; on this occasion he stopped breathing and had severe bronchial constriction and vascular collapse requiring prolonged resuscitation and mechanical ventilation (11).

Second-Generation Effects

Fetotoxicity

A mother with eclampsia was unsuccessfully treated with diazepam, total dose 120 mg, and phenytoin 750 mg; she received thiopental and had an emergency cesarean section at 33 weeks gestation (12). The infant was unresponsive and floppy, requiring intubation and ventilation. At 10 hours after delivery a flumazenil infusion was begun; the baby responded with facial and limb movements within 30 seconds, resumed spontaneous ventilation, and was extubated 4 hours later. She was maintained on a slowly reducing flumazenil infusion over the next 4 days while the benzodiazepines were metabolized.

Susceptibility Factors

In one case, undetected congenital methemoglobinemia caused severe cyanosis during anesthesia with thiopental 500 mg and nitrous oxide 50% (13).

The use of thiopental or any other barbiturate is contraindicated in acute intermittent porphyria; a progressive neuropathy can occur and can be fatal.

Drug Administration

Drug administration route

Inadvertent injection into extravascular tissues causes pain, swelling, and possibly tissue necrosis. Pain on intravenous injection has been noted in 10% of patients (14). Intra-arterial injection causes vascular spasm and can cause gangrene of a distal extremity.

General Information

Thioridazine is a phenothiazine neuroleptic drug.

Organs and Systems

Cardiovascular

Cardiac dysrhythmias

Thioridazine has been associated with QT interval prolongation (1,2) and several cases of torsade de pointes have been reported (3,4).

Two types of T wave changes have also been described after treatment with thioridazine: type I (with rounded, flat, or notched T waves) and type II (with biphasic T waves) (5).

On July 7, 2000, doctors and pharmacists in the USA were notified about the addition of extensive new safety warnings, including a boxed warning to the professional product label for the neuroleptic drug thioridazine (Melleril, Novartis Pharmaceuticals). The text of the new boxed warning read: "Melleril (thioridazine) has been shown to prolong the QT_c interval in a dose-related manner, and drugs with this potential, including Melleril, have been associated with torsade de pointes-type arrhythmias and sudden death. Due to its potential for significant, possibly life-threatening, prodysrhythmic effects, Melleril should be reserved for use in the treatment of patients with schizophrenia who fail to show an acceptable response to adequate courses of treatment with other neuroleptic drugs, either because of insufficient effectiveness or the inability to achieve an effective dose due to intolerable adverse effects from those drugs."

The new labelling changes were based primarily on the FDA's review of three published studies. The first of these showed increased blood concentrations of thioridazine in patients with a genetic defect, resulting in the slow inactivation of debrisoquine (6). In this study, 19 healthy subjects (six poor and 13 extensive metabolizers of debrisoquine) took a single oral dose of thioridazine 25 mg. The poor metabolizers reached higher blood concentrations of thioridazine 2.4 times more quickly than the extensive metabolizers. There was a 4.5-fold increase in the systemic availability of the drug in the poor metabolizers, in whom thioridazine remained in the blood twice as long. The second study showed dose-related prolongation of the QT_c interval from 388 (range 370–406) to 411 (range 397–425) ms 4 hours after an oral dose of thioridazine 50 mg (7). The average maximal increase was 23 ms. This change was statistically greater than that for either placebo or thioridazine 10 mg. In the third study the effect of the selective serotonin re-uptake inhibitor (SSRI) fluvoxamine, 25 mg bd for 1 week, on thioridazine blood concentrations was evaluated in 10 hospitalized men with schizophrenia (8). The concentrations of thioridazine and its two active breakdown products, mesoridazine and sulforidazine, increased three-fold after the administration of fluvoxamine.

The possibility that some of the cardiac effects of thioridazine may be related to these metabolites as well as the parent compound has been explored (5,9) but needs further investigation.

Several regulatory measures (www.mca.gov.uk) (www.medsafe.govt.nz) (www.imb.ie) (www.hc-sc.gc.ca) (www.bpfk.org) (www.fda.gov) (www.who.int/medicines) have been adopted in different countries with regard to thioridazine.

The role of cardiac effects of neuroleptic drugs in sudden death is controversial (SEDA-18, 47) (SEDA-20, 26) (SEDA-20, 36). There may be multiple non-cardiac causes, including asphyxia, convulsions, or hyperpyrexia. However, some cases of sudden death in apparently young healthy individuals may be directly attributable to cardiac dysrhythmias after treatment with thioridazine or chlorpromazine (10), and from time to time, cases of sudden death are reported (SEDA-20, 36) (SEDA-22, 46), including four cases in which thioridazine in standard doses was implicated as the cause of death or as a contributing factor (11).

- A 68-year-old man with a 5-year history of Alzheimer's disease was treated with thioridazine 25 mg tds because of violent outbursts (12). His other drugs, temazepam 10–30 mg at night, carbamazepine 100 mg bd for neuropathic pain, and droperidol 5–10 mg as required, were unaltered. Five days later, he was found dead, having been in his usual condition 2 hours before. Post-mortem examination showed stenosis of the

© 2006 Elsevier B.V. All rights reserved.

coronary arteries, but no coronary thrombosis, myocardial infarction, or other significant pathology. The certified cause of death was cardiac dysrhythmia due to ischemic heart disease. Thioridazine was considered as a possible contributing factor.

Hypotension

Hypotension is the most commonly observed cardiovascular adverse effect of neuroleptic drugs, particularly after administration of those that are also potent alpha-adrenoceptor antagonists, such as thioridazine. A central mechanism involving the vasomotor regulatory center may also contribute to the lowering of blood pressure.

Severe orthostatic hypotension has been observed in older volunteers ($n = 14$; aged 65–77 years) who participated in a randomized, double-blind, three-period, crossover study, in which they took single oral doses of thioridazine (25 mg), remoxipride (50 mg), or placebo (13). Compared with placebo, there were falls in supine and erect systolic and diastolic blood pressures after thioridazine, but not remoxipride. Standing systolic blood pressures fell by a maximum of 26 mmHg. There were similar falls in blood pressure in young volunteers.

Hypotension has been reported in two other elderly patients who were taking thioridazine (14). The patients, men aged 68 and 70 years, had traumatic brain injury and were taking oral thioridazine 25 mg/day for agitation. A few days later they developed mild hypotension (100/50 and 100/60 mmHg respectively).

Ear, nose, throat

Epistaxis has been reported in three patients with hypertension taking thioridazine (15).

Nervous system

In one study, there was no significant difference in serum concentrations of thioridazine, its metabolites, or radioreceptor activity between patients with and without tardive dyskinesia (16).

Sensory systems

Acute toxic effects of thioridazine on the eyes include nyctalopia, blurred vision, and dyschromatopsia, which typically become evident after 2–8 weeks of dosages over 800 mg/day.

Lens and corneal deposits

Deposits in the lens or cornea probably result from melanin-drug complex deposition and are best detected by slit-lamp examination. These deposits are probably dose- and time-related, since they generally occur only after years of treatment. Fortunately, they are in large part reversible, but if undetected they may progress to interfere with vision. They are most often reported with chlorpromazine or thioridazine and can occur in association with pigmentary changes in the skin.

Pigmentary retinopathy

Pigmentary retinopathy, which can seriously impair vision, is specifically associated with thioridazine, and has occurred more often with high and prolonged dosage (for example 1200–1800 mg/day for weeks to months) (17), although in one case the daily dose was only 700 mg (18). Large-scale surveys have confirmed the relative safety of dosages up to 800 mg/day (19); at any dosage, however, any complaint of brownish discoloration of vision or impaired dark adaptation requires immediate evaluation.

- A 28-year-old woman with a long history of psychiatric problems was taking fluoxetine, diazepam, methylphenidate, and thioridazine 800 mg qds (17). Fluorescein angiography showed confluent areas of punctate hyperfluorescence, consistent with diffuse retinal pigment epithelial alteration secondary to acute thioridazine toxic effects.
- A 51-year-old woman with a long history of psychiatric problems and no family history of hereditary retinal degeneration had reduced vision in both eyes for several years while she was taking thioridazine 300 mg/day and chlorpromazine 600 mg/day (20). She had large patches of atrophy outside the arcades and within the macula, with sparing of foveal pigmentation; there were diffuse increases in hyperpigmentation in the peripheries of both eyes, and hypopigmented or unpigmented retinal epithelium.

The authors thought that the pigmentary changes were probably due to thioridazine, as adverse effects on the retina are rare with chlorpromazine.

Fluid balance

Water intoxication has been reported during treatment with thioridazine and may be due to its pronounced anticholinergic properties and/or direct stimulation of the hypothalamic thirst center (21).

Hematologic

The Committee on Safety of Medicines and the erstwhile Medicines Control Agency in the UK received 999 reports of hemopoietic disorders related to neuroleptic drugs between 1963 and 1996; there were 65 deaths (22). There were 182 reports of agranulocytosis; chlorpromazine and thioridazine were associated with the highest number of deaths—27 of 56 and nine of 24 respectively.

Sexual function

Thioridazine and other highly anticholinergic drugs can cause male sexual dysfunction, including impotence and retrograde ejaculation (23,24). A case of thioridazine-induced inhibition of female orgasm has also been reported (25).

Death

A retrospective case-control study conducted by the same group who first identified a relation effect of pimozide and thioridazine on the QT interval (SEDA-24, 55) has been published (26). The study was carried out in five large psychiatric hospitals in England and included all inpatients with sudden unexplained death over a period of 12 years (1984–1995) and two controls for each case from the same hospital matched for age, sex, and duration of inpatient stay, one of whom was also matched for

© 2006 Elsevier B.V. All rights reserved.

primary psychiatric diagnosis. The patients were aged 18–74 years, and there were 69 cases and 132 controls (63 matched for diagnosis). Since the presence of an organic disorder was significantly associated with sudden unexpected death, this was adjusted for. Sudden death was associated with hypertension, ischemic heart disease, and thioridazine therapy (OR = 5.3; 95% CI = 1.7, 15). Among the limitations of this study was the incompleteness of the records, which often lacked information about important risk factors, including underlying cardiac disease, smoking, or the use of alcohol or illicit drugs; furthermore, the low rate of post-mortem examination raises the possibility that some of the deaths were from causes other than cardiac dysrhythmias, although other causes were found in only three of 30 cases when a post-mortem examination was done.

Long-Term Effects

Drug withdrawal

The consequences of restricting the indications for thioridazine in patients with learning disabilities have been a matter of reflection (27). Of 155 psychiatric patients, 18 were regularly taking thioridazine at the time of the directive; all stopped taking it and seven had moderate or severe difficulties during the following 3 months and one developed probable neuroleptic malignant syndrome 4 weeks after switching to an alternative drug. According to the authors, regulatory authorities should take account of the adverse consequences of drug changes when making judgements about the benefit-to-harm balance, especially in vulnerable patients, such as those with learning disabilities and psychiatric illnesses.

Other consequences of banning thioridazine have been reported in a rural general practice in Ireland, in which 29 of 40 GPs responded to a questionnaire and 17 reported management problems and adverse reactions (28). There was increased service demand, as 44% of the GPs described up to a 50% increase in referrals to the mental health service; although most of the GPs (67%) reported satisfaction with alternative agents, 37% described adverse effects associated with the alternative agents. It seems reasonable that directives should incorporate the flexibility required to accommodate the needs of patients who are already successfully stabilized on these drugs.

Susceptibility Factors

Genetic factors

The higher serum concentrations in poor CYP2D6 metabolizers are associated with an increased risk of thioridazine toxicity (11).

Age

Age increases the risk of thioridazine toxicity (11).

Sex

Female sex increases the risk of thioridazine toxicity (11).

Other features of the patient

Several factors increase the risk of thioridazine toxicity: pre-existing cardiac disease, hypokalemia, a glucose load, alcohol, exercise, and concomitant therapy with tricyclic antidepressants, erythromycin, co-trimoxazole, cisapride, risperidone, hydroxyzine, and drugs that inhibit CYP2D6 (some SSRIs, fluphenazine, and perphenazine) (11).

Drug–Drug Interactions

Beta-adrenoceptor antagonists

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). They can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that interact in this way include thioridazine (29).

The combination of propranolol or pindolol with thioridazine should be avoided if possible (30).

Diuretics

Diuretic-induced hypokalemia can potentiate thioridazine-induced cardiotoxicity (10).

Fluvoxamine

Fluvoxamine increased thioridazine concentrations threefold (8) in 10 patients with schizophrenia taking steady-state thioridazine who were given fluvoxamine (25 mg bd) for 1 week. Fluvoxamine interferes with the metabolism of thioridazine, probably via CYP2C19 and/or CYP1A2.

Lithium

Several cases of neurotoxicity in patients taking lithium and thioridazine have been reported. The cause of this interaction has not been resolved, but lithium seems compatible with all neuroleptic drugs, although patients should be carefully monitored (31–33).

Methylphenidate

Multiple involuntary movements, consisting of jaw grinding, oral dyskinesias, bilateral hand rolling, vermiform tongue movements, and bilateral choreiform movements of the digits, have been described in an 11-year-old boy taking thioridazine 150 mg/day and methylphenidate 10 mg bd (34). The methylphenidate was discontinued and within 4 weeks his movement disorder had completely disappeared.

Quinidine

Concurrent administration of quinidine with neuroleptic drugs, particularly thioridazine, can cause myocardial depression (10).

Thiurams

General Information

Thiurams are a group of chemicals that have been in commercial use since the 1920s. Their main uses are as accelerators and vulcanizing agents during rubber processing and as fungicides on seeds and plants.

Organs and Systems

Immunologic

Allergic contact dermatitis following exposure to thiuram compounds in rubber products, such as disposable rubber gloves, is well recognized (1).

- A 49-year-old man developed acute pruritic dermatitis of the hand, which settled quickly with oral glucocorticoids and antibiotics (2). Six months later he developed a similar eruption, which became more widespread, involving the trunk and limbs. He had no personal or family history of atopy, and had no known allergies or previous

© 2006 Elsevier B.V. All rights reserved.

history of skin disease. He had a widespread dry eczematous eruption, most marked in exposed areas. The rash had developed soon after he had handled plants that had been sprayed with a fungicide. The safety data sheet for this product indicated that it contained 80% thiuram. Full blood count and serum electrolytes were normal, and autoantibodies and a porphyrin screen were negative. Biopsy of the lesion showed significantly sun-damaged skin with a superficial perivascular chronic inflammatory infiltrate, confluent surface parakeratosis, and epidermal acanthosis with moderate spongiosis, consistent with a spongiotic dermatitis. He denied any previous contact with rubber gloves in both occupational and social settings, and had not had dermatitis before. He was treated with sun protection, topical and oral glucocorticoids, and a moisturizer. He had no further contact with the fungicide and the eruption resolved completely. He was advised to avoid all thiuram products, including rubber products and fungicides, in the future. Despite this, he subsequently developed one recurrence of hand dermatitis when he again used rubber gloves for protection at work.

Three Chinese national servicemen developed an itchy postauricular rash (3). None had a history of atopy and all three reported prior use of rubberized spectacle retainers as a curved pliable extension to the posterior ends of the earpieces of their spectacles, to stabilize them while undergoing rigorous military physical training. They were all patch-tested with the National Skin Center standard series and were positive to thiuram mix and the rubberized spectacle retainers. They were treated with topical corticosteroids and were advised to stop wearing their rubberized spectacle retainers.

Thorotrast

General Information

Thorotrast (thorium dioxide), which has a radioactive half-life of about 400 years, was widely used in 1928–55 as an X-ray contrast medium.

By 1933 Thorotrast had been shown to induce malignancies in rats. It was prohibited in various countries from 1936 onwards, but continued to be used in some parts of the world for another three decades. Its late effects continue to be reported. Thorotrast deposits are predominantly localized in the liver and reticuloendothelial system; the major late effects have been portal fibrosis, malignant liver tumors, and myeloproliferative disorders, but granulomatous, fibrotic, and malignant changes in many other organs have been described. Thorotrast is the most potent human leukemogen yet identified. The risk of a fatal blood dyscrasia after Thorotrast is very much greater than after external radiotherapy, and the latent period (20 years) is very much longer than after external irradiation (5–7 years).

In a 1993 follow-up study in Denmark of mortality among 999 patients who had received Thorotrast between 1935 and 1947 the excess mortality was explained in part by diseases known to be induced by Thorotrast, such as cirrhosis and cancer of the liver and leukemias and other hematological disorders; it was suggested that non-specific effects induced by the alpha particles emitted by Thorotrast may have contributed to this excess mortality (1).

Organs and Systems

Hematologic

The retention of Thorotrast in the bone marrow leads to the development of leukemia. Chromosome aberrations in bone marrow cells occurred at a high frequency in Japanese patients who had been given Thorotrast (2).

Liver

Various liver neoplasms due to chronic alpha-ray irradiation have been attributed to Thorotrast, most notably hepatocellular carcinoma, angiosarcoma, and cholangiocarcinoma. Multiple Thorotrast-induced primary tumors are rare but have been reported in a report from Japan (3).

- An 86-year-old man received intravenous Thorotrast to investigate a bullet wound to his shoulder in 1939. He presented in 1993 with jaundice, leading to liver failure and death. Autopsy showed four separate carcinomas: a cholangiocarcinoma in the left lobe of the liver, a well-differentiated tubular carcinoma of the antrum of the stomach, an invasive squamous carcinoma of the lung, and a well-differentiated adenocarcinoma of the ampulla of Vater. There were multiple mutations in the p53 tumor suppression gene caused by chronic alpha-ray irradiation.
- A 74-year-old developed nausea, night sweats, generalized fatigue, and weight loss (4). Thorotrast cerebral angiography had been performed 55 years before. Computed tomography of the abdomen showed areas of calcification within the liver, spleen, and peripancreatic lymph nodes, and there was a mass in the liver. Liver biopsy confirmed cholangiocarcinoma.

There has also been a report of nodular regenerative hyperplasia of the liver associated with previous Thorotrast administration (5).

Susceptibility Factors

Genetic factors

Several studies have shown that mutations of the TP53 gene (formerly known as p53) are important in the genesis of Thorotrast-induced tumors (6–8).

Thrombolytic agents

General Information

The major thrombolytic agents are:

- streptokinase
- urokinase
- anistreplase (anisoylated plasminogen streptokinase activator complex or APSAC)
- pro-urokinase (single-chain urokinase-type plasminogen activator or scu-PA)
- alteplase (recombinant tissue plasminogen activator or rt-PA)
- reteplase (r-PA: a deletion mutant of rt-PA)
- tenecteplase (a triple combination mutant variant of alteplase).

Although their pharmacodynamic properties do not differ significantly, some characteristics, as a result of their origin or mode of action, explain specific differences in their adverse effects and pharmacokinetics.

General adverse effects

Hemorrhage is the major risk of thrombolytic drugs; there are some differences in risks between the various agents, and certain susceptibility factors can be identified. Transient hypotensive reactions have been described with all thrombolytic agents, but they are in principle reversible. Hypersensitivity reactions are most often seen in patients who have been treated with compounds derived from cultures of streptococci (streptokinase and anistreplase). Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Transient hypotension can occur after thrombolysis, and the incidence after infusion of streptokinase in myocardial infarction is high. Hypotension has been related to plasminemia, which leads to bradykinin generation from kallikrein, activation of complement, and potentially endothelial prostacyclin release (1). During treatment of myocardial infarction, some other mechanisms may explain hypotension: vagal reflexes precipitated by posterior wall reperfusion (2) and left ventricular dysfunction associated with the infarct process. Hypotension occurs shortly after the start of infusion and can be accompanied by bradycardia, flushing, and anxiety. It is reversible if fluids are given and the infusion temporarily stopped (1); vasopressors may be needed. The magnitude of this hypotensive reaction is directly related to the rate of infusion of streptokinase. The incidence of such reactions does not seem to be affected by premedication with glucocorticoids. Like streptokinase, anistreplase can also cause transient hypotension (3). Alteplase seems to be associated with a lower risk of hypotension than streptokinase or anistreplase. In the ISIS-3 trial, the incidences of profound hypotension necessitating drug therapy were: 6.8% with streptokinase, 7.2% with anistreplase, and 4.3% with alteplase (4).

Embolic detachment of components of venous or mural thrombi can sometimes be involved in the development of thromboembolism or cholesterol embolization. There is a 10% incidence of pulmonary embolism during thrombolysis, lethal in 0–5% (5), pointing to the risk of detachment of white components of venous thrombi, especially if large veins, such as those in the pelvis, are involved (6). However, the risk has not been proven to exceed that reported in patients treated with heparin and/or oral anticoagulants.

Cholesterol embolization is thought to occur after removal of mural thrombi covering atherosclerotic plaques leading to direct exposure of the soft lipid-laden core of these plaques to the arterial circulation. The contents of the soft lipid core, including crystallized cholesterol, shower the downstream circulation. Cholesterol crystals are impervious to dissolution or lysis and they lodge in small arterioles, causing obstruction. Cholesterol embolization shortly after thrombolytic treatment is characterized by livedo reticularis or multiple necrotic lesions of the skin of both legs (7) but can also be associated with

© 2006 Elsevier B.V. All rights reserved.

lower limb ischemia, gangrene, visceral ischemia, or pseudovasculitis (8). Cholesterol embolization is difficult to diagnose, and may therefore be more common than suspected. It can cause acute renal insufficiency (9), and renal biopsy shows acute tubular necrosis, in some instances with arteriolar clefts representing cholesterol crystals (10).

Reperfusion dysrhythmias can occur when thrombolytic drugs are used to treat myocardial infarction. The most common is transient ventricular tachycardia. However, controlled trials have failed to show an increase in serious ventricular dysrhythmias, the incidence of ventricular fibrillation being actually reduced by thrombolytic therapy in myocardial infarction (11).

- A coronary artery aneurysm occurred in a 49-year-old man 1 month after successful percutaneous transluminal coronary recanalization with streptokinase (12).

Phlebitis at the site of infusion of streptokinase has been reported.

Respiratory

Streptokinase can cause acute bronchospasm, sometimes fatal (13), or dyspnea.

Nervous system

Guillain–Barré syndrome has been reported in patients who were treated with streptokinase and anistreplase (14–18). As streptokinase and anistreplase are derived from streptococci, an immunological reaction is thought to have been responsible.

Sensory systems

Iritis and uveitis have been reported with streptokinase (19,20).

Hematologic

Hemorrhage is the major risk of the use of thrombolytic agents and can result from the lysis of thrombi at other sites where hemostasis is required. Hemostatic incompetence related to thrombolysis is also related to reductions in circulating fibrinogen and factors V and VIII and to the generation of fibrin and fibrinogen degradation products with anticoagulant properties. The most serious complication is intracranial hemorrhage, which has a high mortality (60% in the GUSTO-1 trial) and a high rate of severe disability (up to one-third of patients) (21).

In trials of intravenous streptokinase without angiography, hemorrhagic complications, apart from local venepuncture sites, were reported in about 4% of patients, with an absolute excess over controls of about 3% (11). Major bleeding, defined by transfusion requirements, occurred in only 0.5% of patients, and cerebral hemorrhage was seen in only 0.1%. In the AIMS trial, all hemorrhagic complications during hospitalization were 14% with anistreplase and 4.1% with placebo (22). Transfusion was required in 0.8% in each group. The absolute excess of cerebral hemorrhage rates was 0.3% with anistreplase compared with placebo. In the ASSET trial, the absolute excess risks of minor and major hemorrhagic complications with alteplase were respectively 6 and 0.9%. The excess risk of hemorrhagic strokes was 0.2% (23).

Several large clinical trials have compared alteplase and anistreplase with streptokinase. No clear-cut differences in severe or life-threatening bleeding were observed in these studies.

However, in interpreting these results, the role of adjunctive antithrombotic therapy must also be taken into account, since it can increase the risk of hemorrhage (24). In most of the trials, heparin-treated patients had significantly more major bleeding, and in the ISIS-3 trial, the incidence of cerebral hemorrhage was significantly increased by heparin (4). In the TIMI II B trial (25) in patients with unstable angina, the addition of a low dose of alteplase (0.8 mg/kg) to aspirin and heparin was associated with a 2.4% incidence of major hemorrhagic events (versus 0.6% with placebo) and a 0.55% incidence of intracranial hemorrhage (no such event occurring with placebo).

A study in general practice has suggested that intracranial hemorrhage during thrombolytic therapy for myocardial infarction may be more frequent than in clinical trials (10). The authors analysed the data accumulated in a US large registry called NRMI 2 (1484 hospitals, 71 073 patients having received alteplase in the initial treatment of acute myocardial infarction). The overall incidence of intracranial hemorrhage was 0.95%. This is a higher incidence than has been reported in clinical trials, and may have been due to the stringent enrolment criteria.

The susceptibility factors for intracranial hemorrhage have also been examined (10). The main factors were:

- advanced age; compared with patients under 65, the odds ratio was 2.71 (CI = 2.18, 3.37) for individuals aged 65–74 years and as high as 4.34 (3.45, 5.45) for patients aged 75 years or more
- female sex
- black ethnicity
- a history of stroke
- hypertension (an increased risk in patients with a systolic blood pressure of 140 mmHg or more and/or a diastolic of 100 mmHg or more)
- the dose of alteplase.

Because of the significant correlation with age and a previous history of stroke, it is now widely considered that in patients over 75 years with a history of stroke other therapies, such as primary coronary angioplasty, must be considered. As reported in the GUSTO-1 trial, patients with very high systolic blood pressures have an increased risk of death or disabling stroke (26), and the pulse pressure has been reported to be the clearest predictor of the blood pressure as regards the risk of intracranial hemorrhage (27).

The risk of major bleeding during thrombolytic therapy is undoubtedly a real problem, but it has to be considered against the background of the underlying mortality risk and the absolute benefit likely to be achieved in patients with acute myocardial infarction (28). This equation is fundamental in older patients, who have the highest mortality risk after myocardial infarction and thus the most to gain from thrombolysis (29).

Some reports of serious adverse consequences in patients with aortic dissection or pericarditis that mimic

© 2006 Elsevier B.V. All rights reserved.

clinical or electrocardiographic myocardial infarction have emphasized the necessity for accurate diagnosis before thrombolysis is instituted in patients with chest pain or with atypical electrocardiographic changes (30).

The incidence of hemorrhagic complications is particularly high when high doses of streptokinase are used in the treatment of deep venous thrombosis (31). High-dose streptokinase thrombolysis for 2–3 days with an initial dose of 500 000 units followed by a maintenance dose of 3 600 000 U/day led to a 10% rate of major spontaneous bleeding complications, with a fatal outcome in four older subjects out of the total of 98 patients. The fatality rate of bleeding caused by streptokinase amounts to 7% in patients with peripheral arterial occlusion, but is much lower in younger patients with venous thromboembolism.

Secondary intraventricular hemorrhage has been described in two patients who received intraventricular tissue-type plasminogen activator to hasten the lysis of intraventricular hemorrhage (32).

Hemolysis after intravenous streptokinase is rare (33).

Transient lymphopenia, possibly related to immunological destruction of T-helper cells by streptokinase, has been described (34).

Platelet aggregation due to an antibody-mediated reaction has been suggested as a cause of streptokinase-enhanced coronary thrombosis in patients with a specific type of antistreptokinase antibodies (35).

Thrombocytopenia has been described after thrombolytic therapy but it is most probably multifactorial, since patients generally also received intravenous heparin (36).

Disseminated intravascular coagulation has been reported with urokinase (37).

Liver

There were no differences in the activities of serum transaminases, lactate dehydrogenase, or creatine kinase in patients with myocardial infarction who received an 18-hour infusion of urokinase compared with patients who received glucose alone (38), but subacute alterations of liver function tests have been described with streptokinase and anistreplase (39). Unexplained increases in transaminase activities have been reported in almost 25% of patients treated with streptokinase (40). In view of the greater prominence of liver dysfunction with streptokinase than with alteplase it could be wiser to choose alteplase rather than streptokinase in patients with previous impaired hepatic function (41).

A few cases of liver dysfunction with or without jaundice have been reported with streptokinase and urokinase (42–45). Jaundice with hepatic cytolysis can occur after allergic reactions to streptokinase (46).

Urinary tract

Hematuria and proteinuria can occur without alteration of immunohistochemical features, suggesting a non-immune cause, such as a direct effect on the glomeruli or a reflection of the hypocoagulable state.

- Acute interstitial nephritis associated with cholesterol embolization during streptokinase therapy has been reported (47). In this case, cholesterol clefts were found in the preglomerular and interlobular arterioles. Cholesterol embolization can cause acute renal insufficiency (9), and renal biopsy shows acute tubular necrosis with, in some instances, arteriolar clefts representing cholesterol crystals (10).

Immunologic

Since streptokinase is a natural product of cultures of streptococci and therefore has similar antigenic properties, most of the population have anti-streptokinase antibodies. These antibodies may explain both the allergic reactions that can occur and resistance to the drug, which occurs in some cases. Within 3 or 4 days of streptokinase administration, the titer of neutralizing antibodies has become sufficient to inactivate the usual doses. Persistence of these antibodies is observed in up to 80% of patients 1 year after treatment and in about 50% of patients after 2–4 years (48,49). If streptokinase has to be re-administered within 8 months of previous exposure, the neutralizing effects of plasma should be taken into account and the dose of streptokinase should be adjusted to overcome these effects (50). However, the extent to which streptokinase antibodies decline after earlier exposure to streptokinase is controversial, and persistently raised titers are found in a large proportion of patients (51). For this reason, an alternative thrombolytic agent should be recommended in patients who have already received streptokinase. In addition, it appears that allergic reactions occur more often when streptokinase is reused (52).

Anistreplase, a compound consisting of streptokinase and anisoylated plasminogen, can also cause allergic reactions, but has a longer half-life, allowing intravenous administration in a relatively short interval of time.

Urokinase is extracted from human urine or prepared from cultures of fetal kidney cells and does not seem to cause allergic reactions.

Pro-urokinase, alteplase, reteplase, and tenecteplase, which are recombinant products, also appear to be free from allergic reactions. Pro-urokinase and alteplase have short half-lives (3–8 minutes) and require continuous infusion administration, which may in some cases be an advantage as it allows rapid surgical intervention when necessary (53). Reteplase and tenecteplase have substantially longer half-lives, allowing bolus administration.

The incidence of acute generalized allergic reactions in patients treated with streptokinase or anistreplase was originally reported to be high, but with the introduction of more highly purified forms of streptokinase the figure has fallen to 1–5%. The most common manifestations of non-anaphylactic reactions to streptokinase or anistreplase are skin rashes and pyrexia. However, anaphylactic shock with streptokinase is also well known, although rare; it occurred in 0.1% of the patients in the GISSI trial (54). Life-threatening angioedema has been described with streptokinase (55,56) and with alteplase (57–59). Skin rashes are seen especially with streptokinase, but rarely, if ever, with alteplase.

Several cases of low back pain associated with streptokinase or anistreplase injections for acute myocardial infarction have been described, with rapid resolution once the streptokinase was stopped (60,61). It is

© 2006 Elsevier B.V. All rights reserved.

presumed that the mechanism is allergic, since no such report has been published with alteplase (62).

Streptokinase is regularly reported to have induced an immune complex syndrome, characterized by plasmacytosis, often severe, and accompanied by fever and the development of hemolytic anemia, occurring as early as the first week after the start of treatment; in some cases, temporary alterations in renal function also occur (63).

Vasculitis has been rarely described after streptokinase or anistreplase (64–67), but not after urokinase or alteplase. It is characterized by lymphocyte infiltration and deposition of immune complexes, fibrin, and complement in the skin microvasculature.

Other patients have the typical picture of serum sickness, sometimes associated with acute renal insufficiency (68–70) or of Henoch–Schönlein purpura (71) with a purpuric rash, joint and abdominal pains, and sometimes hematuria (72).

Adult respiratory distress syndromes and multisystem organ failure have been reported with streptokinase and anistreplase (73–76); the timing of the onset of symptoms and the antibody profile in one case suggested an immunological response (74).

The clinical efficacy of thrombolytic drugs such as streptokinase does not appear to be compromised by the occurrence of allergic reactions, according to data from GUSTO-1 (77).

There have been three reports of anaphylactoid reactions, mostly orolingual angioedema, after therapy of acute ischemic stroke with alteplase.

- In one patient there was marked edema of the lip about 45 minutes after a bolus dose of alteplase; it subsided within 2 hours without any intervention (78).

Of 105 consecutive patients treated with alteplase for acute ischemic stroke, 2 developed anaphylactoid reactions (79). The first had a rash and extensive bilateral swelling of the tongue, epiglottis, and uvula, requiring intubation. The second developed unilateral swelling of the tongue and lips without a rash or hypotension.

In 230 patients treated with alteplase for acute ischemic stroke, there were two cases of orolingual angioedema (80). Both presented with localized symptoms only, symmetrical in one and asymmetrical in the other.

IgE-associated anaphylactic reactions can also occur.

- A 70-year-old woman was treated with intravenous alteplase for thrombolysis in acute ischemic stroke and 30 minutes later had acute sinus tachycardia and hypotension, followed by cyanosis and loss of consciousness (81). Serum samples analysed by ELISA were positive for IgE antibodies to alteplase.

Such reactions are very rare; there have been four reported cases in over 1 million administrations.

Body temperature

Pyrexia can occur after the initial dose of streptokinase (82). Concurrent administration of glucocorticoids does not prevent it completely. A marked rise in body temperature with chills can be accompanied by hypotension, abdominal pain (particularly low back pain), and very occasionally mild psychotic reactions.

Second-Generation Effects

Pregnancy

Pregnancy is not considered to be incompatible with treatment with thrombolytic agents. No adverse effects on the fetus have been reported. Nevertheless, the possibility cannot be excluded that placental separation and uterine bleeding will occur. Only minimal amounts of streptokinase cross the placenta, and these are not sufficient to cause fibrinolysis in the fetus (83). Although the passage of streptokinase is blocked by the placenta, streptokinase antibodies do cross to the fetus (84). This passive sensitization would have clinical importance only if the neonate required streptokinase therapy. Septicemia during treatment with streptokinase has been also described (85). These different hazards may preclude the use of thrombolytic drugs during pregnancy but in acute life-threatening problems, efficacy has to be weighed up against the risk of adverse effects.

Drug Administration

Drug administration route

Pleural space infection is an important cause of sepsis, and traditional treatment comprises drainage of the pleural space, either through chest tubes or surgically, combined with antibiotics. Attempts at closed drainage with a chest tube often fail, owing to the development of loculations within the fluid and the high viscosity of the infected fluid. This problem has led to the use of intrapleural fibrinolytic drugs to improve drainage, hasten resolution of infection, and reduce the need for surgical intervention. At first, the use of intrapleural streptokinase and streptodornase was complicated by frequent allergic reactions, but with the availability of purified forms of streptokinase and urokinase these agents have been widely used for intrapleural fibrinolysis and this has been reviewed.

Streptokinase

Several reports, predominantly in the form of case series, have described the use of intrapleural streptokinase for complicated pleural effusions (86–92). The dose of streptokinase used varies, but is usually around 250 000 IU instilled once or twice daily, with tube clamping for 2–4 hours, repeated over several days. Local adverse effects are rare, but transient chest pain at the time of instillation occurs occasionally (93).

There are occasional reports of fever attributed to the intrapleural instillation of streptokinase (86,88), but the most important adverse event due to intrapleural streptokinase is systemic fibrinolysis. In many of the case series cited above, simple tests of clotting activity were performed before and after treatment and there were no significant changes. However, in 1984, a case report described major hemorrhage in one patient after the intrapleural use of streptokinase 500 000 IU, with tube clamping for 6 hours (94). Within 12 hours this patient developed a generalized coagulopathy, with features of disseminated intravascular coagulation. Following this report, in a carefully designed study, the systemic fibrinolytic effects of one dose (250 000 IU) and multiple doses of intrapleural streptokinase (250 000 IU bd for 3 days) were examined in

© 2006 Elsevier B.V. All rights reserved.

healthy subjects (95). There were no physiological or statistical changes in any coagulation indices after intrapleural streptokinase. This suggests that the hemorrhage seen in the 1984 case report was probably not related to streptokinase, but was perhaps a complication of underlying sepsis.

Although intrapleural streptokinase does not cause systemic fibrinolytic effects, there can be local fibrinolytic effects. In a case series describing the use of intrapleural streptokinase or urokinase in 26 patients, one developed major "oozing" from rib fractures sustained 1 month before therapy (89). This local bleeding required two thoracotomies. It is not clear from the report if streptokinase or urokinase was used in this patient, but streptokinase was used in most of patients in this series. Furthermore, the dose used was also not clear, with streptokinase doses of 100 000–750 000 IU.

In 1998, major local hemorrhage after the use of intrapleural streptokinase was described in two patients (96). One patient had undergone mitral valve replacement 6 weeks before and collapsed after 2 days of standard intrapleural streptokinase, with hemorrhage into the chest. The second had undergone a mitral valve replacement 9 months before intrapleural streptokinase and collapsed with bleeding into the chest after 3 days. Both patients recovered, but the authors felt that recent cardiac surgery presented a contraindication to the use of intrapleural fibrinolytic drugs. It is not clear from this report if these two patients were taking oral anticoagulants, such as aspirin or warfarin, which may have confounded these findings. Another report of local hemorrhage has recently been published (97). The patient died after the instillation of intrapleural streptokinase for presumed empyema; autopsy showed an unsuspected abdominal aortic dissection with extension of blood clot into the thoracic cavity. These reports suggest that intrapleural streptokinase should be used with caution when there has been prior surgery or trauma involving the thorax.

Another potential adverse event associated with the use of intrapleural streptokinase is the development of antistreptokinase antibodies. These antibodies have been documented after intravenous streptokinase and can cause serious adverse events with re-exposure to streptokinase or can limit the efficacy of streptokinase in myocardial revascularization.

Urokinase

Urokinase has also been widely used intrapleurally for fibrinolysis, in doses of 40 000–250 000 IU and is as effective as streptokinase (98–101). Furthermore, urokinase is not antigenic and does not produce febrile reactions. As with streptokinase, transient chest pain at the time of instillation has occasionally been reported. These considerations have led some authors to prefer urokinase to streptokinase for intrapleural therapy, but urokinase is about twice as expensive and there is also more published experience with streptokinase.

Drug–Drug Interactions

Diltiazem

Clinical and experimental data suggested a possible increase of hemorrhage risk during thrombolytic therapy with alteplase in combination with diltiazem (102).

Heparin

The combination of thrombolytic agents with an anticoagulant and/or aspirin has been said to be life-threatening. An excess of major bleeding episodes with combined subcutaneous heparin and streptokinase or alteplase treatments (1.0% with heparin versus 0.5% without heparin) has been reported in the International Study Group Trial (103) in patients with suspected acute myocardial infarction.

Interference with Diagnostic Tests

Coagulation tests

Thrombolytic agents interfere with the measurement of plasma fibrinogen and other coagulation tests by promoting continuing fibrinolysis after the specimen is taken; thus, fibrinogen cannot be measured in a sample that is taken less than an hour after the administration of a thrombolytic agent.

Thrombopoietin

General Information

Thrombopoietin is an endogenous colony-stimulating factor that increases the number of megakaryocyte colonies in bone marrow and also induces maturation of megakaryocytes (1). Recombinant thrombopoietin is indicated for correction of thrombocytopenia, induced by chemotherapy or radiotherapy (1). It has been tested in subcutaneous doses up to 5 micrograms/kg/day, resulting in increased numbers of platelets at 7 days, with a peak count at 17 days (1).

Organs and Systems

Hematologic

Thrombotic complications (deep venous thrombosis, pulmonary embolism, and superficial vein thrombosis) have been described in a few patients receiving thrombopoietin (2). In none was thrombosis related to the platelet count, since none had more than 1000×10^9/l platelets. It could not be determined if the thrombosis was due to thrombopoietin or if an underlying malignancy predisposed these patients to thrombosis (2).

In in vitro studies thrombopoietin stimulates leukemic cell growth, but in clinical studies restimulation of leukemia has not been observed (2).

Thyroid hormones

General Information

Nomenclature

In this monograph the following terms are used:

- thyroxine (T4): the endogenous hormone;
- triiodothyronine (T3): the endogenous hormone;
- levothyroxine (rINN) and dextrothyroxine (rINN): the stereoisomers of thyroxine, as used therapeutically;
- liothyronine (rINN): triiodothyronine, as used therapeutically.

Physiology

The normal adult thyroid gland secretes about 90 micrograms of thyroxine (T4) and less than 10 micrograms of liothyronine (triiodothyronine, T3) per day. Somewhat less than half of the T4 is converted to T3 by several tissues (especially the liver). Most of the daily production of T3 thus comes from peripheral 5′-deiodination of T4 and not by direct glandular secretion. The thyroid hormones are tightly bound (T4 even more than T3) to plasma transport proteins; this explains their prolonged half-lives (about 8 days for T4 and about 1 day for T3). Nuclear receptors for thyroid hormones bind T3 much more efficiently than T4, explaining the more rapid onset of action and greater biological potency of T3. The intestinal absorption and hepatic clearance of orally ingested thyroid hormones also differ. T3 has higher systematic availability than T4, only about 60% of which appears in the peripheral circulation after oral administration (1). However, some formulations provide higher intestinal absorption of T4 (80%) (2). These basic data form the background of optimal thyroid substitution.

© 2006 Elsevier B.V. All rights reserved.

Thyroid hormones are used either to replace the failing function of the thyroid gland (spontaneous or drug-induced) or to suppress the endocrine function of abnormal thyroid tissues (especially non-toxic struma or goiter or after thyroidectomy for thyroid neoplasms). Although there are abnormalities of the peripheral metabolism of thyroid hormones in some forms of undernutrition or overnutrition, thyroid drug therapy cannot be considered a safe way of treating obesity.

Treatment with thyroid hormones therefore poses only a few essential questions: which dosage should be used, which formulation should be chosen, and how can therapy best be monitored so as to avoid short-term and long-term risks.

Uses

Levothyroxine is used as replacement therapy in hypothyroidism and to suppress the production of thyrotrophin (thyroid-stimulating hormone) in patients with thyroid carcinoma.

Dextrothyroxine has been used as a lipid-lowering agent. It significantly lowers the serum cholesterol (3) as does levothyroxine; however, dextrothyroxine has a much smaller hormonal effect on body tissues than levothyroxine. The literature is confusing, since older formulations of dextrothyroxine contained considerable amounts of levothyroxine.

Liothyronine can be used for thyroid substitution, but it has the disadvantage of having a short-lived action and its intestinal absorption can give rise to unusually high post-absorption peaks, causing tachycardia. Moreover, the dosage necessary to obtain euthyroidism is more difficult to evaluate, owing to fluctuations in serum T3 concentrations; furthermore, in patients taking liothyronine, measurements of thyrotrophin are also probably less reliable, since its secretion by the pituitary gland depends more on the extracellular T4 concentration than on the T3 concentration. Therapeutic use of liothyronine is therefore generally only recommended when a more rapid onset of action is necessary, for example when thyroid therapy needs to be interrupted for the administration of ^{131}I in the treatment of thyroid cancer. In myxedematous coma it is controversial whether the therapeutic choice should be liothyronine, or levothyroxine, or a combination (4). Moreover, long-term therapy with liothyronine is more likely to cause secondary osteoporosis than T4.

The drug of choice for thyroid replacement therapy is therefore levothyroxine since it is the natural secretory product of the thyroid, has a long half-life, and is metabolized to T3 in the peripheral tissues.

Doses

The optimal dosage of levothyroxine should be based on repeated measurements of T3 and TSH serum concentrations. The daily recommended dose depends on the aim of the therapy. Thyroid replacement therapy for control of spontaneous or iatrogenic hypothyroidism should aim at a dosage of levothyroxine that maintains TSH concentrations within the low reference range. This will usually be associated with a free T4 concentration in the high reference range and a T3 concentration within the reference range. The mean requirement for such patients is 112 micrograms/day (2) or 1.57 micrograms/kg per day (5). This dose is lower than that recommended previously because of better knowledge of the real production rate of T4, the availability of better pharmaceutical formulations allowing better availability, and especially because of better methods for drug monitoring (SEDA-12, 353) (SEDA-15, 444) (6–8). Patients stabilized on one pharmaceutical formulation should not be switched to another without proper monitoring of thyroid hormones.

When thyroid therapy is used not only to replace deficiency but also to prevent the growth of remnants of a differentiated thyroid carcinoma, a suppressive dosage is used, aiming at T4 concentrations in the high reference range and an undetectable TSH concentration or at least one that is below the lower end of the reference range, as measured by two-sided assays. Such therapy is warranted because of its long-term safety, efficacy, and tolerance, but some additional therapy for osteoporosis prevention should be considered.

As with all forms of long-term therapy, adherence to the prescribed dosage of levothyroxine is not always optimal, and an unwarranted fear of thyroid-induced osteoporosis can add to this lack of adherence. Inadequacy of thyroxine replacement therapy is not always easily recognized. Several patients were reported with clearly inadequate or excessive consumption of levothyroxine despite a correct prescription. All patients had depression, which could be an additional susceptibility factor by promoting lack of adherence, and the resulting hypothyroidism or hyperthyroidism could further aggravate the depression (9).

When replacement therapy is with levothyroxine only, the T4/T3 ratio is increased compared with healthy subjects, suggesting that thyroid secretion of T3 is physiologically important. Animal studies have shown that euthyroidism is not restored in all tissues by levothyroxine alone (10). Mood and neuropsychological function improved in hypothyroid patients when 50 micrograms of thyroxine was replaced by 12.5 micrograms of liothyronine (11).

Several studies have failed to confirm the benefits of combined levothyroxine and liothyronine therapy. Liothyronine given once a day results in non-physiological peak serum concentrations of T3. Modified-release triiodothyronine plus thyroxine can normalize serum biochemistry, but it is not known whether this formulation is superior to levothyroxine alone (12).

In contrast to other protein-bound drugs for which a loading dose is given to achieve rapid steady-state concentrations, a slow and stepwise increase in thyroid hormone replacement therapy is advisable. This is preferred mainly to avoid sudden cardiac adverse effects, especially in older patients with long-standing myxedema. Moreover, since thyroid hormone substitution can change the metabolic clearance of this drug, steady-state concentrations are obtained only after several months (SEDA-6, 363).

General adverse effects

Ingestion of excessive amounts of thyroid hormones can cause symptoms and signs similar to those that result from endogenous overproduction. However, the symptoms and signs are generally relatively trivial in those who take standard doses of levothyroxine replacement therapy,

© 2006 Elsevier B.V. All rights reserved.

although abnormalities have been evident in detailed studies of those who take levothyroxine in doses sufficient to suppress serum TSH (13). The adverse effects can therefore largely be avoided by adjusting the dosage according to the appropriately selected laboratory tests.

The adverse effects essentially comprise the symptoms of hyperthyroidism and include weight loss despite a normal or increased appetite, increased nervousness, tachycardia or dysrhythmias of various types, and increased general metabolism and its symptoms (hyperactivity, sweating, fever, etc.). Allergic reactions to pure thyroid formulations are rare and were first reported as late as 1986. Tumor-inducing effects have been investigated but not confirmed.

Organs and Systems

Cardiovascular

Overdosage of thyroid hormones causes tachycardia or palpitation but can also cause several types of dysrhythmia, for example atrial fibrillation. Evidence from the Framingham population that suppression of serum TSH is a susceptibility factor for atrial fibrillation has heightened concern that subclinical hyperthyroidism secondary to levothyroxine can also cause atrial fibrillation (14). Five women who reported frequent bouts of palpitation were investigated while taking levothyroxine and again after levothyroxine withdrawal (15). There was a clear increase in mean 24-hour heart rate during levothyroxine treatment, as well as an increase in atrial extra beats and the number of episodes of re-entrant atrioventricular nodal tachycardia. Four of these patients had evidence of abnormal conduction pathways, even when they were not taking levothyroxine, as evidenced by a short PR interval, but exacerbation of atrial dysrhythmias in these predisposed subjects is consistent with the view that thyroid hormones increase atrial excitability and may increase the risk of cardiac morbidity, especially if given in doses sufficient to suppress serum TSH.

Pre-existing cardiac disease, always to be suspected in elderly people or after long-standing hypothyroidism, can be severely aggravated by sudden thyroid substitution, resulting in severe angina pectoris, myocardial infarction, or sudden cardiac death (SEDA-13, 375). In such patients, the initial dosage should be low and the stepwise increase should be spaced out over a prolonged period and with careful clinical and cardiographic monitoring (16). In some circumstances, for example three-vessel disease, substitution should be postponed until after coronary bypass surgery (SEDA-6, 363). Cardiac decompensation can also result from the increased circulatory demand induced by thyroid hormone substitution or overtreatment. Long-term treatment with levothyroxine in doses that suppress thyrotrophin can have significant effects on cardiac function and structure, especially in patients with hyperthyroid symptoms (13,17), but large prospective studies are needed to assess cardiovascular risk in these patients.

In two cases of hypothyroidism myocardial infarction occurred at the start of thyroxine therapy in the absence of evidence of significant coronary artery disease (18).

- A 58-year-old man with a previous smoking history and a history of hypertension was severely biochemically hypothyroid (serum TSH 221 mU/l) and was given thyroxine, initially in a low dose (25 micrograms/day), increasing to 100 micrograms/day after 2 weeks. A month later he sustained a subendocardial myocardial infarction associated with only minor abnormalities on coronary angiography.
- A 61-year-old woman with severe hypothyroidism (serum TSH 115 mU/l) had an acute myocardial infarction (but no demonstrable abnormality on coronary angiography) 1 month after a thyroxine dosage increase from 50 to 100 micrograms/day.

Cautious introduction of thyroxine, especially in elderly people and those with severe or long-standing hypothyroidism, is prudent.

Myocardial infarction can also occur during long-term use of levothyroxine.

- A 71-year-old woman who had undergone total thyroidectomy with subsequent irradiation because of follicular carcinoma 3 years before (19). Since then, she had taken oral levothyroxine 0.15 mg and 0.2 mg on alternate days. When latent hypothyroidism became evident despite replacement therapy, the dose of levothyroxine was increased to 0.3 mg/day. Three weeks later, she had formed an acute posterior myocardial infarction, although she had no previous history of coronary artery disease. Subsequent coronary arteriograms revealed no evidence of disease of the major vessels. Myocardial scintigraphy 3 weeks after infarction still showed a persistent perfusion defect.

In the US Coronary Drug Project (20) a formulation of dextrothyroxine with a so-called low levothyroxine content was used. The study had to be terminated because of an excessive number of cardiac deaths and non-fatal infarcts.

Nervous system

Insomnia, psychic stimulation, general nervousness, and tremor are among the hyperthyroid symptoms that result from relative overdosage. Pseudotumor cerebri has incidentally been observed shortly after levothyroxine was given for juvenile hypothyroidism. The headache and bilateral papilledema without focal neurological defects subsequently disappeared even when levothyroxine was continued (21).

Psychological, psychiatric

Several cases of mania have been reported even after dosages of levothyroxine that are usually considered safe (22).

Musculoskeletal

A slipped capital femoral epiphysis has been described during the treatment of hypothyroidism (SEDA-3, 340). Since slipping occurs more often during the pubertal growth spurt, it is advisable to check for the occurrence of this complication during the pubertal period in children taking thyroid treatment.

Prolonged overtreatment with levothyroxine can result in osteopenia (23). Thyroid hormones have a direct effect on bone cells, thereby increasing both bone resorption

© 2006 Elsevier B.V. All rights reserved.

and formation with subsequent mild adaptation of the systemic calciotrophic hormones (24). Increased bone turnover can result in a small deficit during each cycle and therefore finally result in mild osteoporosis. There are no good data regarding the incidence of fracture, but the bone mineral content of several areas known to be at risk of fracture (lumbar spine, forearm, femur) has been measured, mainly in cross-sectional studies, but also in a few prospective studies. During replacement therapy for hypothyroidism a small bone deficit was associated with a prior history of Graves' disease and/or later therapy with dosages of liothyronine or levothyroxine that suppress TSH concentrations (SEDA-16, 471). Since overt hyperthyroidism is associated with bone loss, it is possible that the reduction in bone density reported in some studies of levothyroxine treatment reflects an adverse effect of previous thyrotoxicosis rather than levothyroxine therapy itself (SEDA-17, 473).

In 50 women taking levothyroxine either for primary thyroid failure or for hypothyroidism secondary to radioiodine treatment for hyperthyroidism, there was no difference between the two groups in terms of bone density at the hip or spine and no difference from the reference population (25). In addition, there was no correlation between bone density and circulating thyroid hormone concentrations or duration of levothyroxine replacement. These findings are reassuring, although large studies of fracture risk are required, in view of previous evidence of an adverse effect of levothyroxine on bone mineral density, especially in post-menopausal women (26).

In a meta-analysis of cross-sectional studies suppressive levothyroxine was associated with mild but significant bone loss in postmenopausal women (SEDA-20, 394). The best measure of the effects of prolonged levothyroxine therapy can probably be obtained from bone mineral content in patients treated with suppressive doses of levothyroxine for thyroid carcinoma (Table 1).

Postmenopausal women with intact parathyroid glands on prolonged suppressive levothyroxine therapy may be more susceptible to osteoporosis and should have their bone mineral density measured and/or take preventive osteoporosis therapy. Cautious use of levothyroxine, avoiding overdosage and unnecessary use, is probably safe for bone.

Immunologic

Fever, liver dysfunction, and eosinophilia occurred during liothyronine or levothyroxine treatment of a hypothyroid patient and disappeared after withdrawal of therapy (31). In vitro lymphocyte testing confirmed sensitization for thyroid hormones.

Progressive re-institution of liothyronine subsequently proved possible in this patient without recurrence of hypersensitivity. Liothyronine was considered preferable because of the shorter biological half-life.

Long-Term Effects

Drug abuse

Abuse of thyroid hormones, causing factitious hyperthyroidism, can have adverse effects (32,33), including sudden death, attributed to ventricular fibrillation (34).

Partial empty sella syndrome (pituitary atrophy) has been described in an elite body builder who had abused various hormones, including testosterone, growth hormone, and triiodothyronine 25 micrograms qds for many years (35). He presented with infertility, and investigations showed suppression of serum TSH, a raised serum T3, and a partially empty pituitary sella.

It is likely that in this case long-standing suppression of pituitary function secondary to negative feedback from exogenous hormone ingestion (including liothyronine) resulted in pituitary atrophy.

Tumorigenicity

A possible link between breast cancer in women and thyroid hormone therapy was suggested on the basis of a retrospective study of patients with breast cancer (SEDA-3, 340). A subsequent statistical re-analysis of the original data failed, as did later studies, to confirm such a relation (SEDA-3, 340) (SEDA-4, 294) (36).

Second-Generation Effects

Pregnancy

The transplacental passage of maternal iodothyronines is quantitatively modest, although it might be sufficient to

Table 1 Summary of studies on the effects of thyroid hormones on bone mineralization

Reference	Number and sex (age in years)	Disease	Follow-up period (years)	Femur	Spine	Radius
(27)	7 F 1 M	Primary hypothyroidism; levothyroxine 125 micrograms/day	1	–	–9% per year	
(28)	6 F 4 M	Hypothyroidism (50 years); levothyroxine 135 micrograms/day	1	–7%	–5%	–
(29)	24 M (50)	Primary hypothyroidism (8 years) after ^{131}I	3	NS	NS	NS
(30)	18 F (60)	Hypothyroidism treated for 14 years	2			
		(a) low TSH (levothyroxine 170 micrograms/day)		–1.4% per year	–2.9% per year	–1.2% per year
		(b) normal TSH		–0.3% per year	–1.1% per year	–0.13% per year

ensure adequate fetal development. Maternal thyroid hormone secretion is markedly increased during pregnancy (by 25–50%); thyroid therapy should therefore be carefully adjusted during pregnancy (37).

Susceptibility Factors

Pre-existing cardiac disease and long-standing hypothyroidism carry serious risks.

Adrenal insufficiency can be associated with hypothyroidism (either by autoimmune destruction or due to hypophyseal disease) and carries the risk of acute Addisonian crisis if thyroid substitution precedes glucocorticoid therapy. The diagnostic problem presented by the fact that a few patients with central hypothyroidism have a moderately increased serum TSH should be kept in mind (38).

Some goitrous patients have autonomous thyroid hormone secretion, which is still within the reference range, but they become hyperthyroid even with relatively small amounts of exogenous thyroid hormones, since the latter accumulate with the endogenous autonomous thyroid secretion.

Rarely severe gastrointestinal disease can reduce the absorption of levothyroxine.

Since levothyroxine is occasionally used in supraphysiological doses to treat euthyroid people with refractory depression, adverse effects in healthy controls ($n = 13$) and patients with refractory depression also taking antidepressants ($n = 13$) have been studied in an 8-week, non-blind study (39). There was a higher rate of discontinuation of levothyroxine in the control subjects than in the patients, because of perceived adverse effects (38% versus 0%), together with a more marked rise in serum free T4 and free T3 in the controls. This suggests that the influence of supraphysiological doses of thyroxine is greater in healthy subjects than in those with psychiatric illness, perhaps reflecting the influence of the illness, or its therapy, on thyroid hormone metabolism in the latter.

Drug Administration

Drug overdose

Inadvertent excessive use of thyroid hormones (for example, by eating ground beef contaminated with thyroid hormones (40), the incorrect use of these drugs for the treatment of obesity (41), excessive thyroid substitution therapy, and factitious use of thyroid hormones for psychiatric reasons (42)) result in mild hyperthyroidism, but serious short-term adverse effects are rare.

Overdosage of levothyroxine causes increased metabolism resulting in increased heat production, with increased sweating and weight loss despite normal or even increased appetite. Accidental or suicidal injection of large amounts of thyroid hormones is exceptional (43). Clinical symptoms do not necessarily correlate well with plasma T4 concentrations and range from anxiety, confusion, or coma to tachycardia, atrial fibrillation, and angina. At least three lethal cases have been reported (SEDA-8, 371).

- A 34-year-old man took 900 tablets of veterinary levothyroxine, a total of 720 mg, and was given 60 g of activated charcoal (44). He became lethargic on days 2 and 3; on day 4 he had vomiting, sweating, and insomnia; on day 5 he became agitated and aggressive and stopped speaking intelligibly; and on day 6 he became combative and confused. He was sweating, mydriatic, hyper-reflexive, and tremulous, with clear lungs and active bowel sounds. He was given activated charcoal, haloperidol, diazepam, and phenobarbital, and had an endotracheal tube inserted. He was rehydrated and given propranolol and diazepam, but remained continuously tachycardic. On day 12 he became afebrile and his tachycardia resolved. Free T4 concentrations ranged from over 130 ng/l on day 6 to 12 ng/l on day 12. By discharge on day 15 he had lost 20 kg in weight, but was clinically euthyroid 2 weeks later.
- Self-induced thyrotoxicosis was associated with a marked rise in circulating free T4 and free T3 concentrations in a pregnant woman with an eating disorder who was abusing both levothyroxine and furosemide (45).

Treatment of thyroid overdosage is not standardized and can include gastric lavage, sedatives, beta-blockers, hydrocortisone, and specific antidysrhythmic drugs. Plasmapheresis (46) and exchange transfusion (47) have been used successfully to treat life-threatening cases. Iodine-containing organic radiographic agents (ipodate) can be effective, since they are potent inhibitors of the peripheral conversion of T4 to T3, but rebound effects can occur (43).

Drug–Drug Interactions

Antacids

Two patients with hypothyroidism taking a fixed dosage of levothyroxine took aluminium hydroxide and magnesium oxide (48). In both cases there was a marked increase in the serum concentration of TSH and low serum T4. After withdrawal of the antacids, TSH again fell. In vitro studies showed a dose-related adsorption of levothyroxine by a combination of aluminium hydroxide, magnesium hydroxide, and magnesium carbonate, but no effect of magnesium oxide alone.

Calcium carbonate

Calcium carbonate can reduce levothyroxine absorption (49).

- A 49-year-old woman, taking levothyroxine 150 micrograms/day and calcium carbonate (three tablets daily) for prevention of osteoporosis, developed symptoms of hypothyroidism and had a raised serum TSH concentration (22 mU/l). She was advised to continue taking the same dose of levothyroxine but to separate her medications. Repeat biochemical testing 8 months later showed a normal serum TSH (3.3 mU/l).
- A 61-year-old woman with hypothyroidism had celiac disease and a history of bowel resection for pancreatic cancer, was euthyroid taking thyroxine 175–188 micrograms/day (50). However, when she simultaneously took calcium carbonate (1250 mg/day) she had a raised serum thyrotropin (TSH) concentration of 41 mU/l. Delaying calcium carbonate ingestion by 4 hours returned her serum TSH concentration to high normal (5.7 mU/l) within a month.

© 2006 Elsevier B.V. All rights reserved.

Because of the possibility that calcium carbonate might impair levothyroxine absorption, another group carried out a prospective study in 20 patients taking stable long-term levothyroxine for hypothyroidism, who were given elemental calcium as calcium carbonate 1200 mg/day, taken with their levothyroxine for 3 months (51). Mean serum concentrations of free thyroxine and total thyroxine were significantly reduced during the calcium treatment period and rose after withdrawal. Mean concentrations of T3 did not change, but serum TSH rose during the calcium period, and 20% of the subjects had a serum TSH concentration above the reference range. The authors also reported the results of an in vitro study of thyroxine binding to calcium, which showed that there is adsorption of thyroxine to calcium at acidic pH. These findings show that calcium salts can have a modest put potentially clinically significant effect on levothyroxine treatment, probably by binding it and reducing its absorption; patients should be advised to separate their medications.

Colestyramine

Colestyramine can reduce thyroxine absorption (52).

Estrogens

Oral estrogens increase circulating concentrations of thyroxine-binding globulin, thereby increasing the bound fraction and reducing the free (bioactive) fraction of circulating thyroxine; this effect does not occur with transdermal estrogens (53). Thus, oral estrogens increase levothyroxine dosage requirements in women with primary hypothyroidism, at least during the first few months after the start of therapy.

Ferrous sulfate

Iron binds thyroxine in vitro (54) and ferrous sulfate can reduce thyroxine absorption (55). This can result in hypothyroidism (54,56). A similar interaction with ferrous fumarate has been described in a patient who took both medications simultaneously (57). Separation of thyroxine from iron may be prudent, since this interaction may reflect the formation of a non-absorbable complex in the gut (54).

Indinavir

Levothyroxine is metabolized in part through the action of glucuronyl transferase, which can be inhibited by some antiretroviral drugs, such as indinavir.

- Clinical and biochemical hyperthyroidism occurred in a 36-year-old woman, after previously stable levothyroxine replacement therapy, when antiretroviral drugs for HIV infection were introduced (58). She was reported to be taking a very large dose of levothyroxine (750 micrograms/day) after partial thyroidectomy for Graves' hyperthyroidism some 6 years before. One month after starting antiretroviral treatment she developed symptoms and signs suggestive of thyroid hormone excess and had markedly raised serum free T4 and free T3 concentrations, with suppression of TSH. The dose of levothyroxine was reduced progressively to 120 micrograms/day, and after about 2 months her thyroid function tests returned to normal.

While this pattern of biochemistry does not exclude transient relapse of Graves' hyperthyroidism (despite the finding of negative TSH receptor antibodies), or a transient thyroiditis, the authors speculated that indinavir (prescribed in this patient together with stavudine and lamivudine) had inhibited the glucuronidation of thyroxine and hence caused a rise in serum thyroid hormone concentrations.

Rifampicin

There was a modest rise in serum TSH concentration when rifampicin was given to a patient previously stabilized on thyroxine replacement (59). Rifampicin is believed to increase the metabolic clearance of both thyroxine and the inactive compound reverse triiodothyronine and in healthy volunteers it reduces circulating concentrations of total and free thyroxine, although in subjects without thyroid disease it has no effect on serum TSH (60).

Monitoring Therapy

Some diseases (liver disease, kidney disease, and malnutrition) interfere with the transport or metabolism of thyroid hormones and thereby alter thyroid function tests.

Several drugs (for example amiodarone, androgens, glucocorticoids, phenytoin, and salicylates) interfere with the transport or metabolism of thyroid hormones and thereby alter thyroid function tests. These have been reviewed (61). In patients taking levothyroxine serum TSH rises after treatment with sertraline (62) and antimalarial prophylaxis with chloroquine and proguanil (SEDA-22, 469).

Thyrotrophin and thyrotropin

General Information

Thyrotrophin is native thyroid-stimulating hormone. Recombinant human thyrotrophin is called thyrotropin.

Thyrotropin stimulates iodine uptake, and this facilitates the diagnosis and treatment of recurrent disease or metastases in the follow-up of differentiated thyroid cancer. It is used as an alternative to thyroid hormone withdrawal, to avoid symptomatic hypothyroidism (1). Headache and nausea occur in 6–40% of patients after intramuscular administration, but are usually mild and transient (2,3).

The adverse effects of thyrotropin have been reviewed (4).

Organs and Systems

Immunologic

Many years ago bovine thyrotrophin was used for diagnostic purposes and to increase ^{131}I uptake. However, for diagnostic purposes it has been replaced by sensitive TSH assays, and because of antibody development and hypersensitivity reactions it is not used therapeutically. There is no evidence that thyrotropin causes allergic reactions, even after multiple injections (4).

Rapid tumor expansion has been occasionally reported after thyrotropin, including four of 55 patients with central nervous system metastases enrolled in a compassionate use protocol (5). Two patients with locally recurrent papillary carcinoma had tumor growth 12–48 hours after their second injection of recombinant thyrotropin (rTSH); rapid improvement in neck pain, stridor, and dysphonia after glucocorticoids suggested an inflammatory etiology (5). There were no features to suggest an allergic reaction; only one such case has been reported and there are no reports of antibody formation even after repeated dosing (1).

Tiabendazole

See also Benzimidazoles

General Information

Tiabendazole is a non-carbamate benzimidazole which inhibits cellular enzyme systems specific to some species of helminths. It is active against *Giardia lamblia*, but less effective than albendazole and mebendazole. It was at

© 2006 Elsevier B.V. All rights reserved.

one time the drug of choice against *Strongyloides stercoralis*, both the enteric and tissue forms, but has been superseded by more modern drugs. It is also effective against *Enterobius*, hookworms, and *Trichuris trichiura*. Normally given orally, it is rapidly absorbed, with peak serum concentrations 1–2 hours after ingestion. It is rapidly metabolized and excreted; 40% of the drug and its metabolites are excreted during the first 4 hours and 80% during the first 24 hours. Its main metabolite, 5-hydroxythiabendazole, is inactive.

General adverse effects

Common toxic effects of tiabendazole include nausea, vomiting, and dizziness. Malaise and drowsiness are also common. Liver disorders can occur and are the most serious complications. Most systems can on occasion be affected. Allergic reactions are essentially due to parasite destruction rather than a direct effect of the drug itself. Chills, fever, lymphadenopathy, angioedema, and pruritic rashes all can occur; and treatment should in that case be stopped, since otherwise more serious reactions (for example Stevens–Johnson syndrome) can follow. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Bradycardia, hypotension, and syncope can occur with tiabendazole, even to the point of collapse (1).

Nervous system

Somnolence has been described with high doses of tiabendazole rectally or orally, and drowsiness, headache, malaise, and fatigue are common (1). Patients should be warned not to drive or carry out other potentially hazardous pursuits during treatment.

More severe symptoms of neurotoxicity are not unusual and include disorientation, confusional states, feelings of detachment, overt psychosis (2), and possibly epileptiform convulsions (3), although the latter have been observed only in a case of Down syndrome.

Sensory systems

Effects of tiabendazole on vision are not uncommon: abnormal sensations in the eyes, xanthopsia (a yellow tinge to objects), blurred vision, drying of mucous membranes, and sicca syndrome all have been described (4).

Allergic reactions to tiabendazole can cause keratoconjunctivitis sicca as part of Sjögren's syndrome (5).

Tinnitus has been attributed to tiabendazole (6).

Metabolism

Instances of both hypoglycemia and hyperglycemia have been recorded in patients taking tiabendazole.

Hematologic

Marked peripheral eosinophilia has also been described after rectal thiabendazole (7).

Gastrointestinal

Nausea, anorexia, vomiting, abdominal pain, and diarrhea are common and occur in a high proportion of patients taking tiabendazole (8).

Liver

Parenchymal liver damage can occur in patients taking tiabendazole and abnormal liver function tests have been documented (9). There have been well-studied cases of bile duct injury, which can lead to micronodular cirrhosis (10), and a case in which these various forms of liver disorder co-existed and liver transplantation proved necessary (11).

Persistent cholestasis can occur in patients taking tiabendazole (12).

- A 27-year-old patient from Surinam with beta-thalassemia took tiabendazole 1250 mg bd for 2 days for strongyloidiasis (13). One week later she became icteric, with raised total and conjugated bilirubin, alkaline phosphatase, gamma-glutamyltransferase, and transaminases. Tests for antinuclear antibodies, parietal cells antibodies, smooth muscle antibodies, mitochondrial antibodies, hepatitis A, B, C, cytomegalovirus, Epstein–Barr virus, mumps, and measles were negative. Ultrasonography showed normal intrahepatic and extrahepatic bile ducts. Liver biopsy showed intrahepatic cholestasis and a slightly increased infiltrate in the portal areas. One week later she developed a generalized urticarial rash. She had mildly abnormal liver tests for the next 7 years, at which time a liver biopsy showed a slight lymphatic infiltrate in the portal fields, without signs of cirrhosis, chronic hepatitis, or primary biliary cirrhosis.
- A 42-year-old woman, also from Surinam, with beta-thalassemia and non-insulin dependant diabetes mellitus took tiabendazole 1250 mg bd for 2 days for strongyloidiasis (13). Five weeks later she developed general malaise, anorexia, weight loss, icterus, and a tender liver. She had raised total and direct bilirubin, gamma-glutamyltransferase, and alkaline phosphatase, but only marginally raised transaminases. Tests for Hepatitis A, B, and C, cytomegalovirus, and schistosomiasis were negative. Tests for antinuclear antibodies and antibodies against liver cell membranes, smooth muscle, and mitochondria were negative, but there were parietal cell antibodies. Ultrasonography and ERCP showed normal intrahepatic and extrahepatic bile ducts. Liver biopsy showed severe centrally localized cholestasis. A year later all clinical and laboratory abnormalities had disappeared.

In view of these and previous cases of severe cholestasis after tiabendazole and the availability of less toxic equally effective drugs (albendazole or preferably ivermectin), tiabendazole must be considered obsolete in the treatment of strongyloidiasis.

Urinary tract

Crystalluria has been noted in patients taking tiabendazole, sometimes with hematuria (1).

© 2006 Elsevier B.V. All rights reserved.

Tiabendazole can give the urine an asparagus-like smell because of the presence of a mercaptan metabolite of tiabendazole (14).

Skin

Pruritus and skin rashes can occur (15). Much more rarely, toxic epidermal necrolysis has occurred after a total dose of 1800 mg, and Stevens–Johnson syndrome and erythema multiforme have also been reported (16).

Very occasionally a topical form of tiabendazole is used, for example to treat rosacea, and in one such case contact dermatitis aggravated by sunlight occurred as a complication, with positive tests for tiabendazole sensitivity (17).

Musculoskeletal

Tiabendazole can cause severe muscle pain on exercise (18).

Second-Generation Effects

Teratogenicity

There is no firm information on adverse reactions during pregnancy, but animal evidence points to teratogenicity and there have been official warnings against use by pregnant women (19).

Susceptibility Factors

Renal disease

Tiabendazole is metabolized almost completely by the liver, and its active metabolites are substantially excreted by the kidney; the risk of toxicity may therefore be greater in patients with impaired renal function (20).

Hepatic disease

Because tiabendazole is metabolized almost completely by the liver (20), it should be used with caution in hepatic impairment.

Drug–Drug Interactions

Theophylline

Tiabendazole can markedly increase serum concentrations of theophylline, with a prolonged half-life and a reduced clearance rate; concomitant administration of theophylline and thiabendazole resulted in severe nausea and vomiting (21).

Tiagabine

See also Antiepileptic drugs

General Information

Tiagabine is a nipecotic acid derivative which inhibits GABA re-uptake. It is highly bound to plasma proteins (96%) and is mainly eliminated by CYP3A-mediated oxidation, with a half-life of about 7 hours (1). It is used in add-on treatment of refractory partial seizures. Its adverse effects are mostly on the central nervous system.

In a review of safety data from nearly 3100 patients included in 53 clinical trials, tiagabine had no significant effect on hepatic metabolic processes, serum concentrations of concomitant anticonvulsants, and blood chemistry and hematology tests (2). Allergic reactions, such as skin rashes, were less common with tiagabine than with most other anticonvulsants. Adverse effects were generally mild and affected mainly the central nervous system, the most common being dizziness, weakness, nervousness, tremor, difficulty with concentration and attention, speech disorders, depression, and abdominal pain. About 1% of patients given tiagabine experienced weakness severe enough to cause falls or inability to walk, and some form of weakness occurred in about 9% of patients, especially at high dosages or after stopping a single concomitant enzyme-inducing antiepileptic drug.

The safety of long-term tiagabine has been studied retrospectively in 42 patients with refractory partial epilepsy who took tiagabine for longer than 6 months (3). The most common adverse events were tiredness (56%), headache (46%), dizziness (44%), visual symptoms (blurring, difficulty in focusing, and diplopia; 39%), altered thinking (32%), and tremor (31%). The adverse events profile was comparable among those who had taken tiagabine for 6–12 months, 12–24 months, and more than 24 months.

The use of tiagabine 4–16 mg/day in preventing migraine has been studied in 41 patients who had failed treatment with divalproex sodium because of adverse effects or lack of efficacy (4). There was at least a 50% reduction in the frequency of migraine headaches in 33 patients. There were adverse events in 12 patients, most commonly tiredness; a few patients had weight gain or confusion.

The effects of tiagabine have been studied in a 4-month, single-blind study in 52 children over the age of 2 years with different syndromes of refractory epilepsy (5). Adverse events, mostly mild to moderate, were reported by 39% of the children during the single-blind placebo period and by 83% of the children during tiagabine treatment. The events predominantly affected the nervous system; weakness (19%), nervousness (19%), dizziness (17%), and somnolence (17%) were the most common. One child had hallucinations that responded to dosage reduction. Only three children withdrew because of adverse events.

The efficacy and safety of tiagabine have been assessed in a study with an open screening phase (in which patients were titrated to the optimal tiagabine dose), followed by a double-blind, placebo-controlled, crossover phase (6). Of the 88 patients who entered the double-blind phase, seizure frequency was significantly reduced in 44, and there was an over 50% reduction of partial seizures in 33%. There were adverse events in 77% of the patients during the screening phase and 22% during the double-blind phase. The most frequent adverse events were dizziness (32%), somnolence (30%), and weakness (19%). Two patients taking tiagabine withdrew during the double-blind phase because of adverse events.

Organs and Systems

Nervous system

In add-on trials, adverse events significantly more common with tiagabine than with placebo were dizziness (30 versus 13%), weakness (24 versus 12%), nervousness (12 versus 3%), tremor (9 versus 3%), depressed mood (5 versus 1%), and emotional lability (4 versus 1%) (SEDA-19, 73) (SEDA-20, 65) (SEDA-22, 91) (7). Somnolence, amnesia, confusion, difficulty in concentrating, paresthesia, headache, and ataxia can also occur.

In a randomized, double-blind, add-on trial of tiagabine (16, 32, or 56 mg/day) in 297 patients with refractory partial seizures, adverse events significantly more common with tiagabine were dizziness in the 32 mg group (33 versus 15% with placebo), tremor in the 32 and 56 mg groups (15 and 21 versus 3%), mental lethargy or difficulty in concentrating in the 56 mg group (14 versus 3%), and depressed mood in the 16 and 56 mg groups (7% in both groups versus 0%) (8). In a similar study with a dosage of 10 mg tds, the most common adverse events were dizziness, weakness, headache, and somnolence (9), but only dizziness was significantly more common than with placebo (29 versus 10%).

A few more cases of non-convulsive status epilepticus associated with tiagabine have been reported (10–12).

Exacerbation of seizures

Tiagabine can reportedly exacerbate seizures and non-convulsive status epilepticus (SEDA-21, 74). Two of nine patients with partial epilepsy in a trial of tiagabine 30 mg/day developed non-convulsive status and features consistent with atypical absence seizures, although neither had had such seizure types before; drug withdrawal was followed by sustained remission (13). GABAergic drugs aggravate absence seizures, but the de novo occurrence of absences in patients with partial epilepsy is unusual. Tiagabine is only recommended for partial seizures (with or without secondary generalization).

- After an increase in tiagabine dose to 32 mg/day, a 28-year-old woman with partial epilepsy developed a prolonged and disoriented state associated with generalized spike-and-wave discharges on the electroencephalogram. Tiagabine was withdrawn and the status did not recur.
- Two similar episodes occurred in a 28-year-old man taking 24 and 32 mg/day (14).
- Both patients were taking a non-enzyme-inducing agent (valproate and lamotrigine respectively), which probably resulted in higher serum tiagabine concentrations than those seen in enzyme-induced patients.

© 2006 Elsevier B.V. All rights reserved.

Although the manufacturer's database suggested that non-convulsive status is rare during tiagabine therapy (2), the possibility of status needs to be considered in patients who develop episodes of confusion or atypical behavior while taking tiagabine, especially high dosages. A critical analysis of the available literature suggests that misdiagnosis can occur and that some reported cases of putative non-convulsive status epilepticus might in fact have been due to drug-induced encephalopathy (2,15). Overall, the risk of tiagabine-induced generalized non-convulsive status is likely to be greater in patients with a history of absence or generalized epileptic discharges, which are known to be aggravated by GABAergic agents, but patients without such a history can be also affected.

Generalized non-convulsive status needs to be differentiated not only from non-epileptic encephalopathy, but also from partial non-convulsive status, which can also be occasionally precipitated by tiagabine (2,15).

There have been cases of generalized non-convulsive status epilepticus in patients with chronic partial epilepsy treated with tiagabine, on one occasion specifically associated with frontal lobe discharges (15).

- A 12-year-old boy with familial bilateral perisylvian polymicrogyria, mental retardation, and refractory partial seizures was given tiagabine in addition to sodium valproate, and the dosage was increased to 10 mg tds (1 mg/kg/day). This produced complete seizure control. After 1 week he developed hypoactivity, reduced reactivity, and affective detachment. Electroencephalography showed subcontinuous sharp-wave discharges, with irregular runs of atypical spike-wave complexes over the anterior regions of both hemispheres, consistent with a diagnosis of frontal non-convulsive status epilepticus. The dosage of tiagabine was reduced to 15 mg/day and there was complete regression of the behavioral and affective changes and normalization of the electroencephalogram.
- A 21-year-old woman with partial epilepsy had seizure aggravation and complex partial status epilepticus after stepwise increase of tiagabine to 60 mg/day in addition to carbamazepine and vigabatrin (16). The electroencephalogram showed bilateral rhythmic slow activity, which disappeared, together with clinical signs, when intravenous clonazepam (2 mg) was given.

Tiagabine 0.45–40.57 mg/kg/day was associated with long-standing non-convulsive status epilepticus in three girls, two aged 12 years and one aged 17 years, with refractory localization-related epilepsy (17). Resolution followed withdrawal of tiagabine or a reduction in dosage.

Dystonias

Three patients had transient dystonic reactions while taking tiagabine 20–30 mg/day in addition to carbamazepine (18). The dystonic reactions occurred during the first few weeks of treatment. The patients each had a different type of dystonia: focal limb dystonia, oromandibular dystonia, and writer's cramp. In each case the dystonia resolved spontaneously without withdrawal of tiagabine and without any other treatment. Although paroxysmal dystonic movements have been well described with carbamazepine, these patients had been taking carbamazepine for years without this adverse effect.

In placebo-controlled trials, the overall incidence of non-convulsive status epilepticus was no higher with tiagabine than with placebo. However, there have been isolated reports of tiagabine-related non-convulsive status epilepticus (19).

The frequency of status during tiagabine trials has been compared with the occurrence of status epilepticus in four large epidemiological cohorts from Rochester (Minnesota), Turku (Finland), New York, and New Haven (Connecticut) (20). A review of 13 cases with non-convulsive status showed that most of them had had generalized discharges on prior electroencephalography. Only three had encephalographic evidence of status during tiagabine treatment. In the placebo-controlled trials, there was no difference in the frequency of status or complex partial status between patients taking tiagabine or placebo (0.8–1.0 versus 1.5%). In long-term safety studies, which included 2248 patients, there was a 5% frequency of status and a 3% frequency of complex partial status in the tiagabine-treated patients, which was similar to the rates of occurrence in the four external cohorts. Thus, tiagabine does not appear to increase the risk of status or non-convulsive status.

Sensory systems

Following reports of concentric visual field defects associated with vigabatrin (SEDA-21, 78), there has been concern that other drugs that enhance GABAergic inhibition might cause a similar disorder. Although visual field defects were detected in six of 12 patients treated with tiagabine in Australia, no details were given, and this report seems to have remained isolated (21). In a controlled study, none of 15 patients who took tiagabine monotherapy for 1.5–3.5 years (mean daily dose 22 mg) had evidence of a concentric visual field defect (22).

The effect of tiagabine on visual function has been studied in 15 patients with chronic partial epilepsy treated for 23–55 months with tiagabine monotherapy after failure with standard antiepileptic drug monotherapy (23). Three patients had localized field losses (two quadrantanopic and one hemianopic) from earlier brain lesions. Tiagabine had no effect on visual fields but acquired color vision defects were found in seven of 14 patients; contrast sensitivity was unaffected.

Psychological, psychiatric

Although psychosis has been described occasionally (24), in three double-blind trials the incidence of psychotic symptoms was comparable to placebo (SEDA-21, 74). However, patients with a past history of psychiatric disturbances are often excluded from trials, and caution is recommended when using tiagabine in these patients.

Metabolism

Changes in body weight have been evaluated in 349 patients taking carbamazepine, phenytoin, or tiagabine. Carbamazepine add-on therapy caused a significant mean weight gain of 1.5% (25). However, tiagabine add-

© 2006 Elsevier B.V. All rights reserved.

on therapy to either phenytoin or carbamazepine caused no significant weight change.

Hematologic

- A 42-year-old woman developed thrombocytopenia (platelet count 4×10^9/l), ecchymoses, and petechiae after taking tiagabine 50 mg/day for about 1 month (26). Bone-marrow biopsy showed a moderate increase in megakaryocytes without signs of disturbed maturation. Withdrawal of tiagabine led to gradual recovery.

However, the authors failed to mention that ecchymoses have been reported before in patients taking tiagabine, as discussed in the manufacturer's prescribing information (7).

Gastrointestinal

Nausea, vomiting, diarrhea, abdominal pain, and ecchymoses can occur, but they are not common (SEDA-22, 91) (7).

Susceptibility Factors

Hepatic disease

Hepatic dysfunction is associated with impaired tiagabine elimination and can result in greater susceptibility to adverse effects (SEDA-21, 75). Tiagabine should only be used cautiously and in reduced dosages in these patients.

Other features of the patient

Caution is also required in patients with a history of depression or behavioral disorders (24).

Drug Administration

Drug dosage regimens

Two different dosage regimens (twice or three times a day) of add-on tiagabine have been compared in a multicenter, open, randomized, parallel-group study in 347 patients (27). The tiagabine dosage was titrated over 12 weeks to a target of 40 mg/day. The patients were followed for a further 12 weeks. Significantly more patients in the thrice-daily group completed the titration period (81 versus 73%). The proportion of responders during the last 8 weeks of the flexible phase was similar in the two groups (42% for twice-daily and 47% for thrice-daily administration). Thus, although both regimens appeared to offer similar efficacy, significantly more patients completed the study in the thrice-daily group, probably because tolerability is less when high doses are given undivided.

In a large comparison of 16 mg bd with 8 mg qds, the twice-daily schedule tended to be associated with more adverse events (SEDA-22, 91).

Drug overdose

In four adults who took 300–800 mg, the most common symptoms were agitation, hostility, and myoclonus. Supportive care, including in some cases gastric lavage and activated charcoal, was effective. One patient developed status epilepticus, which was managed with phenobarbital (SEDA-21, 74).

Tiagabine overdose (1 g) was associated with convulsive status epilepticus in a 39-year-old man, previously well controlled (28). The tiagabine plasma concentration was 2620 ng/ml, over 10 times higher than the concentrations found in trials.

Drug–Drug Interactions

Contraceptive steroids

Tiagabine, unlike carbamazepine and oxcarbazepine, felbamate, phenobarbital, phenytoin, and topiramate, does not affect the metabolism of oral contraceptive steroids (29).

Enzyme-inducing anticonvulsants

The most important interactions of tiagabine involve induction of its metabolism by enzyme-inducing anticonvulsants (30). This results in larger tiagabine dosage requirements compared with patients taking monotherapy or valproic acid co-medication.

Tiapride

See also Neuroleptic drugs

General Information

Tiapride is a substituted benzamide related to sulpiride, a selective dopamine D_2 and D_3 receptor antagonist with little propensity for causing catalepsy and sedation. It has antidyskinetic activity, reflecting its antidopaminergic action, and also anxiolytic activity mediated by mechanisms that are poorly understood. Unlike the benzodiazepines, tiapride does not affect vigilance and has a low potential for interaction with ethanol, and possibly for abuse. From a clinical point of view, it can be considered as an atypical neuroleptic drug. It has reported efficacy in neuroleptic-drug induced tardive dyskinesia, levodopa-induced dyskinesias, psychomotor agitation in elderly patients, and chorea (1).

Tiapride appears to be useful in alcohol withdrawal as an alternative to the benzodiazepines (2). It facilitates the management of ethanol withdrawal, but its use in patients at risk of severe reactions in acute withdrawal should be accompanied by adjunctive therapy for hallucinosis and seizures. Since it may prove difficult to identify such patients and since there is also a small risk of the neuroleptic malignant syndrome (particularly with parenteral administration), the usefulness of tiapride in this setting is likely to be limited. The potential risk of tardive dyskinesia at the dosage used in alcoholic patients following detoxification (300 mg/day) requires evaluation and necessitates medical supervision. It is unlikely to produce problems of dependence or abuse.

Tiapride has been assessed for the treatment of agitation and aggressiveness in elderly patients with cognitive impairment in a multicenter, double-blind study, in which patients were randomly allocated to tiapride 100 mg/day ($n = 102$), haloperidol 2 mg/day ($n = 101$), or placebo ($n = 103$) (3). The percentage of responders after 21 days, according to the Multidimensional Observation Scale for Elderly Subjects (MOSES) irritability/aggressiveness subscale, was significantly greater in both of the active treatment groups (haloperidol 63%, tiapride 69%) than in the placebo group (49%). There were 10 dropouts in the tiapride group, 21 in the haloperidol group, and 16 in the placebo group. The number of patients with at least one extrapyramidal symptom was significantly smaller with tiapride (16%) than with haloperidol (34%) and identical to that with placebo (17%); there was no significant difference across the groups in the numbers of patients with endocrinological adverse events. Four deaths were reported: one with placebo (stroke), one with tiapride (pneumonia), and two with haloperidol (stroke and heart failure).

Organs and Systems

Cardiovascular

Torsade de pointes has been attributed to tiapride.

- A 76-year-old man developed torsade de pointes while taking tiapride 300 mg/day; the QT_c interval 1 day after

starting treatment was 600 ms; the dysrhythmia resolved when tiapride was withdrawn (4).

See also Non-steroidal anti-inflammatory drugs

General Information

Data are available on the incidence of adverse effects of this drug (1–3). A review of published studies showed that about 13–15% of patients have adverse effects. The withdrawal rate because of unwanted reactions was 3.2–12% in short-term studies and 4% in one long-term trial. Adverse effects involved the gastrointestinal tract in 8–12% of patients, the central nervous system in 1–10% and the skin (rash, sweating, and itching) in 1–4%. Cutaneous photosensitivity and edema have also been reported.

The adverse effects profile does not differ from that of other propionic acid derivatives and includes the whole spectrum of gastrointestinal adverse reactions usually found with NSAIDs (SED-10, 166) (SEDA-10, 84) (4). The claim of good tolerance and gastric protection, based on animal data, which the company extrapolated to humans, has not been confirmed by appropriate clinical studies (SEDA-12, 89).

Organs and Systems

Urinary tract

Although many NSAIDs have rarely been reported to be responsible for increased urinary frequency and dysuria, and never for severe cystitis, tiaprofenic acid causes severe cystitis (SEDA-18, 106) (SEDA-20, 94) (SEDA-21, 107) (5,6).

If this complication occurs, the drug should be withdrawn immediately (7). A report has given some data on the frequency with which tiaprofenic acid cystitis-related disorders were reported to the UK's Committee on Safety of Medicines. Between 1981 and 1996, 770 adverse drug reactions involving 221 patients were reported. A peak in the reporting of cystitis was noted in 1994, when tiaprofenic acid product information was changed and advice was sent to UK doctors warning about cystitis-related disorders. This peak was followed by a fall in the number of reports, but it is not clear if this was due to reduced drug usage or also to a fall in the reporting rate of such adverse reactions (8).

Tick-borne meningoencephalitis vaccine

See also Vaccines

General Information

Tick-borne meningoencephalitis vaccine is an adsorbed formalin-inactivated virus vaccine prepared on chicken embryo tissue. Mild local reactions (soreness, redness, swelling) have been reported in 10–25% of vaccinees; systemic reactions occur at similar rates. Fever over 39°C is rare.

Positive merthiolate tests were found in eight of 30 patients with suspected adverse reactions to tetanus or tick-borne encephalitis vaccine (local inflammatory reactions at the injection site, fever, lymphadenopathy, urticarial or lichenoid exanthemas) (1).

An improved tick-borne encephalitis vaccine for children, produced by Baxter, has been licensed and is being used without safety concerns in many countries.

Organs and Systems

Nervous system

In 1989, 172 reports on adverse effects after tick-borne meningoencephalitis immunization were collected in the Federal Republic of Germany, among them 72 reports of suspect neurological complications. Among the 72 reports, there were only three cases of peripheral neuropathy that suggested a causal link with immunization (2). Three cases of mild meningitis, encephalitis, and

© 2006 Elsevier B.V. All rights reserved.

convulsions were, because of incomplete diagnosis, difficult to evaluate.

The database of the Swiss Drug Monitoring Center included 20 spontaneous reports (1987 to July 1992) of adverse events after the administration of tick-borne meningoencephalitis vaccine, among them 11 reports of cases with neurological symptoms (for example meningism, polyradiculitis, ataxia, vestibulopathy, facialis paresis). Most recovered completely within a few days. The incompleteness of the data did not allow conclusions regarding the causality of immunization (3).

Individual reports of neuropathy (SEDA-13, 290), multifocal cerebral vasculitis and infarction (4), cervical myelitis (5), myelopolyradiculitis (5), and suspected encephalitis (SEDA-17, 363) have appeared.

During the period 1987–2000, the Swiss Center for Adverse Events Drug Monitoring (Schweizerische Arzneimittel-Nebenwirkungszentrale) received 33 reports, including 39 neurological adverse events, following the receipt of tick-borne encephalitis vaccine: headache (36% of reports), neuropathy (18%), and meningeal signs (13%); 12 of 33 patients were hospitalized and all recovered (6).

Immunologic

A case of facial edema and pain and swelling of the left knee following the receipt of tick-borne meningoencephalitis vaccine was suspected to be caused by thiomersal allergy (7).

Body temperature

Following the use of tick-borne encephalitis vaccine ("Ticovac," produced by Baxter) in German children, there was a sudden increase in the number of cases of high fever, and 20–30% of vaccinees, primarily those 3 years of age and younger, reacted with a high fever (39°C or more) after the first dose (8). The increased number of cases of high fever was observed after changes in the production of tick-borne encephalitis vaccine were made: the vaccine no longer contains thiomersal and human albumin. Currently, according to the German licensing authority, the Paul Ehrlich institute, the vaccine is no longer recommended for children under 3 years; children aged 3–15 years should only receive half a dose of Ticovac, and the vaccine should only be used when strongly indicated. The reason for the changed reactogenicity is still unclear.

Ticlopidine

General Information

Ticlopidine is a thienopyridine derivative with potent antiplatelet activity associated with inhibition of ADP-induced platelet aggregation. It was first used in Europe in 1978 in the secondary prevention of stroke and coronary events, the treatment of peripheral vascular disease, and after vascular stent placement. However, the use of ticlopidine has been progressively restricted in some countries because of its serious adverse effects. It has largely been superseded by clopidogrel.

General adverse effects

There is a risk of hemorrhage from drugs that inhibit platelet aggregation. The adverse effects most commonly reported with ticlopidine are skin rashes and gastrointestinal effects, including nausea, dyspepsia, vomiting, anorexia, epigastric pain, and diarrhea. Hypersensitivity reactions underly some of the hematological complications of ticlopidine, such as thrombotic thrombocytopenic purpura.

Organs and Systems

Respiratory

Bronchiolitis obliterans organizing pneumonia has been attributed to ticlopidine (1).

- A 76-year-old non-smoking woman with giant-cell arteritis who had a normal chest X-ray was taking prednisone 45 mg/day and ticlopidine 250 mg bd for persistence of cloudy vision. After 1 month of ticlopidine therapy, she developed increasing dyspnea and a pruritic rash. Chest radiography showed diffuse interstitial

© 2006 Elsevier B.V. All rights reserved.

infiltrates, predominantly affecting the peripheries of both lungs. Transbronchial biopsy showed widening of the alveolar fields, with a mixed inflammatory infiltrate. Ticlopidine was withdrawn and prednisone was continued in the same dosage. Her symptoms completely resolved within 3 months and her chest X-ray normalized within 5 months.

Sensory systems

Two patients developed retinal vasculitis 3 and 4 weeks after starting to take ticlopidine (2). The symptoms and signs of retinitis resolved within 4–6 weeks after withdrawal of ticlopidine, with no reactivation within the next 2 or 3 years.

Hematologic

Ticlopidine can prolong bleeding time by up to 30 minutes. In well-controlled studies the incidence of minor bleeding was 10% (menorrhagia, bruises, and epistaxis) (3). Since the effect on platelet function is irreversible, the bleeding time does not return to normal sooner than 5–10 days after withdrawal, although it can be corrected immediately by platelet transfusion. In a retrospective comparison of the hemorrhagic risk in patients who had received platelet antiaggregants preoperatively for coronary surgery revascularization, there was a significant increase in postoperative hemorrhage and a higher incidence of reoperations in the patients who received ticlopidine compared with other antiaggregants (4).

Various other hematological complications have been observed during ticlopidine treatment (5). They include neutropenia, agranulocytosis, thrombocytopenia, aplastic anemia, pancytopenia, and thrombotic thrombocytopenic purpura (6). These reactions are potentially severe and some are fatal. Major bleeding is rare. Among 188 cases of hematological complications associated with ticlopidine and reported to the US Food and Drug Administration, 36 (19%) resulted in death (7).

Neutropenia

Neutropenia was the most common hematological complication in some of the major trials with ticlopidine. Severe neutropenia occurs in about 1% of patients. Neutropenia typically occurs in the first few months after the start of therapy, but is seen infrequently in the first 2–3 weeks. The mechanism has been reported to be inhibition of myeloid colony growth. On the basis of major randomized, controlled studies with ticlopidine, there is a 2.4% overall incidence of neutropenia and a 0.85% incidence of severe neutropenia and agranulocytosis (6). The neutropenia generally occurs at 2–5 weeks after the start of treatment (8). In some cases, neutropenia is delayed (9) or can develop after drug withdrawal. It has therefore been recommended that one should perform a complete blood count at baseline and every 2 weeks for the first 3 months of treatment, and that ticlopidine should be withdrawn if the neutrophil count falls below 1.2×10^9/l. In some cases, granulocyte colony-stimulating factors have been used, but their efficacy needs to be evaluated further (10). Although some fatal cases have been reported, neutropenia induced by ticlopidine is usually reversible.

Thrombocytopenia

Isolated thrombocytopenia has been reported at anything from 4 weeks to 5 years after the start of drug therapy (11,12). In these cases, platelet antibodies were also detected.

Thrombotic thrombocytopenic purpura has been repeatedly reported (6). The incidence has been estimated at 1 in 1600 (based on the observation of 5 cases out of a total of 7842 patients studied after coronary stent placements) (13). This rare adverse reaction is generally observed after a short exposure period of about 3–8 weeks. The clinical features are generally indistinguishable from those of idiopathic thrombotic thrombocytopenic purpura (14). The pathogenesis is unknown. Platelet antibodies were found in one patient, suggesting an immunologic mechanism (6). The outcome appears to be favorable in comparison to that of idiopathic thrombotic thrombocytopenic purpura, but several authors have reported cases in which death resulted (15,16). Early diagnosis and the rapid institution of plasmapheresis provide the best hope of complete recovery.

Sixty cases of thrombotic thrombocytopenic purpura have been reviewed (17). Ticlopidine had been prescribed for under 1 month in 80% of the patients, and platelet counts were normal within 2 weeks of the onset of thrombotic thrombocytopenic purpura in most patients. Mortality rates were higher among patients who were not treated with plasmapheresis than among those who underwent plasmapheresis (50% compared with 24%). The authors concluded that the onset of ticlopidine-associated thrombotic thrombocytopenic purpura is difficult to predict, despite close monitoring of platelet counts.

In 43 322 patients treated with coronary stents and ticlopidine for 1 year there were 9 cases of thrombotic thrombocytopenic purpura (0.02%) (18). The risk of thrombotic thrombocytopenic purpura during the use of ticlopidine after coronary stenting was 50-fold higher than in the general population. Ten other cases of thrombotic thrombocytopenic purpura related to ticlopidine were identified from the participating centers. Four of the 19 patients died, and all four deaths occurred in patients who were not treated with plasmapheresis. The authors stressed that early recognition and treatment is crucial for minimizing mortality.

Deficiency of, or auto-antibodies to, a von Willebrand-cleaving metalloproteinase are pathogenic in idiopathic thrombotic thrombocytopenic purpura (19). Seven consecutive patients, who developed thrombotic thrombocytopenic purpura 2–7 weeks after starting to take ticlopidine, had markedly reduced concentrations of von Willebrand factor metalloproteinase. In six cases initial samples were available and were positive for immunoglobulin G inhibitors to von Willebrand factor metalloproteinase.

Aplastic anemia

Rare cases of aplastic anemia have been reported (20). Some authors have suggested that the incidence of this complication may have been underestimated (21). The reaction is characterized by pancytopenia and the bone marrow shows profound hypocellularity, absence of precursor cells, and fatty replacement. Some studies have suggested a direct toxic effect of ticlopidine on bone

© 2006 Elsevier B.V. All rights reserved.

marrow cells, particularly the myeloid line. In some cases, agranulocytosis or thrombocytopenia have been reported to precede the development of aplastic anemia. One should be alert to the fact that this reaction may still occur after the recommended 3 months of hematological monitoring have elapsed (6).

Gastrointestinal

Diarrhea is among the most common adverse effects of ticlopidine. It can occur in up to 20% of those who take it, in contrast to an incidence of 10% among placebo- and aspirin-treated patients (22) and usually occurs early in the course of treatment. It can be prevented by taking ticlopidine with food or by reducing the dosage. In rare cases, severe chronic diarrhea with marked body weight loss and anorexia can occur, sometimes long after the start of therapy (23).

In a few reports, lymphocytic colitis has been attributed to ticlopidine; in some cases the pathological features in the colon biopsy resolved after withdrawal of the drug (24–26).

Liver

Several cases of ticlopidine-induced hepatotoxicity have been reported (27). Between 10 days and 12 weeks after the start of treatment, patients develop jaundice, usually without fever, eosinophilia, or pain. Laboratory tests show a cholestatic or mixed cholestatic-hepatocellular pattern of injury. There is usually clinical and biochemical recovery within 1–11 months. Frank ticlopidine-associated liver injury is uncommon, but in one study, 44% of patients had abnormal liver function tests and about one-half of them had to stop taking the drug (22).

Skin

In a 1-year prospective study of 136 patients taking ticlopidine to prevent thrombosis after coronary stenting, 16 had adverse skin reactions (28). The most common were urticaria, pruritus, and maculopapular eruptions. Three patients had previously unreported reactions: a fixed drug eruption, an erythromelalgia-like eruption, and an erythema multiforme-like eruption.

Immunologic

A lupus-like illness (fever, rash, arthritis, renal involvement, and positive antinuclear and antihistone antibodies) developed in three patients 2–8 weeks after they started to take ticlopidine (29). After withdrawal, there was slow but complete resolution in all patients.

Susceptibility Factors

If it is considered necessary to withdraw ticlopidine before elective surgery, it should be done 1 week in advance (30). In emergencies, desmopressin or fresh platelet concentrates reduce the risk of bleeding.

Drug–Drug Interactions

Carbamazepine

In one patient taking ticlopidine and carbamazepine, serum carbamazepine concentrations rose in association with nervous system toxicity (31).

Omeprazole

In six Japanese CYP2C19 extensive metabolizers, ticlopidine 300 mg/day for 6 days significantly increased the C_{max} of a single oral dose of omeprazole 40 mg and reduced its oral clearance of omeprazole (32). The authors concluded that ticlopidine inhibits CYP2C19 but not, or to a lesser extent, CYP3A4, and that the magnitude of inhibition by ticlopidine is related to the in vivo activity of CYP2C19 before inhibition.

Phenytoin

Several reports have described ticlopidine-induced phenytoin toxicity with increased serum phenytoin concentrations (33–36). Data obtained in vitro using hepatic microsomal preparations have shown that ticlopidine inhibits the activity of CYP2C19 (37).

Tienilic acid

See also Diuretics

General Information

Tienilic acid, a uricosuric diuretic (1), had to be withdrawn soon after its release in 1980, after it had caused several hundreds of cases of severe liver damage, many of them fatal (SEDA-5, 229). In France almost 500 reports of liver injury were received. Tienilic acid had no advantage over other diuretics; it certainly had the worst benefit:harm balance (SEDA-17, 269). For a time it was considered that the hepatic complication might be geographically limited (for example because of differences in manufacturing in different countries), but there is now no doubt that the drug itself was responsible. The hepatic complication was thoroughly studied in retrospect (SEDA-11, 424). Other adverse effects, including acute renal insufficiency, urate stones, and interactions with other drugs, such as oral anticoagulants and phenytoin, helped tienilic acid to its early demise.

Timegadine

See also Non-steroidal anti-inflammatory drugs

General Information

Timegadine, a guanidine derivative, inhibits cyclo-oxygenase, lipoxygenase, and phospholipase activity. Reported adverse effects are skin rashes, oral lesions, epigastric pain, nausea, dysuria, dizziness, vertigo, and sleep disturbances. Liver enzyme changes and pneumonitis have also been described (1–4).

Timolol

See also Beta-adrenoceptor antagonists

General Information

Timolol is a hydrophilic, non-selective beta-blocker with little partial agonist and membrane-stabilizing activity.

Organs and Systems

Cardiovascular

Of 153 consecutive patients treated with timolol eye-drops, three complained of unexplained falls and two of them had dizziness and blackouts (1). Two had a cardioinhibitory carotid sinus syndrome (a period of asystole greater than 3 seconds after carotid sinus massage) and the third a vasodepressor carotid sinus syndrome (a reduction in systolic blood pressure higher than 50 mmHg after carotid sinus massage). In all three cases, timolol eye-drops were withdrawn. Follow-up carotid sinus massage in the two patients with a cardioinhibitory carotid sinus syndrome was negative, and all reported complete remission of symptoms.

Significant cardiovascular adverse effects have been reported after topical administration of timolol maleate. Bradycardia with frank syncope can occur, especially in elderly patients (2). After topical administration its action begins in 20 minutes, peaks in 4 hours, and lasts 24 hours. Episodes of dizziness and occasional falls can occur 1–2 hours after instillation of timolol, as has been described in an otherwise healthy elderly patient (3).

- An 80-year-old woman with gastrointestinal bleeding had a sinus bradycardia (52/minute) despite acute blood loss. The only drug she had used that was an AV nodal depressant was timolol maleate 0.5%, one drop to both eyes every day. Continuous electrocardiography showed transient complete AV block without ventricular escape for nearly 6 seconds about 1 hour after instillation of timolol eye drops. She also reported having previously had episodes of dizziness and occasional falls 1–2 hours after instillation of her eye drops. Timolol was withheld and a temporary pacemaker was inserted. Rechallenge with timolol was associated with recurrence of third-degree AV block. She subsequently had a permanent dual chamber pacemaker implanted.

Psychological, psychiatric

Depressive symptoms were reported in 17 of 165 patients after the administration of timolol over two decades (4). Depression accounted for 17% of 369 central nervous system reactions to timolol reported to a National Registry of Drug-induced Ocular Side Effects during 7 years: of these, 20 cases were of acute suicidal depression.

Long-Term Effects

Tumorigenicity

The development of liver tumors in mice and an increased incidence of mammary fibroadenomata in female rats at one time caused concern in the USA, although animal studies elsewhere and clinical studies have shown no evidence of tumor-forming potential.

Drug–Drug Interactions

Brimonidine

The effects of topical brimonidine and timolol have been compared in two trials in 926 subjects with glaucoma or ocular hypertension already using systemic beta-blockers (5). Concurrent systemic beta-blocker therapy had no deleterious effects on ocular hypotensive efficacy and no impact on safety with topical brimonidine, but the combination of timolol and brimonidine significantly reduced systolic and diastolic blood pressures and heart rate compared with brimonidine alone. This observation suggests that ocular hypotensive agents other than beta-blockers, such as brimonidine, may be appropriate as a first-choice therapy for glaucoma in patients concurrently taking systemic beta-blockers.

Tinidazole

General Information

The adverse effects of tinidazole resemble those of metronidazole. It can be given intravenously and is well tolerated, although thrombophlebitis has been reported. In one healthy volunteer, fainting with low blood pressure and nausea and tiredness for several hours was reported (SEDA-11, 597) (1).

Organs and Systems

Gastrointestinal

Drug-induced esophagitis is rare, accounting for about 1% of all cases of esophagitis. An incidence of 3.9 in 100 000 has been reported. After the first description, there have been more than 250 observations, with more than 50 different drugs. Among those, the principal antibiotics included tetracyclines (doxycycline, metacycline, minocycline, oxytetracycline, and tetracycline), penicillins (amoxicillin, cloxacillin, penicillin V, and pivmecillinam), clindamycin, co-trimoxazole, erythromycin, lincomycin, spiramycin, and tinidazole. Doxycycline alone was involved in one-third of all cases. Risk factors included prolonged esophageal passage, due to motility disorders, stenosis, cardiomegaly, the formulation, supine position during drug ingestion, and failure to use liquid to wash down the tablet. Direct toxic effects of the drug (pH, accumulation in epithelial cells, non-uniform dispersion) also seem to contribute to the development of drug-induced esophagitis (2).

Skin

Skin reactions can occasionally occur in patients taking tinidazole.

- A fixed eruption with pruritus was observed in a 27-year-old man treated for *Entamoeba histolytica* with tinidazole 500 mg, four tablets in a single dose for 3 days.
- An erythematous patch with a sensation of burning appeared over the left buttock in a 32-year-old man while he was taking tinidazole for giardiasis; the allergic lesion was provoked by a challenge dose.

Both of these patients reacted with the same skin reaction on rechallenge with metronidazole (SEDA-16, 310).

In a patient with a fixed drug eruption to metronidazole, a provocation test showed cross-reactivity with tinidazole but not with secnidazole (3).

Tioguanine

See also Cytostatic and immunosuppressant drugs

General Information

Tioguanine is an analogue of the physiological purines, guanine and hypoxanthine, and is a purine antimetabolite. It is incorporated into DNA and RNA, resulting in a variety of cytotoxic effects. It has been used to treat hematological malignancies, psoriasis, and more recently, inflammatory bowel disease, such as Crohn's disease. Its main adverse effects are liver damage and hemotoxicity.

Among 111 patients taking tioguanine for inflammatory bowel disease, 29 had laboratory abnormalities, most commonly rises in liver enzymes and reduced platelet counts (1). Of the patients who underwent liver biopsy, there was nodular regenerative hyperplasia in 76% of those with laboratory abnormalities and 33% of those without.

Organs and Systems

Hematologic

Tioguanine can cause blood dyscrasias, in particular thrombocytopenia (2).

In 23 children taking tioguanine and a matched group taking mercaptopurine, there was no difference in the pattern of anemia or neutropenia between the two groups, but dose-limiting thrombocytopenia was more common in those taking tioguanine, four of whom had a fall in platelet count to below 20×10^9/l compared with only one taking mercaptopurine (3).

Liver

Nodular regenerative hyperplasia of the liver has been reported in three patients with inflammatory bowel disease who had taken tioguanine for more than a year and who had raised serum liver enzymes; all three had histological foci of nodular regenerative hyperplasia, which was best seen with reticulin silver impregnation (4).

The United Kingdom Medical Research Council Chronic Myeloid Leukemia Group reported 18 cases of tioguanine-induced non-cirrhotic portal hypertension, commonly associated with deterioration in liver function (5).

A patient developed acute sinusoidal obstruction syndrome after taking tioguanine for 14 months for Crohn's disease (6).

- A patient with acute myeloblastic leukemia, who took tioguanine for 2 months, developed severe peliosis hepatis associated with mild lesions of the centrilobular veins; withdrawal was followed by progressive improvement of liver dysfunction (7).

© 2006 Elsevier B.V. All rights reserved.

Several cases of hepatic veno-occlusive disease have been reported (8–11).

- A 23-year-old man with acute lymphocytic leukemia took tioguanine for 10 months and developed intense sinusoidal engorgement which resolved on withdrawal with some residual subintimal fibrosis around the terminal hepatic veins (12).

Of 12 patients aged 3–10 years, who had taken tioguanine 25–77 mg/m^2/day for acute lymphoblastic leukemia, one had persistent pancytopenia and intermittent splenomegaly. MRI/MRA scans showed a dilated splenic vein and collaterals, consistent with portal hypertension; esophagoscopy showed esophageal varices (13). A liver biopsy showed periportal fibrosis and marked dilatation of veins and venules. Of the other 12 patients, nine had abnormal MRI/MRA scans with evidence of varices in four. Liver biopsies in two cases showed periportal fibrosis, dilatation of venules and sinusoids, and minimal focal fatty changes.

Tiopronin

General Information

Tiopronin has been extensively used as an antirheumatic drug in France and Japan. Adverse effects occur in about 45% of patients and led to withdrawal in about one-fifth.

Observational studies

In 140 patients with classic or definite rheumatoid polyarthritis treated with tiopronin 1 g/day over a mean duration of 1 year and retrospectively studied, adverse effects occurred in 55% and required withdrawal in 40% (1). These effects occurred during the first 6 months of treatment in 75% of cases. They mainly affected the skin and mucosae: in 46 cases (33%) treatment was withdrawn because of stomatitis, pruritus, various types of erythema, and pemphigus (1 case). There was renal insufficiency in 14 patients (10%) requiring withdrawal in eight cases (5.7%) because of nephrotic syndrome ($n = 3$) or proteinuria ($n = 5$). There were hematological disorders in 13 (9.2%), justifying withdrawal in 10 cases (7.1%) because of thrombocytopenia or leukopenia. The other adverse effects included digestive disorders ($n = 15$), requiring withdrawal in three, and ageusia ($n = 6$), requiring withdrawal in one case.

Comparative studies

In 69 patients with rheumatoid arthritis, tiopronin 1500 mg/day was as effective as penicillamine (2). The adverse effects of the two drugs were similar. Tiopronin was associated with obstructive bronchiolitis in one case. There was little cross-intolerance: the same unwanted effect was only observed in four cases; one of pemphigus, one of toxic dermatitis, and two instances of proteinuria.

In 66 patients with cystinuria, adverse reactions to tiopronin (mean dose 1193 mg/day) were common, and occurred in 76% of the patients with a history of D-penicillamine treatment and 65% of those without a history of D-penicillamine treatment, compared with 84% who had adverse effects with D-penicillamine (3). Serious adverse reactions requiring drug withdrawal were less common with tiopronin. Among the patients who took both drugs 31% had to stop taking tiopronin, whereas 69% could not tolerate D-penicillamine.

General adverse effects

Tiopronin has a roughly similar pattern of adverse effects to that of penicillamine (1–6), including rashes, toxic dermatitis, ageusia, and proteinuria; these effects resolve on

© 2006 Elsevier B.V. All rights reserved.

withdrawal (6). If a patient has an adverse reaction to D-penicillamine, the risk of that adverse reaction to tiopronin is only slightly increased.

Organs and Systems

Sensory systems

Tiopronin can cause impaired taste and ageusia (6).

Endocrine

Autoimmune hypoglycemia with anti-insulin antibodies, a complication of penicillamine and pyritinol, has also been reported with tiopronin (7).

- Autoimmune hypoglycemia occurred in a 49-year-old woman with regular menstrual periods accompanied by marked enlargement of the breasts, and was probably induced by tiopronin (8). Her breasts were red and painful; histological examination showed extensive lymphocytic inflammation and edema in the connective tissue. She recovered after stopping tiopronin and taking danazol.

Hematologic

Hematological reactions, such as thrombocytopenia and leukopenia, occur in about 6–9% of patients using tiopronin (1,5).

- Aplastic anemia with fever and pancytopenia developed in a 29-year-old woman, probably as a reaction to tiopronin (500 mg/day), which she had taken for 71 days for seronegative rheumatoid arthritis (9). A bone marrow examination confirmed acute marrow aplasia. She recovered within 5 weeks after withdrawal.

Another detailed case report described profound granulocytopenia, probably caused by tiopronin (10).

Gastrointestinal

Gastrointestinal adverse effects of tiopronin include nausea, vomiting, oral ulcers, and stomatitis (1–3,5,6).

Liver

Of 140 patients taking tiopronin, three had cholestasis (1). A detailed report described liver injury, with steatosis, intrahepatic cholestasis, and centrilobular inflammation, in association with tiopronin (11). In another patient cholestatic hepatitis plus toxic epidermal necrolysis developed in suspected association with tiopronin (12).

Urinary tract

Some degree of renal damage occurs in about 10% of patients taking tiopronin (1–3,5,6). As with penicillamine, proteinuria can progress to nephrotic syndrome (13,14). Biopsy may show minimal change membranous glomerulonephritis and granular depositions of IgG and C3 (13,15).

In a comparison of tiopronin and penicillamine in the treatment of cystinuria in 15 children, nephrotic syndrome developed in one of the patients taking tiopronin; no further details were given (16).

Skin

Cutaneous or mucous reactions occur in about 15–30% of patients using tiopronin. Alopecia, erythema, eczema, cutaneous vasculitis, lichenoid eruptions, skin wrinkling, or a perforating elastoma can develop (1–3,5,6).

There have been several cases of tiopronin-induced pemphigus, characterized by intra-epidermal bullae with acantholysis and epidermal intercellular deposition of IgG and C3 (17,18). The eruption can present as multiple red crusted macules. One patient first had pemphigus in association with penicillamine and later had a relapse while taking tiopronin (19). In skin explant cultures, tiopronin can cause acantholysis with intra-epidermal splits and bulla formation (20).

In a patient with a tiopronin-associated lichenoid skin eruption, the rash was associated with alopecia (21). In another report of a lichenoid eruption, positive rechallenge confirmed the role of tiopronin (22).

In four patients with pluriform skin eruptions in association with tiopronin, the pathological findings were characteristic of a graft-versus-host reaction (23).

In one patient, cholestatic hepatitis plus toxic epidermal necrolysis developed in suspected association with tiopronin (12).

Musculoskeletal

There have been a few cases of myasthenia gravis in association with tiopronin (24,25).

Immunologic

Tiopronin can cause fever, with or without a rash (3). In a patient with a prior hypersensitivity reaction to penicillamine, there was no cross-hypersensitivity to tiopronin (26).

Tiopronin has occasionally been described as a cause of polymyositis (27,28).

- A 62-year-old woman with rheumatoid arthritis, hypothyroidism, and hypertension, treated for 6 years with tiopronin (dosage not specified), developed severe polymyositis. She had dysphagia and muscle weakness and pain in all limbs; there were no skin abnormalities. Her creatine kinase activity was 12 000 U/l (reference range 25–160) and her LDH 23 000 U/l (240–480). Her C-reactive protein was 58 µg/ml and the erythrocyte sedimentation rate 42 mm/hour (both raised). Electromyography of her proximal and distal muscles showed pseudomyotonic fibrillations. A biopsy of the deltoid muscle showed necrosis of muscle fibers and interstitial mononuclear infiltrates. There was no evidence of a paraneoplastic syndrome. Tests for toxoplasmosis, trichinosis, picornavirus, HIV, and hepatitis A, B, and C were negative, and there were no autoantibodies (anti-Jo, anti-KU, anti-PM/SCL, anti-DNA, anti-SSA, anti-SSB, anti-ECT, antithyroid, rheumatoid factor, or cryoglobulins), although ANF was positive on one occasion (1/100). Tiopronin was withdrawn, she was given glucocorticoids and methotrexate, and made a good recovery.

Tiotixene

See also Neuroleptic drugs

General Information

Tiotixene is a thioxanthene neuroleptic drug.

Organs and Systems

Nervous system

Neuroleptic malignant syndrome has been reported as a severe complication of tiotixene (SEDA-21, 49).

© 2006 Elsevier B.V. All rights reserved.

- A 42-year-old man with a history of paranoid schizophrenia developed confusion and emesis. His medications included buspirone and tiotixene. He also had a generalized seizure that resolved spontaneously. His serum sodium concentration was 114 mmol/l, which was thought to be secondary to psychogenic polydipsia and which was corrected. The next day his temperature rose to 40°C and the day after that he became lethargic and non-verbal and developed generalized muscle rigidity. A diagnosis of probable neuroleptic malignant syndrome was made, and he was given dantrolene sodium 1 mg/kg intravenously; neuroleptic drugs were withdrawn. The serum creatine kinase activity was over 234 500 U/l. Urinalysis showed more than 3 g/l of protein, a trace of ketones, and hemoglobin and leukocytes. By the following day, his muscle rigidity and fever had resolved and his mental status was markedly improved.

Skin

Cutaneous lesions consisting of telangiectatic macules have been reported with tiotixene (1).

Tiotropium bromide

See also Anticholinergic drugs

General Information

Tiotropium bromide is a long-acting anticholinergic bronchodilator that binds with similar affinity to the three muscarinic receptor subtypes (SEDA-20, 190) (1). However, it dissociates more slowly from M_1 and M_3 receptors in bronchial smooth muscle than from M_2 receptors (1). This results in a long half-life of the bound complex, allowing once-daily administration.

Tiotropium is inhaled from the HandiHaler, a dry-powder, breath-activated inhaler system that delivers particles to the lung over a wide range of airflow limitations in patients with chronic obstructive pulmonary disease (COPD); it can be effectively delivered at inspiratory flow rates as low as 20 l/minute (2). Pharmacodynamic steady-state studies have shown that most of the bronchodilator activity is achieved with one to two doses within 48 hours, although a carryover effect on forced vital capacity was observed beyond 48 hours (3).

The efficacy and safety of tiotropium have been studied in vitro and in early clinical trials, and dose-ranging studies have shown that tiotropium dry powder 18 micrograms/day is safe and efficacious (1,4,5). Since the quaternary structure of tiotropium limits its absorption through the mucous membrane of the respiratory and gastrointestinal tract, systemic adverse effects are in general minimal.

Therapeutic studies

Placebo-controlled studies

In repeated dose studies of 4.5, 9, 18, and 36 micrograms od for 28 days, in 169 patients with COPD, each dose was significantly more effective than placebo, as shown by increased effects with increasing dose on FEV_1 and peak expiratory flow. At doses of 9 micrograms and above there were detectable concentrations of the drug at peak (5 minutes after inhalation), but a trough plasma concentration was only measurable with the 36 micrograms dose. At the highest dose, three of 34 patients reported a dry mouth compared with none of 35 patients taking placebo. This preliminary study suggests that the anticholinergic activity of tiotropium will cause some systemic adverse effects at high doses.

In a randomized, double-blind study, 470 patients with stable COPD (mean FEV_1 38.6% predicted) received tiotropium 18 micrograms or placebo as a once-daily medication via a lactose-based dry-powder inhaler device (6). Spirometry was measured on days 1 and 8 and at regular intervals for 3 months. Tiotropium produced significant improvements in trough FEV_1 and FVC (measured immediately before the next dose), averaging 12% greater than baseline on day 8. The bronchodilatation resulting from tiotropium did not diminish over the 3 months of the study. Upper respiratory tract infections were reported in 15% of the patients in each of the treatment groups and exacerbations of COPD were reported in 22% of patients taking placebo and 16% of patients taking tiotropium. Dry mouth was significantly more common with tiotropium (9.3 versus 1.6%). There was a 6.8% incidence of serious adverse events or events leading to withdrawal (2.5% with tiotropium and 5.8% with placebo). A patient with a long history of cardiovascular disease, who was randomized to receive tiotropium, was found dead and was suspected to have died of a cardiac dysrhythmia. There were no differences in electrocardiograms between the treatment groups or changes in laboratory values.

In a multicenter, double-blind, placebo-controlled trial in patients with stable COPD, tiotropium 18 micrograms/day for 1 year ($n = 550$) significantly improved lung function (mean trough FEV_1, FVC, PEFR) and reduced dyspnea compared with placebo ($n = 371$) (7). Moreover, tiotropium recipients had better health status scores, fewer exacerbations of COPD, and fewer hospitalizations. There was no evidence of tachyphylaxis over one year.

Comparative studies

In a randomized, double-blind trial tiotropium 18 micrograms/day for 1 year ($n = 356$) was compared with ipratropium 160 micrograms/day ($n = 179$) in patients with COPD (8). Tiotropium maintained superior efficacy (FEV_1 and FVC) throughout the study, improved dyspnea, and reduced the number of exacerbations by 24%.

In a placebo-controlled, double-blind study, tiotropium 18 micrograms/day for 6 months ($n = 209$) was compared with salmeterol 50 micrograms bd ($n = 213$) and placebo ($n = 201$) in 623 patients with moderate to severe COPD

© 2006 Elsevier B.V. All rights reserved.

(8). Tiotropium improved dyspnea and trough FEV_1 and FVC significantly more than salmeterol. The patients who used tiotropium had better quality-of-life scores than those who used salmeterol, but the difference was not statistically significant.

Organs and Systems

Mouth and teeth

In placebo-controlled studies adverse events were comparable to those with placebo, except for dry mouth, which was reported in 10–16% of patients (1,7,8).

Titanium

General Information

Titanium is a strong, light, metallic element (symbol Ti; atomic no. 22) that is mostly found as oxides in minerals such as anatase, brookite, ilmenite, rutile, and sphene, and also as the antimonate in lewisite.

Titanium is used in medicine mainly for its mechanical benefits in surgical and dental materials in a host of orthopedic and orthodontic appliances, with or without other metals (for example nickel, cobalt, chromium), and generally without serious adverse effects. Titanium and its alloys are in use as implants in bone surgery (1,2) and in dental materials (3,4). Research on the biocompatibility of metal and tissue continues (5).

Titanium is also a constituent of some anticancer compounds (6). Titanium dioxide is used in sunscreens. Nontherapeutic exposure to the metal also occurs.

Titanium in metal implants and prostheses

Titanium is very biocompatible (7). Complications from the use of metal implants and prostheses can arise because of biochemical and histological reactions to some of the materials used (SEDA-22, 250). These include titanium, stainless steel (10–14% nickel, 17–20% chromium), and cobalt chrome alloys (27–30% chromium, 57–68% cobalt, and up to 2.5% nickel). All of these metals can produce sensitization or elicit toxic reactions when they are solubilized and come into contact with tissues; it can be difficult or even impossible to differentiate between hypersensitivity and toxic reactions.

Metals from prostheses can continue to be released into the system for many years. The development of hypersensitivity takes time, and allergic reactions are usually delayed for weeks, months, or 1–2 years. The symptoms can assume a variety of forms. Local reactions can cause loosening of the device or local pain. Dermatological reactions include eczema, bullous pemphigoid, urticaria, and "muscle tumors."

Attempts continue to predict metal sensitivity in the individual patient so that the choice of material can be made accordingly. In vitro tests for metal allergies have been developed on the basis of lymphokine (MIF) release from sensitized T lymphocytes exposed to metal-protein complexes (8). About 6% of patients without a previous metal implant had positive reactions to nickel, chromium, or cobalt. However, it is still not clear whether such a positive reaction is a reliable predictor of clinical problems. In practice few patients have either local or systemic reactions; when symptoms occur and other causes are ruled out, the implant should be removed. Some workers recommend removal of an implant whenever there is both a positive MIF test and a positive skin test, even in the current absence of a serious reaction. Allergic dermatitis will clear up as soon as the metal has begun to be cleared from the tissue. The type of metal and the amount released into the tissue will affect the time taken for the disappearance of toxic dermatological phenomena.

Of 120 consecutive patients (66 women, 54 men; mean age 66 years) with 126 prostheses inserted between March and December 1989, who were followed prospectively both clinically and radiologically for a mean of 9.1 years (9), 40 (41 hips) died, 9 (9 hips) were interviewed by telephone, and 71 (76 hips) were available for follow-up. Four hips had been revised, two of them because of aseptic loosening of the femoral component, one because of a late infection—all after 9 years—and one because of a periprosthetic fracture after 6 years. The 9-year survival was 97% and for aseptic loosening of the stem 98%. None of the cups had to be revised for aseptic loosening. The result was excellent or good in 88%, moderate in 8%, and poor in 4%. Radiological analysis showed no osteolysis or radiolucent lines in 59 prostheses (78%). Nine stems (12%) showed a radiolucent line. Focal osteolysis was detected in eight cases (10%) in one or more Gruen zones. The distribution of the osteolytic areas showed that zones II, V, VI, and VII were predominantly affected in increasing frequency. There was no osteolysis on the acetabular side. These results do not confirm the high rate of osteolysis and revisions with the Muller titanium alloy Straight Stem used in some other institutions.

Organs and Systems

Skin

Titanium tetrachloride ($TiCl_4$) is an intermediate compound in the production of white pigment, which can cause severe chemical burns (10). In two reported cases titanium tetrachloride caused 18–20% total body surface area burns, as a combined consequence of hydrochloric acid and the heat that was generated in areas in which this otherwise stable compound was mixed with sweat. Titanium tetrachloride combined with water is extremely dangerous, and its immediate treatment (towel drying before irrigation) makes it unique among chemicals. The experience of the authors suggested that in most cases grafting will be required. These chemical burns were self-limiting and had no notable systemic sequelae. Wound biopsy specimens were taken on days 3 and 6 and the burns were subjected to immunostaining, which showed that titanium tetrachloride did not retard wound healing. The exposure time to titanium tetrachloride vapor will determine the pulmonary and ophthalmological effects in each case. Clinical awareness of the propensity of titanium tetrachloride to react with water—even in the form of sweat—is vital, because prompt management can limit the extent of injury.

Exacerbation of atopic dermatitis has been attributed to titanium clips (11).

- A 28-year-old woman with breast cancer underwent breast conservation, and three titanium clips were placed at the margin of the excision cavity, followed 2 months later by rapid exacerbation of her atopic dermatitis. The skin lesions developed progressively and involved the whole body. Patch tests and lymphocyte stimulation tests could not be performed, owing to the severity of the skin lesions. Various drugs were suspected, but the results of a bidigital O-ring test suggested an allergic reaction to titanium clips. She underwent a second operation to remove the titanium clips under local anesthesia. By 12 months after surgery, the atopic dermatitis had not completely resolved.

A contact allergic reaction has been reported in three individuals of a group of 23 volunteers who participated in a study with topically applied ammonium titanium lactate 10% (12).

Immunologic

Allergic reactions to titanium can occur (13). Inflammatory reactions and contact sensitivity have been reported after insertion of titanium implants. Osseointegration of the implant tends to occur, but around the area there can be an intense inflammatory reaction and persistent irritation of soft tissues (SEDA-22, 250) (14,15).

Occasionally, reactions to titanium can occur at a distance from a hip implant, probably because small particles of titanium become detached and enter the system.

- Distant granulomatous reactions occurred in an elderly man, who developed symptomless lymph node histiocytosis, which was discovered incidentally.
- Another man had a visceral granulomatosis reaction (liver, spleen, and lymph node) associated with hepatic and splenic enlargement; in affected tissue specimens particles from the hip arthroplasty were detected, and titanium was found in the spleen (16).

Despite its widespread use, titanium is only rarely linked with contact allergic reactions. A hypersensitivity reaction has been attributed to titanium in a pacemaker (17).

- An 86-year-old Japanese man received a pacemaker for atrioventricular block, and 2 months later developed a scaly erythema over the implantation site and later widespread nummular eczema. Histologically, the lesions showed slight spongiosis, intracellular edema, moderate acanthosis in the epidermis, and perivascular infiltration with thickened capillary walls in the dermis. The pacemaker contained titanium and a variety of other metals, but patch tests were all negative. However, titanium sensitivity was demonstrated by intracutaneous and lymphocyte stimulation tests.

Titanium is so widely used that the risk of contact sensitivity to it must be very small. If a patient shows contact sensitivity to titanium, a replacement pacemaker should be completely encased in patch-tested non-allergenic material.

Long-Term Effects

Tumorigenicity

A rhabdomyosarcoma has been reported near the site of a pacemaker (18).

- An 85-year-old man developed a voluminous, rapidly evolving tumor beneath the right clavicle where a titanium pacemaker had been implanted 5 years before. Immunohistochemistry showed that it was a rhabdomyosarcoma.

© 2006 Elsevier B.V. All rights reserved.

The role of the pacemaker and especially of titanium in the development of this tumor was not clear.

Tizanidine

General Information

Tizanidine is a centrally acting benzothiadiazol derivative with myotonolytic activity. Although its mechanism of action has not been fully clarified, facilitation of glycine-mediated transmission in the spinal cord may play an important role (1). A total daily dose of 15 mg (5 mg 3 times) is reported to be effective and well tolerated by most patients (2).

The documentation of adverse effects is still fragmentary. Tizanidine seems to be a relatively well tolerated and useful antispastic agent. The most frequently reported adverse effects include drowsiness, dry mouth, and muscle weakness (3). Occasionally, hypotension can occur; it is usually mild (4,5) but can be more severe in patients taking antihypertensive drugs (6–8), in whom tizanidine should be used with great caution. A small fall in heart rate has also been reported (9).

In an open study of tizanidine for neuropathic pain, several adverse effects were noted, such as dizziness, drowsiness, fatigue/weakness, dry mouth, gastrointestinal upset, and sleep difficulty (10).

Organs and Systems

Liver

In an open study of tizanidine for neuropathic pain, one patient developed abnormal liver function tests accompanied by nausea and vomiting, fatigue, confusion, weakness, and muscle aches (10). Within three weeks after withdrawal of tizanidine, the liver function tests returned to baseline and the symptoms resolved. Two other patients had transient asymptomatic rises in liver function tests, which returned to normal despite continuation of tizanidine. Transiently raised liver function tests during tizanidine treatment have occasionally been reported before (11–13).

Tobramycin

See also Aminoglycoside antibiotics

General Information

Tobramycin closely resembles gentamicin in its microbiological and toxicological properties. The two drugs have similar half-lives, peak serum concentrations, lack of protein binding, volumes of distribution, and predominantly renal excretion by glomerular filtration. The main advantage of tobramycin may be its greater intrinsic activity against *Pseudomonas aeruginosa*. Not all bacterial strains resistant to gentamicin are invariably also resistant to tobramycin. Because of its inherent potential for ototoxicity and nephrotoxicity, renal function and eighth nerve function should be closely monitored (1,2).

Comparative studies

In a randomized comparison of nebulized tobramycin and nebulized colistin in patients with cystic fibrosis, 26 of 53 patients treated with tobramycin had at least one respiratory adverse event, most commonly pharyngitis (3). In 520 patients, inhaled tobramycin (300 mg bd for three 28-day cycles, each cycle being separated by a 28-day period of no treatment) was compared with placebo. Respiratory function was significantly improved as early as the second week and remained so for the rest of the study, even during periods without aerosol treatment. There was also a parallel reduction in the relative risk of hospitalization, the number of days of hospitalization, and the number of days of intravenous antibiotic treatment (4).

Organs and Systems

Respiratory

Nebulized antipseudomonal antibiotic treatment improves lung function and reduces the frequency of exacerbations of infection in patients with cystic fibrosis and Wegener's granulomatosis (5–7), but the significance of development of antibiotic-resistant organisms remains to be determined (8). In 10 healthy adults, the inhalation of tobramycin 80 mg resulted in the deposition of 11.8 mg in the lungs (9). In a double-blind, randomized, placebo-controlled study, inhaled tobramycin significantly reduced sputum density of *P. aeruginosa*. More patients in the treatment group reported increased cough, dyspnea, wheezing, and non-cardiac chest pain, but the symptoms did not limit therapy (10).

Inhalation of the intravenous formulation of tobramycin can cause bronchoconstriction, as has been confirmed in 26 children with mild to moderate cystic fibrosis (11). Nevertheless, while bronchoconstriction did occur, many patients did not have bronchoconstriction in response to the standard intravenous formulation. The risk of bronchoconstriction may further be reduced by pretreatment with salbutamol.

In a comparison of different dosage regimens, inhaled tobramycin caused bronchial obstruction (12). However, after 10 minutes of inhalation, lung function returned to baseline; the effect was independent of dose.

In two placebo-controlled, randomized studies, inhaled tobramycin significantly reduced sputum density of *P. aeruginosa*; however, more patients in the treatment group reported increased dyspnea and wheezing, although the symptoms did not limit therapy (13,14).

Neuromuscular function

The aminoglycosides have a curare-like action, which can be antagonized by calcium ions and prostigmine. In cases requiring general anesthesia, the effect of muscle relaxants such as D-tubocurarine can be potentiated by aminoglycosides.

Aminoglycoside-induced neuromuscular blockade can be clinically relevant in patients with respiratory acidosis, in myasthenia gravis, and in other neuromuscular diseases. Severe illness, the simultaneous use of anesthetics, for example in the immediate postoperative phase, and the application of the antibiotic to serosal surfaces are predisposing factors to be considered (15). Severe clinical manifestations are rare in patients treated with aminoglycosides that are administered in low doses, such as tobramycin.

Sensory systems

Eyes

Subconjunctival injection of tobramycin has caused macular infarction (SEDA-20, 238). This potentially devastating consequence suggests that care must be exercised when contemplating instillation of aminoglycosides directly into the eye.

Allergic contact dermatitis causing conjunctivitis and blepharitis has been reported with topical ophthalmic tobramycin (16).

© 2006 Elsevier B.V. All rights reserved.

Ears

Tobramycin affects the cochlear and vestibular systems to a similar extent as gentamicin. A survey of 24 trials showed the following mean frequencies of ototoxicity: gentamicin 7.7%, tobramycin 9.7%, amikacin 13.8%, netilmicin 2.3% (17). There was also a lower incidence of netilmicin-induced inner-ear damage compared with tobramycin in two studies (18,19).

Of 60 adult patients with cystic fibrosis randomized to tobramycin, either 10 mg/kg/day or 3.3 mg/kg tds, two patients (one in each group) had bilateral impairment in pure tone audiography after treatment (20).

Histological examination of the temporal bones from two individuals with ototoxicity due to tobramycin showed reductions in the numbers of both ganglion cells and hair cells (21). Spiral ganglion cell loss was not necessarily subadjacent to areas of hair cell loss in cases of aminoglycoside ototoxicity. Instead, there may be a reduction in the number of ganglion cells in segments of the cochlea with normal-appearing hair cells.

Psychological, psychiatric

As with gentamicin, toxic psychoses can occur with tobramycin (22).

Metal metabolism

Repeated courses of intravenous tobramycin can cause hypomagnesemic tetany (23).

Liver

Certain aminoglycosides affect liver function tests. Increases in alkaline phosphatase after tobramycin have been described (24).

Urinary tract

The following order of relative nephrotoxicity was found in animal experiments: neomycin > gentamicin > tobramycin > amikacin > netilmicin (25,26). However, in humans, conclusive data regarding the relative toxicity of the various aminoglycosides are still lacking. An analysis of 24 controlled trials showed the following average rates for nephrotoxicity: gentamicin, 11%; tobramycin, 11.5%; amikacin, 8.5%; and netilmicin, 2.8% (17). In contrast to this survey, direct comparison in similar patient groups showed no significant differences between the various agents in most trials (27–33). One prospective trial showed a significant advantage of tobramycin over gentamicin (34). However, these findings could not subsequently be confirmed (35). Nephrotoxicity remains a serious risk with all the currently available aminoglycoside antibiotics, and no drug in this series can be regarded as safe.

- Nephrotoxicity due to inhaled tobramycin has recently been described in a 20-year-old patient with cystic fibrosis who developed acute non-oliguric renal insufficiency after taking inhaled tobramycin 300 mg bd for 1 week; the clinical and renal biopsy findings were consistent with aminoglycoside-induced changes (36).

Skin

Ultraviolet recall has been reported after piperacillin, tobramycin, and ciprofloxacin, with a reaction pattern different from that of chemotherapy-induced reactions.

- A 31-year-old woman with a *Pseudomonas* pneumonia was given intravenous ciprofloxacin 400 mg 12-hourly, tobramycin 400 mg/day, and piperacillin 4 g 6-hourly (37). Three days after the initial administration of the intravenous antibiotics, she developed a morbilliform eruption on the sun-exposed areas of her chest, back, and arms, corresponding to sites of intense sunburn that had occurred a month before.

Immunologic

- Hypersensitivity to inhaled tobramycin has been reported in a 9-year-old boy who developed a rash after a course of gentamicin (38). The rash resolved after withdrawal, but returned all over his body when inhaled tobramycin was restarted. He was desensitized using escalating doses of inhaled tobramycin, tolerated the procedure well, and was still using once-a-day tobramycin 9 months after desensitization.

Long-Term Effects

Drug tolerance

Intermittent administration of inhaled tobramycin has been recommended in patients with cystic fibrosis, as it improves pulmonary function, reduces the density of *P. aeruginosa* in sputum, and reduces the risk of hospitalization. The proportion of patients with isolates of *P. aeruginosa* with higher minimal inhibitory concentrations of tobramycin may increase (39). Treatment with inhaled tobramycin does not increase isolation of *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, or *Alcaligenes xylosoxidans*; however, isolation of *Candida albicans* and *Aspergillus* species may increase (40).

With nebulized tobramycin the introduction or selection of resistant bacteria is relatively rare but is a matter of concern (41).

Second-Generation Effects

Teratogenicity

During pregnancy the aminoglycosides cross the placenta and they might theoretically be expected to cause otological and perhaps nephrological damage to the fetus. However, no proven cases of intrauterine damage by tobramycin have been recorded.

Susceptibility Factors

Renal disease

Reduced tobramycin clearance can be associated with a normal creatinine clearance in serum concentration-adjusted dosage of once-daily tobramycin therapy in critically ill patients (42).

© 2006 Elsevier B.V. All rights reserved.

Other features of the patient

The pharmacokinetics of tobramycin in patients with cystic fibrosis is significantly altered after lung transplantation, and early and close drug monitoring is recommended (43).

Hydrophilic contact lenses may increase the penetration of tobramycin into the aqueous humor (44).

Drug Administration

Drug dosage regimens

The addition of tobramycin reduced the amount of cefuroxime-induced endotoxin released per killed *Escherichia coli* to a level that was even lower than that of tobramycin alone, despite an increased killing rate (45). Increasing concentrations of tobramycin led to a reduction in endotoxin release, pointing to a possible benefit of once-daily dosing regimens.

In an analysis of sera from 60 adults with cystic fibrosis, it was suggested that the potential benefit of achieving a greater peak/MIC with once-daily aminoglycoside administration may be offset by the significantly greater time that the concentration was below the MIC, compared with that achieved with multiple daily dosing regimens (46).

Based on a study of 10 patients with automated peritoneal dialysis, it was recommended that for empirical treatment of dialysis-related peritonitis, the dosage of intermittent intraperitoneal tobramycin must be 1.5 mg/kg for one exchange during the first day and then 0.5 mg/kg thereafter, to reduce the risk of adverse effects (47).

Drug administration route

With combined inhalational and intravenous tobramycin, toxic serum drug concentrations can occur (48).

Wound irrigation

Although the efficacy of peroperative wound irrigation with aminoglycosides has yet to be firmly established in prospective comparative trials, they are often used during intra-abdominal and thoracic surgery. Depending on the amount of drug used and the nature of the operation, it is likely that significant amounts of tobramycin are absorbed (SEDA-20, 237).

Inhalation

Tobramycin has been used extensively in cystic fibrosis because of its effect on *Pseudomonas* organisms. Used as an adjunct to intravenous antibiotics in acute infections, it can lower sputum colony counts. Aerosolized antibiotics over prolonged periods can improve lung function and reduce hospital admissions, but they carry the potential risk of drug toxicity and resistance. In a review of clinical studies it was concluded that there was no evidence of nephrotoxicity or ototoxicity (49), although long-term toxicity studies at higher dosages are awaited.

The efficacy of nebulized tobramycin 300 mg bd for 4 weeks has been studied in a randomized, double-blind, placebo-controlled trial in 74 patients with bronchiectasis and *Pseudomonas* infection, without cystic fibrosis (31). After 4 weeks there was a significant fall in the density of *Pseudomonas* infection in the sputum of the treated group. This correlated with an improvement in general medical condition, as assessed subjectively 2 weeks later. There was no difference in lung function. Tobramycin resistance (MIC over 16 μg/ml) developed in 4 patients in the treated group and 1 patient in the placebo group. Adverse events were reported by 31 of the 37 patients in each arm. There were significantly increased incidences of dyspnea (32%), chest pain (19%), and wheezing (16%) in the treated group compared with placebo (8%, 0%, 0% respectively). Cough increased in 15 patients (41%) in the treated group and 9 (24%) in the placebo group. The investigators felt that the majority of these respiratory adverse events had been related to the drug. They commented that these adverse events did not generally result in withdrawal of the patients from the trial. No more details were given but the apparent adverse effects profile of nebulized tobramycin in this group is of concern.

Topical administration into the ear

The primary target for the topical effects of aminoglycosides in the ear is controversial. It has been generally believed that outer hair cells are primarily affected, followed by loss of inner hair cells; that degeneration starts basally and proceeds towards the apex; and that neural fibers and ganglion cells would degenerate secondarily to loss of hair cells. However, the possibility that spiral ganglion cells may be a primary target has been raised. In a postmortem study of 10 temporal bones from 6 patients (aged 11–40 years) with cystic fibrosis, whose pulmonary infections had been treated with systemic aminoglycosides (mainly tobramycin), in most cases combined with nebulized tobramycin, cytocochleograms were analysed for each bone (50). Four bones showed typical manifestations of aminoglycoside-induced ototoxicity, with loss of hair cells in the lower turns and degeneration of ganglion cells. Six bones showed no loss or scattered loss of hair cells, but there was degeneration of the spiral ganglion cells. This study supports the hypothesis that degeneration of spiral ganglion cells may occur as a primary manifestation in some cases of aminoglycoside-induced ototoxicity.

Drug overdose

Multiple-dose activated charcoal does not increase the elimination of tobramycin and is therefore not recommended for treatment of poisoning (SEDA24.26.74) (51).

Monitoring Therapy

During multiple daily dosing peak serum concentrations of tobramycin over 5–7 μg/ml are associated with improved survival in patients with septicemia and pneumonia caused by Gram-negative bacteria (52,53). On the other hand, excessive peak concentrations (over 10–12 μg/ml) and trough concentrations (over 2 μg/ml) of tobramycin increase the risk of ototoxicity and nephrotoxicity (54).

Tocainide

See also Antidysrhythmic drugs

General Information

The clinical pharmacology, uses, efficacy, and adverse effects of tocainide have been extensively reviewed (1–9).

The adverse effects of tocainide occur with increasing frequency above plasma concentrations of 10 μg/ml. They are mostly related to the nervous system. In two large series withdrawal of tocainide was required in 11–16% of patients because of adverse effects (10,11). The high incidence of blood dyscrasias severely limits the use of tocainide.

Organs and Systems

Cardiovascular

Adverse cardiovascular effects have been reported in 6–55% of cases. After a single dose of tocainide the most common effect is hypotension with bradycardia (12). Angina pectoris has also been reported (13).

During repeated administration cardiovascular adverse effects are relatively uncommon. Increasing heart failure (14,15), worsening dysrhythmias (15,16), pericarditis (15,17,18), and sinus arrest with sinoatrial block (19) have all been reported. Tocainide can worsen ventricular tachycardia (20).

Respiratory

There have been several reports of interstitial pneumonitis attributable to tocainide (21,22), and it may also cause severe pulmonary fibrosis (23,24).

Nervous system

A wide variety of central nervous system symptoms has been reported in almost every study, varying in incidence from 10 to 100%. Common reactions include dizziness, tremor and tremulousness, dysesthesia and paresthesia, light-headedness, and blurred vision. Various mental changes have been described, including paranoid psychosis (25–27). Nausea is common and probably central in origin, since it occurs after intravenous as well as oral administration. These adverse effects can be reduced in frequency during oral administration by taking the tablets with food.

Sensory systems

There have been not infrequent reports of odd taste sensations (peppermint and menthol) and of coolness of the throat, hands, and feet.

Hematologic

Tocainide can cause blood dyscrasias (neutropenia, thrombocytopenia, pancytopenia, and aplastic anemia) in one in 300 patients (28–31). There have been isolated reports of eosinophilia with an allergic rash and anemia with pericarditis (17,32).

Gastrointestinal

Nausea is very common, particularly during the initial stages of treatment, after which it tends to disappear (14). There have been occasional reports of constipation (17) and of anorexia and vomiting (14).

Liver

Tocainide can increase the activities of serum transaminases (33) and can cause fatty change (33) and granulomatous hepatitis (34).

Urinary tract

Non-membranous glomerulonephritis has been reported (35).

Skin

There have been a few reports of skin rashes attributed to tocainide (17,36).

Hair, nails, sweat glands

Night sweats have been reported in three patients taking tocainide (17).

Immunologic

Arthralgia has been reported in two cases with positive antinuclear antibody titers, suggesting the possibility of a lupus-like syndrome (37). In another case tocainide treatment was associated with both a lupus-like syndrome and neutropenia (38). Cross-reactivity of tocainide with lidocaine has been reported (39).

Drug Administration

Drug overdose

Convulsions, complete heart block, and asystole developed in a case of fatal self-poisoning with 400 mg of tocainide (40).

Drug–Drug Interactions

Theophylline

Tocainide reduces the clearance of theophylline and increases its half-life, but to an extent that is probably clinically insignificant (41).

Tolazoline

General Information

Tolazoline is an alpha$_2$-adrenoceptor antagonist that increases skin blood flow in healthy subjects and has been used to relieve acute vasospasm. However, convincing evidence of its therapeutic value in patients with chronic conditions, such as claudication or cerebrovascular impairment, is not available. It has a pulmonary vasodilator action and seems to be a useful adjunct in the management of neonates with persistent fetal circulation.

Tolazoline has a histamine-like action. Its most common adverse effects are palpitation, tachycardia, flushing, sweating, headache, and paresthesia of the skin with piloerection. Unwanted gastrointestinal effects include nausea, vomiting, and diarrhea. Postural hypotension and failure to ejaculate have also been reported.

Organs and Systems

Gastrointestinal

An infant with persistent fetal circulation treated with tolazoline developed gastric ulceration and perforation (1). The first symptoms occurred 14 hours after the start of therapy, and there was free air in the abdomen 34 hours later. Duodenal perforation also occurred in a 31-hour-old infant with meconium aspiration treated with tolazoline for 6 hours; the defect required surgical correction (2).

Drug–Drug Interactions

Clonidine

Tolazoline can antagonize the effects of intravenous clonidine and prevent the brief hypertensive reaction that it often causes (SEDA-2, 192) (SEDA-3, 180).

Tolcapone

General Information

Tolcapone is an inhibitor of catchol-O-methyltransferase, which catalyses a relatively minor pathway of dopamine metabolism. It therefore enhances the action of dopamine.

The introduction of tolcapone had a major impact on the management of Parkinson's disease, and within months tens of thousands of patients throughout the world were treated with it. Tolcapone was considered to be useful in prolonging the half-life of levodopa, thereby allowing dosage reduction and possibly smoother therapeutic responses.

In early studies the most frequent adverse effects of tolcapone were dyskinesias, nausea, sleep disorders, dystonia, orthostatic hypotension, diarrhea, dizziness, and hallucinations (1). However, very soon tolcapone was withdrawn in most countries, because of reports of severe hepatotoxicity. The background to these events has been briefly reviewed (2).

Organs and Systems

Gastrointestinal

Raised liver enzymes due to tolcapone were often associated with diarrhea and occurred within 6 weeks to 6 months of the start of tolcapone therapy. Diarrhea

© 2006 Elsevier B.V. All rights reserved.

developed in 16–18% of patients taking tolcapone and was severe in 3–4% of the cases.

Liver

A number of cases of severe hepatotoxicity (3) led the health authorities to withdraw tolcapone from most European countries following an EMEA ruling in November 1998. Increases of more than three times the upper limit of the reference range for alanine aminotransferase and aspartate aminotransferase occurred in respectively 1% and 3% of patients taking tolcapone 100 mg tds and 200 mg tds. Increases of more than eight times the upper limit of normal alanine aminotransferase and aspartate aminotransferase occurred in respectively 0.3% and 1.7% of patients taking tolcapone 100 mg tds and 200 mg tds. Subsequently there were three deaths from acute liver failure in patients taking tolcapone during a total exposure of 40 000 patient-years, leading to the complete withdrawal of the drug. An earlier review, predating the withdrawal of tolcapone, had suggested that it could be safely used provided liver function was closely monitored in the first 6 months of therapy (4), and some neurologists believe that this course of action may still be reasonable because of what they regard as the superior efficacy of this drug.

Skin

- Progressive vitiligo occurred in a 50-year-old Caucasian who took tolcapone 300 mg/day in combination with co-careldopa (5). The first depigmented lesions appeared a week after starting the drug.

The authors speculated that the increased concentrations of dopamine may have interfered with melanin synthesis.

Tolfenamic acid

See also Non-steroidal anti-inflammatory drugs

General Information

The main adverse effects of tolfenamic acid (particularly nephrotoxicity) are similar to those of the other anthranilic acid derivatives. However, dysuria has been reported more often and confirmed by rechallenge (SEDA-4, 68). Skin disorders are frequent (40% of all reported effects), and fixed drug eruption has occurred (SEDA-18, 107). Diarrhea (10%) and upper gastrointestinal symptoms (including dyspepsia, nausea, vomiting, gastric pain, and ulcer) (6%) are common (SEDA-19, 98). Hepatitis has been described with positive rechallenge. Six patients with pulmonary infiltrates, possibly caused by tolfenamic acid, were reported to the Finnish National Centre for Adverse Drug Reaction Monitoring over a 12-year period. In some patients with hemolytic anemia, a positive Coombs' test and antinuclear antibodies suggested an immunological mechanism (SEDA-13, 83).

Organs and Systems

Electrolyte balance

Hyperkalemia has been attributed to tolfenamic acid (1).

- A hemodialysis patient with nephritic syndrome and diabetic end-stage renal disease developed severe hyperkalemia with muscle paresis after taking tolfenamic acid 300 mg/day for chronic headache. Five days after starting treatment he reported pain and tenderness affecting the muscles of his back and lower extremities. He had hyponatremia and severe hyperkalemia. During the following days he developed increasing weakness and became unable to move his head and limbs. Tolfenamic acid was withdrawn and aggressive treatment and repeated hemodialysis started, leading to complete recovery in a few days.

In this case, end-stage renal disease with nephrotic syndrome and insulin-dependent diabetes mellitus were predisposing factors to the development of hyperkalemia, but a possible role of accumulated tolfenamic acid metabolites could not be excluded. Patients with severe renal insufficiency should not receive NSAIDs.

Tolmetin

See also Non-steroidal anti-inflammatory drugs

General Information

In 32 207 patients taking part in a short (1–4 weeks) postmarketing study of tolmetin, adverse effects occurred in 12%, and led to withdrawal in 3.6% (1). Tolerability was similar to that of naproxen, indometacin (SEDA-7, 114), and ibuprofen (SED-9, 152) (2). In another retrospective study in patients treated for 1 year or more with tolmetin, 64% reported generally mild transitory adverse effects. In controlled studies, about 10% of patients withdrew owing to adverse effects (3). In another study of 25 000 prescription records (4), tolmetin caused adverse

© 2006 Elsevier B.V. All rights reserved.

reactions severe enough to merit hospitalization in only two cases (drug fever and membranous glomerulopathy).

Organs and Systems

Cardiovascular

Increased blood pressure can occur after long-term treatment with tolmetin (5).

Nervous system

The usual adverse reactions of NSAIDs on the nervous system have been attributed to tolmetin (SEDA-6, 98). One woman developed aseptic meningitis, similar to that seen with ibuprofen (6).

Sensory systems

Hearing loss has been documented (SED-9, 152) (7).

Hematologic

Acute reversible thrombocytopenic purpura and tolmetin-related antibodies have been reported in a patient with a history of multiple allergies; rechallenge was positive (8). Peripheral blood eosinophilia has also been found (SEDA-6, 98).

Gastrointestinal

Gastrointestinal adverse effects occurred in 31% of patients taking tolmetin and peptic ulceration in 2% (3). In older patients, the percentage of peptic ulceration and gastrointestinal bleeding was somewhat higher (9).

Urinary tract

Reversible renal insufficiency and acute interstitial nephritis have been reported. Nephrotic syndrome was attributed to tolmetin, but a firm causal relation was not established (10). Nephrotic syndrome has also been described in a 16-year-old girl after she had taken tolmetin for 6 months (SEDA-16, 122).

Immunologic

From early on, the high incidence of hypersensitivity reactions with tolmetin was striking, for example in spontaneous adverse reaction reports. However, the high incidence was not confirmed in a retrospective comparative review (SEDA-6, 98) (SEDA-7, 134) (11). Several factors can explain the discrepancy. For example, patients covered by the review may have persisted with treatment, since they did not experience such reactions.

Multiorgan failure

Fatal multisystem toxicity including both renal and hepatic failure, with microvesicular fatty change in the liver, has been reported with tolmetin in a young woman (12).

Drug–Drug Interactions

Warfarin

Tolmetin combined with warfarin can markedly prolong the prothrombin time and cause bleeding (SEDA-13, 82).

Toloxatone

See also Monoamine oxidase inhibitors

General Information

Like moclobemide, toloxatone, a selective and reversible inhibitor of monoamine oxidase type A, is thought to be relatively safe in combination with sympathomimetics (SEDA-18, 16). However, sweating, tachycardia, and headache have been reported when terbutaline was added to toloxatone and phenylephrine (SEDA-18, 16). In healthy volunteers, doses up to 600 mg/day did not produce hypertensive reactions on challenge with oral tyramine (SEDA-17, 17). Two fatal cases of fulminant hepatitis have been reported (SEDA-16, 7).

Interactions with toloxatone are similar to those with moclobemide (1).

Tolterodine

See also Anticholinergic drugs

General Information

Tolterodine is an anticholinergic drug that is used to treat bladder detrusor instability. It has antimuscarinic actions that are relatively bladder-selective. Its efficacy and tolerability have been reviewed (1,2). The general conclusion is that tolterodine is better tolerated than the previous standard medication oxybutinin, particularly with regard to the frequency and severity of dry mouth, but also comparing other autonomic adverse effects, although this is not universally agreed (SEDA-22, 157). The rate of adverse effects-related withdrawals was 2–3 times higher with oxybutinin than tolterodine.

The adverse effects of tolterodine and other antimuscarinic anticholinergic drugs have been reviewed in patients with incontinence and bladder overactivity (3–6).

The findings are not unexpected: dry mouth is by far the most commonly reported adverse effect, with a frequency of about 40% in patients taking 2 mg of the immediate-release formulation bd. The next most common effects are consistently headache, constipation, and abdominal discomfort. Hallucinations and tachycardia have also been reported. It is agreed that higher doses should not be used because of the risk of urinary retention. About 5% of patients stopped taking tolterodine because of adverse effects and in about 10% the dosage was reduced. In one comparison of tolterodine 2 mg twice-daily with 4 mg once-daily in a modified-release formulation the latter produced about a 23% lower incidence of dry mouth, with increased efficacy (7).

Comparative studies

Tolterodine and oxybutynin have been compared (8). The authors concluded that the efficacy of tolterodine 2 mg bd is equivalent to that of oxybutynin 5 mg bd, but that tolterodine causes fewer autonomic adverse effects, less need for dosage reduction, and fewer dropouts because of adverse effects.

Organs and Systems

Mouth

In over 300 patients modified-release oxybutynin once-daily produced less dry mouth (28 versus 33%) than immediate-release tolterodine 2 mg bd (9).

Immunologic

Anticholinergic drugs can rarely cause immunological reactions.

- An 81-year-old Swiss woman took immediate-release tolterodine 2 mg bd and 18 days later had fever, malaise, and nausea with vomiting (10). Liver function tests showed a mixed hepatitic and cholestatic pattern and she also had leukocytosis and eosinophilia.

The authors suggested that this was a hypersensitivity reaction; if so it is the first of its kind to be reported with tolterodine.

Tonazocine

General Information

Tonazocine is a partial opioid receptor agonist that has not been reported to have adverse effects on the cardiovascular system or to cause clinically significant respiratory depression. When single doses of tonazocine 2, 4, and 8 mg were compared in 150 adults postoperatively,

© 2006 Elsevier B.V. All rights reserved.

drowsiness was the most frequent adverse effect and visual hallucinations occurred in two patients (1).

Topiramate

See also Antiepileptic drugs

General Information

Topiramate is used in the adjunctive therapy of partial seizures and some types of generalized seizure. Most of its adverse effects relate to the central nervous system.

Observational studies

In an open study of the effects of topiramate 100–1600 mg/day in 292 adults (mean age 33 years) with partial and/or generalized seizures previously resistant to antiepileptic drug therapy over 50% of the patients achieved at least a 50% reduction in seizures (1). The most commonly reported adverse events were related to the central nervous system, including headache, difficulty in concentrating, somnolence, anorexia, fatigue, dizziness, nervousness, nausea, confusion, and paresthesia; 32% discontinued because of adverse events.

Topiramate had a beneficial effect on benign essential tremor in an open study in nine patients (2). Six patients complained of fatigue and two discontinued therapy; four complained of paresthesia.

The effectiveness and tolerability of topiramate has been studied in an open study in 56 patients with bipolar disorder (3). The most common adverse effects were neurological and gastrointestinal, including reduced appetite ($n = 11$), cognitive impairment ($n = 10$), fatigue ($n = 5$), and sedation ($n = 5$). Six patients dropped out during acute treatment and four during maintenance therapy because of adverse effects (cognitive impairment, poor appetite and weight loss, sedation, paresthesia, psychosis, anxiety, tremor, nausea, altered taste, and rash).

In a 3-year retrospective review of the use of topiramate in 51 children aged 3–16 years with partial and generalized epilepsy, 15 children had a greater than 50% reduction in their seizure frequency and four became seizure free (4). Adverse effects were reported in 29 patients; most were related to behavioral and cognitive difficulties; less common effects included anorexia, weight loss, and headache. Topiramate was withdrawn in 25 patients; in 20 cases because of adverse effects.

In 18 patients with severe myoclonic epilepsy in infancy topiramate caused reduced seizure frequency in most (5). There were adverse effects in nine patients, eight with a weekly titration schedule and one with a fortnightly schedule. They were usually minor and transient nervous system effects, except for weight loss, which lasted longer and occurred in four patients.

Among the adverse effects of topiramate are reduced appetite and weight loss, and this has been put to use in the treatment of binge eating in an open study in 13 patients (6). Nine patients had a moderate or better response, two had moderate or marked responses that subsequently diminished, and two had a mild response or none. Neurological adverse effects were the most common. Three patients discontinued topiramate because of adverse effects, and two resumed at a later date without significant recurrence.

The efficacy and tolerability of topiramate have been studied in 170 patients with refractory epilepsy (7). The most common adverse effects resulting in withdrawal were fatigue, weight loss, irritability, paresthesia, depression, and headache. Three patients developed renal calculi but continued therapy.

The effect of topiramate for 6–18 months in 34 children with drug-resistant epilepsy has been studied (8). Adverse effects were reported in nine patients, appetite suppression in five, behavioral disturbances in three, somnolence in two, and poor concentration in one.

In a long-term open extension to a double-blind, placebo-controlled trial of topiramate in 83 children with partial-onset seizures, with or without secondary generalization, seizure frequency over the last 3 months of therapy was reduced by at least 50% in 47 children (9). Anorexia was common during long-term therapy. Five children withdrew because of adverse events.

Topiramate has been used for the treatment of psychiatric disorders, especially bipolar disease. The adverse events profile is similar to that in patients with epilepsy. In a retrospective assessment of 76 patients taking topiramate for bipolar spectrum disorders there was mild improvement in 47% and moderate-to-marked improvement in 13% (10). Responders took a significantly higher mean dose (180 mg/day) than non-responders (83 mg/day). There was weight loss (mean 6.4 kg) in 50% of the patients; the dose was significantly higher in patients who lost weight. Other adverse events were reported by 82% of patients: cognitive effects, sedation, paresthesia, nausea, insomnia, headache, and dizziness. Adverse effects led to withdrawal in 36% of the total patient population. Similar anecdotal experiences in the treatment of bipolar disorders have been reported by others (11,12).

Placebo-controlled studies

In a double-blind, placebo-controlled, add-on trial of topiramate (300 mg/day) in 177 Korean patients with epilepsy, adverse events that were significantly more common in the active treatment group were anorexia (21 versus 6% on placebo), abdominal pain or discomfort (21 versus 2%), speech disturbances (10 versus 1%), psychomotor slowing (9 versus 1%), and weight loss (9 versus 0%) (13). The relatively high incidence of gastrointestinal disturbances was not seen in Western trials, suggesting that Koreans may be more sensitive to this type of adverse effect. Of seven patients who withdrew because of adverse events, four did so because of abdominal symptoms, nausea, and/or vomiting.

© 2006 Elsevier B.V. All rights reserved.

The results of six double-blind, placebo-controlled trials with topiramate in adults with treatment-resistant partial-onset seizures with or without secondary generalization have been analysed (14). Seizures were reduced by at least 50% in 43% of topiramate-treated patients and in 12% of placebo-treated patients. The most common treatment-related adverse events were dizziness, somnolence, fatigue, psychomotor slowing, nervousness, paresthesia, ataxia, memory difficulty, and speech problems. These effects were generally mild to moderate, usually occurred early in treatment, often during titration, and resolved with continued treatment. Other adverse effects were weight loss and, in a few patients, renal calculi.

The efficacy and safety of topiramate has been studied in 46 adult Chinese patients with refractory partial epilepsy in a randomized, double-blind, placebo-controlled study (15). Adverse events were mostly mild and transient, with no significant differences between treatment groups. Two patients taking topiramate had weight loss.

Organs and Systems

Cardiovascular

It is unclear whether topiramate played any role in rare cardiovascular events. These included symptoms of Raynaud's phenomenon in three patients, and third-degree atrioventricular block requiring emergency cardiac pacemaker implantation in one patient with pre-existing right bundle branch block (SEDA-21, 76).

Respiratory

Topiramate inhibits carbonic anhydrase isozymes II and IV, which are present in the central nervous system. Respiratory alkalosis in a 15-year-old girl, who presented with hyperpnea, was not therefore surprising (16). The problem resolved within 24 hours of withdrawal.

Nervous system

In controlled trials, adverse effects with a minimum incidence of 20% in any dosage group included dizziness, fatigue, diplopia, nystagmus, somnolence, confusion, mental slowing, ataxia, anorexia, impaired concentration, and headache (17). The most common complaint was dizziness (40 versus 13% on placebo) in those assigned to the highest dosage (1000 mg/day). Taking events that were probably or definitely drug-related, those with a frequency of 5% or greater were ataxia, impaired concentration, confusion, dizziness, fatigue, paresthesia, somnolence, and mental slowing. All the events were usually mild or moderate and tended to be more frequent at dosages above 600 mg/day, although some, such as dizziness and somnolence, showed no clear dose-dependency. These studies may have overestimated the adverse potential of the drug, because excessively fast dosage escalations were used and maintenance dosages in many groups were larger than those that were later found to be optimal. However, signs of cognitive dysfunction, including word-finding difficulties and impaired memory, have occurred in an appreciable proportion of patients in many studies (SEDA-20, 66).

In monotherapy studies, the incidence of adverse effects was lower than in add-on studies, except for paresthesia which tended to occur more often.

Ataxia was twice as common in patients taking two concomitant anticonvulsants compared with those taking only one other drug (17).

In the comparison of four anticonvulsants mentioned above, the commonest adverse effect of topiramate in 28 patients was irritability, which occurred in seven of ten patients who discontinued therapy because of adverse effects (18).

The response to topiramate has been evaluated in 97 patients with Lennox–Gastaut syndrome in a long-term, open-label extension to a double-blind, placebo-controlled trial (19). The most common adverse events, apart from childhood illnesses, were somnolence and anorexia.

There have been a few reports of hemiparesis in patients taking topiramate.

- Hemiparesis developed in a 41-year-old man and a 59-year-old woman during the first few weeks on topiramate at dosages up to 250 and 200 mg/day respectively (20). The condition resolved gradually after drug withdrawal.

Both patients had pre-existing cerebral damage (contralateral cerebral palsy and temporal lobe infarction respectively), which might have facilitated this hitherto unreported possible adverse effect.

Reversible hemiparesis occurred in a boy taking topiramate (21).

- A 5.5-year-old boy with partial motor seizures secondary to heterotopic gray matter in the atrium of the left lateral ventricle and postictal Todd's paresis was given topiramate in addition to baseline valproate and carbamazepine, and became seizure-free for 6 months. However, he then started to have a new type of seizure, characterized as complex partial. The dosage of topiramate was increased and carbamazepine was withdrawn. He then had a change in behavior, clumsiness, and persistent right hemiparesis. Electroencephalography showed continuous independent left and right centrotemporal epileptiform discharges. There were no changes on an MRI scan. Topiramate was withdrawn and ethosuximide was added. He became seizure-free and his hemiparesis resolved after 1 month. The electroencephalogram improved remarkably.

It is very difficult to find a causal relation between topiramate and this patient's hemiparesis. An alternative interpretation is that he had complex partial status (as suggested by his electroencephalogram) when carbamazepine was withdrawn, associated with reversible hemiparesis.

Sensory systems

On 26 September 2001 OrthoMacneil/Jansen-Cilag issued a "Dear Doctor" letter about an ocular syndrome in patients taking topiramate. The syndrome is characterized by acute myopia and secondary angle-closure glaucoma. Several case reports have been published (22–24).

© 2006 Elsevier B.V. All rights reserved.

As of 17 August 2001 there were 23 reported cases (22 adults and 1 child) out of 825 000 patients. Symptoms typically occur within the first month of therapy, and the patients report acutely reduced visual acuity and/or ocular pain. There is myopia, redness, swelling of the anterior chamber, and raised ocular pressure, with or without pupil dilatation. Supraciliary effusion can displace the lens and iris anteriorly, secondarily causing angle-closure glaucoma. The symptoms are reversible if topiramate is withdrawn. Acute myopia has been described as a rare idiosyncratic reaction to other sulfonamides. It has been postulated that the pathogenic mechanism is related to partial inhibition of carbonic anhydrase and to ciliary body swelling.

Psychological, psychiatric

Psychiatric

Depression and psychosis have been observed in respectively 15 and 3% of patients taking topiramate (SEDA-22, 91) (17). Three patients taking topiramate for bipolar disorder developed substantial depression (25). The symptoms began or increased within 1 week of topiramate treatment (25 mg/day) or with an increase in dosage to 50 mg/day. All had significant relief from depression 1–2 weeks after withdrawal of topiramate. The close association with the onset of the most severe depression these patients had ever experienced suggests an adverse effect of topiramate. However, all these patients had bipolar disorder, so the onset of depression could have been coincidental. Moreover, their depression might also have been due to a synergistic interaction between topiramate and their other medications.

Two adult patients with refractory partial seizures without a previous history of psychosis had an acute psychotic episode with hallucinations and psychomotor agitation after taking topiramate 200–300 mg/day (26).

A single case report of new-onset panic attacks has been described.

- A 24-year-old woman with a history of bipolar disorder and binge eating had a history of "isolated" panic attacks 8 years before and the attacks subsided 14 days after topiramate withdrawal (27).

Because she had a history of psychiatric diseases and panic attacks, the relation of these symptoms to topiramate was doubtful.

Cognitive effects

All anticonvulsants have been associated with adverse cognitive events, and many, sometimes contradictory, studies of classical anticonvulsants have been published (28). Cognitive adverse effects are large for phenobarbital, and possibly larger for phenytoin than for carbamazepine or valproic acid (28). Most often cognitive adverse events result in mild general psychomotor slowing. Although the severity of cognitive adverse effects is considered mild to moderate for most anticonvulsants, their impact may be substantial in some patients, especially in those with pre-existing impaired cognitive function. There is relatively little reliable information on cognitive adverse events of new anticonvulsants. Most of the published studies are on polytherapy and there is little information about healthy volunteers (29).

Topiramate can cause cognitive adverse effects in some patients. Those affected often have impaired verbal learning and fluency. Slow titration reduces the likelihood of cognitive adverse events. Two patients had neuropsychological deficits during topiramate treatment and cognitive improvement after withdrawal (30). One patient was assessed during and after topiramate withdrawal and the other before, during, and after.

The cognitive adverse effects of gabapentin, lamotrigine, and topiramate in healthy volunteers have been compared in a randomized, single-blind, parallel-group study (29). Neurobehavioral testing was conducted at baseline, during the acute oral dosing period 3 hours after medication administration, and at 2 and 4 weeks during chronic dosing. Acutely, those who took topiramate (2.8 mg/kg) performed significantly worse than those who took gabapentin (17 mg/kg) or lamotrigine (3.5 mg/kg) on tasks of letter and category word fluency and visual attention; cognitive effects were not different between those who took gabapentin or lamotrigine. The doses were then increased to topiramate 5.7 mg/kg/day, lamotrigine 7.1 mg/kg/day, and gabapentin 35 mg/kg/day. At 2 and 4 weeks, those taking topiramate had significant verbal memory deficit and slow psychomotor speed compared with baseline; those taking gabapentin and lamotrigine did not. However, the clinical impact of the trial was limited, owing to the small sample size (17 patients) and the very rapid topiramate titration, much faster than is currently recommended (31).

There has been a retrospective analysis of neuropsychological scores before and after the use of topiramate 125–600 mg/day for at least 3 months in 18 patients (32). Topiramate was associated with significant deterioration in verbal IQ, learning, and fluency. Withdrawal or dosage reduction was associated with significant improvement. There was no correlation between individual topiramate dose and the change in test score. This study was retrospective and the patients were selected because they had cognitive problems; the resultant bias makes it difficult to generalize these results to wider populations.

A group of 14 US epilepsy centers has published the results of a post-marketing surveillance study of 701 patients taking topiramate (33). Although 41% of the patients reported cognitive adverse events at any time during treatment, only 5.8% of them discontinued for that reason. Cognitive effects were the most frequent reason for withdrawal because of adverse events (41/170 or 24% of those who discontinued). The central nervous system-related adverse effects profile in these patients included psychomotor slowing, fatigue, slurred speech, irritability, behavioral changes, confusion, inappropriate laughter, and hallucinations. Only 2.4% of the patients were taking monotherapy, and the mean dose of topiramate at 6 months was 385 mg/day, with a mean weekly dose during titration of 36 mg/day. Risk factors for discontinuation were evaluated. A slow titration rate (slower than 25 mg/week), but not the total dose at discontinuation, was significantly associated with a lower discontinuation rate. There was no specific population, dose titration, or concomitant antiepileptic drug that

© 2006 Elsevier B.V. All rights reserved.

increased the risk of treatment discontinuation because of cognitive complaints. Psychomotor slowing was the most common complaint, but most patients elected to continue treatment because of improved seizure control.

In a retrospective survey, behavioral changes occurred in nine of 69 children (median age 12 years) taking topiramate (34). Dosages in the affected children were 2.4–8.5 mg/kg, and three children were taking monotherapy. Manifestations included school difficulties (4), mood swings (2), and aggression, irritability, and hallucinations (one case each). There was no apparent relation to dosage or titration rate.

The cognitive effects of topiramate and valproate as adjunctive therapy to carbamazepine have been compared in 53 patients (35). Topiramate was given in an initial dose of 25 mg and increased weekly by 25 mg/day increments to a minimum of 200 mg/day. Cognition was significantly worsened by topiramate and improved by valproate. Gradual introduction of topiramate reduced the extent of cognitive impairment.

The effects of topiramate and valproate, when added to carbamazepine, on cognitive status in adults have been compared in a randomized, observer-blinded, parallel-group study (35). Topiramate was introduced slowly at a starting dose of 25 mg/day and increased weekly by 25 mg/day increments over 8 weeks to a minimum dosage of 200 mg/day. The target dosages were 200–400 mg/day for topiramate and 1800 mg/day for valproate. There were significant differences between topiramate and valproate in short-term verbal memory—worsening with topiramate and improvement with valproate—but the differences were small. There were no effects on mood disorders, psychiatric symptoms, or motor and mental speed and language tests. These results suggest that if the dose of topiramate is slowly titrated cognitive adverse events can be minimized. However, although most patients tolerated topiramate if properly titrated and dosed, a subset of patients had clinically significant deficits, possibly as an idiosyncratic reaction. In another multicenter, parallel-group, randomized study similar results were obtained when topiramate or valproate was added to carbamazepine (36,37).

The effects of topiramate on tests of intellect and other cognitive processes have been studied in 18 patients (32). Repeat assessments in those taking topiramate were associated with a significant deterioration in many domains, which were not seen in controls. The greatest changes were for verbal IQ, verbal fluency, and verbal learning. There were improvements in verbal fluency, verbal learning, and digit span in patients who had topiramate withdrawn or reduced.

The factors associated with behavioral and cognitive abnormalities in children taking topiramate have been studied retrospectively (38). There were behavioral or cognitive abnormalities in 11 of 75 children at 2–4 months after the start of therapy. The mean dosage (4.6 mg/kg/day) at which these abnormalities were observed was similar to the mean final dose (5.8 mg/kg/day) in children without abnormalities. Five of the eleven children with behavioral or cognitive abnormalities had a previous history of behavioral or cognitive abnormalities, but only nine of the 64 children without abnormalities had a previous history of behavioral or cognitive abnormalities.

Angelman's syndrome, a genetic disorder that involves a defect in the DNA coding for subunits of the GABA-A receptor, is often associated with intractable epilepsy. Topiramate was effective in five children with Angelman's syndrome and epilepsy (39). One patient had transient insomnia and one had akathisia and insomnia that persisted until topiramate was withdrawn.

Slowed mental function is a relatively common adverse effect of topiramate, especially at high dosages, and has been confirmed in a randomized single-blind, parallel-group study in healthy volunteers. After single doses, topiramate (2.8 mg/kg) reduced performance in attention and word fluency tests, whereas lamotrigine (3.5 mg/kg) and gabapentin (17 mg/kg) had no effects (29). After 4 weeks of multiple dosing, topiramate (5.7 mg/kg) was still associated with impairment in verbal memory and psychomotor speed, while there was no impairment with lamotrigine (7.1 mg/kg) or gabapentin (35 mg/kg). While these data suggests that topiramate can cause greater cognitive dysfunction in the short-term than lamotrigine and gabapentin, these findings should be interpreted cautiously. First, the design was less than ideal: the use of a double-blind, crossover design and inclusion of placebo would have been preferable. Secondly, the speed of topiramate titration was much faster than currently recommended, and it is known that neurotoxicity can be reduced by slow dose escalation. Finally, the dosage of topiramate was very high, in view of the fact that no enzyme-inducing co-medication was present.

Word-finding difficulties are a known adverse effect of topiramate. Language disturbances (anomia or impaired verbal expression) without other complaints suggestive of impaired cognition were reported by four of 51 patients; five others had language problems associated with cognitive dysfunction (40). One severely retarded patient with a limited vocabulary became mute, although otherwise alert. Anomia or dysnomia were also seen in two of eight patients treated with zonisamide, which shares with topiramate a sulfa structure and carbonic anhydrase inhibitory properties. Psychotic symptoms are a significant adverse effect in occasional patients. In a retrospective survey, five of 80 patients developed psychosis 2–46 days after starting to take topiramate; manifestations included paranoid delusions in four and auditory hallucinations in three (41). The dosage at the time of onset of symptoms was 50–500 mg/day, and recovery occurred rapidly after drug withdrawal (three patients), dosage reduction (one patient), or neuroleptic drug treatment (one patient). Three of the patients had no significant psychiatric history.

Metabolism

Topiramate causes a fall in body weight, ranging from a mean of 1.1 kg at 200 mg/day to 5.9 kg at 800–1000 mg/day (17). Loss of weight may be linked to anorexia. Women tend to lose more weight than men, and weight loss is greatest in patients with the highest weight at baseline.

Weight loss with topiramate can occasionally be extensive (42).

- A 37-year-old obese white woman with affective instability and obesity taking topiramate (up to

© 2006 Elsevier B.V. All rights reserved.

275 mg/day) lost 10 kg over 10 weeks, although she remained obese (BMI 52 kg/m^2). She also improved mentally.

In this case the weight loss was a beneficial collateral effect of topiramate.

In a retrospective chart review, weight loss was assessed in 214 patients with psychiatric disorders taking topiramate (43). Patients taking either lithium or valproate gained a mean (SD) of 6.3 (9.0) kg and 6.4 (9.0) kg respectively, whereas patients taking topiramate lost 1.2 (6.3) kg. Similar statistically significant results were found in the bone mass index.

Acid–base balance

Topiramate lowers serum bicarbonate by inhibiting carbonic anhydrase. In 20 of 29 children there was a greater than 10% fall in serum bicarbonate after starting topiramate (mean absolute reduction 4.7 mmol/l), but none had significant symptoms of metabolic acidosis, except possibly for anorexia in one (44). In another report, mild to moderate metabolic acidosis (bicarbonate concentrations, 16–21 mmol/l) developed in three topiramate-treated patients aged 25–51 years; the condition was not considered clinically significant, but it led to diagnostic tests to exclude other causes (45).

While the fall in serum bicarbonate is asymptomatic in most cases, special caution is required in patients already at risk of metabolic acidosis, such as those with respiratory acidosis, renal disease, frequent severe infections and sepsis, gastrointestinal disorders with recurrent dehydration, inborn errors of metabolism, or treatment with a ketogenic diet (44).

Mental changes and metabolic acidosis can occur with topiramate, through inhibition of carbonic anhydrase.

- A 20-year-old man taking topiramate, valproate, and phenytoin had acute mental changes with hyperchloremic metabolic acidosis (46). He had been receiving a modest dose of topiramate for 9 months. His mental status returned to normal within 48 hours of withdrawal.

Two children developed symptomatic metabolic acidosis while taking topiramate (47).

- An 11-year-old boy with refractory partial epilepsy who had been taking topiramate 300 mg/day for 13 months developed hyperventilation. He had a hyperchloremic metabolic acidosis with partial respiratory compensation. The hyperventilation and acidosis resolved after the administration of sodium bicarbonate and reduction of the dose of topiramate.
- A 16-month-old girl developed increasing irritability associated with topiramate; it resolved promptly on withdrawal. Venous blood showed a metabolic acidosis.

The authors postulated that the mechanism of topiramate-induced acidosis is inhibition of carbonic anhydrase in the proximal renal tubule, resulting in impaired proximal bicarbonate reabsorption. Blood gases should be obtained in patients taking topiramate who develop hyperventilation and changes in mental status.

Metabolic acidosis developed in eight of nine infants and toddlers aged 5 months to 2.3 years, weights 8.2–26 (median 11) kg, taking topiramate (48). Five patients were taking other antiepileptic drugs. The metabolic acidosis developed early in treatment (after 8–26 days). Four of the nine children had hyperventilation. This study suggests that metabolic acidosis may not be rare in young children taking topiramate, although it is often asymptomatic. However, the very rapid titration and high doses used make it difficult to generalize the data.

Gastrointestinal

Nausea, abdominal pain, and severe constipation occur rarely, although nausea and abdominal symptoms have been seen commonly in Korean patients (13).

Liver

Hepatitis, reversible on topiramate withdrawal, occurred in one child, but no details were given (49).

- Fulminant liver failure developed in a 39-year-old woman after she had taken topiramate for about 4 months, in addition to carbamazepine. The condition occurred after she increased the dosage of topiramate to 300 mg/day, and was preceded for a few days by tiredness and somnolence (50). She made an uncomplicated recovery after liver transplantation. Histological examination showed centrilobular necrosis, compatible with drug-induced fulminant liver failure.

A causative role of the drug could not be determined with certainty in this case.

Urinary tract

By inhibiting carbonic anhydrase, topiramate reduces the urinary excretion of citrate and increases urinary pH, leading to higher calcium phosphate saturation and a risk of nephrolithiasis. During 1074 patient-years of topiramate exposure in 1183 patients, 18 (1.5%) had 21 episodes of renal calculi, suggesting an incidence of nephrolithiasis comparable to that reported for acetazolamide (SEDA-20, 66).

Body temperature

Reduced sweating, heat and exercise intolerance, and fever have been associated with topiramate. Three patients (aged 17 months, 9 years, and 16 years) developed hyperthermia because of reduced sweating capacity during the summer and/or during exercise 2–3 months after reaching the target dose of topiramate (51). A reduction in the dosage of topiramate did not correct the symptoms, which disappeared on topiramate withdrawal. This adverse effect may be related to carbonic anhydrase inhibition by topiramate, as it has been described with zonisamide (another carbonic anhydrase inhibitor).

- A 9-year-old boy with partial epilepsy taking topiramate 4 mg/kg/day developed hyperthermia, reduced sweating, and tiredness after exercise 4 months after the start of treatment (51). Sudomotor function showed 180 sweat glands/cm^2 (normal 286, fifth percentile 221). After topiramate withdrawal he became asymptomatic and 5 weeks later he had 392 sweat glands/cm^2.

Long-Term Effects

Drug withdrawal

Two patients with hemiparesis reversible after topiramate withdrawal have been reported (20).

Second-Generation Effects

Lactation

The concentrations of topiramate have been measured in plasma and breast milk in five women with epilepsy during pregnancy and lactation (52). The umbilical cord plasma/maternal plasma ratios were close to unity, suggesting extensive transplacental transfer of topiramate. The mean milk/maternal plasma concentration ratio was 0.86 (range 0.67–1.1) at 2–3 weeks after delivery. The milk/maternal plasma concentration ratios at sampling 1 and 3 months after delivery were similar. Two of the breast-fed infants had detectable (>0.9 μmol/l) concentrations of topiramate 2–3 weeks after delivery, although they were below the limit of quantification (2.8 μmol/l), and one had an undetectable concentration. Thus, breast-fed infants had very low topiramate concentrations. No adverse effects were observed in the infants.

Drug Administration

Drug dosage regimens

Slow dosage titration of topiramate has been advocated by clinicians for improving tolerability. In a multicenter, double-blind trial in adults with refractory partial epilepsy 188 patients were randomized to add-on topiramate by either "slow" titration (initial dose 50 mg/day increased weekly by 50 mg/day) or "fast" titration (initial dose 100 mg/day increased weekly by 100–200 mg/day) (31). The maximum dosage of 400 mg/day in both groups was achieved by 3 or 8 weeks. Efficacy was comparable, but slow titration was significantly associated with a lower frequency of adverse events or withdrawals because of adverse events.

Drug–Drug Interactions

Digoxin

Topiramate slightly impairs digoxin clearance (53), but the interaction is probably not clinically significant.

Enzyme-inducing anticonvulsants

Enzyme-inducing anticonvulsants reduce serum topiramate concentrations to an important extent (SEDA-20, 67).

Oral contraceptives

Topiramate reduces plasma estrogen concentrations in women taking oral contraceptives, by an unknown mechanism (53), potentially reducing the efficacy of the oral contraceptive. In one study topiramate dose-dependently reduced the plasma concentrations of ethinylestradiol by 18–30% (SEDA-20, 67) (54).

Phenytoin

An increase in serum phenytoin concentration has occasionally been observed in patients taking topiramate, possibly in relation to inhibition of CYP2C19 (SEDA-20, 67), but it is usually of little significance.

In 12 patients taking phenytoin monotherapy, topiramate 400–800 mg/day was added progressively; after stabilization phenytoin was tapered and withdrawn (55). Although there were no changes in phenytoin serum concentrations in nine patients, in three of them the peak phenytoin plasma concentrations increased (from 60 to 84 μmol/l, from 112 to 144 μmol/l, and from 108 to 164 μmol/l). Human liver microsomal studies showed that topiramate partially inhibits CYP2C19 at very high concentrations (about 5–15 times higher than the recommended dose). Topiramate clearance was about two-fold higher during co-administration of phenytoin.

Valproic acid

Topiramate can reduce serum valproic acid concentrations to a minor extent (SEDA-20, 67). Conversely, the metabolism of topiramate can be inhibited by valproate (53).

Three children taking valproate developed hyperammonemia after topiramate was added (56). Ammonia was normalized after topiramate was reduced or withdrawn. Thus, topiramate could potentially enhance the risk of hyperammonemia in patients taking valproate. The authors did not discuss the mechanism of this purported interaction.

Topoisomerase inhibitors

See also Cytostatic and immunosuppressant drugs

General Information

Inhibitors of topoisomerase I and topoisomerase II are the most commonly used anticancer drugs. The camptothecins—topotecan and irinotecan (CPT-11)—interact with the enzyme topoisomerase I; the podophyllotoxins—etoposide and teniposide—target topoisomerase II. They cause various forms of single- and double-strand breaks in DNA (1–7). Other drugs inhibit both enzymes simultaneously (8) (see below).

The anthracyclines and related compounds, such as mitoxantrone and amsacrine (9), also exert their cytotoxic effects via inhibition of topoisomerase II. However, they differ from the camptothecins and podophyllotoxins in respect to DNA intercalation and have a different pattern of cardiac toxicity.

Inhibitors of topoisomerase I

Camptothecins were originally isolated from the wood, bark, and fruit of the oriental tree *Camptotheca acuminata* ("tree of joy"). Why the tree produces these highly toxic alkaloids is not known, but the most likely reason is that the toxins are part of a survival strategy in combating herbivores. Among a lot of isolated plant constituents, the naturally occurring alkaloid camptothecin (CAM, NSC94600) was identified as a highly potent inhibitor of topoisomerase I, which is overexpressed in many cancers. The water-soluble salt CAM-sodium, which was introduced in early preclinical trials in the 1960s, was highly toxic in animals. Hemorrhagic cystitis, leukopenia, and thrombocytopenia were its dose-limiting toxic effects. In addition, sterile hemorrhagic cystitis, myelosuppression, and gastrointestinal toxic effects were common in patients during phase I studies. Clinical testing of CAM-sodium was therefore discontinued in the 1970s. However, the semisynthetic derivatives irinotecan and topotecan are highly active in several malignancies and do not cause hemorrhagic cystitis, because of their greater physicochemical stability and solubility at lower pH values. However, the drugs differ from each other in approved therapeutic uses, recommended doses, toxicity profiles, and pharmacokinetics (1–5).

Several camptothecin analogues are currently being investigated. The water-soluble derivatives lurtotecan (GI147211) and exatecan (DX-8951-f) and the poorly water-soluble analogues 9-aminocamptothecin and 9-nitrocamptothecin, which can be given orally, are in various stages of development (3,10–13).

Exatecan is a novel synthetic camptothecin derivative with a unique hexacyclic structure. It does not require metabolic activation, whereas irinotecan does. In vitro experiments in various cell lines have suggested that exatecan may be 6 and 28 times more active than SN-38 (7-ethyl-10-hydroxycamptothecin, the active metabolite of irinotecan) and topotecan respectively. Furthermore, it has a 2–10 times higher therapeutic index than irinotecan and topotecan. In addition, exatecan may even be active in P-glycoprotein-mediated multidrug-resistant tumor cells. Its dose-limiting adverse effects are neutropenia and liver dysfunction. The recommended dosages of exatecan for phase II trials are 0.5 mg/m^2/day or 0.3 mg/m^2/day as a 30-minute infusion on 5 consecutive days for minimally pretreated and heavily pretreated patients respectively (14,15).

Current clinical investigations with topoisomerase I inhibitors include the feasibility of oral administration of topotecan and irinotecan, the use of a liposomal lurtotecan formulation (NX211), and the use of a pegylated derivative of the naturally occurring camptothecin, which is soluble in aqueous solutions even at low pH values (3,10).

Inhibitors of topoisomerase II

Etoposide and teniposide are semisynthetic derivatives of podophyllin, which was originally isolated from the root of the Indian podophyllum plant. After extensive isolation procedures, the most effective "antileukemic" factor was identified as 4′-demethylepipodophyllin benzylidiene glucoside (DEPBG). Etoposide, its water-soluble derivative etoposide phosphate, and teniposide are semisynthetic analogues of DEPBG with increased antineoplastic activity. Etoposide is active in testicular tumors, non-Hodgkin's lymphoma, Hodgkin's disease, other lymphomas, ovarian carcinoma, gastric carcinoma, breast cancer, small-cell and non-small-cell lung cancers, and cancers of unknown origin. The major indications for teniposide include lymphoma, bladder cancer, acute lymphoblastic leukemia, and glioblastoma (6,7).

Dual inhibitors of topoisomerases I and II

Intoplicin is one of the first congeners of the so-called dual inhibitors of topoisomerases I and II (16). These new antitumor drugs interact with both topoisomerase I and II simultaneously. This mechanism of action appears to be advantageous, because selective inhibition of

© 2006 Elsevier B.V. All rights reserved.

topoisomerase I has been reported to increase topoisomerase II enzyme activity and vice versa, which may be important for the development of drug resistance (17–20). Intoplicin may overcome this limitation. In phase I trials, intoplicin has been reported to cause dose-limiting liver toxicity; other adverse effects were sporadic and mild (16).

Another dual inhibitor of topoisomerase I and topoisomerase II is XR 5000 (N-2-[(dimethylamino)ethyl]acriacridine-4-carboxamine). Its cytotoxicity was not affected by the presence of P-glycoprotein, and it seems to be a promising candidate, even in highly resistant tumor cells. However, neither complete nor partial remission was observed during a phase II trial in 20 patients with advanced or metastatic colorectal cancer (21).

A novel pentafluorinated epipodophylloid characterized by marked antitumor activity in vivo is F11872. It is a dual inhibitor of the catalytic activity of both topoisomerases I and II, with markedly superior activity in vivo compared with other dual inhibitors, such as intoplicin, TAS-103, and others (22).

Mechanisms of action

Topoisomerase I is the target enzyme for the inhibitory effects of camptothecins. It modulates the topological structure of DNA by inducing transient DNA breaks. Single-strand breaks help to remove excessive positive and negative DNA supercoils, which arise during DNA replication and transcription. The interaction between the camptothecins and the enzyme results in the formation of a topoisomerase-I-DNA complex (23).

Etoposide and teniposide interact with topoisomerase II within the tumor cell. This nuclear enzyme catalyses the passage of DNA across adjacent strands during cell division and is most active during the late S and G2 phases of the cell cycle. If the tumor cell is exposed to etoposide during this stage, stabilization of the enzyme-DNA complex results in double- and single-strand breaks in DNA as well as cell-cycle arrest. Several studies have shown that the activity of etoposide is schedule dependent, which means that its antiproliferative effect on tumor cells is greater when it is given over several consecutive days rather than on a single day. At higher dosages, podophyllotoxins may also act as spindle poisons (24).

In contrast to topoisomerase II, cellular concentrations of topoisomerase I are relatively independent of the cell-cycle phase in normal tissues. Thus, topoisomerase I activity is only slightly increased in cells and tissues under conditions of proliferation. However, higher constitutive activities of this enzyme can be detected in several tumor tissues (for example adenocarcinoma of the colon and rectum) compared with healthy tissues (25).

Pharmacokinetics

Camptothecins

Both irinotecan and topotecan contain lactone structures, which can be hydrolysed non-enzymatically into the open-ring form. Under acidic conditions, the equilibrium between the biologically active lactone form and the less active carboxylated form is generally shifted to the lactone form, whereas at physiological or higher values of pH, the lactone form is unstable, because hydrolysis to the open form is favored. In addition, owing to preferential binding of the salt form to serum albumin, the affinity of the carboxylated form for human serum albumin is estimated to be 100 times higher than that of the lactone form. In consequence, when irinotecan is given intravenously, more than 95% of the dose is bound to serum albumin as inactive drug, and is therefore at least transiently unavailable to exert its antineoplastic activity (26–29). Novel camptothecin derivatives, such as exatecan or lurtotecan, are more resistant to rapid hydrolysis because of structural modifications, for example the removal of the 20-OH group (3,10,14,15).

Irinotecan

Irinotecan has been approved for first-line and second-line treatment of advanced colorectal cancer. Conventional dosages range from 350 mg/m^2 intravenously every 3 weeks to 100–125 mg/m^2 intravenously weekly when it is given as a single agent, and 80–180 mg/m^2 intravenously when it is given in combination with 5-fluorouracil and folinic acid weekly (the AIO regimen) or every 14 days (the De Gramont regimen) (4,30).

In contrast to the structurally related topotecan, irinotecan is a prodrug, which has to be converted to its active form, SN-38 (4,30). Cleavage of the side-chain, a bulky piperidino moiety, at the C10 position is rapidly catalysed by carboxylesterases after intravenous administration. SN-38 (7-ethyl-10-hydroxy-camptothecin) is 1000 times more potent than the parent compound. There is an equilibrium between the active lactone and the inactive carboxylated forms in a pH- and protein-dependent manner for both irinotecan and SN-38 (31,32).

The SN-38 is inactivated by conjugation, catalysed by isoforms of uridine diphosphate glucuronosyltransferase, principally UGT 1A7 (33–35). Pharmacogenetic defects in glucuronidation (for example Gilbert's syndrome and Crigler–Najjar syndrome type I) result in impaired glucuronidation. The incidence of Gilbert's syndrome is 0.5–15% in different ethnic groups, and there is significant variability of UGT 1A activity in human livers, with a 17-fold difference between minimum and maximum rates of SN-38 glucuronidation. Patients with Gilbert's syndrome are at increased risk of irinotecan-induced gastrointestinal toxicity and leukopenia if conventional dosages are used (36–40). Paracetamol is a poor predictor of SN-38 glucuronidation capacity based on metabolism by another isozyme (UGT 1A6). However, genotype screening is increasingly becoming feasible. Thus, empirical irinotecan dosage modification or the selection of another anticancer drug is appropriate in patients with poor glucuronidation capacity (36–40).

Both irinotecan and SN-38 are primarily excreted into the bile by the canalicular multispecific organic anion transporter (cMOAT), a member of the ATP cassette of transporters. Therefore, inhibitors of cMOAT, such as ciclosporin, can reduce the clearance of irinotecan and SN-38 (41,42).

The SN-38 glucuronide can be deconjugated in the gut to active SN-38 by bacterial glucuronidases. This enterohepatic circulation of SN-38 results in a further plasma peak, and SN-38 released within the gut lumen has been

© 2006 Elsevier B.V. All rights reserved.

suggested to be an important cause of delayed intestinal toxicity; in animal experiments constitutive bacterial beta-glucuronidase activity correlated with irinotecan-induced cecal damage. In contrast, the prophylactic use of oral antibiotics (for example aminoglycosides or quinolones) or specific glucuronidase inhibitors resulted in attenuation of intestinal toxicity (43).

Aminopentane-carboxylic acid (APC) is a second major metabolite of irinotecan; it is formed by oxidation of the terminal piperidine ring, catalysed by CYP3A4. APC itself is not hydrolysed to SN-38 and is only a weak inhibitor of topoisomerase I (44–48). However, potent CYP3A4 inducers (for example St. John's wort, carbamazepine, and phenytoin) or inhibitors (for example itraconazole) alter irinotecan pharmacokinetics (49–54). Other identified metabolites include NPC (7-ethyl-10-(4-amino-1-piperidono)-carbonyloxycamptothecin), 5-hydroxyirinotecan, and RPR112526 (a decarboxylated product of the acid form of the irinotecan lactone).

Further drug interactions occur if constitutive SN-38 glucuronidation capacity is modified. For example, phenobarbital may induce UGT 1A activity, whereas valproic acid may inhibit it. Thus, co-administration can alter the clearance of irinotecan.

A half-life of 5–14 hours has been reported after intravenous infusion of irinotecan over 30 and 90 minutes. The half-life of the active metabolite SN-38 (total) is 6–14 hours. However, continuous 5-day intravenous infusion schedules result in prolonged half-lives (about 27 hours and 30 hours for irinotecan and SN-38 respectively). In general, the C_{max} of SN-38 is more than 100 times lower than the corresponding value for irinotecan. Plasma concentrations of SN-38 glucuronide were higher than the corresponding concentrations of SN-38: the AUC of SN-38 glucuronide was at least 10 times higher than that of SN-38 (44–47).

Because of the importance of hepatic metabolism in SN-38 elimination by glucuronidation, the biliary clearance of irinotecan and its metabolites is delayed in patients with impaired hepatic function (55–57), and there is a negative correlation between serum bilirubin concentrations and the total body clearance of irinotecan. In a patient with moderately impaired liver function, it was necessary to reduce the dose to 100 mg/m^2 instead of 350 mg/m^2 intravenously thrice-weekly, in order to achieve half-lives and C_{max} values of irinotecan and SN-38 comparable to those observed in patients with normal liver function (55). However, the corresponding AUCs were still significantly increased, resulting in more severe leukopenia and delayed diarrhea. The authors concluded that to improve tolerance, exposure to the drug in a patient of this kind should not exceed 30 mg/m^2 intravenously.

Detailed studies of irinotecan dose modification in patients with liver dysfunction are warranted. According to the results of pharmacokinetic studies, thrice-weekly intravenous doses of irinotecan have been recommended: 350 mg/m^2 in patients with bilirubin concentrations up to 1.5 times the upper limit of the reference range and 200 mg/m^2 in patients with bilirubin concentrations 1.5–3.0 times the upper limit of the reference range (56).

The systemic availability of oral irinotecan is low and variable (10–20%). Transintestinal transport of irinotecan and SN-38 by P-glycoprotein and cytochrome P_{450}-mediated first-pass removal in the intestine accounts for the low absolute availability of irinotecan.

Topotecan

Topotecan has been approved for the treatment of advanced pretreated ovarian and small-cell lung cancer in several countries. After intravenous administration of conventional dosages (for example 1.5 mg/m^2/day for 5 consecutive days) its half-life is 2–4 hours. Prolonged infusion for 3, 5, or 21 days increases drug exposure without affecting the disposition of topotecan (29).

The ratio of the AUCs of the lactone and total topotecan appears to be relatively constant and averages about 0.3, which means that only 30% of the total drug concentration in the plasma represents the closed-ring lactone form. The distribution volume at steady state is 25–75 l/m^2, indicating extensive binding to tissues. Erythrocytes act as a depot for topotecan (lactone), with steady-state concentrations almost 1.7 times those obtained in plasma.

Topotecan is primarily excreted unchanged in the urine. About 49% of the intravenous dose is recovered in the urine as parent drug and 18% in the feces (58). Despite high urinary concentrations, topotecan does not cause urinary toxicity, because of its high water solubility (58,59). Dosage modification is warranted in patients with impaired renal function (60). Reduced doses of 0.75 mg/m^2/day and 0.5 mg/m^2/day have been recommended in untreated and extensively pretreated patients with reduced creatinine clearance (20–40 ml/minute). It has also been suggested that dosage adjustment may even be required if the creatinine clearance is 40–60 ml/minute (61). The recommended starting dose should be 1.2 mg/m^2/day intravenously on five consecutive days, in order to reduce the risk of severe myelosuppression. Because there is no information about topotecan in patients with severe renal insufficiency (creatinine clearance below 20 ml/minute), topotecan should not be given to them (60). There is some evidence that topotecan is hemodialysable (62).

Hepatic metabolism of topotecan, mediated by cytochrome P_{450} isozymes, is of minor quantitative importance (26–29,58). Metabolic pathways include N-dealkylation (producing *N*-demethyltopotecan) and glucuronidation. There is some evidence that potent inhibitors or inducers of CYP3A4 alter the clearance of topotecan (58).

After conventional intravenous dosages of topotecan (for example 1.5 mg/m^2 as a 30-minute infusion on days 1–5) the mean half-life, plasma clearance, and volume of distribution are respectively 2.7 hours, 1.1 ml/minute, and 170 litres. The plasma protein binding of topotecan is low (7–35%). In contrast to many other anticancer drugs, topotecan can penetrate the central nervous system. If the blood–brain barrier is intact, more than 30% of the plasma concentration can be recovered in the cerebrospinal fluid (26–29,58). Nevertheless, based on case reports and experimental data, intrathecal drug administration has been suggested to be advantageous, in order to achieve higher drug concentrations in the cerebrospinal fluid and to avoid systemic toxicity (63,64).

© 2006 Elsevier B.V. All rights reserved.

The systemic availability of oral topotecan is about 30%. Dose-limiting toxicity was reached at a dose of 0.6 mg/m^2 bd and consisted of diarrhea, which started from day 12 to day 20. Other toxic effects, including leukopenia and thrombocytopenia, were mild. The recommended dose for phase II trials was 0.5 mg/m^2 bd for 21 days (65–67).

Podophyllotoxins

Etoposide

At low doses of oral etoposide (for example 50–100 mg), the systemic availability averages 66%, and at higher dosages (100 mg/m^2 and over) 47%. If etoposide phosphate is used, the values are higher (range 66–84%) (68–73).

After intravenous administration of etoposide 150 mg/m^2, the peak plasma concentration averages 20 micrograms/ml and the half-life 7.1 hours. Drug clearance and distribution volume are about 16 ml/minute/m^2 and 17 l/m^2 (6,7,74). With respect to plasma concentrations of etoposide, intravenous etoposide phosphate is equivalent to intravenous etoposide with conventional or intensified dose schedules (75–79). After intravenous administration, the prodrug etoposide phosphate undergoes rapid hydrolysis catalysed by alkaline phosphatase; this conversion is linear even at high intravenous doses of 1200 mg/m^2 infused over 2 hours on days 1 and 2.

About 96% of the dose of etoposide is bound to plasma proteins, the fraction 4% being unbound (80–83). There is a higher risk of myelotoxicity when the unbound fraction is increased by factors such as hyperbilirubinemia or hypoalbuminemia, which is common in patients with hepatic dysfunction or cachexia-inducing tumors (84,85). The variability in unbound drug concentrations has been suggested to be important in the setting of intravenous high-dose etoposide and reinfusion of autologous peripheral blood stem cells. If drug concentrations persist over a longer period of time, the success of engraftment may be severely impaired. Thus, plasma concentration monitoring has been suggested, in order to identify patients at increased risk (86,87).

The renal clearance of etoposide is about 30–40% of the total plasma clearance. Even in patients with nearly normal creatinine concentrations (100–130 μmol/l), there is a slight but significant increase in the AUC, but without more pronounced hematological toxicity. Hepatic etoposide metabolism is mediated by CYP3A4, and results in the production of catechol metabolites. Although these catechols contribute relatively little to the metabolism of etoposide, they may contribute to its late adverse effects, for example secondary malignancies. Further metabolic pathways include glucuronidation and hydroxyacid formation (88). Dosage reductions of 33 and 50% have been recommended for patients with creatinine clearances of 15–25 ml/minute and under 15 ml/minute respectively. In patients with obstructive jaundice and a reduced glomerular filtration rate, a 50% dosage reduction has been recommended empirically (6,7,88,89).

In patients with very severe forms of renal insufficiency, only moderate amounts of etoposide can be eliminated by hemodialysis (90). In patients with brain metastases, high intravenous dosages of etoposide may be needed in order to achieve adequate drug concentrations in the cerebrospinal fluid. In such patients, intrathecal drug administration may be an alternative, in order to reduce systemic toxicity associated with dose-intensive chemotherapy. However, this mode of etoposide administration has not been established (91,92).

There is large interindividual variability in etoposide plasma concentrations with conventional dosages, and some authors have suggested that plasma concentration monitoring would reduce the pharmacokinetic variability and optimize outcomes (93,94).

Teniposide

Teniposide undergoes more extensive metabolic degradation than etoposide, resulting in the catechol derivative 4′-demethyldeoxy-podophyllotoxin. The aglycone and the *trans*/*cis*-hydroxy acids appear to be formed by pH-dependent hydrolysis reactions (7,95,96).

Plasma concentration monitoring has been proposed to be beneficial in patients receiving teniposide. For example, in one study, maintaining steady-state concentrations above 12 micrograms/ml appeared to be important for clinical responses in patients with recurrent leukemia, lymphoma, or neuroblastoma (95). In 10 patients, whose steady-state concentrations were maintained above 12 micrograms/ml, there was shrinkage of the tumor, whereas only five of 13 patients with lower steady-state concentrations had a response. Teniposide has been used as a continuous infusion over 72 hours in intravenous doses of 300–750 mg/m^2.

The mean systemic availability of teniposide after oral administration is about 42% (range 20–71%). Teniposide capsules 50 mg have been suggested to be useful, but no oral formulation has been approved so far (96).

General adverse effects

The dose-limiting adverse effects of irinotecan depend largely on the dosage schedule. Myelosuppression, particularly leukopenia and neutropenia and rarely thrombocytopenia and anemia, have been observed. Gastrointestinal toxicity (that is, diarrhea) is also common and can be acute or subacute. The most dose-limiting adverse effect of topotecan is myelosuppression, which correlates with individual drug exposure. In contrast, gastrointestinal toxicity is generally mild (97–99).

Common adverse effects of etoposide and teniposide (100) include dose-limiting myelosuppression (causing neutropenia more often than thrombocytopenia), dose-dependent nausea or vomiting, and alopecia. Mucositis can be dose limiting, particularly in patients receiving high doses of etoposide. Hypersensitivity reactions are more common with etoposide and teniposide than with etoposide phosphate, because the formulations of the former contain sensitizing solubilizers. Both drugs have been associated with acute myelogenous leukemia.

Organs and Systems

Cardiovascular

There are reports of myocardial infarction in patients who have received combination chemotherapy containing etoposide. The mechanisms have not been clearly elucidated.

© 2006 Elsevier B.V. All rights reserved.

- A 28-year-old man with a non-seminomatous retroperitoneal germ-cell cancer received etoposide (180 mg/day intravenously on days 1–5), bleomycin, and cisplatin (101). He had no cardiac risk factors and no history of cardiac symptoms. On day 3, during infusion of bleomycin, he developed chest pain and dyspnea. The infusion was discontinued and he was given glyceryl trinitrate and diazepam; his symptoms resolved. On day 4 he was given etoposide as scheduled, but four hours later developed severe angina. The electrocardiogram and raised cardiac enzymes were consistent with an acute posterolateral myocardial infarction. He was given heparin, aspirin, and nitrates, and the chemotherapy was discontinued. Within 20 hours his chest pain completely disappeared and his electrocardiogram became normal.

If hypotension occurs during drug administration, it usually subsides when the infusion ends and intravenous fluids or other supportive agents are given. Elderly patients may be particularly susceptible to etoposide-induced hypotension. During a phase I trial of etoposide by continuous infusion, 17 patients were given 75 mg/m^2/day for 5 days and later courses of 100 mg/m^2/day and 150 mg/m^2/day (102). Two patients with pre-existing cardiovascular disease developed myocardial infarctions, one at the 100 mg/m^2/day dose and the other at the 150 mg/m^2/day dose. Another patient developed congestive heart failure at the end of the 5-day infusion and died on day 8; however, this patient also received a saline load of 1500 ml/day for 5 days during etoposide administration and had had previous episodes of congestive cardiac failure. The authors concluded that in patients with underlying cardiovascular disease etoposide must be administered cautiously and that extensive saline loading should be avoided in patients with a history of previous congestive heart failure.

Nervous system

Fatigue is a frequent adverse effect of topotecan and occurs in up to 70% of patients when they receive 1.5 mg/m^2/day (30-minute infusions) for 5 days repeated at day 22; however, only 10% have severe symptoms (4). Topotecan causes headache in some patients.

Rare cases of peripheral neuropathy have been reported after intravenous topotecan, but a causal relation is uncertain.

Neurotoxicity occurs in under 1% of patients who receive teniposide or etoposide, and is more common after high dosages. Adverse nervous system effects, including headache, transient mental confusion, and vertigo, may be related to the blood alcohol concentration, since teniposide and etoposide formulations contain alcohol (103).

Acute neurological dysfunction with exacerbation of pre-existing neurological disorders has been reported after treatment with high-dose etoposide (over 800 mg/m^2/day) given with autologous bone marrow transplantation (104). This happened 9–10 days after the start of treatment, and it abated without sequelae after prompt steroid therapy. Changes in intracranial pressure may explain this acute disturbance.

Peripheral neuropathy, mainly mild and infrequent, has been observed after conventional dosages of etoposide and teniposide. However, during combination therapy with etoposide and vinca alkaloids, more serious forms of peripheral neuropathy have been reported. Of 142 patients with autologous bone marrow transplantation given high-dose etoposide (for example 60 mg/kg combined with melphalan), six developed grade 2–3 polyneuropathy starting 2–8 weeks after transplantation.

About 76% of patients given irinotecan complained of weakness. Grade 3 and 4 weakness has been described in 12–15% with weekly or thrice-weekly administration and during the administration of combination regimens containing fluorouracil.

Hematologic

Myelosuppression, neutropenia, and to a lesser extent thrombocytopenia, are dose-limiting toxic effects of topotecan. Reversible non-cumulative neutropenia usually occurs at between days 8 and 15 after an intravenous dosage of 1.5 mg/m^2 on five consecutive days. The nadir of the neutrophil count occurs on day 11, with recovery on day 21. Neutropenia, with cell counts less than 1.5×10^9/l (grade 2) and 0.5×10^9/l (grade 4), is observed in 70–97% of patients. In addition, 4–33% of patients treated with conventional dosages of topotecan develop neutropenic fever (97–99).

Thrombocytopenia, with platelet counts under 50×10^9/l (grade 3) and 25×10^9/l (grade 4), occurs in 25–77% of patients, with a nadir on day 15 and recovery on day 21. Platelet transfusions are needed in 4–27% of patients. Anemia, defined as a fall in hemoglobin below 8 g/dl (grade 3) or 6.5 g/dl (grade 4), has been reported in 21–41% of patients; erythrocyte transfusions were required in about 25% of treatment courses. More extensive myelosuppression can occur in patients who have been pretreated with cytotoxic drugs. The extent of myelosuppression correlates significantly with both the total topotecan AUC and the topotecan lactone AUC. When prophylactic G-CSF is given, thrombocytopenia is the dose-limiting myelotoxic effect (97–99).

Leukopenia is a dose-limiting adverse effect of irinotecan. Weekly intravenous doses (for example 100–125 mg/m^2) appear to produce a slightly greater incidence of grade 3–4 neutropenia compared with 3-weekly schedules (350 mg/m^2) (16–28 versus 14–22%). The median leukocyte nadir occurs on day 21 (15–27) and recovers 8 days later. Severe anemia (hemoglobin concentrations below 8 g/dl) and severe thrombocytopenia (platelet count below 50×10^9/l) occur in 15 and 2% of patients respectively. There is eosinophilia in up to one-third of patients (2,3).

Myelosuppression is a dose-limiting adverse effect of etoposide and teniposide. Leukopenia is the most common adverse effect associated with oral and intravenous etoposide. Nadirs in neutrophil counts generally occur within 7–14 days. Severe forms following conventional etoposide doses can be expected in about 17% of patients. Thrombocytopenia occurs in 23% of etoposide-treated patients and about 9% are severe (counts below 50×10^9/l). Leukopenia and thrombocytopenia occur

© 2006 Elsevier B.V. All rights reserved.

respectively in 65 and 80% of patients after administration of teniposide (6,7).

Gastrointestinal

Anorexia, nausea and vomiting, and diarrhea are generally mild after the administration of conventional doses of etoposide and teniposide. Stomatitis is uncommon and mucositis starts to be more severe in patients who receive intravenous doses of etoposide up to 1000 mg/m^2. Gastrointestinal toxicity after topotecan is generally mild to moderate. Under 10% of patients complain of grade 3/4 nausea and vomiting, diarrhea or constipation, abdominal pain, or stomatitis. Mucositis is uncommon and mild after intravenous topotecan.

Besides leukopenia, diarrhea is the major dose-limiting adverse effect of irinotecan (105,106). There are two different forms. The acute form occurs very early and is due to inhibition of acetylcholinesterase. The delayed-onset form occurs simultaneously with the leukocyte nadir and depends on the concentration of the active compound SN-38 in the plasma and bowel.

The acute form of diarrhea is short-lived and can be effectively prevented or rapidly suppressed by concomitant atropine. The cholinergic symptoms are accompanied by abdominal cramps (36%), sweating (57%), salivation (11%), visual disturbances (15%), lacrimation (12%), and piloerection (3%). The recommended dose of atropine is 0.25 mg intravenously for prevention or 0.25–1.0 mg for acute treatment of patients with early cholinergic symptoms. As cholinergic symptoms have not been observed with other camptothecin derivatives, it can be speculated that these adverse effects are restricted to irinotecan, whose piperidino group bears some structural similarity to the potent nicotine receptor stimulant dimethylphenylpiperazinium (106).

Delayed-onset diarrhea of all grades of severity occurs in nearly 90% of patients during the first three treatment cycles with irinotecan. It can resemble a cholera-like syndrome, which occurs several days after completion of the infusion. There is grade 3/4 diarrhea (grade 3 being at least 7–9 stools per day, incontinence, or severe cramps; grade 4 being 10 stools or more per day, grossly bloody stools, or a need for total parenteral nutrition) in 31–37% of patients treated weekly and in 35–39% of patients treated with 3-weekly regimens. The median day of occurrence was day 6 (range days 2–12). Of the four major pathophysiological mechanisms of diarrhea (osmotic, secretory, altered motility, and exudative), irinotecan-induced watery diarrhea appears to be secretory, defined by abnormal ion transport in intestinal epithelial cells (105).

There is increasing evidence that the extent and severity of gastrointestinal toxicity correlates with concentrations of the active compound SN-38 in the plasma and bowel. The role of plasma pharmacokinetics in predicting the severity of irinotecan-induced diarrhea has been highlighted by the introduction of a biliary index, which is the product of the relative area ratio of SN-38 to SN-38 glucuronide and the total AUC. According to preliminary evidence, preventive measures should be considered when the biliary index exceeds 3.484 hours.micrograms/ml (107,108).

Because SN-38 glucuronide undergoes deconjugation by bacteria-derived beta-glucuronidase in the bowel after biliary excretion, a strategy for reducing irinotecan-induced subacute diarrhea has been proposed: inhibition of intestinal microflora by a broad-spectrum antibiotic. In one study, this ameliorated subacute diarrhea in subsequent cycles; in six of seven patients, the prophylactic oral use of neomycin resulted in less severe forms of diarrhea compared with controls (43). About 30% of irinotecan is excreted via the bile unchanged and may be directly converted to SN-38 in the bowel by intestinal carboxyesterases; however, specific non-absorbable inhibitors of intestinal carboxyesterases for oral use are not yet available.

Because the equilibrium between the active lactone form and the ring-opened carboxylate form is pH dependent, oral alkalinization with a mixture consisting of sodium bicarbonate (2.0 g/day), magnesium oxide (2.0–4.0 g/day), water (pH over 7.2, 1.5–2 l/day), and ursodeoxycholic acid (300 mg/day), combined with "controlled" defecation was used in a phase II trial to reduce subacute gastrointestinal toxicity. Anticancer activity was maintained and the incidences of diarrhea and myelosuppression were significantly reduced compared with a non-randomized control group (109–111).

The efficacy of symptomatic antidiarrheal treatment with several drugs, including loperamide, octreotide, racecadodril, and budesonide, has been assessed (105,112,113). Loperamide is recommended when the first signs of subacute, late-onset diarrhea occur; the dose is 4 mg at the start, followed by 2 mg every 2 hours, continued until the diarrhea has stopped for at least 12 hours. Premedication with loperamide is not indicated. Some authors also recommend dosage modification in subsequent cycles. If loperamide alone is insufficient, racecadodril (acetorphane, Tiorfan) 100 mg tds can be added. Racecadodril belongs to a group of drugs that block cAMP-mediated hypersecretion in the gut by inhibiting the intestinal enzyme enkephalinase. The somatostatin analogue octreotide is effective in loperamide-refractory patients with severe diarrhea despite loperamide and/or acetorphane. Subcutaneous doses of 100 micrograms tds up to 500 micrograms every 8 hours for 48–96 hours have produced improvement in diarrhea by one WHO toxicity grade or even more (105).

Oral budesonide has also been proposed to be beneficial in patients with subacute diarrhea. It has 90% first-pass removal in the liver, and so its systemic activity is low. Budesonide controls symptoms of diarrhea in most patients with inflammatory bowel disease. Preliminary data have suggested that the use of budesonide in patients with irinotecan-induced diarrhea could reduce the severity of symptoms. In addition, in a phase III trial budesonide 3 mg tds prevented irinotecan-induced diarrhea to a moderate extent. Budesonide is an option in patients who do not respond to high-dose oral loperamide (113).

The use of oral immunomodulators (for example interleukin-15 and Kampo medicines) has been suggested in order to reduce irinotecan-related diarrhea; however, randomized clinical trials are required, to assess efficacy (42).

Liver

Etoposide has been associated with increased liver enzymes, but a causal relation has not been established (114).

Urinary tract

Camptothecin can cause hemorrhagic cystitis (115), which has not been reported with semisynthetic camptothecin derivatives, supposedly because they are highly soluble in aqueous solutions even at low pH values. However, in a study of the use of camptothecin conjugated to a water-soluble polymer, two of three patients who received 80 mg/m^2/week developed hemorrhagic cystitis (grade 1/3 dysuria and grade 2/3 hematuria) during the second and third cycles; at 120 mg/m^2/week there was grade 1 bladder toxicity in two of three patients (116).

Skin

Skin rashes involving the trunk, scalp, and limbs have been reported in 17–25% of patients receiving topotecan as a short-term infusion, whereas continuous drug infusion appears to be very rarely associated with rashes. These skin reactions typically appear on days 4–8 and resolve on day 15.

- A 45-year-old woman received topotecan and colony-stimulating factor for ovarian cancer and developed erythematous and slightly pruritic plaques on the upper and lower limbs and ear lobes about one week later (117). The lesions subsided spontaneously in about 10 days and recurred after the next dose. A skin biopsy showed neutrophilic eccrine hidradenitis; all skin cultures were negative.

Skin rashes due to podophyllotoxin derivatives may be hypersensitivity reactions and can be related to the drug itself or more commonly to the vehicles used. Dose-related, non-IgE-mediated hypersensitivity has been reported in 16 children receiving teniposide (118). Other published reports of hypersensitivity or anaphylactoid reactions to teniposide include degranulation of basophils (119,120), and eight anaphylactic reactions in children, all associated with the use of intravenous teniposide 150 mg/m^2 (121).

There has been a single report of etoposide-induced hand–foot syndrome (122).

Hair

Reversible alopecia is very common at standard doses of podophyllotoxin derivatives, starting at doses of 500 mg/m^2 of etoposide. It is also common even with low, continuous oral doses of etoposide (for example 50 mg/m^2/day). Partial or complete alopecia occurs in 12–70% of patients taking topotecan or irinotecan (123).

Immunologic

The epipodophyllotoxins etoposide and teniposide can cause hypersensitivity reactions, which appear to be of type I (124). In a review of 93 cases, the characteristic features of the hypersensitivity reactions that occurred after intravenous etoposide included bronchospasm, facial flushing, rashes, dyspnea, fever, chills, tachycardia, chest tightness, cyanosis, and changes in blood pressure (hypotension and hypertension) (125).

Hypersensitivity to etoposide or tenoposide has been reported in 50 of a series of 108 patients. The risk is related to the cumulative dose, reaching a maximum at 1500–2000 mg/m^2 in the case of tenoposide and 2000–3000 mg/m^2 for etoposide (126). Acute hypersensitivity reactions, characterized by hypotension, bronchospasm, and facial flushing, have been associated with etoposide (127,128). Rechallenge with appropriate prophylactic cover supported the association.

Very severe forms of hypersensitivity reactions, such as Stevens–Johnson syndrome, are very rare (129). Anaphylactic-like reactions have occurred in 0.7–2% of patients after etoposide administration. Some data suggest that the overall frequency of hypersensitivity reactions to teniposide may be as high as 50% if all forms of hypersensitivity are considered. With very few exceptions, patients recover quickly when the drug infusion is stopped immediately (124).

Hypersensitivity reactions to etoposide or teniposide usually occur within minutes after intravenous administration, and are probably related to release of vasoactive substances by basophils and/or mast cells. Several reports have suggested that premedication with an antihistamine and/or a corticosteroid may prevent further hypersensitivity reactions, even in patients with a history of previous reactions. However, this strategy should not be followed when patients have had severe hypersensitivity reactions, such as long-lasting bronchospasm or severe hypotension (130,131). Etoposide was successfully restarted in 78% of patients who had had a hypersensitivity reaction, especially when the drug was infused at a slower rate after premedication with an antihistamine and/or a glucocorticoid (132).

Hypersensitivity reactions to etoposide and teniposide occur in 33–51% of patients (123,124) and are primarily related to adjuvants in the parenteral formulations rather than the drugs themselves. In the case of teniposide, the solubilizing adjuvant polyethoxylated castor oil (Cremophor EL) has been implicated. However, in nine children who had facial edema and flushing after receiving teniposide, the drug alone degranulated basophils in vitro, causing histamine release, while Cremophor did not (119). In addition, etoposide formulations for parenteral use contain several adjuvants, including polysorbate 80, benzyl alcohol, and polyethylene glycol, because it is sparingly soluble in aqueous solutions, and these may contribute to hypersensitivity reactions. Polysorbate 80 may also be implicated in rare cases of hypotension and metabolic acidosis, particularly with high dosages (133).

In contrast, the structurally related etoposide phosphate is highly soluble in aqueous solutions and no solubilizing adjuvants are necessary. Preliminary data suggest that the incidence of hypersensitivity reactions is lower with etoposide phosphate than with etoposide, strengthening the hypothesis that adjuvants have a major role in the development of allergic reactions (123,124). In one case, a patient who had a type I hypersensitivity reaction to etoposide was successfully retreated with etoposide phosphate (134).

On the other hand, cross-reactivity to etoposide has been observed in patients with hypersensitivity reactions

© 2006 Elsevier B.V. All rights reserved.

to teniposide, suggesting that allergic reactions are not exclusively restricted to the use of the solvents. In addition, hypersensitivity reactions have also been reported after oral etoposide (123,124).

- Hypotension, bronchospasm, and facial flushing occurred in a 38-year-old man with advanced testicular cancer associated with an intravenous infusion of etoposide (127). The reaction began within 3 minutes after the start of the infusion and resolved with intravenous fluids and diphenhydramine. Later, he was given four doses of etoposide after pretreatment with diphenhydramine and dexamethasone, without incident.

Successful rechallenge has been reported after a reaction to etoposide in a 19-year-old man, who was successfully re-treated with etoposide phosphate with only antiemetic doses of glucocorticoids as cover (134). This case tends to support the old assumption that etoposide hypersensitivity is due to the excipients in the formulation.

Long-Term Effects

Mutagenicity

Etoposide and teniposide are mutagenic in various bacterial and mammalian genotoxicity tests (135).

Tumorigenicity

Based on animal experiments, etoposide and teniposide should be classified as potential carcinogens (136).

Exposure to etoposide and teniposide has been reported to be an important risk factor for the development of secondary acute myelogenous leukemia (137–143). Etoposide has been suggested to have considerable leukemogenic activity. Of 119 patients with advanced non-small-cell lung cancers, 24 survived for more than 1 year after treatment with etoposide and cisplatin with or without vindesine (144). Of these 24 patients, four developed secondary acute myelogenous leukemia at 13, 19, 28, and 35 months from the start of treatment, having received a two-fold greater cumulative dose of etoposide (6.8 versus 3.0 g/m^2). Podophyllotoxin-related secondary acute myelogenous leukemia has a rather short latent period (2–3 years), and differs from malignancies caused by other drugs (for example alkylating agents) by its unique molecular marker, a balanced translocation involving the mixed-lineage leukemia (MLL) gene on chromosome 11 ("11q23 abnormalities") (145). Southern blot analysis of enzyme-digested DNA from etoposide-treated cell lines and from peripheral blood cells after treatment with etoposide showed frequent rearrangements of MLL, but not of other genes (146). There are differences between the chromosomal abnormalities and the subsequent acute myeloid leukemia associated with the alkylating agents and those following topoisomerase inhibition by podophyllotoxins (147). The alkylating agents cause abnormalities of chromosomes 5 and 7, singly or together, and the podophyllotoxins damage the 11q23 chromosome locus (145).

- A 15-year-old white girl with stage II Hodgkin's disease, who was treated with a combination of vincristine, doxorubicin, bleomycin, and etoposide (total dose 2000 mg/m^2) over 4 months followed by radiotherapy, developed secondary acute myelogenous leukemia 16 months after the initial diagnosis (142).
- An 11-year-old boy with virus-associated hemophagocytic syndrome was treated with intravenous and oral etoposide (0.3 g and 2.8 g/m^2 respectively) and developed acute myelogenous leukemia 26 months after the diagnosis (142).

These reports and others confirm that even conventional doses of etoposide can be associated with a risk of secondary acute myelogenous leukemia. The risk appears to be related to both the schedule and the cumulative dose, and it can be aggravated by addition of alkylating agents and/or radiotherapy (148,149).

Two of 21 adults with Hodgkin's disease developed secondary acute myelogenous leukemia after receiving a regimen that included a cumulative dose of etoposide of 945–3640 mg/m^2 given over 3–6 months (141). Both patients also received MOPP after primary treatment failure, and the disease itself is associated with a high risk of secondary malignancies; however, the short latency period before the development of acute myelogenous leukemia (17–32 months) was thought to be typical of podophyllotoxin-associated disease. Altogether the etoposide-related incidence of secondary acute myelogenous leukemia in three retrospective case series was 0.4–8.1%. Secondary leukemia developed 9–68 months after the diagnosis of the first cancer.

Teniposide is about 10 times more potent than etoposide in causing DNA damage in vitro and in vivo. In 21 of 733 children with acute lymphoblastic leukemia in remission, who received maintenance therapy with teniposide once or twice weekly in combination with other anticancer drugs, the risk of secondary acute myelogenous leukemia was about 12 times higher than in patients who had been treated with less intensive schedules (for example a short course of teniposide for induction chemotherapy) (149).

In conclusion, podophyllotoxin-containing regimens carry a small but significant risk of secondary acute myelogenous leukemia. The risk may be increased by higher total cumulative doses (for example etoposide over 2 g/m^2), weekly or twice-weekly schedules, the concomitant administration of drugs that inhibit DNA repair, concomitant radiotherapy, or the use of high doses of cisplatin. It has therefore been recommended that etoposide be used cautiously in low-risk diseases.

Second-Generation Effects

Fertility

The effects on fertility of inhibitors of topoisomerases I and II have not yet been fully elucidated. However, ovarian failure, amenorrhea, anovulatory cycles, and hypomenorrhea have been described in women receiving etoposide (150).

Teratogenicity

Anticancer drugs can be classified as potentially teratogenic and embryocidal, and can cause embryonic

© 2006 Elsevier B.V. All rights reserved.

resorption, spinal defects, decreased fetal weight, and fetal abnormalities. However, there are no controlled studies of the use of these drugs in pregnant women, and women of childbearing potential should be advised to avoid pregnancy while they are receiving chemotherapy and should be informed about the potential hazards to the fetus (151).

Drug Administration

Drug administration route

The safe intraventricular administration of etoposide has been reported (152).

Drug–Drug Interactions

Ciclosporin

The coadministration of etoposide and high-dose ciclosporin resulted in increased etoposide serum concentrations (153). Lower doses of etoposide were therefore recommended when combined with high-dose ciclosporin.

Cisplatin

Co-administration of cisplatin before topotecan has a sequence-dependent effect on the disposition of topotecan. Cisplatin-related acute changes in glomerular filtration rate can temporarily alter topotecan clearance, causing more severe myelosuppression. Nevertheless, this sequence has been recommended in clinical trials, based on its high antineoplastic efficacy. Patients therefore have to be monitored closely when the two agents are given together (154).

Docetaxel

Topotecan reduced docetaxel clearance by 50% and increased the severity of neutropenia when given over three consecutive days before the combination (155). The underlying reason for this interaction has not been elucidated; however, when combination therapy is used, docetaxel should be scheduled on day 1 and topotecan on days 1–4.

Enzyme inducers

Etoposide and teniposide are substrates of CYP3A4, and their clearance rate is increased by inducers such as carbamazepine, phenobarbital, phenytoin, rifampicin, and St. John's wort (49,51–54,156).

Enzyme inhibitors

Potent inhibitors of CYP3A4, such as ketoconazole or itraconazole, reduce the formation of inactive aminopentane-carboxylic acid from irinotecan, resulting in higher concentrations of the active metabolite SN-38. In seven patients who received irinotecan 350 mg/m^2 alone intravenously for 90 minutes and followed 3 weeks later by irinotecan 100 mg/m^2 in combination with ketoconazole 200 mg orally for 2 days, ketoconazole reduced the formation of aminopentane-carboxylic acid by 87% and increased the formation of SN-38 by 109%; irinotecan clearance and the formation of SN-38 glucuronide were not affected (50).

Fluorouracil

If irinotecan is combined with 5-fluorouracil and calcium folinate, an infusion regimen of fluorouracil rather than bolus administration is associated with a lower incidence of severe toxicity (leukopenia and life-threatening sepsis) (157).

Neomycin

Diarrhea ameliorated in six of seven patients treated with irinotecan in combination with oral neomycin at 1000 mg tds (43). Neomycin had no effect on the pharmacokinetics of irinotecan and its major metabolites.

Oxaliplatin

Irinotecan (80 mg/m^2 intravenously) given as a 1-hour infusion immediately after oxaliplatin (85 mg/m^2 intravenously) was associated with hypersalivation and abdominal pain (158,159). These symptoms disappeared after an injection of atropine but recurred when irinotecan was given as a single agent or when the two drugs were separated by 24 hours. However, restarting the original schedule once more resulted in extended cholinergic symptoms. It has been postulated that oxaliplatin potentiates the direct inhibitory effect of irinotecan on acetylcholinesterase.

St. John's wort

St. John's wort (300 mg tds, starting 14 days before administration) reduced the AUC of the active metabolite of irinotecan, SN-38, by 42% and the severity of expected myelosuppression (51). Leukocyte and neutrophil counts were reduced by 8.6% and 4.3% after St. John's wort co-administration in contrast to monotherapy (reductions of 56% and 63%). In addition, the AUC of aminopentane-carboxylic acid was reduced by 28%. Whether the concomitant use of dexamethasone had some effect on this interaction has not been elucidated.

Valspodar

Valspodar significantly increased the AUC and half-life of etoposide, and dosage reductions of up to 66% are required to minimize toxicity when these drugs are used together.

Torasemide

See also Diuretics

General Information

Torasemide is a long-acting loop diuretic promoted for use in hypertension. Like piretanide, it is claimed to be potassium neutral, but the assertion is premature. There is no evidence that torasemide has metabolic advantages over thiazides (SEDA-16, 226) (SEDA-17, 264) (SEDA-18, 237).

Organs and Systems

Skin

Torasemide has been associated with various rashes, including non-specific erythematous lesions, pruritus, and photoallergic lichenoid lesions (SEDA-22, 239).

Immunologic

Two possible cases of vasculitis with renal insufficiency have been reported in patients taking torasemide (1,2). This adverse effect is not surprising, since torasemide is structurally similar to sulfa drugs, which can cause vasculitis.

- A 70-year-old man developed heart failure secondary to ischemic heart disease and severe aortic stenosis (1). Furosemide 20 mg/day was replaced by torasemide 5 mg/day. After the second dose he developed oliguria and an erythematous morbilliform rash with palpable violet petechial lesions on the legs. Chest X-ray showed bilateral alveolar infiltrates. Serum creatinine and potassium were raised (212 μmol/l and 6.7 mmol/l respectively). Skin biopsy showed leukocytoclastic vasculitis. After withdrawal of torasemide, his renal function improved (serum creatinine 97 μmol/l) and the skin lesions resolved (leaving residual pigmented areas) within 8 days.
- An 84-year-old man with ischemic heart disease and hypertension took torasemide 10 mg/day for persistent edema (1). About 24 hours after the first dose of torasemide, he developed painless, non-palpable, petechial lesions on the limbs and trunk, with oliguria. His serum creatinine was 256 μmol/l and his serum potassium 6.2 mmol/l. Skin biopsy showed non-leukocytoclastic vasculitis with a mixed inflammatory infiltrate including eosinophils. He was symptom free 15 days after withdrawal of torasemide.

Neither patient had a previous history of drug hypersensitivity. Both patients had previously tolerated furosemide, another sulfonamide derivative. The temporal correlation with torasemide administration suggested a causal relation, but the mechanism was unclear.

Drug–Drug Interactions

NSAIDs

NSAIDs block the natriuretic effect of torasemide (SEDA-21, 229).

Probenecid

Probenecid blocks the natriuretic effect of torasemide (SEDA-21, 229).

Tosufloxacin

See also Fluoroquinolones

General Information

Tosufloxacin is a fluoroquinolone antibacterial with properties similar to those of ciprofloxacin.

Observational studies

In 58 Japanese patients with typhoid fever, 42 with paratyphoid fever, and one with both typhoid fever and paratyphoid fever, almost 80% of whom were treated with tosufloxacin, there were adverse effects (nausea, urticaria, aphthous stomatitis) in 3.6% and raised serum amylase in 8.3% (1). All the adverse reactions resolved with or without a change in drug therapy.

General adverse effects

The most common adverse reactions to tosufloxacin are gastrointestinal disorders, including diarrhea, abdominal discomfort, nausea and vomiting, and skin disorders, including rash and pruritus (2). Central and peripheral nervous system disorders were observed in 0.36% of patients and the most common symptoms were headache and dizziness.

Organs and Systems

Respiratory

- A syndrome of pulmonary infiltration with eosinophilia occurred in an 83-year-old man who was given piperacillin plus tosufloxacin (3).

© 2006 Elsevier B.V. All rights reserved.

In vitro blastogenesis of his peripheral blood lymphocytes was strongly enhanced by piperacillin and tosufloxacin, and they generated a large amount of interleukin-5.

Skin

There is a low incidence of phototoxicity with tosufloxacin (2).

Musculoskeletal

Rhabdomyolysis has been reported in 13 patients taking tosufloxacin (2).

Drug–Drug Interactions

Antacids

The C_{max} and AUC of tosufloxacin tosilate 300 mg were significantly reduced by aluminium hydroxide gel fine granules 1 g or magnesium oxide 1 g (2).

Tosylchloramide sodium

See also Disinfectants and antiseptics

General Information

Tosylchloramide has been used as a wound disinfectant, a general surgical antiseptic, and for the disinfection of water (1).

Organs and Systems

Respiratory

Asthma has been attributed to tosylchloramide (2).

Immunologic

Contact sensitization to tosylchloramide has been reported (3).

- Urticaria, rhinitis, dyspnea, and edema of the face were reported in a female nurse after contact (SEDA-11, 492) (4). Specific IgE antibodies to tosylchloramide were demonstrated.

Tramadol

General Information

Tramadol is a synthetic opioid analgesic with activity at OP_3 (μ) opioid receptors, but it also inhibits the re-uptake of both 5-HT and noradrenaline and stimulates the presynaptic release of 5-HT. It produces a similar analgesic effect to pethidine and is about one-tenth as potent as morphine.

The reported adverse effects of tramadol are nausea, vomiting, sweating, dry mouth, dizziness, sedation, headache, and hypertension (SEDA-17, 84) (SEDA-20, 81). The atypical analgesic effects of tramadol and its associated adverse effects profile have been reviewed (1).

The metabolism of tramadol by CYP2D6 is important for its analgesic effect; tramadol may therefore be a poor analgesic in poor metabolizers by CYP2D6, while extensive metabolizers may have better analgesia and more adverse effects (SEDA-21, 90).

In a review of the use of tramadol in musculoskeletal pain the authors concluded that tramadol can be used at Step 2 of the analgesic ladder, since its efficacy, alone or in conjunction with NSAIDs, in the management of chronic musculoskeletal pain without increasing the frequency of adverse effects has been confirmed (2,3).

Comparative studies

Bupivacaine

In a randomized, controlled study in 60 boys (aged 1–7 years) undergoing unilateral herniorrhaphy, caudal 0.25% bupivacaine 1 mg/kg plus tramadol 1.5 mg/kg resulted in superior analgesia (quality and duration) with no significant increase in opioid-related adverse effects compared with children who received 0.25% bupivacaine 1 mg/kg alone or caudal tramadol 1.5 mg/kg in 0.9% saline alone (4).

Thirty children (1–5 years old) in an open, controlled study were randomly given caudal block with 0.25% bupivacaine 0.8 mg/kg or tramadol 0.8 or 2 mg/kg (5). The duration of analgesia was longer (9.1 hours) in those given tramadol but the incidences of opioid-related

© 2006 Elsevier B.V. All rights reserved.

adverse effects (gastrointestinal effects and sweating) were significantly higher.

Clomipramine + levomepromazine

Since the monoamine effects of tramadol resemble the effect of antidepressants, it has been compared with clomipramine + levomepromazine in patients with postherpetic neuralgia. The incidence of adverse effects was 77% with tramadol and 83% with clomipramine (SEDA-20, 81).

Codeine

In a 4-week, double-blind, multicenter, randomized study, tramadol plus paracetamol (37.5/325 mg) was as effective as codeine plus paracetamol (co-codamol 30/300 mg) in chronic non-malignant low back pain and osteoarthritis pain, with acceptable tolerability (6).

When tramadol was compared with codeine in 65 patients undergoing elective intracranial surgery, there was a significantly higher incidence of postoperative nausea, vomiting, and sedation with tramadol 75 mg (7). The patients given codeine had significantly lower pain scores over the first 48 hours postoperatively.

Non-steroidal anti-inflammatory drugs

Tramadol and non-steroidal anti-inflammatory drugs have been compared in two studies of patients with joint pain associated with osteoarthritis (8,9). In an open, randomized study 60 patients with osteoarthritis taking NSAIDs were given either modified-release tramadol 100 mg 8-hourly or modified-release dihydrocodeine 60 mg 8-hourly for 4 days; the controls were 30 patients who took an NSAID alone (8). Both opioids provided adequate analgesic adjuncts to NSAIDs, but tramadol caused significantly more minor initial adverse effects.

Diclofenac

In a double-blind, randomized, crossover study in 60 patients with osteoarthritis of the hip or knee, tramadol 50–100 mg up to three times daily was compared with diclofenac (25–50 mg up to three times daily) over 4 weeks (10). Both regimens gave modest pain relief, with no significant differences between the two groups, although within individual patients there were marked differences in analgesic effectiveness. Tramadol was associated with a significantly higher rate of adverse effects (20 versus 3.3%), notably headaches, nausea, constipation, tiredness, and vomiting, but there was no significant difference in adverse events that required withdrawal.

Ketorolac

Intravenous tramadol 1.5 mg/kg has been compared with a single dose of intravenous ketorolac 10 ng in 60 patients scheduled to undergo day-case laparoscopic sterilization in a prospective, randomized, double-blind comparison (11). Tramadol was associated with significantly less postoperative pain. There was no difference in the incidence or severity of nausea and vomiting between the two groups. Dry mouth was significantly more common with tramadol (60 versus 27%).

Opioid analgesics

Fentanyl

In a comparison of tramadol (1 or 2 mg/kg) and fentanyl (2 μg/kg) for postoperative analgesia after pediatric anesthesia, the two drugs had equal analgesic potency and produced similar hemodynamic stability and a similar incidence of adverse effects (12).

Hydrocodone

A randomized, double-blind comparison of the effectiveness of a single dose of tramadol 100 mg with a single dose of hydrocodone 5 mg plus paracetamol 500 mg in acute musculoskeletal pain in 68 subjects after minor trauma has been published (13). Tramadol gave significantly worse analgesia. Adverse effects (nausea and vomiting, drowsiness and dizziness, and anxiety) were uncommon and there was no significant difference between the two drugs.

Morphine

In a comparison of the analgesic effects of intermittent boluses of tramadol or morphine after abdominal surgery in 523 patients, tramadol caused more adverse effects (43 versus 34%), although the difference was not statistically significant. The commonest adverse effects were nausea (32 and 22%), vomiting (4.9 and 3.8%), urinary retention (3.0 and 2.7%), and sweating (3.8 and 0.4%) (SEDA-20, 81).

Tramadol and morphine have been compared in 40 women undergoing hysterectomy (14). At the start of wound closure, patients received either tramadol 3 mg/kg or morphine 0.2 mg/kg intravenously, which did not cause changes in arterial pressure or heart rate. There were no differences in times to spontaneous respiration, awakening, or orientation between the two groups, and ventilation frequency and pain scores were similar throughout 90 minutes. Similar numbers in each group required supplementary analgesia. Performance of the p-deletion test, a measure of psychomotor function, was more rapid in the tramadol group, but the performance of all subjects was impaired at 90 minutes compared with their preoperative scores.

In a randomized, double-blind study in 20 patients with severe postoperative pain given either intravenous tramadol 1 mg/kg or morphine 0.1 mg/kg, both drugs were effective analgesics but higher dosages than those usually administered were necessary (15). Tramadol did not cause any severe adverse effects, but with morphine there was one case each of severe sedation and respiratory depression.

A comparison of tramadol and morphine for subcutaneous patient-controlled analgesia after orthopedic surgery showed that tramadol 40 mg subcutaneously and morphine 2 mg subcutaneously were equally effective in providing analgesia (16). Drug use in the first 24 hours averaged 800 mg for tramadol and 40 mg for morphine. However, mean arterial blood pressure fell significantly in both groups after 24 hours, with a 17% mean maximal fall from baseline concentrations for tramadol and 20% for morphine; heart rate increased by 17 and 15% respectively. Oxygen saturation also fell significantly in both groups, but was not associated with changes in respiratory

© 2006 Elsevier B.V. All rights reserved.

rate. Nausea and vomiting were more common with tramadol (65%). In this study, patients required significantly more tramadol than had been predicted, and the authors commented that at this dosage, the adverse effects profile was similar to that of morphine.

In a double-blind study 150 patients with post-traumatic musculoskeletal pain were allocated to either tramadol 100 mg, with possible increases to a total of 200 mg, or morphine 5 mg or 10 mg with a total increase to 20 mg (17). Analgesic efficacy and adverse effect profiles were similar in the two groups.

Non-opioid analgesics

In a double-blind, randomized study in 120 patients scheduled to undergo outpatient hand surgery with intravenous regional anesthesia, tramadol 100 mg was compared with either metamizol 1 g or paracetamol 1 g, all 6-hourly (18). Seven patients given tramadol withdrew because of severe nausea and dizziness. Tramadol was the most effective analgesic, but none of the drugs alone provided effective analgesia in all patients and 40% needed rescue analgesia.

Tramadol has been compared with a paracetamol derivative in a double-blind, randomized, controlled study in 80 patients undergoing elective thyroidectomy (19). They were randomly assigned to propacetamol (an injectable prodrug of paracetamol) 2 g or intravenous tramadol 1.5 mg/kg. A single dose of tramadol provided better analgesia than propacetamol during the first 6 hours after surgery, but failed to ensure optimal analgesia subsequently. The incidences of nausea, vomiting, and sedation were comparable in the two groups.

Placebo-controlled studies

In two randomized, double-blind studies tramadol provided effective and safe long-term relief of pain in diabetic neuropathy (20) and fibromyalgia (21). The adverse effects (constipation, nausea, and headache) were well tolerated.

The postoperative analgesic efficacy of tramadol 2 mg/kg has been studied in 80 children (aged 1–3 years) undergoing day-case adenoidectomy without premedication in a double-blind, randomized, placebo-controlled study (22). General anesthesia was induced with intravenous alfentanil 10 μg/kg plus lidocaine followed by propofol and mivacurium. The children received intravenous tramadol 2 mg/kg or placebo immediately after induction of anesthesia. Those given tramadol required fewer pethidine rescue medication doses than those given placebo. In fact, 45% of the children who were given tramadol did not require postoperative analgesia at all, compared with 15% of the children who were given placebo. The incidences of adverse effects were similar in the two groups.

The use or addition of tramadol in children undergoing lower abdominal surgery has been examined in three studies (4,5,23). In a double-blind, randomized, controlled study, 125 children undergoing inguinal herniorrhaphy were allocated to receive tramadol 2 mg/kg or morphine sulfate 0.03 mg/kg before surgery; the control group received morphine sulfate 0.03 mg/kg at the end of surgery (23). Caudal tramadol 2 mg/kg provided reliable postoperative analgesia and there were no inter-group differences in postoperative adverse effects or quality and duration of pain relief.

In 129 patients with severe joint pain associated with osteoarthritis, tramadol was significantly more effective than placebo, but 26 patients taking tramadol and 43 taking placebo withdrew because of ineffectiveness or adverse effects; the main adverse effects of tramadol were nausea and constipation (9).

Tramadol has been used in the treatment of shivering after anesthesia. In one study, 150 patients scheduled for general anesthesia and surgery were randomly allocated to intravenous tramadol 1 or 2 mg/kg or 0.9% saline given at the time of wound closure (24). The authors concluded that both doses of tramadol were effective and safe. Of the patients in the higher-dose group, 2% had shivering, compared with 4% in the lower-dose group and 48% in the control group. In a similar study in 96 patients, the optimal dose of tramadol in preventing shivering after anesthesia was 0.5–1 mg/kg intravenously (25).

Combination studies

Tramadol has been combined with various drugs in order to enhance efficacy or reduce adverse effects.

Aspirin

The analgesic efficacy of tramadol can be further enhanced by adding injectable lysine acetyl salicylate (aspirin) after orthopedic surgery with no significant increase in adverse effects (26).

Dexamethasone

In a randomized, placebo-controlled study, the addition of an intravenous bolus of dexamethasone 150 micrograms/kg with a PCA system programmed to deliver tramadol 20 mg in a 1 ml solution on demand in 50 patients after major abdominal surgery significantly reduced the incidence of nausea, vomiting, and subsequent administration of rescue antiemetic therapy (27).

Droperidol

The use of tramadol for postoperative analgesia by intravenous patient-controlled analgesia (PCA) has gained popularity, mostly because it is less likely to cause sedation and respiratory depression (28). However, it is associated with nausea, vomiting, dry mouth, and sweating. The addition of droperidol to tramadol PCA reduced the incidence of gastrointestinal symptoms without significantly increasing sedation (29). In a double-blind, randomized study, 40 patients undergoing coronary artery bypass grafting and/or valve replacement surgery were given droperidol 0.1 mg/ml plus either tramadol 10 mg/ml or morphine 1 mg/ml. The results in the two groups were comparable in efficacy, adverse effects profiles, and dose requirements, and the authors argued that there may be no advantage in using tramadol rather than morphine in conjunction with droperidol (30).

Ketamine

In 44 patients the addition of ketamine 1 mg/ml to PCA tramadol significantly reduced the consumption of tramadol at 6, 12, and 24 hours postoperatively, with no

© 2006 Elsevier B.V. All rights reserved.

differences in the incidence of nausea and sedation (31). Diplopia was reported by two patients.

Magnesium sulfate

In 44 patients the addition of magnesium sulfate 30 mg/ml to PCA tramadol both significantly reduced the consumption of tramadol at 6, 12, and 24 hours postoperatively, with no differences in the incidence of nausea and sedation (31).

Morphine

In a double-blind, randomized, controlled study, the addition of a tramadol infusion to morphine for PCA in 69 patients undergoing elective abdominal surgery resulted in improved analgesic efficacy and reduced morphine requirements, with a relative lack of adverse effects (32).

Observational studies

The role of tramadol in the treatment of rheumatological pain has been reviewed (33). Tramadol causes fewer opioid adverse effects for a given level of analgesia compared with traditional opioids. Common adverse effects, such as nausea and dizziness, usually occur only at the beginning of therapy, abate with time, and are further minimized by up-titrating the dosage over several days (34).

When tramadol 1 mg/kg was given intravenously to 110 adults for postoperative shivering, few adverse effects were reported; two had transient hypotension and two complained of nausea without vomiting. Similarly, mild adverse effects were reported in 20% of patients in a trial of tramadol in cancer pain (SEDA-16, 86), and when it was used to relieve severe pain in sports injuries (SEDA-16, 86).

Organs and Systems

Respiratory

Tramadol is said not to cause respiratory depression (SEDA-17, 84) (SEDA-18, 82), but it has been reported that equipotent doses of tramadol did produce respiratory depression, albeit less severe and for a shorter time than morphine (SEDA-17, 84) (35). This was confirmed in an extensive review of the literature (SEDA-21, 90).

The effect of oral tramadol on the ventilatory response to acute isocapnic hypoxia has been studied in 20 healthy volunteers. Tramadol had a small but significant depressive effect on the hypercapnic ventilatory response but no effect on the hypoxic ventilatory response (36). This is in contrast to morphine, which causes 50–60% suppression of the hypoxic ventilatory response.

Nervous system

Tramadol-associated seizures have been studied retrospectively in 9218 adult tramadol users and 37 232 non-users (37). Seizures occurred in under 1% of all tramadol users, but the risk of seizure was increased two- to six-fold among users adjusted for selected co-morbidities and polydrug prescription. The risk of seizure was higher in those aged 25–54 years, those who had more than four tramadol prescriptions, and those who had a history of alcohol abuse, stroke, or head injury.

In a nested case-control study of 11 383 patients, there were 21 cases of idiopathic seizures, only three of whom had been exposed to tramadol alone, the other having taken other analgesics (opioids or others) (38). The findings did not suggest an increased risk of seizures among patients taking tramadol alone.

Seizures followed by opioid withdrawal symptoms have been reported in a patient taking tramadol (39).

- A 29-year-old woman took tramadol 50 mg 6-hourly for pain associated with the carpal tunnel syndrome. She slowly increased the dose of tramadol and obtained it from several physicians and different hospitals, so that after 3 years she was taking 30 tramadol 50 mg tablets daily. She had two generalized seizures and stopped taking tramadol; 1 day later she developed severe opioid withdrawal symptoms, including diarrhea, headache, insomnia, and blurred vision. She was detoxified with tapering doses of tramadol and discharged after 6 days.

Psychological, psychiatric

Hallucinations have been attributed to tramadol, both visual (40) and auditory (41).

- A 66-year-old tetraparetic man developed hallucinations while taking tramadol, paroxetine, and dosulepin for chronic pain (40).
- A 74-year-old man with lung cancer took tramadol 200 mg/day for chest pain (41). Soon afterwards (time not specified) he had vivid auditory hallucinations in the form of "two voices singing accompanied by an accordion and a banjo." They resolved 48 hours after withdrawal.

Gastrointestinal

In one study the incidence of nausea was high (30–35%) when tramadol was used for postoperative pain (SEDA-20, 81).

Intravenous tramadol (1.25 mg/kg), codeine (1 mg/kg), morphine (0.125 mg/kg), and saline have been compared for their effect on gastric emptying (using the paracetamol absorption test) in 10 healthy subjects in a randomized, double-blind study (42). Tramadol had a measurable but statistically insignificant inhibitory effect on gastric emptying, whereas morphine and codeine significantly delayed gastric emptying. The implication of this is that the risk of regurgitation is less with tramadol than with the other opioids investigated and that tramadol is less likely to alter the pharmacokinetics of other drugs administered simultaneously.

In mild to moderate postoperative pain, rectal tramadol has been compared with standard treatment with co-codamol (paracetamol plus codeine) suppositories in 40 patients who were given either tramadol 100 mg suppositories 6-hourly or 1000/20 mg of co-codamol 6-hourly (43). Nausea and vomiting were significantly more frequent with tramadol (84%) than with co-codamol (31%).

The effect of tramadol on postoperative nausea and vomiting after ENT surgery has been studied in a prospective, randomized, double-blind comparison with

© 2006 Elsevier B.V. All rights reserved.

nalbuphine, pethidine, or saline in 281 patients (44). The three opioids caused a similar incidence of postoperative nausea and vomiting (40, 52, and 37% respectively) and more than placebo (32%).

In a randomized, double-blind placebo-controlled study of 76 women undergoing abdominal hysterectomy, tramadol 100 mg was a more effective analgesic than ketorolac 30 mg given every 6 hours intravenously (45). However, of those given tramadol 38% had vomiting compared with only 8% of those who were given ketorolac.

Urinary tract

The Netherlands Pharmacovigilance Foundation (LAREB), has reported five cases of transient difficulty in urinating, which spontaneously resolved on withdrawal of tramadol and was suspected to be induced by tramadol; none needed catheterization (46). In all five cases tramadol had been prescribed for back pain in relatively healthy individuals in a dose range of 50–150 mg.

Skin

- A 47-year-old man taking tramadol 100 mg for low back pain developed a maculopapular rash with secondary erythroderma, which resolved after withdrawal of tramadol (47).

Long-Term Effects

Drug abuse

Tramadol abuse was monitored in the USA during the 3 years (1995–1998) after the drug was marketed there, through the systematic collection and evaluation of reports of suspected abuse in high-risk populations from a network of drug abuse specialists and reports sent through the FDA's Med Watch system (48). The overall conclusion was that experimentation with tramadol during the first 18 months of its introduction peaked at two cases per 100 000 patients exposed. This figure subsequently fell to less than one case per 100 000 patients in the second 18 months of the study period. Of cases of abuse 97% occurred among individuals with a history of substance abuse.

Drug Administration

Drug formulations

The incidence of adverse effects is reduced with the use of an oral, modified-release formulation of tramadol in the treatment of chronic pain (49), starting at the lowest dose, increasing gradually according to the patient's response during chronic oral administration (50,51), and using a loading dose immediately after the start of surgery.

The results of postmarketing surveillance of modified-released tramadol in Germany have been published (52). Modified-release tramadol (mean daily dose 236 mg usually divided into two doses) was used in 3153 patients, of whom most had severe or very severe pain. During the 6-week trial, 316 adverse effects were reported by a total of 206 patients (6.5%). Adverse effects were, in decreasing order of frequency, nausea (3.4%), dizziness (1.5%), vomiting (1.1%), constipation (0.5%), tiredness (0.5%), sweating (0.4%), dry mouth (0.3%), and pruritus (0.3%). Confusion, hypotension, sleep disturbances, abdominal pain, stomach upset, gastrointestinal hemorrhage, and cerebral hemorrhage were all among the less frequently reported adverse events, and 28% of events were classified as severe. Age did not affect the frequency of events, but women reported a higher frequency of adverse events than men (7.3 versus 5.7%).

The use of modified-release tramadol in chronic malignant pain has been examined in an open, prospective study in 146 patients with moderate to severe cancer pain; 90 patients completed the 6-week trial (53). Dropouts were due to opioid adverse effects (20%), inadequate pain relief (9%), or both (2.5%). There was at least one adverse effect in 86%. Overall, 433 adverse effect events were reported but some reduced in frequency over the 6 weeks. Modified-release tramadol (400 mg/day) provided fast and efficient pain relief in almost 60% of patients both during initial dosing and long-term treatment.

Drug overdose

- A 26-year-old male nurse died of tramadol intoxication (54). The peripheral blood concentration of tramadol was 9.6 micrograms/ml (target concentration 0.1–0.3 micrograms/ml). There was no objective evidence at postmortem of any pre-existing disease or use/overuse of ethanol or other drugs that could have contributed to or caused death.

Drug–Drug Interactions

Ondansetron

Tramadol dosage requirements for patient-controlled analgesia increased when ondansetron was given as a prophylactic antiemetic in 40 patients undergoing lumbar laminectomy in an open, controlled study (55). During the first 4 hours postoperatively tramadol consumption increased by about 30% in those given ondansetron and remained 22–25% higher thereafter. A single dose of ondansetron 4 mg given during induction did not reduce the 24-hour incidence of nausea or vomiting.

In a randomized, controlled study of postoperative PCA using tramadol with or without ondansetron in 59 patients undergoing ear, nose, and throat surgery, ondansetron reduced the overall analgesic effect of tramadol, increased doses of tramadol being needed in the first 12 hours after surgery. This increase in tramadol requirements in those given ondansetron resulted in a significantly higher vomiting scores at 4 and 8 hours postoperatively and an overall increase in the number of episodes of vomiting, despite the use of ondansetron (56).

Oral anticoagulants

Tramadol may increase the anticoagulant effect of phenprocoumon or warfarin (SEDA-22, 103).

© 2006 Elsevier B.V. All rights reserved.

Quinidine

Inhibition of the hepatic metabolism of tramadol to morphine by quinidine may reduce its opioid effects (SEDA-21, 90).

Selective serotonin re-uptake inhibitors (SSRIs)

Fluoxetine

Serotonin syndrome and mania occurred in a 72-year-old woman taking fluoxetine 20 mg/day and tramadol 150 mg/day 18 days after she started to take the combination (57). Inhibition of CYP2D6 may have played a part (58).

Sertraline

The serotonin syndrome has been reported after concurrent use of tramadol and sertraline (SEDA-22, 103).

- Serotonin syndrome occurred in an 88-year-old woman who took sertraline 50–100 mg/day and tramadol 200–400 mg/day for 10 days; the symptoms subsided 15 days after withdrawal of tramadol (59).

Venlafaxine

The death of a 36-year-old patient with a history of alcohol dependence who was taking tramadol, venlafaxine, trazodone, and quetiapine has highlighted the increased risk of seizures with concomitant use of tramadol and selective serotonin re-uptake inhibitors (60).

Trandolapril

See also Angiotensin converting enzyme inhibitors

General Information

Trandolapril is a non-sulfhydryl ACE inhibitor that has been used in patients with hypertension, congestive heart failure, and myocardial infarction. It is a prodrug that is hydrolyzed to the active diacid trandolaprilat.

Comprehensive reviews and the results of a large trial have shown that trandolapril has a pattern of adverse effects reflecting those usually documented with other ACE inhibitors (1).

Organs and Systems

Respiratory

In 3402 patients with hypertension taking trandolapril, cough, assessed by visual analogue scale, was less common in smokers than in non-smokers (2).

Tranexamic acid

General Information

During normal fibrinolysis, inactive circulating plasminogen binds to fibrin through an active site that binds lysine. The bound plasminogen is then converted to plasmin by activators (such as tissue plasminogen activator, t-PA) and converted to plasmin, which breaks down the fibrin. Tranexamic acid (Cyklokapron) and aminocaproic acid (ε-aminocaproic acid, EACA, 6-aminohexanoic acid, Amicar) are structural analogues of lysine, which bind irreversibly to the lysine-binding sites on plasminogen, inhibiting binding to fibrin and thus the whole process of fibrinolysis (1,2). These agents inhibit the natural degradation of fibrin and so stabilize clots.

Aminocaproic acid was the first such agent to be used widely, but it has largely been superseded in clinical practice by tranexamic acid, which is about 10 times more potent. Para-aminomethylbenzoic acid (PAMBA) is similar to aminocaproic acid, but is about three times more active in inhibiting plasminogen activators (3). However, it is no longer used despite the fact that it is well tolerated.

Uses

Antifibrinolytic agents are of benefit in the treatment of primary menorrhagia (4–7), recurrent epistaxis (8), oral bleeding in patients with congenital and acquired coagulation disorders (9,10), hemorrhage associated with thrombolytic therapy, and to reduce blood loss associated with surgery (especially cardiac surgery, joint replacement, and orthotopic liver transplantation) (11–14). Antifibrinolytic therapy can be of value in other conditions as well (15–21). It is effective in the bleeding diathesis that can accompany acute promyelocytic leukemia (22,23), but it does not improve outcome after subarachnoid hemorrhage (24).

Tranexamic acid used during cardiopulmonary bypass reduces mediastinal blood losses by about one-third, while transfusion requirements remain unchanged (25). In over 950 patients, not a single thromboembolic complication could be ascribed to it.

General adverse effects

Adverse effects of tranexamic acid are rare and mainly limited to nausea, diarrhea, or abdominal pain (4,5,26–29). These symptoms are usually associated with high doses, and subside if the dose is reduced. The dose of tranexamic acid in patients with renal insufficiency must be reduced to avoid accumulation and associated adverse effects. Hypotension is occasionally observed, typically after rapid intravenous infusion (30). The better safety profile with regard to minor adverse effects of tranexamic acid compared with aminocaproic acid is due to the lower daily dose required for tranexamic acid (3–6 g) compared with aminocaproic acid (18–30 g). Tranexamic acid has very occasionally been associated with skin rashes, including fixed drug eruption (31) and bullous eruptions (32).

Organs and Systems

Sensory systems

Central venous retinopathy was reported in two young women after oral treatment with tranexamic acid for menorrhagia (33).

- A 56-year-old man, who had been undergoing hemodialysis for 1 year after 10 years of peritoneal dialysis, was given intravenous tranexamic acid after an emergency operation for bleeding peptic ulcers; he had gradual loss of sight over about 1 week, and 2 weeks after the operation became blind (34). Retinography was flat and his visual field was narrowed. Fluorescein angiography showed microgranular hyperfluorescence, suggesting malfunction of the pigmented layer of the retina. There were no abnormalities in the brain or optic nerve on MRI scanning. Withdrawal of tranexamic acid restored his sight within a few days. He had received tranexamic acid once before because of a bleeding ulcer, and his sight had been impaired at that time too.

However, in 14 patients who had taken tranexamic acid for an average period of 6 years there was no evidence of ocular damage (35).

Hematologic

Inhibition of plasminogen by tranexamic acid and aminocaproic acid could theoretically facilitate the development of thrombosis, but whether it actually does so has been the subject of contradictory reports. Episodes of venous and arterial thrombosis have been reported in association with treatment using either tranexamic acid or aminocaproic acid. These include thrombosis at unusual sites such as mesenteric thrombosis (36), the aorta (37), retinal artery occlusion (38), and intracranial arterial thrombosis (39–41), as well as deep-vein thrombosis in the legs (42).

- Massive pulmonary thromboembolism was reported in a 62-year-old woman 7 days after treatment with high doses for subarachnoid hemorrhage (43).

However, in a large retrospective study from Sweden, the incidence of thrombosis in women receiving tranexamic acid for menorrhagia was no different to that of the rest of the population (44). During a 9-year period, corresponding to over 238 000 women-years, 11 thromboembolic complications were reported. This corresponds to an annual incidence of 0.005%, which is not higher than the expected incidence in fertile women. Furthermore, a retrospective study of 256 pregnant women treated with tranexamic acid for abruptio placentae or other hemorrhagic problems showed no evidence of a thrombogenic effect of the drug (45), and a study of patients undergoing cardiac surgery who received tranexamic also showed no increased risk of thrombotic complications (46). Thus, the association between use of inhibitors of fibrinolysis and thrombosis appears to be fortuitous and the risk of this potential hazard is very low. However, the data sheet issued by the manufacturers still states that tranexamic acid is contraindicated in patients with a previous history of thromboembolic disease.

Caution should also be exercised in the administration of antifibrinolytic agents in disseminated intravascular coagulation (47,48).

Urinary tract

Acute renal cortical necrosis has been attributed to tranexamic acid in a patient with hemophilia A (49,50).

- A 21-year-old man developed oliguria and uremia after 3 days of treatment with tranexamic acid 3 g/day for epistaxis. He did not recover. Renal angiography showed reduced cortical contrast enhancement, compatible with renal cortical necrosis. No other susceptibility factors for renal cortical necrosis were present.

Renal impairment associated with acute renal cortical necrosis caused by tranexamic acid is rare. The authors found only three previously reported cases in English, of which at least one other was without any known susceptibility factor for acute renal cortical necrosis (49).

Second-Generation Effects

Teratogenicity

There is no evidence of a teratogenic effect with tranexamic acid (51).

Lactation

Tranexamic acid passes into breast milk but reaches a concentration of only about one hundredth of that in maternal blood (51), which should not result in significant inhibition of fibrinolysis in a neonate.

Drug–Drug Interactions

All-*trans* retinoic acid

Tranexamic acid has been used without thrombotic complications for the attempted prophylaxis of hemorrhage in patients with acute promyelocytic leukemia treated with combination chemotherapy, in whom hemorrhage is a significant problem. Since several studies have shown that all-*trans* retinoic acid can produce complete remission, it has become part of standard treatment. Fatal thromboembolism in acute promyelocytic leukemia during all-*trans* retinoic acid therapy combined with antifibrinolytic therapy has been reported (52). Of 31 patients with acute promyelocytic leukemia, treated with different combinations of all-*trans* retinoic acid and chemotherapy, 21 were given tranexamic acid (53). Of the 28 patients who received all-*trans* retinoic acid, 7 died during the study, but of these 7, only 4 were early deaths (within 42 days). All four early deaths were in those who received all-*trans* retinoic acid plus tranexamic acid, and three of the four had sudden and rapid deterioration in their condition; postmortem findings implicated thrombosis in the microvasculature as the predominant cause of death. The authors suggested that in patients taking all-*trans* retinoic acid, tranexamic acid should be used cautiously; supportive therapy with platelets and fresh frozen plasma alone can be used.

Tranilast

General Information

Tranilast is an orally active antiallergic agent. It may have a similar mechanism of action to that of cromoglicate.

Its adverse reactions include liver function abnormalities, anorexia, nausea, vomiting, abdominal pain, reduced hemoglobin, headache, drowsiness, insomnia, dizziness, and general malaise (1).

Organs and Systems

Urinary tract

Some patients taking tranilast develop severe bladder symptoms, unrelieved by antibiotic treatment (2). Fourteen patients have been reported in detail. In patients whose bladder wall was biopsied there was eosinophilic inflammation. Drug-induced lymphocyte stimulation showed that tranilast and its major metabolite are causative agents. The symptoms disappear within a few days of stopping the drug (SEDA-12, 145) (SEDA-14, 139) (SEDA-17, 205) (3).

- A 59-year-old man who had been taking tranilast 600 mg/day for 15 weeks developed bladder irritability (4). Cystoscopy showed extensive mucosal edema, strongly suggestive of drug-induced cystitis. He stopped taking tranilast and the symptoms disappeared within 3 weeks.

Immunologic

Immune thrombocytopenia caused by tranilast has been reported in a 17-year-old man. The drug was withdrawn and oral prednisolone was started. He recovered within 1 week. Antiplatelet antibodies were not detected, but there was a platelet-associated IgG, which increased when a sample of his serum was incubated with tranilast in vitro (5).

Tranylcypromine

See also Monoamine oxidase inhibitors

General Information

Tranylcypromine is a non-hydrazine monoamine oxidase (MAO) inhibitor with actions and uses similar to those of phenelzine, but with less prolonged inhibition. Its half-life is 90–190 minutes. It is structurally related to amfetamine, to which it is metabolized in overdose (1).

Long-Term Effects

Drug abuse

Four cases of addiction to tranylcypromine have been described, in addition to the three reported since 1965 (2). The dosage was 150–300 mg/day. The mild euphoriant properties of tranylcypromine reflect its structural resemblance to amfetamine, and probably account for tolerance and addiction in predisposed individuals. Tranylcypromine abuse in 18 patients has been reviewed (3), and two further reports have appeared (SEDA-17, 17) (4). In one case (5), the patient took 440 mg/day without any adverse effects. The patient reported that she was longing for the "energizing" effect of the drug and for the feeling of "freedom and power." Withdrawal resulted in repeated generalized seizures and status epilepticus.

Susceptibility Factors

Hepatic disease

A carefully controlled study showed that patients with impaired liver function are especially sensitive to tranylcypromine, sometimes developing obtunded consciousness and slow electroencephalograms similar to those found in hepatic encephalopathy (6).

Drug Administration

Drug overdose

The fatal effects of antidepressants in England, Scotland, and Wales during 1975–1984 and 1985–1989 have been compared in retrospective epidemiological studies (7,8). There were 24 deaths due to tranylcypromine, the fatality index for which was significantly higher than the mean for all antidepressants, while that for the other MAO inhibitors was lower.

Trastuzumab

See also Monoclonal antibodies

General Information

Trastuzumab is a recombinant humanized monoclonal antibody that binds to the proto-oncogene, HER-2/neu gene product, which is expressed in 25–30% of primary breast cancers. It has been used to treat selected patients with metastatic breast cancer whose tumors overexpress the HER2 protein, which is amplified in 25–30% of breast cancers and is associated with an aggressive form of disease (1). Adverse effects mostly consisted of infusion-related constitutional symptoms, digestive disorders (diarrhea, vomiting), pain, cough, headache, dyspnea, mild infections, and insomnia. Compared with chemotherapy alone, the addition of trastuzumab more often produced moderately severe adverse hematological effects (leukopenia and anemia) and diarrhea. Severe congestive cardiac failure is a major adverse effect of trastuzumab. According to the product labelling, severe cardiac failure was observed in 5–19% of patients (trastuzumab alone versus trastuzumab plus anthracycline and cyclophosphamide). Other serious adverse events, including death, have occurred in 0.25% of patients treated with trastuzumab. They fall into three categories: infusion reactions; hypersensitivity reactions, including fatal anaphylaxis; and pulmonary events, including adult respiratory distress syndrome.

Organs and Systems

Cardiovascular

Cardiotoxicity is a major concern with trastuzumab, particularly as it is often used in patients who are receiving or who have previously received anthracycline antibiotics (2). It occurs in 5% of patients given trastuzumab alone, in 13% of patients given trastuzumab with paclitaxel, and in 27% of patients given trastuzumab in combination with anthracyclines and cyclophosphamide (3).

The efficacy and safety of trastuzumab have been evaluated in 235 women with metastatic breast cancer receiving standard chemotherapy (4). The most important adverse event was cardiac failure, which occurred in 27% of those who were given anthracycline, cyclophosphamide, and trastuzumab, 8% of those who were given anthracycline and cyclophosphamide alone, 13% of those who were given paclitaxel and trastuzumab, and 1% of those who were given paclitaxel alone. The incidence of cardiac failure of New York Heart Association class III or class IV was highest among patients who had received an anthracycline, cyclophosphamide, and trastuzumab. The mechanism is unknown. In a retrospective analysis of all patients with cardiac failure by an independent review and evaluation committee, the only significant risk factor was older age. Although the cardiotoxicity was severe, and in some cases life-threatening, the symptoms improved with standard medical management.

Seven phase II and III clinical trials of trastuzumab in patients with metastatic breast cancer have been reviewed (5). The physiopathology of trastuzumab-associated cardiac disease is poorly understood, and baseline MUGA scanning is recommended to identify cardiac disease. The rates of cardiac disease were highest when trastuzumab was given in combination with anthracyclines or when there had been previous exposure to anthracyclines. Given the 25% improvement in overall survival in these patients with metastatic disease, the use of trastuzumab is justified.

- A 60-year-old woman with coronary heart disease and hypertension developed breast cancer and a core biopsy showed ER+/PR+/HER2–3+ (3). She enrolled in an institutional study with neoadjuvant trastuzumab with docetaxel. A pretreatment blood pool radionuclide angiography (MUGA) scan revealed a left ventricular ejection fraction of 56%. She had a good clinical response to treatment at 3 months. Before surgery a repeat MUGA showed a dilated left ventricle and a reduced ejection fraction (35%). She underwent surgery and 2 months later her ejection fraction was 44%.
- An overweight 59-year-old woman with hypertension and asthma developed breast cancer (ER+/PR+/HER2–2+) (3). Her MUGA scan showed a left ventricular ejection fraction of 57%. She was given trastuzumab with docetaxel and had a good response after 4 months. Before surgery she became dyspneic, and a

© 2006 Elsevier B.V. All rights reserved.

MUGA scan showed an ejection fraction of 24%; even 7 months after surgery her MUGA scan showed no improvement.

The efficacy and tolerability of trastuzumab in clinical trials has been reviewed (6). Of the first 48 patients treated in Sweden with or without chemotherapy, two had serious cardiac events and both had previously been treated with an anthracycline. As not all patients who received trastuzumab had echocardiography, the number of cardiac events was probably underestimated. It has been postulated that HER2 pathways may be involved in myocyte repair, and that concomitant administration of trastuzumab may interfere with the repair of anthracycline-damaged myocytes (7). Evidence from 20 patients has shown that cardiotoxicity is related to trastuzumab uptake in the myocardium, suggesting that the extent of HER2 receptor expression, or a related cross-reactive antigen in the myocardium, may be the underlying mechanism.

Respiratory

The toxicity of five escalating doses of trastuzumab (1–8 mg/kg) when combined with a fixed dose of interleukin-2 has been determined in 45 patients with non-hematological malignancies that overexpressed HER2 (8). There was no evidence of increasing toxicity related to the dose of trastuzumab. Five patients had pulmonary toxicity of grade 3 or higher; these were primarily attributed to interleukin-2, as the patients improved on reduction of the dose of interleukin-2.

Drug–Drug Interactions

Paclitaxel

In primates, trastuzumab clearance was reduced when it was administered with paclitaxel (9).

Travoprost

See also Prostaglandins

General Information

Travoprost is a derivative of fluprostenol and $PGF_{2\alpha}$ and has intraocular pressure-lowering activity.

Organs and Systems

Sensory systems

Travoprost causes changes in iris pigmentation (3.1–5.0%) and changes in eyelash characteristics, including length, thickness, density, and color (44–57%), similar to those described with latanoprost, after 12 months (1).

Reference

Travoprost compared with latanoprost and timolol in patients with open-angle glaucoma or ocular hypertension. Am J Ophthalmol 2001;132(4):472–84.

Trazodone

See also Antidepressants, second-generation

General Information

Trazodone (SEDA-7, 19–21) is a triazolopyridine derivative that selectively but weakly inhibits 5-hydroxytryptamine (5-HT) re-uptake and is an alpha-adrenoceptor antagonist at both presynaptic and postsynaptic receptors

© 2006 Elsevier B.V. All rights reserved.

(1). During long-term administration it down-regulates serotonin receptors (2).

Experience with therapeutic and toxic dose ranges of trazodone has thrown much doubt on earlier claims for its greater safety, and some unanticipated problems have surfaced.

Trazodone is rapidly absorbed, with peak plasma concentrations at 0.5–2 hours. It is extensively metabolized and eliminated mainly via the kidneys, with a half-life of 13 hours for total drug and metabolites.

A review of controlled clinical studies in depressed patients in Europe and the USA showed that trazodone is superior to placebo (3) and can be as effective as imipramine or amitriptyline (3,4). The doses needed to secure an equivalent effect (150–800 mg/day) were generally double those of the tricyclic antidepressants.

In 28 depressed patients treated with up to 600 mg/day for 4 weeks, plasma concentrations varied eightfold (5). There was a significant correlation between dosage and plasma concentration, but no association with outcome and no significant difference between the mean plasma concentrations in responders (1.51 μg/ml) and non-responders (1.64 μg/ml).

The short half-life of trazodone naturally raises the question of the optimal dosage frequency. The General Practitioner Research Group in Britain (6) has conducted a series of comparisons of trazodone given once, twice, and thrice a day to anxious and depressed patients taking up to 200 mg/day. Efficacy was the same with all three regimens, although there were more complaints of dizziness and fewer of drowsiness with the thrice-daily regimen.

Organs and Systems

Cardiovascular

Based on animal research and restricted experience in overdosage (SEDA-7, 19–21), early attempts to differentiate trazodone from tricyclic antidepressants suggested that it might be relatively free of cardiotoxic effects. However, a preliminary report of a study of the effects of trazodone on the cardiovascular system in 20 subjects mentioned two patients who had ventricular dysrhythmias (7). Others have reported ventricular tachycardia (8–10), atrial fibrillation (11), and complete heart block (12).

Additive hypotensive effects of trazodone and phenothiazines have been reported (13).

Trazodone can cause peripheral edema, as outlined in a report of 10 cases (14).

Nervous system

Trazodone is markedly sedative, very similar in profile to amitriptyline. It produces marked sedation and lethargy within an hour, lasting up to 6 hours, and is about half as potent as imipramine (4).

Although it is claimed to be relatively free of effects usually attributed to anticholinergic activity, trazodone does cause complaints of dry mouth and blurred vision, which may be mediated through its actions on alpha-adrenoceptors. Urinary retention has been reported in a 69-year-old woman taking a combination of trazodone and an anticholinergic drug (isopropamide iodide) (15). Cholinergic overactivity has also been described in two patients after withdrawal (16).

The manufacturers of trazodone received 30 unpublished reports of seizures in patients, most of whom had evidence of seizure predisposition or concurrent contributory conditions. Two reports are detailed here (17,18).

- A 50-year-old woman with an electroencephalographic abnormality but no history of epilepsy, who had taken amitriptyline and perphenazine uneventfully for years, suffered two seizures 18 days after switching to trazodone 50 mg/day.
- A 47-year-old man developed 30-second episodes of facial contortions, aphasia, garbled speech, neologism, nocturnal episodes of deep breathing, swallowing, and incomprehensible speech after taking trazodone 150 mg/day for 3 weeks. On withdrawal of trazodone, his symptoms abated, but an electroencephalogram showed a left anterior lobe spike. He was treated with carbamazepine and within 6 months was not depressed and had no further convulsive symptoms.

Sensory systems

Three cases of palinopsia (the persistence or reappearance of an image of a recently viewed object) have been reported (SEDA-17, 22); the authors speculated that this may have been due to pharmacological effects resembling those of LSD and mescaline.

Psychological, psychiatric

Conversion to mania has been reported in patients with unipolar depression (19,20) and bipolar illness (20).

Delirium, which also occurs with tricyclic antidepressants, has been reported with trazodone (21).

Liver

Hepatotoxicity, a known hazard of tricyclic compounds, has been reported with trazodone (22,23).

Skin

Trazodone has caused generalized erythematous maculopapular eruptions (24), erythema multiforme (although the patient was also taking lithium) (25), and generalized pustular psoriasis in a patient who had had stable plaque psoriasis for 19 years (26).

Sexual function

Inhibition of ejaculation was reported in a middle-aged man 1 week after he started taking trazodone 100 mg at night (27). The symptoms abated 3 days after withdrawal and did not return when treatment was changed to doxepin 50 mg/day. Because trazodone has relatively more alpha-adrenoceptor blocking action and less anticholinergic activity than doxepin, the author speculated that this was the mechanism.

Trazodone can cause severe and persistent priapism. In a communication from the manufacturers in 1987, it was noted that there had been 136 reports of "increased penile tumescence" in patients taking trazodone. These included

© 2006 Elsevier B.V. All rights reserved.

all reports of abnormal erectile activity. The company reported that the incidence of all abnormal erectile activity was about one in 6000 men, that in 36 of the 136 patients surgical interventions had been performed, and that at least nine of these patients were impotent. They suggested that early intervention is the treatment of choice, and that trazodone should be withdrawn immediately at the first signs of prolonged erections. They recommended that if conservative measures fail, intracavernosal irrigation with a weak solution of adrenaline should be considered (28). This rare adverse effect has been reported previously with a number of psychoactive and antihypertensive drugs (phenothiazines, guanethidine, prazosin, hydralazine) and has been ascribed to their alpha-adrenoceptor antagonist activity. The same mechanism probably explains the effect of trazodone.

Increased libido (29) and anorgasmia (30) have been reported with trazodone.

Drug Administration

Drug overdose

In a 1980 review there were 68 cases of trazodone overdosage in amounts ranging up to 5 g (12 times the maximum therapeutic dose) (31). The predominant symptoms were drowsiness, dizziness, and rarely coma. There were no deaths in patients who took trazodone alone, and only two in those who took it in combination with other potentially lethal drugs. A brief review of data obtained from 46 cases of trazodone overdose reported to the National Poisons Information Service in London showed that 25 of the patients took overdoses of trazodone alone, while 21 took trazodone in combination with other drugs (32). This retrospective questionnaire study had inherent methodological flaws, but it did lend credence to the belief that trazodone is safe in overdose.

Trazodone is less cardiotoxic than tricyclic antidepressants, although it has rarely been reported to cause ventricular tachycardia. QT interval prolongation has been reported in overdose (33).

- A patient who took an overdose of trazodone (3 g) had sinus bradycardia (57 beats/minute) and a prolonged QT_c interval (60 msec). The abnormal QT_c interval gradually normalized over the next 3 days with supportive hospital treatment.

Drug–Drug Interactions

Amiodarone

A patient taking both trazodone and amiodarone developed prolongation of the QT interval and a polymorphous ventricular tachycardia, perhaps by mutual potentiation (34).

Carbamazepine

In a 53-year-old man, trazodone produced a clinically significant increase in carbamazepine concentrations (35). This suggests that trazodone inhibits CYP3A4. It should be used with caution in combination with carbamazepine.

MAOIs and SSRIs

Although trazodone is related to nefazodone it probably potentiates 5-HT neurotransmission less. Trazodone is often added to monoamine oxidase inhibitors and serotonin re-uptake inhibitors at low doses (50–150 mg/day) as a hypnotic. In one case the combination of trazodone with nefazodone provoked the serotonin syndrome (36).

- When a 60-year-old woman taking nefazodone 500 mg/day also took trazodone 50 mg/day she developed confusion, restlessness, sweating, and nausea after 3 days. Her symptoms settled quickly on withdrawal of both antidepressants.

Trecovirsen

General Information

Trecovirsen is a 25-met antisense phosphorothioate oligonucleotide, which is targeted at the gag site of the HIV gene. In an early clinical experiment it was given to HIV-positive volunteers by intravenous infusion in single escalating doses of 0.1–2.5 mg/kg in groups of 6–12 subjects (1). The only significant adverse event was an isolated transitory increase in activated partial thromboplastin time at doses of 2.0 mg/kg or more; it was related to plasma trecovirsen concentrations and was attributed to the polyanionic character of the molecule. Headache occurred in 12% of subjects, and there were some cases of abdominal pain, back pain, diarrhea, and weakness.

Triamterene

See also Diuretics

General Information

Triamterene is a potassium-sparing diuretic that acts in the distal convoluted tubule independently of the action of aldosterone, inhibiting sodium channels (1).

Patients with congenital nephrogenic diabetes insipidus are often treated with a combination of a thiazide and a potassium-sparing diuretic, without consensus on the preferred potassium-sparing diuretic. A Japanese adult was systematically studied to determine the renal effects of hydrochlorothiazide plus amiloride and hydrochlorothiazide plus triamterene (2). The combination with amiloride was superior to that with triamterene in preventing excessive urinary potassium loss, hypokalemia, and metabolic alkalosis. These results suggest that amiloride is the preferred add-on therapy to hydrochlorothiazide in nephrogenic diabetes insipidus.

Organs and Systems

Hematologic

Triamterene blocks dihydrofolate reductase and can cause folate deficiency with megaloblastic anemia and pancytopenia, particularly in patients with hepatic cirrhosis, who have reduced clearance of the drug (SED-11, 431). When this has been reported, all patients were taking doses of 150–600 mg/day for ascites and all had hepatic cirrhosis, often due to alcohol abuse (SEDA-17, 269). It is advisable to use spironolactone rather than triamterene in patients with cirrhosis.

Gastrointestinal

Of the milder adverse effects of triamterene, nausea, vomiting, and diarrhea are fairly common (3).

Urinary tract

Like other diuretics, triamterene occasionally causes interstitial nephritis (4), but it has also been responsible for other renal problems, notably reversible non-oliguric renal insufficiency when it is given along with indometacin (or presumably any other inhibitor of prostaglandin synthesis) (5).

Triamterene can cause transient asymptomatic crystalluria in acidic urine (6). In most cases, the crystals are associated with brown casts, also due to triamterene.

© 2006 Elsevier B.V. All rights reserved.

Triamterene crystals should be regarded as a potential cause of severe tubular injury.

Triamterene can cause nephrolithiasis. Microcrystals of the parahydroxy metabolite form a particularly suitable nucleus for crystalline calcium oxalate deposition (7). However, a cause-and-effect relation has been questioned on epidemiological grounds and in the light of a controlled study that found no link (8), and triamterene could be an innocent bystander in stone formation (SEDA-11, 200). Nevertheless, triamterene is sometimes detected in urinary calculi. In a French analysis of 22 510 urinary calculi performed by infrared spectroscopy, drug-induced urolithiasis was divided into two categories: first, stones with drugs physically embedded ($n = 238$; 1.0%), notably indinavir monohydrate ($n = 126$; 53%), followed by triamterene ($n = 43$; 18%), sulfonamides ($n = 29$; 12%), and amorphous silica ($n = 24$; 10%); secondly, metabolic nephrolithiasis induced by drugs ($n = 140$; 0.6%), involving mainly calcium/vitamin D supplementation ($n = 56$; 40%) and carbonic anhydrase inhibitors ($n = 33$; 24%) (9). Drug-induced stones are responsible for about 1.6% of all calculi in France. Physical analysis and a thorough drug history are important elements in the diagnosis.

Skin

Rashes, including photodermatitis (10), sometimes occur with triamterene.

Pseudoporphyria has been attributed to co-triamterzide (hydrochlorothiazide plus triamterene, Dyazide) in a patient with vitiligo (11). It is uncertain which constituent was responsible.

Body temperature

Drug fever has been attributed to triamterene (12).

Second-Generation Effects

Pregnancy

Because of the potential risk of folate deficiency it is sensible to avoid triamterene in pregnancy (13).

Teratogenicity

Neural tube defects, characterized by a failure of the neural tube to close properly after conception, affect about one in 1000 live births in the USA. Periconceptional folic acid supplementation reduces the risk. To determine whether periconceptional exposure to folic acid antagonists might therefore increase the risk of neural tube defects, data from a case-control study of birth defects (1979–98) in the USA and Canada have been examined (14). Data on 1242 infants with neural tube defects (spina bifida, anencephaly, and encephalocele) were compared with data from a control group of 6660 infants with malformations not related to vitamin supplementation. Triamterene is a folic acid antagonist and in this series was associated with the development of neural tube defects, but there were too few cases to estimate an odds ratio.

Susceptibility Factors

Age

Triamterene is often given in combination with the thiazide diuretic bemetizide. The pharmacokinetics and the pharmacodynamics of a fixed combination of bemetizide 25 mg and triamterene 50 mg have been evaluated in 15 elderly patients (aged 70–84 years) and 10 young volunteers (aged 18–30 years) after single doses (on day 1) and multiple doses (at steady state on day 8) (15). Mean plasma concentrations of bemetizide, triamterene, and the active metabolite of triamterene, hydroxytriamterene, were significantly higher in the elderly subjects after single and multiple doses and urine flow and sodium excretion rates fell in tandem with the accumulation of these drugs. The glomerular filtration rate, known to be reduced in elderly people, was further reduced at higher concentrations of bemetizide and triamterene, which may explain why there were limited diuretic and saliuretic effects after multiple doses. This study clearly points to a modulating effect of the degree of renal function on the diuretic actions of these compounds in the elderly.

Drug–Drug Interactions

Methotrexate

An interaction between triamterene and methotrexate (also an inhibitor of dihydrofolate reductase), leading to pancytopenia, has been reported (16). Dehydration due to diuretic treatment may have contributed to renal impairment and reduced clearance of methotrexate, further increasing the risk of bone marrow suppression.

Triazolam

See also Benzodiazepines

General Information

The history of the introduction of triazolam has been reviewed (SEDA-4, v). Triazolam continues to be controversial (1) and much of the controversy has been reviewed (2–5).

Much of the literature on the adverse effects of triazolam is based on doses of 0.25 mg and above; the reduction in recommended dose to 0.125 mg may improve therapeutic safety, at the cost of compromising hypnotic efficacy in most patients. A low therapeutic index is also suggested by the possibility of amnesia, even after a single dose (6), and triazolam appears to be associated with a greater incidence of behavioral disturbances than other hypnotic benzodiazepine agonists, such as temazepam and zopiclone.

A case of recurrent iatrogenic Kleine–Levin syndrome with irritability, hyperphagia, and amnesia (7) has provided a further example of the bizarre behavior not infrequently seen with triazolam in a high dose (0.5 mg); see also the monograph on flunitrazepam. At this dose, triazolam produces too many adverse effects on sleep, memory, and judgement to be useful to the military or to commercial airline pilots; elderly patients are particularly sensitive, even to lower doses, owing in part to reduced drug clearance (SED-12, 99). Amnesia and confusion, which can occur even after single doses of triazolam, are accentuated by continued use, and frank psychopathology occurred in psychiatric patients during 2 weeks' use and during withdrawal (8).

The demonstrated ability of triazolam to impair acetylcholine release (SEDA-19, 36) suggests a mechanism for its amnestic effects, and should further caution prescribers about its use in elderly people, particularly those with pre-existing cognitive impairment. The extent to which this anticholinergic effect is shared by other benzodiazepines is yet to be established. The ability of triazolobenzodiazepines, such as triazolam and alprazolam, to inhibit the noradrenergic neurons of the locus ceruleus is unlikely to explain the prominent adverse effects of these drugs (SEDA-21, 37). For one thing, all GABA enhancers share this property; for another, a far more specific and selective inhibitor in the locus ceruleus (clonidine) has an adverse effects profile that is dramatically different from that of the benzodiazepines, whose adverse effects probably relate to their actions at a far wider range of GABA-ergic synapses.

Organs and Systems

Psychological, psychiatric

The effect of triazolam on muscarinic acetylcholine receptor binding has been investigated in living brain slices by the use of a positron-based imaging technique (9). Stimulation of GABA/benzodiazepine binding sites lowered the affinity of the muscarinic acetylcholine cholinergic receptor for its ligand, which may underlie benzodiazepine-induced amnesia, a serious clinical adverse effect of benzodiazepines.

Ten healthy men participated in a randomized, double-blind, crossover study involving placebo and triazolam 0.125 mg (10). Resting electroencephalography and event-related potentials under an oddball paradigm were recorded before drug administration, and at 1, 2, 4, 6, and 8 hours after. P300 waveforms were analysed by peak amplitudes. Triazolam can cause cognitive dysfunction without general sedation or apparent sleepiness, and this effect appeared up to 6 hours after administration of a low dose of triazolam.

The subjective and behavioral effects of triazolam were investigated in 20 healthy women, who took oral triazolam 0.25 mg or placebo at the follicular, periovulatory, and luteal phases of their menstrual cycle in a within-subject design (11). After triazolam most of them reported the expected increases in fatigue and decreases in arousal and psychomotor performance. Neither plasma concentrations of triazolam nor mood and performance differed across the three phases. This study shows that the effects of triazolam are highly stable across the menstrual cycle.

Liver

Liver damage has been attributed to triazolam (12).

- A 64-year-old woman developed anorexia, fatigue, and jaundice. She had occasionally taken triazolam 0.25 mg for insomnia, and her liver function tests had been normal 5 months before. There was no history of liver disease or alcohol misuse or other serious medical history. She was jaundiced, with spider angiomata, and gradually deteriorated over the next 16 days, finally losing consciousness. Liver histology was consistent with submassive necrosis, extensive coagulation necrosis, and marked inflammation secondary to triazolam. She had a liver transplant 31 days after the initial presentation and 2 years later was in good health.

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug overdose

Death has been attributed to an overdose of triazolam (13).

- A 77-year-old woman was found dead in her bathtub. She had a history of depression, liver disease, spinal stenosis, and diabetes mellitus. An empty bottle of triazolam was found in the bin. At autopsy there was no injury or evidence of drowning. There was triazolam 0.12 mg/l in the heart blood.

Drug–Drug Interactions

Fluconazole

Fluconazole increases blood concentrations of triazolam (14).

Grapefruit juice

In a randomized, four-phase, crossover study, the effect of grapefruit juice on the metabolism of triazolam interaction was investigated. Even one glass of grapefruit juice increased plasma triazolam concentrations, and chronic consumption produced a significantly greater increase. The half-life of triazolam is prolonged by repeated consumption of grapefruit juice, probably due to inhibition of hepatic CYP3A4 activity (15).

Isoniazid

Isoniazid is a potent hepatic enzyme inhibitor and interferes with the metabolism of many drugs (SEDA-8, 287) (SEDA-11, 271). In healthy volunteers the half-life of triazolam was prolonged from 2.5 to 3.3 hours when it was given with isoniazid, whereas isoniazid did not affect the kinetics of oxazepam (SEDA-9, 267).

Ketoconazole

Ketoconazole can increase the concentrations of triazolam through inhibition of CYP3A4 (16).

If erythromycin, also a CYP3A4 inhibitor, is given in combination with ketoconazole, there is an even more dramatic effect on triazolam concentrations.

In a double-blind, crossover kinetic and dynamic study of the interaction of ketoconazole with alprazolam and triazolam, two CYP3A4 substrate drugs with different kinetic profiles, impaired clearance by ketoconazole had more profound clinical consequences for triazolam than for alprazolam (17).

Macrolide antibiotics

Interactions of macrolides with triazolam are clinically relevant. Increases in serum concentration, AUC, and half-life, and a reduction in clearance have been documented (18–20). These changes can result in clinical effects, such as prolonged psychomotor impairment, amnesia, or loss of consciousness.

In a randomized, double-blind, pharmacokinetic–pharmacodynamic study, 12 volunteers took placebo or triazolam 0.125 mg orally, together with placebo, azithromycin, erythromycin, or clarithromycin. The apparent oral clearance of triazolam was significantly reduced by erythromycin and clarithromycin. The peak plasma concentration was correspondingly increased, and the half-life was prolonged. The effects of triazolam on dynamic measures were nearly identical when triazolam was given with placebo or azithromycin, but benzodiazepine agonist effects were enhanced by erythromycin and clarithromycin (21).

Erythromycin

Erythromycin can increase concentrations of triazolam by inhibition of CYP3A4, and dosage reductions of 50% have been proposed if concomitant therapy is unavoidable (22).

Miocamycin

CYP3A4 is mainly responsible for catalyzing the hydroxylation of miocamycin metabolites, which can alter the metabolism of concomitantly administered drugs by the formation of a metabolic intermediate complex with CYP450 or by competitive inhibition of CYP450 (23). This can cause excessive sedation with benzodiazepines such as triazolam.

Nefazodone

Nefazodone is a weak inhibitor of CYP2D6, but a potent inhibitor of CYP3A4, and increases plasma concentrations of drugs that are substrates of CYP3A4, such as triazolam (24,25).

Ritonavir

The inhibitory effect of ritonavir on the biotransformation of triazolam and zolpidem has been investigated (26). Short-term low-dose ritonavir produced a large and significant impairment of triazolam clearance and enhancement of its clinical effects. In contrast, ritonavir produced small and clinically unimportant reductions in zolpidem clearance. The findings are consistent with the complete dependence of triazolam clearance on CYP3A activity, compared with the partial dependence of zolpidem clearance on CYP3A.

Tribenoside

General Information

Tribenoside, ethyl-3,5,6-tri-*O*-benzyl-D-glucofuranoside, is used as an anti-hemorrhoidal in oral and suppository formulations.

Organs and Systems

Skin

- A 57-year-old woman developed erythema exsudativum multiforme after using tribenoside 200 mg tds orally for 10 days (1). Patch tests with tribenoside (1% and 10% in petrolatum) showed erythema on days 2 and 3. Five controls were negative.

Tribuzone

See also Non-steroidal anti-inflammatory drugs

General Information

The usual adverse effects of NSAIDs have been observed with tribuzone, namely gastric effects, fluid retention, and headache (SED-9, 145) (1).

Reference

1. Pavelka K, Vojtisek O, Bremova A, Kaukova D, Handlova D. A new pyrazolidine derivative—Benetazone Spofa—in short- and medium-term treatment of rheumatoid arthritis. (Double-blind comparative study with phenylbutazone). Int J Clin Pharmacol Biopharm 1976;14(1):20–8.

Trichloroethylene

See also General anesthetics

General Information

Trichloroethylene is a volatile halogenated anesthetic with weak anesthetic properties compared with other halogenated anesthetics and poor muscle relaxant activity. It has been used in dry cleaning, for metal degreasing, and as a solvent for oils and resins.

Long-Term Effects

Tumorigenicity

The incidence of cancer among 803 Danish workers exposed to trichloroethylene has been evaluated (1). There was no overall increase. However, the standardized incidence ratio was significantly higher in men with non-Hodgkin's lymphoma or esophageal cancer and in women with cervical cancer.

Triclabendazole

See also Benzimidazoles

General Information

Triclabendazole is a benzimidazole derivative primarily used in veterinary medicine but has also been used experimentally in man. Chills, fever, leukopenia, and upper abdominal colic have been described (SEDA-14, 263).

Several reports have suggested that triclabendazole may be of use in the treatment of *Fasciola hepatica* infection. In 20 patients with fascioliasis treated with two single doses of triclabendazole 10 mg/kg, the plasma concentrations of triclabendazole, its active metabolite triclabendazole-SO, and its sulfone metabolite were doubled by food (1). There were no serious adverse effects, except for some right-sided upper abdominal pain in several patients, which was relieved by oral spasmolytics. Triclabendazole should be administered with food.

Triclocarban

See also Disinfectants and antiseptics

General Information

Triclocarban is mainly used as an antibacterial agent in soaps and antiperspirants (1).

Organs and Systems

Hematologic

Methemoglobinemia was attributed to triclocarban in seven neonates (2). There was no history of familial methemoglobinemia, but in one case the mother had been taking phenacetin before labor and this was most probably the cause. In five of the six other cases the methemoglobinemia was thought to be due to the use of disinfecting solutions or ointments containing triclocarban that had been used as a vaginal disinfectant in four cases and as a powder for the umbilicus in one case. The authors advised against the use of triclocarban in maternity units and by those dealing with neonates.

Skin

Several patients developed relatively minor dermatological problems after treatment with triclocarban (3). Three developed very extensive erosive cutaneomucosal lesions after using triclocarban for periods ranging from 20 days to 3 months.

Immunologic

There have been several cases of allergic contact dermatitis after the use of antiperspirants containing triclocarban and propylene glycol (4).

Tricyclic antidepressants

See also Individual agents

General Information

There are no accurate data on the worldwide use of the many tricyclic compounds listed in Table 1, and the availability of particular drugs varies from country to country. The dosage range for all these compounds is 50–300 mg/day, with the exception of nortriptyline, which has an upper limit of 200 mg, and protriptyline, which is more potent (range 10–60 mg/day). Well-controlled comparisons are few, but it is clear that these drugs resemble each other more than they differ. Their adverse effects will be discussed for the class as a whole, with distinguishing features of specific compounds mentioned when appropriate.

Tricyclic antidepressants interfere with the activity of at least five putative neurotransmitters by several different potential mechanisms at both central and peripheral sites. This gives rise to uncertainty in understanding the mechanisms that underlie a bewildering variety of untoward effects, which are in turn further modified by temporal factors, probably related to changes in receptor sensitivity. Differences between drugs are often inferred on the basis of selective effects on isolated organs in specific species, but their relevance to actions in man is largely unsubstantiated, owing to a lack of early clinical

Table 1 Tricyclic antidepressants that have been widely studied or are currently available for treating depression (all rINNs)

Compound	Structure	Comments
Imipramine	Dibenzapine; tertiary amine	Prototype compound
Desipramine	Secondary amine	First metabolite of imipramine
Amitriptyline	Dibenzocycloheptene; tertiary amine	Meta-analyses suggest the most effective
Nortriptyline	Secondary amine	First metabolite of amitriptyline
Protriptyline	Secondary amine	Most potent; least sedative
Doxepin	Dibenzoxepine ring	Sedative
Clomipramine	Halogenated ring	Available for intravenous use
Dimetacrine	Acridine ring	
Lofepramine	Propylamine side-chain	Relatively safe in overdose
Noxiptiline	Oxyimino side-chain	
Butriptyline	Isobutyl side-chain	More potent dopamine effects
Imipramine oxide	Oxygenated ring	Metabolite of imipramine
Amitriptyline oxide	Oxygenated ring	Metabolite of amitriptyline
Dibenzepin	Dibenzodiazepine ring	
Melitracen	Anthracene ring	
Amoxapine	Dibenzoxazepine ring; piperazine side-chain	Less potent than other tricyclics; dopamine D_2 receptor antagonist
Iprindole	6,5,8 ring structure	Weak action on amino pump mechanism
Dosulepin	Dibenzothiepine ring	
Trimipramine	Propyl side-chain	Little effect on monoamine re-uptake
Amineptine	Seven-carbon side-chain	Less sedative than other tricyclics

pharmacology studies. There is a high base rate for spontaneously occurring complaints or placebo-induced adverse effects in psychiatric populations, which complicates interpretation, even in controlled studies. There is also a wide range of interindividual sensitivity and susceptibility between patients, and very little consistent correlation between plasma concentrations and particular adverse effects.

All tricyclic compounds (with the possible exception of protriptyline) have sedative effects, and this may be desirable or undesirable, depending on a particular patient's state of apathy or agitation. They have a spectrum of anticholinergic activity, presenting as troublesome adverse effects, such as dry mouth, sweating, confusion, constipation, blurred vision, and urinary hesitancy, depending on individual patient susceptibility. Weight gain is a common and troublesome adverse effect; it is mediated in part by histamine H_1 receptor antagonism.

The adverse effects of most serious concern relate to the cardiovascular system and seizure threshold. Actions on the adrenergic and cholinergic systems probably contribute to both hypotensive and direct cardiac effects, including alterations in heart rate, quinidine-like delays in conduction, and reduced myocardial contractility. The seizure threshold is lowered, increasing the frequency of epileptic seizures. All of these adverse effects can occur at therapeutic dosages in susceptible populations, such as elderly people, children, and people with cardiac problems or epilepsy, but are also a major cause of morbidity and mortality in accidental or intentional overdosage. Doses in excess of 500 mg can be seriously toxic, and death is fairly common when doses of 2 g or more are taken.

Tricyclic antidepressants rarely cause cholestatic jaundice and agranulocytosis due to hypersensitivity reactions. The rare liver necrosis may reflect severe hypersensitivity. Two fatal cases of hypersensitivity myocarditis and hepatitis have been described (1). A variety of dermatological manifestations have been reported (rash, urticaria, vasculitis), but their relation to drug ingestion is often uncertain. A single case of pulmonary hypersensitivity with pleural effusions and eosinophilia has been reported with desipramine (2).

Tumor-inducing effects have not been reported.

Plasma concentrations and adverse effects

Plasma concentrations of antidepressants are influenced by pharmacogenetic factors, age, and drug interactions. Several studies have attempted to define the relation between plasma concentrations of tricyclic antidepressants and their therapeutic or adverse effects. However, the results are conflicting (SEDA-3, 12) (SEDA-5, 15) (3). Sometimes there is a clear relation between cardiac toxicity and high plasma concentrations (4–6), but in some individuals cardiotoxic effects occur at presumed therapeutic concentrations. Sporadic reports of severe adverse effects, mostly of the anticholinergic type, have often been associated with high plasma concentrations of amitriptyline or nortriptyline (7,8), although these vary with each drug and from patient to patient. The risk of central nervous system toxicity in patients treated with tricyclic antidepressants may be correlated with plasma concentrations, age, and sex (SEDA-16, 8) (SEDA-17, 17). It can be concluded that routine plasma concentration monitoring is generally of little practical value in managing patients with adverse effects, but in view of the great interindividual variability in the pharmacokinetics of the tricyclic antidepressants, monitoring may be useful in those patients who report adverse effects at low doses.

Once-daily dosage

Most comparisons of once-daily with divided regimens for a variety of tricyclic compounds have shown equal efficacy and reduced adverse effects with once-daily regimens (SEDA-3, 10). However, the significance of such regimens for compliance may have been exaggerated.

© 2006 Elsevier B.V. All rights reserved.

Multiple drugs have a much clearer impact on compliance than do multiple dosages of a single drug. Compliance is not usually impaired until more than three tablets a day are prescribed (9). A patient who forgets to take a single dose of a once-daily regimen loses more therapeutic effect than a patient who is equally forgetful about a divided regimen. Divided regimens may also be useful for patients who benefit from short-term sedation during the daytime.

Some adverse effects are more marked with single large doses, particularly in vulnerable patients. One study showed an increased frequency of frightening dreams when tricyclic antidepressants were given in a single bedtime dose (10). Elderly patients who take large single doses at bedtime may be at risk of dizziness, ataxia, and confusion caused by postural hypotension when they attempt to get out of bed in the dark (8).

Compatibility with electroconvulsive therapy

An important practical question concerns the compatibility of tricyclic antidepressants and electroconvulsive therapy (ECT). This has been studied in 15 patients taking 150–250 mg/day of imipramine or amitriptyline who received 4–16 ECT treatments (11). Continuous monitoring of cardiac function by oscilloscopy showed dysrhythmias in 40% of the ECT sessions. There were single extra atrial beats in 46 of 151 sessions and 1–3 premature ventricular beats in 12 sessions. Transient ventricular tachycardia occurred in one 32-year-old woman taking amitriptyline 250 mg/day who received 12 ECT treatments. The authors concluded that the cardiac effects are similar to those observed in previous studies of electrocardiographic changes during ECT in patients not taking antidepressants, and expressed the opinion that combined therapy does not involve any increased risk of serious cardiac dysrhythmias. A controlled comparison of ECT given to 19 patients taking tricyclic antidepressants and 27 control patients showed no differences in heart rate, blood pressure, or ectopic heart beats (12).

Tricyclic antidepressants in the treatment of enuresis

Although pediatric psychopharmacology is much neglected, nocturnal enuresis is an area of extensive research. An earlier review catalogued almost 100 publications on the topic (13). The tricyclic antidepressants have been shown to be effective in well-controlled trials, and over 40 publications had appeared before 1970. At that time adverse effects in children appeared to be minimal and comparable to those in adults. Since then considerable concern has developed over cardiotoxic effects and the risks of accidental overdose in children. The earlier reports have been summarized (SEDA-1, 10); managing overdose in children has been reviewed (SEDA-2, 10); death in a 16-month-old infant has been reported (SEDA-3, 9).

Sudden death, possibly related to cardiac effects in children and adolescents, has been discussed (SEDA-15, 13) (SEDA-16, 9) (SEDA-18, 18); it was concluded that children taking tricyclic antidepressants require careful monitoring of the electrocardiogram, even when relatively low doses are used (SEDA-18, 18).

Symptoms of intoxication in children taking tricyclic antidepressants may fail to be recognized in time, as shown by a number of cases published in the former German Democratic Republic (14), which led to serious consideration of the abandonment of such treatment there.

The British Committee on Review of Medicines recommended that these drugs should not be used in children under 6 years of age and should be given for periods not exceeding 3 months, and then only after a full examination (including electrocardiography) and consideration of other treatment options.

Long-term adverse effects

Treatment guidelines for depression and anxiety increasingly emphasize the value of longer-term maintenance treatment with antidepressants in order to prevent recurrence of illness. It is therefore important to assess the adverse effects burden of longer-term medication. The change in adverse effects profile over 1 year of treatment has been studied in a double-blind, placebo-controlled study of maintenance treatment with imipramine (average daily dose 160 mg) in 53 patients with panic disorder (15). Adverse effects of imipramine, such as sweating, dry mouth, and increased heart rate, persisted over the year of treatment, while rates of sexual dysfunction fell. Weight gain became increasingly problematic, and by the end of the trial imipramine-treated patients had a mean increase in weight of 4.5 kg, significantly more than the placebo-treated subjects, who gained only 1.3 kg. Data of this kind are helpful when advising patients on which adverse effects may remit and which are likely to persist during longer-term treatment. These data suggest that relative to SSRIs, such as fluoxetine and sertraline, maintenance treatment with imipramine is less likely to cause sexual dysfunction but has a greater risk of weight gain.

Organs and Systems

Cardiovascular

The cardiac toxicity of tricyclic antidepressants in overdose has been a source of continued concern. Undesirable cardiovascular effects, besides representing a major therapeutic limitation for this category of drugs, delineate an area in which tricyclic compounds with novel structures, as well as second-generation antidepressants, may have significant advantages. The cardiovascular effects of tricyclic antidepressants and the new generation of antidepressants have been reviewed (SEDA-18, 16) (16).

Since the inception of SEDA in 1977, each volume has included a review of the evolving literature, focusing on specific aspects, including direct myocardial actions (SEDA-12, 13), hypotension (SEDA-12, 13), and the incidence, severity, and management of overdosage in adults and children (SEDA-10, 19) (SEDA-11, 16) (4,17–21).

Direct myocardial actions

Tricyclic antidepressants are highly concentrated in the myocardium; this may account for the vulnerability of the

© 2006 Elsevier B.V. All rights reserved.

heart as a target organ as well as for inconsistently and inconclusively reported relations between plasma drug concentrations and specific manifestations of cardiac toxicity. These drugs interfere with the normal rate, rhythm, and contractility of the heart through actions on both nerve and muscle that are mediated by at least four different mechanisms (singly, in combination, or due to imbalance), including an anticholinergic action, interference with re-uptake of catecholamines, direct myocardial depression, and alterations in membrane permeability due to lipophilic and surfactant properties.

Acute experiments in dogs have shown a negative inotropic effect sufficient to cause congestive cardiac failure, but a carefully conducted long-term study in man did not show impaired left ventricular function in depressed patients with concurrent congestive failure (SEDA-9, 18). In another study (22) nortriptyline (mean dose 76 mg/day, mean plasma concentration 107 ng/ml) was given to 21 depressed patients with either congestive heart failure or enlarged hearts. In this study, nortriptyline was effective and well tolerated, producing only one episode of intolerable hypotension.

The most readily observable change in cardiac function is sinus tachycardia, which occurs to a greater or lesser extent in more patients and which correlates weakly or inconsistently with plasma concentrations (4,17,18). The mechanism may be related to both central and peripheral effects on cholinergic and adrenergic systems, but is not simply a reflex response to hypotension (4). The presence of tachycardia can serve as an indirect measure of compliance (4), but it is seldom a cause for concern, except in individuals who anxiously monitor their own physiological functions.

The complex changes that occur in cardiac rhythm have been intensively studied using 24-hour high-speed and high-fidelity cardiographic tracings, His bundle electrocardiography (23,24), and cardiac catheterization (25,26). Changes in conduction and repolarization cause prolongation of the PR, QRS, and QT intervals and flattening or inversion of T-waves on routine electrocardiograms; conduction delay occurs distal to the atrioventricular node and is apparent as a prolonged HV interval (the time from activation of the bundle of His to contraction of the ventricular muscle). This effect resembles that due to type I cardiac antidysrhythmic drugs, such as quinidine and procainamide. These conduction changes can cause atrioventricular or bundle branch block and can predispose to re-entrant excitation currents with ventricular extra beats, tachycardia, or fibrillation.

The implications and complications of these changes in cardiac function and rhythm are less clear; knowledge of their existence provoked concern about the incidence of sudden death in patients with cardiovascular disease, but the evidence from epidemiological sources is equivocal (19). General guidelines for the use of these drugs in the elderly have been discussed above, and a review of studies on the cardiovascular effects of therapeutic doses of tricyclic antidepressants has supported their use in elderly patients and those with pre-existing cardiovascular disease, provided precautions are taken. Atrial fibrillation has been reported in predisposed elderly subjects (SEDA-18, 19). In children taking desipramine there have been reports of sudden death (27,28) and tachycardia, and cardiographic evidence of an intraventricular conduction defect (SEDA-18, 18) (29).

The antidysrhythmic effect of imipramine was first reported in 1977 during treatment of two depressed patients whose ventricular extra beats improved during treatment (30). Tricyclic compounds can trigger serious dysrhythmias at high doses and perhaps also when the myocardium is sensitized.

Care should be taken in patients with a recent myocardial infarction who show evidence of impaired conduction (first-degree heart block, bundle-branch block, or prolongation of the QT_c interval), since tricyclic antidepressants can theoretically add to the already increased risk of ventricular fibrillation in such patients (31). Reviews in earlier editions of Meyler's *Side Effects of Drugs* discussed these effects and gave practical guidelines on the use of tricyclic antidepressants in patients with heart disease (32).

There is sometimes a clear-cut correlation between cardiac toxicity and high plasma concentrations (SEDA-18, 18) (4–6), but this may not always be so in individuals who are highly sensitive to the drug or in whom prolonged treatment may have led to drug accumulation in the myocardium, despite plasma concentrations in the usual target range. Routine plasma concentration monitoring does not seem indicated, since plasma concentrations account for only a small part of the variance in cardiac effects (17). If an individual shows significant changes clinically or cardiographically, a spot measurement may show a high plasma concentration, requiring dosage reduction.

To date there have been no prospective studies that clearly show increased mortality in cardiac patients who use tricyclic antidepressants. It has been suggested that overall mortality due to cardiac disease may be higher in depressed patients who remain untreated than in those who receive either an antidepressant or electroconvulsive therapy (33). Even in patients who have chronic heart disease, the risks of effective treatment with a tricyclic appear to be minimal (34).

Hypotension

As many as 20% of patients taking adequate doses of a tricyclic antidepressant experience marked postural hypotension. This effect is not consistently correlated with plasma concentrations and tolerance does not develop during treatment (35–37). The mechanism for this effect is uncertain; it has been attributed to a peripheral antiadrenergic action, to a myocardial depressant effect, and to an action mediated by alpha-adrenoceptors in the central nervous system (38). Studies of left ventricular function in man are conflicting. One study of systolic time intervals showed a decrement in left ventricular function with therapeutic doses (39), while two in which cardiac function was observed directly during cardiac catheterization after overdosage showed no evidence of impaired myocardial efficiency, whereas the hypotension persisted after left ventricular filling pressures and cardiac output had returned to normal (40,41).

Postural hypotension can lead to falls. Its occurrence may be predictable, since patients who have raised systolic pressures and who have a pronounced postural drop before treatment are most likely to experience

© 2006 Elsevier B.V. All rights reserved.

drug-induced hypotension (37). Such patients should be cautioned to rise slowly from sitting positions and, since elderly people are especially at risk of falling at night, single large bedtime doses of sedative tricyclic drugs should be avoided. These preventive measures are the most helpful, since the hypotensive effect is not directly related to plasma drug concentrations and may not improve with dosage reduction. The wisdom of using sympathomimetic drugs to counter this undesirable effect is questionable (42).

Use in patients with cardiac disease

The diagnosis of depression and the use of antidepressant medication are both associated with an increased risk of myocardial infarction. The relative contribution of these two factors is uncertain. In a case-control study of 2247 subjects, taking antidepressants was associated with a 2.2-fold (CI = 1.3, 3.7) increase in the risk of myocardial infarction (43). This increased risk seemed to be accounted for entirely by the use of tricyclic antidepressants, because selective serotonin re-uptake inhibitors were not associated with an increased risk, although the confidence intervals were wide (relative risk 0.8; CI = 0.2, 3.5). These findings support the usual clinical advice that tricyclic antidepressants are best avoided in those with known cardiovascular disease or significant risk factors.

Cardiovascular complications of overdosage

The relation between the dosage of a tricyclic antidepressant and the development of life-threatening cardiovascular complications is unclear and individually variable (44,45), although plasma concentrations above 1000 ng/ml give cause for serious concern. Plasma concentrations vary widely, and absorption can be delayed or deceptive, owing to gastric stasis and enterohepatic recycling (46). Dysrhythmias can occur for the first time up to 36 hours after drug ingestion or admission to hospital (46). The frequency of serious cardiac conditions in one series of 68 cases (47) was 46% in patients who took over 2000 mg of imipramine or its equivalent, almost twice that of those who took less (25%). An intensive study of cardiovascular complications among 35 overdose patients showed that 51% had significant hypotension and 80% had abnormal electrocardiograms (40). The latter consisted of sinus tachycardia (71%) and various abnormalities that reflect impaired conduction, including prolongation of the QT_c interval (86%), QRS complex (29%), and PR interval (11%). The ST segments and T-waves were abnormal in 28% of patients. Despite these manifestations of disturbed conduction and repolarization, there were relatively few dysrhythmias; 13 patients (37%) had ventricular extra beats, which lasted up to 72 hours after admission and subsided within 36 hours in 10 cases. No patients developed sustained repeated ventricular tachydysrhythmias, and the authors speculated that bizarre wide QRS complexes seen in aberrantly conducted supraventricular tachycardia (present in some cases) may sometimes be misinterpreted as ventricular tachycardia.

The basic principles of intensive supportive care should be applied early, and artificial ventilation is often necessary, since respiratory depression is more frequent than is commonly supposed (48,49). Patients should be monitored for 24 hours if the initial (or subsequent) electrocardiogram shows a dysrhythmia. Among 75 patients with overdose, none who had a normal electrocardiogram and level of consciousness for 24 hours went on to develop any significant dysrhythmia (50). However, a case was subsequently reported of a patient who died an acute cardiac death 57 hours after admission and 33 hours after normalization of the electrocardiogram (51). The authors suggested that prolonged monitoring may be justified in individuals who have taken antidepressants for prolonged periods, compared with those who overdose early in treatment.

More specific treatment to combat cardiotoxic effects is usually necessary in only a minority of instances; in the series reported above (40), five patients (14%) had marked hypotension. Initial low left ventricular filling pressures were corrected within 3 hours by infusion of isotonic saline. Systemic hypotension persisted and was corrected by infusion of sympathomimetic amines. Routine insertion of a pulmonary artery catheter, with continuous monitoring of blood gases, pulmonary arterial pressure, left atrial wedge pressure, and cardiac output have been recommended (40). Volume expansion is suggested for low left atrial pressure, with dopamine infusion to improve myocardial contractility if cardiac output remains low.

The management of ventricular extra beats is based on recognition of the quinidine-like basis of the conduction defect. In the series reported above (40) all 13 patients with ventricular arrhythmias responded to intravenous infusion of lidocaine (mean dose 2.0 mg/minute). This alone might account for the absence of deaths in this series.

Another indirect method of benefiting the patient with cardiotoxic effects has been the alkalinization of plasma to a pH of 7.50–7.55 using sodium bicarbonate infusion (52). This enhances plasma protein binding, making the drug less available to the tissues. It is claimed that this technique reverses both hypotension and cardiac dysrhythmias without the risk of the undesirable effects of antidysrhythmic drugs (46). Recommendations for the management of poisoning with tricyclic antidepressants given in a recent review have been summarized (SEDA-16, 8).

Differences among tricyclic compounds

There is evidence that doxepin is significantly less cardiotoxic than other tricyclic compounds (53). However, a complete review of all the animal and clinical data has suggested that doxepin overdose can still cause lethal dysrhythmias in man, probably by producing more marked respiratory depression.

Three different studies have shown that there is less risk of hypotension in patients treated with nortriptyline (54–56) than with other tricyclic compounds. However, a similar claim has been made for doxepin (57).

Increased pulse rate and blood pressure have been associated with desipramine in the treatment of bulimia nervosa (SEDA-17, 18).

Respiratory

There has been one case report of reduced ventilatory response to hypercapnia after nortriptyline in a

© 2006 Elsevier B.V. All rights reserved.

woman with chronic obstructive pulmonary disease (SEDA-18, 19).

Nervous system

Miscellaneous symptoms that have been attributed to the tricyclic antidepressants include fatigue, weakness, dizziness, headache, and tremor; patients are likely to fall because of these disturbances.

Seizures are serious adverse events associated with the use of antidepressants, and the relative frequencies for different antidepressants have for a long time been a matter of controversy. The literature has been critically evaluated, taking into account predisposing factors, drug doses, plasma drug concentrations, and the duration of treatment (58). A significant proportion of seizures occurred in predisposed individuals, and the risk of seizure for most antidepressants increased with dose or blood concentration. After overdose the risk was higher for amoxapine and the tetracyclic drug maprotiline than for other antidepressants, but for several drugs there are not enough data to estimate the risk. Imipramine was the most frequently studied tricyclic, with a seizure risk of 0.3–0.6% at effective doses. For several of the second-generation antidepressants, a lower seizure risk has been reported in large clinical trials. Caution with all antidepressants should certainly be exercised in people who are predisposed to seizure activity because of brain damage or alcohol or drug abuse.

Concurrent use of lithium may be a risk factor for neurological adverse effects.

- A 34-year-old woman took amitriptyline 300 mg each night for several years. Six days after starting lithium 300 mg tds she had several generalized tonic-clonic seizures. A second episode occurred on re-exposure to lithium (59).

Patients with phobias or panic disorders are extremely sensitive to the adverse effects of tricyclic drugs early in treatment. They often have a syndrome of fine tremor, insomnia, and anxiety, which can be characterized as "jitteriness" and which is sometimes attributed to adrenergic hypersensitivity (SEDA-13, 9). Serum iron concentrations were significantly lower in jittery patients than in those who were not affected (SEDA-17, 19) (60). The authors suggested that this may be related to the role of iron as a co-factor for tyrosine hydroxylase.

Because tricyclic antidepressants suppress REM sleep, they have been used in the management of narcolepsy and cataplexy when amphetamines fail or abuse potential is high. Clomipramine is the most effective, possibly because it has more pronounced actions on serotonergic mechanisms (61).

Three reports have referred to a type of difficulty in articulation described as "speech blockage" or "dysarthria" (62–64). The disturbance was described as a delay in thinking and speech, in which the patient has difficulty in conceptualizing or transferring the next logical thought into words. The effect resembles stammering.

There have been sporadic reports of bilateral foot-drop with peroneal nerve involvement (65). A major neuropathy, with high stepping gait and inability to dorsiflex the foot, occurred in an 84-year-old woman; this presumed adverse effect remitted 8 weeks after withdrawal (66).

Unusual neurological reactions have been observed in some patients, generally when combinations of drugs (often including maprotiline) have been used (67). The symptoms were ataxia, akathisia, hypokinetic disorders of speech and motion, a dream-like state, and transiently impaired memory.

Confusion was observed in 13% of 150 patients taking tricyclic drugs, and in as many as 35% of patients over 40 years of age. All responded rapidly to drug withdrawal (SEDA-9, 26).

Aggressiveness during treatment in patients taking imipramine and amitriptyline in relatively low doses has been described (68). Violent behavior has also been attributed to amitriptyline (SEDA-17, 18).

Anticholinergic actions

Several organs are the target for the anticholinergic (antimuscarinic) activity of the tricyclic antidepressants. They constitute the most common and troublesome adverse effects of the tricyclic antidepressants, but the peripheral anticholinergic actions can also be put to therapeutic use in conditions such as irritable bowel syndrome, premature ejaculation, and nocturnal enuresis.

Experiments on receptor binding in rat brain and guinea-pig ileum have shown a spectrum of activity at muscarinic acetylcholine receptors for different tricyclic antidepressants (69). A comparison of five compounds showed that amitriptyline and doxepin were the most and desipramine the least potent, imipramine and nortriptyline being intermediate. Single-dose experiments in volunteers (given up to 100 mg of each drug) have confirmed the same rank order for both the peripheral anticholinergic actions (on salivary flow) and the central effects (sedation and other measures on a mood scale) (70). The significance of these differences between relatively low single doses of these drugs in healthy volunteers should not be uncritically extrapolated to clinical practice. However, they do provide a rationale for selecting among the different drugs for patients in whom either a high degree of sedation is desirable or anticholinergic effects are likely to be troublesome. No tricyclic is entirely free of anticholinergic action, and individual differences in susceptibility or metabolism can still cause serious problems in some patients. It is also difficult to predict which particular organ will become the major target for anticholinergic activity; some patients complain bitterly of a dry mouth, others report blurred vision, and some develop bowel or bladder symptoms. Careful history taking and physical examination will often reveal a possible cause for concern, based on the patient's previous response to similar drugs, existing disease (such as narrow-angle glaucoma, enlarged prostate, constipation), or advancing age.

Older people are supposedly susceptible to delirium caused by centrally acting anticholinergic drugs. This can take the form of anxiety, agitation, or frank hypomania. Such difficulties are more likely if the patient is also taking antipsychotic drugs (many of which also have anticholinergic effects) or anticholinergic antiparkinsonian drugs. Although such effects have long been recognized as a risk associated with the anticholinergic

© 2006 Elsevier B.V. All rights reserved.

properties of these drugs, it has been suggested that their incidence may be lower than is often assumed (71). In an epidemiological study from a West German multicenter drug surveillance system in almost 14 000 patients for 5 years, exposure-related incidence rates were 1.2% for tricyclic antidepressants compared with 0.8% for both tranylcypromine and neuroleptic drugs (72). The risk increased steadily with age in both sexes and all diagnostic subgroups, and was six-fold higher (3.4%) in those over 60 years. Also at greater risk were women and patients with affective psychosis.

Adverse anticholinergic effects can occur immediately after the first dose of a tricyclic antidepressant. They are a major cause of poor compliance in patients who expect immediate relief, but who are not properly prepared for the delay that can occur in the beneficial effects of these drugs on mood and energy.

Sensory systems

Loss of accommodation and blurred vision are common inconveniences that can usually be tolerated in the knowledge that they lessen with the duration of treatment. Exacerbation of narrow-angle glaucoma in the elderly can occur, but is not an absolute contraindication to treatment with a tricyclic antidepressant, since the anticholinergic effects can be balanced by judicious use of pilocarpine (73,74).

Damage can occur to the corneal epithelium, due to reduced lacrimation and relative accumulation of mucoid secretions in patients who wear contact lenses (75).

Mouth and teeth

Rampant dental caries due to xerostomia occurred in a patient who took doxepin up to 300 mg/day for over 2 years (76). The author warned of the need to counsel patients to carry out rigorous and regular dental hygiene, as well as simple measures to promote increased salivation, such as sugarless lemon drops or chewing gum. In another study there was an increase in the number of decayed teeth in 35 children treated with amitriptyline or nortriptyline for enuresis, compared with a smaller group of untreated children with enuresis and a larger matched population control group (77).

Gastrointestinal

Simple dietary advice about bulk foods can mitigate minor bowel disturbances. More serious complications that can arise include paralytic ileus, which can be life-threatening, especially in the elderly (78). A less well-known adverse effect is the potential for aggravating or even possibly inducing a hiatus hernia, presumably due to an anticholinergic effect on the cardiac sphincter (79).

Urinary tract

The tricyclic antidepressants increase bladder sphincter tone and the volume of fluid necessary to trigger detrusor contraction (80). Such effects may account for their efficacy in nocturnal enuresis, in which the benefit occurs early and at a low dosage, consistent with anticholinergic activity. However, this pharmacological action can cause hesitancy and urinary retention, especially in predisposed men who have prostatic hyperplasia.

Renal damage from tricyclic antidepressants has been suggested on only one occasion.

- A 65-year-old man taking imipramine 300 mg/day developed toxic psychosis, anorexia, and nausea after 24 days. He was mildly azotemic, but these changes quickly reverted after withdrawal. No biopsy or renal function tests were reported.

The findings are entirely compatible with prerenal azotemia associated with diminished fluid intake during a drug-induced psychosis (81).

Neuroleptic malignant syndrome

The neuroleptic malignant syndrome, which is classically associated with antipsychotic drugs and is usually attributed to excessive dopamine D2 receptor blockade, can rarely occur with other medications, including tricyclic antidepressants.

- A 62-year-old man was found unresponsive in his apartment. He had a past history of bipolar disorder, for which he was taking nortriptyline and sodium valproate (dosages not stated). On admission to hospital his rectal temperature was 107.1 °F and he had increased muscle tone. He was intubated and cooled with ice packs. His creatine kinase activity was raised (1046 IU/l) but valproate and nortriptyline concentrations were within the target ranges. Extensive investigations, including biochemical screens and brain scans, showed no clear cause for his condition. Shortly afterwards he developed disseminated intravenous coagulation and died.

The authors concluded that the features of the illness were consistent with nortriptyline-induced neuroleptic malignant syndrome (82). However, a contributory role for sodium valproate was also possible.

The neuroleptic malignant syndrome has also been reported in association with the antidepressants trimipramine (SEDA-21, 11) (83), desipramine (SEDA-17, 18), and amoxapine (SEDA-16, 9) (SEDA-17, 18) (84). Amoxapine in particular has significant dopamine D2 receptor antagonistic properties. In most cases the patients were taking several other drugs, but there have been reports of the syndrome in association with amoxapine or desipramine alone.

Serotonin syndrome

The serotonin syndrome is usually associated with the use of combinations of drugs that potentiate brain serotonin function. This syndrome has been associated with several tricyclic antidepressants when used in combination with monoamine oxidase (MAO) inhibitors (85). Rarely it can be associated with the use of a single agent, such as clomipramine, a tricyclic antidepressant with potent serotonin re-uptake inhibitor properties (86).

- A 60-year-old woman, with a history of hypertension, type 2 diabetes mellitus, and depression, took clomipramine 200 mg/day for 8 months and then 250 mg/day for 3 months. Her other medications were glibenclamide 7.5 mg/day, lisinopril 5 mg/day, and clonazepam 0.5 mg/day. Without any change in medications or other precipitants, she began to feel confused and weak. She became pyrexial (41.6°C), confused, and

© 2006 Elsevier B.V. All rights reserved.

tremulous, with myoclonic jerking. The combined plasma concentrations of clomipramine and desmethylclomipramine were 2230 nmol/l, somewhat over the usual target range (below 1900 nmol/l). Within hours her condition deteriorated, with seizures, ventricular tachycardia, and disseminated intravascular coagulation. Rhabdomyolysis led to acute renal insufficiency, which required dialysis. She remained severely ill over the next 4 weeks and eventually died of opportunistic Gram-negative infections.

This case illustrates that the serotonin syndrome can occasionally occur apparently spontaneously in patients taking a single serotonergic drug. The authors were unable to find any reason why the syndrome developed so catastrophically when it did, except for the modestly increased concentrations of clomipramine and its metabolite.

Extrapyramidal symptoms

Tricyclic antidepressants are often listed among the many drugs that can produce buccofaciolingual or choreoathetoid movements (87). A putative mechanism is a central anticholinergic action, which upsets the balance between the dopaminergic and cholinergic systems. The spontaneous occurrence of this syndrome makes it difficult to establish a cause-and-effect relation, although both patients described in the above report had symptoms again when rechallenged.

There is a more clear-cut cause-and-effect relation in the parkinsonian symptoms that occasionally occur with high-dosage tricyclic therapy in susceptible individuals (particularly elderly women). Because of its piperazine side-chain and structural resemblance to the phenothiazines, amoxapine has antidopaminergic properties that appear to produce typical dystonic reactions (88), but other tricyclic antidepressants may also be implicated in producing the full range of so-called extrapyramidal syndromes, including akathisia, dystonic reactions, parkinsonism, and tardive dyskinesia. Case reports have been described before (SEDA-16, 9) (SEDA-17, 18) (SEDA-18, 18). In the reports of tardive dyskinesia the problem is often that these patients have taken many different drugs.

Sensory systems

Eyes

Loss of accommodation and blurred vision are common inconveniences that can usually be tolerated, in the knowledge that they lessen with the duration of treatment. Exacerbation of narrow-angle glaucoma in the elderly can occur, but is not an absolute contraindication to treatment with a tricyclic antidepressant, since the anticholinergic effects can be balanced by judicious use of pilocarpine (73,74).

Treatment with bright light is used for mood disorders, and it has been suggested that antidepressants, which may act as photosensitizers, could enhance the effect of bright light on the eye, giving rise to adverse effects (SEDA-18, 17).

Ears

Tinnitus can occur after prolonged treatment with tricyclic antidepressants. In an early trial of imipramine (89) there were two cases of transient deafness, but in the subsequent 20 years no auditory effects have been recorded. In 1980, a report appeared (90) concerning four patients, all taking imipramine in dosages below 150 mg/day. Each complained of buzzing or ringing in the ears. In each case the symptoms improved or disappeared on dosage reduction, with maintenance of therapeutic benefit, and in one case the patient was switched to an equivalent dosage of desipramine without recurrence. A further report concerned a patient taking protriptyline 45 mg/day who developed ringing in both ears after 12 days (91). Symptom severity fell with dosage reduction and disappeared entirely after desipramine 100 mg/day was substituted. The authors postulated that non-vibratory tinnitus had originated from either neurological factors or changes in blood flow. In a chart review of 475 patients treated with tricyclic antidepressants there were five patients with tinnitus. Each developed the symptom in the second or third week of treatment at dosages of imipramine of 150–250 mg/day, with plasma concentrations of 200–400 ng/ml (92). In every case tinnitus subsided spontaneously within a further 2–4 weeks after onset, even though dosage and plasma concentrations remained constant.

Another unusual disturbance of hearing has been reported in a child taking tricyclic antidepressants (93). Auditory acuity was normal, but discriminative ability for both clear and distorted speech was depressed. The disorder cleared within some days of withdrawal.

Psychological, psychiatric

Cognitive impairment has been associated with nortriptyline in elderly subjects (SEDA-17, 19).

Musical hallucinations have been reported in association with clomipramine (SEDA-17, 18).

Mania

It is widely believed that there is a significant risk that tricyclic antidepressants can precipitate mania or rapid cycling in up to 10% of patients, and that various factors increase this possibility, including being female or younger, having an earlier onset of illness, and having a positive first-degree family history (SED-11, 40). Biochemical risk factors have been alleged to include patients with a low urinary excretion of the noradrenaline metabolite methoxyhydroxyphenol glycol (MHPG); the risk is possibly greater in patients taking tricyclic antidepressants rather than MAO inhibitors, and particularly in the case of clomipramine. The data on which these conclusions were based have now been rigorously analysed (94) in a review of the controversy surrounding the alternative suggestion that the so-called switch effect is a random manifestation of bipolar illness. There is a paucity of both prospective and long-term placebo-controlled studies, and existing research has suffered from unrepresentative samples and poor definition of manic outcomes. The reviewers concluded that "... some bipolar patients and few, if any, unipolar patients become manic when they are treated with antidepressants. A small number of patients develop rapid cycling."

This more cautious conclusion is supported by the results of a prospective study of 230 carefully selected patients with recurrent depression (at least two episodes,

© 2006 Elsevier B.V. All rights reserved.

with an average of six) who took imipramine (200 mg/day) for an average of over 46 weeks (95). Mania and hypomania were defined and measured by the Raskin rating scale. Only six patients (2.6%) developed hypomania, and four of these did so after withdrawal. Younger patients, women, and those with a previous history of hypomania (bipolar II) were no more likely to switch than unipolar patients.

These results suggest that the risk of mania or hypomania in the long-term treatment of recurrent unipolar depressed patients is relatively small. The 12 placebo-controlled studies of acute treatment in less carefully defined samples support higher incidence rates (around 6–7% for hypomania and 1–2% for mania), but these figures may be inflated owing to the inclusion of bipolar patients with a high risk of a spontaneous switch (94).

Metabolism

Weight gain has long been recognized as a concomitant of antidepressant and antipsychotic drug therapy. This may in part reflect improvement in mental state, but there also appears to be a physiological component, with an increased craving for sweets (96). No abnormalities have been found in fasting glucose and insulin concentrations or in intravenous insulin tolerance tests (96,97). Another possible suggestion for weight gain is that taste perception in depression improves after therapy with tricyclic antidepressants (98). A study of 50 depressed patients attempted to address some of these issues (99). Increased energy efficiency during antidepressant treatment has also been suggested as a reason for weight gain (SEDA-17, 8). A warning to patients with diabetes that hypoglycemia can be masked seems appropriate (100).

Endocrine

The "Division of Drug Experience" of the US Department of Health and Welfare issued a note on five cases of the syndrome of inappropriate antidiuretic hormone secretion and drugs to which it has been attributed (101). All involved drugs with a tricyclic structure; one patient was taking imipramine, three carbamazepine, and the others the closely related muscle relaxant cyclobenzaprine. The dosage of imipramine was 50 mg/day for 3 weeks and the patient was a 72-year-old woman. Other cases have been reported, involving amitriptyline (101), imipramine, and protriptyline (SEDA-17, 17).

Tricyclic antidepressants, presumably through blocking the re-uptake of noradrenaline, can cause a crisis in a patient with a pheochromocytoma (SEDA-21, 11) (102).

Prolactin concentrations are very rarely altered during treatment with tricyclic antidepressants, but this is more likely to occur and to produce galactorrhea or amenorrhea with clomipramine and amoxapine and when there are other contributory factors that may stimulate prolactin secretion, such as stress or electroconvulsive therapy (103).

Hematologic

Occasional cases of blood dyscrasias with tricyclic antidepressants continue to be reported (SEDA-12, 46) (SEDA-18, 18) (SEDA-21, 10). Antidepressant-induced blood dyscrasias have recently been reviewed (104).

Agranulocytosis has been associated with tricyclic antidepressants (105). Of 20 cases, eight were fatal and 12 recovered after 3–20 days.

Two cases of non-thrombocytopenic purpura occurred in patients taking tricyclic antidepressants. Both improved on withdrawal (106). True thrombocytopenia, with platelets counts as low as 120×10^{12}/l, occurred in a 79-year-old woman taking doxepin. During later treatment with amitriptyline, thrombocytopenia recurred, but not when she took imipramine (107). Cross-sensitivity must be highly specific to chemical structure, doxepin and amitriptyline being more like each other than imipramine.

Liver

Cholestasis was among the first adverse effects reported with phenothiazines, tricyclic antidepressants, and MAO inhibitors. Its incidence appears to have fallen, for reasons that are not understood, but under-reporting may be a factor. Increases in liver enzymes, especially transaminases and alkaline phosphatase, are quite common during treatment with both phenothiazines and tricyclic antidepressants. Such effects are usually benign, but one careful study of a patient taking amitriptyline showed biopsy findings of mononuclear and eosinophilic infiltration; cholestasis and jaundice were absent (108). In a controlled comparison of lofepramine and fluoxetine, there were significant increases in alkaline phosphatase, alanine aminotransferase, and gammaglutamyl transferase in patients taking lofepramine but not fluoxetine (109).

More serious and sometimes fatal liver necrosis has been reported with a number of different tricyclic structures and probably represents an extreme form of hypersensitivity (110,111). Liver necrosis in a 33-year-old woman who took imipramine 300 mg/day for over 1 month led the authors to suggest that once-daily dosage may pose a special hazard, because peak concentrations can exceed the toxic concentration, even though steady-state plasma concentrations are in the usual target range (112). A particular hazard appears to be posed by amineptine (qv).

There is no indication for routine liver function tests in patients taking tricyclic antidepressants; raised transaminases and alkaline phosphatase within the limits of the reference ranges are not a cause for serious concern, unless they are accompanied by clinical signs or symptoms indicative of liver dysfunction.

Skin

Skin rashes are so common that it is difficult to determine a cause-and-effect relation. A choice must be made between waiting to see if the rash clears despite continued treatment or switching to a different compound and, if necessary, rechallenging at a later date. Serious reported skin reactions include cutaneous vasculitis, urticaria, and photosensitivity. A grey discoloration of the skin in light-exposed areas has been associated with long-term therapy with imipramine and desipramine (SEDA-17, 19) (SEDA-18, 18). Pigmentary changes in the iris were also reported in one of the cases. Amineptine has been reported (113) to cause a particularly active acne, occurring beyond the usual distribution on the body and beyond the usual age, especially in women. The remedy

© 2006 Elsevier B.V. All rights reserved.

recommended is withdrawal of amineptine. A single case of a rosacea-like eruption on the face of a 76-year-old woman was also caused by this drug, and the association was confirmed by re-challenge (114).

Hyperpigmentation is a recognized adverse effect of the antipsychotic drug chlorpromazine. Four cases of hyperpigmentation have been described in patients taking the structurally related tricyclic antidepressant imipramine (115). All were women and had taken imipramine for at least 2 years. The hyperpigmentation occurred in a photodistribution on the face, arms, and the backs of the hands. In two patients who discontinued imipramine the hyperpigmentation resolved within 1 year. The authors speculated that the pigmentation might have been due to deposition of melanin in an unusual form, possibly in a complex with a metabolite of imipramine.

Sexual function

A review of sexual dysfunction due to antidepressant drugs in men, citing both published findings and reports provided by the manufacturers, drew a distinction between erectile dysfunction, ejaculatory problems, and changes in libido (116). A complicating factor is the lack of information concerning the base rate of these problems in depression itself. Erectile impotence has been reported with all of the commonly used tricyclic compounds in low normal dosages. Delayed and occasionally painful ejaculation occurs, and four cases of painful ejaculation in association with imipramine and clomipramine have been reported (SEDA-17, 18). Priapism can occur (116). Both increased and decreased libido have been reported, but it is virtually impossible to distinguish drug relatedness from the natural history of the condition. A small number of uncontrolled studies have shown therapeutic benefits in patients with premature ejaculation or disturbed sexual function accompanied by depression (117).

Delayed orgasm or loss of ability to obtain orgasm has been reported in women taking desipramine (118).

The sexual dysfunction is probably due to 5-HT re-uptake blockade, because similar effects are seen in patients taking SSRIs.

Long-Term Effects

Drug withdrawal

There is compelling evidence for a withdrawal syndrome due to abrupt discontinuation of tricyclic antidepressants (SEDA-5, 16), and the literature has been reviewed (119). Reports have involved both imipramine and doxepin (120). Symptoms occur as early as the morning after a missed dose (121), but more often after 48 hours and up to 2 weeks after withdrawal. They include anxiety, restlessness, sweating, diarrhea, hot or cold flushes, and piloerection. Amitriptyline withdrawal was followed by similar physical symptoms 36 hours after the last dose, followed by severe depressive illness (SEDA-17, 18).

Delirium after withdrawal of doxepin has been reported (122), as well as instances of mania (123). Pronounced neurological symptoms have been described after sudden withdrawal of amitriptyline (SEDA-18, 18).

The existence of a withdrawal syndrome was subjected to a controlled test (120) in seven patients who had been taking long-term amitriptyline up to 250 mg/day, imipramine 200 mg/day, or desipramine 250 mg/day. After 4 weeks placebo was substituted double-blind for 10–21 days. Both plasma and urine MHPG concentrations increased by an average of 74% above baseline, starting within 36 hours and reaching a peak 3 weeks after withdrawal. Despite these pronounced neurochemical changes there were no alterations in pulse rate or heart beat, and only two patients had definitely worse anxiety.

There is clearly a need for larger controlled studies to determine the incidence and severity of withdrawal effects after withdrawal of tricyclic antidepressants. Based on uncontrolled observations, it has been suggested that the incidence varies from under a quarter to over half of all patients.

A report of three cases (124) has suggested that central cholinergic overactivity is implicated, and that atropine sulfate 3 mg/day or synthetic anticholinergic agents (such as benzatropine mesylate 4 mg/day) ameliorate withdrawal symptoms within a few hours. The authors suggested that this technique may be especially useful in patients in whom tricyclic antidepressants must be abruptly withdrawn because of allergic or idiosyncratic reactions.

Second-Generation Effects

Teratogenicity

In chick embryos there was a high prevalence of abnormalities, including microphthalmia, micromelia, and reduced body size, after the administration of imipramine, but the dosages of imipramine were close to lethal (125).

The issue of dysmorphogenesis due to these drugs was first seriously discussed after a report on three possible cases from Australia in 1972 (126). Although the data underlying this report were later discredited, it led to a careful study of the case records of women who had taken tricyclic antidepressants in pregnancy, and more than 300 cases were rapidly identified in which such treatment had been followed by the birth of a normal infant. Other negative reports exonerating the drugs have appeared since (127–130), although sporadic case reports continue to appear (131).

In spite of these reports, which negate a possible association between tricyclic antidepressants and teratogenicity, it may be advisable to avoid these drugs during pregnancy, especially in the early stages, unless there is a compelling need. In many of the reports the drugs were given in low doses or for indications not justifying their use.

Fetotoxicity

Instances of distress in the newborn have been reported after treatment of their mothers with tricyclic antidepressants in the period before delivery (132). In one case, a neonate had signs of congestive heart failure without cardiac abnormality; another had tachycardia and myoclonus; a third had respiratory distress and neuromuscular spasms. These effects were thought to have resulted from both the adrenergic and anticholinergic effects of the

© 2006 Elsevier B.V. All rights reserved.

tricyclic antidepressants, which readily pass the placenta and should be avoided during the perinatal period.

Infants born to mothers taking tricyclic antidepressants can become jittery in the first few days of life (133).

- A healthy boy (weight 3370 g) was born to a mother who had taken clomipramine 100 mg/day throughout pregnancy. On the second day after delivery, the child was jittery and on the fifth day he developed myoclonic jerking of his arms and legs. There was no epileptic activity on a 10-channel electroencephalogram, and clonazepam and phenobarbital did not suppress the movements. However, the movements were suppressed by a single dose of intravenous clomipramine 0.5 mg. The myoclonus recurred only occasionally over the next 4 days. Examination at one month later was normal, apart from mild jitteriness in response to touch.

Maternal clomipramine use is associated with seizures in neonates but this case appears to have been caused by a withdrawal state that was relieved by clomipramine administration.

Another report has suggested that effects in the neonate may be due to withdrawal from maternal antidepressants after birth (134). Two cases of neonatal convulsions have been reported in infants whose mothers had been treated with clomipramine. In both cases the seizures occurred on the first day of life coincident with a fall in plasma clomipramine concentrations. In one case the convulsions were controlled by administration of clomipramine followed by tapered withdrawal.

Hypotonia has been described in four children, one of whom also developed jitteriness (SEDA-17, 18).

Lactation

There are few reports on the excretion of antidepressant drugs in breast milk, even though postpartum depression is relatively common. In a 32-year-old woman who took imipramine 200 mg/day from 1 month postpartum imipramine and desipramine were detectable in breast milk (135). There have also been reports that amitriptyline (136), desipramine (137), and nortriptyline (138,139) were detectable in the milk of nursing mothers and in the plasma of the mothers and infants. Neither parent compound nor metabolite were detected in infants' serum, except for two infants who had low concentrations of 10-hydroxynortriptyline. There were no adverse effects in any of the infants. The use of antidepressants during lactation has been reviewed, including 15 studies in which serum concentrations of antidepressants were obtained from nursing infants (140).

There has been a report of an 8-week-old breast-fed infant whose mother was taking doxepin (141). Four days after an increase in the daily dosage from 10 to 75 mg the infant developed respiratory depression; desmethyldoxepin was detected in the baby's plasma.

Susceptibility Factors

Age

Elderly people

Elderly people have high rates of depression but tend to be excluded from randomized trials of antidepressant treatment. In general, older people metabolize tricyclic antidepressants more slowly and have higher steady-state plasma concentrations. There is an increased risk of adverse effects of tricyclic antidepressants in elderly patients (SEDA-18, 17). Elderly people often take other drugs that can cause depression or interact with its treatment (142). These potential sources of variation are superimposed on the wide range of plasma concentrations reported among individuals, and on the differences between drugs in dose–response profiles. The dictates of safe practice are that treatment in elderly people be begun with low dosages (50 mg/day of imipramine or equivalent) in divided amounts, with dosage increases in small increments (50 mg/day of imipramine each week) and a reduced total dose range (75–150 mg/day, except in exceptional circumstances) (143). Close attention should be paid to the potential anticholinergic, neurological, or cardiovascular complications to which elderly people are especially vulnerable (31).

The adverse effects profile of fixed-dose clomipramine (150 mg/day) has been assessed in 112 hospitalized depressed patients (aged 22–70 years), of whom 38 were over 55 years of age (144). The only adverse effect that distinguished patients over 55 years was orthostatic hypotension: older subjects had a significantly greater fall in systolic blood pressure on standing. Orthostatic hypotension can lead to falls and injuries, particularly in patients being treated at home, and this suggests that blood pressure should be monitored in older patients who are taking psychiatric doses of tricyclic antidepressants. It is also worth noting that the upper age limit of patients in this study was only 70 years, so it is unclear how more elderly patients would fare with this rather substantial dose of clomipramine.

Drug Administration

Drug overdose

Both accidental and intentional overdose are relatively frequent and pose difficult management problems. Particular concern has been expressed for children, either because they gain access to parents' tablets or have been treated for enuresis. During one year a Melbourne hospital admitted 35 children poisoned with tricyclic antidepressants (145). In 1979 it was reported that tricyclic antidepressants had replaced salicylates as the most common cause of accidental death in English children under the age of five. Concern was expressed about this (146), and Swiss federal statistics raised similar worries (147).

The majority of all deaths from antidepressant poisoning in Scotland, England, and Wales, during 1975–1984 and 1985–1989 were due to two tricyclic drugs, amitriptyline and dosulepin, and they, as well as the entire group of older tricyclic antidepressants, had a fatality index (deaths per million prescriptions) significantly higher than the mean (148).

A nation-wide analysis of suicide mortality in Finland showed that between 1990 and 1995 the overall suicide mortality fell significantly from 30 per 100 000–27 (149). However, the use of antidepressants in completed suicide showed an upward trend, while the use of more violent methods (gassing, hanging) fell. During this time
